The final diagnosis of TEF was made by esophagoscopy, during which the exact characteristics of the fistula, i.e. size and its relationship with the upper esophageal sphincter as well as the distance of the most proximal end of the lesion from the incisors, were carefully recorded.

Stent placement

A self-expandable, covered -proximal release type-Ultraflex stent [Microvasive, Boston Scientific Corp., Natick, Mass] with a proximal flare of 28 mm, a body diameter of 23 mm, and a length of 120 mm or 150 mm, was used in all cases except two patients with esophagocutaneous fistulae after laryngectomy. In these cases, a Flamingo Wall stent [Microvasive Endoscopy, Boston Scientific Corp., Natick, Mass] with a proximal diameter of 24 mm, distal diameter of 16 mm, and length of 120 mm, was considered the most suitable for fistula sealing.

All stents were placed over a guide wire and no fluoroscopy was used in any case. Patients with malignant lesions were treated under diazepam-induced conscious sedation; benign TEF patients were under mechanical ventilatory support due to the underlying illness and had no need for supplementary anesthesia. The whole procedure was performed at the bedside in the ICU.

The stent delivery catheter was passed over the pre-inserted guide wire and advanced so that the proximal end of the stent was at the estimated distance from the incisor teeth. Generally, all stents were gradually deployed in such a position so that at least 2 cm of the prosthesis was over both sides of the lesion. However, our landmark was the upper esophageal sphincter. The stent was thus deployed to achieve the minimal harmful sensation with maximum security regarding stent migration as well as early overlapping by tumour overgrowth, i.e. the upper end of all stents was just within the upper esophageal sphincter or at the hypopharynx.

After stent insertion, its proper position was controlled by endoscopy and under direct vision. In some cases x-ray imaging was additionally performed (Figures 1 and 2).

RESULTS

Prosthesis implantation was technically successful in all patients and there was no procedure-related mortality. No complications occurred and no patient experienced severe pain at the site of stent placement, lasting more than 24 h and needed narcotic analgesics. Dysphagia score was improved from a median value of 3 (range, 2-4) to

Figure 1 Endoscopic view of the soft funnel of the Ultraflex stent placed in the hypopharynx, posterior to the larynx. The stent was partially compressed in the antero-posterior direction at the level of arytenoid cartilages.

Figure 2 Plain radiograph of Ultraflex stent *in situ*, shows the fully expanded stent. Its proximal edge slightly protrudes in the hypopharynx (posterior endplate of C4).

a value of 2 (range,1-3) in esophageal stenosis patients. Fistula sealing was achieved in all cases, both benign and malignant (Table 3).

Regarding foreign body sensation, all conscious patients could well tolerate the stent placement in the first few days with no further difficulties. The two patients with esophagocutaneous fistula stented by Flamingo tubes experienced a foreign body sensation when the head/neck was bent since the proximal end of the stent was at the level of the mesopharynx, easily visible through the mouth opening (Figure 3). Both stents remained in place for three months until the fistula was totally closed, and were then removed by being grasped with retrieval forceps and pulled out without difficulty.

The median hospital stay was 3 d (range 2 - 4 d) for the 9 patients with stenosis and/or malignant esophagotracheal fistula. The other two patients with esophagocutaneous fistula remained hospitalised for 12 and 15 d, respectively due to cutaneous trauma debridement. Seven out of the eight TEF patients remained hospitalized in the ICU until their death, after 10 to 60 d, due to sepsis in 4, respiratory insufficiency in 2 and heart failure in one. The remaining patient, a 21-year-old multiple trauma victim, was weaned from a ventilator 33 d later and scheduled to be operated on for tracheoplasty. The Ultraflex stent was easily removed by simply grasping it with a pair of retrieval forceps under direct vision, just before the operation.

Table 3 Results after stent placement

Obstruction due to malignancy		**7 cases**
Stenting related mortality	0	
Improvement of dysphagia [score]	From 3 to 2	
Median hospital stay after stenting	3 d	
Malignant esophagotracheal fistula		**2 cases**
Stenting related mortality	0	
Sealing of fistula	2/2 (100%)	
Median hospital stay after stenting	3 d	
Malignant esophagocutaneous fistula		**2 cases**
Stenting related mortality	0	
Sealing of fistula	2/2 (100%)	
Median hospital stay after stenting	13.5 d	
Benign esophagotracheal fistula		**8 cases**
Stenting related mortality	0	
Sealing of fistula	8/8 (100%)	
Disease related mortality	7 cases	

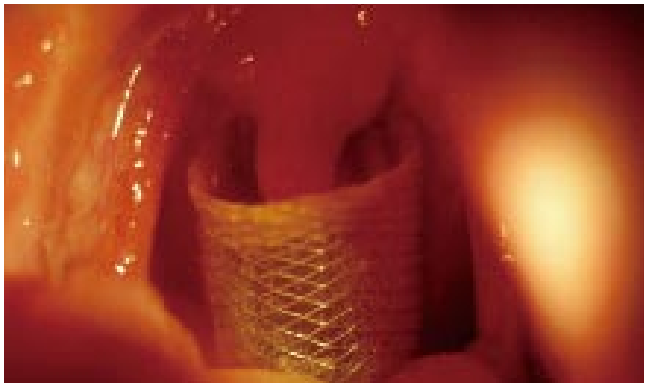

Figure 3 Direct view through the mouth opening of the upper part of the Flamingo stent placed temporarily at the cervical esophagus in the patient suffering from esophagocutaneous fistula after laryngectomy.

The 11 patients with malignancies were followed up every month. One patient with esophagocutaneus fistula died 7 months later, i.e. 4 months after fistula closure and stent removal. having developed total dysphagia due to recurrence of the disease. Unfortunately, this patient had totally refused a second stent; the second patient with esophagocutaneus fistula was alive 8 months after stenting. 5 months after fistula closure and stent removal, He is able to eat (dysphagia score 3) and no leakage has been reported; Seven patients remained alive for a median of 8 months (range 4 to18 months) and two patients were alive 10 months and 3 months after stenting. All these patients could eat semi-solid food and needed no other nutritional support.

DISCUSSION

The cervical esophagus is accepted as a segment between C6 at the pharyngoesophageal junction and the thoracic inlet at T1. It is endoscopically between 15 cm and 19cm from the incisor teeth and radiologically projects above the sternoclavicular joint[8,10]. At that level, any endoscopic procedure is more problematic even in the presence of a normal anatomical situation, since flexible endoscopy of the hypopharynx and upper esophageal sphincter is tech-

nically difficult, due to the reduced efficacy of insufflation and movements-related swallowing.

Generally, there is no report supporting placement of esophageal prosthesis for cervical lesions because of concerns about the increased risk of proximal migration of the stent into the hypopharynx and most importantly, the intolerable sensation of a foreign body[11,12]. However, there is no other acceptable means of palliating a terminal-stage tumor disease patient. This is because of the rapid decline of the patient's general condition upon the development of an esophagotracheal fistula due to aspiration pneumonia and malnutrition. On the other hand, as tumor stage is generally advanced and life expectancy is short, the major interest of any therapeutic procedure must be a rapid and successful palliation, ensuring acceptable quality of life, reducing the duration of hospital stay and cost.

There exists a general hesitation about applying stents in patients with benign diseases because of concerns regarding short-term complications and the absence of information regarding long term sequelae[3,13-15]. In our study, the patients with TEF of benign origin were all critically ill with a short term expectation of life if left untreated.

We question the risk of stent migration. In benign cases the risk is reported to be as high as 24%[15], which is probably related to a smaller mucosal surface area with less inward force anchoring the device. We experienced no migration in our cases, which might be attributed to the upper conical configuration of the stent, the external pressure induced by the cuff of the endotracheal tube, the constriction of the upper part of the stent by the upper esophageal sphincter, and mainly the absence of head-neck movements as well as swallow movements, due to the deep sedation of the patients. Moreover, the small number of patients could explain the absence of this complication in our series.

In the malignant cases, the risk of cervical stenting relates to the possibility of proximal migration, which shares the danger of sudden upper respiratory tract occlusion[3,8,10,16]. We experienced no migration in our patients, since the tumour masses were hard and protrusive and occluded the esophagus, which kept the stent in place, while in the two laryngectomy cases, it was impossible for the stent to impair breathing.

The second main concern for stenting at the level of cervical esophagus is the theoretical probability of a foreign body sensation[3,10-12]. Although such a sensation was experienced by some of our tumour-bearing patients, this was minimal and well tolerated. Most likely, by the time when a prosthesis becomes necessary, such patients especially those after laryngestomy with a Flamingo stent no longer have normal sensation, probably due to local infiltration of the nerves innervating the hypopharynx, cricopharyngeal sphincter and upper esophagus resulting in hypo/anesthesia. This propensity to infiltrate local neural structures is reflected by the frequent occurrence of unilateral or bilateral vocal cord paralysis. In addition, previous radiotherapy or surgery also impairs normal sensation. The two patients who were placed Flamingo stents for sealing the esophagocutaneous fistula after laryngectomy experienced a foreign body sensation every time they moved their heads forward. However, in these cases the stent was high at the level of the mesopharynx and easily visible even though the mouth was opened.

The procedure of stenting itself is totally uneventful. The use of local anesthesia and conscious sedation, in conjunction with a slim endoscope, can facilitate the procedure, which is time consuming only in the case of a very rigid and narrow malignant stricture requiring a guidewire to be advanced blindly through the stricture for bougie dilatation. Otherwise, the total endoscopic procedure takes only a few minutes, that is, the time needed for passing the endoscope through the lesion, making the appropriate measurements of total length of the lesion and distances of its proximal margin from upper esophageal sphincter and from incisor teeth, and advancing a guidewire through the endoscope into the stomach. The endoscope is then withdrawn and the stent is advanced 'blindly' over the guidewire, using only the numerical marks on the stent's sheath (centimeters from its proximal edge) for correct positioning. The use of general anesthesia does not facilitate the endoscopic maneuvering. However, insertion of the scope under direct inspection of the esophageal opening, by means of a laryngoscope as for tracheal intubation, is easier, but is not a reason to give general anesthesia to an otherwise conscious patient.

Thus, the eight mechanically ventilated TEF patients were under general anesthesia, while the remaining malignant lesion patients were simply given midazolam for conscious sedation. We experienced no problem with the latter group, but we could not give any favor to the former. However, this fact may be partially related to the benign nature of the disease in this group of patients.

With regard to the technical problems of proper positioning, the theoretical point of difficulty is the proximity of the mesopharynx and epiglottis. Profili *et al*[10] and Conio *et al*[17] have advised peroral administration of iodinated contrast medium for exclusive fluoroscopy guidance throughout the procedure. However, we found it was not useful and adds excessive difficulties, either because of the inability of a sedated patient to swallow or simply because of the increased time required to complete the procedure, or just because the procedure should be done on the ICU bed. We consider that the main difficulty is the accurate deployment of the proximal end of the stent close to the cricopharynx, because of the retraction of the expandable stent on deployment. The radiopaque markers used for stent placement under fluoroscopic assistance are not always reliable, because they are intended to indicate the position of a fully expanded stent. The problem was overridden when the proximally released type of Ultraflex prosthesis was used, allowing more accurate placement because we carefully measured the distances of the orifice of the upper esophageal sphincter and the proximal edge of the lesion from the incisor teeth, thus enabling us to know exactly where the proximal end of the stent should begin to deploy.

Additionally, the use of the Ultraflex stent has the advantages of being less rigid, thus reducing pain during movements of the head and neck, and has smooth edges, making it atraumatic when positioned in the hypopharynx,

despite continuous soliciting during swallowing. This prosthesis can exert a constant, gentle radial force on the esophageal wall, but withstand angulation forces better than the Song and Gianturco stents, as well as the Wallstent which is stiffer and thus less suitable for lesions in this area[12,17].

A further advantage is the rapid expansion to the full diameter, enabling all patients to ingest well-chewed food two days after intervention. The rapid expansion also results in tight fixation to the esophageal wall without any tendency to dislocate and an immediate and complete sealing. In the case of tracheoesophageal fistula, it has successful rate of 73%-100%[5,16,18-20], referring both to malignant and benign fistulae. Moreover, its funnel-shape facilitates the collection of saliva and maintains proper positioning.

For the esophagocutaneus fistula patients we preferred the Flamingo Wall stent due to a number of distinct characteristics: conical shape with proximal flaring and lange braiding angle in the upper part and small in the distal part of the stent. When swallow movements and oesophageal peristalsis propel the stent downwards, its upper end becomes trapped in the laryngoplasty area, whereas the lower end becomes stretched, thus resisting distal migration. Moreover, its polyethylene cover is on the inside of the stent, thus increasing the possibility of anchoring the metal mesh to the esophageal mucosa, since there is no stricture to hold it in place[12,21]. To the best of our knowledge, there are no comparative studies on types of stents except two which relate to the distal esophagus, suggesting that all stents offer the same degree of palliation while Ultraflex and Flamingo stents are both equally less atraumatic than the Gianturco stent[21, 22].

Stent placement in the setting of chemoradiotherapy may be associated with life-threatening complications such as esophageal perforation or bleeding. Kinsman *et al*[23] reported that the complication rate is 36.4% and the mortality rate is 23% in patients receiving radiation and/or chemotherapy, compared with 2.5% and 0% of those without prior therapy. Sumiyoshi *et al*[24] have recorded 6 sudden massive hemorrhages in a group of 22 patients. Additionally, it is likely that T4 cancers are susceptible to pressure necrosis from stent with a consequent increase in the risk of perforation into adjacent structures[24]. Fortunately, we did not experience such complications in our patients. This could be partially explained by the fact that by using the Ultraflex stent, excessive dilatation of the malignant stricture is avoided.

Finally, the quality of life becomes an overriding issue in patients with inoperable cancer, therefore the ability to swallow their saliva and maintain oral intake is important to most patients with esophageal tumours[25]. Since the most realistic goal of any palliative therapy is maximal relief of symptoms with minimal risk, the insertion of a stent with no or little risk of dilation and a minimum of post-procedure complications are the optimum. Good symptom relief of dysphagia and successful occlusion of fistulae are clearly possible by the use of a stent as shown in our malignant and benign cases and more importantly, many patients with malignant strictures or fistulae are able to swallow their saliva after stent placement.

In conclusion, the results of the present series support the thesis that the presence of a lesion within 2 cm of the cricopharyngeal muscle should no longer be considered a contraindication for the palliative or temporary use of an endoprosthesis.

Abstract

AIM: To investigate whether adrenomedullin, a potent vasodilator peptide, plays a role in the circulatory disturbance in cirrhosis.

METHODS: Cirrhosis was induced in rats by weekly gavage of carbon tetrachloride. Hemodynamic studies were performed *in vivo* using radioactive microspheres and *in vitro* using isolated aortic rings. The adrenomedullin concentrations were measured by radioimmunoassay.

RESULTS: Acute administration of adrenomedullin to the control rats reduced the systemic arterial pressure along with an increase of serum levels of the stable metabolite of nitric oxide (NOx), in a dose-dependent manner. Chronic infusion of adrenomedullin reduced the vascular resistance and increased the blood flow in the systemic and splanchnic circulation. Intravenous administration of anti-adrenomedullin antibody did not affect any hemodynamic parameters in the cirrhotic rats, whereas this antibody ameliorated the blunted contractile response to phenylephrine, α-adrenergic receptor agonist, in the aortic rings of the cirrhotic rats. The adrenomedullin concentrations in the aorta were higher in the cirrhotic rats than in the controls, and correlated with the mean arterial pressure in the cirrhotic rats. Moreover, adrenomedullin blunted the contractile response to phenylephrine in both of the control aorta and cirrhotic aorta, but not in the presence of NG-nitro-L-arginine methyl ester, an NO synthase inhibitor.

CONCLUSION: Adrenomedullin overproduced in the vascular wall may contribute to the circulatory disturbance in cirrhosis as a local regulator of the vascular tonus rather than a circulating hormone.

INTRODUCTION

Arterial hypotension, high cardiac output, low vascular resistance, and hyporeactivity to vasoconstrictors are hemodynamic features in human and experimental liver cirrhosis[1-3]. These circulatory disturbances may be attributed to arterial vasodilation that results from overproduction or reduced degradation of vasodilator substances[1-3]. Several circulating vasodilator peptides including substance P, calcitonin gene-related peptide, and glucagon are increased in the cirrhotic patients[4-6]. Moreover, many studies have suggested that the vasodilator substances produced in the vascular wall such as nitric oxide (NO) and carbon monoxide, an end product of the haeme oxygenase pathway, may be coordinately associated with arterial vasodilation in cirrhosis[7-9]. Therefore, the high levels of the circulating vasodilator peptides and the increased vascular production of vasodilators can contribute to the pathogenesis of arterial vasodilation leading to the circulatory disturbance in liver cirrhosis.

Adrenomedullin (AM) is the potent hypotensive peptide discovered in the human pheochromocytoma, and is considered to cause a potent vasodilation via synthesis of NO in the vascular endothelial cells as well as an increase of the intracellular adenosine 3',5'-cyclic monophosphate in the vascular smooth muscle cells[10-11]. AM is abundant in the adrenal medulla, but is widely distributed in the human and rat organs including the vascular tissue[12,13]. Several clinical studies have

demonstrated that the circulating AM levels are increased along with progression of the liver disease and correlate with the hemodynamic parameters in cirrhosis[14-17]. Moreover, the gene expression of AM in the vascular tissue was more enhanced in the cirrhotic rats than in the controls[18]. These findings raise the possibility that AM may be involved in the circulatory disturbance in cirrhosis. However, whether the increased circulating AM and/or the enhanced vascular production of AM plays a role in the circulatory disturbance in liver cirrhosis remains to be established. In this study, the role of the circulating AM in the hemodynamic derangement in cirrhosis was investigated in the presence of exogenous AM and/or anti-AM antibody using radioactive microspheres. Moreover, the AM concentrations in the aorta were evaluated in relationship to the systemic blood pressure, and the effect of AM on the vascular tonus was investigated in the presence of exogenous AM and/or anti-AM antibody using isolated aortic rings. This study aimed to investigate whether the increased circulating AM and/or the enhanced vascular production of AM plays a role in the circulatory disturbance in liver cirrhosis.

MATERIALS AND METHODS

Animal preparation

The experiments were performed on male Sprague-Dawley rats. Liver cirrhosis was induced by weekly intragastric administration of carbon tetrachloride[19]. The rats weighing about 150 g were given phenobarbital (35 mg/dL) in the drinking water. After 2 weeks when the rats were about 250 g, the initial dose (0.04 mL) of intragastric carbon tetrachloride was begun. Body weight was monitored and the dose of intragastric carbon tetrachloride was adjusted according to the change of body weight. After 8-10 doses of carbon tetrachloride, micronodular liver cirrhosis was induced in the most rats and the half of cirrhotic rats developed ascites. The control rats were treated with phenobarbital alone. All animals received humane care and all experiments were performed according to the guidelines of the Committee for the Care and Use of Laboratory Animals in Nara Medical University.

Hemodynamic studies

Hemodynamic studies were performed by the same operator to reduce the operator-dependent variability. Ketamine (100 mg/kg, i.m.) was used as an anesthetic drug, because it closely resembled the conscious state in terms of hemodynamics[20]. The left femoral artery, right jugular vein, femoral vein, and portal vein were cannulated with PE-50 catheters. The left ventricle was catheterized with another PE-50 tube. Each catheter used was filled with heparinized saline. The cardiac output and regional blood flow were measured using radioactive microspheres[21]. A reference sample was obtained from the femoral artery for 75 seconds at a rate of 1 mL/min using continuous withdrawal pump (CFV2100; Nihon Kohden, Tokyo, Japan). Approximately 60 000 microspheres labeled with ^{57}Co (15.5 ± 0.1 μm diameter, specific activity: 610 MBq/g; New England Nuclear, Boston, MA, USA) were injected into the left ventricle 15 seconds after the start of blood withdrawal. The cardiac output was calculated as follows: The cardiac output (mL/min) = injected radioactivity (cpm) × reference blood flow (mL/min) / reference blood radioactivity (cpm). The cardiac index was expressed per 100 g of body weight. The abdominal organs were cut into small pieces and placed in counting tubes. The radioactivity of each organ was determined with a gamma counter. For calculation of the regional blood flow, the injected radioactivity was replaced by radioactivity of each organ in the previous equation. The portal venous inflow was calculated as the sum of the blood flows to the stomach, spleen, small and large intestines, pancreas, and mesentery. The vascular resistance was calculated from the ratio between the perfusion pressure and the blood flow in each vascular territory. The hemodynamics were investigated as follows: 1) Control rats were infused with either vehicle (n = 6) or human AM (0.1, 0.3, 1.0 nmol/kg/min for 10 min, n = 6, respectively) via a femoral vein catheter. Another six control rats were given human AM at a dose of 0.3 nmol/kg/min for 10 min after an intravenous injection of anti-AM antibody (500 μg/kg). The mean arterial pressure and serum levels of NO× (NO_2^- + NO_3^-), a stable metabolite of NO, were determined before and after the infusion. 2) To compare the magnitude of depressor response of the exogenous AM, cirrhotic rats were also infused either vehicle (n = 6) or human AM (0.1, 0.3, 1.0 nmol/kg/min for 10 min, n = 6, respectively) and the mean arterial pressure was determined before and after the infusion. 3) Control rats were chronically infused with either vehicle (n = 8) or human AM (1.0 μg/h, n = 8) for 14 d using a mini-osmotic pump (alzet model 2002, Alza, CA, USA). The pumps were connected to the left jugular vein cannulated with PE-60 and placed in the subcutaneous tissue. The human AM dose was determined according to a previous study[22]. On d 14 of chronic infusion, hemodynamic studies were performed using radioactive microspheres. 4) Cirrhotic rats with ascites were repeatedly injected with either anti-AM antibody (500 μg/kg, n = 8) or vehicle (n = 8) via the tail vein on the day of, and 3 and 6 d after the development of ascites. Hemodynamic studies were performed on the day after the final injection.

Isolated aortic ring studies

On the day of the experiment, the thoracic aorta was removed from control rats and cirrhotic animals with ascites and cut into 3-mm rings. The rings were suspended between two triangular stainless steel stirrups in a 20-mL jacketed organ chamber containing modified Krebs-Henseleit solution (118 mmol/L NaCl, 4.6 mmol/L KCl, 1.2 mmol/L $MgSO_4$, 1.2 mmol/L KH_2PO_4, 11.1 mmol/L glucose, 27.2 mmol/L $NaHCO_3$, 0.03 mmol/L Na_2 ethyle nediaminetetraacetic acid, 1.8 mmol/L $CaCl_2$) at 37 ℃ and bubbled with 950 mL/L O_2 and 50 mL/L CO_2. The lower stirrup was anchored and the upper stirrup was attached to a force-displacement transducer (TB-652T; Nihon Kohden) to record the isometric force. All rings were

stretched to generate a resting tension of 2 g, which was optimal for contractions of the aortic rings in response to phenylephrine, an α-adrenergic receptor agonist. After 1 h of equilibration, the presence of functional endothelium was determined by the addition of acetylcholine (10 μmol/L). All rings were rinsed and allowed to equilibrate for an additional 1 h in the presence of indomethacin (10 μmol/L) to prevent the influence of the endogenous prostanoids. The aortic rings of the control rats or cirrhotic animals with ascites ($n = 8$, respectively) were incubated for 30 min with anti-AM antibody (1 mg/L) or vehicle. Another control and cirrhotic rings were incubated with either human AM (100 nmol/L) or vehicle in the presence or absence of NG-nitro-L-arginine methyl ester (L-NAME) (30 μmol/L) ($n = 8$, respectively). Then, the cumulative dose-response curves to phenylephrine (1 nmol/L to 10 μmol/L) were evaluated. On completion, the rings were dried and weighed. The force of contraction was expressed as mg of contraction per mg of dried tissue. From each dose-response curve, the maximum response (Rmax) and phenylephrine concentration required for 50% of the maximum response (EC_{50}) were calculated with a nonlinear regression method using computerized curve-fitting software (StatView 5.0 program, Abacus Concept Inc., Berkeley, CA, USA), and were used to compare the contractility and reactivity of phenylephrine-induced contraction, respectively.

Measurements

The AM concentrations in the aorta were measured in the control rats and the cirrhotic animals with/without ascites ($n = 10$, respectively). The aorta was homogenized for 1 min in 10 volumes of 1 mol/L acetic acid and immediately heated at 100 ℃ for 10 min. The homogenates were centrifuged at 15 000 g for 10 minutes at 4 ℃. The supernatants were frozen until analyzed. The AM concentrations were measured by radioimmunoassay[18]. The protein concentrations were determined by Bradford's method[23]. Serum NOx levels were measured as previously described[24].

Chemicals

The human AM and anti-AM antibody were kindly supplied from Diagnostic Science Division, Shionogi & Co., Ltd. (Settsu, Japan). The anti-AM antibody which specifically binds to the C-terminal structure of AM and neutralize the effect of AM, belongs to immunoglobulin G1 subclass and equally cross-reacts with the rat AM [1-50], but not with calcitonin gene-related peptide or amylin[25]. The mouse IgG, KCl, acetylcholine, L-NAME, indomethacin, and phenylephrine were purchased from Sigma Chemical (St. Louis, MO, USA).

Statistic analysis

All analyses were performed with StatView 5.0 program (Abacus Concept Inc.). Comparisons were made using the two-tailed Student's t test for quantitative variables. All data are expressed as mean ± SE. $P < 0.05$ was considered statistically significant.

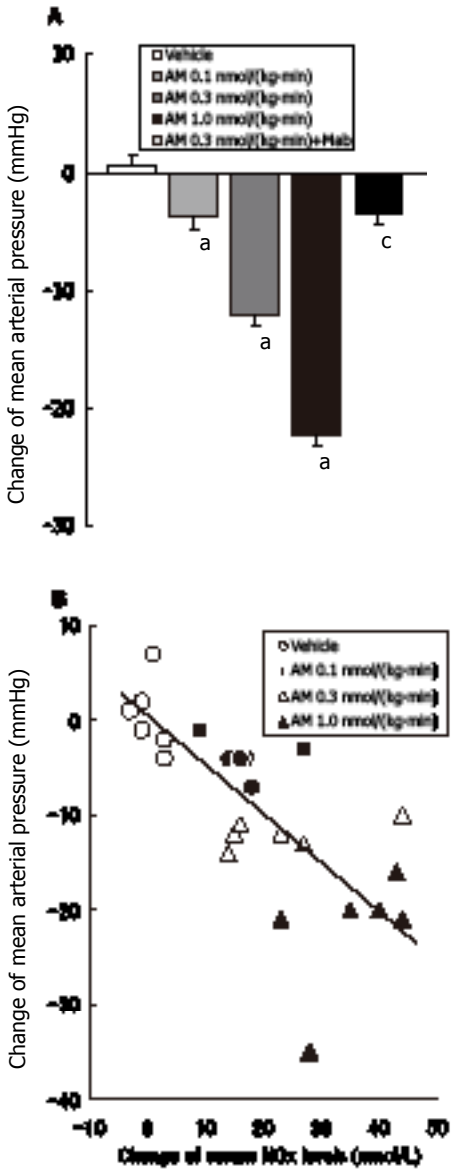

Figure 1 Changes of the mean arterial pressure and serum NOx levels by acute administration of exogenous adrenomedullin. **A**: Arterial pressure; $^{a}P < 0.05$ *vs* vehicle; $^{c}P < 0.05$ *vs* AM 0.3 nmol/(kg·min); **B**: serum NOx levels. mean ± SE. $r = -0.72$, $P < 0.05$, $n = 6$.

RESULTS

Acute administration of exogenous AM

Acute administration of human AM reduced the systemic arterial pressure in the control rats in a dose-dependent manner (Figure 1A, the changes of the mean arterial pressure, vehicle: 0.5 ± 1.6 kPa, AM 0.1 nmol/(kg·min): -3.8 ± 0.8 kPa, $P < 0.05$ *vs* vehicle, AM 0.3 nmol/(kg·min): -12.0 ± 0.6 kPa, $P < 0.05$ *vs* vehicle, AM 1.0 nmol/(kg·min): -22.2 ± 2.7 kPa, $P < 0.05$ *vs* vehicle, respectively). The changes of the mean arterial pressure by AM infusion (0.3 nmol /(kg·min)) were abolished by the pre-treatment with anti-AM antibody (-3.5 ± 0.6 kPa, $P < 0.05$). Moreover, AM infusion increased serum NOx levels in a dose-dependent manner, and the changes of serum NOx levels

Table 1 Hemodynamic effects of chronic administration of adrenomdullin in control rats

	Vehicle ($n=8$)	AM ($n=8$)	P value
Mean arterial pressure (mmHg)	132±3	122±4	<0.05
Cardiac index (mL/min·100g bw)	26.0±2.1	34.1±2.9	<0.05

Control rats were chronically infused with either vehicle or human adrenomedullin (AM) (1.0 mg/h) for 14 d using mini-osmotic pump. On day 14 of chronic infusion, hemodynamic study was performed using radioactive microspheres. Values are presented as mean±SE of 8 separate experiments.

Table 2 Effects of anti-adrenomedullin antibody on hemodynamics and aortic ring contraction of cirrhotic rats.

	Vehicle	Anti-AM antibody
Hemodynamic effects		
Mean arterial pressure (mmHg)	117 ± 3	121 ± 4
Cardiac index (mL/min·100g bw)	39.5 ± 2.9	38.2 ± 3.8
Systemic vascular resistance (mmHg·min·100g bw/mL)	3.1±0.4	3.4±0.4
Portal pressure (mmHg)	13.0 ± 0.4	12.8 ± 0.5
Portal venous inflow (mL/min·100g bw)	6.8 ± 0.8	5.6 ± 1.0
Portal venous system resistance (mmHg·min·100g bw/mL)	2.2 ± 0.3	2.6 ± 0.4
Aortic ring contraction		
Rmax (mg/mg tissue)	998 ± 96	1499 ± 137a
EC50 (nmol/L)	85.7 ± 11.8	53.8 ± 6.2

Cirrhotic rats with ascites were repeatedly injected either vehicle or anti-adrenomedullin (anti-AM) antibody [500 mg/(kg·times)] via tail vein on the day of occurrence of ascites, 3 and 6 d after. Hemodynamic study was performed on the next day of the final injection. Values are presented as mean±SE of 8 separate experiments. The contraction of aortic rings to phenylephrine was evaluated in the presence of vehicle or anti-AM antibody. Values are presented as mean±SE of 8 rings. Rmax: maximal contraction to phenylephrine, EC_{50}: phenylephrine concentration required for 50% of Rmax, $^aP<0.05$ *vs* vehicle.

by AM infusion negatively correlated with the changes of the mean arterial pressure (Figure 1B, $r=-0.72$, $P<0.05$). Exogenous AM reduced the systemic arterial pressure in the cirrhotic rats, as well (vehicle: -0.5±1.8 kPa, AM 0.1 nmol/(kg·min): 0.3±1.9 kPa, AM 0.3 nmol/(kg·min): -4.0±0.6 kPa, AM 1.0 nmol/(kg·min): -13.2±1.7 kPa, $P<0.05$ *vs* vehicle, respectively), but the magnitude of depressor response in the systemic arterial pressure was lower in the cirrhotic rats than in the controls.

Chronic administration of exogenous AM

In agreement with the results of acute administration, chronic administration of exogenous AM caused systemic hypotension as compared with vehicle infusion (Table 1). Chronic infusion of AM increased the cardiac index and reduced the systemic vascular resistance as compared with vehicle infusion. Moreover, chronic AM infusion increased the portal venous inflow and reduced the splanchnic arterial resistance as compared with vehicle infusion. The portal pressure and portal venous system resistance were unchanged by chronic AM infusion.

Effects of anti-AM antibody on hemodynamics and vascular tonus in cirrhotic rats

To evaluate whether the circulating endogenous AM is associated with the circulatory disturbance in cirrhosis, the effects of anti-AM antibody on the hemodynamics were investigated in cirrhotic rats with ascites (Table 2A). Despite the repeated administration of anti-AM antibody that neutralizes the circulating AM, the systemic and splanchnic circulations of the cirrhotic rats were both unchanged. To evaluate whether the endogenous AM in the vascular tissue plays a role in the vascular tonus in the cirrhotic rats, the effects of anti-AM antibody on the phenylephrine-induced contractile response of the control and cirrhotic aortas were evaluated. In the cirrhotic aorta, the anti-AM antibody enhanced the contractility of the phenylephrine-induced contraction without affecting the reactivity as compared with vehicle-treatment (Table 2B). On the other hand, this antibody did affect the contractile response of the control aortas as compared with vehicle.

AM concentrations in the aorta

The AM concentrations in the aorta were higher in the cirrhotic rats than in the controls (Figure 2A, 21.9±2.3 *vs* 12.9±1.2 fmol/mg, $P<0.05$). The cirrhotic rats with

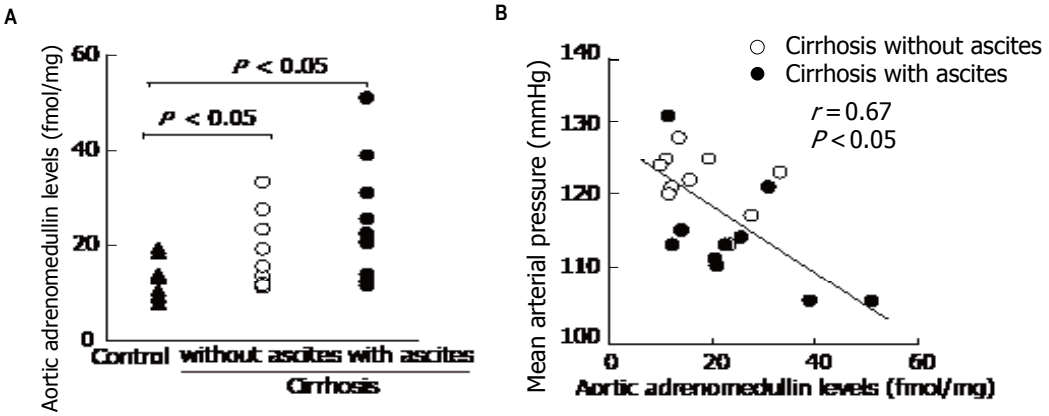

Figure 2 Adrenomedullin concentrations in the aorta in the control and cirrhotic rats (**A**) and their relation with the mean arterial pressure (**B**). ▲ : Control rats, ○ : Cirrhotic rats without ascites, ●: Cirrhotic rats with ascites. mean ± SE. $n = 10$.

Table 3 Contractile response of control and cirrhotic aortic rings to adrenomedullin and/or N^G-nitro-L-arginine methyl ester

	Control		Liver cirrhosis	
	Rmax (mg/mg tissue)	EC_{50} (nmol/L)	Rmax (mg/mg tissue)	EC_{50} (nmol/L)
Vehicle	1860±152	68.8±9.4	998±96[a]	85.7±11.8
AM	1330±118[a]	82.7±12.3	698±94[c]	91.0±12.8
L-NAME	2362±182[a]	61.8±7.1	2274±148[c]	72.1±6.7
L-NAME+AM	2242±91[a]	55.7±9.5	2092±219[c]	53.8±6.2

The contraction of aortic rings to phenylephrine was evaluated in the presence of vehicle or anti-AM antibody. Values are presented as mean±SE of 8 rings. Rmax: maximal contraction to phenylephrine, EC^{50}: phenylephrine concentration required for 50% of Rmax, [a]$P < 0.05$ *vs* vehicle-treated control aorta, [c]$P < 0.05$ *vs* vehicle-treated cirrhotic aorta. AM, adrenomedullin; L-NAME, N^G-nitro-L-arginine methyl ester.

ascites showed the highest aorta AM concentration (24.8 ± 4.0 fmol/mg) which was approximately two-fold increased as compared with that in the controls. Moreover, the AM concentrations in the aorta negatively correlated with the mean arterial pressure in the cirrhotic rats ($r = -0.67$, $P < 0.05$, Figure 2B).

Interaction of AM with NO in phenylephrine-induced contraction of the aortic rings

To investigate the interaction between AM and NO on the vascular tonus, the effect of AM on phenylephrine-induced contraction of the aortic rings was examined in the presence or absence of L-NAME (Table 3). AM-treatment reduced the contractility of the aorta as compared with vehicle-treatment in both of the control and cirrhotic aortas (Rmax: control; 1330 ± 118 *vs* 1860 ± 152 mg/mg tissue, $P < 0.05$, cirrhosis; 698 ± 94 *vs* 998 ± 96 mg/mg tissue, $P < 0.05$), whereas the reactivity showed no difference between AM-treatment and vehicle-treatment (EC_{50}: control; 82.7 ± 12.3 *vs* 68.8 ± 9.4 nmol/L, cirrhosis; 91.0 ± 12.8 *vs* 85.7 ± 11.8 nmol/L). L-NAME potentiated the contractility of both the control and cirrhotic aorta as compared with vehicle without affecting the reactivity (Rmax: control; 2362 ± 182 mg/mg tissue, $P < 0.05$, cirrhosis; 2274 ± 148 mg/mg tissue, $P < 0.05$, EC_{50}: control; 61.8 ± 7.1 nmol/L, cirrhosis; 72.1 ± 6.7 nmol/L). When the aortic rings were pre-treated with L-NAME, AM had no effects on the contractile response of both the control and cirrhotic rings (Rmax: control; 2242 ± 91 mg/mg tissue, cirrhosis; 2092 ± 219 mg/mg tissue, EC_{50}: control; 55.7 ± 9.5 nmol/L, cirrhosis; 53.8 ± 6.2 nmol/L).

DISCUSSION

Arterial vasodilation leading to a low systemic vascular resistance is the most outstanding hemodynamic alteration in the human and murine liver cirrhosis[1-3]. This vasodilation has been suggested to be a major pathogenic mechanism for hyperdynamic circulation characterized by arterial hypotension, hypervolemia, and high cardiac output[1-3]. Although the precise mechanism of the vasodilation in liver cirrhosis remains unknown, the overproduction or reduced degradation of endogenous vasodilators may play a major role. AM, a potent vasodilator peptide, is overproduced by various stimuli including endotoxin, cytokines, vasoactive substances and/or shear stress[26,27], which are enhanced in liver cirrhosis[28,29]. Moreover, the circulating AM levels and the gene expression of AM in the vascular tissues are both elevated in the human and/or murine liver cirrhosis[14-18]. These findings indicate that AM may be implicated in the circulatory disturbance in liver cirrhosis. The aim of this study was to investigate whether the increased circulating AM and/or the enhanced vascular production of AM plays a role in the circulatory disturbance in liver cirrhosis.

Acute administration of exogenous AM to control rats reduced the systemic arterial pressure along with an increase of serum NOx levels in a dose dependent manner, and

the changes of serum NOx levels correlated with the changes of the mean arterial pressure. Moreover, chronic infusion of AM (1.0 μg/h for 14 d) which keeps plasma human AM concentrations within the physiological limit[22] reduced the vascular resistance and increased the blood flow in both of the systemic and splanchnic circulations. These results, together with the existence of AM receptors in the vascular endothelial cells[11], suggest that AM may cause arterial vasodilation via NO synthesis in the vascular wall and lead to a hemodynamic alteration resembling liver cirrhosis.

Whether the circulating endogenous AM is associated with the circulatory disturbance in liver cirrhosis remains to be established. In this study, we used the anti-AM antibody to abolish the effect of the circulating endogenous AM. This antibody possesses an extremely potent neutralizing potency against AM[25], which may allow us to elucidate the role of the endogenous AM in the circulatory disturbance in cirrhosis. Five hundred μg/kg of the anti-AM antibody abolished hypotension following AM infusion at the dose of 0.3 nmol/kg/min for 10 min. Our previous study showed that plasma concentrations of AM in the cirrhotic rats with ascites were 19.2 ± 5.4 fmol/mL[18]. Therefore, the dose of anti-AM used in this study corresponds to that to neutralize the 200-fold of the circulating AM levels of the cirrhotic rats, indicating the enough dose to neutralize the effect of the circulating AM. However, this neutralizing antibody did not affect any hemodynamic parameters in the cirrhotic rats. Moreover, most of the circulating AM is reportedly occupied by glycine-extended AM, an inactive intermediate form of AM, and reflects the process of AM production in the tissue[30]. Therefore circulating endogenous AM may not play a significant role in the circulatory disturbance of liver cirrhosis.

There are no significant difference among the AM levels in plasma samples obtained from the hepatic vein, renal vein, pulmonary artery and femoral artery in cirrhotic patients[15]. The lack of significant arterio-venous difference in the AM levels in various vascular territories suggests that the increased plasma AM levels in cirrhotic patients do not result from an increased production in a specific organ. In this study, the AM concentrations in the aorta were more enhanced in cirrhotic rats than in the controls, and correlated with the mean arterial pressure in the cirrhotic rats. It is, therefore, possible that the endogenous AM contributes to the circulatory disturbance in cirrhosis as a paracrine and/or autocrine regulator of the vascular tonus rather than a circulating hormone. To investigate the role of the endogenous AM in the vascular tonus of cirrhotic rats, we performed isolated aortic ring studies. The cirrhotic aorta showed a blunted contractile response to phenylephrine as compared with the controls. The anti-AM antibody ameliorated the blunted contractile response in the cirrhotic aorta, but did not affect the contraction of the control aorta. This finding, together with the increased AM concentrations in the cirrhotic aorta, indicates that the endogenous AM in the aorta may play a role in the vascular tonus in liver cirrhosis.

It is widely recognized that NO plays a major role in the blunted vascular tonus in cirrhosis[31,32]. Moreover, AM and NO stimulate the synthesis and secretion of each other[11,33]. We, therefore, investigated the interaction between AM and NO in the contractile response of the cirrhotic aorta. In both of the control and cirrhotic aortas, AM reduced the contractile response, but not in the presence of NO synthase inhibitor. Prostanoids are unlikely to explain the blunted contractile response caused by AM, because sufficient indomethacin was used to inhibit cyclooxgenase. These findings, together with an increase in serum NOx levels by the exogenous AM infusion, indicate that AM overproduced in the vascular wall of cirrhotic rats may regulate the vascular tonus via NO synthesis in a paracrine and/or autocrine manner. In liver cirrhosis, an increase in hepatic vascular resistance is the initial phenomenon leading to portal hypertension. This is primarily due to the structural distortion of the hepatic microcirculation caused by cirrhosis, but is also associated with a deficient NO production in the liver, which results in an increased hepatic vascular resistance in contrast to an increased portal inflow via a vasodilation in pre-hepatic (splanchnic) vessels[34]. Considering the interaction between AM and NO, AM may be associated with portal hypertension through an imbalance of the NO production in the hepatic and pre-hepatic vessels.

Interestingly, the magnitude of hemodynamic alteration caused by AM infusion to the control rats was less than that in the cirrhotic animals with ascites, despite the similar hypotension in both groups. It has been considered that the circulatory disturbance in cirrhosis is initially caused by arterial vasodilation and thereafter promoted by an increase in the blood volume resulting from the impaired water and sodium excretion by activation of the endogenous vasoconstrictive systems[1-3]. Because the chronic infusion of AM suppresses the renin activity and aldosterone concentration[22,35], the lack of activation of the vasoconstrictor system may result in a less hemodynamic alteration in the AM-infused rats as compared with the cirrhotic animals. This finding provides further support for the concept that activation of the vasoconstrictive system as well as arterial vasodilation is essential for the circulatory disturbance in liver cirrhosis.

In conclusion, the AM concentrations in the aorta were elevated and negatively correlated with the systemic arterial pressure in the cirrhotic rats. Anti-AM antibody ameliorated the blunted contractile response of the cirrhotic aorta, whereas neutralization of circulating AM by anti-AM antibody did not affect the hemodynamic parameters in cirrhosis. These findings indicate that increased AM production in vascular tissue may contribute to the circulatory disturbance in cirrhosis, acting as a local regulator of the vascular tonus rather than a circulating hormone.

Abstract

AIM: To evaluate whether the cellular proliferation rate in the large bowel epithelial cells is characterized by circadian rhythm.

METHODS: Between January 2003 and December 2004, twenty patients who were diagnosed as suffering from primary, resectable, non-metastatic adenocarcinoma of the lower rectum, infiltrating the sphincter mechanism, underwent abdominoperineal resection, total mesorectal excision and permanent left iliac colostomy. In formalin-fixed and paraffin-embedded biopsy specimens obtained from the colostomy mucosa every six hours (00:00, 06:00, 12:00, 18:00 and 24:00), we studied the expression of G_1 phase cyclins (D_1 and E) as well as the expression of the G_1 phase cyclin-dependent kinase (CDK) inhibitors p16 and p21 as indicators of cell cycle progression in colonic epithelial cells using immunohistochemical methods.

RESULTS: The expression of both cyclins showed a similar circadian fashion obtaining their lowest and highest values at 00:00 and 18:00, respectively ($P < 0.001$). A circadian rhythm in the expression of CDK inhibitor proteins p16 and p21 was also observed, with the lowest levels obtained at 12:00 and 18:00 ($P < 0.001$), respectively. When the complexes cyclins D_1-p21 and E-p21 were examined, the expression of the cyclins was adversely correlated to the p21 expression throughout the day. When the complexes the cyclins D_1-p16 and E-p16 were examined, high levels of p16 expression were correlated to low levels of cyclin expression at 00:00, 06:00 and 24:00. Meanwhile, the highest expression levels of both cyclins were correlated to high levels of p16 expression at 18:00.

CONCLUSION: Colonic epithelial cells seem to enter the G_1 phase of the cell cycle during afternoon (between 12:00 and 18:00) with the highest rates obtained at 18:00. From a clinical point of view, the present results suggest that G_1-phase specific anticancer therapies in afternoon might maximize their anti-tumor effect while minimizing toxicity.

Key words: G1 phase proteins; CDK inhibitors; Cell proliferation; Circadian rhythm

INTRODUCTION

Eukaryotic cell division occurs in four phases of the cell cycle. The cells are prepared for DNA replication in G_1-phase. DNA is replicated during the S phase, a gap (G_2) period which allows preparation for mitosis before chromosome segregation and cytokinesis in M phase (mitosis). During development, differentiation, or growth factor withdrawal, cells can enter an inactive period (G_0-phase) before returning to G_1-phase[1].

Cyclins represent important regulators of cell cycle process. There are at least 15 distinct cyclin genes in the human genome that fall into three categories, and each category regulates specific passage through the cell cycle[2,3]. Passage through G_1 to S phase is regulated by cyclins C,

regulated by cyclins A and B$_{1-2}$[4-7]. Their levels in cell cytoplasm increase or decrease depending on the stage of cell cycle[2, 3, 8, 9].Elevated nuclear expression of cyclins favour the progression from one phase to the next while their low expression decelerates this progression[2-4, 7].

Cell cycle progression is mediated by the activation of a family of protein kinases, known as cyclin-dependent kinases (CDKs). CDKs constitute a large family of proteins, which act in a variety of key regulatory pathways, including control over the cell cycle and gene transcription[2, 9]. They are also divided in G$_1$-phase CDK (CDK4), S-phase CDK (CDK2) and M-phase CDK (CDK1)[8, 9]. Their levels in the cells remain fairly stable, but each must bind to the appropriate cyclin (whose levels fluctuate) in order to be activated[3, 8]. Cyclin D$_1$ (an early G$_1$-phase cyclin) mainly binds to and activates CDK4 and CDK6[8, 10] while cyclin E (a late G$_1$-phase cyclin) binds to and activates CDK2[8, 10].

CDK inhibitors inhibit the passage through the various phases of the cell cycle[11, 12]. The CDK inhibitors p16 and p21 protein families mediate regulation of cyclin/CDK activity[11, 12]. p16 family contains four members and inhibits CDK4 and CDK6, forming binary complexes with CDK4 *in vitro*[11, 12]. p21 family contains three members and interacts with both cyclin D and E complexes in G$_1$-phase and preferentially inhibits CDK2 activity[10].

In mammals, physiological (e.g. cardiac rhythm) or biochemical (e.g. hormone levels) processes vary in a regular and predictable periodic manner, with respect to the time of the day, which is called endogenous circadian rhythm[13, 14]. At the cellular level, each cell goes through the cell cycle in an orderly and controlled fashion, where the multiple steps associated with each phase should be successfully completed before progressing to the next phase[15]. At the tissue level, experimental[10, 16, 17] and clinical[18-26] studies suggest that a greater proportion of cycling cells in a specific organ, enters S-phase and mitosis at specific times of the day.

The present study was designed to evaluate whether the cellular proliferation activity in the large bowel epithelial cells shows variation over the 24 hours of a day and if this variation is characterized by circadian rhythm. As indicators for cellular proliferation activity we examined the quantitative expression of cyclins D$_1$ and E, as well as the inhibitor proteins p16 and p21 in biopsy specimens taken from the normal bowel mucosa of a permanent colostomy at six-hour intervals.

MATERIALS AND METHODS

Patients

Between January 2003 and December 2004, eighty-six patients suffering from colon and rectal cancer were surgically treated in our department. Among them, there were twenty patients (twelve men and eight women, median age 67 years, interquartile range 55-78 years) who were diagnosed as suffering from adenocarcinoma of the lower rectum infiltrating the sphincter mechanism. In all patients, the preoperative and intraoperative staging work-up revealed primary, resectable, non-metastatic lower rectal cancer. In order to achieve an oncological procedure, all patients underwent abdominoperineal resection, total mesorectal excision and permanent left iliac colostomy. All patients were operated on electively and neither neoadjuvant nor adjuvant chemo-radiotherapy was administered during the period of the study.

Biopsies

Biopsy specimens of bowel mucosa were obtained from the site of colostomy of these twenty patients undergone an abdominoperineal resection. Biopsies were collected at the time when the bowel retained its normal function after the operation and the colostomy was fully functional. Patients received the usual in-hospital low fibre diet. In order to avoid disturbance of cell proliferation, no enemas, bowel preparations and paraffin oil were used[18, 25]. All patients followed their usual sleep schedule (sleeping between 22:00 and 07:00) without receiving any sedatives[18, 19, 22, 25]. Their sleep pattern was interrupted only at the time when the colostomy specimens were taken. Specimens of 2-4 mm^2 were collected every 6 hours from the colostomy mucosa, approximately 3 cm lower to the colostomy orifice, using biopsy miniforceps. The examinations were performed at 00:00, 06:00, 12:00, 18:00 and 24:00. The biopsies were fixed in 10% buffered formalin and embedded in paraffin wax using conventional techniques.

Immunohistochemistry

Immunostainings for cyclins and CDK inhibitors were performed using mouse monoclonal antibody for cyclin D$_1$, rabbit polyclonal antibody for cyclin E, mouse monoclonal antibody for p16 protein and mouse monoclonal antibody for p21protein (Santa Cruz Biochemicals, Santa Cruz, California, USA) with a Vectastain Elite ABC-peroxidase kit (Vector Laboratories, Peterborough, United Kingdom) and a liquid DAB substrate-chromogen system (DAKO, Glostrup, Denmark) according to the manufacturer's instructions. An additional step of antigen retrieval (citrate buffer at pH 6.1 and microwave heating) was performed before antibody incubation for p21. The sections were counterstained with hematoxylin (Merck, Darmstadt, Germany). The percentage of positively stained cells in immunohistochemistry experiments was obtained by counting epithelial cells in each case by two independent observers.

Statistical analysis

All graphics were constructed using Microsoft Excel for Windows XT Professional. Statistical differences between the groups were determined by the Student's *t*-test. $P < 0.05$ was considered statistically significant. All statistical calculations were performed using the STATA statistical package (StataQuest Version 4.0, College Station, Texas, USA, 1995).

RESULTS

The median and interquartile range (IR) values of the percentage of the positively stained cells in immunohistochemistry for every single protein examined throughout the day of the present study, are presented in Table 1. The observed differences in the expression of the studied proteins between 00:00 and 24:00, could be explained by the fact that more bowel mucosa epithelial cells entered the

Table 1 Percentage of stained cells in immunohistochemistry for cyclin D1, cyclin E, protein p16 and protein p21 expression in bowel mucosa specimens

TIME	Cyclin D1 (Median + IR)	Cyclin E (Median + IR)	p16 (Median + IR)	p21 (Median + IR)
00:00	6 (4 - 8)	4 (2.75 - 5)	13 (11 - 15.25)	14 (10.75 - 16.25)
06:00	7 (5 - 8)	5.5 (5 - 7)	10 (8 - 11.25)	10 (8 - 11)
12:00	8 (6 - 9)	8.5 (7.75 - 10)	8 (6.75 - 8.25)	8 (6.75 - 8)

IR: Interguartile range.

proliferative activity as time passed.

The interindividual values for cyclin D_1 expression varied between 3% and 19%. Its expression gradually increased between 00:00 and 18:00 and gradually decreased between 18:00 and 24:00, obtaining the lowest and highest values at 00:00 and 18:00, respectively. The differences between the highest values of cyclin D_1 expression at 18:00, as compared to the values of the remaining examined periods, were highly statistically significant ($P < 0.001$).

The inter-individual values for cyclin E expression varied between 1% and 17%. Its expression gradually increased between 00:00 and 18:00 and then gradually decreased, obtaining its lowest and highest values at 00:00 and 18:00, respectively. Similarly to cyclin D_1, the differences between the values of cyclin E expression at 18:00, as compared to the values of the remaining examined periods, were highly statistically significant ($P < 0.001$).

The inter-individual values for the inhibitor protein p16 expression varied between 4% and 19%. Its expression gradually decreased between 00:00 and 12:00 and gradually increased between 12:00 and 24:00, obtaining its lowest and highest values at 12:00 and 24:00, respectively. The differences between the low values of p16 expression at 12:00, as compared to the higher values of the remaining examined periods, were highly statistically significant ($P < 0.001$).

The inter-individual values for the inhibitor protein p21 expression varied between 6% and 14%. Its expression gradually decreased between 00:00 and 18:00 and gradually increased between 18:00 and 24:00, obtaining its lowest values at 18:00 and its highest values at 00:00 and 24:00. The differences between the lowest values of p21 expression at 18:00, as compared to the values at 00:00, 06:00 and 24:00, were highly statistically significant ($P < 0.001$).

The present study concluded that expression of both cyclins showed circadian rhythm in a similar fashion. The higher levels of both proteins were obtained between 12:00 and 24:00 (highest at 18.00), while the lower levels were observed between 00:00 and 12:00 (lowest at 00:00).

A circadian rhythm in the expression of inhibitor proteins p16 and p21 was also observed. The lower levels of p16 expression were obtained between 06:00 and 12:00 (lowest at 12:00), while the lower levels of p21 expression were obtained between 12:00 and 18:00 (lowest at 18:00).

When the complexes of cyclins D_1 - p21 (Figure 1A) and E - p21 (Figure 1B) were examined, the present the expression of both cyclins was adversely correlated to the p21 expression throughout the day. The highest levels of cyclins were correlated to the lowest levels of p21.

When the complexes of cyclins D_1 - p16 (Figure 1C) and E - p16 (Figure 1D) were examined, high levels of p16 expression were correlated to low levels of cyclin expression at 00:00, 06:00 and 24:00. Meanwhile, the highest expression levels of both cyclins were correlated to high expression levels of p16 at 18:00.

DISCUSSION

How the circadian variation in proliferation at the tissue level relates to the control of the cell cycle, is a subject of continuous study[22]. The predictable association between certain cell cycle proteins and defined events during the cell cycle may be used to study the timing of cell cycle phases in normal tissues[22]. In malignant tissue, the expression level of cyclins and their inhibitors may have important prognostic and therapeutic implications, especially in the cell cycle phase-dependent toxicity of anticancer agents[20, 21].

Bucchi *et al*[18] are the first to investigate the presence or absence of rhythm in normal bowel mucosa proliferation. In their study, rectal biopsies were obtained every 2 or 3 h for 24 h using standard biopsy forceps during flexible sigmoidoscopy from 16 volunteers under fasting and fed conditions. Incorporation of [^{3}H] thymidine was measured in each specimen. Both fed and fasting subjects showed circadian variation in DNA synthesis in rectal mucosa that peaked at 07:00. Although thymidine incorporation fell during fasting, the circadian rhythm remained intact.

Marra *et al*[19] investigated the proliferation rhythm within the rectal crypt epithelium using the ^{3}H-thymidine autoradiographic method and calculated the ratio (labeling index) of the S-phase cells to total cells in the crypt. By taking biopsies every 4 h using standard biopsy forceps via rectoscopy from 23 normally fed subjects, they found a circadian rhythm in the labeling index with a peak at 01:28 in the morning. The base of the crypt and the upper 40% (which contains mainly differentiated cells) did not show circadian variation in the labeling index.

Brandi *et al*[25] studied the circadian variations of rectal cell proliferation in five patients by taking biopsies via proctoscopy from apparently normal mucosa 10 cm from the anal verge every 6h in a 24h period. Labeling index was evaluated as the percentage of labeled cells with respect to the whole cell population in the crypt. The results of the study suggest that rectal cell proliferation fluctuates during the day with the lower rates noted between 22:00 and 02:00.

By measuring the ratio of the S-phase cells to the whole cell population with the [^{3}H] thymidine technique, all previously mentioned studies[18, 19, 25] have demonstrated a rhythmicity in the rectal mucosa proliferation. Due to potential limitations of the [^{3}H] thymidine technique [27], most recent studies on the cellular proliferation rhythm in different tissues, are focused on the immunohistochemically quantitative expression of phase specific proteins. In the present study we examined the quantitative expression of the G_1-phase specific cyclins D_1 and E and the CDK

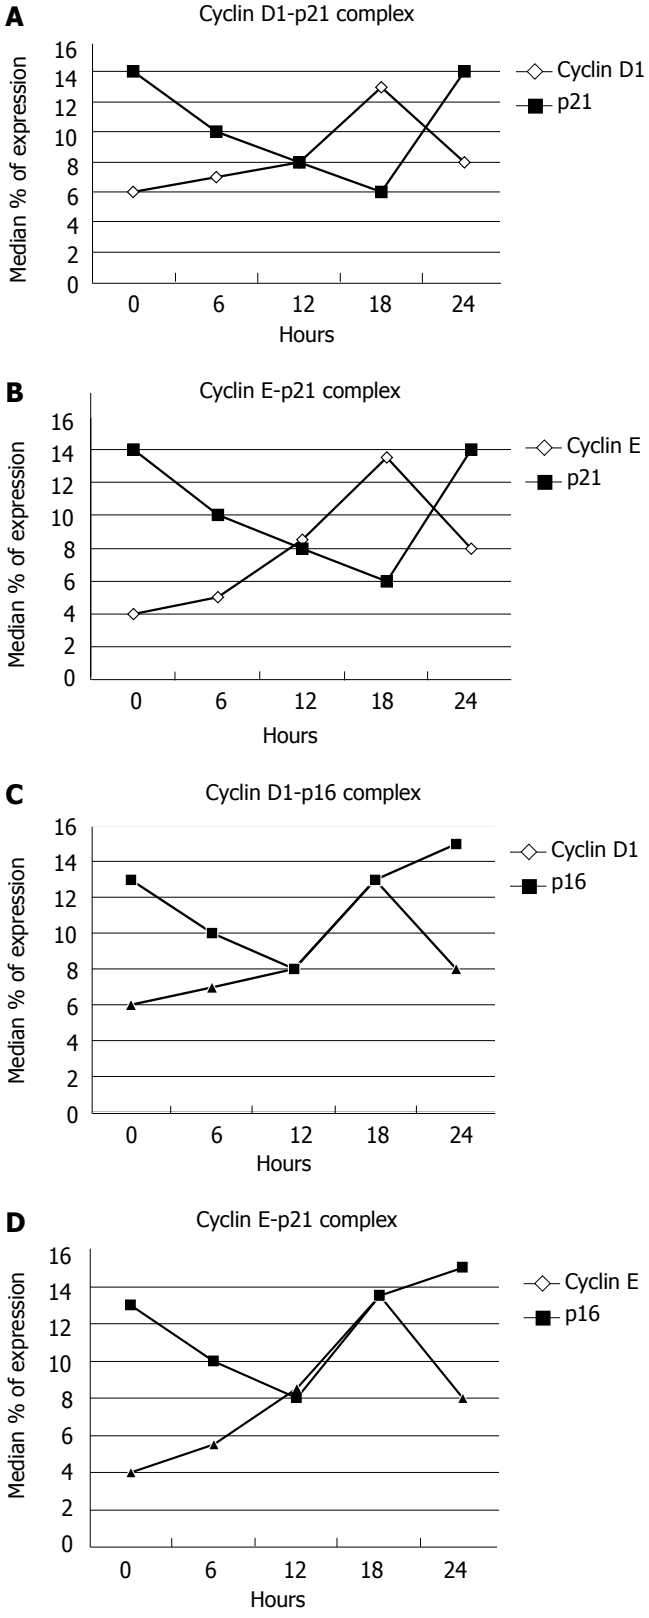

Figure 1 Graphical presentation of simultaneous quantitative expression of cyclin D1 and p21 (**A**), cyclin E and p21 (**B**), cyclin D1 and p16 (**C**), and cyclin E and p16 (**D**) in colostomy specimens sampled every 6 hours for 24 hours.

inhibitors p16 and p21 in normal large bowel mucosa.

Quantitative cyclin D_1 expression has been observed in normal bowel mucosa[28], dysplastic and non-dysplastic adenomatous polyps of the small and large bowel[18, 23, 29]. Its over-expression is related to adenocarcinoma of the colon and rectum (independently of the differentiation or Dukes' stage)[23], pancreatic[30], esophageal[30], endometrial[30], head and neck cancers[31].

Normal cells maintain strict control of cyclin E activity, while its deregulation plays a fundamental role in carcinogenesis. Cyclin E activities mainly consist of passage of cells through the restriction point "R" for cells entering the division from the resting state to G_1-phase[32]. Cyclin E functions not only as a S-phase entry regulator, but also plays a direct role in the initiation of DNA replication, by inducing S-phase specific genes[33, 34]. It is expressed higher than in many human tumors[35, 36] and the accumulation of cyclin E is considered a marker for the transition from adenoma to adenocarcinoma[37, 38].

p16 is a tumor suppressor gene and regulates cell proliferation by inhibiting CDK4 and CDK6 activities. Transient expression of p16 leads to inhibition of DNA synthesis by hypophosphorylating the retinoblastoma (Rb) gene protein[39-42]. The p16/Rb tumor suppressor pathway is frequently defective in many human tumors either by inactivating p16 or Rb or by over-expressing cyclin D_1 or CDK4. In cases of colorectal cancer, only a low frequency of p16 mutation has been found[39, 43]. Dai *et al*[44] hold that p16 expression begins in the earliest detectable stages of human colonic neoplasia and exerts a continuous constraint of tumor growth. A recent experimental study[45] showed that interaction of p16 expression and CDK4 may become a new prognostic marker in colorectal cancer. Tada *et al* [46] studied the possible role of p16 in the development of colonic neoplasms and found that p16 is overexpressed in 98% of adenocarcinomas and that colorectal cancer with reduced p16 expression is more aggressive in lymphatic infiltration.

The p21 protein family can interact with both cyclin and CDK subunits. Members of the p21 family interact with cyclins D and E during the G_1-phase of the cell cycle, preferentially inhibiting CDK2 activity and promoting assembly of cyclin D/CDK 4 complex *in vivo* and *in vitro*[47]. p21 constitutes the first molecule which is considered as a wild-type activated factor (WAF1) due to its upregulation by the tumor suppressor protein p53 and also as a cell-derived inhibitor of DNA synthesis[48]. Expression of p21 has been detected *in vivo* by immunohistochemistry in cells of upper crypts and lower villus. The above mentioned areas are associated with enterocyte differentiation[48] which is associated with a withdrawal from the cell cycle and the transcriptional activation of p21 either dependently or independently of the tumor suppressor p53[48-50].

The results of the present study demonstrated that the expression of both cyclins showed a similar circadian fashion, with the higher levels obtained between 12:00 and 24:00 (highest at 18.00) and the lower levels between 00:00 and 12:00 (lowest at 00:00). These findings partly support the theory for coordinating and cascading activity between them during the G_1 phase of the cell cycle [10]. As cyclin D_1 represents an early G_1 phase cyclin, while cyclin E constitutes a late G_1 phase cyclin, simultaneous increase and decrease of their expression during the same periods of time, require further investigation. A future study focusing on their expression at shorter intervals may disclose more accurately their fluctuation during the day. Circadian rhythm was also observed in the expression of

both inhibitor proteins, with the lowest values obtained at 12:00 and 18:00 for p16 and p21 expression, respectively. By comparing cyclins D_1-p21 and E-p21 complexes, the lowest expression levels of p21 and the highest expression levels of both cyclins were observed at 18:00. When the complexes of cyclins D_1-p16 and E-p16 were examined, the inhibitory action of p16 protein, successfully arrested the cell cycle during the night and early in the morning. Why high expression levels of p16 correlate to the highest expression levels of both cyclins at 18:00 remains unclear.

In conclusion, the expression of all examined parameters (which are involved in the progression from the G_1- to S-phase of the cell cycle) is characterized by circadian rhythm. Colonic epithelial cells seem to enter the G_1 phase of the cell cycle during afternoon between 12:00 and 18:00, because during that period the higher expression levels of cyclins D_1 and E correlate to the lower expression levels of the expression of CDK inhibitor proteins p16 and p21. From a clinical point of view, the present results suggest that G_1-phase specific anticancer therapies in afternoon might maximize their anti-tumor effect while minimizing toxicity[2, 3, 51-53]. Further studies on the accurate circadian rhythm in anatomically intact human colonic epithelium and malignant tissues are required.

Abstract

AIM: To assess the lifetime cumulative incidence of portal venous thrombosis (PVT) in the general population.

METHODS: Between 1970 and 1982, 23 796 autopsies, representing 84% of all in-hospital deaths in the Malmö city population, were performed, using a standardised protocol including examination of the portal vein. PVT patients were characterised and the PVT prevalence at autopsy, an expression of life-time cumulative incidence, assessed in high-risk disease categories and expressed in terms of odds ratios and 95% CI.

RESULTS: The population prevalence of PVT was 1.0%. Of the 254 patients with PVT 28% had cirrhosis, 23% primary and 44% secondary hepatobiliary malignancy, 10% major abdominal infectious or inflammatory disease and 3% had a myeloproliferative disorder. Patients with both cirrhosis and hepatic carcinoma had the highest PVT risk, OR 17.1 (95% CI 11.1-26.4). In 14% no cause was found; only a minority of them had developed portal-hypertension-related complications.

CONCLUSION: In this population-based study, PVT was found to be more common than indicated by previous clinical series. The markedly excess risk in cirrhosis and hepatic carcinoma should warrant an increased awareness in these patients for whom prospective studies of directed intervention might be considered.

Key words: Epidemiology; Venous thrombosis; Portal hypertension; Cirrhosis; Gastrointestinal cancer

INTRODUCTION

Extrahepatic portal vein thrombosis (PVT) may be caused by a variety of conditions including cirrhosis, cancer and abdominal infectious and inflammatory processes. In the wake of thrombus organisation and vessel involution follows development of tortuous collaterals, so called cavernous transformation[1]. Symptom development is often insidious and related to the progression of portal hypertension. The concept of PVT as a rare disease is mainly based on clinical series and case reports[2-7]. Estimates of frequency and of distribution of etiological fractions vary widely between studies[2, 4,5,6, 8,9,10,11]. To some extent this may be explained by lack of precision in these small series, but a contribution of case selection and ascertainment bias should also be considered.

For several decades, the city of Malmö in southern Sweden has been a centre for epidemiological research, including clinical and autopsy-based studies of cardiovascular diseases[12,13,14,15]. Between 1970 and 1982, close to 24 000 autopsies, comprising 84% of all in-hospital deaths in the city, were performed. All procedures followed a standardised protocol including examination of the portal vein and its major tributaries. In consequence with the course in PVT, the prevalence at autopsy can be regarded as a proxy for the cumulative incidence during lifetime to develop PVT. The size of the cohort together with the high autopsy rate thus provides a unique opportunity to yield a robust estimate of risk in the general population. Further aims have been to evaluate likely causes to PVT and clinical characteristics related to portal hypertension, and to estimate the absolute risk of PVT in high-risk disease categories as characterised by autopsy findings.

MATERIALS AND METHODS

Study cohort

Malmö is a city with a single referral centre for post-

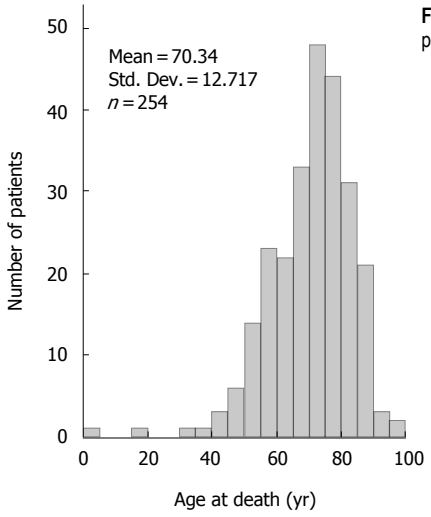

Figure 1 Age distribution of patients at death.

mortem examinations, the Department of Pathology at Malmö University Hospital. Between January 1, 1970 and December 31, 1982, when the city population declined from 264 000 to 230 000 inhabitants, 35 784 deaths occurred in the Malmö population. Among the 28 196 deaths occurring among in-patients at the three hospitals, which served the Malmö population during this period, a total of 23 796 clinical autopsies were performed, corresponding to an autopsy rate of 84%.

All autopsies were performed using a standardised protocol and carried out or supervised by senior pathologists. All findings were classified and coded according to the Standardised Nomenclature of Pathology (SNOP), as defined by the College of American Pathologists in 1965. The death certificates were issued by the pathologist. Based on the clinical picture and on autopsy findings, an underlying cause of death and up to six contributing causes were determined and classified using the ICD-8 code.

Classification of PVT patients in relation to potential causes

All cases with SNOP code 48-80-3700/3703, denoting *portal vein thrombosis* (*PVT*), were identified and validated individually. The following disease categories in the literature regarded as major causes of PVT were identified[5]:

-*cirrhosis,* where classification was based on SNOP codes 4850 - 4857 and/or cirrhosis as underlying or contributing death cause (ICD 8 code 571.00 - 571.99). PVT patients with cirrhosis were further classified according to presence or absence of *primary hepatic cancer* (hepatocellular carcinoma or intrahepatic cholangiocarcinoma);

-*primary hepatobiliary cancer,* comprising primary hepatic cancer (with or without cirrhosis), extrahepatic cholangiocarcinoma and gall bladder carcinoma;

-*secondary malignancy of the hepatobiliary region* (metastatic malignancy to the liver, biliary tract, gall bladder, duodenum or pancreas), further classified according to primary tumour location as expressed by SNOP code;

-*myeloproliferative disorders*: non-specific myeloproliferative disorder (SNOP code 7690); agnogenic myeloid metaplasia (7691); myelofibrosis (7692); histiocytic medullary reticulosis (7698); megablastic erythropoesis (7706); neutrophilic (7711) and eosinophilic (7713) leukocytosis; leukaemoid reaction (7714); erythrocytosis (7715); reticulocytosis (7716); lymphocytosis (7718); thrombocytosis (7719); erythrophagocytosis (7763); erythroid (7771), granulocytic (7772), reticular cell (7777) and megakaryocytic (7778) hyperplasia; polycythaemia vera rubra (7779); and chronic myeloic leukaemia (9867);

-*major abdominal infections and inflammations,* including liver abscess, abdominal abscess, purulent peritonitis, acute necrotising pancreatitis and ulcerative colitis.

In consequence with the possibility PVT being the result of more than one factor, a patient might be included in more than one of these categories. PVT patients in whom none of the above causes could be established were identified and analysed separately.

Classification of risk groups for PVT

PVT prevalence and risk, expressed as odds ratio, were assessed in relation to the following disease categories: *cirrhosis* (with and without primary hepatic cancer), *primary hepatobiliary cancer* (with and without cirrhosis), *secondary hepatic malignancy* (secondary malignancy of the hepatobiliary region not being readily definable in terms of SNOP codes) and *myeloproliferative disorders*. Presence of secondary hepatic malignancy was based on SNOP code 56-8006. Among these, patients with metastatic disease from pancreatic, gastric and colorectal carcinoma were further identified and similarly analysed. For the other disease categories, patients were classified using the definitions stated in the previous section.

Definition of clinical complications in PVT patients

In patients with PVT, the prevalence at autopsy of the following complications typically related to portal hypertension was ascertained and analysed in relation to disease categories: ascites, oesophageal varices and gastrointestinal bleeding.

Statistical analysis

Distributions of age at death were expressed in terms of means and variance and groups defined by presence or absence of potential causal factor compared with one-way analysis of variance (ANOVA). Proportions were compared using two-sided Fisher's exact test for univariate analyses. The PVT risks in relation to respective disease category were also expressed in terms of odds ratios with computation of 95% confidence intervals.

RESULTS

PVT prevalence and patient demographics

PVT was found at autopsy in 254 (1.1 %) of the 23 796 patients; in 125 (1.0 %) out of 12 157 men and 129 (1.1 %) of the 11 639 women ($P = 0.57$). The age distribution is depicted in Figure 1. With the exception of one patient, who was less than 1 year old, the age ranged between 17 and 96 years. Mean (95 % CI) age was 68 (66-70) years in

men and 71 (69 - 74) years in women. Median age at death was 72 years; 70 years in men and 74 years in women.

Distribution of potential causative factors in PVT patients

Seventy-two (28 %) of the PVT patients had cirrhosis, and one third of those had also primary hepatic cancer (Table 1). In all 59 PVT patients (23 %) had primary hepatobiliary cancer and 111 (44 %) had secondary malignancy of the hepatobiliary region. Major abdominal infectious or inflammatory disease was present in 25 (10 %), 7 (3 %) had myeloproliferative disorders, whereas in 36 (14 %) of the patients with PVT, none of the above causal factors could be identified. The age distribution in these categories was similar (Table 1). Sixty-one per cent of the PVT patients with cirrhosis were men ($P = 0.018$), otherwise there were no gender differences.

PVT prevalence and risk in relation to presence of disease

Cirrhosis was present in 5 % (1193 / 23796) of the cohort and related to a 7.9 times increased odds for PVT (95 % CI: 6.0-10.5) (Table 2). Patients who also had primary hepatic cancer had a 3.5 times higher odds for PVT (95 % CI 2.1-5.8) than cancer-free cirrhosis patients, with a PVT prevalence of more than 14 %. Secondary hepatic malignancy was associated with 4.9 times increased odds (95 %

[1] Categories not mutually exclusive; [2] in comparison with all PVT patients not belonging to category.

CI 3.8 - 6.2). Within this group, pancreatic cancer patients had a 6.7 times higher odds for PVT (95 % CI: 3.4 - 13.1) than patients with liver metastatic disease from colorectal cancer.

Complications related to portal hypertension

Among the patients with PVT, the highest rates of complications related to portal hypertension were found in the subgroup with concomitant cirrhosis: 62 % had developed ascites, 58 % had oesophageal varices and 47% terminal gastrointestinal bleeding (Table 3). Corresponding figures in all PVT patients were 43 %, 19 % and 25 % ($P<0.001$ for all three comparisons), whereas of the 36 patients where no cause of PVT could be identified at autopsy only a minority had these signs of portal hypertension: ascites was only present in 6 (17 %; $P<0.001$), oesophageal varices in 2 (6 %; $P=0.036$) and only 3 (8 %; $P=0.020$) had developed gastrointestinal bleeding.

DISCUSSION

Our finding of an overall risk in the general population of 1 % to develop PVT during lifetime does not corroborate the concept of PVT being a rare disease. The figure might even be an underestimation, since it cannot be ruled out that in some cases of partial thrombosis earlier in life a spontaneous resolution may have occurred. It should therefore be relevant to view these patients with renewed interest.

Among the major causes of PVT in adults, cirrhosis is generally named the most common, followed by neoplasia[5-6]. In this study the order of magnitude was reversed, with cancer in two thirds of the patients. By nature of being an autopsy study it is a selection of the sickest patients, and in some of these the thrombosis may be a late event in advanced cancer disease. Discrepancies in proportion of cirrhosis patients compared with previously published case series might also reflect patient selection and ascertainment bias resulting from an increased diagnostic activity in high-risk categories, but one should also consider the impact of disease duration. An intriguing finding was the heterogeneity of risk within the group of metastatic malignancy, with a significantly higher risk with pancreatic cancer in comparison with other major gastrointestinal adenocarcinomas.

When assessing the risk for a patient with a certain condition to develop an infrequent complication like PVT, knowledge from case series on the distribution of causes to that complication may be helpful and is sometimes the only available information. It may be misguiding, though. In this study, secondary malignancies accounted for a twice as large fraction of PVT cases as primary hepatobiliary cancer, but the actual risk of PVT in patients with secondary malignancies was less than half of that associated with primary hepatic cancer. In patients with both cirrhosis and hepatic cancer the risks appeared to be additive resulting in a prevalence of 14%. Whether increased diagnostic and therapeutic activities would be effective to reduce this rate is to be considered for further studies. A recent study, though, indicates that even hepatocellular cancer patients, who have developed portal vein tumour thrombosis, may benefit from an active treatment if timely diagnosed with respect to hepatic function[16].

In one sixth of the PVT patients no explanation could be found despite the thorough examination. This group differed from the other patients by a low frequency of complications typical to portal hypertension. A cross-sectional study like the present has obvious limitations for assessment of previous diseases, and this group may harbour some cases of juvenile PVT, though recent longitudinal studies indicate that PVT is an infrequent complication to umbilical vein sepsis, and in the western world the risk of this complication to umbilical vein catheterisation has declined considerably over time[5,17-18]. Similarly, it cannot be ruled out that the thrombosis in the odd case might have been caused by surgical trauma not evident from the recent patient history. With increasing possibilities to detect various trombophilic disorders the proportion of non-explainable, so called idiopathic PVT has gradually become smaller[5,10,19-22]. The present study does not allow an investigation of markers of the haemostatic system, but it is not unreasonable that the

PVT in some of these cases may be an expression of a hypercoagulability state.

Autopsy rates have declined considerably also in Malmö, following changes in legislation, and it is unlikely that a similar study will ever be performed again. With regards to the setting in time, some limitations should be discussed. Apart from aspects of the design previously viewed, the potential effects on the epidemiology of an increasing use of antithrombotic therapies should be considered. The study does not allow an assessment of actual medications, but even today the majority of these conditions would not warrant primary or secondary anticoagulant prophylaxis according to guidelines[23].

From this first population-based study we conclude that PVT is more common than previously indicated by clinical series. The greatly increased risk in patients with cirrhosis and hepatic carcinoma should warrant an increased awareness in these patients. While anticoagulation therapy might be considered for certain patient categories, this remains to be evaluated in prospective studies.

Abstract

AIM: To explore the effect of hypobaric hypoxia on mitochondrial energy metabolism in rat liver.

METHODS: Adult male Wistar rats were exposed to a hypobaric chamber simulating 5000 m high altitude for 23 h every day for 0 (H0), 1 (H1), 5 (H5), 15 (H15) and 30 d (H30) respectively. Rats were sacrificed by decapitation and liver was removed. Liver mitochondria were isolated by differential centrifugation program. The size of adenine nucleotide pool (ATP, ADP, and AMP) in tissue and mitochondria was separated and measured by high performance liquid chromatography (HPLC). The adenine nucleotide transporter (ANT) activity was determined by isotopic technique. The ANT total protein level was determined by Western blot.

RESULTS: Compared with H0 group, intra-mitochondrial ATP content decreased in all hypoxia groups. However, the H5 group reached the lowest point (70.6%) ($P < 0.01$) when compared to the control group. Intra-mitochondrial ADP and AMP level showed similar change in all hypoxia groups and were significantly lower than that in H0 group. In addition, extra-mitochondrial ATP and ADP content decreased significantly in all hypoxia groups. Furthermore, extra-mitochondrial AMP in groups H5, H15 and H30 was significantly lower than that in H0 group, whereas H1 group had no marked change compared to the control situation. The activity of ANT in hypoxia groups decreased significantly, which was the lowest in H5 group (55.7%) ($P < 0.01$) when compared to H0 group. ANT activity in H30 group was higher than in H15 group, but still lower than that in H0 group. ANT protein level in H5, H15, H30 groups, compared with H0 group decreased significantly, which in H5 group was the lowest, being 27.1% of that in H0 group ($P < 0.01$). ANT protein level in H30 group was higher than in H15 group, but still lower than in H0 group.

CONCLUSION: Hypobaric hypoxia decreases the mitochondrial ATP content in rat liver, while mitochondrial ATP level recovers during long-term hypoxia exposure. The lower level of extra-mitochondrial ATP may be related to the decrease of ANT activity during hypoxia exposure.

Key words: Adenine nucleotide pool; Hypoxia; Liver; Mitochondria

INTRODUCTION

The liver is the largest metabolic organ in the body. It performs a number of important and complex biological functions that are essential for survival. It also plays important roles in metabolism of carbohydrates, proteins, lipids, drugs, as well as in bile formation and secretion. Energy metabolism is closely related to these normal functions of liver. Mitochondria are the "energy factory" of cells. The adenine nucleotide transporter (ANT) is the most integral protein in inner mitochondrial membrane and consists of two identical subunits of 32 KD[1]. It catalyzes the transporter of cytosolic ADP and mitochondrial ATP in the process of phosphorylation[1]. Consequently, ANT is an important link between the cytosolic energy consumption and mitochondrial energy process yield[1,2]. Hypoxia could influence mitochondrial oxygenation respiration function[3,4] and F0-F1 ATPase activity of rat brain[4]. However, little is known about the relationship between the effects of hypobaric hypoxia on mitochondrial energy metabolism changes and ANT function in rat liver exposed to hypoxia. We therefore used

HPLC, isotopic assay and Western blot to examine the inner- and extra-mitochondria adenine nucleotide pool, ANT activity and its total protein level of rat liver exposed to hypobaric hypoxia.

MATERIALS AND METHODS

Chemicals

[2,8-^{3}H] ADP was obtained from Perkin-Elmer. Atractyloside (ATR), adenosine-5'-diphosphoric acid (ADP), albumin bovine serum (BSA), nitroblue tetrazolium chloride (NBT), 5-bromo-4-chloro-3-indolye-phosphate (BCIP) and mouse anti-goat IgG-alkaline phosphatase (IgG-AP) were supplied by Sigma. Goat anti-human ANT polyclonal antibody was purchased from Santa Cruz.

Animals and treatments

Adult male Wistar rats (150-200 g) were used in the experiments. The rats were exposed to a hypobaric chamber simulating 5000 m high altitude for 23 h every day for 0 (H0), 1 (H1), 5 (H5), 15 (H15) and 30 d (H30) respectively. Animals were fed with laboratory chow and tap water *ad libitum*. Rats were sacrificed by decapitation at seal level (H0 group) and hypobaric chamber simulating 4000 m high altitude (H1, H5, H15, H30 groups). After decapitation the liver tissues were immediately excised, and part of it was frozen in liquid nitrogen, and then transferred to -70℃ for storage until use. The remaining liver tissues were rapidly placed into ice-cold isolation medium [0.25 mol/L sucrose, 10 mmol/L 4-(2-hydroxymethyl)-1-piperazine ethane sulfonic acid (HEPES), 1 mmol/L ethylene diamine tetraacetic acid (EDTA), pH 7.4][5]. The tissues were chopped finely with scissors while being washed three times with ice-cold isolation medium and then manually homogenized by 15 up and down strokes with Teflon glass pestle. The liver mitochondria were isolated by centrifugation as established in our laboratory[3,4]. The protein content in the mitochondria suspension was assayed by Lowry's method using BSA as the standard.

Assay of mitochondria adenine nucleotide pool

Adenine nucleotides were separated and quantitated by HPLC[4,6]. Briefly, 500 mmol/L ice-cold $HClO_4$ was added to 200 μL liver mitochondria suspension and after 5 min incubation at 4 ℃, the liquid was centrifuged (12 000 r/min, 20 min) at 4 ℃ and the supernatant was saved and neutralized with 1 mol/L K_2CO_3 to pH 6.5-7.0. The liquid was centrifuged (12000 r/min, 10 min) at 4 ℃ again. The samples were maintained frozen at -70 ℃ until defrosted and analysed by HPLC equipped with high pressure pumps (Waters, USA), fit with 4.6 mm× 250 mm hypersil 18 (5 μm pore size, from Sigma). The samples were applied in a total volume of 20 μL. The results were shown as nmol adenine nucleotides/mg mitochondrial protein.

Assay of liver tissue adenine nucleotide pool[5,6]

The liver tissues stored at -70 ℃ were rapidly transferred into ice-cold 0.5 mol/L $HClO_4$, chopped finely with scissors, and then manually homogenized by 10 up and down strokes with Teflon glass pestle. The homogenate was placed at 4℃ for 5 min, centrifuged (12 000 r/min, 20 min) at 4 ℃. The supernatant was saved and neutralized with 1 mol/L K_2CO_3 to pH 6.5-7.0. The liquid was centrifuged (12 000 r/min, 10 min) at 4 ℃ again and maintained frozen at -70 ℃ until supernatant was analyzed by HPLC as described above. The results were expressed as nmol/mg tissue.

^{3}H- ADP label and liquid scintillation

The activity of ANT was determined at 4℃ by isotopic technique[1]. ^{3}H- ADP label was stopped by atractyloside, a specific inhibitor of ANT. Fifty microliter mitochondrial suspension solution was diluted by 150 μL ice-cold isolation medium. Twenty microliter ^{3}H- ADP (specific activity 33.9 Ci/mmol ADP) 0.3 μmol/L were added. After 10 s incubation at 4 ℃, the reaction was inhibited by 50 μL 3.2 nmol/L ATR, then centrifuged (12 000 r/min, 20 min) at 4 ℃. The precipitation was dissolved with 1 ml ice-cold isolation medium, centrifuged (12 000 r/min, 20 min) at 4℃ again for 20 min and the process was repeated three times. The pellet was digested at 70 ℃ with 7 mol/L $HClO_4$ 200 μL, 8.8 mol/L H_2O_2 400 μL for 40 min. The 200 μL sample was dissolved in 1 ml scintillator (5 g PPO was dissolved by 700 mL dimethylbenzene and 300 mL anhydro-ethanol) and measured in liquid scintillation counter. ANT activity was calculated from the radioactivities of H^3-ADP [count per min (cpm)]. Nonspecific binding of H^3-ADP to mitochondria was determined by incubation of mitochondrial samples with 50 μL 3.2 nmol/L ATR prior to addition of 0.3 μmol/L ^{3}H- ADP. The results were expressed as pmol ADP/min per milligram mitochondrial protein.

Western blot

The rat liver mitochondrial ANT protein level was determined by Western blot[1]. The mitochondria sample was solubilized in sample buffer and supplemented with 5 μL β-mercaptoethanol. Following that, it was heated for 10 min at 100 ℃ and supplemented with 5 μL β-mercaptoethanol again. Electrophoresis was performed on a 12% polyacrylamide slab gel with Tris/glycine running buffer. The staking gel contained 5% polyacrylamide. The lanes were loaded with 30 μL aliquots of solubilized mitochondria (10 μg). After separation the protein bands were stained with Commassie blue for 4 h or transferred to polyvinylidene difluoride (PVDF) sheet for 90 min. The PVDF sheet was washed twice with Tris-buffered saline (TBS) containing 0.1% Tween-20 (0.1% TBST), pH 7.4 at room temperature. ANT polyclonal antibody at a 1:1000 dilution was used. Incubation was performed in 0.1% TBST, pH 7.4 for at least 12 h at 4℃. The sheet was washed six times with 0.1% TBST at room temperature. Mouse anti-goat IgG coupled with alkaline phosphatase at a 1:1000 dilution was used as secondary antibody. Incubation was performed in 0.1% TBST, pH 7.4 for 1 h at room temperature. The sheet was washed six times with 0.1% TBST again. Antigen was visualized by luminescence (NBT/BCIP). Signals were quantified with Smartview (Furi

Science and Technology Co., Ltd., Shanghai, China).

Statistical analysis

Results were expressed as mean ± SD. Significant difference was determined by one-way ANOVA followed by LSD test between different groups. Statistical analyses were performed using SPSS 12.0 software.

RESULTS

Changes of adenine nucleotide pool in rat liver tissue during hypoxia exposure

Compared with H0 group, liver tissue ATP and ADP content decreased significantly in all hypoxia groups ($P<0.01$). Tissue AMP in groups H5, H15, and H30 was significantly lower than in H0 group ($P<0.05$ and $P<0.01$), while H1 group had no marked change compared to H0 group (Table 1).

Changes of intra-mitochondrial adenine nucleotide pool of rat liver during hypoxia exposure

Compared with H0 group, intra-mitochondrial ATP content decreased in all hypoxia groups, which in H1 group was 70.6% of that in H0 group ($P<0.01$) reaching the lowest point. Intra-mitochondrial ADP and AMP levels showed the same change and were significantly lower in H0 group than that in all hypoxia groups ($P<0.01$) (Table 2).

Changes of adenine nucleotide pool in extra-mitochondria of rat liver during hypoxia exposure

Compared with H0 group, extra-mitochondrial ATP and ADP content decreased significantly in all hypoxia groups ($P<0.05$ and $P<0.01$). Extra-mitochondrial AMP in groups H5, H15, and H30 was significantly lower than

that in H0 group ($P<0.01$), while in H1 group it had no marked change compared with H0 group (Table 3).

Change of mitochondrial ANT activity of rat liver during hypoxia exposure

Compared with H0 group, the activity of ANT decreased significantly in all hypoxia groups, which in H5 group was 55.7% of that in H0 group ($P<0.01$), being the lowest. Activity in H30 group was higher than that in H15 group ($P<0.01$), but was still lower than in H0 group ($P<0.01$) (Figure 1).

Effect of hypoxia on mitochondrial ANT protein expression

ANT protein expression in H5, H15, and H30 groups, compared with H0 group, decreased significantly, which in H5 group was the lowest point (27.1%) ($P<0.01$). The expression in H30 group was higher than that in H15 group ($P<0.01$), but was still lower than that in H0 group ($P<0.01$) (Figures 2 and 3).

DISCUSSION

ATP is the direct energy for cell usage. Mitochondrial ATP level is influenced by two factors. First, mitochondrial ATP is produced by oxidative phosphorylation. Mitochondria oxidative respiration and phosphorylation states are the main factors that affect the ATP level. Second, mitochondrial ATP provides energy for cytoplasm as well as for its own demand such as the synthesis of mitochondrial DNA, RNA and proteins, etc. Our previous work showed that during hypoxia exposure, mitochondrial

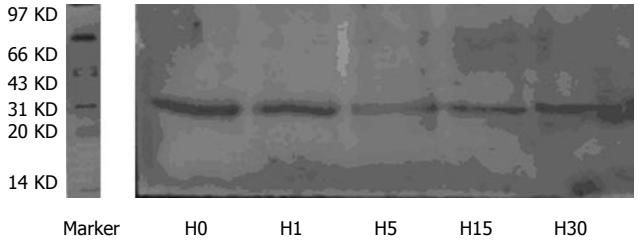

Figure 2 Western blot results of mitochondrial ANT protein in rat liver exposed to hypobaric hypoxia.

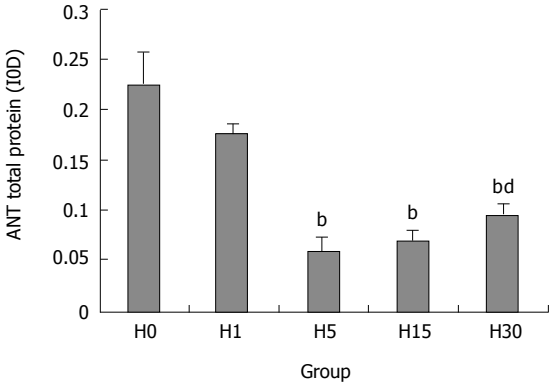

Figure 3 The effect of hypoxia on mitochondrial ANT total protein level (mean± SD). $^{b}P < 0.01$ *vs* H0 group; $^{d}P < 0.01$ *vs* H15 group.

ATP content and F_0-F_1 ATPase activity of rat brain decreased significantly compared with control [4,7]. This indicates that hypoxia could influence ATP production and then the mitochondrial ATP level. However, there were no reports about the hypobaric hypoxia effect on rat liver mitochondrial adenine nucleotide pool.

The current results showed that ATP level in rat liver mitochondria reduced during hypoxia exposure, which in H1 group was the lowest point, 70.6% of control ($P<0.01$). The decrease of mitochondrial ATP content may be related to the following factors. First, mitochondrial oxidative respiratory function was inhibited. Our previous study showed that hypobaric hypoxia inhibited the oxidative respiratory function of mitochondria in rat brain[3,4,6]. Our results (data not shown) also revealed that hypoxia significantly decreased the mitochondrial three state oxygen consumption and respiratory control rate in rat liver, while significantly increased the rat liver mitochondrial four state oxygen consumption. Second, hypoxia decreased the mitochondrial membrane potential (MMP). Our results (data not shown) demonstrated that hypoxia inhibited the MMP of rat hepatocytes. However, MMP is the motive power of mitochondrial ATP synthesis. Thirdly, hypoxia lowered the mitochondrial F_0-F_1 ATPase activity[4,8]. Fourthly, the lower mitochondrial ATP content may be also related to the reduction of intra-mitochondrial ADP concentration[1], intra-mitochondrial Ca^{2+} content[9] and extra-mitochondrial adenine nucleotide pool[10, 11] .

ANT is the most integral protein in inner mitochondrial membrane and consists of two identical subunits of 32 KD[1]. It is a key energy link between the mitochondria and cytoplasm since it catalyses the transmembrane exchange between ATP synthesized by the F1-Fo ATP synthase inside mitochondria and ADP generated by the metabolism in cytoplasm[1,6]. The ADP/ATP exchange follows the Michaelis-Menten kinetics and ANT activity is moderate, 1500-2000 molecules per min[12]. Schonfeld et al reported that matrix adenine nucleotides and the ANT protein content are associated with the changes of the ANT activity in rat heart mitochondria[1]. Rulfs et al also reported that matrix adenine nucleotide concentration influenced the ANT activity in rabbit liver mitochondria[13]. However, little is known about the effect of hypobaric hypoxia on mitochondrial ANT activity in rat liver.

Our study showed that the activity of ANT after hypoxia exposure decreased significantly. The ANT activity was the lowest point, 55.7% of control after hypoxia exposure for 5 d ($P<0.01$), while after hypoxia exposure for 30 d it was higher than after 15 d exposure ($P<0.01$), but was still lower than control. This indicates that hypoxia could inhibit the mitochondrial ANT activity in rat liver. The decrease of ANT activity may be related to the following factors. First, the ANT protein level and content was the main factor. Our results showed that ANT protein expression decreased significantly in H5, H15, H30 groups, which in H5 group was 27.1% of that in H0 group. Second, MMP also influenced the ANT activity[14]. Passarella *et al* reported that helium neon laser increased the rate of ADP/ATP exchange through increasing the MMP in rat liver[15]. In the presence of an MMP of about 100 mV positive inside, the rates of the [^{14}C] ATP_{out}/ADP_{in} exchanges were stimulated[3]. All these indicate that MMP is one of the most important factors that affect the ANT activity. The mechanism that decrease of MMP reduced ANT activity is not clear. Thirdly, the change of ANT conformation also influenced its activity. ANT has two conformational states, cytosolic conformation (c-confromation) and matrix conformation (m-conformation)[16,17]. ANT is not a pore, which opens or closes simply as a response to stimuli. Conformational changes have to occur to release nucleotides to the matrix (and the reverse) without creating leakage in the membrane. Fourthly, it was reported that the size of mitochondrial adenine nucleotide pool influenced the ANT activity. Previous studies showed that the postnatal increase in the matrix adenine nucleotides concentration contributed to the increase of ANT activity in rat liver[13] and heart[1].

The decrease of extra-mitochondrial ATP level influences the mitochondrial carrier family including ANT synthesis and transport. Extra-mitochondrial ATP level is mainly determined by the ANT activity. However, the lower ANT protein level has an identical role in influencing ANT activity during hypoxia. So the ANT activity-ANT protein level- ATP content form the vicious cycle and aggravate the dysfunction of cell energy metabolism during hypoxia exposure.

Abstract

We report a case of liver cell adenoma (LCA) in a 33-year-old female patient with special respect to its clonality status, pathogenic factors and differential diagnosis. The case was examined by histopathology, immunohistochemistry and a clonality assay based on X-chromosomal inactivation mosaicism in female somatic tissues and polymorphism at androgen receptor focus. The clinicopathological features of the reported cases from China and other countries were compared. The lesion was spherical, sizing 2 cm in its maximal dimension. Histologically, it was composed of cells arranged in cords, most of which were two-cell-thick and separated by sinusoids. Focal fatty change and excessive glycogen storage were observed. The tumor cells were round or polygonal in shape, resembling the surrounding parenchymal cells. Mitosis was not found. No portal tract, central vein or ductule was found within the lesion. The tumor tissue showed a positive reaction for cytokeratin (CK) 18, but not for CK19, vimentin, estrogen and progesterone receptors. Monoclonality was demonstrated for the lesion, confirming the diagnosis of an LCA. Clonality analysis is helpful for its distinction from focal nodular hyperplasia.

INTRODUCTION

Liver cell adenoma (LCA) is a rare benign liver tumor. It is considered a hepatocellular neoplasm, while some authors hold that LCA originated from liver progenitor cell[1]. A female predominance was noticed for the development of LCA based on the reports from Western countries, with a majority of cases associated with a long-term use of oral contraceptives or other steroids. Other diseases should be excluded before establishing the diagnosis of an LCA. It is indeed a difficult task to distinguish LCA from focal nodular hyperplasia (FNH) when the morphologic features are not prominent and a central scar is absent. Then some molecular approaches, including clonality analysis, may be helpful. In this article, a case of LCA in a female Chinese patient is presented, with its clonality status demonstrated.

CASE REPORT

A hepatic mass was found in the right lobe of a 33-year-old woman during her routine medical check-up. She was then admitted to Tangdu Hospital in Xi'an in January 28, 2003. She had never used oral contraceptives, and she had no history of alcohol abuse or hepatitis. No record of HCC or any hereditary disease was found among her family members. The parameters of routine clinical biochemistry, including values of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH), γ-glutamyltransferase (γ-GTP) and concentrations of α-fetoprotein (AFP) and plasma proteins, were all within normal ranges. The laboratory tests failed to show any positive signal in her serum for hepatitis B surface antigen (HBsAg) or anti-hepatitis C virus (HCV) antibody.

Ultrasonography revealed a solid mass in the posterior part of the right lobe of liver. Computed tomography (CT) scanning showed reduction of density for the lesion sizing 2.0 cm in diameter (Figure 1), indicating malignant potential. Laparotomy was then performed on February 1, 2003. Size of the liver appeared normal, with a mass found in the right lobe. Partial hepatectomy was then performed. Appearance, color and texture of the surrounding liver

were normal, without any indication of cirrhosis, pronounced fibrosis or cholestasis.

Histological and immunohistochemical procedures

The sample was fixed in 40 g/L formaldehyde solution, embedded in paraffin. Sections of 4 μm in thickness were prepared and stained by hematoxylin and eosin (HE), Masson trichrome methods and periodic acid-Schiff (PAS) reaction. Immunostaining was carried out using a streptavidin-labeled peroxidase (S-P) kit (KIT9730) as described previously[2]. The primary antibodies used in this study included those against cytokeratin (CK) 18, CK19, vimentin, CD34, estrogen receptor (ER), progesterone receptor (PR), AFP, S-100 protein, HBsAg, hepatitis B core antigen (HBcAg), as well as an anti-HCV antibody. All of the reagents for immunostaining were supplied by Maxim Biotechnology Corporation Limited, Fuzhou, China.

Clonal analysis

Sections of 10 μm in thickness were prepared, deparaffinized, rehydrated and HE stained. Neoplastic tissues were dissected using a syringe needle from 4 different tumor areas, sizing 0.5 cm × 0.5 cm for each. Normal liver tissue was also isolated from the surrounding parenchyma at 3 different sites of the same size and analyzed in a parallel way as reference samples. Genomic DNA was extracted using a QIAamp kit (Qiagen, Mannheim, Germany). Polymorphism was examined at the androgen receptor (AR) and phosphoglycerokinase (PGK) loci as described previously[3,4], with the former gene proved polymorphic at the CAG short-tandem repeat (STR) located in exon 1. Loss of X-chromosomal inactivation mosaicism was demonstrated by pretreatment of DNA with methylation-sensitive restriction enzyme *Hba* I and amplification via nested PCR. The CAG STR-polymorphic alleles were resolved on a 100 g/L denaturing polyacrylamide gel at 120 V for 4 h. A reduction of at least 50% in density of either band, as compared to that obtained using the sample not treated with *Hba* I, is regarded as loss of X-chromosomal inactivation mosaicism [5].

RESULTS

A partial resection liver specimen, sizing 4.0 cm × 3.0 cm × 2.0 cm, presented with a spherical mass of 2.0 cm in its maximal dimention. The mass was beneath the hepatic capsule, yellow brown in color and soft in its texture, without any necrotic focus or fibrotic scar in its cut surface. There was a clear border, but not a fibrotic septum between the lesion and surrounding liver tissue that appeared red brown and apparently normal. Microscopically, the lesion was composed of cells arranged in two-cell-thick cords, with the cell cords separated by sinusoids (Figure 2A). Focal fatty change and excessive glycogen storage were present (Figure 2A and 2B). The tumor cells were round or polygonal, apparently resembling the surrounding liver parenchyma cells in size and shape. Mitosis was not found. There was no portal tract or hepatic venule in the tumor. Ductule or scattered ductular cells (the so-called "oval cells"[6,7] or "liver progenitor cells"[1]) were absent, and immunostaining for the ductular cell markers, including CK19 and S-100 protein[7,8], failed to show any positive cell within the lesion. The tumor cells were positive for CK18 (Figure 2C), but negative for AFP, vimentin and p53 protein. They did not show any positive signal for ER or PR. Both neoplastic and the adjacent parenchymal tissues were negative for HBsAg, HBcAg and HCV antigen.

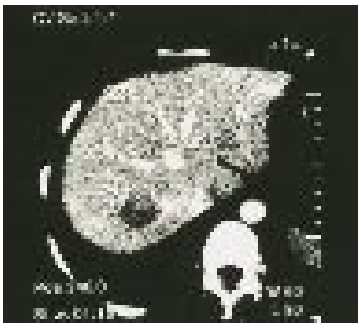

Figure 1 CT scanning showing a lesion with reduction of density in the posterior part of the right lobe of liver.

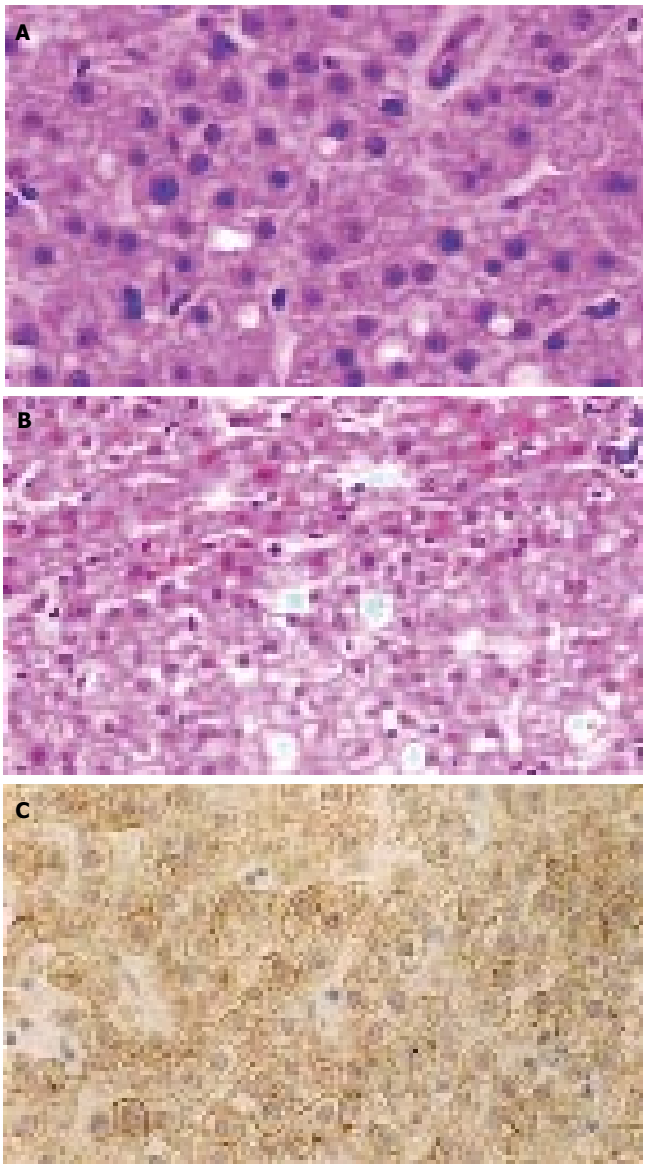

Figure 2 Liver cell adenoma (× 400). **A:** Similar to normal hepatocytes, arranged in two-cell-thick cords separated by hepatic sinusoids (HE); **B:** Showing the border between LCA (lower) and surrounding liver parenchyma (upper) (HE); **C:** CK18 immunoreactivity (S-P).

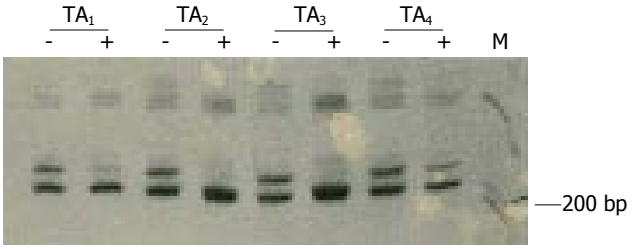

Figure 3 Clonal analysis on tissues from 4 tumor areas (TAs). The pretreatment with *Hha* I results in loss of the upper band for TA_2 and TA_3, and intensity reduction by factors of 71.8% and 57.1% for TA_1 and TA_4, respectively. +, with H*ha* I pretreatment; -, without *Hha* I treatment.

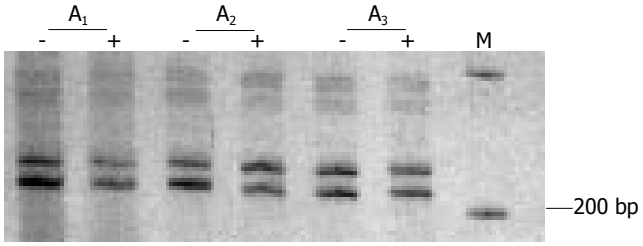

Figure 4 Data of clonality test of three areas of liver parenchymal tissues (A_1-A_3). Neither of the bands on gel shows marked intensity change for the samples pretreated with Hha I (+) compared to those not treated (-).

Clonality status of the lesion was determined by an assay based on the CAG-STR polymorphism at exon 1 of AR gene. Pretreatment with *Hha* I resulted in pronounced reduction or loss of the upper band for all of the tissue samples from 4 different areas of the lesion (Figure 3), demonstrating loss of the X-chromosomal inactivation mosaicism. The adjacent liver parenchyma, however, did not show the change (Figure 4). The data proved the monoclonal, neoplastic nature of the lesion, confirming the diagnosis of LCA. The patient has survived for 30 mo after the operation without any indication of recurrence.

DISCUSSION

LCA is a rare benign hepatic neoplasm, accounting for less than 2% of all hepatic tumors[9]. A pronounced female predominance was noted mainly by authors from Western countries. It often occurs in women of 20 to 40 years during their child-bearing period[10,11], being closely associated with long-term use of steroids, mainly oral contraceptives[12-14]. In fact, it was rarely reported before the introduction of oral contraceptives in 1960s. Edmondson *et al*[15] found only two cases in 48 900 necropsies performed in Los Angeles General Hospital during the period from 1918 to 1954. In 1973, Baum *et al*[16] pointed out the possible link between the use of oral contraceptives and LCA development. Data from several reports has confirmed the etiologic association. Leese *et al*[17] reported 24 cases of HA, 16 (66.7%) of them with a history of using oral contraceptives. Tumor regression was observed in some cases after withdrawal of the hormones[18,19], and then the tumor remained silent or grew slowly for many years, or even progressed to HCC[20], albeit infrequently. Complete remission was observed in an LCA patient, who had used oral contraceptives for 8 years, after the hormone withdrawal for 9 months[21].

Through literature review, the clinicopathological data of 127 cases of LCA reported from Chinese patients were collected and compared to those of 130 patients from Western countries, with the male/female ratios being 1.8/1 and 1/2.9, respectively. The ages of the Chinese patients ranged from 2 to 73 years, with their mean and average values estimated to be 31.0 and 35.8 years, respectively. For patients from Western countries, the ages ranged from 11 months to 82 years, with their mean and average values 30.0 and 31.6 years, respectively. Only 3.9% (5/127) of Chinese patients had a history of using oral contraceptives, the percentage being much lower than that for the patients from Western countries (54/130, 41.5%). Difference is evident, therefore, between the LCAs occurring in China and in Western countries in their etiologic associations, indicating possibly different pathogenic pathways. This, at least partly, provides an explanation for the distinct gender distribution pattern in Chinese patients.

Other factors are also linked to LCA development, including glycogen storage diseases [22] and administration of danazol[23], phenobarbital[24] and androgenic/anabolic steroids[9,25-33]. Among the 130 cases from Western countries, 4 (3.1%) were found to have glycogen-storage diseases, but only one (0.8%), in the Chinese group, was with the association. For some LCA cases, there seemed no identifiable pathogenic factor. The majority of the cases from the Chinese group fell into this category. Among the 127 Chinese patients, 13 (10.2%) were seropositive for HBsAg, and 8 of them were with chronic hepatitis[34-37]. Among the patients from Western countries, however, only one (0.8%) was shown to be an HBsAg-carrier. In consideration of the high prevalence (up to 10%[38]) of HBsAg-carrier state in China, the data does not provide support for the role of persistent HBV infection in development of the solitary LCA.

Most of LCAs grow slowly and are asymptomatic or cause only mild symptoms, while rupture and hemorrhage may occur in some tumors (15%-33%[39]), and malignant transformation was also observed in a minority of the cases (5/39, 12.8%[20]). Ultrasonography, CT scanning and magnetic resonance imaging (MRI) are useful for detecting hepatic occupation and determining its location and size. Imaging approaches may be helpful for identifying LCA from other hepatic lesions, and a peritumorous halo, demonstrated by CT scanning, was considered indicative of LCA[40,41]. These features, however, are not specific[40], and the accurate preoperative diagnosis of LCA, particularly the distinction from HCC, is frequently problematic. This is even more serious as a surgical consideration in China where incidence of HCC is overwhelmingly high compared to that of LCA. For the pathologists, well differentiated HCC and FNH are among the hepatic lesions that should be excluded before making a diagnosis of LCA.

HCC is diagnosed usually at ages between 40 and 60 years, with a pronounced male predominance. In China, including Hong Kong and Taiwan, about 80% of HCCs were found in patients with chronic hepatitis B and cirrhosis or advanced liver fibrosis. An elevated level of circulating AFP is indicative of HCC, but this change may

not be evident in patients with an early-stage, often well differentiated, HCC. Liver-cell plates more than three cells thick, acinar structures, increased nuclear/cytoplasmic ratio, prominent nucleoli, mitoses, increased cytoplasmic basophilia, loss of the reticulin fibers, absence of Kupffer cells, presence of vascular invasion or immunoreactivity for AFP, all indicate HCC. However, none of these features can be relied upon with certainty, as some are also seen in the hepatic lesions with high-grade SCC, including the premalignant nodules of altered hepatocytes[2], adenomatous hyperplasia[42-46] and LCA. The most helpful parameters, in our consideration, are thickness of the liver-cell plates (more than three cells), cell density (an increase of two folds compared to the surrounding liver parenchyma) and vascular invasion[38]. It should be noted that male, cirrhosis, and chronic HBV infection strongly indicate that a hepatic neoplasm is malignant. Conversely, female and a history of oral contraceptive use support the diagnosis of LCA. Exceptional difficulties may be encountered in some of the LCAs associated with long-term use of anabolic steroids or metabolic disorders. Some of them may show pronounced architectural disturbance and cellular atypia, which make their distinction impossible from well-differentiated HCCs based on histological grounds alone. Malignant transformation is proposed for such cases[13,20,47,48], but they often show more favorable clinical courses, or even regression after withdrawal of the steroid[21]. Such lesions may represent the borderline hepatocellular neoplasm, and their behaviors should be determined by careful postoperative observations.

FNH occurs most commonly in young women, having similar etiological associations and clinical manifestations to LCA[49-51]. It is a localized lesion, frequently solitary, within an otherwise normal or nearly normal liver. The lesion is similar to cirrhosis by its histology, and a central stellate fibrous region containing large vessels can often be found. Its development has been attributed to the vascular malformation[52,53]. Usually, FNH is readily distinguished from LCA by its central scar, multinodularity and presence of proliferating bile ductules in the fibrous septa. It may become a diagnostic problem, however, when the central fibrous region is not evident. Data from different laboratories have demonstrated the polyclonal cell composition and indicated non-neoplastic nature for the lesion[54,55]. In contrast, an LCA was shown to be monoclonal[56], and our data confirm the conclusion that LCA is a neoplastic lesion. The clonality assays, therefore, are helpful for the differential diagnosis between LCA and some FNH lesions without an identifiable central scar.

Abstract

We experienced a case of intussusception caused by cystic lymphangioma of the colon in a 32 years old female who was admitted to our hospital for the chief complaint of bloody stool. In the colonoscopic examination, cystic mass with stalk which had smooth mucosal surface was noted at the descending colon. Abdominal ultrasonography and computed tomography revealed left colon intussusception with a multilocular cystic tumor as a leading point. Emergent operation was performed. On the histopathologic examination, the cystically dilated spaces lined by endothelium and septated by fibrous septa were present. The pathological diagnosis was cystic lymphangioma of the colon. Although intussusception due to lymphangioma in an adult are rare, it should be taken into consideration that it is possible diagnosis.

Key words: Cystic lymphangioma of the colon; Adult intussusception

INTRODUCTION

Lymphangioma is a benign tumor consisting of several expanded lymphatics, each lymphatics is surrounded by benign endothelial cells and it could be developed in any parts of the body. However, it is developed primarily in the neck, the axillary area, the scapula and other areas where lymphatic organs are abundant[1,2]. Lymphangioma is hardly developed in the digestive organs and the development of the colon is very rare. It was reported for the first time by Chisholm and Hillkowitz in 1932 and recently, with the increased application of colonoscopy and endoscopic ultrasonography, these cases are on the rise[4,5]. We report a case who was diagnosed as intussusception due to cystic lymphangioma by abdominal ultrasound, computed tomography and colonoscopy.

CASE REPORT

A 32-year-old female was admitted to our hospital due to bloody stool for 3 d. In her past, family and social history, specific findings were not detected. At the time of visit, blood pressure of 100/60 mmHg, pulse rate of 76 per min and body temperature of 36.7 ℃ was recorded. In physical examination, the acute ill appearance was detected and she were conscious. The conjunctiva was pale and the head-neck lymph node was not palpated. In abdominal examination, the liver or the spleen was not palpated and the bowel sound was normal. But, left lower quadrant pain was detected, however, the rebound tenderness was not detected. In laboratory findings, in peripheral blood test, the number of leukocyte was 16 140/mm^3, hemoglobin was 128 g/L, and platelet was 317 000/mm^3. In biochemical test was all normal. CEA, CA 125 and CA 19-9 showed normal limits.

In colonoscopic examination, a cystic mass with a stalk of the descending colon was detected (Figure 1). The mass was covered with the normal mucosa with smooth surface and palpated with the tissue biopsy forceps, it was cystic that changed readily. On the next day, the patient reported severe abdominal pain and thus abdominal ultrasonography and abdominal computed tomography were performed. In abdominal ultrasonography, a cystic mass divided by several septa was detected and the situation was that intussusception by this mass (Figure 2). In abdominal computed tompgraphy, a mass was detected and in the proximal area, intussusception was detected (Figure 3). The patient underwent emergent surgery and the partial resection of the descending colon was performed. The resected specimen was a mass 2.5 cm× 3.5 cm× 5.0 cm in size and similarly to ultrasonographic finding. The specimen was a bag shape, its inside was divided into several fibrous septa and filled with clear serous liquid (Figure 4). In histological finding, the cyst was located below the mucosal mem-

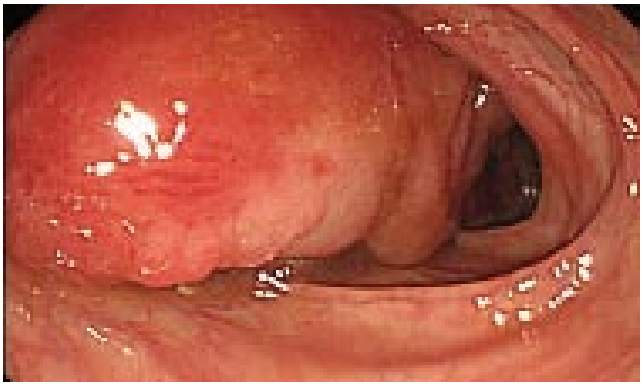

Figure 1 Colonoscopic examination shows a 2.5 cm x 2.5 cm x 5.0 cm sized round, smooth surfaced mass covered by normal mucosa in the descending colon. This mass is pedunclated cystic nature, and compressible pillow sign positive.

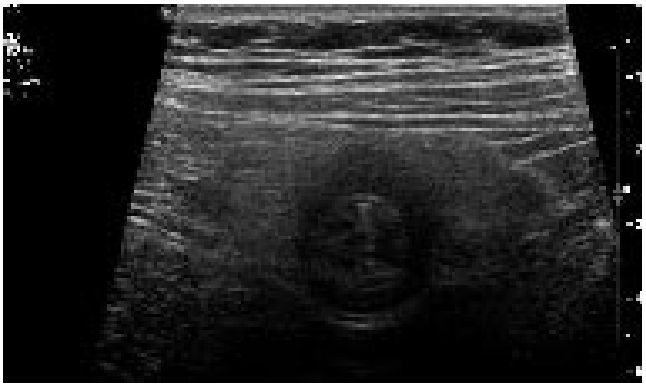

Figure 2 Ultrasonography of the mass shows a multilocular cystic lesion with septa.

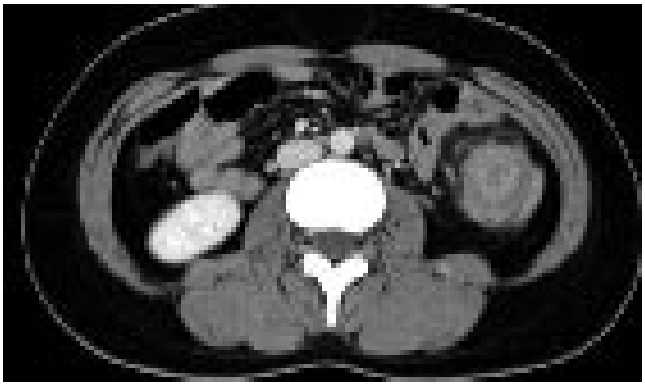

Figure 3 Computed tomography shows the cystic lesion in the descending colon, occupying the whole lumen, and also shows multicentric target sign and sausage-shaped inhomogeneous soft-tissue mass.

Figure 4 Macroscopic finding of the resected specimen reveals 2.5 cm x 3.5 cm x 5.0 cm sized multiseptated submucosal cystic tumor, which changed shape easily. The tumor shows fluctuation and serous clear fluid was aspirated by needle puncture.

brane, the inside was surrounded by normal epithelial cells and divided by several fibrous septa (Figure 5). Based on the above findings, she was diagnosed as intussusception caused by cystic lymphangioma.

DISCUSSION

Intussusception in adults is developed relatively infrequently. They are equivalent to 1% of colonic obstructive patients and they are equivalent to 5 - 10% of total intussusception[1,2]. Different from in children, they occur secondarily by definite lesions. For the diagnosis of such intussusception in adults, computed tomography has been reported to be the most useful radiological method[1]. This case is a patient that intussusception is caused by the cystic lymphangioma in the descending colon. Lymphangioma within the abdominal cavity is rare, and it occupies less than 5% of the entire lymphangioma[3]. Most reported cases are the cases detected accidentally during colonoscopy or barium enema and definitely diagnosed histologically by the resection of the lesion[5, 7]. Pathophysiologically, according to its shape, it is classified into 3 types: (1) simple capillary, (2) cavernous and (3) cystic. As in our case, cystic cases are most frequent. Recently, with the increase of the application of colonoscopy, the reported cases of the lymphangioma of the colon are increased [4,5]. The findings suggesting lymphangioma are the characteristics that are the round and soft surface, a wide base area, pink color and semi-transparent. In response to the peristaltic movement or the position of patient, its shape changes and it has the characteristic that the diameter and the location change upon pressing by forceps. In our case also, it was stalked cystic and the smooth surface of mass was covered with the normal mucosa of large intestine, and palpated with the biopsy forceps, it showed the pattern of readily changing its shape. The disease should be differentiated from other mass lesions, such as lipoma, cavernous angioma, leimyoma and enteric duplication cyst. However, endoscopic findings are very diverse, subjective and it is not of help to the diagnosis. So, the confirmation of its structure by endoscopic ultrasonography is important for the differential diagnosis[6]. In ultrasonography, it is detected as a mass limited to the submucosal area, separated well from adjacent tissues, and divided by several septa and for the cases showing such findings, it could be definitely diagnosed without further tests, and for the asymptomatic cases, the follow-up observation without treatment is sufficient[7]. Occasionally, nonspecific symptoms, in other

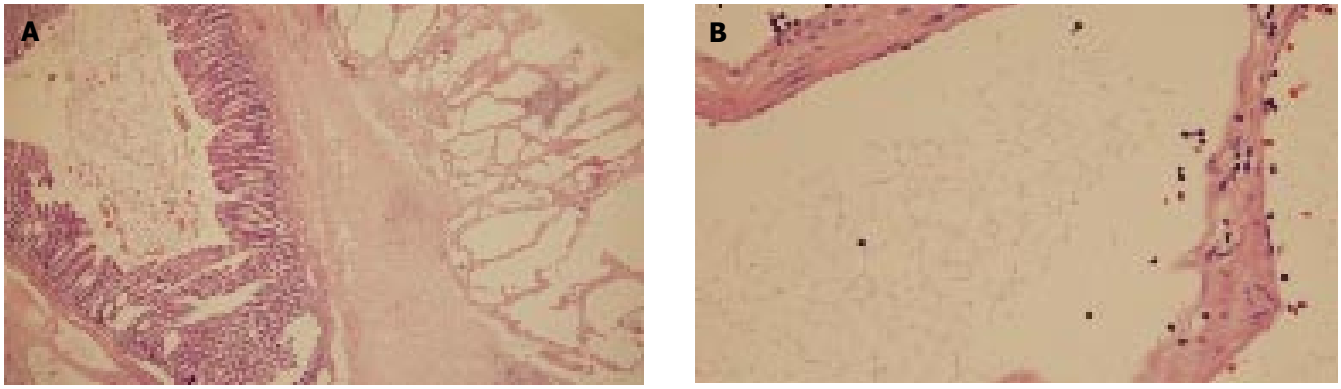

Figure 5 (**A**) Cystically dilated spaces are covered with single layer of endothelial cells and separated by fibrous septa are present in the submucosa. The overlying colonic mucosa is normal (H & E stain, x100). (**B**) Atypical cell are not noted, and endothelium is lined by benign cuboidal cells (H-E, original magnification, x400).

words, hemorrhage or abdominal pain may be reported, it may induce protein loss enteropathy, and intussusception may be developed by the mass[8]. Our case is also the example that the patient was admitted for bloody stool and developed intussusception on the next day. In such cases, if symptomatic or with complications, it should be removed by surgery or endoscopic resection. The indications of endoscopic polyp resection are staked masses or partially staked masses less than 2 cm in size[6]. However, in the cases of masses with a large diameter, surgical resection is required. It has been reported that generally, in the patient with intussusception, there are a large volume of hemorrhage, or protein loss enteropathy, a large mass in size, and asymptomatic patients showed a mass in a small size[9]. We experienced a case of intussusception in a 32-year-old female patient admitted for bloody stool, and it is an important causality although rare, therefore, the case is reported here together with a review of the literature.

Abstract

Spontaneous rupture is a rare complication of splenic hamartoma. A review of the literature revealed only four such cases. To the best of our knowledge, this is the first report of spontaneous rupture of splenic hamartoma associated with liver cirrhosis and portal hypertension. A 53-year-old woman, who was followed up for aortic dissection and hepatitis C virus (HCV)-related liver cirrhosis, was referred with sudden left chest and shoulder pain. An abdominal ultrasound showed intraabdominal bleeding, and computed tomography indicated rupture of a splenic tumor. Emergent splenectomy was carried out. The postoperative course was uneventful, and the patient was discharged on the 13th postoperative day. Pathology revealed the tumor to be a ruptured splenic hamartoma. The non-tumorous splenic parenchyma revealed congestive changes. We consider that the presence of liver cirrhosis and portal hypertension are risk factors for spontaneous rupture of the splenic hamartoma.

INTRODUCTION

Splenic hamartoma is a rare benign tumor, and is usually asymptomatic. Its spontaneous rupture is an uncommon, but life-threatening, complication. A review of the literature revealed only four such cases [1-4]. Furthermore, there has been little discussion of underlying disease and no previous reports of a ruptured splenic hamartoma in a patient with chronic liver disease. Here we report a case of spontaneous rupture of splenic hamartoma associated with hepatitis C virus (HCV)-related cirrhosis and portal hypertension.

CASE REPORT

A 53-year-old woman was referred to our emergency care center with sudden left chest and shoulder pain without a history of trauma. She was being followed up for aortic dissection (DeBakey typeⅢb) and HCV-related liver cirrhosis. The aortic dissection had been stable for seven years and the pseudo-lumen was also patent. Portal hypertension and moderate splenomegaly was associated with the liver cirrhosis. During the clinical examination, the patient lost consciousness and her blood pressure dropped below 60 mmHg, though rapid infusion of saline prompted a swift recovery of consciousness and blood pressure. Initially, ischemic heart disease was suspected, but a chest X-ray and electrocardiogram showed no abnormal findings. Laboratory data were: hemoglobin, 8.2 g/dL; platelets, $5.9 \times 10^4/m^3$; total bilirubin, 1.2 mg/dL; asparate aminotransferase, 63 IU/L; alanine aminotransferase, 53 IU/L, albumin, 2.8 g/dL; prothrombin time, 74% to control. An abdominal ultrasound revealed fluid collection suggestive of intraabdominal bleeding. Computed tomography indicated rupture of a splenic tumor, which had been not detected by the previous screening for the aortic dissection (Figure 1). The patient was transferred to our intensive care unit, where conservative treatment was started, beginning with a blood transfusion. Interventional treatment was not initially selected because of the aortic dissection. However, her blood pressure dropped again, necessitating an emergency operation.

At laparotomy, there was a massive hemorrhage with recovered blood weighing 2 880 g. Active bleeding continued from the ruptured spleen, and a splenectomy was performed. The spleen weighed 520 g and measured 15 × 10

Figure 1 Enhanced computed tomography showed intraabdominal fluid collection near the spleen, and contrast material outflow from the splenic tumor.

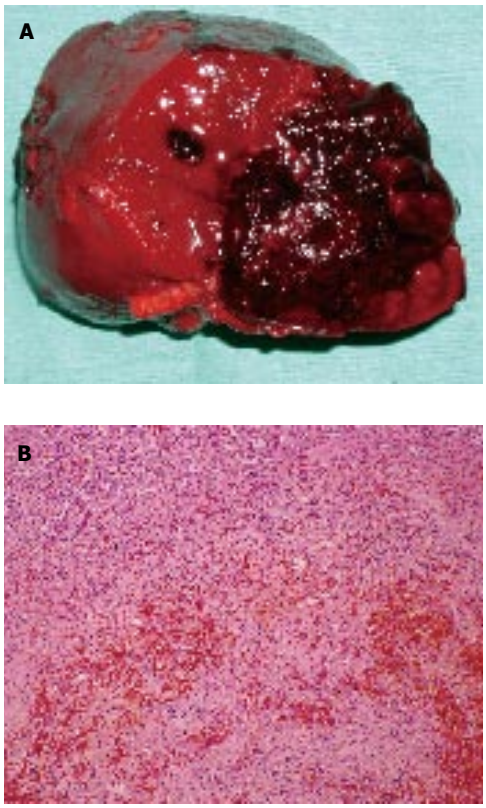

Figure 2 **A:** Macroscopic findings for the ruptured splenic hamartoma. The hamartoma is well demarcated from the surrounding parenchyma and significant hemorrhage is shown; **B:** Microscopy showed a red pulp with no lymphatic structures, or trabeculae of the spleen. (hematoxylin-eosin, original magnification, ×200).

cm with subcapsular hemorrhage. Macroscopically, there were four nodules on the cut surface of the specimen. The nodule near the upper pole was the largest, 4.5 × 3.0 cm in diameter, and ruptured, causing intraabdominal hemorrhage (Figure 2A). Microscopically, the nodules were not encapsulated and composed of sinusoidal spaces and cords of Billroth as in normal red pulp without lymphatic follicles or fibrous trabeculae (Figure 2B). The vessel spaces linked by plump endothelial cells were filled with a mixed population of erythrocytes and lymphoreticular cells. Pathology revealed the tumor to be a ruptured splenic hamartoma, of the red pulp type. The non-tumorous splenic parenchyma showed proliferation of splenic sinuses and cords with extramedullary hematopoiesis, indicating congestive changes. These findings corresponded to the splenomegaly caused by portal hypertension. The postoperative course was uneventful, and the patient was discharged on the 13th postoperative day.

DISCUSSION

Splenic hamartoma is a rare benign tumor composed of all the normal constituents of splenic parenchyma arranged in a disorganized fashion. The incidence has been reported as 0.024-0.13% from autopsy cases [5, 6]. Clinical symptoms include mass effect due to splenomegaly, pancytopenia, hematological disorders, and spontaneous rupture [5-7]. The average spleen weight and size of all reported hamartomas were about 600 g and 5.1 cm, respectively [6, 7].

Spontaneous rupture of splenic hamartoma is rare. The cause of rupture has not been specified in any of the small number of cases reported to date (Table 1). The cases discussed in these reports showed mild to moderate splenomegaly, however, the weight of the spleen (117-459 g) was below the average, and the size of the hamartomas (2.5 cm-5.4 cm in diameter) did not far exceed the average. There were also no underlying diseases, except for one case, in which the patient had lung cancer. These cases indicate that the weight of the spleen, the size of the hamartoma, or any underlying diseases, is not closely related to rupture of the hamartoma. In contrast to these cases, our case was characterized by moderate splenomegaly in association with hepatitis C virus-related cirrhosis. The patient had no other risks of spontaneous

splenic rupture, such as a history of trauma.

Whether or not hepatitis C virus-related cirrhosis contributed to the rupture of the splenic hamartoma in our case is unclear. Spontaneous rupture of the spleen is a rare complication of liver cirrhosis [8-14]. In these reported cases, portal hypertension associated with liver cirrhosis has been suspected of playing a role in splenic rupture. In our case, portal hypertension and splenomegaly due to cirrhosis was apparent, and microscopy revealed congestive changes in the non-tumorous splenic parenchyma. Since the hamartoma nodules are not encapsulated and composed of sinusoidal spaces and cords of Billroth as in normal red pulp, it is quite likely that the hamartoma itself was affected by portal hypertension. Although an association of splenic hamartoma with liver cirrhosis and portal hypertension has been demonstrated in several studies [1, 15-17], to the best of our knowledge, this is the first report of spontaneous rupture of splenic hamartoma associated with liver cirrhosis and portal hypertension.

Recent progress in imaging enables us to detect splenic tumors, and elective surgery is sometimes conducted [18-20]. Operative indications for splenic hamartoma include the possibility of malignant disease and the risk of spontaneous rupture. If splenic hamartoma is suspected by image findings, elective splenectomy should be taken into consideration to make a definitive diagnosis and to prevent rupture [21]. We consider that the presence of liver cirrhosis and portal hypertension are risk factors for spontaneous rupture of the splenic hamartoma.

Abstract

A 46-year-old woman was diagnosed with palmoplantar pustulosis (PPP) at the Department of Dermatology, Fukushima Medical University Hospital in 2000, and was treated with ointment. However, because liver dysfunction developed in 2003, she was referred to our department, where primary biliary cirrhosis (PBC) was also diagnosed on the basis of clinical findings. One year later, at the age of 49, she developed manifestations of Behçet's disease (BD), including erythema nodosum in the lower extremities. Because she had a history of uveitis, recurrent oral ulceration was present, and the HLA typing was positive for B51, BD was additionally diagnosed. Liver function normalized within three months of the start of treatment with ursodesoxycholic acid (UDCA). This is the first case of PBC associated with BD and PPP.

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease associated with a variety of other conditions, including Sjögren's syndrome, Hashimoto's thyroiditis, scleroderma or other components of CREST syndrome, and inflammatory arthritis [1,2], but its association with Behçet's disease (BD) is very rare, and so is its association with palmoplantar pustulosis (PPP) [3]. We report the first case of PBC associated with BD and PPP, and discuss the relationship among these three diseases in terms of the environmental factors, such as infectious agents, described in the literature.

CASE REPORT

A 37-year-old woman suffered from uveitis in 1991. In 2000, she was diagnosed with palmoplantar pustulosis (PPP) at the Department of Dermatology, Fukushima Medical University Hospital, and was treated with ointment. However, liver dysfunction developed, and she was referred to our department in March 2003 at the age of 49 years.

At our first medical examination, she complained of no symptoms involving the oral mucosa or extremities except the lesion of pustulosis. Blood pressure was normal, and there was no history of diabetes mellitus or hyperlipidemia. Laboratory data showed liver dysfunction with elevated levels of AST (149 IU/L), ALT (340 IU/L), ALP (428 IU/L; normal, 125-335 IU/l), GGT (228 IU/L; normal, 6-30 IU/l), T-Bil (0.7 mg/dL) and IgM (130 mg/dL; normal, 52-270 mg/dL). The titer of anti-mitochondrial autoantibodies (AMA) was 1:20, and the index of AMA-M2 antibody was 32 (normal, <7). Results of hepatitis B and C serologic tests were negative. After one month, subarachnoid hemorrhage occurred owing to the bursting of a cerebral artery aneurysm. An emergency brain operation was performed, revealing four cerebral artery aneurysms including the ruptured one (Figure 1), which were clipped successfully. Her hospital course was otherwise uneventful, and her slight cerebral signs resolved within days of the operation, and she was discharged from the hospital, neurologically intact. Liver biopsy was, therefore, postponed. PBC associated with PPP was diagnosed on the basis of clinical findings based on 'Criteria for Diagnosis of PBC in Japan' by the Study Group for Autoimmune Hepatitis, a subdivision of the Research Group for Intractable Hepatitis, sponsored by the Ministry of Health and Welfare of Japan [4]. Liver function normalized within three months of the start of treatment with ursodesoxycholic acid (UDCA) (600 mg/d).

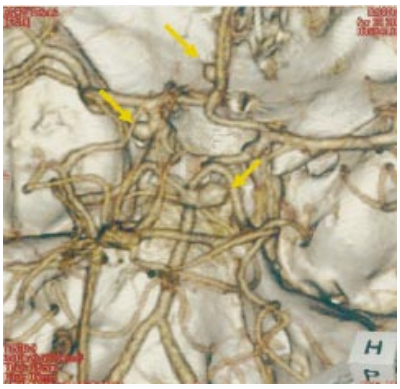

Figure 1 Computed tomographic angiography shows aneurysms of the left. internal carotid-posterior communicating artery, left. anterior communicating artery, and right. posterior cerebral artery (arrows).

Figure 2 Typical eruption of erythema nodosum shows erythematous nodules on the anterior aspect of the leg.

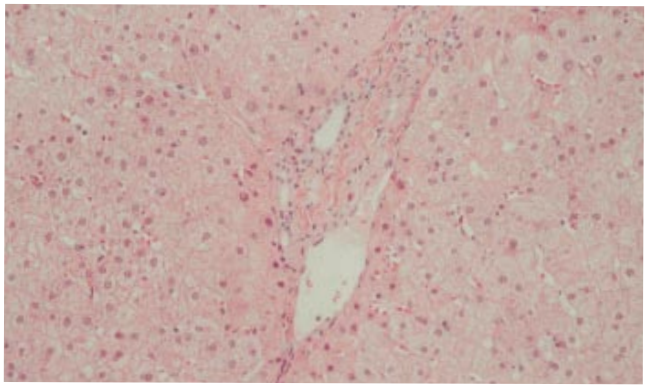

Figure 3 Liver biopsy specimen shows slightly enlarged portal tracts with no evidence of chronic nonsuppurative destructive cholangitis. Hematoxylin and eosin, original magnification ×100.

Erythema appeared in the lower extremities in July 2004 (Figure 2). Oral aphthous ulcers were sometimes noted, too. Lymphadenopathy was not recognized. No abnormal findings were noted in the chest or abdomen. Laboratory data at the time were as follows: increased level of CRP, 3.1mg/dL (normal, <0.3) and ESR, 73mm/h (normal, 3-15); WBC, 9 400/mm^3, (normal, 2800-8800). Liver function and renal function were normal. HLA typing was positive for A2, A30 (19), B54 (22), B51 (5), Cw1 and DR9. Because HLA B51 was positive, a skin biopsy of the erythema was performed. Histological examination showed erythema nodosum characterized by a neutrophilic inflammatory infiltrate involving the septa of the subcutaneous tissue. Incomplete type Behçet's disease (BD) was diagnosed on the basis of recurrent oral aphthous ulcers, erythema nodosum, and past history of uveitis according to the diagnostic criteria from the Behçet's Disease Research Committee of Japan (1987 revision)[4]. A non-steroidal anti-inflammatory drug was administered orally as palliative treatment, and erythema nodosum resolved.

Liver biopsy was performed in January 2005, but histological examination did not show typical chronic nonsuppurative destructive cholangitis (CNSDC) (Figure 3) because liver function was improved by 2-year UDCA treatment.

DISCUSSION

BD is a well-known multisystem inflammatory disorder of unknown etiology that is characterized by oral and genital ulcers, uveitis, and a variety of other manifestations, such as erythema nodosum, polyarthritis, thrombophebitis, and ulceration of the intestinal mucosa [6]. Involvement of the liver is less common; however, systemic amyloidosis and Budd-Chiari syndrome have been documented [7, 8]. Susceptibility to BD is associated with the HLA B51 allele.

There have been only a few cases of PBC associated with BD [9]. In the present case, the clinical manifestations of BD were oral aphtha, erythema nodosum and uveitis, and there was no genital ulcer or intestinal involvement. However, it is possible that the intracranial aneurysms were related to BD. Cerebral artery aneurysms in patients with BD are uncommon, but there are 14 cases reported in the literature [10]. These cases are quite similar to ours in which the aneurysms are multiple. Furthermore, in our case there was no risk factor that would produce a cerebral vessel event: hypertension, hyperlipidemia, or diabetes mellitus. Some BD case reports describe the efficacy of steroid therapy for multiple nonruptured cerebral artery aneurysms [11-13]. Kerr *et al*, however, report a patient with BD who developed multiple aneurysms and subarachnoid hemorrahge in rapid succession under steroid therapy [14]. In our patient, follow-up brain computed tomographic angiography was performed after surgical treatment, but no aneurysms were detected.

PBC is an autoimmune liver disease characterized by the occurrence of AMA. Clinically, PBC is associated with a large variety of other diseases, such as arthropathy, CREST syndrome, and autoimmune thyroiditis [15]. To our knowledge, however, no report has ever described the simultaneous development of three autoimmunological diseases, PBC, BD, and PPP.

This is the first case report of PBC complicated by BD and PPP, which is a localized type of psoriasis. Although psoriasis is characterized by proliferation of the epidermis, the immune system plays a prominent role in its development [16]. Interaction between keratinocytes and T cells is involved in the pathogenesis, just as interaction between biliary epithelial cells and T cells is in the pathogenesis of PBC. In BD, lymphocytic infiltration is observed around the arteries. Moreover, some workers suggested that some microbial antigen is closely associated with the development of these three diseases [17-19].

Memory T cells specific to these bacterial antigens may be activated by antigens on the arteries, skin or liver. We believe that patients with PBC associated with BD and PPP hold the key to clarifying the nature of these diseases.

Abstract

Previous reports of a solitary metastatic hepatocellular carcinoma have been rare. Because this tumor has a different treatment modality and prognosis, an accurate differential diagnosis is essential. Here we report a rare case of a solitary chest wall metastasis from unknown primary site of hepatocellular carcinoma. It involves a 51-year-old man who was admitted to our hospital because of a palpable left upper chest wall mass. The mass was resected and pathologic examination confirmed a diagnosis of metastatic hepatocellular carcinoma. Despite our investigation, no evidence was found that indicated the primary origin of the hepatocellular carcinoma. Four months later, the patient was admitted again because of spinal cord compression at the third and fourth thoracic vertebrae. Emergent decompressive laminectomy was performed and microscopic features revealed the same pathology as the initial chest wall mass resected 4 months earlier. After one year, a follow-up abdominal computed tomography (CT) still revealed no evidence of primary hepatocellular carcinoma.

Key words: Chest wall; Hepatocellular carcinoma; Metastasis

INTRODUCTION

The most common causes of a chest wall mass in adults are infection or tumor,[1] and the majority of the malignant masses are hematological in origin. Malignant chest wall masses arising from a primary focus in the lung (metastatic lung cancer) or the liver (metastatic hepatocellular carcinoma) are rare.[2] Primary hepatocellular carcinoma often metastasizes out of the liver. Metastasis typically occurs in patients with advanced stages of the disease, and the most common site is the lungs, followed by the abdominal wall, lymph nodes, bone, adrenal gland, pancreas, kidney and spleen.[3,4] Katyal *et al* [5] categorized the intrahepatic stage of the tumor according to TNM staging, and reported that extrahepatic metastasis of small hepatocellular carcinomas (confined to stage one) was rare. References indicates that hepatocellular carcinomas found outside the liver without a primary focus are usually due to carcinogenesis of ectopic liver. Cases of hepatoid adenocarcinoma have previously been reported, but a solitary extrahepatic hepatocellular carcinoma that has metastasized to the chest wall has rarely been reported. Because these types of tumors have different treatment modalities and prognoses, an accurate differential diagnosis is essential. Here, the authors have diagnosed a solitary metastatic hepatocellular carcinoma of the chest wall, with an unknown primary focus, and have been closely following the patient for one year since the diagnosis.

CASE REPORT

A 51-year-old male visited the hospital because of a left upper chest wall mass that developed during the prior 8 months. Ten years ago he was diagnosed with chronic viral hepatitis B but was lost to follow-up in the intervening period. The patient had not received any treatment since the mass was first discovered, and the mass progressively grew in size until the patient sought treatment at the hospital. The patient was a heavy drinker and smoker, with a drinking history of two bottles of beer per week for 30 years, and a smoking history of 15 pack years. There was no significant family history. The patient's initial vital signs were stable and he appeared relatively well, and was alert and responsive. On physical examination, a hard, palpable mass about 10 cm × 12 cm in size was noted on the left upper anterior chest wall. Palmar erythema and spider angioma on the anterior chest wall were noted, but there were no other specific complaints. Initial laboratory findings were

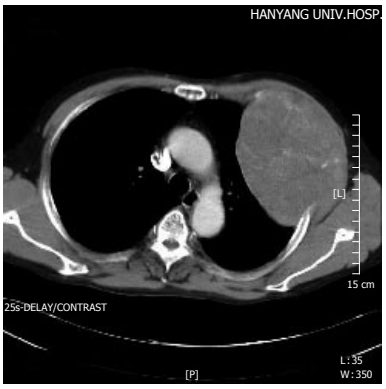

Figure 1 Chest helical CT. A mass on the anterolateral aspect of the left chest wall. The inner part of the mass is heterogeneously attenuated and consistent with mottled calcification. There is no evidence of metastasis in the mediastinum or the lung parenchyma.

Figure 2 Gross findings of the chest wall tumor. The cut surface shows an encapsulated, yellowish-white solid mass with areas of hemorrhage and necrosis.

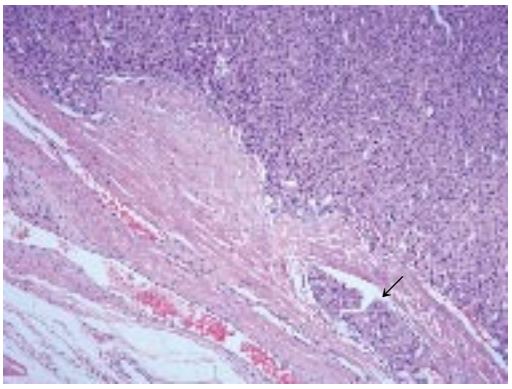

Figure 3 Microscopic findings of the chest wall tumor. The tumor displays typical features of well-differentiated, trabecular liver cell carcinoma with intravascular tumor emboli (arrow) (H&E stain, ×200).

as follows: WBC 10 000/mm^3, hemoglobin 134 g/L, platelets 216 000/mm^3, serum protein 56 g/L, albumin 34 g/L, total cholesterol 214 mg/dL, serum glucose 113 mg/dL, total bilirubin 0.9 mg/dL, AST 38 U/L, ALT 52 U/L, alkaline phosphatase 104 U/L, and prothrombin time 135%. Patient's viral markers were as follows: HBsAg(+), HBcAb(+), HBeAg(-), HBeAb(+) and HBV DNA < 2.5pg. Serum alpha-fetoprotein was 308.3 ng/mL.

The density of the soft tissue protruding inwards towards the lung was noted, with accompanying evidence of rib destruction along the anterolateral aspect of the third left rib on the chest film. A 9.5 cm× 12.7 cm sized heterogeneous tumor with a mottled calcification was noted on the anterolateral aspect of the left chest wall on the CT, but there was no evidence of metastasis within the lung parenchyma or the mediastinum (Figure 1). An additional study of abdominal ultrasonography and whole body bone scan revealed no evidence of an intrahepatic mass, abdominal lymphadenopathy, or bone metastasis. A primary bone tumor on the left upper chest wall was suggested, and radical resection of the tumor around the rib and soft tissue was performed.

The resected tumor was well-encapsulated with dimensions 14 cm× 10 cm× 7.5 cm and weighed 650 mg including the excised rib tissue. The cut surface of the tumor was whitish-brown with accompanying hemorrhage and necrosis, and was solid and hard but tended to crumble easily (Figure 2). Microscopic examination revealed large polygonal cancer cells separated by thin vessels resulting in a pole-like arrangement, and multiple cells undergoing mitosis were seen. Cancer cell emboli were seen inside the vessels surrounding cancer cells, and there was no evidence of normal liver tissue within the microscopic field (Figure 3). Immunohistochemical staining showed positive results for alpha-fetoprotein, hepatocyte specific antigen and cytokeratin, and showed negative results for vimentin and smooth muscle actin (Figure 4).

Abdominal computerized tomography (CT) and abdominal magnetic resonance imaging (MRI) were performed in search of the primary focus of the hepatocellular carcinoma. The surface of the liver was slightly irregular which was suspicious of liver cirrhosis, but there was no evidence of hepatocellular carcinoma, and no lipiodol uptake nor tumor vessels were seen in the hepatic arteriography. Mild lobular necrosis with mild portal inflammation and macronodular cirrhosis on the portal area were noted upon liver biopsy, but there was no evidence of a tumor. Upon esophagogastroduodenoscopy, antral gastritis was present but there were no gastric or esophageal varices, and there was no significant sigmoidoscopic finding. Postoperative alpha-fetoprotein level decreased from 308.3 ng/mL to 42.4 ng/mL. Follow-up abdominal CT was performed three weeks after the first hepatic arteriography, and like before, no lipiodol uptake was seen. There were no operation-related complications, and the patient was discharged to be regularly monitored as an outpatient.

Four months after discharge, the patient visited the emergency room due to back pain radiating to both lower extremities. On physical examination, there was evidence of motor weakness in both lower extremities, and the patient complained of paresthesia and hyperesthesia in the dermatome below the forth thoracic vertebra. Immediate thoracic MRI revealed spinal cord compression due to a metastatic lesion to the third and forth thoracic vertebrae, with spinal deviation to the right of the posterolateral position (Figure 5). Emergent decompressive laminectomy was performed. Further evaluation with a whole body bone scan revealed a newly developed increased uptake at the left side of the third to fifth thoracic vertebrae, while abdominal ultrasonography showed no significant change from the initial diagnosis of metastatic hepatocellular carcinoma in the chest wall. Histological examination of the metastatic vertebral lesions revealed metastatic hepatocellular carcinoma, which was the same finding observed dur-

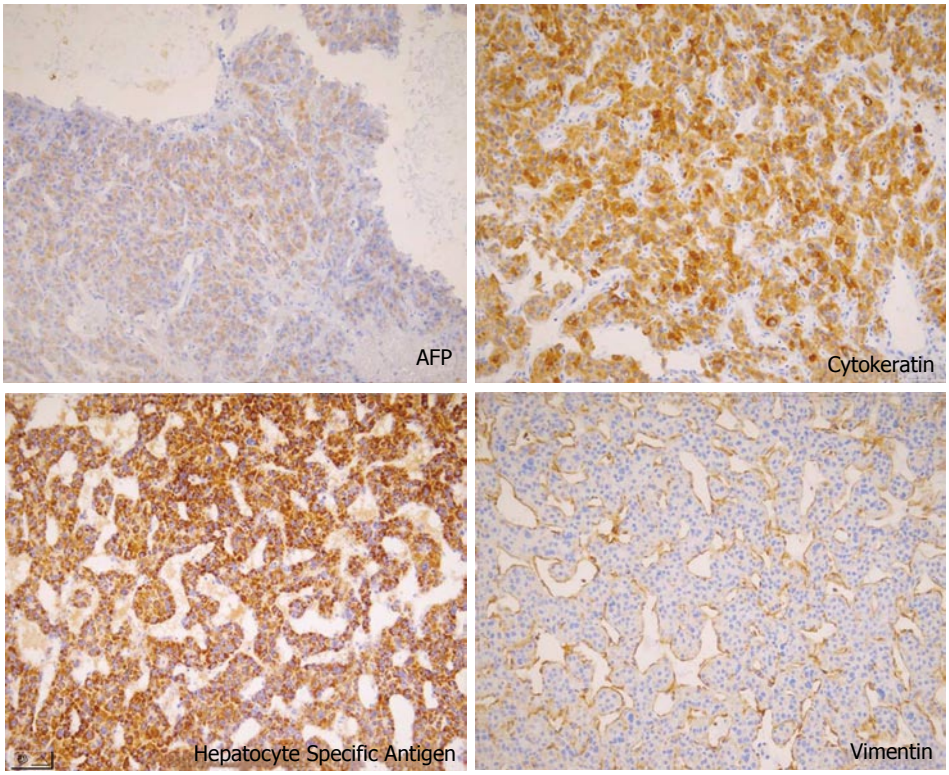

Figure 4 Microscopic findings of the chest wall tumor. The tumor cells are positive for AFP, cytokeratin, and hepatocyte specific antigens. This section shows positive staining for hepatocyte-specific antigens (IHC, ×400).

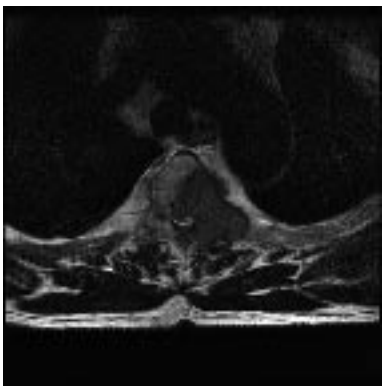

Figure 5 Thoracic spine MRI. The metastatic tumor of the third vertebra compressing the spinal cord (T2 weighted image).

ing microscopic examination of the chest wall mass. Afterwards the patient received radiotherapy and adriamycin-based chemotherapy. One year later, no lesion suggesting primary hepatocellular carcinoma has been found in the follow-up abdominal CT scan.

DISCUSSION

An extrahepatic hepatocellular carcinoma without a primary intrahepatic hepatocellular carcinoma can be explained in two different ways. The first is ectopic liver carcinogenesis and the second is a hepatoid adenocarcinoma.[6-8]

Ectopic liver is a rare developmental abnormality that can originate in the gall bladder, hepatic ligament, omentum, posterior peritoneal cavity, or the thorax.[8-11] Because ectopic liver does not have perfect functional architecture as does a normal liver, it is more likely to develop hepatocellular carcinoma, if carcinogenic factors such as viral hepatitis infection or liver cirrhosis are involved.[6]

Characteristically, the pathologic examination of hepatocellular carcinoma arising from ectopic liver reveals normal liver tissue, including portal triads. It may be connected to the liver by a fibrous stalk, which is composed of the portal vein, hepatic artery, or bile duct. If no evidence of primary cancer of the liver is present after a long term follow-up with various liver imaging studies, a malignancy originating from ectopic liver should be suspected .[7] In Japan, 25 cases of hepatocellular carcinoma of ectopic liver were described. This can be treated with complete resection of the tumor, which yields a good prognosis.

Hepatoid adenocarcinoma is a variant form of adenocarcinoma, characterized by vast hepatic differentiation. It produces alpha-fetoprotein, while having the same function and form as hepatocellular carcinoma, but originates from the endoderm and mucosa of urogenital organs and therefore can manifest itself in the gastrointestinal tract, ovaries, pancreas, lungs, kidneys, uterus or bladder. It contains a characteristic moderately to well-differentiated tubular or papillary shaped adenocarcinoma[8].

The present case differs from the two aforementioned examples because it was discovered as a solitary metastatic hepatocellular carcinoma of the chest wall, with an unknown primary focus. First, it was composed solely of hepatocellular carcinoma, and microscopic examination revealed no evidence of adenocarcinoma nor normal liver tissue including portal triads. This finding was entirely different from that expected in the carcinogenic sequence of ectopic liver or hepatoid adenocarcinoma. Second, cancer cell emboli were found within the vessels near the cancer cells, which is a characteristic microscopic finding of metastatic cancer. Thirdly, there was no evidence of an intrahepatic tumor in the liver imaging studies, and this result was again seen during the follow-up abdominal CT one year later. Fourthly, four months after resection of the chest wall tumor, metastatic hepatocellular carcinoma was found in the thoracic vertebrae. The thoracic vertebrae

are a region of intense bone marrow replication, and are among the most important metastatic sites for hepatocellular carcinoma[12].

In summary, when hepatocellular carcinoma is found outside the liver without a primary focus within the liver, a tissue biopsy must be obtained. Tissue biopsy must confirm the presence of normal liver tissue, including portal triads and cancer emboli within vessels near the tumor, for an accurate differential diagnosis. Chest CT, abdominal ultrasonography, and whole body bone scans must be used in order to confirm the presence of metastasis to other organs. To discern between hepatocellular carcinoma of ectopic liver and solitary metastatic hepatocellular carcinoma without a primary focus in the liver, a follow-up study is essential after the operation in order to find the primary site of origin.

Although the patient had no evidence of an intrahepatic tumor, he was a hepatitis B carrier with liver cirrhosis which suggested a latent primary hepatocellular carcinoma metastasizing to the chest wall that spontaneously regressed. In cases like this, in which extrahepatic hepatocellular carcinoma exists without evidence of tumor within the liver, one has to consider the possibility of a tumor originating from ectopic liver tissue, hepatoid adenocarcinoma, or, although rare, metastatic hepatocellular carcinoma without an intrahepatic mass.

World J Gastroenterol 2006 April 7; 12(13):2145-2146
World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in double-spaced and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

World Journal of Gastroenterology
Volume 12 **Number** 14 **April** 14, 2006

Contents

World Journal of Gastroenterology (*World J Gastroenterol* , *WJG*), a leading international journal in gastroenterology and hepatology, has an established reputation for publishing first class research on esophageal cancer, gastric cancer, liver cancer, viral hepatitis, colorectal cancer, and *Helicobacter pylori* infection, providing a forum for both clinicians and scientists, and has been indexed and abstracted in *Index Medicus*, MEDLINE, PubMed, Chemical Abstracts, EMBASE, Abstracts Journals, Nature Clinical Practice Gastroenterology and Hepatology, CAB Abstracts and Global Health. *WJG* is a weekly journal published by The *WJG* Press. The publication date is on 7th, 14th, 21st, and 28th every month. The *WJG* is supported by The National Natural Science Foundation of China, No. 30224801 and No.30424812, which was founded with a name of *China National Journal of New Gastroenterology* on October 1,1995, and renamed as *WJG* on January 25, 1998.

Abstract

The human gastrointestinal (GI) tract is colonized by non-pathogenic commensal microflora and frequently exposed to many pathogenic organisms. For the maintenance of GI homeostasis, the host must discriminate between pathogenic and non-pathogenic organisms and initiate effective and appropriate immune and inflammatory responses. Mammalian toll-like receptors (TLRs) are members of the pattern-recognition receptor (PRR) family that plays a central role in the initiation of innate cellular immune responses and the subsequent adaptive immune responses to microbial pathogens. Recent studies have shown that gastrointestinal epithelial cells express almost all TLR subtypes characterized to date and that the expression and activation of TLRs in the GI tract are tightly and coordinately regulated. This review summarizes the current understanding of the crucial dual roles of TLRs in the development of host innate and adaptive immune responses to GI infections and the maintenance of the immune tolerance to commensal bacteria through down-regulation of surface expression of TLRs in intestinal epithelial cells.

Key words: Toll-like receptor; Gastrointestinal tract; Intestinal disease

INTRODUCTION

Innate immunity is considered to be important for the elimination of invading microbes from the gastrointestinal tract and for the control of their systemic dissemination. Mammalian toll-like receptors (TLRs) are members of the pattern-recognition receptor (PRR) family and play a central role in the initiation of innate cellular immune responses and the subsequent adaptive immune responses to microbial pathogens[1,2]. The capacity to recognize diverse pathogen-associated molecular patterns (PAMPs) that are unique to microorganisms and therefore absent from host cells makes TLRs well-suited to act as an early warning system against invading pathogens. Activation of the TLR signal transduction pathway leads to the induction of numerous genes that function in host defense, including those for inflammatory cytokines, chemokines, antigen-presenting molecules, and costimulatory molecules[1,2]. Recognition of PAMPs by TLRs differs from the recognition of microorganism-specific antigens by the adaptive immune system, in that PAMPs are typically highly conserved across several species of microorganisms, such as surface lipoproteins common to several bacterial species, or genetic material from an entire family of viruses. The ability of TLRs to recognize a broad spectrum of microbial molecules enables the host to detect the presence of pathogens rapidly, before a more widespread infection occurs.

In this review, we have briefly summarized the recent progress in the understanding of the role of TLRs in the host defense against gastrointestinal pathogens and in the maintenance of immune tolerance to commensal microflora. For more general information on the biological functions of TLRs and the TLR signaling pathway, the readers are referred to a number of excellent review articles in this field[3-7].

TLRs, TLR LIGANDS AND TLR SIGNALING PATHWAYS

To date, 11 related TLR genes have been identified and characterized (*tlr1* to *tlr11*) (Table 1)[3,4,7-9]. Some TLRs, such as TLR3, TLR5 and TLR9, only recognize one type of PAMP, while others, such as TLR2, appear to recognize several different microbial molecules. Among these, TLR4 is the signal-transducing element of the

Table 1 Toll-like receptors and known microbial ligands[4,7,18]

TLR family	Microbial ligands
Lipid ligands	
TLR1	Tri-acyl lipopeptides (bacteria, mycobacteria)
TLR2	Lipoprotein/lipopeptides (a variety of pathogens)
	Peptidoglycan (Gram-positive bacteria)
	Lipoteichoic acid (Gram-positive bacteria)
	Lipoarabinomannan (mycobacteria)
	A phenol-soluble modulin (*Staphylococcus epidermidis*)
	Glycoinositolphospholipids (*Trypanosoma Cruzi*)
	Glycolipids (*Treponema maltophilum*)
	Porins (*Neisseria*)
	Zymosan (fungi)
	Atypical LPS (*Leptospira interrogans* and *Porphyromonas gingivalis*)
	Hemagglutinin (measles)
TLR4	LPS (Gram-negative bacteria)
	Fusion protein (respiratory syncytial virus)
	Envelope proteins (mouse mammary tumor virus)
	HSP60 (*Chlamydia pneumoniae*)
TLR6	Di-acyl lipopeptides (mycoplasma)
Nucleic acid ligand	
TLR3	Double-stranded RNA (virus)
TLR7 or 8	U-rich ssRNA
TLR9	CpG DNA (bacteria)
Protein ligand	
TLR5	Flagellin (bacteria)
Uropathogenic bacteria	
TLR11	Uropathogenic bacteria
Ligand unknown	
TLR10	?

lipopolysaccharide (LPS) receptor complex, and is also involved in the signaling response to other exogenous stimuli [*e.g.*, bacterial HSP60 and fimbriae, *Streptococcus pneumoniae* pneumolysin, lipoteichoic acid (LTA) from gram-positive bacteria, and respiratory syncytial virus coat protein][10,11]. TLR2 binds to bacterial lipoproteins, LTA and peptidoglycan[11-13], although some recent studies have argued that peptidoglycan recognition does not occur through TLR2[14], or that TLR2 alone is not sufficient to detect peptidoglycan[15]. Flagellin, a bacterial protein involved in motility, binds TLR5[16]. CpG, a repetitive sequence of unmethylated nucleic acids found in high quantities in bacterial DNA, is recognized by TLR9[17]. Also, although the specific ligand is not yet known, murine TLR11 is involved in protection from uropathogenic bacterial infection in mice[18]. Certain bacterial virulence factors, such as fimbriae or enterotoxins, have been shown to activate TLR2 and/or TLR4[19-23]. Some viruses are also recognized by TLRs. Double-stranded RNA (dsRNA), which is found in many types of virus, elicits immune responses through TLR3[24] and probably another PRR[25, 26]. Human TLR7 and/or TLR8 are known to bind single-stranded RNA (ssRNA) from viruses, such as human immunodeficiency virus (HIV)-1, influenza and human parechovirus-1[27-29]. TLR specificity is not limited to bacterial or viral PAMPs. TLR2 and/or TLR4 have been implicated in the detection of *Candida albicans* and *Entamoeba histolytica*[30-34]. In addition, some TLRs also bind endogenous molecules, such as HSP60, fibronectin, surfactant protein A, and β-defensin-2[4, 9].

TLRs vary from one another by their ligand specificity, determined by the extracellular portion of the receptor. The cytoplasmic tails of TLRs appear to be associated with the tails of other TLRs in a process known as TLR cooperation[35]. This can occur between receptors of similar or different specificity. For example, TLR2 requires association with TLR6 in order to propagate the correct intracellular signal after binding peptidoglycan or zymosan (a yeast cell-wall particle)[35]. In the cytoplasmic domain of TLRs, the element common to all TLRs is the Toll-interleukin-1-related (TIR) domain. After homo- or heterodimerization of TLRs, the intracellular TIR domains self-associate, and bind TIR domains of intracellular adaptor molecules. All TLRs except TLR3 associate with the TIR-containing myeloid differentiation factor (MyD) 88[36], which upon activation mediates a signaling cascade leading to activation of the NF-κB transcription factor[6]. The end result of TLR signaling is an upregulation of pro-inflammatory cytokines and chemokines, such as TNF-α and IL-8, and the induction of a localized immune response.

TLR4 was the first PRR to be properly identified as having a specific ligand[10], and the mechanism of TLR/LPS interaction is thus the best studied. LPS is transferred to cell-surface CD14 by LPS-binding protein (LBP)[37,38]. CD14 does not signal LPS presence directly to the cell because it lacks a cytoplasmic domain. Instead, the proximity of CD14 to TLR4 allows CD14 to "present" LPS to TLR4[10,39,40], which itself is bound to MD-2 on the cell surface. A physical association on the cell surface between MD-2 and TLR4 is essential for TLR4 function[41], and MD-2 is in fact essential for TLR4 to be trafficked to the cell surface in the first place[42].

TLR ACTIVITY IN THE GASTROINTESTINAL (GI) TRACT

Emerging evidence has shown that TLR expression and activation is specially regulated in the GI tract. This is probably due to the continuous presence of physiological microflora in the gut. It is essential that TLRs do not react to PAMPs expressed by commensal microflora, yet retain the ability to detect and mount effective immune responses against invading pathogens. This is mainly accomplished by the down-regulation of surface expression of TLRs, such as TLR2, TLR4 and MD-2, in the gut epithelium[5,43-47]. Although intestinal epithelial cells (IEC) can and sometimes do express TLR2 and/or TLR4[46,48-50], these TLRs usually relocate to either intracellular compartments such as the Golgi apparatus, or to the basolateral membrane of the cell as a result of the continuous stimulation by varying components of the commensal bacteria[50-53]. Indeed, *in vitro* studies of an IEC line have shown that LPS or peptidoglycan stimulation relocates the constitutive surface expression

of TLR2 and TLR4 into intracellular compartments near the basolateral membrane[51]. Others have shown that both primary and immortalized IEC responded to TLR ligand stimulation, and that prolonged exposure to these ligands reduced surface expression of TLRs without reducing mRNA levels[49]. It is important to note that intracellular TLR4 retains its full signaling capability, and detects both internalized LPS and intracellular bacteria[52,53]. This mechanism allows the host to detect the pathogenic organisms that have penetrated the intestinal epithelium without overreaction to commensal bacteria on the surface of intestinal epithelium.

There have been some debates over the precise cellular localization of TLR5, the receptor for flagellin, in IEC[54-57]. One group has shown that TLR5 was only expressed on the basolateral membrane[55], whereas another group using a different cell line showed both basolateral and apical TLR5 expression following the stimulation with *Escherichia coli* flagellin[54]. Apical TLR5 expression has also been demonstrated *ex vivo* in the murine ileum[54]. In addition, *Salmonella typhimurium* flagellin can translocate across epithelial cells to the basolateral membrane, a process that is essential for *S. typhimurium* flagellin to induce inflammatory responses[55,58,59]. These data strongly suggest the possibility that under normal circumstances TLR5 is only expressed at the basolateral membrane in IEC. The basolateral expression of TLR5 may be important for the maintenance of GI homeostasis since flagellin from commensal bacteria generally does not translocate to the basolateral membrane and thereby does not induce an inflammatory response[58].

The intestinal epithelium also uses specific tissue distribution and compartmentalization of TLR-expressing cells to avoid unnecessary TLR activation and at the same time allow the development of rapid and efficient host defense against invasion by pathogenic organisms. In this regard, intestinal myofibroblasts are capable of upregulating TLR2, TLR3, TLR4, TLR6 and TLR7 expression after LPS or LTA stimulation, thereby allowing a functional TLR response to invasive pathogens in the subepithelial compartment[60]. It has also been shown that crypt epithelial cells express TLR2 and TLR4, whereas mature IEC express TLR3 only[44]. Since crypt epithelial cells do not come into direct contact with commensal bacteria, their expression of TLR2 and TLR4 should not be detrimental to the host. TLR3 expression in the intestinal lumen is also non-detrimental because the TLR3 ligand, viral dsRNA, is not a natural presence in the gut microflora.

Another strategy in the regulation of TLR activities in the GI mucosa is through high expression of TLR-antagonists to suppress the activation of these TLRs still present at the cell surface. For example, TLR9 is constitutively expressed in IEC, but remains completely unresponsive to CpG[61]. In this regard, various proteins, termed TLR-attenuating factors, are known to attenuate TLR signaling, and this was extensively reviewed by Liew *et al*[6]. Some of these TLR-attenuating factors have been shown to be highly expressed in TLR-hyporesponsive IEC, or to be lacking in cases of intestinal inflammation. Toll-interacting protein (TOLLIP) inhibits TLR signaling by interfering with IL-1 receptor-associated kinase (IRAK), an important component of the TLR signaling cascade[62]. TOLLIP was found to be upregulated in TLR-hyporesponsive primary and immortalized IEC after prolonged exposure to TLR ligands[45,49], and TOLLIP mRNA was highly expressed in healthy colonic mucosa[49]. Peroxisome proliferator-activated receptor γ (PPARγ) limits TLR activity by inhibiting NF-κB activation[63,64]. PPARγ was more highly expressed in the colon compared to the small intestine[65], and has been shown to have a crucial role in the induction of tolerance to commensal bacteria[66]. Stimulation of IEC by TLR ligands or by intestinal microflora extracts increased PPARγ expression[67]. Thus, TOLLIP and PPARγ appear to down-regulate TLR activity in direct response to the continual exposure of IEC to commensal bacteria.

It has recently been identified that TIR8/single Ig IL-1-related receptor (SIGIRR) can negatively regulate TLR activity, possibly by interfering with TLR4 and IRAK signaling[68,69]. Studies in TIR8$^{-/-}$ mice showed that these mice developed more severe intestinal inflammation than wild-type control mice after LPS treatment[70], implicating the role of TIR8 in the suppression of the intestinal inflammatory response. In addition, it has been shown in a mouse model of colitis that vasoactive intestinal peptide (VIP) treatment can restore the overexpressed TLR2 and TLR4 to baseline levels[71]. The mechanism of action was unknown, but might involve either VIP-mediated suppression of NF-κB activation (leading to a cessation of further TLR expression) or suppression of cytokines known to contribute to TLR upregulation in IEC[71]. This appears to be a novel mechanism by which a natural intestinal peptide suppresses TLR activity. Finally, macrophages isolated from the intestinal lamina propria of IL-10$^{-/-}$ mice, which develop inflammatory bowel disease (IBD)-like colitis, were shown to express reduced levels of IκBNS, an inhibitor of NFκB activation[72]. IκBNS is responsible for suppression of LPS-induced cytokine production by lamina propria macrophages[72]. The lamina propria macrophages are normally hyporesponsive to TLR stimulation except in cases of intestinal inflammation[73], but these from IL-10$^{-/-}$ mice were responsive.

There are some known cases where commensal bacteria actually enhance anti-inflammatory activity in the intestinal epithelium. One example is the aforementioned upregulation of TOLLIP and PPARγ by commensal bacteria[45,49,66]. Others have shown that non-pathogenic *S pullorum* could block the activation of NF-κB by *S typhimurium*[74]. Furthermore, Backhed *et al*[75] showed that hypo-acylated LPS was less stimulatory towards TLR4 compared to normally acylated LPS, and that it actually inhibited the pro-inflammatory effects of wild-type LPS. Several species of commensal bacteria produce hypo-acylated LPS, which may contribute to the down-regulation of TLR4 activities[75].

TLRs AND INFLAMMATORY BOWEL DISEASE

IBD, comprising Crohn's disease (CD) and ulcerative colitis (UC), is a chronic, relapsing GI disorder of

unknown etiology. The development of IBD is hypothesized to be the result of dysregulated immune responses to one or more intestinal luminal antigens (loss of tolerance) in genetically predisposed individuals. While the pathophysiological features of IBD are uncontrolled, excessive inflammation in the GI mucosa and the upregulation of a host of pro-inflammatory and T cell cytokines[76,77], the root of the problem may lie in the defective immune tolerance to commensal bacteria and other intestinal luminal antigens. Experimental and clinical studies suggest that the over-expression of certain TLRs and down-regulation of TLR antagonists in IEC can be one of the underlying mechanisms leading to an improper reaction to commensal bacteria by the host. In this regard, TLR4 expression was reported to be elevated in colonic tissue of UC and CD patients[47], and TLR4 polymorphisms at Asp299Gly and Thr399Ile have been linked to the development of both CD and UC[78,79]. It was also shown that TLR2 activity was increased in a mouse model of colitis[80]. The presence of high titers of flagellin-specific antibodies in the serum of CD patients raises the possibility that flagellin from commensal bacteria might trigger an improper immune response in the GI mucosa through TLR5[81,82] and that TLR5 may also play an important role in the pathogenesis of IBD. In addition, as discussed above, intestinal myofibroblasts express TLR2 and TLR4 and respond to LPS and LTA stimulation, and have been implicated in the development of CD-associated fibrosis[60]. Moreover, PPARγ was found to be decreased in intestinal epithelial tissue of UC patients[67]. Thus, TLR mutations and dysregulation are likely major contributing factors in the predisposition and perpetuation of IBD.

More recently, it has been shown that TLRs may contribute to the pathogenesis of IBD in conjunction with another family of PRRs termed nucleotide-binding oligomerization domain proteins (Nod). Specific genetic variations in Nod2 have been strongly linked to the development of CD[83,84] and to excessive NF-κB activity[85]. Interestingly, the Nod2 variations may also have a direct effect on TLR-mediated control of intestinal inflammation. In IEC from Nod2-variant patients, TLR2 stimulation led to excessive production of both pro-inflammatory and Th1 cytokines[15,86,87]. These cytokines are heavily involved in the pathogenesis of IBD[77]. It appears that the association between Nod2 and TLRs seen in normal intestinal tissue[88] is important for intestinal homeostasis. Alteration of this association by genetic variation in Nod2 leads to the development of chronic intestinal inflammation. Further exploration into how Nod2 mutations affect TLR function will undoubtedly shed light on novel interactions between Nod1/2 and TLRs in the GI mucosa.

TLRs AND *HELICOBACTER PYLORI* INFECTION

Helicobacter pylori (*H pylori*) is a Gram-negative bacterium that colonizes the gastric mucosa and causes chronic gastritis and gastric ulcers. The bacterium adheres strongly to the surface of gastric epithelial cells (GEC) without actually invading them[89,90]. As is the case with IBD, the host inflammatory response to *H pylori* infection directly contributes to disease pathogenesis[91]. Although the host mounts a strong specific immune response to the pathogen, this response is for the most part ineffective[92]. *H pylori* infection is relatively common worldwide, yet less than one quarter of infected individuals progress to disease[93]. Whether or not an individual proceeds to a disease state might be influenced by any combination of host, bacterial and environmental factors.

Because of the clinical significance of *H pylori* infection, the interaction between TLR and *H pylori* is probably the most extensively studied. Since the first step in *H pylori* infection is the adherence to GEC by the bacterium, it is logical to postulate that TLRs would play a role in *H pylori* detection, as well as the subsequent mounting of the deleterious cellular and inflammatory immune response. Despite extensive studies on this subject, as yet there is no clear consensus as to which TLR(s) is involved in the detection of *H pylori* by GEC. Several groups have shown the apical and basolateral expression of TLR4 in *H pylori*-infected GEC[94,95]. TLR5 and TLR9 were also expressed both apically and basolaterally in the GEC of healthy individuals, but the apical expression of these TLRs was lost in *H pylori*-induced gastritis[95]. GEC expression of TLR2, another important receptor for bacterial PAMPs, has yet to be fully characterized.

Several studies have suggested that TLR4 may play an important role in the recognition of *H pylori* infection by gastric mucosa[94,96] as TLR4 and MD-2 expression, as well as responsiveness to *H pylori* LPS stimulation, in gastric biopsy samples of patients with *H pylori* infection were up-regulated[94]. However, others have reported that the detection of *H pylori* by primary GEC is TLR4-independent[97]. Interestingly, Smith *et al*[98] found that the gastric epithelium recognizes *H pylori* LPS through TLR2 rather than TLR4, suggesting the possible disassociation between the up-regulation of TLR4 and the pro-inflammatory potential of *H pylori* LPS. Similarly, Mandell *et al*[99] showed that whole *H pylori* elicited an immune response through TLR2, not TLR4, in mice. These findings are not entirely surprising since it has been long recognized that *H pylori* LPS does not share all the characteristics of other Gram-negative GI bacteria.

Although *H pylori* flagellin was initially shown to be able to interact with TLR5[100], more recent studies have found that TLR5 was unresponsive to *H pylori* flagellin, suggesting the low immunogenicity of this molecule[101-103]. Anderson-Nissen *et al*[101] have recently mapped low TLR5 responsiveness to a specific area of the amino acid sequence in the *H pylori* flagellin. Introduction of this sequence into *Salmonella* flagellin renders the new construct devoid of all TLR5-activating activity[101]. Thus, it is possible that *H pylori* uses TLR5 evasion to avoid immune detection. The ability of *H pylori* to induce chronic and persistent gastric inflammation suggests that PAMP(s) other than flagellin may be involved in the pathogenesis of the infection. Indeed, Takenaka *et al*[104] have shown that *H pylori* heat shock protein (HSP) 60 is able to activate TLR2 and TLR4 and increase NF-κB activity and IL-8 production in GEC.

Evidently, there is still much to be discovered regarding the interactions of *H pylori* with TLRs in the gastric epithelium. While it is likely that host factors in the

immune response might play a role in disease pathogenesis, there does not appear to be any evidence in the literature demonstrating an association between genetic variation in TLRs and *H pylori* disease progression, as is the case in IBD.

TLRs AND INFECTIONS WITH INTESTINAL BACTERIA

Despite a relatively large amount of information available concerning the roles of TLRs in the GI tract, there is surprisingly little data showing the actual *in vivo* role for TLRs in combating enteric pathogens. The obvious assumption is that invasive pathogens expressing known bioactive PAMPs will trigger a TLR-mediated immune response upon invasion of the IEC barrier. However, *in vivo* models of this scenario are scarce. Of the most common enteric pathogens, the interplay between TLRs and *S typhimurium* has been most extensively studied.

Invasion of IEC by *S typhimurium* leads to bacterial replication in intracellular vacuoles, localized inflammation, and lysis of infected cells. Several TLRs (TLR2, TLR4 and TLR5) appear to play a crucial role in the host defense against *S typhimurium* infection. Allelic variation in chicken TLR4 has been linked to the susceptibility to *S typhimurium*[105]. Studies of systemic *S typhimurium* infection in TLR4-deficient mice have also shown an important role for TLR4 in controlling the infection, TNF-α and chemokine production, and cellular immune responses[106-108]. Moreover, results from several recent studies have implicated TLR4 in the immediate detection of *S typhimurium* and early macrophage responses, and TLR2 as a key player in late responses after cellular invasion and intracellular replication have occurred[109,110].

S typhimurium flagellin induces a strong, TLR5-mediated inflammatory response in IEC[55,59]. Interestingly, this phenomenon does not require cellular invasion; adherence to IEC is sufficient[55,58,111]. The fact that IECs do not express TLR5 on the apical membrane[55,58] implies that *S typhimurium* actually has to translocate flagellin molecules through IEC to the basolateral membrane where TLR5 is expressed[55,58,59]. This process is dependent on the presence of *S typhimurium* pathogenicity island 2 (SPI2)[59,112], and probably also *S typhimurium* guanine nucleotide exchange factor, SopE2[113]. Therefore, it appears that the interplay between TLR5 and *S typhimurium* flagellin is a major determinant in the host response to IEC infection and the clinical outcome of the infection. Indeed, Sebastiani *et al*[114] linked the murine TLR5 gene to an *S typhimurium* susceptibility locus, and showed that susceptible mice expressed decreased levels of TLR5. Also, Zeng *et al*[115] found that *S typhimurium* strains lacking flagellin expression induced minimal inflammatory responses, suggesting that flagellin is the primary cause of inflammation in enteric *S typhimurium* infection.

The important role of TLRs in the immunopathogenesis of *Salmonella* infection is further verified in infection with *S typhi*, the etiological agent of typhoid fever. Unlike *S typhimurium*, *S typhi* infection fails to induce IL-8 production or neutrophil recruitment to the intestinal epithelium that is characteristic of *S typhimurium* infection, thereby allowing the systematical dissemination of the infection. It has been suggested that the ability of the *S typhi* capsular antigen (Vi, a virulence factor not expressed in *S typhimurium*) to inhibit the TLR4 and TLR5 response to the infection may partially contribute to its pathogenesis[116].

The role of TLRs in the pathogenesis of and immunity to other enteric bacterial infections remains largely unexplored. Recognition of LPS by TLR4 is unlikely to be a major contributing factor in diarrheagenic *E coli* infection because lipid A, the structure within LPS which activates TLR4, is highly conserved, and is therefore common to both pathogenic strains and non-pathogenic commensal strains of *E coli*. Although the O antigen of *E coli* LPS is more variant between strains, this antigen does not activate TLR4[75]. In addition, commensal bacteria-derived LPS is known to induce the intracellular relocalization of TLR4 in IEC[51]. It is, therefore, reasonable to assume that IECs do not react to LPS from *E coli* adhered to the outer apical membrane of the cell. However, other *E coli* PAMPs may play a role in the up-regulation of TLR activities in IEC. In this regard, it has been shown that flagellin from several strains of pathogenic *E coli* can induce NF-κB activation and IL-8 production through TLR5[117-119]. In addition, it has recently been shown that aggregative adherence fimbriae (AAF), an EAEC virulence factor, is involved in cell adhesion and contribute to inflammation and IL-8 production in IEC[120], although it is unclear whether this effect is TLR-mediated. Since both *Porphymonas gingivalis* fimbriae and *E coli* P fimbriae, a virulence factor in uropathogenic *E coli*, can activate TLR2 and/or TLR4[20,22,121,122], it is possible that the inflammatory response induced by EAEC AAF is mediated through TLR recognition as well. Furthermore, it has been shown that the *E coli* type II heat-labile (LT-II) enterotoxin, expressed by ETEC, activates TLR2 *via* its B subunit[21].

Campylobacter jejuni infection is one of the most common causes of food-born gastroenteritis. *C jejuni* infection leads to adhesion to IEC, followed by cellular damage due to invasion, toxins and excessive inflammation[123,124]. Infection of IEC by *C jejuni* leads to an enhanced IL-8 production, which is dependent on bacterial adhesion to IEC[125]. However, it is not known whether this inflammatory response is TLR-mediated and, if so, which TLR(s) and ligand(s) are involved. Studies of TLR4 and CD14 polymorphisms commonly associated with susceptibility to other infections showed no link to *C jejuni* infection or disease progression, suggesting that TLR4 does not play a role in the immune response to this pathogen. Moreover, *C jejuni* flagellin failed to stimulate TLR5[101,125], as it possesses the same site-specific mutations as *H pylori* that allow it to avoid TLR5 recognition[101]. One possible candidate for the induction of the inflammatory responses seen in the above study could be *C jejuni* fimbriae, as is the case with the fimbriae of other bacterial species[20,22,121,122]. However, it remains controversial whether *C jejuni* expresses any sort of fimbriae[126,127].

Shigella flexneri , the causative agent of dysentery, is able to survive in a highly acidic environment such as the stomach. As a result, a relatively low dose of *S flexneri* can initiate an intestinal infection[128]. *S flexneri* lipoproteins

can activate TLR2 in non-intestinal epithelial cell lines[129], but TLR2 reactivity to *S flexneri* lipoproteins in IEC remains to be demonstrated. The ability of *S flexneri* to invade IEC plays an important role in the induction of inflammation[130]. Cellular invasion by *S flexneri* induces NF-κB activation and IL-8 production in both IEC and non-intestinal epithelial cells[130-133]. However, this response appears to be independent of TLR and MyD88, and is mediated by Nod1[132]. Some clinical isolates of *S flexneri* have been shown to express a type I fimbriae[134], which could potentially be detected by TLRs similar to fimbriae of other enteric bacteria[20,22,121,122].

TLRs AND INTESTINAL VIRAL INFECTIONS

Viral infection in the GI tract can lead to invasion and destruction of IEC and gastrointestinal inflammation. In most cases, an individual becomes immune to reinfection, suggesting that an effective adaptive immune response occurs in viral gastroenteritis[135]. Although it has been proposed that TLR3, TLR7 and TLR8 are likely to play a major role in sensing the viral infection in the GI tract and initiating an effective mucosal immune response, there is little published evidence to support this notion. The four most common viruses associated with viral gastroenteritis are rotavirus, calicivirus, astrovirus and adenovirus (serotype 40, 41). Of these, only rotavirus infection of IEC has been examined for TLR involvement. It appears that extracellular TLR3 was not involved in the response to rotavirus dsRNA since dendritic cells pretreated with TLR3-blocking antibodies, thereby blocking the surface TLR3, remained responsive to rotavirus dsRNA[136]. Because viruses are intracellular pathogens, the viral genetic material is more likely to be exposed after invasion of the cell. Indeed, intracellular expression of TLR3 has been demonstrated in several cell types[136-138]. However, studies on TLR3-deficient mice showed that responses to infection by reovirus, a dsRNA virus which is known to infect the gastrointestinal epithelium, were TLR3-independent[26]. Therefore, it seems that despite its constitutive expression in IEC[44], TLR3 may not play an important role in the host defense against GI infection by dsRNA viruses.

The role of TLR7 and TLR8 in the GI infection with ssRNA viruses, such as calicivirus, has not been directly investigated, despite the importance of these TLRs in the recognition of ssRNA viruses. It is worth noting that of the four major types of viral gastroenteritis, calicivirus infection tends to occur equally in adults and children, whereas infections with rotavirus, astrovirus and adenovirus are mostly seen in children. Glass *et al*[135] suggested that this could be caused by short-lived immunity to calicivirus or because of antigenic variation, rendering the adaptive immune response less effective in the face of future infection. If the former is the case, it would be interesting to know if the short-lived immune response could be attributed to a unique property of TLR7 and/or TLR8-mediated detection of calicivirus in IEC, compared to detection of the other three dsRNA viruses.

TLRs IN PARASITIC GASTROINTESTINAL INFECTION

Despite the high incidence and economic significance of parasitic GI infections, particularly in the developing countries, there is very limited information in literature on the role of TLRs in the parasitic GI infection, with the exception of *E histolytica* infection. *E histolytica* can be ingested with contaminated food or water, and colonize the colon. The infection can sometimes remain asymptomatic, but can also cause diarrhea, vomiting and ulcers. Studies performed prior to the discovery of TLRs showed that *E histolytica* infection induced neutrophil influx into the site of infection[139,140] in mice and IL-8 production in IEC lines as well as in human IEC xenografted into immunodeficient mice[141,142]. In the IEC cell line, the IL-8 response was contact-independent, and presumably mediated by *E histolytica* soluble factors[142]. It has recently been shown that *E histolytica* lipopeptidophosphoglycan (LPPG) induces TLR2- and TLR4-dependent IL-8 production in human kidney cell lines and monocytes[33,34]. These studies also suggest that LPPG might be a novel PAMP, and the factor responsible for induction of IL-8 and the neutrophil response seen in previous studies of *E histolytica* infection.

CONCLUSION AND PROSPECTIVE

Emerging experimental and clinical evidence have shown that TLR expression and activation are specially regulated in the GI tract, probably due to its unique environment (the presence of commensal microflora and the exposure to invading pathogens). This is mainly accomplished by: (1) the down-regulation of surface expression of TLRs by the gut epithelium; (2) the specific tissue distribution and compartmentalization of TLR-expressing cells in the gut; and (3) the high expression of TLR-antagonists/attenuating factors that suppress the activation of these TLRs still present at the cell surface. These mechanisms render the GI mucosa able to avoid unnecessary TLR activation to commensal microflora yet retain the ability to detect and mount rapid and efficient immunity against the invasion of pathogens.

TLRs are expressed by both epithelial and non-epithelial cells throughout the entire GI tract. The unique patterns of cellular localization and tissue distribution of TLRs in GI tract allow the host to differentiate between commensal non-pathogenic and pathogenic microbes. Recent studies strongly suggest that dysfunction or dysregulation of TLR expression and activation in IEC is one of the underlying mechanisms leading to the development of IBD. Although there is little doubt now that TLRs play important roles in both the predisposition and perturbation of IBD, caution must be exercised in the interpretation of the clinical and experimental data on TLR studies because it remains to be determined whether the TLR dysregulation seen in patients with IBD is the pathological consequence or the underlying cause of the chronic inflammation. In addition, conflicting results have been reported in regard to the TLR4 activity[80], and the

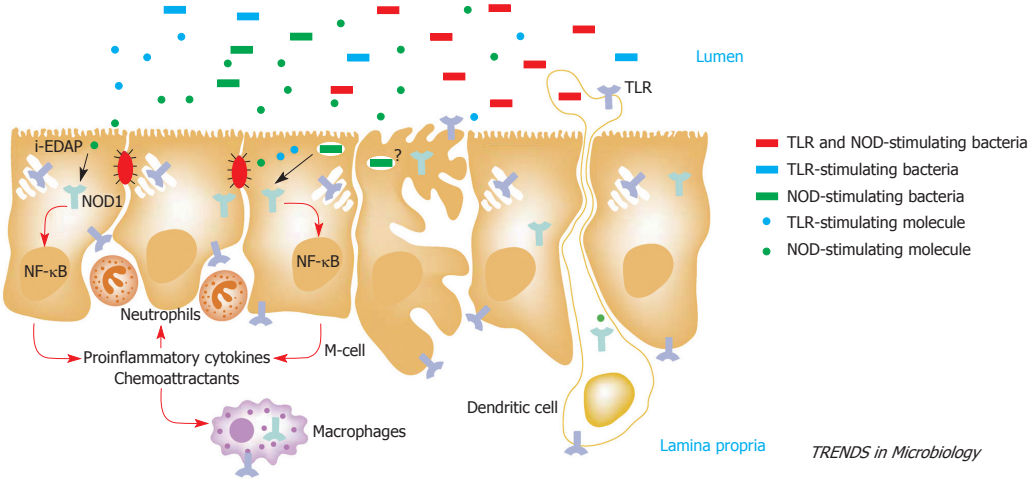

Figure 1 Host sensing of enteropathogenic bacteria. Enteroinvasive bacteria are sensed by specific cells (intestinal epithelial cells, M cells, macrophages and dendritic cells) located in the intestinal mucosa. Resident and invasive bacteria and their molecules released into the intestinal lumen could be recognized by host cells. Sensing of bacteria and their products are mediated by surface Toll-like receptors (TLRs) and cytosolic Nod1 receptors. Intestinal epithelial cells lack functional TLR2 and TLR4 but they might express TLR5 at the basolateral surface. Thus, some entero-invasive flagellate bacteria might stimulate epithelial cells through both TLR5 and Nod1 (depicted in red), whereas other invasive bacteria might activate Nod1 but not TLRs (depicted in green). Flagellate Gram-positive bacteria lacking Nod1-stimulating molecules are expected to trigger TLRs but not Nod1 signaling (depicted in blue). Soluble TLR- and Nod1-stimulating products are found in the intestinal contents but their role in host defense is unknown. Certain TLRs might be also localized to intracellular compartments (e.g., Golgi apparatus for TLR4), but the relevance of intracellular TLR signaling in the intestinal mucosa remains elusive. Reprinted from Chamaillard *et al*. Battling enteroinvasive bacteria: Nod1 comes to the rescue.*Trends Microbiol* 12:529-532[154]. Copyright (2004), with permission from Elsevier.

expression of some TLRs by IEC was found unchanged (TLR9) in patients with IBD[47,61]. This is hardly surprising and probably reflects the complexity of the nature of the disease, the diversified patient populations, and the different research approaches employed.

Despite the demonstrated roles of TLRs in host defense against many microbial infections, there is surprisingly little data on the actual *in vivo* role for TLRs in combating GI pathogens, particularly in viral and parasitic infections. For bacterial pathogens, although the interaction between *H pylori* and GEC has been extensively studied, there is no clear consensus as to which TLR(s) is involved in the recognition of *H pylori* by the host, or the role of TLRs in the pathogenesis of *H pylori*-induced gastritis and gastric ulcer. *S typhimurium* is another well-studied GI pathogen although many studies regarding the interaction between TLR and this pathogen were conducted in animal models where the infection was initiated by systemic injection rather than the natural GI route. In this regard, studies on systemic and respiratory infections have shown that the requirement of different subtypes of TLRs in host defense against microbes appears to be dependent on the type of pathogen, the route of infection, and the initial dose of infection[143-145].

Many virulent strains of pathogens have evolved multiple mechanisms to evade recognition by TLRs. In this regard, a new family of PRRs, the NACHT-LRRs (NLRs), which include both nucleotide-binding oligomerization domains (NODs) and NALPs [NACHT-, LRR- and pyrin domain (PYD)-containing proteins], has been recently identified and implicated in the recognition of bacterial components in the cytosol[146]. It has been suggested that the Nod family of proteins is a major contributor to innate immunity in IEC when TLR activity is attenuated[147-149]. The intracellular location of NODs allows the detection of invasive pathogens in a similar fashion to intracellular or basolateral TLR expression (Figure 1). In addition, Nod1/2 can activate NF-κB through a different signaling pathway from TLRs[150-152], thus rendering them functional even in the presence of TLR-attenuating factors such as TOLLIP and TIR8/SIGGIR that are highly expressed in IEC. Furthermore, Nod1/2 can positively influence TLR activity[15,88,153], and may contribute to the pathogenesis of IBD in conjunction with TLRs. The discovery of the NLR family definitely adds further complexities to the host immune regulation but is also likely to shed new insights into the pathogenesis of GI disorders and provide additional opportunities for the development of novel immunotherapeutic strategies.

TLRs were discovered relatively recently, and their involvement in health and diseases of the GI tract remains a new and exciting field of study. Future work in this field will lead to a better understanding of the unique mechanisms involved in the fine balance between tolerance and immune response. An array of new treatment options for IBD, *H pylori* infection, and other GI disorders could involve tissue-specific suppression of TLR signaling pathways by either chemical means, introduction of natural TLR suppressors and antagonists such as PPARγ, or use of gene therapy to correct TLR gene defects. In this regard, further exploration of the recently characterized negative regulatory mechanisms, that have evolved to attenuate TLR signaling by the host, may be fruitful for the development of new generation of more effective immunotherapeutic agents for the treatment of GI disorders.

Abstract

Nonalcoholic fatty liver disease (NAFLD) is the most common cause for elevated liver enzymes in the developed nations. Beyond prevention programs which are of particular interest because of the increasing number of overweight children, treatment should be focussed on the most important risk factors, obesity and insulin resistance. As a consequence of elucidating the pathomechanisms of NAFLD, the number of potential therapeutic options increased. However, many studies investigating the therapeutic effect show shortcomings in at least one of the following points: lack of a serial liver biopsy, short term of treatment and limited number of included patients. The second generation insulin sensitizer pioglitazone and rosiglitazone show the most promising improvements in NAFLD, but weight gain and potential hepatotoxicity calls for attention. In conclusion, a general recommendation for the application of specific drugs cannot be given. Besides controlled clinical trials, weight reduction and physical activity to improve insulin sensitivity in obese patients should be the priority objective.

Key words: Nonalcoholic fatty liver disease; Treatment

INTRODUCTION

Insulin resistance and obesity represent the most important risk factors for development of NAFLD[1]. Fatty liver has a benign prognosis, whereas up to 20% of patients with NASH develop cirrhosis[2, 3]. Risk factors for development of fibrosis are age, BMI>30, glutamic-oxaloacetic transaminase (AST)/glutamic-pyruvic transaminase (ALT)>1, and diabetes[4]. In addition, the risk for development of hepatocellular carcinoma (HCC) is comparable to that of patients with hepatitis C infection[5]. The pathophysiology of NAFLD is described as a "two hit model". The first hit is supposed to be the increase of free fatty acids in hepatocytes which results in a decrease of β-oxidation. Downregulation of β-oxidation further aggravates accumulation of fatty acids. The second step includes all mechanisms contributing to the development of inflammation and fibrosis[6]. In detail, increase of fatty acids enhances the expression of cytochrome peroxidase 2E1 (CYP2E1). CYP2E1 stimulates generation of oxidative species and thereby enhances lipid peroxidation of the hepatocyte membrane[7, 8]. Endotoxin and TNF-α have been demonstrated to play a harmful role in development of alcoholic steatohepatitis[9]. Injection of lipopolysaccharide (LPS) in leptin-deficient, obese ob/ob mice resulted in a significantly more severe liver injury probably caused by TNF-α compared to lean control animals[10]. Administration of anti-TNF-α-antibody ameliorated liver damage in this model of NAFLD[11]. Both endotoxin and oxidative stress upregulate expression of CD95 ligand and contribute to apoptotic cell death[12]. In fact, increased hepatocyte apoptosis correlating with disease severity was described in patients with NASH[13].

Here we discuss the role of a drug-free management in improvement of insulin resistance and NASH and give a critical summary of recent data on medical treatment. The potential concepts of treatment are summarized in Figure 1.

REDUCTION OF BODY WEIGHT

Although insulin resistance occurs in patients with normal BMI and anthropometric measurements, the majority of these patients are adipose with increased visceral fat. So, in overweight or obese patients, weight loss is usually recommended as the first line management[14]. The American Gastroenterological Association recommends a target of 10% of baseline weight as an initial goal of weight loss if BMI exceeds 25 kg/m^2. Weight loss should proceed at a rate of 1-2 lb/wk. Rapid weight loss due to a very low energy diet (<500 kcal daily) or jejunoileal bypass has been associated with exacerbation of steatohepatitis in obese patients[15-17]. Weight loss should be achieved by restricting calorie intake and physical exercise. Both have been shown to improve insulin resistance[18]. Physical exercise is proven to be beneficial for coronary heart disease and peripheral vascular disease. Rollins demonstrated that moderate to high-intensity exercise (30 min 3-5 times/wk) reduces the

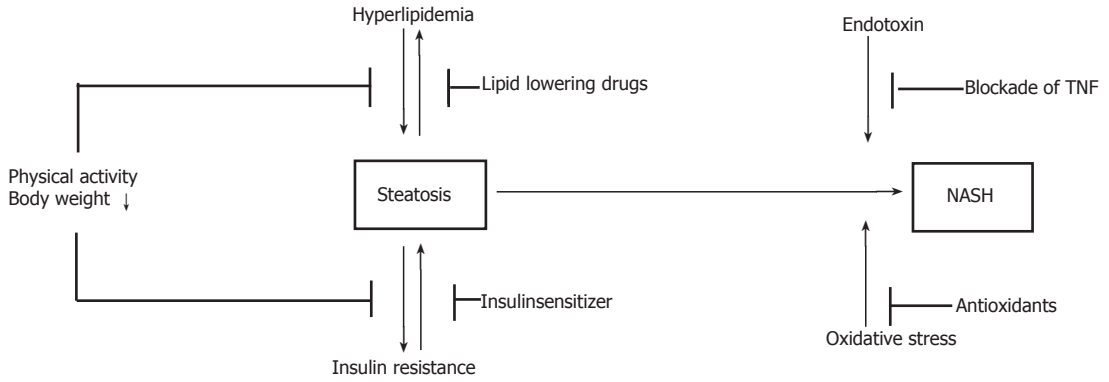

Figure 1 Potential treatment options of NAFLD

risk of complications associated with obesity[19]. However, it is not clear whether patients with NAFLD would benefit from merely increasing physical activity. The goal of weight management is to induce a negative calorie balance. A calorie deficit of 500-1 000 calories/d for those who are overweight or obese appears to be rational, although there are no specific studies on this subject. Dietary recommendation should include reduction of dietary carbohydrates, because lipid profile of overweight patients improves[20, 21]. However, weight loss is rarely achieved or maintained over a long period. Most studies to date have been short term with a small number of patients included. Children with NASH may benefit from weight loss, because serum liver enzymes normalized and sonographic abnormalities disappeared[22]. Another study investigated 48 patients with elevated liver enzymes and clinical, histological, and sonographic characteristics of fatty liver disease[23]. Eighty-one percent of these patients were obese, 73% were glucose-intolerant or diabetic, and 85% had dyslipidemia. Dietary intervention as well as lipid-lowering medication and oral antidiabetics as needed were included into the treatment protocol. These dietary interventions resulted not only in a moderate weight loss, but also in a reduction of serum liver enzymes in 96% of patients. However, it remains unclear, if improved liver enzymes were accompanied by an improvement of liver histology, because serial liver biopsies were not performed. In another study, 15 obese patients followed a restricted diet (25 calories per kilogram ideal body weight) and exercise regimen over a 3 mo period[24]. Liver enzymes decreased in all patients and steatosis determined by biopsy was reduced compared with patients from control group.

A recently published study analyzed the effect of short term weight loss on liver histology[25]. Twenty-three obese patients (BMI>25kg/m^2) with biopsy-proven NASH received standardized nutritional counseling to reduce insulin resistance and body weight. Each subject received individualized nutrition counseling in order to achieve dietary goals. The dietary adjustments included increased intake of fiber and a decreased intake of calories. The daily calory intake consists of 40%-45% carbohydrates with an emphasis on complex carbohydrates with fiber, 35%-40% fat with emphasis on mono- and polyunsaturated fats, and 15%-20% protein. In addition, all participants were encouraged to increase their physical activity to achieve a heart rate of 70% of the calculated target heart rate. Food frequency questionnaires were performed to assess dietary intake and the Paffenberger Activity Questionnaire was used to evaluate the level of physical activity. Sixteen patients successfully completed 12 mo of intense dietary intervention. Mean weight decreased from 98.3 kg to 95.4 kg. There was also a reduction of mean waist circumference, visceral fat, fasting glucose, insulin resistance, triglycerides, serum levels of liver enzymes and histological score, but the differences were not statistically significant. Fifteen patients underwent repeat liver biopsy. Nine of these 15 patients had a histological response, 6 patients had a stable score and none had worsened.

Pharmacological treatment of obesity may be applied to patients with a BMI>27 kg/m^2 and obesitiy-associated comorbidities. Sibutramine is a serotonin reuptake antagonist which should not be used in patients with coronary heart disease and moderate or severe hypertension[26]. The intake of orlistat results in fat malabsorption. Sabuncu and coworkers analyzed the effects of orlistat and sibutramine in obese patients with clinically presumed NASH. Both orlistat and sibutramine improved liver enzymes and decreased the sonographic hallmarks of fatty liver. However, liver biopsies were not performed and the level of alkaline phosphatase increased[27].

Those patients with a BMI>35 kg/m^2 and obesity-associated comorbidities may be considered for more aggressive weight management, including bariatric surgery. Because liver failure occurs after jejuno-ileal bypass, the later has been replaced by the proximal gastric bypass operation. Two studies demonstrated improvement of liver histology after weight reduction and stabilization of weight for long term[28, 29]. However, occasional cases of worsening liver function can also occur during period of rapid weight loss following this procedure. The results of studies investigating the safety of such surgery in patients with severe NASH have to be awaited. Patients considered for this procedure should be monitored carefully and the pros and cons should be discussed with the patient in detail.

ANTIOXIDANTS

Oxidative stress is proposed to act as the "second hit" in

the pathogenesis from steatosis to NASH and fibrosis. Therefore, using antioxidant substances seems to be rational in the treatment of steatohepatitis. Several *in vitro* and animal *in vivo* studies revealed that application of vitamin E decreased levels of profibrogenic TGF beta, improved liver histology and inhibited hepatic stellate cell activation[30-32]. Two open-label pilot trials examined the effect of vitamin E in patients with NAFLD[33, 34]. Eleven pediatric patients with presumed NASH were prescribed 400-1 200 IU of oral vitamin E. Diagnosis was based on the presence of chronically elevated levels of AST and ALT, and fatty liver on ultrasound. Other causes for hepatitis were excluded. Two patients had biopsy-proven NASH. Treatment resulted in normalization of liver function test. However, serial biopsies were not performed, liver remained increased echogenic during treatment and improvement of enzymatic values was not sustained after discontinuation of vitamin E[33]. In another study[34], 10 patients with the clinical diagnosis of NAFLD and 12 patients with biopsy proven NASH were treated with vitamine E (300 mg/d) for 1 year. Treatment resulted in a significant improvement of liver enzymes. In the nine patients with steatohepatitis who had a posttreatment liver biopsy, the degree of steatosis, inflammation, or fibrosis also improved or remained unchanged. The plasma levels of TGF-β decreased significantly with vitamin E. However, these promising results were not confirmed in a subsequent randomized, double-blind, placebo-controlled trial[35]. In this study, vitamin E (1 000 IU/d) in combination with vitamin C (1 000 mg/d) to potentially enhance the regeneration of oxidized vitamin E was given to 23 patients with NASH, while 22 patients were randomized to placebo. The duration of treatment was 6 mo. In addition, a low fat, low calorie diet in combination with increased physical activity was recommended. The degree of adherence to these recommendations remained unclear. The results showed a significant improvement of ALT levels in the placebo group but not in the treatment group. The fibrosis stage of 11 (48%) patients of the vitamin group and 9 (41%) of the placebo group improved by at least one stage. The authors concluded from this within group comparison that vitamin C and vitamin E are effective in improving liver fibrosis, although only two more patients in the vitamin group showed a regression of fibrosis. Adams and Angulo[36] criticized that the effect of placebo treatment was ignored, because no comparison between groups was performed. A between group analysis revealed that 6 mo of therapy with the combination of vitamin E and C is not better than placebo for patients with NASH.

URSODEOXYCHOLIC ACID

This hydrophilic bile acid is approved for the treatment of primary biliary cirrhosis. Ursodeoxycholic acid (UDCA) has been shown to reduce the portion of hydrophobic bile acids which contribute to oxidative stress. This is of particular importance, because fatty hepatocytes reveal an increased sensitivity to hydrophobic bile acids[37]. A pilot study published in 1996 analyzing the effect of UDCA on serum liver enzymes and histology in patients with NAFLD showed promising results[38]. The hepatic steatosis decreased on repeat liver biopsy in 12 of 19 patients and there was also a statistically significant improvement in liver enzymes, but there were no changes in the histological grade of inflammation or fibrosis. In a subsequent controlled trial 166 patients were randomized with liver-biopsy proven NASH to receive 13 and 15 mg/kg of UDCA daily[39]. One hundred and twenty-six patients completed 2 years of therapy and serial liver biopsies were available in 107 patients. Analysis of serum liver chemistry, changes in the degree of steatosis, necro-inflammation or fibrosis revealed no significant difference between the verum and placebo-treated groups. However, the results from this study showed a high rate of spontaneous improvement in hepatic steatosis in the placebo arm probably explaining in part why the data were negative. In addition, the dose of 13 and 15mg/kg pre day was possibly insufficient to improve NAFLD, so effect of higher doses needs to be evaluated in further studies.

INSULINSENSITIZER

The association of insulin resistance and hyperinsulinemia with NAFLD suggests a possibility of therapeutical intervention. The first evidence came from leptin-deficient, obese ob/ob mice. Metformin, a biguanide that reduces hyperinsulinemia and improves hepatic insulin resistance, reduced hepatomegaly and hepatic steatosis in ob/ob mice, whereas caloric restriction did not result in a substantial improvement[40]. The authors postulated that metformin improve hepatic insulin resistance by decreasing hepatic expression of TNF-α, a cytokine that promotes insulin resistance. A pilot study evaluated the effect of metformin in 20 patients with histological proven NASH[41]. When compared with the six patients not complying with treatment, intake of metformin for 4 mo significantly reduced levels of transaminases. They normalized in 50% of treated individuals. Also, insulin sensitivity improved significantly and liver volume decreased by 20%. Metformin was well tolerated and there was no case of lactic acidosis. However, the authors did not provide a serial liver biopsy to evaluate the effect of metformin on liver histology. These promising results were only in part supported by another open label trial [42]. Fifteen patients with biopsy proven NAFLD completed 12 mo of treatment with metformin (20 mg/kg). During the initial 3 mo, liver enzymes improved significantly. There was also an improvement in insulin sensitivity detectable. However, after 3 mo, insulin sensitivity did not further improve and levels of AST and ALT gradually increased back to pretreatment levels. Among the 10 patients with posttreatment biopsy, three showed improvement in steatosis, two showed improvement in inflammation score and one in fibrosis.

Another trial evaluating the effect of metformin was performed by a Turkish group from Ankara[43]. Uygun and coworkers randomized 36 patients with NASH into two groups. The first group was given lipid and calorie-restricted diet alone, while the second group was treated with metformin in addition to the diet for a period of 6 mo. The comparison between both groups showed no

significant differences in inflammatory activity or fibrosis, although more patients in the treatment group showed an improved liver histology. The improvements of liver enzymes, insulin, insulin resistance index and c-peptide levels in the metformin group were significantly greater than those detected in the group with dietary treatment alone. The most recently published controlled trial by Bugianesi and colleagues demonstrated a better effect of metformin on improvement of liver enzymes compared to a prescriptive diet or the administration of vitamin E[44]. Unfortunately, the histological data were limited to support an association between improvement of liver chemistry and histological findings.

Another class of agents presumably improving insulin sensitivity is the thiazolinediones. These compounds are ligands for the peroxisome proliferator-activated receptor gamma (PPAR gamma), which is expressed at high levels in adipocytes. Troglitazone, a first generation thioglitazone, and metformin were shown to inhibit the expression of sterol regulatory element binding protein-1 (SREBP-1), a key regulator of lipogenic enzymes[40, 45]. Troglitazone was investigated in a pilot study including 6 patients with biopsy-proven NASH[46]. Patients received 200 mg of troglitazone twice daily, which was well tolerated. Levels of ALT normalized in 4 of 6 patients on therapy and they persisted in normal range 3 mo after discontinuation of troglitazone. However, the Food and Drug Administration removed troglitazone from the market in March 2000 because of serious hepatotoxicity[47, 48]. The second-generation thioglitazones rosiglitazone and pioglitazone appear to be safer, although their use is currently contraindicated in the presence of active liver disease or of ALT more than 2.5 times normal. An open label trial including 26 biopsy-proven NASH patients analyzed the effect of rosiglitazone, 4 mg twice daily for 48 wk[49]. All patients were overweight, and 23% had a BMI>35 kg/m^2. Twenty-six patients had posttreatment biopsy. The mean necro-inflammatory score significantly improved with treatment and biopsies of 10 patients did not fulfill published criteria for NASH anymore after treatment . Twenty-five patients completed 48 wk of treatment and showed a significant improvement in liver enzymes and insulin resistance. However, 3 patients had to be withdrawn because of adverse events. One of these individuals discontinued because of increased ALT levels. In addition, weight gain occurred in more than two-thirds of participants and liver enzyme levels increased to near pretreatment level 6 mo after discontinuation of study medication. Another pilot study demonstrated similar results in 18 patients with biopsy proven NASH, who were treated with pioglitazone[50]. By 48 wk, levels of ALT normalized in 72% of patients. Hepatic fat content and size decreased which was determined by magnetic resonance imaging. There was also a significant improvement in liver histology regarding features of steatosis, inflammation and fibrosis. Histological improvement occurred in two-thirds of patients. The main side effect in this study was also weight gain and increase in total body adiposity.

In a recently published pilot study by Sanyal and coworkers 20 nondiabetic patients with biopsy-confirmed NASH were randomized to take the combination of pioglitazone (30 mg daily) and vitamin E or vitamin E (400 IU daily) alone for a period of 6 mo[51]. ALT levels normalized in all patients within 6 mo. Compared to baseline, treatment with vitamin E alone resulted in a significant decrease in steatosis, whereas the combination therapy produced a significant improvement in steatosis, cytologic ballooning, Mallory´s hyaline and pericellular fibrosis. Although vitamin E did not have any significant effects on metabolic endpoints, combination therapy improved insulin sensitivity, lowered fasting free fatty acid (FFA) levels and decreased metabolites of FFA oxidation. However, like in the previous trial by Neuschwander-Tetri and coworkers[49] , one of 10 patients receiving pioglitazone plus vitamin E had a significant increase in ALT level and was withdrawn from the study.

LIPID LOWERING DRUGS

Because NAFLD frequently occurs with a disordered lipid homeostasis, lipid-lowering drugs are considered as possible treatment for NAFLD. Hypertriglyceridemia and reduced HDL-cholesterol level are typical dyslipidemias associated with NAFLD. Gemfibrozil reduces very low-density lipoprotein triglyceride production. In a small controlled study of 46 patients with NASH, levels of AST were significantly decreased in 74% of the gemfibrozil group compared with 30% in the control group after 4 wk of treatment[52]. There was no correlation with pretreatment serum triglyceride levels. Posttreatment liver biopsies were not performed and the duration of biochemical response was not evaluated.

In NASH patients with hyperlipidemia statins are another potential treatment option. However, existing data are predominantly uncontrolled with a small number of patients. One study analyzed 28 hyperlipidemic patients with biopsy-proven NASH. Patients were given atorvastatin 20 mg daily for 24 wk. Both significant reduction of LDL-cholesterol and liver enzymes were detectable after treatment[53]. Statin-induced hepatoxicity did not occur and the risk seems to be not increased in patients with presumed NAFLD[54]. However, controlled trials with a bigger number of patients are required to demonstrate the benefit and elucidate potential risks of administrating statins.

BLOCKADE OF TNF-α

Adipose tissue produces several cytokines and biologically active proteins, denoted as adipokines, regulating hepatic and peripheral glucose and lipid metabolism. These adipokines include leptin, resistin, adiponectin and TNF-α. Expression of resistin is not increased in patients with insulin resistance, although resistin inhibits insulin action in animal models[55]. NASH patients show increased serum leptin levels, suggesting the attempt to overcome hepatic leptin resistance to stimulate hepatic lipid turnover[56]. In several studies investigating the pathomechanisms of fatty liver disease increased TNF-α levels have also been demonstrated[57, 58]. TNF-α contributes to insulin resistance and thereby increases hepatic steatosis and plays a

potentially proinflammatory role[59]. This was supported by studies in leptin deficient ob/ob mice. Treatment of anti-TNF-α antibody improved liver histology, reduced hepatic total fatty acid content, and decreased ALT levels[11]. However, studies of ob/ob mice lacking type I and II TNF receptors have suggested that TNF-α is not involved in the liver disease[60]. Further evidence of the involvement of TNF-α came from studies of pentoxifylline which acts as an inhibitor of TNF-α[61, 62]. In these two studies 20 patients and 18 patients, respectively, with biopsy confirmed NASH were enrolled. Pentoxifylline was given for 6 or 12 mo. Both studies demonstrated a significant improvement of AST and ALT levels after application of pentoxifylline in patients with NASH, although histological evidence of its benefit remains unknown.

Adiponectin is exclusively secreted from adipose tissue in inverse proportion to BMI[63, 64]. Although the three dimensional structure of adiponectin closely resembles that of TNF-α[65], these two proteins have completely opposite effects. Adiponectin and TNF-α suppress each other´s production and antagonize their biological effects[66]. Adiponectin acts to reduce body fat[67], improve hepatic and peripheral insulin sensitivity[68] and decrease fatty acid levels[69]. Adiponectin has also antiinflammatory effects which could prevent liver disease. Xu and coworkers replenished recombinant adiponectin in mice fed with a high fat ethanol containing diet and in obese ob/ob mice with NASH. In both mice, administration of adiponectin ameliorated hepatomegaly, steatosis, and elevated ALT levels[70]. Both hepatic TNF-α expression and serum levels of TNF-α significantly decreased, which is further evidence for a harmful role of TNF-α.

This concept was further supported by a study of over 100 patients with NAFLD[71]. Multivariate analysis revealed that decreased serum adiponectin levels and increased TNF-α and soluble TNFR2 levels correlated with the presence of NASH independent of the presence of insulin resistance. NASH patients showed lower adiponectin levels than patients with simple steatosis. Levels of adiponectin correlated with the degree of hepatic necroinflammation. These data provide evidence for the involvement of TNF-α and adiponectin in human NAFLD. Therefore, studies evaluating the effect of adiponectin in treatment of NASH are required.

LIVER TRANSPLANTATION

NASH is considered the most common cause of cryptogenic cirrhosis[72]. Patients with pure steatosis have a benign prognosis, whereas the risk for developing cirrhosis and hepatocellular carcinoma in NASH patients is increased[73, 74]. Complications of cirrhosis or hepatocellular carcinoma may require liver transplantation. In one study by Laurin and colleagues six of eight patients who underwent transplantation for NASH developed recurrent NASH. In three of these six patients, perivenular fibrosis recurred[75]. The patients with recurrences revealed post-transplant hyperlipidemia and increases in body weight. In two subsequent studies the recurrence rate of steatosis was between 60 to 100% of transplant recipients[76, 77]. In one third of these patients progression to steatohepatitis occurred.

CONCLUSIONS

Because of increasing incidence of obesity and insulin resistance NAFLD has become increasingly the focus of basic and clinical research. Whereas fatty liver shows a benign prognosis, patients with NASH should be treated. Progress in understanding the pathomechanisms which contribute to aggravation of fatty liver pathology offers potential treatment options. However, a standard therapy has not been established. The most promising results came from trials with second generation insulin sensitizer in obese patients with insulin resistance. Blockade of TNF-α by adiponectin showed impressive improvement of NASH in an animal model. Clinical trials investigating therapeutic effect of inhibiting TNF-α in NAFLD have to be awaited. So, beyond clinical studies, the first step in treatment should be improvement of insulin sensitivity by weight loss and physical activity.

Abstract

AIM: To study the role of *CDH1/E-cadherin* (E-cad) gene alteration profiles including mutation, loss of heterozygosity (LOH), promoter polymorphism and hypermethylation in mechanisms of *CDH1* inactivation in gastric carcinoma (GC).

METHODS: Specimens were collected surgically from 70 patients with GC. Allelotyping PCR and detection of LOH, denaturing high pressure liquid chromatography and DNA sequencing, restriction fragment length polymorphism analysis, methylation specific PCR, and immunohistochemical staining were used.

RESULTS: Promoter polymorphism was not a major mechanism of E-cad inactivation. Only one truncating mutation was found in a diffuse type tumor (3%). Both LOH and promoter hypermethylation were major mechanisms of E-cad inactivation, but interestingly, there was a negative association between the fraction of allelic loss (LOH) in tumors and hypermethylation of *CDH1*. Therefore LOH and hypermethylation were two different tumorigenic pathways involved in GC.

CONCLUSION: Given the findings that somatic mutation was extremely low and the relationship between LOH and hypermethylation was inverse, any two combinations of these three factors cannot fulfill the classical two-hit hypothesis of *CDH1* inactivation. Thus, other mechanisms operating at the transcriptional level or at the post-translational level might be required to induce E-cadherin inactivation.

Key words: Gastric carcinoma; E-cadherin gene alteration profiles; Inactivation of E-cadherin

INTRODUCTION

CDH1/E-cadherin (E-cad) is a member of the family of transmembrane glycoproteins expressed on epithelial cells and is responsible for calcium-dependent cell-to-cell adhesion[1]. E-cad forms complexes and connects actin filaments with α-, β-, and γ-catenins[2,3], which are essential to neoplastic transformation and metastasis[4, 5]. Loss of cell adhesion may contribute to loss of contact inhibition of growth, which is an early step in the neoplastic process. Furthermore, loss of cadherin activity may result in cancer cell detachment and metastasis[6, 7].

Gastric carcinogenesis is a multi-step process with morphological progression involving multiple genetic and epigenetic events. E-cad gene (*CDH1)* is an important putative tumor suppressor gene. In gastric carcinomas (GCs), the reduction in E-cad expression activation of *E-cad* gene varies from 17% to 92%, and is more frequent in diffuse type than in intestinal type tumors[8-13]. Germline mutation of the *CDH1* gene is found in all familial GCs[14, 15]. Somatic mutations of *CDH1* are found in more than

50% of diffuse type GCs but are not found in intestinal type GCs in Caucasians and Japanese populations[16-19]. The rate of loss of heterozygosity (LOH) ranges from 2.8% to 60% in diffuse and intestinal type tumors[16-20]. In addition to the well-known 'two-hit'inactivation mechanism proposed by Knudson (1971), *CDH1* can be silenced in GC by epigenetic promoter hypermethylation[17, 21]. Besides, Li *et al*[22] reported that the-60C/A polymorphism has a direct effect on the transcriptional regulation of *CDH1*. All above previous studies of the inactivation of this gene in patients with GC have been limited in their analyses. In this study, we investigated a range of alterations in *CDH1* expression profiles, including genetic mutations, LOH, promoter polymorphism, promoter hypermethylation, and immunohistochemical stain of E-cad protein together to determine possible genetic and epigenetic mechanisms of *CDH1* inactivation.

MATERIALS AND METHODS

Patients and samples

Specimens were collected surgically from 70 Taiwanese patients with GC between July 1999 and July 2002 at the Division of General Surgery, Department of Surgery, Tri-Service General Hospital, Taipei, Taiwan. None of the subjects received preoperative anticancer therapy. Clinical information was obtained from medical records. Samples were taken from representative cancerous lesions and the adjacent non-cancerous epithelial parts of the tissues were flash frozen in liquid nitrogen and stored at -80℃. All tumor DNA samples were obtained by micro-dissection from 5-μm thick hematoxylin and eosin stained and paraffin embedded tissue sections[23]. Non-cancerous DNA was extracted from tissues which were flash-frozen in liquid nitrogen and stored at -80℃. All 70 samples were classified according to the Lauren's criteria[23]: 27 were intestinal and 43 were diffuse types. The tumors were staged at the time of surgery using the standard criteria by TNM staging, with the unified international gastric cancer staging classification[24].

Allelotyping PCR and detection of allelic loss or loss of heterozygosity (LOH) of CDH1

DNA samples from tumor and normal mucosal specimens were used for allelotyping PCR with fluorescent primers (markers). Three micro-satellite markers (D16S3043, D16S3050, and D16S3021) at 16q22.1 were used to detect LOH at the CDH1 locus. PCR amplification was carried out as previously described[26]. PCR products were separated electrophoretically on an ABI PRISM 377 DNA sequencer, and fluorescent signals from the differently sized alleles were recorded and analyzed using Genotyper version 2.1 and GeneScan version 3.1 software packages. A given informative marker was considered to display LOH when a threefold or greater difference was seen in the relative allele intensities of the tumor and normal DNA samples.

Denaturing high pressure liquid chromatography (DHPLC) analysis and DNA sequencing for CDH1 mutation analysis

We used DHPLC and direct sequencing to determine inactivating mutations responsible for the loss of *CDH1* expression. The promoter region and 16 exons including the exon-intron boundaries were analyzed using the previously described protocol and primer pairs[26]. The optimal conditions for DHPLC analysis of each amplicon were available as requested. All variants detected by DHPLC were re-amplified and the site of variation was identified by direct DNA sequencing using an ABI PRISM 377 DNA sequencer.

Restriction-fragment length polymorphism (RFLP) analysis to identify nucleotide changes at –160 of the CDH1 promoter

The -160 polymorphic site contained either a C or A residue. The tumor type was determined by *Bst*EII digestion of the PCR products amplified using the primer set 5′-TGATCCCAGGTCTTAGTGAG-3′ (upstream) and 5′-AGTCTGAACTGACTT CCGCA-3′ (downstream). The 318-bp PCR product was cut into two fragments (208 and 110 bp) if it contained the A residue. To ensure that the observed polymorphism was specific and not an experimental artifact, the results were confirmed by direct DNA sequencing.

Methylation-specific PCR (MSP) and bisulfite-modified genomic sequencing to detect promoter hypermethylation of CDH1

Genomic DNA was modified by bisulfite treatment, converting unmethylated cytosines to uracils and leaving methylated cytosines unchanged. MSP was performed on the treated DNA to detect all three CpG islands in the *CDH1* promoter region as previously described[27]. Each unmethylated–methylated primer pair set was engineered to assess the methylation status of 4-6 CpGs with at least one CpG dinucleotide positioned at the 3′ end of each primer to discriminate between methylated and unmethylated alleles following bisulfite modification. Hs578t cells, which contain a heterogeneously methylated CpG island 1 and methylated CpG islands 2 and 3, served as the positive control, and MCF7 cells were used as the negative control.

Immunohistochemical staining and evaluation of E-cad expression

Sections (5 μm thick) were treated with monoclonal anti-E-cad antibody (Cappel, Aurora, OH, USA), then with secondary antibody. The signal was detected using a kit containing avidin–biotin complex and diaminobenzidine (DAB; Vector Laboratories, Burlingame, CA, USA). DAB produced a yellowish brown staining if the sample was positive. If more than 90% of the tumor cells exhibited intense membranous staining similar to that of normal cells, the result was considered positive (++). If the staining intensity was demonstrably reduced relative to that of normal cells and/or the staining pattern was heterogeneous (10%-90% positive), the result was deemed to be weakly positive (+). If IHC expression was completely lost or positive in less than 10% of cells, the result was defined as negative (–).

Statistical analysis

Analyses were performed using S-Plus® 2000 for

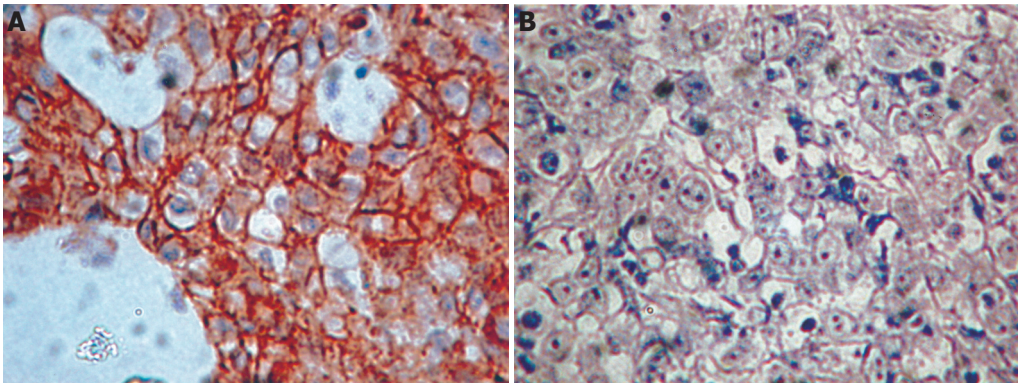

Figure 1 Immunohistochemical staining for positive (**A**) and negative (**B**) E-cad expression in diffuse type tumor.

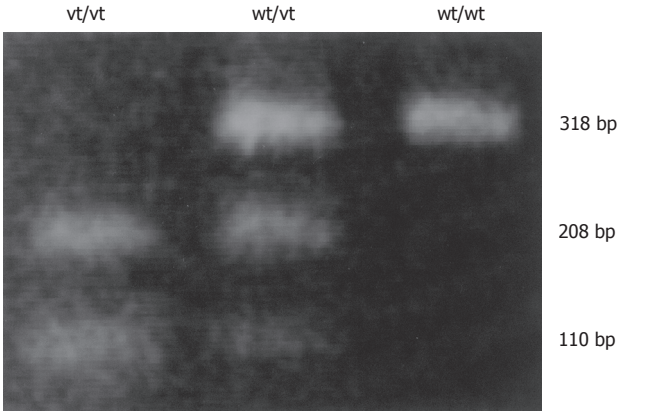

Figure 2 PCR-restriction fragment length polymorphism (RFLP) analysis of genetic polymorphism of the -160 site of the *E-cad* promoter. The C/A polymorphism was differentiated by *BstEII* digestion of PCR products homozygous for the wild-type (high-activity) allele (*wt/wt*, CC gentoype), heterozygous for the variant (low-activity) allele (*wt/vt*, CA genotype), and homozygous for the low-activity allele (*vt/vt*, AA genotype)

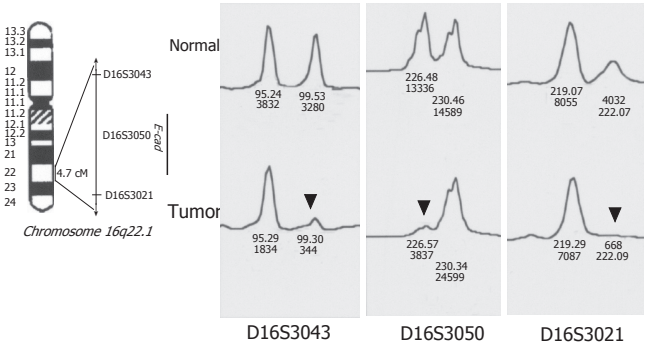

Figure 3 Allelic loss or loss of heterozygosity (LOH) of *CDH1*/*E-cad*. Left panel: *E-cad* detected by allelic loss or loss of heterozygosity (LOH) of the *E-cad* locus, reflected by three microsatellite markers (*D16S3043*, *D16SS3050* and *D16S3021*) at 16q22.1. *Right panel*: LOH in a representative GC. The locius of markers *D16S3043*, *D16S3050*, and *D16S3021* were considered to be informative when they were heterozygous in normal tissue (i.e. two alleles were seen), and showed LOH when a 3-fold or greater difference was seen in the relative allele intensity ratio between the tumor and normal DNA (arrow).

Windows statistical software (CANdiensten, Amsterdam, Netherlands). Significance was assumed at $P<0.05$ for all tests. Categorical variables were tested using Fisher's exact test.

RESULTS

Of the 70 patients, 52 were men and 18 were women. Their median age was 69.7 years (range 32-88 years). According to Lauren's classification, 27 and 43 tumors were intestinal and diffuse histotypes, respectively. Reduced gene expression was more frequent in diffuse type tumors (38/43, 88%) than in intestinal type tumors (13/27, 48%; $P=0.006$). Representative examples of immunohistochemical staining for E-cad expression in diffuse type tumors are shown in Figure 1.

Promoter polymorphism

Three of the 70 patients were omitted from our analysis of the -160C/A polymorphism due to insufficient samples. Among the other 67 patients, 29 were genotype C/C (43%), 24 were genotype A/C (36%) and 14 were genotype A/A (21%) (Figure 2). There was no significant difference in the frequency of the C/A + A/A genotypes between diffuse and intestinal type tumors (27/42, 64% *vs* 11/25, 44%). There was no significant difference in LOH between the C/C and C/A + A/A genotypes (10/25, 40% *vs* 13/33, 39%). There was also no significant difference in hypermethylation between C/C and C/A + A/A genotypes (20/29, 69% *vs* 24/37, 65%). There was no significant difference in the frequency of the C/A + A/A genotypes between tissues with reduced and normal E-cad expression (12/17, 71% *vs* 27/50, 54%).

Loss of heterozygosity

To detect allelic loss at *CDH1*, three micro-satellite markers (D16S3043, D16S3050, D16S3021) at 16q22.1 were used (Figure 3). The allelic status of this gene was reflected well by these three markers, because its locus was very close to the loci of these markers (LOD score > 4 estimated by linkage analysis). We considered the results for all three markers together and found heterozygosity in at least one. Of the 70 samples collected, 10 were omitted from the analysis or homozygous and could not be detected. A high frequency of allelic loss at *CDH1* was detected (23/60, 38%). The frequency of LOH at *CDH1* was similar between diffuse type tumors (15/38, 39%) and intestinal type tumors (8/22, 36%). Reduced E-cad expression was more frequent in LOH-positive tumors (21/23, 91%) than in LOH-negative tumors (24/37, 65%; $P=0.03$).

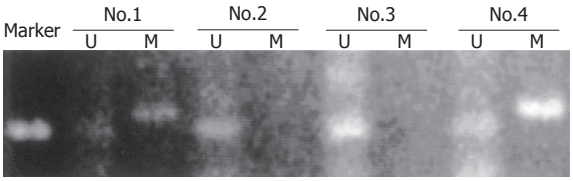

Figure 4 Promoter hypermethylation of the *CDH1/E-cad* detected by methylation-specific PCR (MSP). The presence of a visible PCR product in the lanes marked U indicates the presence of an unmethylated allele, while the presence of the product in the lanes marked M indicates the presence of a methylated allele. The intensity of each methylated band was further semi-quantitated, and as shown in the figure, cases 1 and 4 were defined as "hypermethylation"with "+"and "++", respectively, and cases 2 and 3 were defined as "unmethylation".

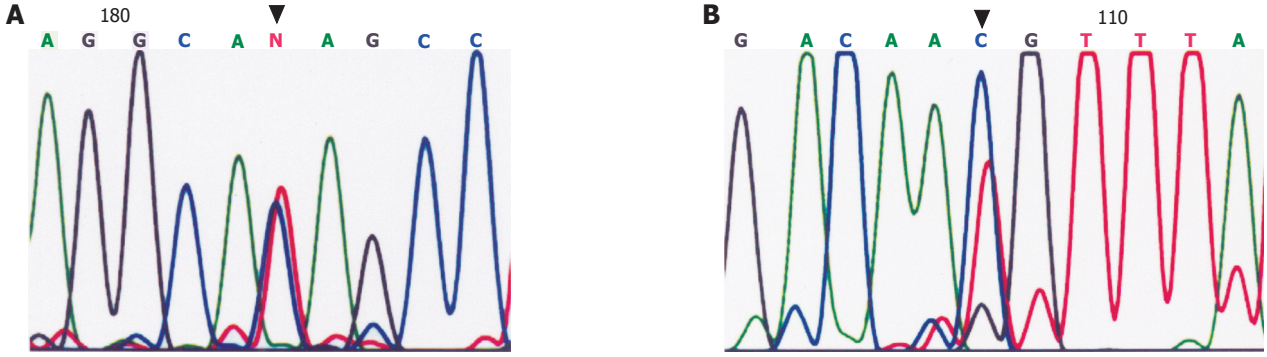

Figure 5 *CDH1*/E-cad mutation and polymorphism detected by direct DNA sequencing. Two tumors subjected to DNA sequencing were found to harbor C-to-T transversion in exon 13 (**A**), resulting in a truncated mutation (Gln to stop condon TAG) and C-to-T transversion in exon 14 (**B**), resulting in no amino acid change, which was considered to be polymorphism.

Promoter hypermethylation

The degree of hypermethylation estimated by MSP was defined as strongly detectable (+++, ++), detectable (+), or not detectable (–)(Figure 4). Three of the 70 samples were omitted from our analysis of hypermethylation due to insufficient samples. The *CDH1* promoter was hypermethylated in 45 of these 67 GCs (67%). Hypermethylation was more frequent in diffuse type tumors (31/41, 76%) than in intestinal type tumors (13/26, 50%; $P=0.03$ by Fisher's exact test). Furthermore, hypermethylation was more frequent in GCs with reduced E-cad expression than in those with normal levels (37/45, 82% *vs* 12/22, 55%; $P=0.02$). The fraction of allelic loss (FAL) of *CDH1*, calculated as the frequency of LOH at *CDH1* locus, was generally inverse to the degree of hypermethylation (Tables 1, 2).

Mutation

In these 70 patients, five diffuse type tumors (Case No. 15, 24, 29, 30, and 39) had a single-nucleotide polymorphism (SNP) at amino acid 692, and four diffuse type tumors (Case No. 35, 40, 59, and 63) had an SNP at position 755 . Case No.15 had a truncated mutation at position 699 (Figure 5). No *CDH1* mutation was found in intestinal type tumors.

DISCUSSION

In this study, 27 and 43 tumors were of the intestinal and diffuse histotypes, respectively. Inactivation of the *CDH1* gene and loss of normal E-cad expression were involved more frequently in diffuse type than in intestinal type tumors (88% *vs* 48%; $P=0.006$). However, the percentage of reduction in E-cad expression of GC varies from 17% to 92% in previous reports[8-13]

Promoter polymorphism

Li *et al*[22] reported that the A allele of the -160C/A promoter polymorphism alters transcriptional binding, resulting in a reduction in transcriptional efficiency of 68% relative to that of the C allele. In our study, there was no significant difference in the frequency of the C/A + A/A genotypes between diffuse and intestinal type tumors. There was no significant difference in LOH and hypermethylation between the C/C and C/A + A/A genotypes. There was also no significant difference in the frequency of the C/A + A/A genotypes between tumors with reduced and normal E-cad expression, suggesting that the A allele does not play a major role in the inactivation of *CDH1* and can not serve as the 'second hit'.

Mutations

Somatic mutations of *CDH1* are found in more than 50% of diffuse type GCs but not in intestinal type GCs in Caucasian and Japanese populations[16-19]. A review by Berx *et al*[28] noted that the predominant defects in diffuse type tumors are splice mutations causing skipping in exon 8 or 9, which account for in-frame deletions, whereas mis-sense and truncating mutations are less frequent in diffuse GCs. Moreover intragenic polymorphisms arise from changes in the third (wobble) position of the respective codons and are more frequent in codons 692 and 751. In the present study, five of the diffuse type tumors had a codon 692 polymorphism and four diffuse type tumors had a codon 755 polymorphism. Only one of 38 diffuse type tumors had a truncated codon 699 mutation. Because consistent findings have been obtained by repeated detection of the same specimens, we considered this finding to be valid. Therefore, this low rate of *CDH1* mutation in the Taiwanese GCs may suggest different tumorigenic mechanisms to inactivate this gene.

Table 1 Fraction of allelic loss (FAL) in tumors with different hypermethylation statuse

Promoter hypermethylation	FAL	
Yes (++,+++)	0.098	
Yes (+)	0.214	
No	0.377	$P=0.03$

FAL was estimated by allelic status at D16S3043, D16SS3050 and D16S3021. FAL (fraction of allelic loss) = number of loci showing LOH / number of informative loci in each tumor. The FALs of tumors with different hypermethylation status were calculated as the mean of FALs of individual tumors with the same hypermethylation status.

Table 2 Association between loss of heterozygosity and promoter hypermethylation of *CDH1*

	Loss of heterozygosity		
	Yes (%)	*n* (%)	Promoter
hypermethylation			
Yes (++,+++)	1 (9.1)	17 (34.7)	
Yes (+)	2 (18.2)	21 (42.9)	
No	8 (72.7)	11 (22.5)	$P=0.001$

LOH status is defined by D16S3043

Loss of heterozygosity

It was reported that the rate of LOH ranges from 2.8% to 60% in diffuse and intestinal type tumors [16-20]. A high frequency (38%) of allelic loss at *CDH1* was identified in our study. The frequency of LOH was similar between the diffuse and intestinal type tumors (39% *vs* 36%). Reduced E-cad expression demonstrated by immunohistochemical analysis was more frequent in LOH-positive tumors than in LOH-negative tumors (91% *vs* 65%; $P=0.03$), suggesting that LOH is a major mechanism for the inactivation of *CDH1*.

Promoter hypermethylation

Tamura *et al*[29] and Graziano *et al*[30] indicated that *CDH1* promoter methylation may play a major role together with mutations or deletions, in causing the inactivation of the *CDH1* gene in GCs, especially in diffuse type tumors. They also reported that *CDH1* promoter hypermethylation is associated with reduced E-cad expression detected immunohistochemically. In the present study, the *CDH1* promoter was hypermethylated in 67% of GCs. Hypermethylation was more frequent in diffuse type tumors than in intestinal type tumors ($P=0.03$). Furthermore, hypermethylation was more frequent in tumors with reduced E-cad expression than in normal E-cad expression (82% *vs* 55%; $P=0.02$), suggesting that *CDH1* promoter hypermethylation is a major mechanism for gene inactivation.

Methylation of the *CDH1* promoter has been documented as the 'second hit' responsible for the development of hereditary diffuse GCs[31] and sporadic diffuse GCs[17] among Caucasians. Because there was only one genetic mutation in diffuse type tumors and no mutation in intestinal type tumors in this series, we examined the hypermethylated status of tumors with or without LOH at the *CDH1* locus. We investigated the relationship between hypermethylation and FAL, which was estimated from the allelic status at D16S3043, D16S3050, and D16S3021. Hypermethylated tumors tended to have significantly lower FAL values (Table 1). This is contrary to the result predicted by the two-hit hypothesis. Further examination using individual markers to redefine the LOH status of tumors yielded similar results (Table 2). Therefore, cancers having lost one *CDH1* allele and those carrying hypermethylated *CDH1* alleles may be involved in two different tumorigenic pathways. Because the somatic mutation rate is extremely low, any two combination of these three factors cannot fulfill the classic 'two-hit' hypothesis. Other molecules involved in the E-cad-mediated cell-cell adhesion complex, such as the intracellular attachment proteins α, β, and γ-catenin, may be subjected to targeted inactivation[32-36]. Receptor tyrosine kinase (RTK), the main positive regulator of progression and tissue expansion, can repress E-cad function by transcriptional repression of *CDH1* via the transcription factor SNAI1[37,38], posttranscriptional repression via direct or indirect phosphorylation of adheren junction components such as β-catenin[39], or RTK-associated endocytosis and degradation of the E-cad protein[40]. This more flexible status achieved either by retaining an intact allele subsequent to LOH or by regulation via epigenetic mechanisms operating at the transcriptional or posttranslational levels, could provide an advantage in counteracting the changing microenvironment during tumor progression. Further investigation is needed at the transcriptional level and the post-translational level into E-cad inactivation of GC.

In conclusion, given the finding that somatic mutation was extremely low and the relationship between LOH and hypermethylation was inverse, any two combinations of these three factors can not fulfill the classical two-hit hypothesis of E-cadherin inactivation. Thus, other mechanisms operating at the transcriptional level or at the post-translational level, might be required to inactivate E-cadherin in GC.

Abstract

AIM: To determine whether *Helicobacter pylori* (*H pylori*) vacuolating cytotoxin (VacA) regulates release of pro-inflammatory cytokines (IL-1β, IL-8, TNF-α, and IL-6) or alters gastric epithelial cell viability and to determine whether NaCl affects these VacA-induced changes.

METHODS: Vacuolating activity was determined by measuring the uptake of neutral red into vacuoles of VacA-treated human gastric epithelial (AGS) cells. AGS cell viability was assessed by direct cell counting. Specific enzyme-linked immunosorbent assays (ELISA) and reverse transcriptase-polymerase chain reaction(RT-PCR) were performed to examine the effects of *H pylori* VacA and NaCl on cell pro-inflammatory cytokine production in AGS cells. Immunohistochemical staining of gastric tissue from Mongolian gerbils was used to confirm VacA-induced pro-inflammatory cytokine production and the effects of NaCl on this VacA-induced response.

RESULTS: Addition of VacA alone reduced AGS cell viability ($P < 0.05$), and this reduction was enhanced by high doses of NaCl ($P < 0.05$). VacA alone induced expression of TNF-α, IL-8 and IL-1β, while NaCl alone induced expression of TNF-α and IL-1β. Changes in mRNA levels in the presence of both VacA and NaCl were more complicated. For the case of TNF-α, expression was dose-dependent on NaCl. IL-6 mRNA was not detected. However, low levels of IL-6 were detected by ELISA. Positive immunohistochemical staining of IL-1, IL-6, and TNF-α was found in gastric tissue of *H pylori*-infected gerbils fed with either a normal diet or a high salt diet. However, the staining of these three cytokines was stronger in *H pylori*-infected animals fed with a 5g/kg NaCl diet.

CONCLUSION: VacA decreases the viability of AGS cells, and this effect can be enhanced by NaCl. NaCl also affects the production of pro-inflammatory cytokines induced by VacA, suggesting that NaCl plays an important role in *H pylori*-induced gastric epithelial cell cytotoxicity.

INTRODUCTION

Gastric cancer is one of the leading causes of cancer-related death[1, 2]. Epidemiological studies in humans and rodents have demonstrated that chronic gastritis caused by *Helicobacter pylori* (*H pylori*) is a strong risk factor for this malignancy[3]. Current models suggest that *H pylori* is not directly carcinogenic but rather acts indirectly on inducing cancer. For example, it may act through inflammatory mediators or by decreasing gastric acid secretion, thus favoring the formation of mutagenic adducts[4]. *H pylori* expresses several major proteins that are critical to the pathogenicity of the bacterium[5]. The vacuolating cytotoxin, VacA, is an *H pylori*-secreted virulence factor that induces the formation of large cytoplasmic vacuoles in epithelial cells, which precedes cultured cell death both *in vitro* and *in vivo*[6-9]. In the past decade, a considerable number of studies have contributed to our understanding of the mechanism of VacA-induced intracellular vacuolation[6].

Salt consumption is considered a risk factor for gastric cancer[10]. *H pylori*-associated mucosal atrophy is partially associated with a high salt diet[11]. Excessive NaCl intake enhances *H pylori* colonization in mice and humans, while chronic salt intake may exacerbate gastritis by increasing *H pylori* colonization[12]. Furthermore, salt intake may interfere with *H pylori* infection and modify the cancer risk[13]. The high prevalence of *H pylori* infection and high salt diets may significantly affect the rate of occurrence of gas-

tric carcinogenesis[14-17].

It has been reported that cytokines play an important role in gastric cancer. Proinflammatory cytokines such as interleukin-8 (IL-8) and tumor necrosis factor-α (TNF-α) may up regulate cyclooxygenase-2 (COX-2) during gastric carcinogenesis[18]. Genotypes of IL-1β (-511 T/T) and TNF-α (-308 A/A) are associated with the risk of non-cardia gastric cancer. The presence of TNF-α SNPs -308 and -1031 might favor *H pylori* infection and promote an inflammatory response in infected gastric mucosa[19]. IL-1β genotype has been found to increase the risk of distal gastric cancer[20]. IL-1β is one of the potent proinflammatory cytokines elicited by *H pylori* infection[21, 22]. In human gastric cancer cells, IL-1β induces vascular endothelial growth factor (VEGF), a dominant angiogenic factor in gastric cancer[23]. Moreover, levels of IL-1β and IL-8 have been found to be significantly higher in *H pylori*-positive gastric cancers compared with controls, and eradication of *H pylori* can significantly reduce the levels of these cytokines[24]. Genetic polymorphisms identified in *IL-6* can be attributed to ethnicity and appear to be independent of the clinical outcome of *H pylori* infections[25].

The present study was to examine the combined effects of VacA and NaCl on cell viability and pro-inflammatory cytokine expression both in AGS cells and in Mongolian gerbils.

MATERIALS AND METHODS

Preparation of VacA

The toxin-producing strain, *H pylori* ATCC49503, was used as the source of VacA. *H pylori* was grown under microaerophilic conditions on Columbia blood agar plates with vigorous shaking in a controlled microaerophilic atmosphere of 50 mL/L O_2 and 100 mL/L CO_2 at 37℃ for 3-4 d, harvested and re-suspended in brucella broth (Difco) supplemented with 100 mL/L fetal calf serum. *H pylori* cells were grown for 48 h at 37℃ in an Erlenmeyer flask with shaking at 60 r/min. Cells were then pelleted by centrifugation at 500 r/min for 20 min. The culture supernatants were collected and pooled. Solid ammonium sulfate was added to the pooled material at 4℃ to 50% saturation. The precipitate was collected by centrifugation at 12000 r/min for 20 min, dissolved in 60 mmol/L Tris-HCl (pH 7.7) containing 0.1 mol/L NaCl and subjected to liquid chromatography on a Superose 6 HR 10/30 column (1cm × 30 cm) equilibrated with 60 mmol/L Tris-HCl (pH 7.7) containing 0.1 mol/L NaCl. The material was eluted with the same buffer at a flow rate of 0.5 mL/min. The eluted protein was monitored by Western blotting using polyclonal anti-VacA (Santa Cruz Biotechnology, Inc., Santa Cruz, CA). The fractions containing VacA were collected, pooled, diluted with deionized water to the intended concentration and maintained at -20℃[26]. VacA concentration was determined by Micro-BCA assay (Bio-Rad, Hercules, CA).

Vacuolating activity assay

The human gastric epithelial cell line AGS (ATCC CRL 1739) was maintained in Ham's F-12 medium supplemented with 100 mL/L fetal calf serum and 50 mg/L penicillin-streptomycin (Life Technologies, Inc.) under 50mL/L CO_2 at 37℃. AGS cells were seeded in 96-well culture plates (5×10^3 cells/well in 90 μL) and cultured as monolayers for 20 h in a 50 mL/L CO_2 atmosphere at 37℃. Samples (10 μL) of VacA were added to achieve the indicated final concentrations and cells were incubated for an additional 2-8 h at 37℃[27]. Vacuolating activity was determined by measuring the uptake of neutral red into vacuoles in VacA-treated cells. Cells were incubated for 5 min at room temperature with 50 μL of freshly prepared 0.5 g/L neutral red in PBS containing 3 g/L BSA and washed three times with 0.1 mL of PBS containing 3 g/L BSA. After addition of 0.1 mL 700 mL/L ethanol in water containing 0.4 mL/L HCl, absorbance at 540 nm (A_{540}) was measured. Vacuolating activity was determined by subtracting the A_{540} of cells incubated without VacA from the A_{540} of VacA-treated cells. To evaluate the effect of NaCl on vacuolating activity, AGS cells were incubated with 40 mg/L VacA and 0-10 mmol/L NaCl for the indicated periods.

Assessment of AGS cell viability

AGS cells were seeded to a subconfluent density of 5×10^4 cells/well in 24-well plates and incubated at 37℃ overnight. The supernatant was discarded before co-incubation. AGS cells were grown with NaCl alone or in the presence of VacA and NaCl in F-12 medium supplemented with 100 mL/L FBS. Control cells were inoculated into F-12 and incubated for up to 72 h in triplicate. At the end of each time of incubation, cell viability was determined in a hemacytometer by trypan blue exclusion.

Cytokine and cytokine mRNA measurement

After AGS cells were incubated for 24 h. *H pylori* VacA (40 mg/L) and 10 mmol/L NaCl were added. The cells were incubated for an additional 4 h. The supernatants were then collected and stored at -20℃ until assay. The levels of IL-6, IL-8, IL-1β and TNF-α in the culture supernatants were determined by enzyme-linked immunosorbent assay (ELISA) using commercially available kits (Immunotech, France) according to the manufacturer's instructions. In these assays, the lower limits of detection were 3 ng/L for IL-6, 8 ng/L for IL-8, 1.5 ng/L for IL-1β and 5 ng/L for TNF-α.

Total RNA was extracted from AGS cells (incubated as indicated above, under cytokine measurement) using Isogen (Nippon Gene, Tokyo, Japan). Aliquots (2.5 μg) of total RNA were incubated at 70℃ for 5 min, chilled on ice and reverse transcribed in a final volume of 10 μL of a solution containing 200 MU/L Moloney murine leukemia virus reverse transcriptase (M-MLV RT) (Invitrogen Life Technologies), first-strand buffer (250 mmol/L Tris-HCl, pH 8.3 at room temperature, 375 mmol/L KCl, 15 mmol/L $MgCl_2$) containing 0.1 mol/L DTT and 2.5 mmol/L dNTPs plus random primer (6 mer) pd(N)6 (TaKaRa, Japan). Reactions were incubated at 22℃ for 10 min, at 37℃ for 60 min, heated to 80℃ for 5 min, and stored at -20℃ until use.

The resultant cDNA from above (1 μL) was added to a 29-μL reaction containing PCR reaction buffer, 1 μL of 4 nmol of each primer (IL-1 β, IL-6, IL-8, TNF-α),

0.1 μL of 5 MU/L of Taq DNA polymerase and water. Oligonucleotide primers were designed based on previous reports[28]. PCR was performed with an automatic thermal cycler using an initial denaturation step at 95 ℃ for 5 min followed by 36 cycles of denaturation at 94 ℃ for 1 min, annealing at 60 ℃ for 1 min, and an extension at 72 ℃ for 1 min. The final cycle included an extension for 7 min at 72 ℃ to ensure full extension of the products. Aliquots (5 μL) of each PCR product were analyzed by electrophoresis on 1.5 g/L agarose S gels (Wako Chemical Co., Ltd., Osaka, Japan) containing ethidium bromide, and the bands were examined under UV light to detect amplified DNAs.

Animal experiment

H pylori-infected and non-infected 7-wk-old male Mongolian gerbils (MGS/Sea; Seac Yoshitomi, Fukuoka, Japan) were housed in steel cages on hardwood chip bedding in an air-conditioned biohazard room with a 12 h light-12 h dark cycle. The animals were classified into four groups according to *H pylori* infection and NaCl diet ($n = 3$). *H pylori*-infected and non-infected gerbils were given autoclaved distilled water *ad libitum* and CE-2 irrigated with 50 g/kg NaCl (Kyudo Co. LTD, Japan) or CE-2 only (normal diet). After 4 mo, the gerbils were sacrificed and stomach tissue was obtained and frozen.

The frozen tissue blocks were sectioned (6 μm thick) as previously described[28] and the sections were fixed with 4 g/L paraformaldehyde and acetone for 10 min each. The sections were treated with 30 mL/L H_2O_2 (Wako, Japan) in methanol for 5 min followed by blocking with 10 ml/L normal rabbit serum (Vector Laboratories, Inc., Burlingame, CA) for 10 min. We used goat polyclonal antibodies as primary antibodies directed against the following mouse proteins: TNF-α, IL-1β, and IL-6 (R & D Systems, Inc.). Tissue sections were incubated for 60 min at room temperature in a moist chamber with the desired primary antibody diluted according to the manufacturer's instructions. Biotinylated rabbit anti-goat immunoglobulin G (Vector Laboratories) was then applied for 30 min at room temperature. After three times of 5-min rinse with PBS, the signals from the antibodies were amplified using an ABC kit (Vector Laboratories) for 30 min and visualized with DAB reagent (Vector Laboratories) for 5 min. The sections were counterstained with Mayer hematoxylin (Muto Pure Chemicals Co., Ltd., Tokyo, Japan), dehydrated and mounted using histological mounting medium (Fisher Scientific). Negative control reactions contained purified goat IgG (Vector Laboratories) instead of specific primary antibodies.

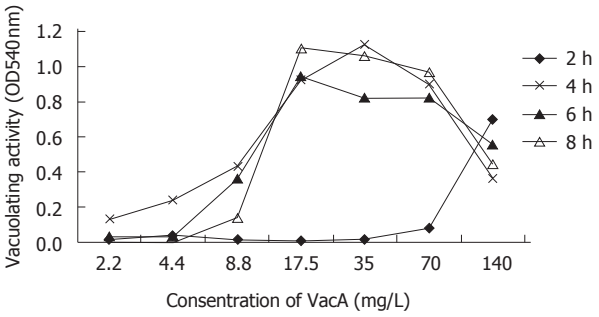

Figure 1 Activity of VacA-induced vacuolization.

Statistical analysis

All data in each experiment were expressed as the mean ± SE. The statistical significance of the response of cytokine production to VacA was evaluated using the Student's *t*-test. Differences between cytokine levels were considered significant at $P < 0.05$.

RESULTS

VacA visualization

VacA, partially-purified from a toxin-producing *H pylori* strain, was visualized on a Western blot with a VacA-specific antibody (Table 1). An antibody-reactive protein at 87 ku, the molecular weight expected for the mature toxin[26] was found.

VacA-induced vacuolation in AGS cells

AGS cells showed dose-dependent vacuolation induced by VacA (Figure 1). Different VacA concentrations were shown for the indicated incubation times. Vacuolization was quantified by measuring the uptake of neutral red into vacuoles. The experiments were carried out in triplicate. When VacA was incubated with AGS cells at 4, 6 and 8 h, its activity was stable in the range of 17-70 mg/L. Vacuolation was not seen in AGS cells in response to VacA after incubation for 2 h, except at the maximum concentration.

VacA-induced vacuolating activity was not influenced by NaCl

The time course for vacuolation within cultured cells in the presence of VacA and NaCl showed the effect of NaCl on the vacuolating activity (Figure 2). The vacuolating activity was shown as a function of incubation time at different NaCl concentrations. Cells were induced with 40 mg/L VacA. The experiments were carried out in triplicate.

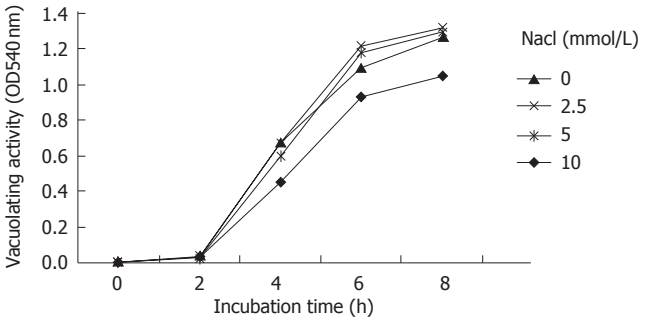

Figure 2 Time course of VacA-induced vacuolization of AGS cells at different NaCl concentrations.

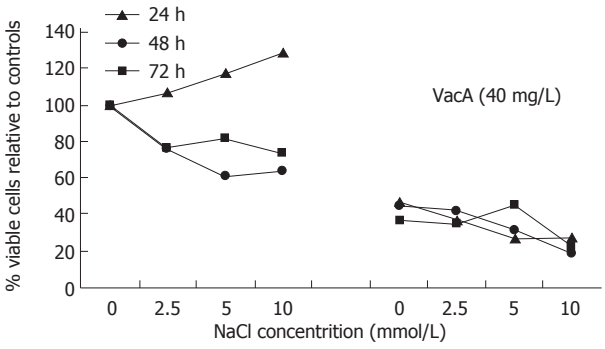

Figure 3 Viability of AGS cells grown in the presence of NaCl alone or VacA and NaCl.

At all NaCl concentrations, the vacuolating activity was minimal after incubation for 2 h. Time-dependent vacuolating activity increased linearly, doubling every two hours between 2 and 6 h of incubation. Because the curves at all NaCl concentrations were similar, NaCl did not appear to significantly affect VacA-induced vacuolation. As a control, the same concentrations of NaCl were added to AGS cells without VacA and no vacuolating activity was observed (data not shown).

Viability of AGS cells was decreased after coculture with VacA and NaCl

The effect of NaCl on AGS viability was assessed with and without VacA at the indicated incubation times. Cell viability was determined by trypan blue exclusion. The experiments were carried out in triplicate. Upon incubation with increasing levels of NaCl for 72 h, there was an apparent slight increase in the viability of AGS cells. However, culture for 24 or 48 h apparently decreased the viability of AGS cells (Figure 3). These results, however, were not statistically significant ($P > 0.05$) compared with control AGS cells at all incubation time (Table 1). Furthermore, the viability of AGS cells cultured with VacA and 10 mmol/L NaCl was significantly reduced ($P < 0.05$) compared with VacA alone after incubation for 48 and 72 h. Although the average viability values after incubation for 24 h were similar to those at 48 and 72 h, the viability at 10 mmol/L and 0 mmol/L NaCl was not significantly different ($P > 0.05$) because large variances were obtained for the 24-h samples. The reduced viability in the presence of VacA was similar at all three incubation times.

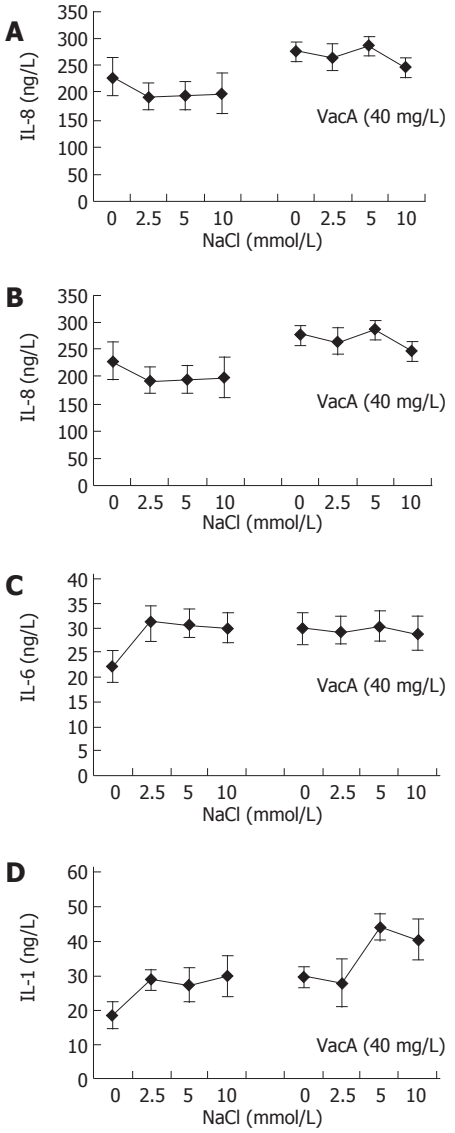

Figure 4 Production of cytokines induced by NaCl alone or VacA and NaCl.

VacA-induced cytokine production in AGS cells

To examine cytokine production after cell culture with VacA combined with NaCl, AGS cells were incubated with VacA or VacA and NaCl. The secretion of TNF-α, IL-8, IL-6 and IL-1β assessed by ELISA, is shown in Figure 4. The experiments were carried out in triplicate. In addition, we assessed the cytokine response of cultured human AGS cells to NaCl alone. The secretion of TNF-α increased in cells exposed to VacA, but this increase was inhibited in the presence of both VacA and NaCl. However, the secretion of TNF-α seemed to increase slightly in culture with NaCl alone ($P > 0.05$, Figure 4A). The secretion of IL-8 increased in cells exposed to VacA compared with cell-only control cultures or those exposed to NaCl alone. The secretion increased when VacA was combined with NaCl. However, NaCl did not appear to increase IL-8 secretion in the presence of VacA. NaCl did not induce IL-8 secretion from AGS cells at any concentration tested (Figure 4B). IL-6 secretion increased in cultures incubated with VacA or NaCl or both VacA and NaCl (Figure 4C). IL-1β secretion increased after culture with VacA or NaCl

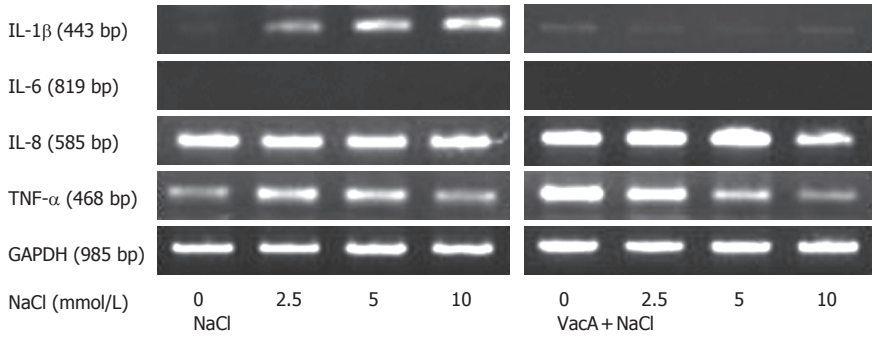

Figure 5 Expression of cytokines induced by NaCl or VacA with NaCl (RT-PCR) in gastric tissue of *H pylori*-infected gerbils (×200) fed with a normal diet (top) and a 50g/kg NaCl diet (bottom).

alone. The addition of 5 or 10 mmol/L NaCl enhanced VacA-induced IL-1β secretion, although it was not dose-dependent (Figure 4D).

Cytokine mRNA expression induced by VacA in AGS cells

To examine the ability of VacA combined with NaCl to induce the production of cytokines, cytokine-specific mRNA expression in AGS cells was analyzed by RT-PCR at 4 h post-induction. The expression of TNF-α, IL-8, IL-6 and IL-1β mRNAs is shown in Figure 5. TNF-α mRNA expression increased slightly after culture with NaCl, and there was a significant increase in TNF-α expression after culture with VacA. TNF-α mRNA expression decreased after culture with VacA combined with NaCl and displayed a significant NaCl dose-dependence. IL-8 mRNA expression was not stimulated by NaCl alone. However, the IL-8 mRNA PCR product increased after culture with VacA especially with VacA combined and NaCl, although a decrease was observed at the highest NaCl concentration. IL-6 mRNA was not detected in the control cells or upon exposure to any of the above conditions. IL-1β mRNA expression was induced in response to NaCl in a dose-dependent manner. Expression was also induced upon exposure to VacA, but this effect was not stimulated by NaCl.

Proinflammatory cytokine production in gastric tissue

Positive staining of IL-1β, IL-6, and TNF-α in gastric tissue was found in all but one of the *H pylori*-infected subjects ($n=6$) regardless of diet. However, we observed more staining of all three cytokines in *H pylori*-infected gerbils on a 50 g/kg NaCl diet than in infected gerbils on a normal diet, suggesting a potential role of NaCl in the up-regulation of VacA-induced pro-inflammatory cytokine production in gastric epithelium. IL-6 displayed less increase in staining than the other two cytokines, consistent with the *in vitro* ELISA results. There was no significant difference between the specific primary antibody staining and the IgG negative control staining in tissues from uninfected animals fed with 50 g/kg NaCl and positive staining was not observed in the untreated gerbils (data not shown).

DISCUSSION

The neutral red uptake assay is often used for quantitatively determining *H pylori* cytotoxicity *in vitro*[9]. Because the shortest time point at which vacuolation was induced in this study was 4 h, 4 h incubation was chosen for further experiments. The appropriate dose of VacA to induce vacuolation was determined to be 17.5 mg/L, and 40 mg/L VacA decreased AGS cell viability to 40% after 24 h. Therefore, 40 mg/L VacA was used in experiments to assess VacA-induced cytokine production.

Significant vacuolating activity is stimulated by acidic ($pH<5.5$) or alkaline ($pH>9.5$) conditions[27]. We evaluated the effect of high Na^+ and Cl^- concentrations on vacuolization induced by VacA. AGS cells exposed *in vitro* to VacA at various concentrations of NaCl had vacuolization rates similar to those exposed to VacA alone, suggesting that VacA may be activated by exposure to acidic or alkaline conditions but not under the osmotic conditions.

H pylori has been shown to either reduce or enhance gastric epithelial cell viability *in vitro*[29]. All strains of *H pylori* decrease cell viability of microvascular endothelial cells after 72 h[30]. Furthermore, co-culture of *H pylori* with AGS cells significantly decreases cell viability[29]. Consistent with these studies, our results demonstrated that VacA alone could reduce AGS cell viability ($P<0.05$), which was enhanced by high doses of NaCl ($P<0.05$).

Increased levels of proinflammatory cytokines induced by VacA in AGS cells and gerbils can be considered a cytotoxic effect. Consistent with our findings, others have noted that the damage caused by *H pylori* is partially attributed to the enhanced secretion of the proinflammatory cytokines IL-1β, IL-6, IL-8, and TNF-α, particularly in response to VacA-expressing *H pylori* strains[31,32]. It has been reported that gastric *H pylori* infections induce mucosal production of various cytokines, including IL-1β, IL-6, IL-8 and TNF-α[33]. Our study further confirmed the cytokine response to the combined effect of NaCl and VacA *in vitro* and *in vivo*. First, we examined the expression profile of proinflammatory cytokines in response to stimulation by NaCl alone. The addition of NaCl alone to AGS cells resulted in a dose-dependent increase in IL-1β mRNA level, whereas expression of the other three cytokine mRNAs did not change significantly both *in vitro* and *in vivo*. It has been reported that normal human dermal fibroblasts ele-vate IL-1β mRNA levels upon exposure to 0.5 mmoL/L NaCl and that normal human epidermal keratinocytes increase levels of IL-6 and IL-8 mRNA in response to NaCl[34]. These reported differences in IL-6 and IL-8 expression in response to NaCl exposure may be attributable to differences in cell types or the higher NaCl concentration used in the other studies, which was fivefold higher than that in our study. We found that NaCl could

not alter VacA-induced IL-8 expression. However, the induction of IL-8 by VacA alone is consistent with previous studies that *H pylori* infection increases mucosal production of IL-8 and interaction between viable *H pylori* and AGS cells increases levels of IL-8 mRNA expression and protein secretion[33, 35].

It has also been reported that polymorphisms within the IL-1β and TNF-α genes are associated with a risk for gastric carcinoma in individuals infected with *H pylori*[36]. Our study demonstrated that VacA-induced expression of IL-1β and TNF-α mRNAs could be up-regulated by NaCl in gerbils, whereas NaCl increased IL-1β expression and decreased VacA-induced TNF-α expression in AGS cells.

IL-6 is a multifunctional cytokine that plays a central role in host defense mechanisms[37-40]. IL-6 production upon *H pylori* infection could be induced in response to urease in human AGS cells[41]. IL-6 can also be induced by VacA in bone marrow-derived mast cells[42]. These findings are consistent with our ELISA results, but we were unable to detect IL-6 mRNA with RT-PCR under any of the conditions we tested.

VacA directly activates AGS cells to produce proinflammatory cytokines, which might be a host early innate immune response, suggesting that VacA plays a role in the pathogenesis of *H pylori*-infected gastritis although the cag pathogenicity island is closely related to induction of proinflammatory cytoikine[43]

High-salt diet (NaCl 75g/kg versus 2.5g/kg) intake enhances *H pylori* colonization in mice and humans, while chronic salt intake might exacerbate gastritis by increasing *H pylori* colonization[12]. Our study indicated that excessive dietary NaCl (50 g/kg) influenced cytokine production in the Mongolian gerbil model of *H pylori* infection. VacA may be regulated by NaCl to influence cytokine production through a variety of mechanisms. One mechanism might be through an effect on VacA channels, which are likely to be an important component in the mode of action of this toxin[36].

In conclusion, the virulent *H pylori* cytotoxin, VacA, decreases the viability of AGS cells, which can be enhanced by NaCl. NaCl also affects the production of proinflammatory cytokines induced by VacA. Our results suggest that NaCl plays an important role in *H pylori*-induced AGS cell cytotoxicity. However, the interactions between *H pylori*, NaCl and gastric cancer are complex, more studies are required to understand the mechanism by which NaCl affects the progression of *H pylori*-related gastric cancer.

Abstract

AIM: To investigate the presence of *Helicobacter* species by nested PCR of 16S rRNA genes followed by the presence of *Helicobacter pylori* (*H pylori*) 16S rRNA, *ureA*, *cagA* genes in bile obtained at endoscopic retrograde cholangio-pancreatography (ERCP) from 60 Indian subjects.

METHODS: Sixty bile samples were obtained from patients diagnosed with various hepato-biliary diseases and control subjects at ERCP. PCR analysis was carried out using primers for *Helicobacter* genus 16S rRNA gene and *H pylori* (16S rRNA, *ureA* and *cagA*) genes. Gastric *H pylori* status was also assessed from biopsies obtained at endoscopy from patients with various hepato-biliary diseases and controls. The control group mainly consisted of subjects with gastric disorders. Sequencing analysis was performed to confirm that PCR products with 16S rRNA and *cagA* primers were derived from *H pylori*.

RESULTS No *Helicobacters* were grown in culture from the bile samples. *Helicobacter* DNA was detected in bile of 96.7% and 6.6% of groups I and II respectively. Ten from group I were positive for 16S rRNA and *ureA* and 9 were positive for *cagA* gene. In contrast of the 2 from the control, 1 amplified with 16S rRNA, *ureA* and *cagA* primers used. The sequences of the 16S rRNA genes and *cagA* were 99% similar to *Helicobacter pylori*.

CONCLUSION: *Helicobacters* are associated with the pathogenesis of various hepato-biliary disorders.

INTRODUCTION

The re-discovery of *Helicobacter pylori* (*H pylori*) as a curved bacterium in the stomach by histological examination of gastric biopsies[1, 2] and its subsequent first isolation by Warren & Marshall in 1983 have probably etched new avenues in the management of various gastro-duodenal disorders. Since its discovery, this microaerophilic Gram negative pathogen has been linked to various gastric pathologies including gastric carcinoma and mucosa associated lymphoid tissue (MALT) lymphoma[3, 4]. Numerous other *Helicobacter* species along with *Helicobacter pylori* have subsequently been isolated from sites other than the stomach, including oral cavity, liver and biliary tree of animals and humans[5-7]. Recent studies have implicated the association between *Helicobacter* infections with certain diseases of the liver of some animal species such as *H canis* in dogs[8] and *H hepaticus* & *H bilis* in mice[9-11].

In humans, other *Helicobacter* species including *H pylori* DNA has been detected in the liver of patients suffering from cholestatic diseases[12, 13]. In one study, a high frequency of *H pylori* and *H pullorum* sequences were detected by PCR, in the liver of patients with cirrhosis and superimposed hepatocellular carcinoma[14]. More recently, a study by Pellicano *et al* suggests that presence of *Helicobacter spp* in liver samples could possibly serve as a co-factor in the development of end-stage of liver disease in humans[15]. These concerns have spurred considerable interest in determining the mechanisms by which these extra cellular bacteria and the associated inflammatory response endorse hepatic and biliary disease.

Therefore, we investigated the presence of *Helicobacter*

spp genomes in the bile specimens obtained from patients with different hepato-biliary diseases and among control group (without any hepatic and biliary disease but with different gastric disorders) at endoscopic retrograde cholangio-pancreatography (ERCP). We also evaluated the association between the presence of *Helicobacter* species with various hepato-biliary disorders.

MATERIALS AND METHODS

Subjects

The study population consisted of 60 subjects categorized into two groups (thirty in each) *viz*., Group I (those with hepato-biliary disorders) and Group II (those with no pathologically proven liver or biliary disease but with different gastric disorders, served as control). Patients of both sexes and age range: 23-68 years, average age: 48.1 years were included in the study. Subjects from either group underwent ERCP followed by upper gastrointestinal endoscopy at the Department of Gastroenterology, Deccan College of Medical Sciences, Hyderabad. The study protocol was approved by the Institutional Review Board (IRB) and Institutional Ethical Committee (IEC). Approval was obtained from IEC for the initiation of the study. Informed consent was obtained from all the patients before their enrolling in the study according to the Helsinki Declaration. None of the patients included for the study were on antibiotics prior to ERCP or endoscopy.

Patients' details and diagnoses were recorded and 5-10 mL bile samples were collected in glycerol by aspiration during the ERCP procedure and 3 gastric biopsies were collected during endoscopy from the same patient: one in urea solution for rapid urease test (RUT), one in brucella broth supplemented with fetal calf serum (FCS) for culture and 1 in phosphate buffered saline (PBS) for DNA isolation. Aspirated bile samples and the biopsy collected in PBS were stored at -80 °C until DNA was isolated.

Helicobacter culture

The gastric biopsy collected in supplemented brucella broth was immediately transported to the laboratory and streaked on the chocolate brucella agar supplemented with 70 mL/L sheep blood and 6 mg/L-vancomycin, 2 mg/L-amphoteracin-B and polymixin-B 2500/L (Sigma Chemicals, USA) and incubated at 37 °C in microaerobic conditions. A small aliquot (about 0.5 mL) of the collected bile sample was also instantaneously homogenized within half an hour of collection in 0.5 to 1 mL brucella broth (Becton and Dickinson, USA) containing 50 mL/L fetal calf serum (Gibco BRL, Germany) and streaked over the same medium for primary isolation of *H pylori* and incubated as described above. Approximately 50 μL of the sample was plated onto each plate and the remaining sample was used for DNA isolation.

DNA extraction

The genomic DNA from the gastric tissue, isolated culture and bile samples was isolated *as per* the standard protocol previously described[16]. In case of bile sample, briefly 450 μL of the sample was diluted with equal volume of PBS and centrifuged at 15000 g for 20 min. The supernatant was discarded and the pellet was again subsequently mixed with 250 μL of the PBS and DNA isolated by modified cetyl trimethyl ammonium bromide (CTAB) method. The DNA was extracted and preserved at -20°C until amplification was performed. Appropriate care was taken during extraction to remove the PCR inhibiting substances present in the bile[17]. Briefly as *Helicobacter* DNA was isolated from an unusual source, there is possibility of existence of specific inhibitors and competing substrates. For such situations, dilution of inhibited samples provides a rapid and straightforward way of permitting amplification. This dilution exploits the sensitivity of PCR by reducing the concentration of inhibitors relative to target DNA.

PCR amplification

Amplification was performed *as per* standard protocol described previously[13] with minor modifications. All primers were synthesized at Bioserve Biotechnologies Pvt Ltd, Hyderabad, India. Amplification was performed in a PTC 100 thermocycler (M J Research Inc. Water town, USA).

PCR amplification with Helicobacter genus-specific primers

Nested PCR was carried out using two oligonucleotide pairs previously reported by Pellicano *et al*[15] and designated as Heli in Table 1. The primers (Helinest-S & R, Heli-S & R) used in our study were reported to amplify 26 species of *Helicobacter* genus[15]. At each amplification, *H pylori* DNA was used as a positive control, while water instead of DNA served as a negative control.

First amplification

Amplification was carried out in a total volume of 20 μL containing 0.5 μL DNA, PCR buffer (1×), 200 μmol/L dNTPs, 1.5 mmol/L Mg^{2+}, 0.2 μmol/L primers (Heli-nest-S and Heli-nest-R), 1U Taq DNA polymerase (Invitrogen Life Technologies, Germany). Amplification conditions were optimized and are enlisted in Table 2. A sample was scored positive if an amplification product of 1300 bp could be resolved after electrophoresis on 15 g/L agarose gel.

Second amplification

One microliter of amplicon from the first amplification

Table 2 Conditions of polymerase chain reactions used in the study

Target gene	Initial denaturation step	Temperature o denaturation, annealing and	Cycle	Final extension step extension

ureA	95℃ for 5 min	94℃ for 30 s 52℃ for 30	35	72℃ for 6 min 72℃ for 1 min
cagA	95℃ for 5 min	94℃ for 1 min 52℃ for 1 min 72℃ for 2 min	35	72℃ for 10 min

step was used with primers Heli-S and Heli-R (Table 1) and amplification was repeated with minor alterations (Table 2). The expected product size of the amplicon was 480 bp.

Specificity test of genus specific primers

The specificity of genus specific primers *viz.,* Helinest-S, Helinest-R, Heli-S and Heli-R as well as primers specific to *H pylori* was assessed by using 6 bacterial strains. This included two different *Helicobacter pylori* strains along with 4 other enteric bacteria commonly residing the stomach.

H pylori specific 16S rRNA PCR

The samples positive with *Helicobacter* genus PCR were further analyzed for the presence of *H pylori* DNA in the culture, biopsy and bile samples by targeting the 16S rRNA gene using primers enlisted in Table 1. Amplification was carried out as per the mentioned protocol (Table 2). The amplification product size was 534 bp typical of *H pylori.*

Amplification of ureA gene

Samples positive for *H pylori* were subsequently analyzed with a different set of primers designated *ure*A, in Table 1. The sense and anti-sense primers of this gene were used for PCR as per the mentioned protocol in Table 2. The amplification product size was 411 bp typical of *H pylori.*

Amplification of cagA gene

Samples positive for *H pylori* were subsequently screened for the presence of *cag*A gene using specific primers (Table 1). Amplification was carried out as per the program given in Table 2 with minor alterations increasing the annealing time to 1 min and extension time to 2 min. The expected product size of the primers used was 349 bp.

Sequencing of the 16S rRNA products and cagA amplification product

The *H pylori* positive DNA fragments from the bile samples were sequenced. Comparison of DNA sequences of the genomic 16S rRNA amplicons and *cag*A amplicons with those of *H pylori* was performed using sequence alignment with the BLAST programme. The presence of *H pylori* sequence was thus confirmed in these bile samples.

Statistical analysis

Helicobacter genus positivity and negativity was compared using the Fisher's exact test. $P < 0.05$ was considered as significant.

RESULTS

Culture

Of the 60 gastric biopsies streaked, colonies could be isolated from 54(90%) subjects (26 from group I and 28 from group II). No *Helicobacter pylori* colonies could be grown of the 60 bile samples streaked, even after prolonged incubation for up to 2 wk under microaerophilic conditions.

Specificity test

Helicobacter genus specificity was tested using a panel of *H pylori* strains by PCR with specific primer sets used for this study. All the *H pylori* DNA gave a positive amplification with the expected product size. The non-*Helicobacter* species DNA extracts did not yield any result with the oligonucleotide primers used.

PCR amplification with Helicobacter genus-specific primers

Helicobacter DNA was detected by nested-PCR in 29(96.7%) of the 30 bile samples collected from group I patients and 2(6.6%) of the subjects from group II sub-group respectively. All the 29 samples from group I and 2 from group II amplified at both first and second amplification reactions. The amplification product sizes of both the PCR are shown in Figures 1A and 1B respectively. DNA isolated from 60 biopsy and 54 cultures, gave a positive amplification with the expected product size.

Screening for H pylori DNA in bile

Of the 29 *Helicobacter* genus positive samples from group I subjects, 10(33.3%) bile samples were amplified with the *H pylori* specific 16S rRNA primers, yielding a product size of 534 bp on electrophoresis (Figure 1C). While of the 2 *Helicobacter* genus positive from group II, only 1 was amplified with the *H pylori* 16S rRNA primers used (Table 3).

Confirmation of gastric H pylori colonization

Screening of the 60 biopsy DNA and 54 culture DNA from both the study groups gave positive amplification with the specified primers used, yielding a product size of 534 bp.

Analysis of ureA and cagA gene

Of the 29 subjects analyzed for the presence of *ure*A and *cag*A sequences from group I sub-group, we found that 10 (33.5%) were amplified with *ure*A gene while 9 (30%) amplified with the *cag*A primer. On the other hand, 1 sample which was amplified for *H pylori* 16S rRNA gene in group II, also gave positive amplification for *ure*A and *cag*A respectively (Table 3). The amplified products of these genes are represented in Figure 1D, E.

Table 3 Details of *Helicobacter* genus, *H pylori* 16S rRNA, ureA, cagA positivity in the study subjects

No	Category ($n=60$)	*Helicobacter* genus positivity *n* (%)	*H pylori* 16S rRNA positive *n* (%)	*ureA* positive *n* (%)	*CagA* positive *n* (%)
1	Group I	29(96.7)	10(33.3)	10(33.3)	09(30)
2	Group II	02(6.6)	01(3.3)	01(3.3)	01(3.3)

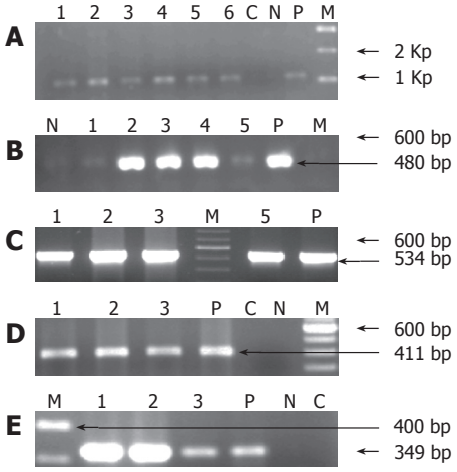

Figure 1 A schematic representation of the PCR products of the *Helicobacter spp* DNA. **A:** Gel image showing first amplification products of 16S rRNA PCR with *Helicobacter* genus specific primers at 1 300 bp. Lanes 1 to 6 represent *Helicobacter* DNA isolated from bile samples, 'P' represents positive control andLanes C, N and M represents negative control, reaction negative control and 1 Kb molecular weight marker. **B:** Second amplification products of 16S rRNA PCR with *Helicobacter* genus specific primers at 480 bp. Lanes 1 to 5 represent bile DNA, 'P' represents positive control. Lanes N and M represent reaction negative control and 100 bp molecular weight marker ladder respectively. **C:** Gel picture showing 16S rRNA amplification products specific to *H pylori* of bile samples at 534 bp. Lanes 1, 2, 3 and 5 represent bile DNA samples while Lanes M and P represent 100 bp ladder and positive control respectively. **D:** *ureA* amplification products at 411 bp. Lanes 1 to 3 represent bile DNA, Lane 'P' represents positive control and Lanes C, N and M represent negative control, reaction negative control and 100bp molecular weight ladder respectively. **E:** Gel picture illustrating the *cagA* amplification products at 349 bp. Lanes 1, 2 and 3 represent bile DNA while Lanes M, P, N and C represent 100bp molecular weight ladder, positive and reaction negative control, negative control respectively.

Sequence analysis of PCR product from bile DNA with 16S rRNA and cagA primers

To confirm that the PCR product obtained with the 16S rRNA and *cag*A primers belonged to *H pylori*, we examined the sequence of the PCR product in 4 bile samples (3 from Group I and 1 from Group II). The nucleotide sequence of the amplified products shared 99% identity with the 16S rRNA and *cag*A gene of *H pylori* respectively.

DISCUSSION

The presence of *Helicobacter* species DNA in the bile samples of patients with different hepato-biliary diseases is interesting since some reports in the past have suggested a positive association of *Helicobacter* and the evolution of liver diseases[9, 15, 18, 19]. Recent studies on *Helicobacter spp* in different diseases of liver and bile ducts have shown that *Helicobacter* can be detected not only in the extremely hostile milieu of the stomach but also in human bile[20, 19]. Although none of the previous studies including the present study have not been able to isolate *H pylori in vitro,* it has been proven that some of *Helicobacter* species live in the gall bladder. In a recent study[15], by PCR and subsequent sequencing of the 16S rDNA and amplification of *cag*A gene, *Helicobacter spp* was detected in 17 of 20 patients operated for hepatocellular carcinoma (HCC). The same study reported the presence of a 290 bp product of 128 KDa CagA protein specific only for type I *H pylori*. Further, it has been shown that several *Helicobacter spp*. secrete a liver specific toxin that causes hepatocyte necrosis in cell culture and might also be involved in damaging liver parenchyma *in vivo*[15]. In contrast, other authors did not detect any *Helicobacter* or *H pylori* DNA in the patients with similar diseases[21, 28]. These observations impelled us to explore a possible association of *Helicobacter* and hepato-biliary disease among Indian patients.

In the present study, which comprised of two groups (I & II), of the 30 subjects from group I with various hepato-biliary ailments, we could detect *Helicobacter* genus specific 16S rRNA sequence in 29 bile samples by nested PCR and only 1 sample did not give any amplification with the specific primers used. By contrast, in Group II subjects, i.e. those with no significant hepato-biliary disease but with various gastric disorders (Control subjects) only 2 subjects gave positive amplification with the *Helicobacter* genus specific primer used yielding the desired fragment. We carried out 16S rRNA amplification specific to *H pylori* on 29 subjects positive from group I and 2 from group II for *Helicobacter* genus, followed by subsequent sequencing of the amplified products to confirm the presence of *H pylori* DNA in the bile samples. We found that 33.3% samples from group I and 3.33% from group II were amplified giving a product of 534 bp (Figure 1C). Further, we also investigated the presence of *ure*A and *cag*A gene in all the bile specimens followed by sequencing of the 16S rRNA and *cag*A amplified products of 4 bile samples (3 from group I and 1 from group II). Sequence comparison of the sequenced samples confirmed the presence of *H pylori* DNA sequence in the bile samples.

The usage of less invasive ERCP procedure to obtain bile is an adequate method for this purpose compared with other invasive approaches currently in practice. This procedure also avoids contamination with *H pylori* colonizing the stomach, as the sampling devices are inserted inside the endoscope and hence never traverse the stomach[28].

This is the first Indian study to simultaneously investigate the presence of *Helicobacter* DNA in bile specimens and gastric tissues and underscore the association of *Helicobacter* in bile obtained from patients with various hepato-biliary disorders. We detected *Helicobacter* DNA by nested PCR using two sets of primer. Further, our study also successfully demonstrated the presence of *ure*A and virulence genes such as *cag*A specific to *H pylori* in the DNA isolated from bile samples. As evident from the results, 33.3% carried *ure*A gene whereas 30% were amplified with the primers used for *cag*A detection (Table 3). Of the 9 positive for *H pylori cag*A

gene, 5 belonged to cholangio-carcinoma, 2 belonged to common bile duct stones and the remaining subjects had pancreatico-biliary malignancies (Data not shown). In addition, we also found that among 10 subjects positive for *H pylori* in group I, *ure*A and *cag*A were simultaneously detected in 9 subjects, 1 subject gave amplification only for *ure*A gene and the only sample which was amplified with the 16S rRNA specific primer of *H pylori* from group II was found to possess both genes respectively (data not shown). The only subject whose bile sample gave positive results with 16S rRNA, *ure*A and *cag*A primers in group II was found to suffer from antral gastritis endoscopically and was co-incidentally positive for *H pylori* by culture and PCR of both the biopsy and culture DNA (data not shown). Every possible precautionary measure was taken to assure that laboratory contamination did not account for the positive amplification results such as diluting the bile with sterile distilled water, centrifuging the samples at 15 000 × *g* for 20 min, and the supernatant being discarded, thus by concentrating the bacterial cells in the pellet, enabling removal of some of the inhibitors predominantly present in the bile. Collection of bile in glycerol and immediate plating nevertheless did not prove to be successful for *in vitro* isolation of *Helicobacters* from any of the bile samples as we could not get any growth even after extended incubations for up to 15 d.

The present study also investigated the gastric *H pylori* status of the patients enrolled in both the sub-groups to see if at all the gastric *H pylori* status had any impact on the etiology of the hepato-biliary diseases. Unfortunately from the results we could neither associate the severity of the hepato-biliary disease with that of the gastric diseases nor could we link the gastric *H pylori* status and the detection of *H pylori* DNA in bile of the hepato-biliary diseases. Even though 29 subjects from group I showed the presence of *Helicobacter* species DNA, only 10 showed the presence of *H pylori* DNA in the bile thus signifying the possibility of the presence of the other bile-resistant *Helicobacters* that normally reside in the liver and biliary tract. Besides the above results obtained in this study, we noticed that patients with various hepato-biliary disorders had much greater probability of positive *Helicobacter* species DNA compared to those with no pathologically proven liver and biliary diseases. Why these intestinal *Helicobacters* have been identified in Chilean patients[26] and *H pylori* has been identified in patients in other geographical regions, as we observed in this study warrant further investigations. In fact, the typical finding of the present study, correlates well with those of Kuroki *et al*[22], who recently demonstrated that the level of epithelium proliferation was higher in *Helicobacter*-positive biliary epithelium than in bacterium-negative epithelium.

The results of our study also suggest that besides *Helicobacter spp* sequences, even sequences pertaining to the virulence genes of *H pylori* are consistently found at a high frequency in bile samples and that they may be a significant cause of biliary diseases. Several hypotheses have been proposed[23-25], by which these *Helicobacters* find their way into the liver and bile duct. But these hypotheses entail strong evidences to underline the precise mechanism by which the *Helicobacter* species anchor the liver and aggravate the clinical outcome.

The findings of this study are in concert to those obtained by Fox *et al*[26] and Linn *et al*[18] who reported *Helicobacter spp* in gall bladder tissue from Chileans with chronic cholecystitis but different from those of Fallone *et al*[28] and Mendez-Sanchez *et al*[21] who were not able to detect *Helicobacter* sequences in the bile samples of North Americans and Mexicans respectively. The raison d'être for these discordant results could be the regional variations in the distribution of bile-resistant *Helicobacter* species[20]. The other alternative reason for the inconsistent results in their studies could be the methodology used, the selection of primers used, as both the studies had used a single primer set for the amplification of the conserved 16S rRNA gene. In contrast, our study used nested PCR for 16S rRNA amplification of *Helicobacter* genus, which according to Stark *et al*[27] is 10^4 times more sensitive than a 1-step PCR. Though we used only one set of oligonucleotide primers each for amplifying *ure*A and *cag*A, the specificity and sensitivity of the selected primers were previously determined during our routine screening. The primers were found to possess the sensitivity and specificity of 90% and 95% for *ure*A and 89% and 85% for *cag*A, particularly in this geographical area.

In conclusion, this study demonstrated that *Helicobacter spp* DNA can be detected in bile by PCR and that gastric presence of *H pylori* in patients with proven hepato-biliary disease had no clinical correlation with the hepatic and biliary disease. However, like other previous studies, we were unable to isolate the bacterium in culture. There are different reasons to justify this finding. Firstly, this could be due to the bacterial conversion from viable helicals to non-viable coccoids in an adverse bile rich environment. It is also possible that the number of bacterium is very few and that they may have been partially inhibited by unfavorable environment that exists in the biliary milieu. In addition, our study also confirmed by DNA sequencing that sequences specific to *H pylori* (16S rRNA, *cag*A) can be found at a high frequency in the bile samples, thus instilling strong evidence that presence of *Helicobacter spp* may in someway aggravate the etio-pathogenesis of hepato-biliary diseases. However, mere detection of *Helicobacter* DNA from patients with different hepatic and biliary disease does not confirm the precise role played by these organisms. Further, future studies unraveling the molecular mechanisms by which these *Helicobacter* members contribute to the clinical outcome of hepato-biliary disorders would be helpful to assess the true impact of enterohepatic *Helicobacters* and its metabolites in the genesis of biliary diseases.

Abstract

AIM: To provide the accurate alternative metrical means of monitoring the effects of new antiviral drugs on the reversal of newly formed collagen.

METHODS: Digitized histological biopsy sections taken from 209 patients with chronic C virus hepatitis with different grade of fibrosis or cirrhosis, were measured by means of a new, rapid, user-friendly, fully computer-aided method based on the international system meter rectified using fractal principles.

RESULTS: The following were described: geometric perimeter, area and wrinkledness of fibrosis; the collation of the Knodell, Sheuer, Ishak and METAVIR scores with fractal-rectified metric measurements; the meaning of the physical composition of fibrosis in relation to the magnitude of collagen islets; the intra- and inter-biopsy sample variability of these parameters; the "staging" of biopsy sections indicating the pathway covered by fibrosis formation towards its maximum known value; the quantitative liver tissue architectural changes with the Hurst exponent.

CONCLUSION: Our model provides the first metrical evaluations of the geometric properties of fibrosis and the quantitative architectural changes of the liver tissue. The representativeness of histological sections of the whole liver is also discussed in the light of the results obtained with the Hurst coefficient.

Key words: Liver; Fibrosis; Cirrhosis; Staging; Image analysis; Fractals

INTRODUCTION

Background

Experimental medical research based on reductionism retains in principle that the causes governing the processes and controls of the formation, growth and behavioral dynamics of living beings at macro-scalar levels can be derived from the processes and controls that take place at micro-scalar level.

This conception has led the hepatological disciplines to seek exact quantitative descriptions of the contents of liver fibrosis on the basis of the blood molecules related to the presence of the newly formed structure[1-5]. The basic idea is that the laws governing the set of processes and controls acting at the scale of the formation of septal and anular collagen structures can be translated into the set of laws that regulate the dynamics of these molecules at micro-scalar level when they enter the blood stream.

Sophisticated mathematical, physical and environmental studies suggest that these phenomena are governed by different multiple processes and controls (causality) at every larger or smaller scale rather than that of observation. The set of these multiple processes and controls is known as multiple scale causality (MSC)[6]. The macro-scalar growth of liver collagen fibres evolving into the septa and annuli of fibrosis is regulated by the physical events of diffusion, percolation, stratification and contraction of the extra-cellular matrix (ECM), and by the processes of neo-vascularisation. These physical processes are not involved in generation of microfibrils and fibrils, which is limited on ECM deposition. This phenomenon depends on the relationships between the processes of collagen synthesis and lyses, which are different from the biochemical processes that at a lower scale, regulate the quantitative and qualitative behaviors of the molecules formed during fibrogenesis and found in circulating blood. In other words, this means "what happens in the test tubes may be the same, the opposite, or bear no relationship at

all to what happens in the living cells, still less the living organisms".

In brief, the MSC-based conception rejects the idea that the laws regulating phenomena at one scale can in principle be derived from those regulating phenomena at a lower scale. In other words, every scale is characterized by different degrees of entropy[6].

As the characteristics of MSC are not universal, it is almost always impossible to establish a strict connection between the phases leading an observed object from micro- to macro-scalar positions and *vice versa*. Consequently, it is very difficult to identify a one-to-one relationship between the macro- and micro-scalar processes and controls of liver fibrosis production.

These considerations have convinced us to improve a direct, rapid and friendly method of measuring fibrosis using a meter that is suitable for its naturally irregular shape, provided that the biopsy procedures are performed by experts[7-12].

Liver biopsy is the only direct means of discovering the changes in liver tissue induced by chronic B or C virus-dependent inflammation and the fibrosis it causes[12-17]. Although it is the canonical point of reference for establishing the progression of the process, fibrosis has so far only been estimated on the basis of semi-quantitative evaluations[18-21] or morphometric methods[22-26] that must be considered approximate because of their use of the international system (IS) meter, which is unsuitable for measuring irregular shapes[7-11].

Like all natural objects, the collagen islets making up the fibrosis appear to be difficult to measure at all degrees of magnification because of their highly irregular shapes[7-11]. Furthermore, they do not have a single measurement because, at each enlargement (scale), their shape changes as a result of the addition of new details which are imperceptible at smaller scales. Mandelbrot have termed these irregular bodies fractal objects[27].

The studies of Perrin[28] in 1906, Hausdorff[29] in 1919, Richardson[30] in the 1950s, and Mandelbrot *et al*[26] in the 1970s and 1980s suggested a new geometry that has made it possible to measure such objects using a method that can be made simple with aid of computer technology.

The aim of this paper was to present the first results of the quantitative analysis of histological liver bioptical sections made using new metrics suggested by the concepts of fractal theory.

Our contribution to the quantitative evaluation of fibrosis in liver biopsies concerns: (1) the closest to real metric estimate of the surfaces covered by fibrosis and the quantitative classification of collagen islets; (2) the collation of metric and traditional semi-quantitative evaluations of collagen area; (3) considerations concerning the relationships depending on specific estimates defined by real numbers as a means of identifying the stadium of fibrosis; (4) the interior-to-edge metric relationship of the collagen islets used as an index of wrinkledness; (5) the definition of the harmonic state of the architectural structure of liver tissue, and the recognition and classification of its disharmonic states or architectural disorder using Hurst's exponent; (6) the intra-sample variability of fibrosis (area, wrinkledness and Hurst's exponent); and (7) the variability of the latter parameters in eight samples taken from the explanted liver of a transplant patient.

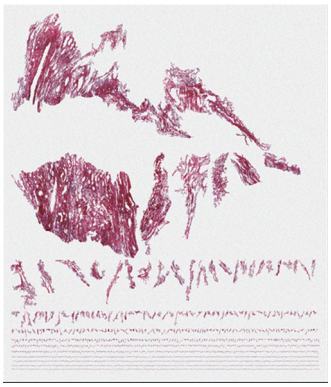

Figure 1 Prototypical catalogues of the Sirius-red stained collagen islets forming liver fibrosis, which consists of a set of irregularly shaped (wrinkled) objects.

Theory and objects

Characteristics of collagen islets The spaces occupied by the collagen islets making up fibrosis (Figure 1), and those occupied by the surviving fragments of parenchymal tissue, are both characterized by irregular shapes that exclude them from the application of Euclidean geometry[7-11]. However, their configurations make them members of the family of asymptotic statistical fractals (also called truncated fractals as they cannot be endlessly fracted)[31].

Dimension The dimension of an object indicates the Euclidean space it occupies. The fractionable "smooth" objects of classic geometry (a point, straight line, plane, and solid figure) occupy spaces whose dimensions are expressed by the whole numbers zo, 1, 2 and 3, whereas the irregular objects that are frangible into irregular pieces (sets of points, broken lines, undulating planes and irregular solids) occupy the intermediate spaces, and therefore have dimensions that cannot be expressed by whole numbers. In 1977, Mandelbrot[27] defined the objects whose dimensions are denoted by non-whole numbers as "fractals". The fractal dimension is indicated by D, and the Euclidean (or topological) dimension by Dγ.

Harmonic state of liver tissue The use of an analytical method based on a new geometry requires a brief formal description of the natural history of chronic virus-related hepatitis starting from the axiom that is defined by the persistence of a discreet necro-inflammatory process maintaining the activity of the ECM→collagen→fibrosis production system. The growth of fibrosis interrupts the continuity of the parenchyma, dissects it into irregular pieces, and compresses and atrophies the pieces enclosed in the fibrotic mass. This has two consequences: 1) it disrupts the natural harmonic state of the metric spaces covered by both natural fibrosis and the parenchyma, and 2) it alters the typical lobular architecture of hepatic tissue.

Using these axioms, the process can be represented by the first-order general equation:

$$z = f(x, y) \qquad 1)$$

in which z denotes the harmony of the natural architecture of liver tissue, x the metric space covered by fibrosis, and y the metric space covered by the parenchyma. The relationship of z to x and y can be indicated by the

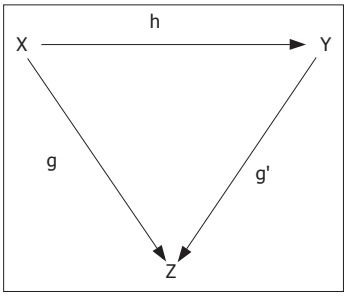

Figure 2 Categorial model of the harmonic state of liver tissue, in which z denotes the harmony of the natural architecture of liver tissue, x the metric space covered by fibrosis, and y the metric space covered by the parenchyma.

categorial representation (Figure 2), which shows the dependence of the state of z on the extension over z of the relationships between the "objects over" indicated by *x* and *y* in $f(x \rightarrow y)$.

As the variations in *x* and *y* are interconnected by the equality $(z\text{-}x)+(z\text{-}y)=1$, we can consider *x* and *y* as complementary spaces, and so the expression $z = f(x \rightarrow y)$ can be simplified to the form $z = f(x)$. The harmony of natural architecture of liver tissue is characterized by 3% fibrosis and 97% lobular parenchyma[32].

The evaluation of the metric space covered by the fibrosis induced by pathogenic agents is therefore sufficient by itself to describe the variations in the harmonic state of liver tissue architecture.

An alteration in the natural quantitative relationship between fibrosis and the parenchyma leads to the loss of the natural lobular architecture of hepatic tissue in a continuous but irregular progression that fractal geometry calls a random walk, or Brownian process[33,34].

MATERIALS AND METHODS

Patients

Two hundred and seven consecutive needle biopsy specimens (≥10 mm long) were taken from 74 female and 135 male patients (mean age: 52 ± 13 years) with chronic C virus-related liver disease. To evaluate the inter-sample variability of geometric characteristics of fibrosis, a total of six biopsy specimens were sampled from a liver explanted from a patient with clinically and histologically proved cirrhosis undergoing orthotopic liver transplantation. Each biopsy specimen was taken from a single segment of the liver.

Histological procedure

The study was performed in accordance with the guidelines of the Ethics Committee of the Istituto Clinico Humanitas, Rozzano and Ospedale Maggiore, Milan, Italy. All the patients were informed of the possible discomforts and risks of bioptic sampling. The liver specimens were fixed in 10% formalin and embedded in paraffin, and 2 μm thick sections were cut and stained with a freshly made 0.1% Sirius red staining solution[35].

Semi-quantitative evaluations

At least three expert pathologists independently staged the biopsies using Knodell's histology activity index (HAI), and the Sheuher, Ishak and METAVIR scoring systems. The number of available portal tracts in the liver fragment was assured on the basis of the indications established for the individual methods[18-21].

Quantitative image analysis

Our specially developed computer program could ensure: computer-driven microscopy focusing, digitation of the whole histological section and its fractal dimension and Hurst's exponent, less-biased measurements of each collagen islet and fibrosis mass raster perimeter length and area magnitude corrected by the fractal dimension, and wrinkledness of the fibrosis[7-11]. The time required for the whole analytical operation using this software was 30 s/mm^2, as determined on a standard reference needle specimen section, and was carried out at a microscopic magnification of ×200 (the measurements were valid only for that scale). The observed objects were measured using the IS meter rectified by their fractal dimension. When present, Glisson's capsule was included in the physiological amount of ECM, which was estimated as being 3% of the true area of the section[32].

Fractal dimension estimates

The fractal dimensions were automatically estimated using the box-counting method and the formula:

$$D_B = \lim_{\varepsilon \to 0} \frac{\mathrm{Log}N(\varepsilon)}{\mathrm{Log}(1/\varepsilon)} \qquad 2)$$

in which, D_B is the box-counting fractal dimension of the object, ε the side length of the box, and $N(\varepsilon)$ the smallest number of boxes of side ε required to cover the surface or the outline of the object completely[7-11,33,34]. As the zero limit could not be applied to biological objects, the dimensions were calculated as D = d, where d is the slope of the graph of log [N(ε)] against log 1/ε. The log-log graphs were plotted, and the linear segments were identified using least squares regression. Their gradients were calculated using an iterative resistant line method.

Computation of Hurst's exponent

Hurst's exponent, which gives a measure of the heterogeneous distribution of a set of irregularly-shaped objects[36-38], was obtained using the general relationship:

$$H = E + 1 - D \qquad 3)$$

where E indicates the Euclidean topological dimension, and D the fractal dimension of the surface covered by the extensions of all the collagen islets making-up the fibrosis. This exponent is capable of evaluating the loss of natural order that occurs in the histological picture as a result of the disruption of the natural quantitative relationship between the metric spaces covered by fibrosis and the parenchyma[11]. This could give the alterations the significance of a physical variable, make Hurst's exponent the descriptor of the configurational disorder of the hepatic tissue, and leave the fractal dimensions of the collagen islets and fibrosis the significance of an evaluation of how "densely" they occupy the metric space in which they lie and their spatial position.

In brief, Hurst's exponent values near to 1 quantitatively indicate a large loss of architectural harmony in the system (*i.e.* disordered states), whereas values near to zero indicate its preservation (*i.e.* states of structural order).

The reduction in Hurst's exponent could also be

interpreted as an index of the limited stability of a fractal object progressing towards more advanced states of stability.

Unit of measure

The construction of a meter with the most favorable spatial dimension for measuring the perimeter and area of the collagen islets was based on the assumptions that broken or mixed (in any case irregular) lines could be described as a "dilatative" (expanded) state of a straight line, and that their irregularity could be measured using the fractal dimension with similar criteria to those with which the coefficient of dilatation (λ) could be used to describe the length of a linear object before (s) and after (S) its exposure to the effect of heat expressed in the following formula:

$$S = s\,(1+\lambda t) \qquad 4)$$

where t is the duration of heat exposure[10].

According to this principle (which has been discussed elsewhere), the meter suitable for measuring a fractal object (m_F) could be obtained using the formula:

$$m_F = m\,[1 + \beta\,(D_P - D\gamma)] \qquad 5)$$

in which, m_F indicates the rectified meter, m the IS meter, β the dilatation constant of the unit of measure, D_P the fractal dimension of the perimeter, and $D\gamma$ the topological or Euclidean dimension[10]. The metric perimeter and area measurements were detected using the true liver biopsy area (indicated by the symbol A_B), by which we meant the surface area excluding any vascular, bile channel, sinusoidal or other empty spaces created by tissue loss during specimen manipulations.

Statistical analysis

All the data were expressed as mean±SD. The linear regression analysis was made using Spearman's correlation and Student's t test with Statistica software (StatSoft Inc., Tulsa, OK, USA). $P<0.05$ was considered statistically significant. The degree of intra- and inter-sample variability was quantitatively evaluated using the coefficient of variation (CV) given by the formula CV = SD/mean. Quantitative measures of fibrosis surfaces were compared (collated) with those of the score categories of the four currently used semi-quantitative methods.

RESULTS

Measurement of fractal dimension

By evaluating this parameter in our case-list of patients with chronic C virus-related hepatitis, we obtained dimensional values (D) ranging from 1.22 to 1.79. The value of this parameter increased depending on the extension of the fibrosis, with a regression curve ratio of $r=0.81$.

Perimeter measurements

The fibrosis perimeter (P_C) defined the sum of the perimeters all of the Sirius Red-stained areas of collagen in each biopsy section measured using the IS meter. The fractal fibrosis perimeter (P_{CF}) defined the same sum of perimeters measured using the fractal-rectified meter. The mean P_C was 860.64±588 μm, and the mean P_{CF} was 2966.1±2304.4 μm ($P<0.0005$). The marked difference

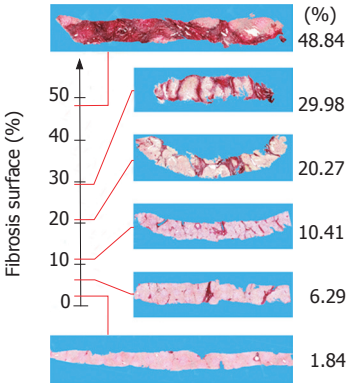

Figure 3 Trajectory of the dynamics of the fibrotic process considered as a continuous straight line going from *0%* to *48.84%* (the highest empirically observed percentage), without any jumps or abrupt swervings. The interaction of every experimental scalar expressing the state of the propositus fibrosis and the points of the geometric model gives the staging of fibrogenesis.

Δ was 225.21±38.69% due to the rectification, which included most of the fine, irregular particulars escaping the IS meter, thus making the result very close to reality. In this study, we only used the measurements corrected using the fractal dimension. The scalars indicating the length of the perimeters of fibrosis in each of the sections of the 209 bioptic samples fell within a range that was only closed at the zero point because the maximum value was not defined and could theoretically be greater.

Area measurements

The area of fibrosis (A_C) defined the sum of the areas of the Sirius Red-stained collagen islets measured using the IS meter. The fractal area of fibrosis (A_{CF}) was the sum of the areas of Sirius Red-stained collagen islets measured using the fractal-rectified meter. Both were expressed as a percentage of the total true area. The minimum and maximum values of A_C were 1.01% and 48.47% of the specimen area, the corresponding A_{CF} values were 1.34% and 48.84%. In this case, although statistically significant ($P<0.005$), the Δ(6.61%±4.79%) was small because histological sections were planar and the fractal measure of area depended only on its irregular contour. The scalars indicating the extent of the area of fibrosis in each of the sections of the 209 bioptic samples also fell within a range that was only closed at the zero point because the maximum value was not yet defined and could theoretically be greater.

Fibrosis staging of histological section

We constructed a geometrical model of the set of all states of ECM deposition on the line of real numbers as their state space using the scalars obtained from the fibrosis measured in our biopsies. The α (start) of the fibrotic process was fixed at 0% and the ω (end) at 48.84% of the area of the section (Figure 3). This model could represent a conventional interpretation of the ideal path that could be covered by potential fibrosis deposition in liver tissue. The staging observed in the histological section under examination was given by the relationship between the scalar expressing the actual fibrotic state of the section and the point indicated by this geometric model.

Classification of collagen islets

During the course of chronic hepatitis, fibrosis appeared under the control of stellate cells in the form of thin

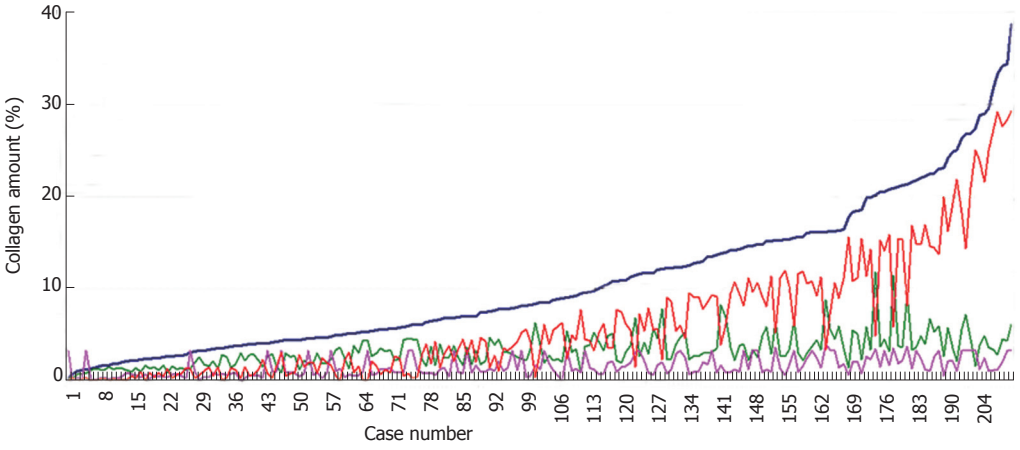

Figure 4 Comparative analysis of Markovian sequence of the amount of fibrosis, and the three sequences expressing the classes of magnitude of the collagen islets identified in 209 needle biopsy specimens. (1). Markovian sequence of the total amount of fibrosis in a histological biopsy section (blue line); (2). Percentage of collagen islets with a magnitude of 10^4-10^6 μm^2 (red line); (3). Percentage of collagen islets with a magnitude of 10^3-10^4 μm^2 (fuchsia line); (4). Percentage of collagen islets with a magnitude of 10^1-10^3 μm^2 (green line).

fibers that tended to grow in width and length within the portal space, around these structures and the central veins, and along the capillarised sinusoidal network. The three-dimensional interconnections of these collagen structures led to the formation of a fibrous network in which irregular meshes appeared as a set of collagen islets on different magnitudes on planar histological sections.

The logarithmic distribution of this set of 2.8 million collagen islets from 209 cases showed that it could be divided into three classes of elements of different magnitude: the collagen islets of 10-10^3 μm^2, those of between 10^3 and 10^4 μm^2, and those between 10^4 and 10^6 μm^2. All the histological sections contained islets with these classes of metrical values. In order to clarify the meaning of their presence, we first ordered the results of the fibrosis surface areas and constructed them in function of their magnitude as a Markovian curve (Figure 4).

The values of the islets belonging to the three subclasses in each bioptic section were plotted on the basis of the order of a Markovian curve, which generated the three irregular curves formed by the sets of islets belonging to each subclass. The fractal dimension of these curves showed that the Markovian reference curve had a fractal dimension of 1.1, whereas the curves of the three subclasses of the largest, medium-sized and smallest islets were respectively 1.9, 1.99 and 1.95. Fractal geometry suggested that the high fractal dimensions of the collagen islet subclasses could describe the instability of the collagen structure as it passed towards more stable fibrotic states[33].

Collagen area metric and semi-quantitative evaluations

The relationships between our measurements of fibrosis, the semi-quantitative Knodell histology activity index, and Sheuer, Ishak and METAVIR scores were investigated by comparing the portraits of each category of elements obtained by labeling the different semi-quantitative values on a geometric model using the line of real numbers as state space (Figure 5). The overlapping metric measures showed that samples with very similar metric surface areas fell into different categories while specimens with different metric surface areas fell into similar categories. Incidentally, our results reinforced the criticism by Rousselet *et al*[39] who have recently criticized the METAVIR system for evaluating fibrosis.

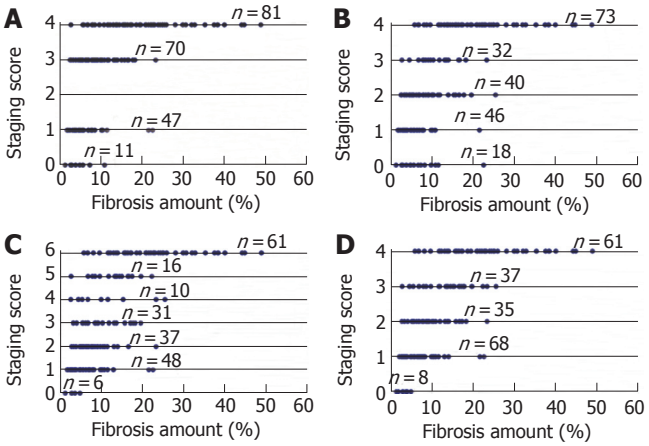

Figure 5 Comparison of the phase portraits obtained using the scalar values of the rectified areas of fibrosis projected onto the state spaces of each Knodell HAI (**A**), Sheuer (**B**), Ishak (**C**), and METAVIR category (**D**). All the graphs highlight the considerable overlapping of the data referring to different categories.

Wrinkledness

Wrinkledness (W), a typical characteristic of all natural fractal objects[11], could be obtained using the formula:

$$W = \frac{P_{CF} - R}{2\sqrt{\pi A_{CF}}} \qquad 6)$$

where R is the roundness coefficient of each islet.

The mean W value obtained by measuring the 209 biopsy sections was 731.3±298.72. As expected, this variable did not depend on the area of collagen (r=0.14), but was highly dependent on the length of its perimeter (r=0.80). Preliminary data showed that W was independent of the degree of necro-inflammatory activity (data not shown).

Measurement of Hurst's index

The same 209 patients provided us with H values ranging from 0.21 and 0.71. As said in the premises, we considered this index a quantitative variable of the alteration in hepatic tissue architecture. The ratio between H and the extension of the area of fibrosis indicated that the increased fibrotic area could lead to an extended loss of the natural harmony of this architecture (r=-0.81).

Table 1 Intra-sample variability in the area and wrinkledness of fibrosis

Patient number	*n*	A_{CF}(%)	CV	W	CV	H	CV
1	30	5.97±4.95	0.83	788.63±590.48	0.75	0.51±0.14	0.27
2	30	9.77±2.64	0.27	830.52±124.93	0.15	0.475±0.04	0.08
3	30	20.15±5.51	0.27	69±140.88	0.18	0.38±0.03	0.09

Note: Patient No.1 = Without pathology; Patient No.2 = Chronic hepatitis with intial fibrosis; Patient No.3 = Cirrhosis; *n* = number of sequential sections; A_{CF} = Fractal fibrosis area; CV = Coefficient of variability (standard deviation/mean); H = Hurst' exponent.

Intra-sample variability in area, wrinkledness and Hurst's exponent of fibrosis

In order to define the usefulness of generating numbers (or other kinds of invariants) to label the investigated structures in such a way that those with the same label could be considered alike and those with different labels could be considered different, the irregular tectonics of fibrosis was investigated in 30 sections taken at equal intervals from two patients with different degrees of disease severity and one was considered normal. The data (Table 1) showed the highly multifarious areas and wrinkledness of the collagen islets in the different sections. However, the Hurst's exponent was found less variable.

Inter-sample variability in area and wrinkledness of fibrosis

There was a high degree of inter-sample variability in the area (CV = 41%), outline perimeter (CV = 61%), and wrinkledness of fibrosis (CV = 38%). The inter-sample variability in Hurst's exponent was less (CV = 13%).

DISCUSSION

We have described a purely quantitative method of assessing liver fibrosis based on the theory of measure, which is the point of departure of all our concrete knowledge of the physical world, and the main reference for the construction of predictive and monitoring models[40].

During this study, our first difficulty was to measure the collagen islets making up liver fibrosis using standard metrics, because their irregularity excluded them from Euclidean geometry, which was created to describe smooth objects. Collagen islets can therefore only be measured using the principles of fractal mathematics and geometry[7-11].

Unlike the regular objects of Euclidean geometry, fractal objects do not have a single measure because it changes at every scale of observation as the result of the appearance of details that are imperceptible at lower magnifications, thus measurements have to be made at a well-defined scale[41].

The second difficulty was to identify the epistemological difference between the meanings of quantitative metric measures and the definition of a diagnosis of fibrosis in chronic inflammation or its progression to cirrhosis, which could be considered a radically different clinical condition. After making numerous experiments with our computer program, to analyze entire Sirius red-stained biopsy sections we established that the most favorable magnification was 200×, thus this magnification was used to digitize the microscope images.

After this methodological study, which considered the process of fibrogenesis as nothing rather than a physical phenomenon, we asked ourselves three basic questions, namely what have we learned about the meaning of liver tissue fibrosis? what new knowledge have we acquired after having measured the new canons of liver tissue architecture and classified their changes with scalars? and how much can these new notions be used in clinical practice to discriminate the progression or regression of fibrosis?

The first new notion was to extend the concept of the fractal dimension to metric measurements that might closely approximate the real magnitude of the irregular objects under observation.

Sensu stricto, the results of the intra-sample behavior and inter-sample variability study showed the non-representativeness of the perimeter and areas of fibrosis: the former due to its dependence on the extension of the bioptic specimen, and the latter for the high variability of the distribution of the inflammation process in the organ.

We added the staging of the evolution of ECM deposition towards stages of non-tolerability using the scalars obtained from the two-dimensional measurements of the area of the fibrotic mass. Although hardly representative and no more than a resonance of the mesomorphic process taking place in the environment, this information has some clinical interest if only as a very generic quantitative portrait of the general condition of the liver.

The quantitative relationships between the edge-interior of the fibrosis mass generated the new concept of its wrinkledness.

The collagen islets were categorized into three classes on the basis of the magnitude of their areas, which provided clues to their state of instability that indicated the activity of the fibrogenetic process. High presence of islets belonging to these subclasses according to the fractal geometry, is a signal of collagen structure instability in transition towards more stable states.

The distribution of the quantitative values of the areas covered by fibrosis in each category of the four semi-quantitative methods of evaluation clearly and simply confirmed the unreliability of the semi-quantitative systems themselves. This inadequacy could also be seen even when the histological preparations were analyzed by expert hepato-pathologists whose experience encompasses a large number of observed cases.

Interest in the collagen/parenchyma ratio led us to recognize the canons (mathematical laws) governing the natural "harmonic state of liver tissue", by which the order that characterizes its organized fibrous and parenchymal components (considered prime bodies) in such a way can provide a definition of the natural histological architecture of liver tissue. This can be defined in two dimensions on the basis of the extension of the metric spaces covered by fibrous tissue (no more than 3%) and the parenchyma (97%). It can be intuitively understood

that altered proportions between these spaces disrupt the natural harmonic state by creating disorder in the natural lobular structure of the liver tissue. In this sense, the words "measure" and "architectural alteration" in Ishak' s classical semi-quantitative definition (1995) …"[Staging] … is a measure of fibrosis, and architectural alteration, i.e. structural progression of the disease…" really indicate a rigorous metric value, and the term architectural alteration of this definition acquires the consistency of a measurable, scientific variable of state.

In order to quantify the architectural alteration, we used Hurst's exponent, and analysis of its variability gave the following promising results: the least variability in thirty sequential sections (intra-sample variability), the greatest representativeness in six samples of hepatic tissue obtained from different parts of the liver (it was not possible to speak of lobes because of the advanced structural alterations induced by cirrhosis). This last result is currently further investigated in our laboratories.

In conclusion, although a number of serum fibrosis markers have been discordantly proposed[1-5,42-46], the results of this study strongly underline the primary role of liver biopsy in the qualitative diagnosis of chronic liver disease and its usefulness in evaluating fibrosis in a metrically rigorous manner. The use of quantitative descriptors of irregularly-shaped fibrosis should shed new insights into the dynamics of viral and non-viral liver diseases. We are concentrating on the clinical use of Hurst's exponent after antiviral drug treatment as it can quantitatively demonstrate a drug's effect on fibrosis with a very low error.

Abstract

AIM: To observe the effect of protocatechuic aldehyde on the proliferation of hepatic stellate cells (HSCs).

METHODS: Liver fibrosis was induced in rats by carbon tetrachloride (CCl_4). Then normal and fibrotic drug sera were extracted from rats. The effects of protocatechuic aldehyde, raw *Radix Salvia miltiorrhiza* and drug sera of *Salvia miltiorrhiza* on HSC growth were determined by CCK-8. The protocatechuic aldehyde was separated by high performance liquid chromatography (HPLC) in a Alltima C18 column (250 mm × 4.6 mm, 5 μm) with a mobile phase of acetonitrile-4% glacial acetic acid solution (gradient elution) at the wavelength of 281 nm.

RESULTS: Protocatechuic aldehyde, raw *Radix Salvia miltiorrhiza* and drug sera of *Salvia miltiorrhiza* were found to have inhibitory effects on proliferation of rat HSCs. Raw Radix Salvia miltiorrhiza had a stronger inhibitory effect than the drug sera. The fibrotic drug sera showed a higher suppressive effect than the normal drug sera ($P < 0.05$). Protocatechuic aldehyde was found in crude materials of both *Radix Salvia miltiorrhiza* and its corresponding drug sera. The average recovery ($n = 6$) was 110.5% for raw *Salvia miltiorrhiza Bge,* 102% for normal drug sera and 105.2% for fibrotic drug sera. The relative standard deviation (RSD) was 0.37%, 1.96% and 1.51%, respectively ($n = 6$). The contents of protocatechuic aldehyde were 0.22%, 0.15% and 0.19%, respectively ($n = 6$) ($P < 0.05$). The RSD was 0.33%, 0.75% and 1.24% ($n = 6$) for raw material of *Radix Salvia miltiorrhiza,* normal drug sera and fibrotic drug sera, respectively. The samples were stable for 6 d.

CONCLUSION: Protocatechuic aldehyde can inhibit the growth of HSCs. HPLC is suitable for the determination of virtual bioactive components of Chinese herbal medicines *in vitro.*

INTRODUCTION

Radix Salvia miltiorrhiza is an important traditional Chinese medicine (TCM) for activating blood and eliminating stasis[1]. Its effects on chronic hepatic diseases, such as liver fibrosis and cirrhosis, have been proved in experiments *in vitro* (cell culture) and *in vivo* (animal experiment)[2-4]. Liver fibrosis is a necessary stage during the development of liver cirrhosis. The activation and proliferation of hepatic stellate cells (HSCs) are the critical steps in hepatic fibrogenesis[5,6]. *Radix Salvia miltiorrhiza* could markedly inhibit the activation and proliferation of HSCs. Protocatechuic aldchyde is one of the bioactive components of *Radix Salvia miltiorrhiza*, which could inhibit the proliferation of HSCs and might be one of the efficient components of *Radix Salvia miltiorrhiza* acting on HSCs.

"Traditional seropharmacological method" usually utilizes healthy animals (such as rats) as medicine takers. The effect *in vitro* can be studied by isolating the drug sera (normal drug sera) from healthy animals to clarify the functions of the components in drug sera [7]. But different functional status of liver, which is the biggest organ for biological metabolism, could lead to some differences in the conversion of the same drug. Therefore, we used rats with liver fibrosis as the drug receivers and drug serum resources in our study. The corresponding

drug sera (pathological drug sera) were drawn after oral administration of the herbs. We termed it "modified seropharmacological method".

We compared the contents of protocatechuic aldchyde in raw *Radix Salvia miltiorrhiza* in normal and fibrosis rats before and after administration. Whether this method could predict the curative effects of *Radix Salvia Miltiorrhiza* was evaluated.

MATERIALS AND METHODS

Materials

Twenty male Sprague-Dawley (SD) rats weighing 200-250 g were provided by the Laboratory Animal Center of Hebei Medical University. All rats were randomized into group A (normal rats) and group B (liver fibrotic rats), 10 in each group. The rats in group A were treated with saline, while the rats in group B were treated with 40% carbon tetrachloride (CCl_4). Hepatic fibrosis was induced in rats of group B by 40% CCl_4 4 mL/kg body weight for the first injection, then 2 mL/kg body weight, twice a week, for 9 wk.

HSC cell line was presented by Professor Greenwell, Marion Bessin Liver Research Center, Albert Einstein College of Medicine. The phenotype of *CFSC* was obtained from CCl4-cirrhotic liver of rats after spontaneous immortalization in culture.

RPMI-1640 was from GIBICO. CCl_4 was of analytical grade. *Radix Salvia miltiorrhiza* was provided by Hebei Lerentang Chinese Medicine DrugStore Co. Drug sera were drawn from rats.

Methods

Preparation of samples for HSC cultivation

Radix Salvia miltiorrhiza was ground into powder and filtered with a sieve plate. The powder was dissolved into pure RPMI-1640 media to make the concentration 15 times that of the decoction for adults (within the range of safe concentration for HSCs). Then the dissolution was filtered to remove the bacteria for HSC cultivation.

SD rats weighing 200-250 g were randomized into group A and group B, 10 in each group. Liver fibrosis was induced in rats of group B by 40% CCl_4, 4 mL/kg body weight first, then by 2 mL/kg body weight, twice a week, for 9 wk. The rats in group A were treated with saline. The decoction of *Radix Salvia miltiorrhiza* was administrated to all rats for 5 d. The quantity of raw *Radix Salvia miltiorrhiza* in solution was 1.33 g/mL. Blood was drawn from inferior vena cava 2 h after the drugs were given on the fifth day. Then drug sera were obtained by centrifugation at 3000 r/min for 20 min at 4 ℃. The sera were deactivated at 56 ℃ for 30 min. Then the drug sera were dissolved in RPMI-1640 to obtain 10% drug sera-1640 medium for analysis.

Detection of inhibitory rate of protocatechuic aldchyde, raw Radix Salvia miltiorrhiza and drug sera of Salvia miltiorrhiza on HSC growth by CCK-8

Cell suspension (100 μl) was incubated on a 96-well plate. When HSCs grew to 90% confluence they were incubated in pure RPMI-1640 overnight to synchronize HSCs into the G_0 period. The solutions of protocatechuic aldchyde, raw *Radix Salvia miltiorrhiza* and the corresponding 10% normal and fibrotic drug sera-1640 media in the wells were changed. The results were obtained. A group of controls was set at the same time. One hundred microliters of CCK-8 solution were added to each well of the plate after the drug sera were allowed to work for 24 h. Then the plate was incubated for 4 h. The absorbance (A) at 450 nm was measured with a microplate reader. The inhibitory rates (IR) of all solutions on the growth of HSCs were calculated (IR = experiment group-control group /control group×100%).

Systems for HPLC

Waters 810 controller, Waters 486 tunable absorbance detector, Waters 510 HPLC pump, Millipore Waters U6K, Waters system interface module, Waters baseline 810 chromatography workstation (America) were used for HPLC. Sep-Park C18 purification column, ultrafree-MC filters (10000 NMWL filter unit) and Autoscience ultrasonic producer were all from Millipore Corporation, America. Standard of protocatechuic aldchyde (NO. 110810-200205), glacial acetic acid and methanol were all special for HPLC. All reagents used in HPLC were filtered and deprived of vapor by ultrasound.

Preparation of samples for HPLC

Radix Salvia miltiorrhiza (100 g) was ground into powder and filtered with a sieve plate. The powder of *Radix Salvia miltiorrhiza* was put into a volumetric flask containing methanol. Then ultrasound was used to facilitate the dissolution of the powder for 5 min and methanol was added to obtain 100 mL solution. This solution was then filtered through filters with 0.45 μm Millipore, purified by Sep-Park C18 column, and repeatedly filtered through Ultrafree-MC filters. Finally, the filtered solution was used as samples of raw *Radix Salvia miltiorrhiza* and kept in darkness at 4 ℃.

Samples of Radix Salvia miltirrhiza drug sera (normal and fibrotic drug sera)

The preparation of drug sera was the same as that of the sera for HSC cultivation. After the drug sera were obtained by centrifugation at 3000 r/min for 20 min at 4 ℃, acetonitrile was mixed with the sera to get rid of protein by centrifugation. Then the supernatant was filtered through filters with 0.45 μm Millipore, purified by Sep-Park C18 column, and filtered through filters. Finally, the filtered solutions were kept in darkness at 4 ℃.

Parameters of HPLC

The parameters for HPLC included: HPLC column: Alltima C18 column (250 mm × 4.6 mm, 5 μm); velocity of flow: 0.5 mL/min; detection wavelength: 281 nm; temperature for HPLC column: 30 ℃; mobile phase: A: acetonitrile; B: 4% glacial acetic acid; gradient elution: A-B (2:98): 0-10min; A-B (10:90): 10-26 min.

Linear relation

Protocatechuic aldchyde (4.125 mg) was added into a volumetric flask. Then methanol was used to dissolve the powder to a final volume of 100mL (final concentration was

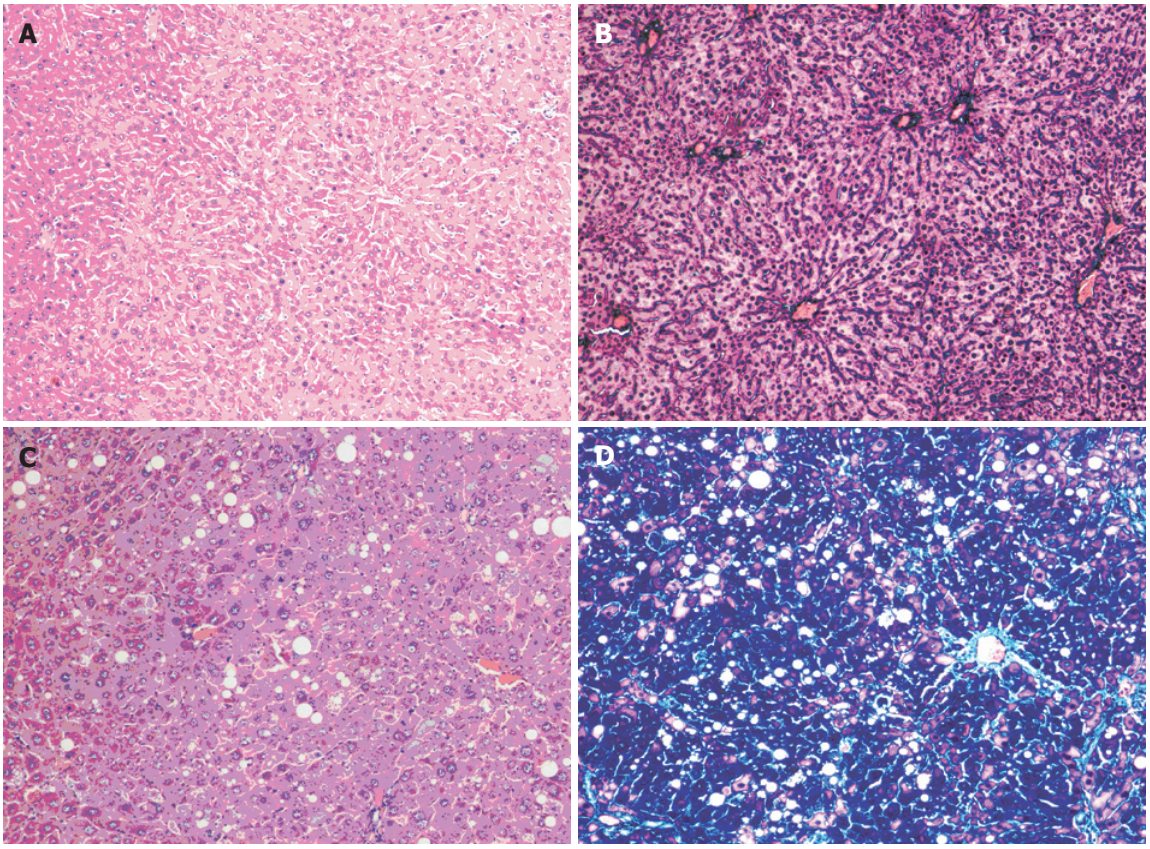

Figure 1 Healthy liver tissue of rats of group A (**A**, **B**) and fibrotic liver tissue of rats of group B (**C**, **D**). **A** and **C** (HE, 100×); **B** and **D** (Masson, 100×).

0.04125 mg/mL). Afterwards, 2, 5, 8, 10, 12, 15, 18 and 20 μL of protocatechuic aldchyde standard solution were injected into U6K for detection. Each volume was detected 3 times by HPLC under the conditions as described above. The standard curve was plotted with X axis (μg) to Y axis (mv.min).

Experiment of exactitude and evaluation of stability of samples

For the experiment of exactitude, 10 μL of protocatechuic aldchyde standard solution (41.25 μg/ml) was injected into U6K for detection. The detection was repeated 6 times, 10 μL for each time. Then the relative standard deviation (RSD) of the peak areas was calculated to evaluate the exactitude of the experiment.

For the experiment of stability, the same volume of standard solution was injected into U6K for detection, 6 times each day for 9 d. The RSD of the peak areas each day was calculated to evaluate the stability of the samples during the 9 d.

Experiment of recovery rate

In brief, 0.05 mg of protocatechuic aldchyde was put into 25 mg powder of raw *Salvia miltiorrhiza*. Then the samples for research were injected into U6K for detection. The average recovery rate ($n = 6$) was calculated.

Six samples of drug sera (400 μL for each sample) were taken out and 10 μL of protocatechuic aldchyde standard solution (0.04125 mg/mL) was dispensed into each sample of drug sera. Then the products were detected by HPLC ($n = 6$) to calculate the average recovery.

Experiment of repeatability

Radix Salvia miltiorrhiza (100 mg) was disposed as in preparation of samples of raw *Radix Salvia miltiorrhiza*. Then the samples were detected by HPLC for the content of protocatechuic aldchyde ($n = 6$). The detection was repeated 6 times independently. RSD of the peak areas was calculated to evaluate the repeatability of the experiment.

Four hundred μL of a certain drug serum was disposed as in preparation of samples of drug sera. The samples were detected for the content of protocatechuic aldchyde by HPLC ($n = 6$). RSD of the peak areas was calculated to evaluate the repeatability of the experiment.

The content of protocatechuic aldchyde in samples was detected by HPLC.

Statistical analysis

SPSS 10.0 was used to perform χ^2 test and $P < 0.05$ was considered statistically significant.

RESULTS

Obvious proliferation of fibers appeared in the livers when the rats in group B (Figures 1C and 1D) were treated with 40% CCl_4 for 9 wk. There were obvious signs of vacuole degeneration, lobular inflammation and necrosis in the tissues of fibrotic liver. No evident changes appeared in the rat liver of group A (Figures 1A and 1B).

It showed that protocatechuic aldchyde, raw *Radix Salvia miltiorrhiza*, the corresponding normal and fibrotic drug sera could all inhibit the proliferation of HSCs compared with blank control group ($P < 0.05$). The raw *Radix Salvia*

Table 1 Inhibitory rates of protocatechuic aldchyde, raw Radix Salvia miltiorrhiza and corresponding normal and fibrotic drug sera on proliferation of HSCs

Group	IR (%)	A
A (Protocatechuic aldchyde)	24.36	1.565±0.08[a]
B (raw Radix Salvia miltiorrhiza)	36.10	1.322±0.10[a]
C (Normal drug sera of Salvia miltiorrhiza)	16.14	1.735±0.12[ab]
D (Fibrotic drug sera of Salvia miltiorrhiza)	21.41	1.626±0.53[ab]
E (Control)	–	2.069±0.37

[a]$P < 0.05$ *vs* group E; [b]$P < 0.05$ *vs* group D

IR = (experiment group–control group) ÷ control group × 100%.

miltiorrhiza had a stronger inhibitory effect than the corresponding drug sera. The fibrotic drug sera of *Salvia miltiorrhiza* from fibrotic rats showed a higher suppressive effect on HSC growth than the normal drug sera from healthy rats ($P < 0.05$) (Table 1). The contents of protocatechuic aldchyde showed a nice linearity within the range of 0.1-0.8 μg ($Y=2.14\times10^4X+2.77$, $r=0.9999$).

Protocatechuic aldchyde standard solution was detected 6 times. The RSD was 0.33% for the peak areas of protocatechuic aldchyde. Within the 9 d of observation, the peak areas of protocatechuic aldchyde in standard solutions did not change significantly in the first 6 d. The RSD was 0.45% ($n=6$) for the peak areas of protocatechuic aldchyde in the first 6 d. It indicated that the solutions of standards could be kept in darkness at 4 ℃ for 6 d.

The average recovery of raw *Radix Salvia miltiorrhiza* was 110.5%. RSD was 0.37% ($n=6$). The average recovery of drug sera of *Salvia miltiorrhiza* was 102%, and the RSD was 1.96% ($n=6$). The average recovery of fibrotic drug sera was 105.2%, and the RSD was 1.51% ($n=6$).

Protocatechuic aldchyde in raw *Radix Salvia miltiorrhiza* was 0.22%, and the RSD was 0.33% ($n=6$). The ratio of protocatechuic aldchyde in normal drug sera was 0.15%, and the RSD was 0.75% ($n=6$). The ratio of protocatechuic aldchyde in fibrotic drug sera was 0.19% and the RSD was 1.24% (Table 2, Figures 2A-2C).

Table 2 Results of sample determination (mean±SD, %)

Group	Content of protocatechuic aldehyde
Salvia miltiorrhiza Bge	0.22±0.07

Fibrotic drug sera of Salvia miltiorrhiza Bge	0.19±0.01[a c]

[a]$P < 0.05$ *vs* Salvia miltiorrhiza Bge; [c]$P < 0.05$ *vs* Normal drug sera of Salia miltiorrhiza Bge.

DISCUSSION

Radix Salvia miltiorrhiza is the dried root of labiate-*Salvia miltiorrhiza Bge,* an important drug in traditional Chinese medicine for activating blood flow and eliminating stasis. *Radix Salvia miltiorrhiza* has certain curative effect on coronary heart diseases and chronic liver diseases with few adverse effects. No ideal anti-fibrosis drugs in Western medicine have been developed so far. A series of blood-activating and stasis-eliminating Chinese medicines such as *Radix Salvia miltiorrhiza*, have a positive effect on prevention and reversion of fibrogenesis. However, it is difficult to clarify the working mechanism and real active components of Chinese anti-fibrosis herbs. *Radix Salvia miltiorrhiza* can improve liver function and ameliorate hepatic pathological changes in rats and humans. In our study, when the aqueous extract of *Radix Salvia miltiorrhiza* was given to rats before the injection of CCl_4, liver fibrosis was produced. On the other hand, in cell culture *in vitro*, *Radix Salvia miltiorrhiza* showed its inhibitory effect on lipid peroxidation and some key signal transduction circuits in HSCs, delaying the activation and proliferation of HSCs. A kind of extract from *Radix Salvia miltiorrhiza*-monomer IH764-3 could activate caspase-3 and induce apoptosis of HSCs.

Many bioactive components in *Radix Salvia miltiorrhiza*, including soluble and insoluble parts have various pharmacological effects such as blood-activating and stasis-eliminating and facilitate the circulation of blood and oxygen. The insoluble components mainly include compounds of phenanthrenequinone (PAQ), such as tanshinones I and II cryptotanshinone and isotanshinone. The soluble components are mainly composed of phenolic acids. Salvianolic acid B[8] is one of the bioactive parts of *Radix Salvia miltiorrhiza* to inhibit the activation and proliferation of HSCs by blocking the intracellular signal transduction of transforming growth factor-β1 (TGF-β1).

Protocatechuic aldchyde is one of the water-soluble components of *Radix Salvia miltiorrhiza* and can be used to treat dysmenorrhea in gynaecology. Protocatechuic aldchyde can inhibit the proliferation of HSCs (CCK-8) *in vitro* and might be used to treat liver fibrosis. In this study, the peak areas maintained stable for 6 d. Since the stability of protocatechuic aldchyde is much better than other components (such as salvianolic acid B) in *Radix Salvia miltiorrhiza*, protocatechuic aldchyde performs the pharmacological effects for a longer time *in vivo* and *in vivo*. The content of protocatechuic aldchyde in raw *Radix Salvia miltiorrhiza* is higher than that in the corresponding drug sera, which could explain the phenomenon that the inhibitory effect of raw *Radix Salvia miltiorrhiza* was stronger than that of drug sera. It indicates that only part of metabolites of protocatechuic aldchyde in raw *Radix Salvia miltiorrhiza* could enter blood to exert pharmacological effects after metabolism *in vivo*. If crude medicines are used to work on HSCs directly *in vitro*, the pharmacological effect of the medicine would be exaggerated. On the other hand, some other herbs could perform their pharmacological effect only after decocted *in vitro* and metabolized *in vivo*, because the process of decoction and metabolism would promote the activation of the bioactive components in this kind of crude medicines. Under this condition, the herbs seem useless if they are directly used on cells *in vitro*, suggesting that the effect of raw *Radix Salvia miltiorrhiza* is not equal to

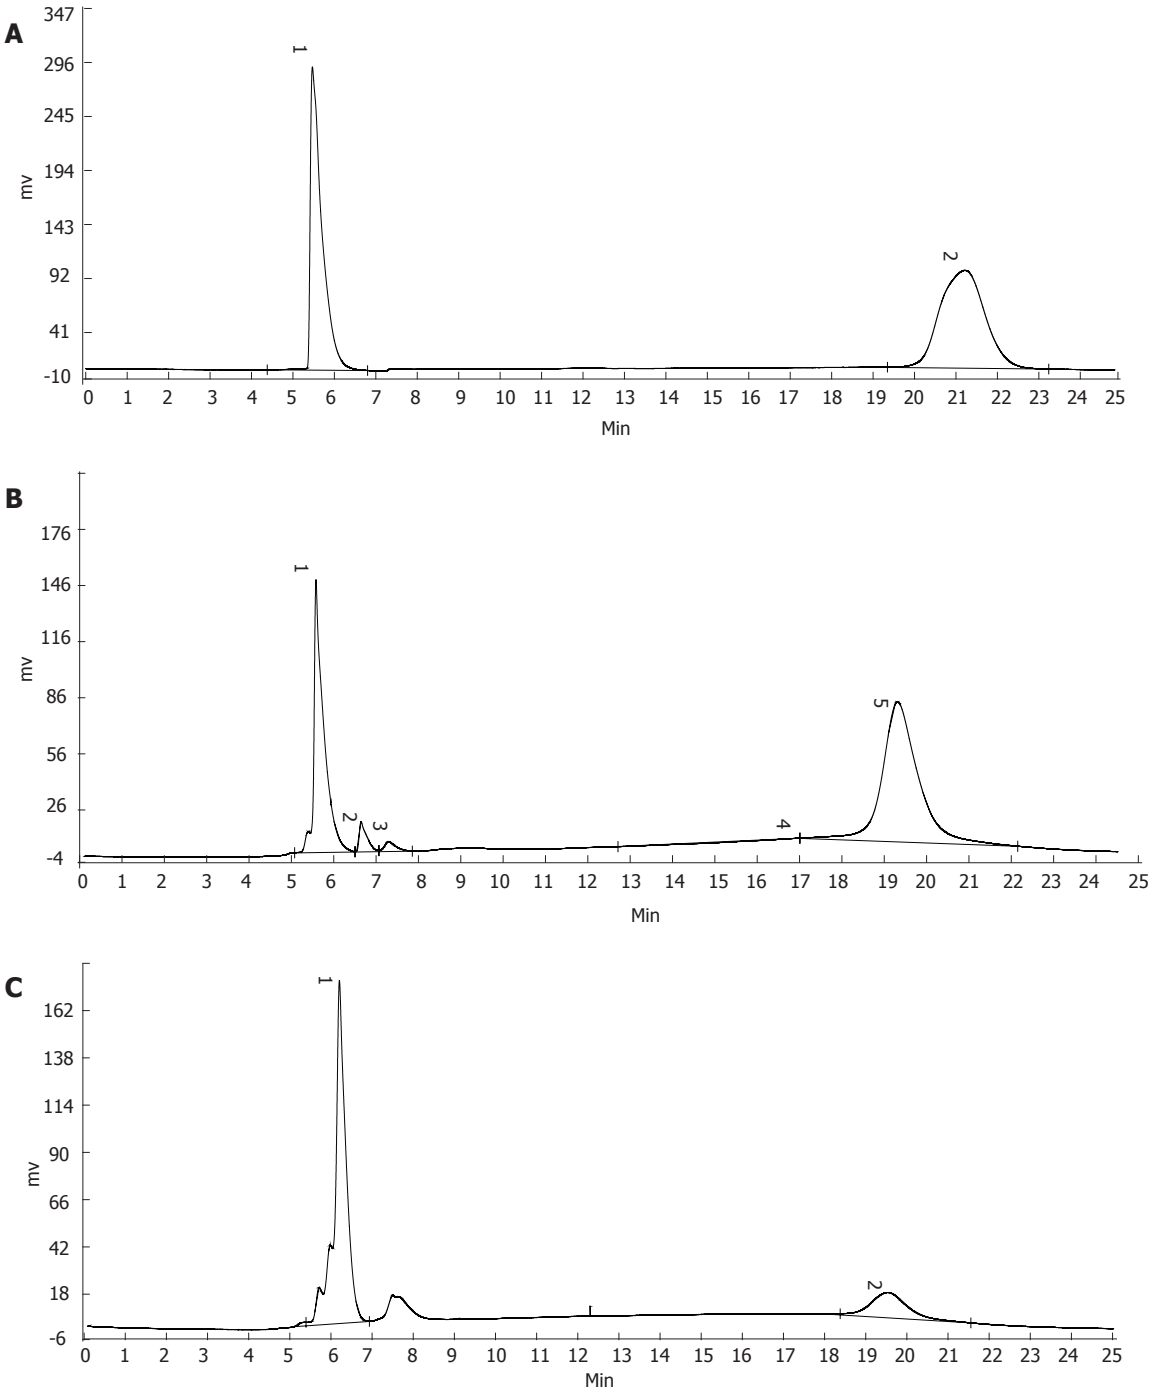

Figure 2 Chromatography of raw *salvia miltiorrhiza Bge* (**A**), pathological drug sera of *Salvia miltiorrhiza Bge* (**B**) and normal drug sera of *Salvia miltiorrhiza Bge* (**C**).

the effect of *Salvia miltiorrhiza in vivo*. The differences are related to the characteristics of herbs. Active constituents of TCM are influenced by soils, climates, growth stages, and factors *in vitro* and *in vivo*. So the "Pharmacological method" is more suitable for researching herbs.

Protocatechuic aldchyde in pathological drug sera is more than that in normal drug sera, which is in accordance with the different effects of normal and fibrotic drug sera [3]. Because of this difference between the two kinds of drug sera and the phenomenon that most of the medicine takers are patients with hepatic diseases, it is better to use "modified seropharmacological method" and " pathological drug sera" to carry out research on herbs *in vitro* (*vs* " traditional seropharmacological method" and "normal drug sera"). In this way, the impact of different liver functional status on herbs' metabolic process could be included as a parameter in experiment. The phenomenon that the content of protocatechuic aldchyde is higher in fibrotic drug sera than in normal sera, coincides with the working characteristics of herbs, which might be caused by different "first pass effect" of the liver under different liver conditions and metabolism of drugs. From the traditional Chinese medicinal theory of "diagnosis and treatment on the basis of an overall analysis of the illness and the patient's different symptoms and pathogenesis" and "bidirectional regulation", TCM works best only when

the symptoms and etiology are just their corresponding indications. *Radix Salvia miltiorrhiza* is one of the blood-activating and stasis-eliminating drugs. Liver fibrosis is considered as "blood obstruction"[9] in traditional Chinese medicine. Undoubtedly it is the indication for *Radix Salvia miltiorrhiza*. So the blood-activating and stasis-eliminating herbs such as *Radix Salvia miltiorrhiza* have better pharmacological effects on fibrotic rats. The active components in *Radix Salvia miltiorrhiza* might be activated and released more efficiently to perform stronger pharmacological effects. The ability of fibrotic liver to transform and inactivate drugs might decrease because the metabolic functions of fibrotic liver decrease, thus making the concentration of the effective components higher, prolonging the effective working period.

The value of this research lies in that we could get the real active components of *Radix Salvia miltiorrhiza* by "modified seropharmacological method" after they are metabolized *in vivo*. HPLC is a quick and sensitive method the determination of effective components in drugs *in vitro* and *in vivo*.

Abstract

AIM: To report our experience with the use of granulocytapheresis (GCAP) in 14 patients with active steroid-refractory inflammatory bowel disease (IBD) in order to evaluate its efficacy in achieving remission and maintaining a long lasting symptom-free period.

METHODS: The activity of the disease was evaluated by clinical activity index (CAI) and endoscopic index (EI) in ulcerative colitis (UC), while by Crohn's disease activity index (CDAI) in Crohn's disease (CD). The patients were treated using the Adacolumn™ system, an adsorption column which selectively binds to granulocytes and monocytes. One session/week of GCAP was performed for 5 wk. Steroids were stopped during apheresis.

RESULTS: All the patients completed the five-week course showing no complications. At the end of the last session, 93% of patients showed a clinical remission of the disease that persisted for 6 mo. Nine months after the end of the treatment, 60% of the cases maintained remission, while 23% of the patients were still in clinical remission after 12 mo.

CONCLUSION: Even if the number of our patients with steroid-refractory IBDs was not big, we can assert that GCAP is well tolerated and effective, especially in the first six months after the treatment, in a significant percentage of cases. The rate of sustained response drops slightly after 6 mo and significantly after 12 mo, however the absence of severe side effects can be a stimulus for further evaluating new schedules of treatment.

Key words: Granulocytapheresis; Ulcerative colitis; Crohn's disease; Steroid-refractory

INTRODUCTION

The term "inflammatory bowel disease (IBD)" usually means two similar but distinct chronic diseases of the gut: ulcerative colitis (UC) and Crohn's disease (CD) characterised by episodes of remission and exacerbation with systemic complications[1-4].

During the last 20 years the treatment of IBD has been greatly improved although it is still empirical due to its unknown aetiology[5-8]. It seems that both ulcerative colitis and Crohn's disease are multifactorial in origin. However, regardless of the cause, the final pathway of tissue damage in IBD is mediated by the cellular immune response through white blood cells in the intestinal mucosa. Corticosteroids are a mainstay of acute therapy for moderate to severe ulcerative colitis or Crohn's disease. However, up to 40% of patients do not respond to the high-dose steroid therapy. So, new therapeutic approaches are needed to improve the clinical outcome of active steroid-refractory IBD.

Classic immunosuppressant drugs like azathioprine or mercaptopurine need some weeks to exert their full activity, so they are useless during the acute phases of the disease. Moreover, newer immunosuppressants like cyclosporine A have shown only a temporary benefit and often serious side effects.

In recent years some trials have suggested that leukocytapheresis can be a useful and safe way to induce clinical remission in patients with IBD[9-11, 15]. Subsequent trials have proved that granulocytapheresis (GCAP), a technique that sequestrates much selectively granulocyte and monocyte subpopulations, is equally effective in patients with active IBD[16, 17].

Even if with a limited casuistry, we aimed at bulking the published data by referring our experience with GCAP. We analyzed the clinical, endoscopic and laboratory parameters of patients with active, steroid-refractory IBDs,

Table 1 Baseline characteristics of UC patients ($n = 8$) (mean ± SD)

Female/Male	3/5
Age (yr)	35.2±7.4
Colonic involvement	All PanUC
Disease duration (yr)	7.8±3.0
Basal CAI	10.0±3.4
Basal EI	10.5±2.5

CAI:clinical activing index;
EI: endoscopic index.

Table 2 Baseline characteristics of CD patients ($n = 6$) (mean ± SD)

Female/Male	3/3
Age (yr)	37.8±2.5
Disease location	All ileal CD
Disease duration (yr)	7.1±3.2
Basal CDAI	213.3±32.0

before and after the completion of GCAP during a follow-up period of 12 mo. This work was to get more information about the real effectiveness of GCAP in achieving remission and possibly in maintaining it.

MATERIALS AND METHODS

All the patients with UC or CD treated with GCAP in our department because of steroid-resistant IBD were followed up by monitoring clinical, laboratory and endoscopic parameters for UC.

Before admitted for GCAP, all patients signed an informed consent and underwent routine laboratory tests and basal ECG. Moreover, they were visited by a cardiologist in order to exclude serious cardiovascular diseases.

All patients received a 5-session (1 session/wk) treatment with GCAP. This was an extracorporeal procedure in which 1.8 L of blood was filtered through an Adacolumn™ (JIMRO, Takasaki, Japan). Adacolumn™ is a 335 mL capacity column filled with 35 000 cellulose diacetate beads (2 mm in diameter) that bind to granulocytes and monocytes via the CR3 receptors present on these cells. Each apheresis procedure required the addition of 1500 UI of sodium heparin as an anticoagulant. Blood was obtained by antecubital vein puncture. Methylprednisolone daily dose was progressively reduced until discontinuation in a 6-wk period (one week after the last apheresis procedure). Concomitant treatment with aminosalicylates was maintained during the treatment and follow-up at the same dosage.

In ulcerative colitis patients, the activity of the disease was evaluated by clinical activity index (CAI): Clinical remission was defined if less than 6 and endoscopic index (EI): endoscopic remission was defined if less than 4. In the subjects with Crohn's disease, the activity was measured by Crohn's disease activity index (CDAI): clinical remission was defined if less than 150.

After the end of the five-week course of granulocytapheresis and every 3 mo, each patient was visited for a clinical and endoscopic assessment, paying particular attention to the activity indices. The subjects who achieved clinical remission were followed up for 12 mo by the last session of GCAP.

Relapse was defined as an increase of clinical and endoscopic scores (CAI, EI, CDAI) more than 6, 4 or 150 respectively. Patients who were on 5-aminosalicylic acid continued this medication but no additional treatment.

Hemograms, biochemistry and coagulation were recorded during the apheresis treatment.

Statistical analysis

Data were expressed as mean ± SD if required. Student's t test for paired variables was performed. Statisticcal analyses were analysed with SPSS 11.5 (®SPSS inc. 2002).

RESULTS

We treated and followed up 14 patients (8 with ulcerative colitis and 6 with ileal Crohn's disease).

Baseline characteristics

Baseline characteristics of the 8 UC patients were mean age: 35.2±7.4 years; female/male ratio: 3:5; mean time of disease history: 7.8±3 years. All patients had an active pancolitis with a mean CAI of 10.0±3.4 at baseline and a mean endoscopic index (EI) score of 10.5±2.5 (Table 1). All the patients showed an active disease and were treated with 0.8-1 mg/kg pre d of i.v. or i.m. methylprednisolone and 2.4 g/d of oral mesalazine during the 8 wk period prior to GCAP initiation, without achieving response. None of the patients was under inmuno-supressor therapy at baseline but all of them were on mesalazine at 2.4 g/d.

Baseline characteristics of the 6 CD patients were mean age: 37.8±2.5 years; female/male ratio: 3:3; mean time of disease history: 7.1±3.2 years. All patients had an active ileal CD with a mean basal CDAI of 213.3±32.0 (Table 2).

Induction of remission in UC patients

One week after GCAP treatment, all UC patients achieved remission (Figures 1A and 1B) and stopped methylprednisolone treatment. The mean CAI decreased from 10.0 ± 3.4 to 3.5 ± 1.2 ($P < 0.001$). Also EI decreased from 10.5±2.2 to 2.6 ± 0.5 ($P < 0.001$). The mean values of CRP and ESR decreased from 32.5 ± 11.2 to 4.5 ± 4.7 mg/L ($P < 0.001$) and 48.5 ± 8.6 to 15.0 ± 2.3 mm/h respectively ($P < 0.001$) (Figures 3A and 2B).

Induction of remission in CD patients

One week after GCAP treatment, 5 out of 6 patients achieved remission (Figure 3A) and stopped methylprednisolone treatment. The mean CDAI decreased from 213.3 ± 32.0 to 135 ± 50 ($P < 0.015$). The mean CRP values decreased from 39.0 ± 12.6 to 9.5 ± 9.1 mg/L ($P < 0.01$) and ESR values from 52.3 ± 9.8 to 21.7 ± 18.0 mm/h ($P < 0.05$) (Figures 3B and 3C).

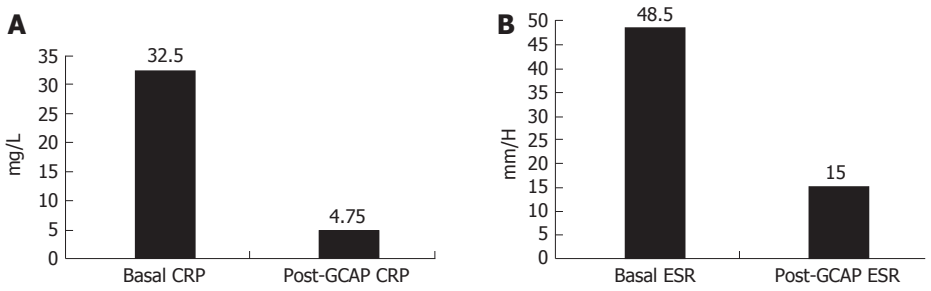

Figure 2 Mean evolution of CRP (**A**) and ESR (**B**) in UC patients.

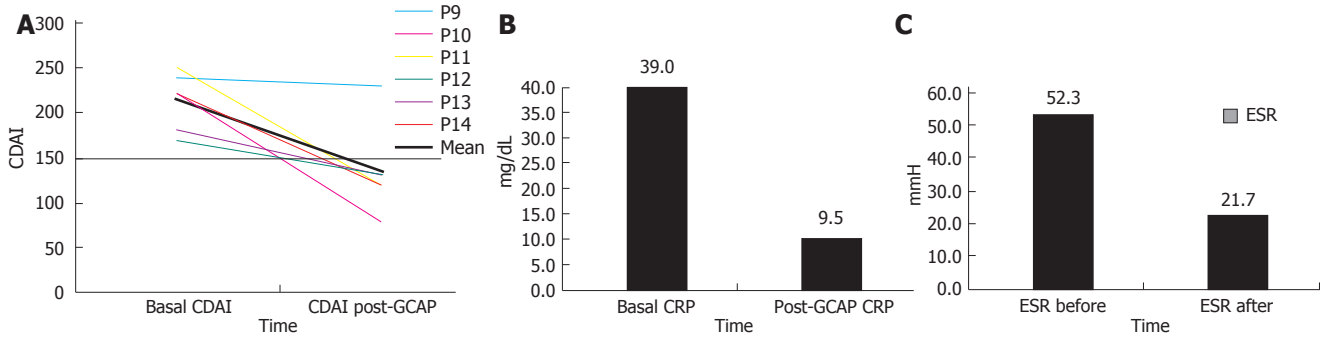

Figure 3 Mean evolution of CDAI (**A**), CRP (**B**) and ESR (**C**) in CD patients.

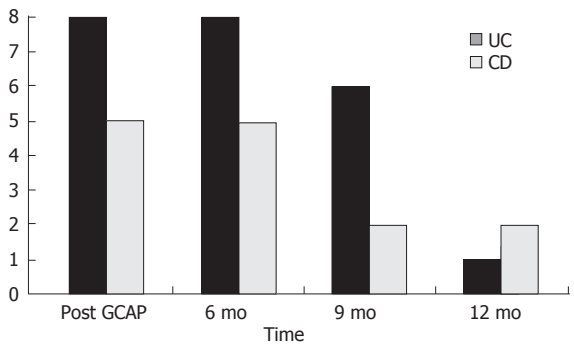

Figure 4 Remission during follow-up.

Adverse events

All the patients completed GCAP without severe side effects. Only a transient mild headache was recorded in two patients during the procedure.

Follow-up

All the patients were followed up for 12 mo after GCAP treatment and no additional treatment was added. Clinical remission persisted for 6 mo in all the patients and was achieved early after apheresis (93%). At the 9th mo of follow-up, 6 of 8 UC patients and 2 of 5 CD patients were still in clinical remission. At the 12th mo of follow-up, only 1 of 8 UC patients and 2 of 5 CD patients were in remission (Figure 4).

DISCUSSION

Currently, the use of steroid drugs is a common strategy for the treatment of acute inflammatory bowel disease. However, large doses of steroids are often necessary to control active diseases and some patients do not respond to this conventional treatment. Colectomy rate varies from 10% to 40% in these patients[12]. The treatment with cyclosporin in these patients can avoid acute colectomy in 57% of cases, but after a 6-mo follow-up period 73% of patients undergo surgery[13]. Azathioprine or 6-mercaptopurine has been reported to be beneficial for steroid resistant cases, but their use requires several weeks to get full effects[14].

Recent data from literature have pointed out that

granulocytapheresis, which acts on specific subpopulations of leukocytes involved in the inflammatory process, can represent a useful and probably much safe treatment for patients with ulcerative colitis or Crohn's disease[16, 17].

In fact it is well known that inflammatory bowel disease is associated with elevated circulating and tissue levels of leukocytes. Granulocytes are the first cells mobilizing to inflammation sites and interact with lymphocytes to orchestrate the inflammatory response. For these reasons the removal of granulocytes may be a logical therapeutic manoeuvre. Moreover, the good results obtained so far by granulocytapheresis have been attributed not only to the removal of granulocytes and monocytes, but also to its immunomodulatory effect[10, 11, 15, 16].

The goal of this study was to assess the safety and efficacy of GCAP in patients with active inflammatory bowel disease that was refractory to conventional drug therapy. In our small casuistry, the procedure was well tolerated and 93% of cases showed remission at the end of a five-week course of GCAP. No serious side effects were recorded and clinical/endoscopic remission lasted for six months in all the patients, achieved at the end of the therapeutic course ("responders"). Nine months after GCAP treatment, about 60% of responders were still in remission, without any significant difference between UC and CD patients. The remission rate dropped dramatically at the 12th mo, with slightly better outcome in CD patients.

In conclusion, this new approach to active steroid-refractory IBD seems an important innovation and a useful therapy after the failure of conventional treatments. GCAP is able to achieve clinical remission in a large proportion of "difficult" IBD patients. This new technique is virtually free of severe side effects and could be repeated more times if necessary.

We hope that our data could represent a stimulus for further trials aimed to evaluate the real usefulness of apheresis in IBD, to clarify the optimal length of treatment and to know which patients could get most benefit from it.

Abstract

AIM: To describe and discuss echo-enhanced sonography in the differential diagnosis of cystic pancreatic lesions.

METHODS: The pulse inversion technique (with intravenous injection of 2.4 mL SonoVue®) or the power-Doppler mode under the conditions of the 2nd harmonic imaging (with intravenous injection of 4 g Levovist®) was used for echo-enhanced sonography.

RESULTS: Cystadenomas frequently showed many vessels along fibrotic strands. On the other hand, cystadenocarcinomas were poorly and chaotically vascularized. "Young pseudocysts" were frequently found to have a highly vascularised wall. However, the wall of the "old pseudocysts" was poorly vascularized. Data from prospective studies demonstrated that based on these imaging criteria the sensitivities and specificities of echo-enhanced sonography in the differentiation of cystic pancreatic masses were > 90%.

CONCLUSION: Cystic pancreatic masses have a different vascularization pattern at echo-enhanced sonography. These characteristics are useful for their differential diagnosis, but histology is still the gold standard.

Key words: Cystic pancreatic lesions; Differential diagnosis; Echo-enhanced sonography

INTRODUCTION

Cystic tumours of the pancreas are rare, accounting for about 1% of all pancreatic neoplasms[1]. Cystadenomas and cystadenocarcinomas are the most frequently encountered cystic lesions[1-3]. There are problems in the differentiation of cystic pancreatic masses. It is obvious that the discrimination between these lesions is critical for prognosis and therapy[4].

Conventional transabdominal ultrasound displays no characteristic signs for the differentiation of cystic pancreatic tumours and the diagnostic accuracy is low[5-7]. The vascularization pattern is helpful for the tumour differentiation and can be investigated by fundamental power and colour Doppler sonography. However, there is a low sensitivity of these procedures for detecting low blood flow velocity or small vessels. The sensitivity can be increased by echo-enhancers, such as SonoVue®. Therefore, echo-enhanced sonography is an increasingly used procedure for the differentiation of pancreatic tumours[8, 9].

In this review, echo-enhanced sonography in the differential diagnosis of cystic pancreatic tumours is depicted and discussed.

MATERIALS AND METHODS

All patients were investigated first by conventional sonography using a dynamic sector scanner. A special preparation of the patients was not necessary. The pulse inversion technique or the power-Doppler mode under the conditions of the 2nd harmonic imaging was used for echo-enhanced sonography. The pulse inversion mode was used more frequently than the 2nd harmonic imaging.

For echo-enhanced sonography, the pulse inversion 2.4 mL SonoVue® (sulfur hexafluoride gas-based contrast agent, Bracco International B.V., Amsterdam, Netherlands) was injected intravenously, and the mechanical index varied between 0.1 and 0.2 (low MI procedure). The investigation could be done in real time, and lasted for approximately 2 min.

Echo-enhanced power Doppler sonography was started immediately after intravenous injection of 4 g

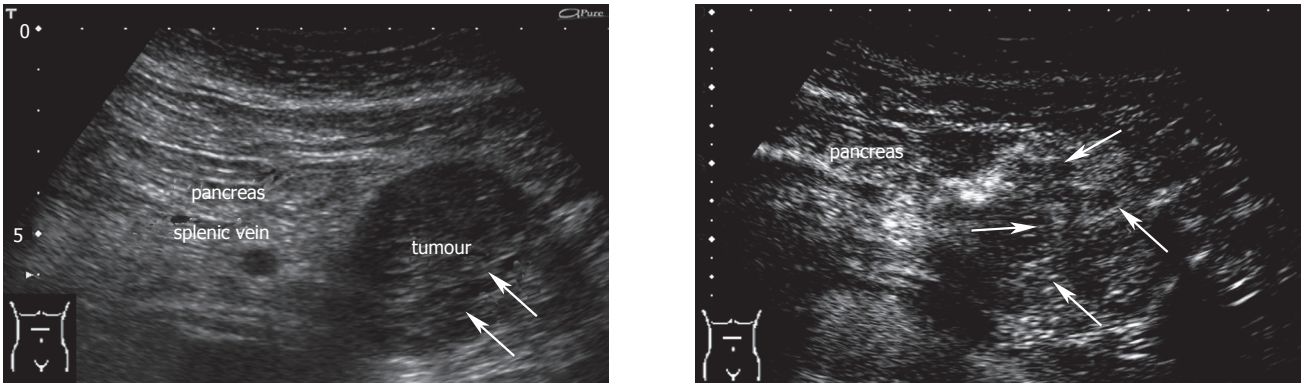

Figure 1 Cystadenoma at conventional and echo-enhanced ultrasound. **A**: A tumour at the pancreatic tail (5 cm in diameter) with small cystic areas (small arrows) and thin fibrotic strands; B: Highly vascularized tumour arteries (large arrows) along the fibrotic strands (maximum of contrastation 15 s after injection of the echo-enhancer).

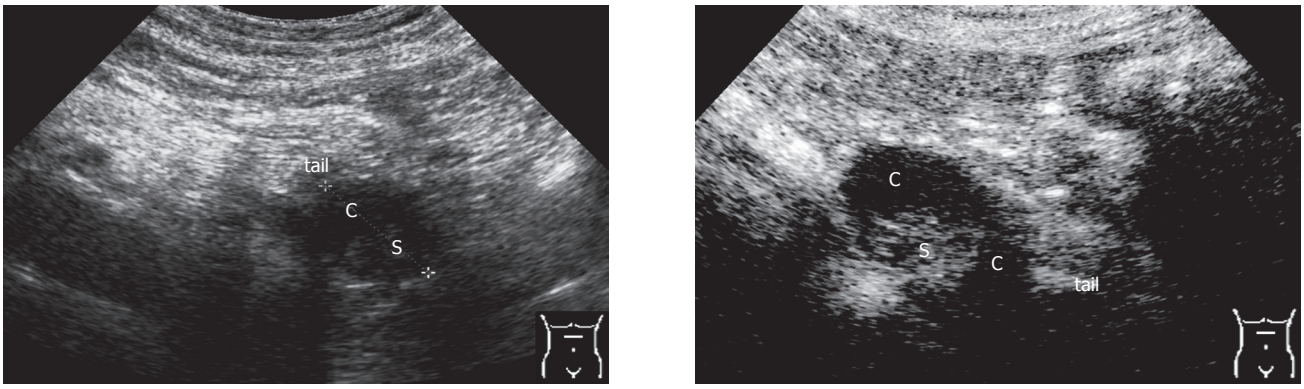

Figure 2 Cystadenoma at conventional and echo-enhanced ultrasound A: A tumour (7 cm in diameter) at the pancreatic tail with large cystic (c) and solid areas (s); **B**: A poorly vascularized solid (s) tumour (maximum of contrastation 15 s after injection of the echo-enhancer).

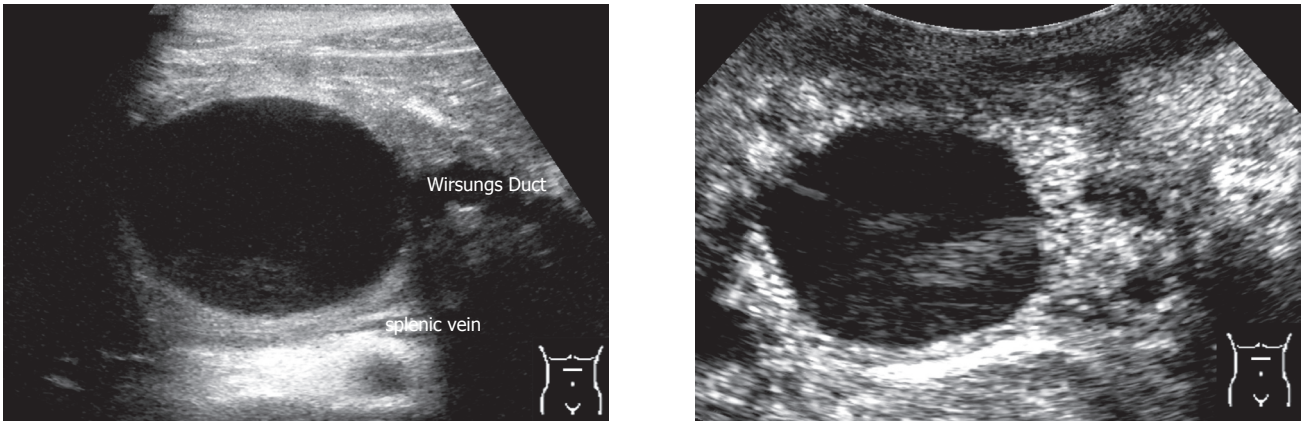

Figure 3 Pseudocust at conventional and echo-enhanced ultrasound A: A lesion with an echo-free pattern and a sharply delineated wall. The Wirsungs Duct is dilated; **B**: A highly vascularized wall (maximum of contrastation 20 s after injection of the echo-enhancer).

Levovist® (galactose-based contrast agent, concentration 300 mg/mL, Schering AG, Berlin, Germany). Intermittent sweeps were done, and the investigation lasted for approximately 2 min. One focus zone with depth adapted to the area of interest and a mechanical index of 0.8-1.3 (high MI procedure) should be used.

RESULTS

Criteria for the differentiation of pancreatic masses by conventional and echo-enhanced sonography[10, 11] are shown in Table 1. Cystadenomas consisting of small cystic areas (< 3 cm) and thin fibrotic strands are shown in Figure 1A. At echo-enhanced sonography highly vascularized solid tumour parts and arteries along the fibrotic strands are shown in Figure 1B. On the other hand, cystadenocarcinomas were found to have large cystic areas (about 5 cm) and solid tumour parts in the conventional ultrasound examination (Figure 2A). After injection of an echo-enhancer, poorly vascularized solid

Table 1 Criteria for differentiation of cystic pancreatic tumours with conventional ultrasound, fundamental power Doppler sonography, and echo-enhanced ultrasound[10, 11]

	Conventional ultrasound	Fundamental power Doppler sonography	Echo-enhanced sonography
Cystadenoma	• small cystic areas (often < 3 cm) • spoke-like pattern of fibrotic strands with small calcifications • no dilated Wirsung's duct	• no tumour vessels detectable	• highly vascularised tumour arteries along the fibrotic strands
Cystadeno-carcinoma	• large cystic areas (often > 5 cm) • solid areas • no dilated Wirsung's duct	• rarely tumour vessels with chaotic pattern detectable	• poorly and chaotic vascularised solid areas
Pseudocyst	• often echo-free pattern • sharply delineated wall • features of acute and/or chronic pancreatitis • signs of bleeding and/or calcifications • bowel infiltration is possible	• rarely tumour vessels detectable in "young cysts"	• "young cysts" (a few weeks of age) show often a highly vascular-ised wall • "old cysts" (a few months of age) show often a poorly vascularised wall

areas could be detectable (Figure 2B). Pseudocysts were found to be characterised by an echo-free pattern and a sharply delineated wall (Figure 3A). In the remaining pancreatic parenchyma features of chronic inflammation such as calcifications and a dilated Wirsung's duct could also be found. After injection of an echo-enhancer the wall of the pseudocysts was highly ("young cyst", Figure 3B) or poorly vascularized ("old cysts").

A recently published study with 31 patients showed that echo-enhanced sonography could differentiate cystic neoplasms from pseudocysts[12]. The sensitivity of echo-enhanced sonography with respect to diagnosing cyst adenomas was 95% and its specificity was 92%. The corresponding values for pseudocysts were both 100%. However, one cystadenoma was misdiagnosed as a cystadenocarcinoma, and vice-versa. The morphological variability of these cystic lesions at conventional ultrasound and the difficulties in the evaluation of the vascularization of cystic masses might be responsible for the false results. On the other hand, only 27% of cystadenomas and 67% of pseudocysts could be correctly classified by conventional ultrasound[12].

DISCUSSION

So far not a single ideal diagnostic procedure is available for the differentiation of cystic pancreatic tumours. Histology is the gold standard but nevertheless can produce false negative results. The correct differential diagnosis of cystic neoplasms of the pancreas has proven to be difficult and imaging techniques have low correct diagnosis percentages[5, 13-15], which can be attributed to the particular anatomicropathological features of these tumors and the difficulty to discriminate them from pseudocysts.

Conventional ultrasound cannot provide the reliable characteristics of different cystic pancreatic lesions. Thus, it is difficult to distinguish these tumours. Cystadenomas often consist of small cystic areas and a spoke-like pattern of fibrotic strands. In contrast, cystadenocarcinomas often show large cysts (frequently larger than 5 cm in size). Pseudocysts are frequently echo-free and have a sharply delineated wall.

The angiographic vascularization pattern contributes to the differentiation of pancreatic tumours[16-18]. Since cyst-adenomas are characterised by their hypervascularization, they are often found to be hypovascularized with a chaotic pattern. However, the diagnostic accuracy of angiography is low because it is not possible to investigate the macroscopic tumour features[17].

The vascularization of tumours may also be studied by fundamental power and colour Doppler sonography. However, the sensitivity of these procedures is low in detecting low blood flow velocity or small vessels. This sensitivity can be improved by echo-enhancers, such as SonoVue® and Levovist®. Levovist® consists of air-filled microbubbles which enhance the Doppler signal at 20-30 dB[19-21]. However, the signal intensity of echo-enhanced sonography from flowing blood is lower than that of tissue movements. To overcome these difficulties the technique of the 2nd harmonic imaging has been developed based on the property of microbubbles to resonate and emit harmonic waves in an ultrasound field with a frequency of 1-5 MHz. If the harmonic frequency is to be detected at twice the transmitted frequency, the procedure is called the 2nd harmonic imaging. Since tissue particles have fewer of the 2nd harmonic waves than microbubbles, the signals of echo-enhancers are better distinguishable[19].

The new contrast agent Sonovue® is used more frequently for echo-enhanced sonography. Furthermore, the 2nd harmonic imaging can be replaced partially by the pulse inversion imaging technique. There are observations that with this new procedure more favourable results can be achieved than with the 2nd harmonic imaging. The 2nd harmonic imaging cannot separate the transmitted and

received harmonic signals completely because of limited bandwidth. However, pulse inversion imaging avoids these bandwidth limitations using characteristics specific to microbubble vibrations to subtract rather than filter out the fundamental signals. Because this imaging technique transmits two reciprocal pulses, leading to a subtraction of the two fundamental signals, it allows the use of broader bandwidths for the transmission and reception yielding an improved resolution and can provide an increased sensitivity to contrast[22]. However, comparative results of large prospective studies are missing.

We want to point out that according to our experience, conventional ultrasound, power and colour Doppler sonography, and echo-enhanced sonography should not be used as single imaging techniques, exclusively. Conventional ultrasound is the basic sonographic method, and tumour differentiation is hardly possible based on an echo-enhanced sonographic examination alone. Echo-enhanced sonography offers more diagnostic criteria than conventional ultrasound alone, but similar to the angiography it is impossible to investigate macroscopic tumour features with this procedure alone. Therefore, all sonographic procedures should be performed in combination.

The characteristic signs of pancreatic tumours at echo-enhanced sonography have been published [10, 11]. Solid areas of cystadenocarcinomas and the wall of the " old pseudocysts" are found to be hypovascularized. In contrast, solid parts of cystadenomas and the wall of the "young pseudocysts" are mostly hypervascularized. A recently published study showed that echo-enhanced sonography can differentiate cystic neoplasms better than conventional ultrasound alone[12].

The successful treatment of cystic pancreatic tumours requires a highly sensitive and specific diagnostic procedure. Echo-enhanced sonography can fulfil this requirement. However, histology is still the gold standard for the differentiation of cystic pancreatic lesions.

Abstract

AIM: To clarify the innervation of the antro-pyloric region in humans from a clinico-anatomical perspective.

METHODS: The stomach, duodenum and surrounding structures were dissected in 10 cadavers, and immersed in a 10mg/L solution of alizarin red S in ethanol to stain the peripheral nerves. The distribution details were studied to confirm innervations in the above areas using a binocular microscope. Similarly, innervations in 10 Suncus murinus were examined using the method of whole-mount immunohistochemistry.

RESULTS: The innervation of the pyloric region in humans involved three routes: One arose from the anterior hepatic plexus via the route of the suprapyloric/supraduodenal branch of the right gastric artery; the second arose from the anterior and posterior gastric divisions, and the third originated from the posterior-lower region of the pyloric region, which passed via the infrapyloric artery or retroduodenal branches and was related to the gastroduodenal artery and right gastroepiploic artery. For Suncus murinus, results similar to those in humans were observed.

CONCLUSION: There are three routes of innervation of the pyloric region in humans, wherein the route of the right gastric artery is most important for preserving pyloric region innervation. Function will be preserved by more than 80% by preserving the artery in pylorus-preserving pancreaticoduodenectomy (PPPD). However, the route of the infrapyloric artery should not be disregarded. This route is related to several arteries (the right gastroepiploic and gastroduodenal arteries), and the preserving of these arteries is advantageous for preserving pyloric innervation in PPPD. Concurrently, the nerves of Latarjat also play an important role in maintaining innervation of the antro-pyloric region in PPPD. This is why pyloric function is not damaged in some patients when the right gastric artery is dissected or damaged in PPPD.

INTRODUCTION

With the concept of less invasive surgery, pylorus-preserving pancreaticoduodenectomy (PPPD) has taken the place of conventional Whipple pancreaticoduodenectomy as a standard operative procedure for the treatment of various benign and malignant diseases in the periampullary region, even pancreatic head carcinoma, since 1978[1-5]. Early delayed gastric emptying has been described as a common and frustrating complication after this procedure, which occurs in 20% to 46% of patients[6-16]. Although delayed gastric emptying is self-limiting, not life-threatening, and can be treated conservatively[7,9,17], it results in discomfort and a significant prolonging of

the hospital stay, and so contributes to increased hospital costs[7,8,18,19]. However, the pathogenesis of delayed gastric emptying after PPPD remains controversial.

The procedure may impair gastric peristalsis. The duodenal pacemaker, which is located 0.5 to 1 cm distally from the pylorus, should therefore be preserved to avoid disturbances in normal gastric peristalsis[20]. Gastric arrhythmias may be another cause of delayed gastric emptying in the early postoperative period, probably exacerbated by intra-abdominal complications[21]. Problems caused by the surgical procedure itself include injury to the nerves of Latarjat or the placement of suture material through the pyloric muscle. In addition, ischemia of the duodenal stump and antropyloric muscle mechanisms could influence gastric emptying, although mucosal edema at the site of anastomosis and peri-anastomotic fluid collection seem to be more common problems[22]. In regard to maintaining the pylorus as a functional unit, it is of paramount importance to maintain normal innervation of the antro-pylorus, an adequate blood supply and a pyloric muscle unimpeded by sutures[1,23].

Moreover, there has been no detailed description concerning clinico-anatomical and morphologic studies of the innervation of the antro-pyloric region in other literature, although there are some records of human pyloric innervation in literatures[24-27]. Therefore, we attempted to clarify the innervation of the antro-pyloric region in humans from a clinico-anatomical point of view, and to evaluate the innervation-preserving procedure of PPPD and its modified procedures, by using the peculiar method of labeling and dissecting the autonomic nerves of the viscera, not the current dissection of gross anatomy as in our previous studies[28-30]. Furthermore, the experimental animal, *Suncus murinus*, has been used for a comparative study to demonstrate general morphologic characteristics more similar to humans than other current laboratory animals, e.g., mouse, rat and rabbit[28-31].

MATERIALS AND METHODS

Cadavers

The study was performed on 10 cadavers (5 men and 5 women) with a mean age of 79.8 (range, 50 to 94) years. All cadavers were selected from bodies used for research and practice of anatomy at Kanazawa University School of Medicine during the years 1999-2000, and were free from diseases of the liver, stomach, duodenum, pancreas, and their surrounding areas (Table 1).

Animals and tissue preparation

Adult laboratory house musk shrews, *S. murinus*, were obtained and maintained from a closed breeding colony bred in our laboratories in the Department of Anatomy and Neuroembryology, Kanazawa University, Japan. The animals were housed and handled in accordance with the Guide for the Care and Use of Laboratory Animals and the Guide for the Care and Use of Experimental Animals of the Canadian Council on Animal Care. Briefly, all shrews were kept individually after weaning (20 d after birth) in plastic cages equipped with a wooden nestbox containing paper strips, and were kept in a conventionally conditioned animal room: 23 ℃ to 27 ℃, no humidity control, and 14 L: 10 D. Commercial trout pellets containing 45.0% protein, 3.5% fat, 3.0% fiber, 13.0% ash and 26.2% complex carbohydrate (Nippon Haigou Shiryou, Tokyo, Japan) and water were supplied *ad libitum*. The mother colony, JIc: CR, is maintained in the Central Institute for Experimental Animals, Kawasaki, Japan[28]. Adult animals (6 females and 4 males, weighing 45-80 g) were first anesthetized with ether and received an intraperitoneal injection of a solution of urethrane (sodium ethyl carbamate, 900 mg/kg). After each *S. murinus* was completely narcotized, the abdominal cavity was opened, and a catheter was inserted retrogradely into the abdominal aorta at the level immediately above the bifurcation of this artery into the common iliac arteries. Perfusion was commenced with normal saline containing heparin (10 KU/L), and thereafter with phosphate-buffered saline (PBS) containing 40 g/L paraformaldehyde. After perfusion, the animals were injected with neoprene latex to label the blood vessels in the pylorus region. Thereafter, the abdominal organs including the stomach, duodenum, common bile duct, and pancreas were extracted en bloc with the related nerves and vessels, postfixed with 40 g/L paraformaldehyde in PBS (pH 7.4) at 4 ℃ overnight to prepare for whole mount immunostaining.

Anatomical procedures of under-stereoscopic microscopy

The anatomical procedures of the cadavers were performed, according to our previous description[29,30], as follows. From the adult autopsy, the viscera of the upper abdomen (including the liver, pancreas, lower esophagus, stomach, and duodenum) were resected en masse with the abdominal aorta (region including the celiac artery and superior mesenteric artery), portal system, and nerves (including the vagus nerve, celiac ganglion, and plexus). The resected specimens were immersed in a 10 mg/L solution of alizarin red S (Wako, Osaka, Japan) in ethanol to melt the fat tissue and stain the peripheral nerves. The solution was changed 3 times every 2 to 3 d, in principle, but this process may be prolonged if necessary depending on the degree of progression of elimination of fat and staining. The area of each sample surrounded by the horizontal plane that passed through the portal region and the lower margin of the horizontal part of the duodenum and the sagittal plane that passed through the descending part of the duodenum and hilum of the spleen was dissected to the depth of the celiac plexus with the aid of a stereoscopic microscope (magnification, ×40), keeping the sample immersed completely in 100% ethanol. In dissection, the lymphatic vessels and lymph nodes were removed, and particular attention was paid to preserve not only the nerves but also the arteries and veins around the stomach including the hepatogastro mesenteriolum, hepatoduodenal ligament and lower esophagus. Figures 1 and 2 show two such dissections.

Whole mount immunohistochemistry

The whole mount immunostaining procedures for the *S. murinus* were performed as previously described[28,30]. Briefly, after rinsing in PBS, the fixed specimens were treated with 10 g/L periodic acid for 20 min to prevent

any intrinsic peroxidase reaction. They were then incubated in freshly prepared 5 g/L papain (Sigma) in 0.025 mol/L Tris-HCl buffer (pH7.6) for 1 h and 25 g/L, 50 g/L, and 100 g/L sucrose in PBS for 30 min, respectively, followed by freezing and thawing thrice. The specimens were incubated with primary antibody (NFP-Ab) in PBS containing 2 g/L bovine serum albumin (BSA), 3 g/L Triton X-100, and 1 g/L sodium azide for 3 d at 4 ℃. After a thorough wash in PBS, the specimens were then incubated with secondary antibody labeled with peroxidase-conjugated affinity-purified sheep anti-mouse IgG (HRP) in PBS containing 2 g/L BSA and 3 g/L Triton X-100 for 3 d at 4 ℃. After a thorough wash in PBS, coloration was performed in 0.05 mol/L Tris-HCl buffer containing 20 mg/L 3,3'-diaminobenzidine (DAB) and 0.1 ml/L H_2O_2 for 1 to 3 d at 4 ℃. The stained preparations were then stored in glycerin to obtain transparency. The primary antibody was anti-neurofilament protein (NFP) antibody, a monoclonal mouse anti-all neurofilament consisting of three subunit proteins: NF-H (200 ku), NF-M (160 ku), and NF-L (70 ku) (M0762, lot 089, clone: 2F11, Dako).

RESULTS

In human

The innervation of the pyloric region in human involved three routes: via the right gastric artery, the nerves of Latarjet, and the infrapyloric artery.

Via the suprapyloric/supraduodenal branch of the right gastric artery

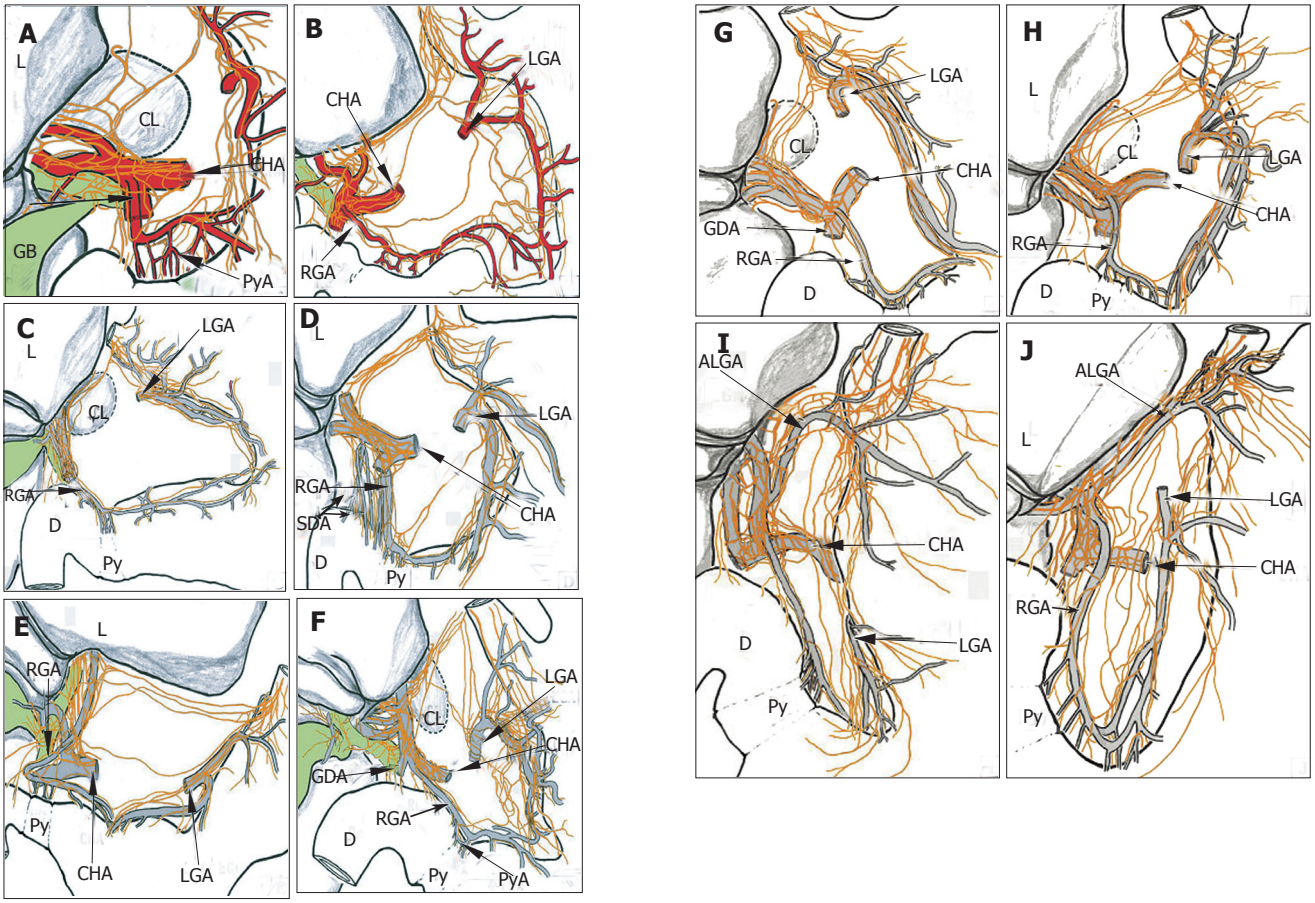

Figure 3 Diagram indicating the distribution in and around the cardia, the lesser curvature, the porta hepatica and the antro-pyloric region in 10 cadavers. Among them, **A** and **B** are diagrams of Figures 1A and 2, respectively. Five specimens, **B, D, F, I** and **J**, showed hepatic divisions joining directly to the right gastric artery, while, for the other specimens, after joining to the proper hepatic or hepatic artery, the nerves sent off some offshoots to the right gastric artery, and innervated the pyloric region. ALGA, accessory left gastric artery; CHA, common hepatic artery; CL, caudal liver; GB, gallbladder; L, liver; LGA, left gastric artery; Py, pylorus; PyA, pyloric artery; RGA, right gastric artery; SDA, supra-duodenal artery.

The hepatic division of the vagus, arising from the anterior vagal trunk, ran through the hepatogastric ligament near the edge of the liver (caudal liver), and joined the anterior hepatic plexus in the hepatoduodenal ligament. The plexus, containing the parasympathetic and sympathetic fibers (the latter originate from the celiac plexus), wound around the proper hepatic artery, then the suprapyloric or supraduodenal branch which comes from the right gastric artery, sent some branches to the pyloric region in the superior part of the pyloric regions (Figures 1, 2). This route was displayed in all ten specimens.

There was variation in the number of hepatic divisions. The total number of hepatic divisions was 46 (average, 4.6) in the 10 specimens in this study. The position where the hepatic division joined the anterior hepatic plexus occurred at different levels between the hepatic hilum and the root of the right gastric artery(Table 1, Figure 3). There were 2 cases of accessory left gastric artery in the 10 specimens. The hepatic division ran along the arteries to the hepatic hilum in these 2 cases(Figures 3I and 3J).

The branches, arising from the origin of the hepatic division, sent single or double descending branches of the hepatic division, ran in the lesser omentum, did not reach the proper hepatic artery or join the anterior hepatic plexus, joined directly to the right gastric artery, and then entered the pyloric region. Five cases of this route were observed in the 10 cadavers (Table 1, Figures 3B, 3D, 3F, 3I, and 3J).

Via the anterior and posterior gastric divisions

The anterior and posterior gastric divisions, namely the nerves of Latarjet, extended to and ran along the gastric lesser, while giving off some offshoots to the lesser curvature, sending some peripheral nerve fibers to the antro-pyloric region. The nerves of Latarjet passed through the lesser omentum, which lies 0.5 to 1.0 cm from the lesser curvature, or extended and anastomosed with the offshoots along the right gastric artery, or lay beneath the serosa of the gastric wall, entered the antro-pyloric region. The route was observed in all cases (Table 1, Figures 1, 2, and 3).

Via the infrapyloric artery or retroduodenal branches

There is always one or several infrapyloric arteries or/and retroduodenal branches, intended for the posterior-lower region of the pylorus. All of these arteries arise either from the gastroduodenal artery, or from one or the other of these two terminal branches, the right gastroepiploic

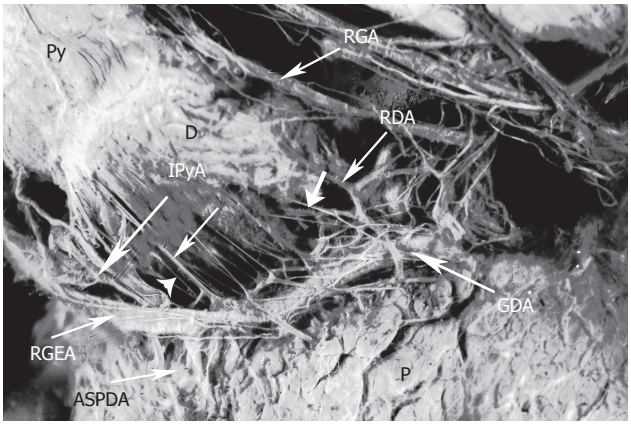

Figure 4 An example of innervation in the posterior part of the pylorus. The stomach was raised. The nerves originating from the right gastroepiploic artery (RGEA) or the gastroduodenal artery (GDA) running along the retroduodenal artery (RDA) (white arrow) or the infrapyloric artery (IPyA) (white arrowhead) reached the first duodenum posterior part and the pylorus of the posterior part.

artery, or the cranial and ventral pancreaticoduodenal artery.

This route with the arteries supplying the posterior-lower region of the pylorus, passed the nerve branches to the pyloric region. The nerve branches, arising from the anterior hepatic plexus, ran along the gastroduodenal artery, or the right gastroepiploic artery, to the infrapyloric artery or/and retroduodenal branches, reached the posterior-lower region of the pylorus. The route was observed in all cases (Figure 4).

In suncus murinus

Firstly, it is necessary to describe the morphological characters of the pyloric region in *S. murinus*. The pylorus closed the duodenal papilla, supplied by the branches of the gastroduodenal artery. The latter sent the branches to the duodenal papilla and the pyloric region. The arterial branch that supplied the pyloric region corresponded to the right gastric artery in humans. However, there existed no ramus anastomoticus between this artery and the left gastric arteries in *S. murinus* (Figure 5). There was the lesser omentum in this animal, and the right gastric artery sent anterior and posterior branches to the anterior and posterior of the pyloric region. Furthermore, there was no infrapyloric artery arising from the gastroduodenal artery in contrast to humans. Even though there are these differences, the innervation of the pyloric region in *S. murinus* was very similar to that in humans.

Via the branches of the right gastric artery

In *S murinus*, the nerves originating from hepatic plexus, ran along the gastroduodenal artery, the right gastric artery, and reached the pyloric region. This route was simple, and did not form the ramus anastomoticus with the anterior or posterior gastric branches, which originate from the vagal trunk or the left gastric artery. The innervation was observed in all cases (Figure 5).

Via the lesser omentum

In *S murinus*, the anterior and posterior gastric branches, corresponding to the Latarjet nerves in humans, while giving off some divisions to the lesser curvature and the gastric wall, sent some branches to the pyloric regions in all cases (Figure 5). The posterior-lower region of the pylorus in *S murinus* was innervated by nerve branches originating from the right gastric artery, in constrast to humans. The anterior and posterior gastric branches ran along the lesser omentum and close to the lesser curvature, or lay beneath the serosa of the gastric wall. Similarly, the route passing through the lesser omentum was also observed in some specimens, and these nerves originated from the anterior or posterior vagal trunk directly. The innervation was observed in all cases (Figure 5).

DISCUSSION

The present paper is concerned with a detailed observation of the innervation of the antro-pyloric region, with the objective of providing an anatomical basis for surgical operations in this region, especially concerning 'organ and function-preserving surgical procedures' like PPPD.

There are three routes of pyloric innervation in humans. One is the superior region of the pylorus, which is related to the hepatoduodenal ligament, whereby the nerve branches arose from the anterior hepatic plexus containing the branches coming from the hepatic division of vagus. The nerves ran along the right gastric artery, via the suprapyloric or supraduodenal branch, intended for the antro-pyloric region. The second route is the posterior-lower region of the pylorus, which is related to the gastro-pancreatic ligament. The nerves ran along the gastroduodenal or right gastroepiploic artery, to the infrapyloric artery, and reached the antro-pyloric region. The third route is the lower antrum region, which is related to the left gastric artery and the nerves of Latarjet. This route involves the branches of Latarjet nerves passing through the lesser curvature, and entering the antro-pyloric region. The animal model, *S murinus,* used in this study, allowed the complete anatomic observation of cadavers, exhibited the important arterial supply routes of the pylorus and anterior and posterior gastric divisions for the innervation of the pylorus.

The route of the superior region is the most important for pyloric innervation, in which the right gastric artery shows a core mission (main rule). The nerves of this route contain both sympathetic and parasympathetic fibers, originating from either the anterior hepatic plexus which arise from the celiac plexus, or the hepatic division of the anterior vagal trunk which joins the proper hepatic artery to the right gastric artery. The route was observed in all 10 cadavers. There were 4 cases of hepatic division distal to the hepatic edge, the division passing through the hepatogastric ligament, terminating in the right gastric artery in 10 cadavers. But only one case showed the pattern illustrated by McCrea[24], whereby a single descending branch of the hepatic division directly reached the pylorus. We agree with Skandalakis *et al*[27] that this pattern is typical but not universal. Namely, pyloric branches of the hepatic division do not, usually, directly reach the pyloric region, but pass via the arterial supply of the region, as the right hepatic artery and its branches.

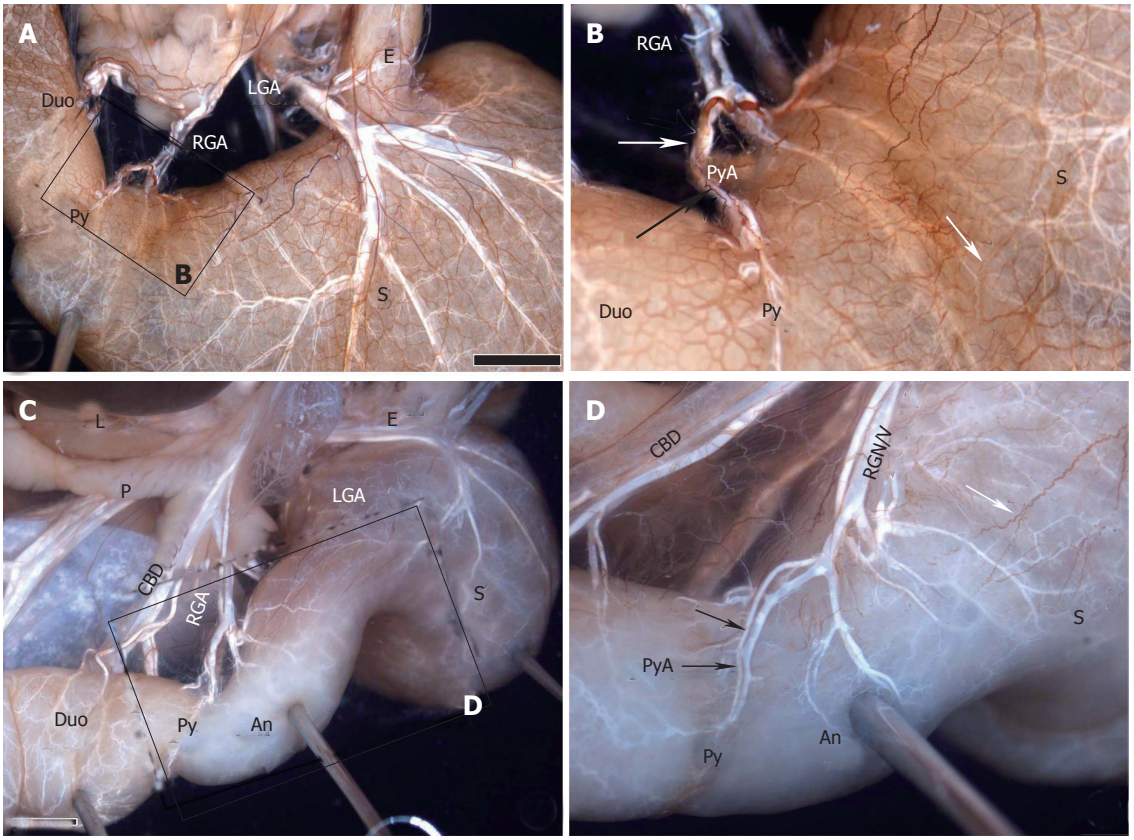

Figure 5 Two cases showing innervation of the pyloric region (Py) in *Suncus murinus* by whole-mount immunostaining. High magnifications of the boxed areas in **A** and **C** are shown in **B** and **D.** White arrows show the nerves of Latarjet intended for the antro-pyloric region. Black arrows indicate the nerves arising from the right gastric artery (RGA), running along the pyloric artery (PyA), and reaching the pyloric region. An, pyloric antrum; CBD, common bile duct; Duo, duodenum; E, esophagus; L, liver; LGA, left gastric artery; P, pancreas; RGA/V, right gastric artery/vein; S, stomach. Scale bar = 2 mm in A and B.

The right gastric artery arises from the hepatic artery and proceeds to the first portion of the duodenum (the supraduodenal artery), the pylorus and the antrum (the suprapyloric branch) along the lesser curvature. These routes via these arteries are important for pyloric innervation via the superior region of the pylorus. The preservation of the right gastric artery and its branches is potentially of great importance in providing earlier gastric emptying after operation. The drawback of pyloric preservation is a prolonged period of gastric suction. This time can be shortened by attention to the preservation of the supraduodenal artery and vagal innervation of the antrum, which is essential for gastric emptying[7]. In any event, as there was a reliable route of the right gastric artery, it is not necessary to preserve the hepatogastric ligament in order to preserve the route in clinic practice. In principle, it is only important to preserve the right gastric artery in order to preserve the innervation and function of the pylorus in PPPD.

For the route of the nerves of Latarjet, innervation originating from the anterior and posterior gastric branches of the nerves of Latarjet passed through the lesser omentum close to the lesser curvature, or extended to and anastomosed with the offshoots along the right gastric artery, or lay beneath the serosa of the gastric wall, and entered the antro-pyloric region. Skandalakis *et al* [26] reported that the nerves of Latarjet could be traced distally to about the level of the incisura in most specimens, but in many cases it reached the pylorus, and in six cases it was visible as far as the first part of the duodenum. It is possible that the nerves of Latarjet innervate the antro-pyloric region according to our observations in humans and *S. murinus*. Great care must be taken to preserve the blood supply from the left gastric artery to the lesser curvature of the stomach and pylorus in PPPD.

For the innervation of the posterior-lower region of the pylorus, it was disregard ordinarily. The route is via the arterial supply of the posterior-lower region of the pylorus. The branches are sent off by the gastroduodenal or the right gastroepiploic artery, termed by the infrapylorus branch or artery, or the retroduodenal branches. These branches come from the gastroduodenal artery in 30% of cases, from the right gastroepiploic artery in 44% of cases or from the ventral pancreaticoduodenal arch in 20% of cases[32]. The gastroduodenal artery should probably be severed distally to its first branch and should be preserved in cases of chronic pancreatitis where dissection could proceed by taking the pancreaticoduodenal artery at its origin from the gastroduodenal artery. Equal attention must also be given during the procedure to preserving innervations to the antrum and pylorus[9]. The gastroepiploic artery, with its large ascending pyloric branch, should probably be taken close to its origin from the gastroduodenal artery[9]. The origin of the innervation in

this route is similar to that of the superior region, coming from the anterior hepatic plexus. Hence, the innervation also contained both the sympathetic and parasympathetic fibers. If the right gastric artery is damaged, the route is able to compensate by its function in innervation. Grace *et al*[33] emphasized that an intact neurovascular supply to the pylorus and the first part of the duodenum is essential for the success of the pylorus preserving operation. By not ligating the gastroduodenal artery and right gastric artery at their origins and not freeing the tissues along the lesser curvature of the antrum and the gastrohepatic ligament-all these tissues remaining intact-the surgeon cannot rotate the proximal duodenum and antrum anteriorly and to the patient's left in PPPD. Thereby, it is advantageous to preserve all blood supply and innervation to antrum, pylorus, and proximal duodenum[16]. In fact, innervation of the antro-pyloric region takes several routes. When dissecting the lymph nodes in the hepatoduodenal ligament, the nerve branches originating from the anterior hepatic plexus to the right gastric artery could be damaged, however, as there are other routes of the posterior-lower region of the pylorus and the nerves of Latarjet, their influence on pyloric function may often be unclear.

In conclusion, we demonstrated the detailed description of the innervation of the antro-pyloric region from clinico-anatomical and morphologic perspectives in this study. The useful methods of whole mount immunostaining with a peripheral neuron marker for *S murinus*, and the alizarin red S staining technique for humans are effective for peripheral nerve labeling, as shown in our studies. There are three routes of pyloric innervation in humans, wherein the route of the right gastric artery is the most important for preserving pyloric region innervation. The function is preserved by more than 80% by preserving the artery in PPPD. However, the route of the infrapyloric artery should not be disregarded. This route is related to several arteries (the right gastroepiploic and gastroduodenal arteries), and the preservation of these arteries is advantageous for preserving pyloric innervation in PPPD. Concurrently, the nerves of Latarjet also perform an important role in maintaining innervation of the antro-pyloric region in PPPD. This is why the pyloric function is not damaged in some patients if the right gastric artery is dissected or damaged in PPPD.

Abstract

AIM: To estimate the standard liver weight for assessing adequacies of graft size in live donor liver transplantation and remnant liver in major hepatectomy for cancer.

METHODS: In this study, anthropometric data of body weight and body height were tested for a correlation with liver weight in 159 live liver donors who underwent donor right hepatectomy including the middle hepatic vein. Liver weights were calculated from the right lobe graft weight obtained at the back table, divided by the proportion of the right lobe on the computed tomography.

RESULTS: The subjects, all Chinese, had a mean age of 35.8 ± 10.5 years, and a female to male ratio of 118:41. The mean volume of the right lobe was 710.14 ± 131.46 mL and occupied 64.55% ± 4.47% of the whole liver on computed tomography. Right lobe weighed 598.90 ± 117.39 g and the estimated liver weight was 927.54 ± 168.78 g. When body weight and body height were subjected to multiple stepwise linear regression analysis, body height was found to be insignificant. Females of the same body weight had a slightly lower liver weight. A formula based on body weight and gender was derived: Estimated standard liver weight (g) = 218 + BW (kg) x 12.3 + gender x 51 (R^2 = 0.48) (female = 0, male = 1). Based on the anthropometric data of these 159 subjects, liver weights were calculated using previously published formulae derived from studies on Caucasian, Japanese, Korean, and Chinese. All formulae overestimated liver weights compared to this formula. The Japanese formula overestimated the estimated standard liver weight (ESLW) for adults less than 60 kg.

CONCLUSION: A formula applicable to Chinese males and females is available. A formula for individual races appears necessary.

Key words: Estimated standard liver weight; Liver tranplantation

INTRODUCTION

Small-for-size graft is a common problem in live donor liver transplantation[1]. In major hepatectomy, a small remnant liver is a key factor attributing to hospital mortality[2], even in the non-cirrhotic liver[3]. Size of the partial liver graft or the remnant liver is often expressed as a percentage of the estimated standard liver weight (ESLW) of the patient. Very often, the native liver of a transplant recipient is small and cirrhotic, and that of a patient undergoing major hepatectomy houses a large tumor. The size of the patient's liver, therefore, has little bearing on the preoperative assessment. Under both circumstances, reference to ESLW has a clinical relevance. The Shinshu group of Japan deduced a formula by drawing a relationship between the estimated standard liver volume (ESLV) and body surface area (BSA) from 96 patients who underwent abdominal computed tomography (CT), yet without liver diseases: ESLV (mL) = 706.2 × BSA (m^2) + 2.4[4]. BSA was derived from the clinical parameters of body weight (BW) and body height (BH) as described by DuBois and DuBois[5]. In view of the low mean age (11.1 years) of the patients in the study, the Shinshu group subsequently validated the formula by the same methodology in an independent sample of 96 adult live liver donors[6]. Nonetheless, this formula when applied to Caucasians underestimates the liver volume from studies based on autopsy data[7] and CT of patients without liver diseases[8].

Underestimation of liver volume was even found in another group of Asian population, the Koreans. In this Korean group the increase in liver volume in relation to BSA showed a nonlinear relationship. A piecewise linear model and a nonlinear model have thus been developed

in Korea[9]. In another study, a sample of 33 Chinese in-patients admitted for abdominal ailments apart from liver diseases were evaluated by CT. The main purpose of the study was to use them as control in comparison with cirrhotic livers and not intended for a broader application of liver size estimation[10]. As early as the sixties, it was pointed out that females of the same body size as males have a smaller liver[11]. A study of a wider scale recently has affirmed this concept[12]. Our study was to clarify the above issues by analyzing the right lobe graft weight which was measured directly on the back-table during donor right hepatectomy in healthy live liver donors. The weight of the whole liver was calculated by the measurements of the liver volumes from CT.

MATERIALS AND METHODS

Study design

From May 10, 1996 to October 25, 2004, 182 consecutive right lobe live donor liver transplants were performed at the University of Hong Kong, Queen Mary Hospital. These 182 live liver donors being evaluated and operated were healthy with normal liver biochemistry. None of them was hepatitis B or C carriers, or had the habit of alcohol consumption. Donor anthropometric data including age, gender, BW (measured to the nearest 0.5 kg), and BH (measured to the nearest 1 cm) were recorded prospectively and entered into a liver transplantation database by 2 designated liver transplant research assistants. BSA was calculated by the formula by DuBois and DuBois: BSA (m^2) = BW (kg)$^{0.425}$ × BH (cm)$^{0.725}$ × 0.007184[5]. Body mass index = BW/BH × BH. CT of the donors was performed before the donor operation. Estimation of the liver volumes on CT was done by 3 dedicated radiologists using the Heymsfield method[13]. They had no information of the body size of the live liver donors or the liver transplant recipients. All subjects underwent single slice spiral CT (HiSpeed Advantage System; General Electric Health Care, Milwaukee, WI) and multi-slice CT study (LightSpeed QX/i 4-MDCT or LightSpeed 16-MDCT, General Electric Health Care, Milwaukee, WI) from 2000. Cuts were made at 5 to 7.5 mm intervals and continuously. Demarcation of the right and left portions of the liver was made by tracing along the middle hepatic vein, corresponding to the Cantlie's line. Volumes of the right lobe plus right caudate lobe (segment 1r) and the left lobe plus left caudate lobe (segment 1l)[14,15], were measured independently. All but 1 donor underwent donor right hepatectomy including the middle hepatic vein. This donor's right lobe graft did not include the middle hepatic vein for anatomical reason (case no. 85). The donor was a non-Chinese, and was therefore excluded. Details of the donor right hepatectomy have been described elsewhere[16]. In short, the transection line was determined by temporary inflow control. Transection by Cavitron ultrasonic surgical aspirator (CUSA; Valleylab, Boulder, CO), was just onto the left of the middle hepatic vein, including the latter into the right lobe liver graft. The right lobe liver grafts were perfused with University of Wisconsin Solution (NPBI, Emmer-Compascuum, the Netherlands), and from case no. 110 of the series, with histidine-tryptophan-ketoglutarate solution (Dr. Franz Köhler, Chemie GmbH, Alsbach-Hähnlein, Germany). The gallbladder was removed in the early phase of the hepatectomy during hilar dissection. No parts of the inferior vena cava, triangular ligament, or coronary ligament were included. The right lobe liver grafts were then weighed at the back-table. The weight of the whole donor liver was calculated by the right lobe graft weight (GW) divided by the volume fraction of the right lobe in relation to the entire liver as measured on the CT.

Exclusion criteria

We excluded 23 donors over this entire period of 8 years from this study. These included fatty change of the liver over 10% as documented by biopsy of the liver graft intraoperatively (n = 9). Non-Chinese donors (n = 6) were also excluded. The above 2 conditions occurred in 1 of the donors (n = 1). Donors with missing data of height were also excluded (n = 4). Donors with BW (n = 2) or BH (n = 1) lying beyond 97.5% were excluded. The number of subjects for analysis thus became 159.

Statistical analysis

Following testing for normal distribution (Kurtosis and Skewness tests), data were expressed as mean ± SD. Simple linear regression analysis by the least-squares fit method was used to plot the relation between calculated liver weight against BSA. This was then done with BW, and also BH as independent variables. Male and female subjects were analyzed separately. By stepwise multiple linear regression analysis, the correlation between calculated liver weight as a dependent variable and with BW and BH as independent variables, and gender as a binary factor, was tested. Goodness of fit of the formula was tested by analysis of residuals. Formulae deduced from other studies and this study were used to calculate the ESLW using BW, BH, BSA, and gender of these 159 subjects as appropriate[4,7-9,11,12,17,18]. ESLV derived from the respective formulae[4,7-10,18] was converted to ESLW by a factor of 1.19 mL/g as derived from analysis of data from this study. This was obtained by plotting liver volume on CT against calculated liver weight of these 159 subjects. The ESLW so derived was compared with the calculated liver weight of this series by 2-sided paired-samples t test. $P < 0.05$ was considered statistically significant. Regression lines of representative series were drawn and compared with the regression line of this study[4,8,9,12]. All statistical analyses were performed by SPSS Version11.0 program (SPSS, Chicago, IL).

RESULTS

Baseline characteristics

Characteristics of the 159 subjects and their livers are listed in Table 1. They were young. Females outnumbered males by 2 fold. Such a female preponderance was attributed to a higher proportion of male recipients (n=118), and their wives volunteered as the donor (n=58). Donors who were healthy had normal built as reflected from the BMI.

Liver weights and volumes

From the measurements made on the preoperative CT,

Table 1 Characteristics of subjects (mean ± SD, *n* = 159)

Age (yr)	**35.8 ± 10.5 (18-57)**
Gender (M : F)	53 : 106
Body weight (kg)	56.3 ± 8.4 (41.0-78.5)
Body height (cm)	161.7 ± 7.5 (144.5-181.3)
Body mass index (kg/m^2)	21.5 ± 2.6 (16.5-29.1)
Body surface area (m^2)	1.59 ± 0.14 (1.30-2.13)
Computed tomography liver volume (mL)	1,099.10 ± 181.51
Right lobe graft volume on CT (mL)	710.14 ± 131.46
Right lobe to total liver volume on CT (%)	64.55 ± 4.47 %
Right lobe graft weight (g)	598.90 ± 117.39
Estimated whole liver weight (g)	927.54 ± 168.78

CT: computed tomography.

the mean volume of the right lobe was 710.14 ± 131.46 mL and the whole liver was 1099.10 ± 181.51 mL. On the back-table, the right lobe grafts after being perfused with preservation solution, weighed 598.90 ± 117.39 g. The right lobe accounted for an average of 64.55% ± 4.47% of the entire liver on the CT. The total liver weight calculated was 927.54 ± 168.78 g.

Regression models

When the calculated liver weight was plotted against BSA for males ($R^2 = 0.37$) and females ($R^2 = 0.26$), the linear relationships were distinctly different (Figure 1A). Those females with the same BSA as males had a lower calculated liver weight. When BW was used instead of BSA, a similar pattern occurred for males ($R^2 = 0.38$) and females ($R^2 = 0.34$) (Figure 1B). The correlation of calculated liver weight with BH was much weaker for males ($R^2 = 0.13$) and in particular for females ($R^2 = 0.02$) (Figure 1C).

By stepwise multiple linear regression analysis, the relation of calculated liver weight with BW, BH, and gender (male = 1, female = 0) was tested. BH was excluded by the collinearity statistics of tolerance from the following formula so derived:

ESLW (g) = 218.32 + BW (kg) × 12.29 + gender × 50.74 (R^2 = 0.48)

or more conveniently:

ESLW (g) = 218 + BW (kg) × 12.3 + gender × 51

The ESLW is predictably correlated with ESLV. Based on linear regression analysis, the relation between ESLW and ESLV is as follows: ESLV (mL) = 302.34 + ESLW (g) × 0.859 (R^2 = 0.64), ESLW (g) = 111.25 + ESLV (mL) × 0.743 ($R^2 = 0.64$). For simplicity, the conversion factor is 1.19 mL/g (Figure 1D).

Comparison of different formulae to estimated liver size

Using the formulae for ESLV and ESLW from other studies[4,7-9,11,12,17,18], and the anthropometric data of the 159 subjects of this study, the ESLV and ESLW were calculated. The ESLW was converted from ESLV by factor of 1.19 mL/g. The ESLWs calculated from each formula were compared with the calculated liver weight of these 159 subjects by two-sided paired-samples *t* test. All except that calculated from the Urata formula ($P = 0.098$) were found to deduce a higher ESLW, with statistically significant differences ($P < 0.000$, Table 2). Amongst these, 4 regression models were selected for comparison using the regression line of best-fit method. In one German study using autopsy data, the ESLW was markedly higher[12], whereas the other series had fairly close ESLWs[4,8,9]. The regression line of the model from Urata correlated nicely in subjects of the middle range of body weights. Nonetheless, divergence was seen in subjects with body weight less than 60 kg, resulting in a higher ESLW.

DISCUSSION

The results of this study demonstrate that in healthy Chinese adults, ESLW was positively related to BW, and such correlation was also gender-dependent. The liver of the male was slightly heavier than that of the female of the same body weight. Furthermore, BH was found to be not required in the estimation of the standard liver weight. Statistically, by the test of collinearity for tolerance, BH was eliminated as an independent factor. Though many studies have used BSA as the independent factor for liver size estimation, in which BH is a key component in calculating BSA, our findings here corroborate with those studies which evaluated BW, BH , and BSA independently[8,12]. This is also in concordance with the use of only body weight as reference in determining the adequacy of the size of the liver graft from studies of North America[19] and Europe[20]. In such convention, the graft weight to recipient body weight ratio is expressed as graft recipient weight ratio (GRWR). However, the intercept of the regression line in this study did not meet at zero, using body weight as denominator as in GRWR, accuracy may be compromised in subjects who deviate much from the mean body weight of the population.

The DuBois formula for calculating BSA[5] has been used for estimating liver size in 4 formulae[4,7,11,18]. The deficiency of the BSA formula is that it is published in 1916 and deduced from planometric measurements of the body castings made on 9 subjects spanning a wide age range[5]. Larger series of BSA estimation by geometric methods revealed that the DuBois equation can predict lower BSA values[21]. The Mosteller equation which illustrates that BSA (m^2) = square root BH (cm) × BW (kg) /3600[22] has been used in 2 series for the sake of easier calculation[8,17]. On the whole, convenience of using BSA is in using the simple formula from linear regression. The easy access to personal computer nowadays may make this point relatively invalid. Using BW and BH from which BSA is derived also evades all possibilities of using data not applicable to the local population from which BSA formulae are deduced. One study showed that liver volume had a curvilinear relation with BSA[9]. The formula for calculating BSA itself has a curvilinear nature with BW and BH. Thus, a pure relation with BW and BH should rather be addressed.

The gender factor in relation to liver weight is alluded to as early as in the sixties[11]. This has been recently validated by another study which included gender in the formula deduced in estimating the ESLW[12]. Such phenomenon of gender difference can be anticipated as the female has a smaller fat-free mass given the same BW and BH[23-25]. A slightly small liver is therefore required to

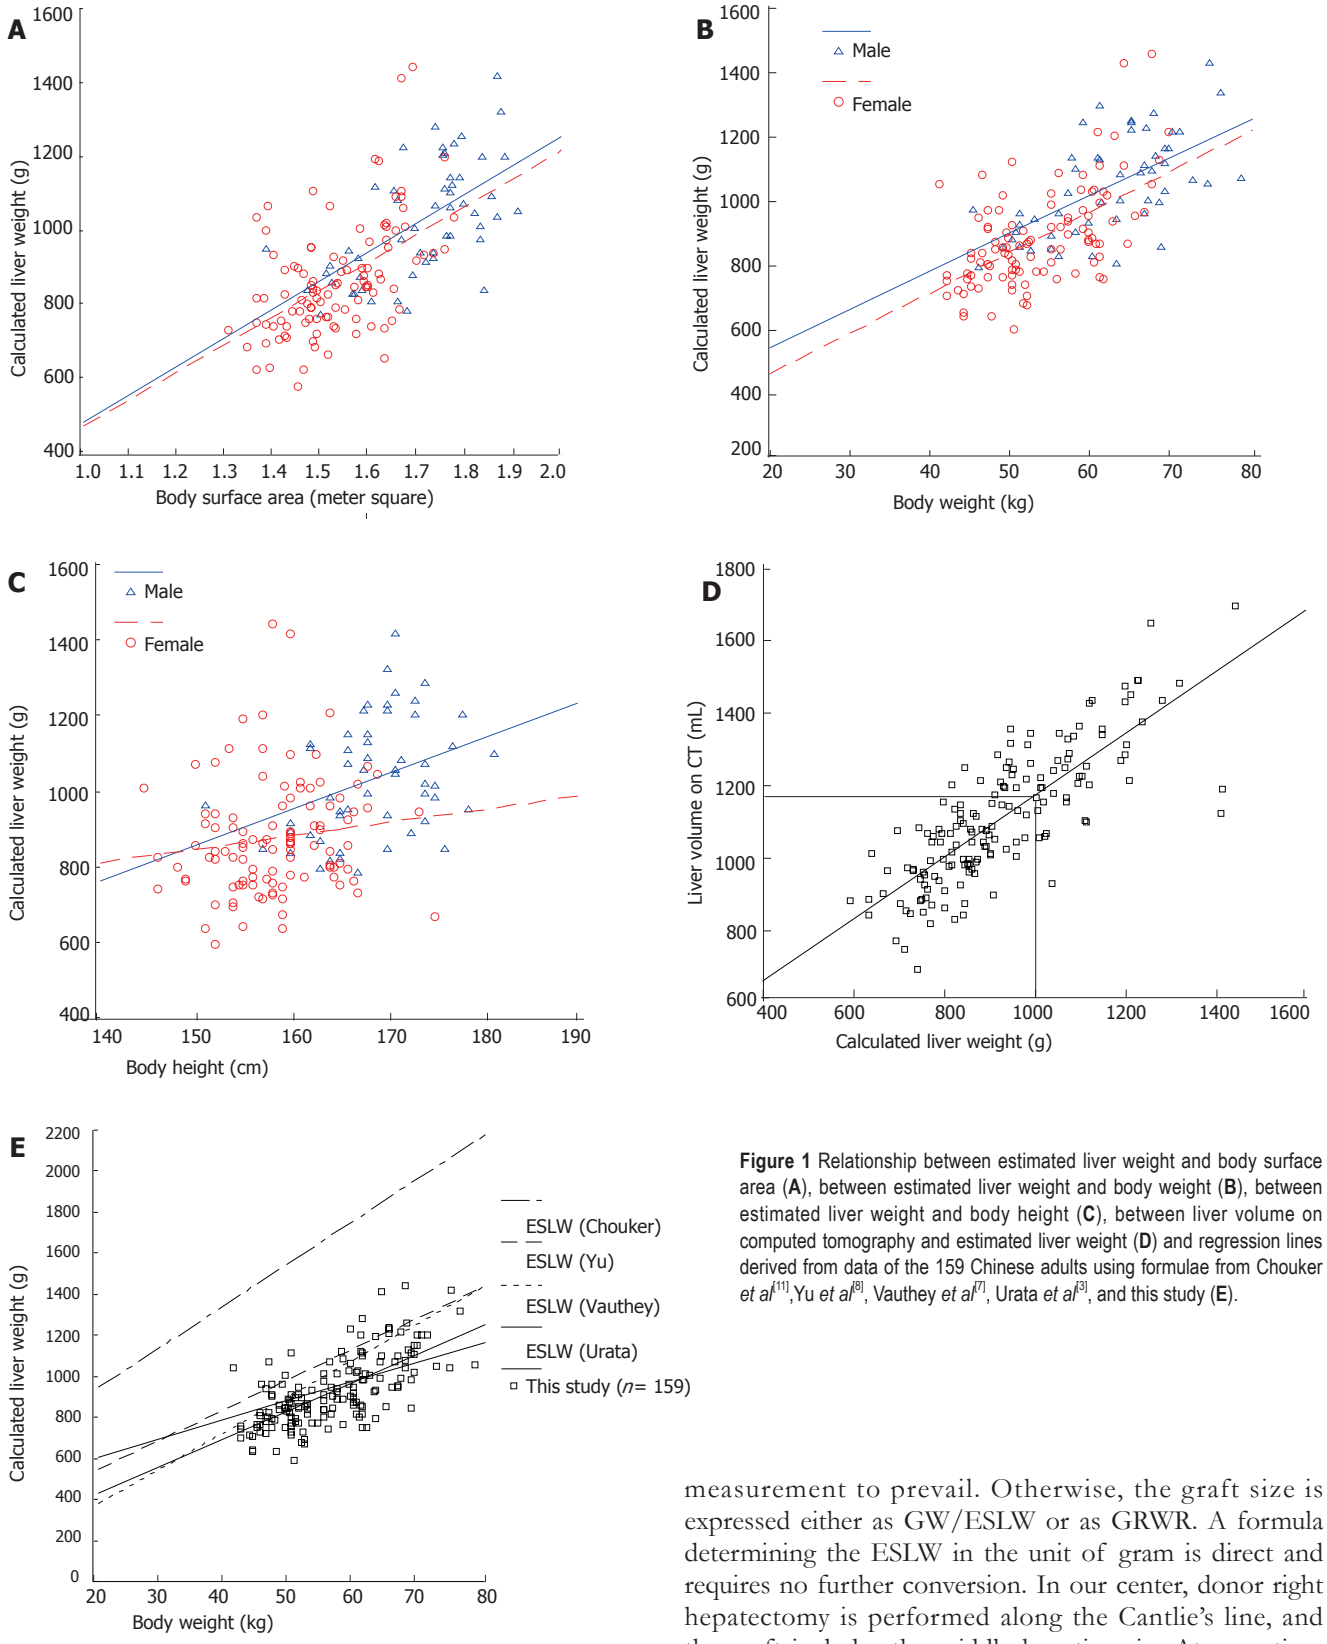

Figure 1 Relationship between estimated liver weight and body surface area (**A**), between estimated liver weight and body weight (**B**), between estimated liver weight and body height (**C**), between liver volume on computed tomography and estimated liver weight (**D**) and regression lines derived from data of the 159 Chinese adults using formulae from Chouker *et al*[11],Yu *et al*[8], Vauthey *et al*[7], Urata *et al*[3], and this study (**E**).

meet her metabolic need. The gender factor is also age-dependent, and becomes less important as the subjects become older[12]. This helps to explain why the gender factor was significant in our series in which the mean age of the subjects was 35.8 years.

Weight in gram is the common unit used in liver transplantation for quantifying the size of the liver graft. Handiness at the back-table enables this unit of measurement to prevail. Otherwise, the graft size is expressed either as GW/ESLW or as GRWR. A formula determining the ESLW in the unit of gram is direct and requires no further conversion. In our center, donor right hepatectomy is performed along the Cantlie's line, and the graft includes the middle hepatic vein. At operation, the line of demarcation between the right and left lobes is determined by temporary inflow control and marked by diathermy. It is our experience that the middle hepatic vein is predictably encountered during the course of liver transection employing the CUSA from the demarcation line to the mid portion of the inferior vena cava. Intraoperative ultrasonography certainly helps to define this plane and navigates the liver transection[26]. Weighing of the right lobe graft obviates the reliance on volume

Table 2 Comparison of regression models

Study	Formula	Mean ESLW (ESLV)	Difference in ESLW	*P*
Deland and North[11]	ESLW = 1020 × BSA^1 – 220	1400.41 g	- 472.86 g	0.000[a]
Heinemann[7]	ESLV = 1072.8 × BSA^1 - 345.7	1141.67 g (1358.59 mL)	- 214.12 g	0.000[a]
Yoshizumi[17]	ESLW = 772 × BSA^2	1225.50 g	- 297.95 g	0.000[a]
Yu[9]	ESLV = 21.585× $BW(kg)^{0.732}$ × $BH(cm)^{0.225}$	1087.32 g (1293.91 mL)	- 159.77 g	0.000[a]
Choukér[12]	ESLW = 452 + 16.434 × BW(kg) + 11.85 × age – 166 × gender (F=1, M=0)	1690.90 g	- 763.35 g	0.000[a]
Urata[4]	ESLV = 706.2 × BSA^1 + 2.4	944.79 g (1124.30 mL)	- 17.24 g	0.098
Vauthey[8]	ESLV = 1267.28 × BSA^2 -794.41	1022.95 g (1217.30 mL)	- 95.40 g	0.000[a]
Lee[18]	ESLV = 691 × BSA^1 + 95	1002.31 g (1192.75 mL)	- 74.76 g	0.000[a]
Lin[10]	ESLV = BH × 13 + BW × 12 - 1530	1048.85 g (1248.13 mL)	- 121.30 g	0.000[a]
This study	ESLW = 218.32 + BW × 12.29 + gender × 50.74 (M=1, F=0)	927.47 g	7.60E-2	0.994
Calculated liver weight		927.54 g		
Conversion factor 1.19 mL/g			paired samples *t* test	[a]$P < 0.05$

[2]Mosteller[22]

determination of the liver by CT. Instead, it is the volume ratio of the right versus the left lobe that calculates the weight of the entire liver.

There is no perfect way of measuring the liver volume as this cannot be done with the organ *in-situ* in a healthy human subject. Many attempts have been made to get closest to the actual liver volume. ESLV can be obtained from measurement of the cadaveric internal organs. By definition, these measurements are acquired from non-healthy subjects with age bias, and influenced by sequelae of either the major illness leading to the demise, or the treatments like fluid resuscitation. Autopsy data excluding those with severe postmortem changes, extensive burns, blood transfusion, fluid infusion, and injury and pathological changes of the organ can minimize such errors[27]. By the principle of Archimedes, the liver volume is measured. An average tissue density of 1.04 kg/L[9] to 1.08 kg/L[7] is derived from correlation with the liver weight. Heinemann *et al*[7] have not pointed out the findings of the increase in liver volume in those with longer periods of survival before death. Furthermore, a gradual increase in liver volume has also been observed during the time interval between death and postmortem[7]. Deceased donor livers might be weighed with deduction of 2.3% for the weight of the gallbladder. The time from brain death to organ harvesting is usually short. Nonetheless, changes of volume status as a result of diabetes insipidus and fluid resuscitation, which are common in donors with intracerebral pathologies and perfusion with preservation solution, can still affect the liver size.

The accuracy of CT in assessing the liver volume has been evaluated. Inflow and outflow vessels of the liver from cadavers can be retrieved and dissected free of fascia and fat. They are weighed and underwent CT scan *ex-vivo*. A high correlation between the actual liver volume and the volume assessed by CT has been identified by Heymsfield *et al*[13]. Urata *et al*[4], reported that 19 children with end-stage liver disease undergoing liver transplantation also have their liver volume assessed preoperatively by CT. The liver volume obtained from CT is accurate. Another study reported the livers of fresh sheep can be scanned *in-vitro* and the volume can be measured by water displacement method[28]. All these 3 studies showed that the error of the CT is less than 5%. Nevertheless, it is worth noting that these are measurements of organs excised from deceased or diseased subjects. Misregistration errors made in tracing the peripheries of the liver on CT occur particularly in the thin portions such as the left lateral segment. Partial volume effect and respiratory movements are also possible sources of error. Overestimation for small livers and underestimation for large livers have also been observed[28]. Spiral CT which requires a shorter breath-holding period theoretically should minimize artifacts from breathing movements. This has, however, shown to be of no significance[29].

A potential major source of error in this study might come from the measurement of BW and BH in the ward. As donors were weighed wearing clothes, BW could be expected to have a systematic error of overestimation due to the weight of the clothes. As the BW and BH were measured in different wards over a long period, potential systematic errors from the equipments could be expected to be random instead of systematic. With continuous data collection, accuracy of the formula could be improved by more meticulous recording of BW and BH.

In comparison with ESLW/ESLV derived from other formulae, except that from Urata, the ESLW of the subjects in the current study was significantly smaller. Though statistically not significant, the Urata formula did overestimate liver weight in our adults less than 60 kg. The discrepancy between our formula and the others might be attributed to the fact that our liver grafts were weighed blood-free on the back-table. The liver already flushed with perfusion solution and devoid of back-perfusion via hepatic vein as *in-situ* is smaller and lighter. This nonetheless is the state at which the liver graft harvested is weighed. The conversion factor of 1.19 mL/g could be used for converstion of weight to volume. It is also possible that a smaller liver may be required to meet the metabolic need of the adult Chinese. The racial difference in the amount of visceral adipose tissue has been demonstrated by whole-body magnetic resonance imaging.

Asian Americans have a higher amount of visceral adipose tissue, thus less lean mass for the same body size[30]. A word of caution ought to be made in the application of data obtained from healthy and relatively young subjects to patients with various morbidities like wasting, edema, ascites, and perhaps to those of an older age.

In conclusion, these data demonstrate that ESLW can be derived from simple clinical parameters of weight and gender. The formulae for Caucasians may not be applicable to Chinese adults. Additional studies of more age- and weight-diverse subjects can provide additional information to this subject of interest.

Abstract

AIM: To investigate the prevalence and clinical pattern of gastrointestinal stromal tumors (GISTs) in Hong Kong Chinese, and to assess the impact of introduction of CD117 on the disease incidence.

METHODS: From the database of the Department of Pathology of Yan Chai Hospital, 47 patients, with GISTs from September 1995 to December 2003 were included in this study. Ten GISTs were diagnosed before the introduction of CD117. The clinical features, tumor characteristics, and treatment were analyzed. Factors predicting tumor related death or recurrence were studied with Cox proportional hazard model.

RESULTS: The patients included 26 males and 21 females, with a mean age of 66.6 years (SD 13.1, range 29-87 years). The estimated prevalence of GISTs was 13.4-15.6 per 100 000 people, with an annual incidence of 1.68-1.96 per 100 000 people. The annual incidence of GISTs before and after the introduction of CD117 was 1.1 per 100 000 people and 2.1 per 100 000 people respectively. Stomach (34 patients, 72.3%) was the most common location for the tumor, followed by the small intestine (8 patients, 17.0%), esophagus (2 patients, 4.3%), omentum (2 patients, 4.3%) and colon (1 patient, 2.1%). Thirty-one patients (66%) had complete tumor resection. Eleven out of 16 deaths (23%) were tumor-related. The median survival time was 26 mo. Five-year survival rate was 61.3%. The significant factors associated with tumor-related death or recurrence were incomplete resection, tumor size 5 cm or above, invasion to the adjacent organ or presence of metastasis.

CONCLUSION: The incidence of GIST in Hong Kong is comparable to that in the United States but lower than that in Finland. The true incidence of GISTs could be underestimated before the introduction of CD117. Incomplete resection, tumor size 5 cm or above, invasion to the adjacent organ or presence of metastasis are factors predicting tumor-related death or recurrence.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are uncommon mesenchymal tumors that have been a controversial topic since their first description by Golden and Stoot in 1941[1]. In the past three decades, there has been considerable debate regarding its nomenclature, cellular origin, diagnosis, and prognosis[2]. Before the discovery of gain-of-function mutations in the *c-KIT* proto-oncogene in GISTs by Hirota and colleagues in 1998[3], most GISTs were thought to be smooth muscle neoplasm, and were classified as leiomyosarcoma due to their similar appearance by light microscopy. At present, GISTs are defined as spindle-cell, epithelioid, or occasionally pleiomorphic mesenchymal tumours of the gastrointestinal tract that express the *c-KIT* protein[4]. The precise cellular origin of GISTs recently has been proposed to be the interstitial cell of Cajal, an intestinal pacemaker cell[5]. The definition of *c-KIT*-negative GISTs remains a focus of research. In this study, we analyzed 47 Chinese patients with GISTs in Yan Chai Hospital to study their clinical, pathological characteristics, survival pattern and recurrence. The impact of introduction of CD117 on the incidence of this tumor was assessed, as well.

MATERIALS AND METHODS

Patient selection

From the database of the Department of Pathology of Yan Chai Hospital, we selected patients with the diagnoses of gastrointestinal stromal tumors (GISTs), leiomyoma, leiomyoblastoma and leiomyosarcoma from September 1995 to December 2003. Their histology slides were reviewed by a separate pathologist of the Department of Pathology. Patients with the diagnosis of GISTs were recruited to our study.

Clinical information including age, sex, comorbidity of the patients and presentation status of the tumor were recorded. The presentation status of the tumor reflected the extent of disease and the history of prior treatment when the patient was first seen in our hospital. The tumor was categorized as primary, metastatic or locally recurrent. Acute gastrointestinal haemorrhage was defined as significant blood loss requiring transfusion or haemodynamically significant blood loss. The criteria for chronic gastrointestinal haemorrhage were intermittent melena, guaiac-positive stool or iron deficiency anaemia. Ranges of diagnostic tests were used in these patients. They involved evaluating the gastrointestinal tract with contrast such as barium studies, endoscopies or ultrasound of abdomen. Computerized tomography scan and mesenteric angiography were used in some patients. Histology with or without adjacent organ involvement was also recorded. Histological subtype was determined by examination of light microscopy applying different staining methods. Immunohistochemistry stain included vimentin, alpha-smooth muscle actin, desmin, neuron-specific enolase (NSE), S100 protein and CD 34. CD117 was introduced to our Department of Pathology since October 1998. Electronic microscopy was also performed.

Tumor size was tabulated based on actual measurement of the gross surgical specimen or imaging when the tumor was inoperable. It was recorded as the largest diameter in any dimension of the primary tumor and was classified into < 5 cm, 5 to 10 cm, or >10 cm. Resection margins were checked closely for presence of microscopic disease. Tumors were also grouped according to their mitotic numbers as no mitosis (0/10 HPF), low mitotic index (1-4/10 HPF) and high mitotic index (≥5/10 HPF). Tumor cellularity, presence or absence of invasive growth, tumor necrosis and the presence or absence of haemorrhage were also examined.

Complete resection was defined as the excision of all gross disease regardless of microscopic margins. Resections were classified as incomplete when gross residual disease was present after resection. Inoperable was defined as when the tumor was unresectable at surgical exploration. Patients with incompletely resected tumor, metastatic or unresectable tumor were referred to oncology units for chemotherapy and radiation therapy as indicated. In total, 47 patients satisfied the diagnosis of GISTs.

Survival analysis

All times were calculated from the first presentation to the date of last follow-up or death. Time of last follow-up of dead patient was recorded as the time of certification of death. Others were censored at the time of last follow-up in specialist outpatient clinic or admission (clinical or emergency) whichever was later. Clinical variables, tumor characteristics, as well as modality of treatment were analyzed against tumor recurrence or death.

Statistic analysis

Statistical analyses were performed using SPSS 10.0(SPSS Inc., Chicago, USA). Influence of the factors in predicting tumor recurrence or death was assessed by univariate analyses. Multivariate analysis was performed with the Cox proportional hazards model to identify significant prognostic factors. $P<0.05$ was considered statistically significant.

RESULTS

Patient characteristics

Between September 1995 to December 2003, 47 patients (26 men and 21 women) were diagnosed with GIST. Mean follow up time in this cohort was 31 mo (range 0-99 mo). Mean age was 66.6 years (SD 13.1, range 29 to 87). Stomach (34 patients, 72.3%) was the most common site for the tumor, followed by the small intestine (8 patients, 17.0%), esophagus (2 patients, 4.3%), omentum (2 patients, 4.3%) and colon (1 patient, 2.1%). Gastrointestinal bleeding was the most common presenting symptom (28 patients, 60%), followed by epigastric pain (21 patients, 45%), and the presence of an abdominal mass (10 patients, 21%). Three patients (6%) with GIST were diagnosed incidentally. Endoscopically, the most common finding was a round tumor mass, either pedunculated or sessile, resembling a leiomyoma. Huge tumor usually presented as submucosal mass bulging into the lumen. Active bleeding ulcer or ulcer with stigmata of recent haemorrhage was present in 5 cases (71%) (Table 1). Radiological imaging including computerized tomography (CT) scan of the abdomen and barium studies were employed in most of our patients to identify the site and to assess the size of the lesions as well as the presence of any local invasion or distant metastases (Figure 1). Two patients had metastases delineated by CT scan, one in liver and one in omentum respectively, which precluded any curative surgical intervention.

Tumor characteristics

Tumor size ranged from 0.3 to 24 cm (median 4.5 cm, inter-quartile range 3-7.5 cm). Twenty-seven (57%) patients had tumor size less than or equal to 5 cm, 14 (30%) patients with tumor size between 5 cm to 10 cm, whereas 6 (13%) patients presented with tumor size greater than 10 cm. Seven (15%) patients had high mitotic index (≥ 5/10 HPF), 18 (38%) patients low (1-4/10 HPF) and 22 (47%) no mitotic index (0/10 HPF). Necrosis inside the tumor was found in 15 patients (32%) with GISTs. Seven out of 47 patients (15%) had presence of tumor metastases or invasion to adjacent organs. Immunohistochemical analyses were performed in all cases. Eleven (23%) GISTs had markers for neuronal and neuroendocrine tumors,

Table 1 Characteristics of patients with GISTs

Characteristics		*n* (%)
Number of patients		47
Male/Female (ratio)		26:21 (1.23:1)
Mean age at the time of diagnosis(SD)		66.60 (SD 19.1)
Median follow up time in months (IQR)		26.00 (10-43)
Presenting symptoms		
	GI bleeding	28 (60%)
	Epigastric pain	21 (45%)
	Abdominal mass	10 (21%)
	Incidental finding	3 (6.3%)
Locations		
	Stomach	34 (72.3%)
	Small bowel	8 (17.0%)
	Esophagus	2 (4.3%)
	Colon	1 (2.1%)
	Omentum	2 (4.3%)
Resection[1]		
	Complete	31 (66%)
	Incomplete	7 (14.9%)
	Inoperable	5 (10.6%)
Recurrence (after initial surgery)	Total	4 (8.5%)
	Local recurrence	1 (2.1%)
	Distal metastasis	3 (6.4%)
Death	Total	16 (34%)
	Tumor related	11 (23.4%)
	Tumor unrelated	5 (10.6%)

[1]Two patients refused resection of tumor. Two GISTs were discovered incidentally during autopsy. IQR: Inter-quartile range

Table 2 Tumor characteristics of 47 patients with GISTs

		n (%)
Number of patients		47
Median tumor size in cm (IRQ)		6.05 (3-7.5)
	≤5 cm	24 (51)
	>5-10 cm	13 (28)
	>10 cm	4 (9)
Mitotic index		
	High	7 (15)
	Low	18(38)
	No	22(47)
Presence of distal metastasis or local invasion		7 (15)

8(17%) demonstrated immunohistology markers for myoid series. Twenty-eight (60%) GISTs were undifferentiated tumors (Table 2).

Treatment

All patients were assessed for tumor resection either endoscopically or surgically. Thirty-one patients (66%) had complete resection of the tumor, and 7 patients (15%) underwent incomplete resection. In 5 patients (10%), resection of tumor was impossible because of extensive tumor metastases or poor general condition at the time of diagnosis. Endoscopic resection was possible only in 7 patients (15%) (5 gastric, 1 oesophageal and 1 colonic GISTs). All small bowel GISTs required surgical resection. Adjuvant chemotherapy by Imatinib (Glivec) was given in 2 patients post-operatively.

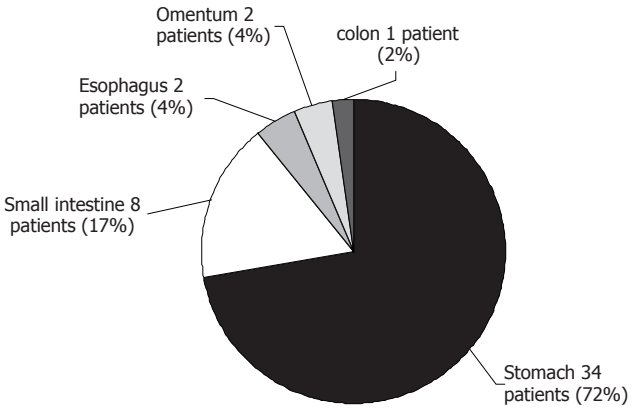

Figure 1 Tumor Locations of 47 GISTs

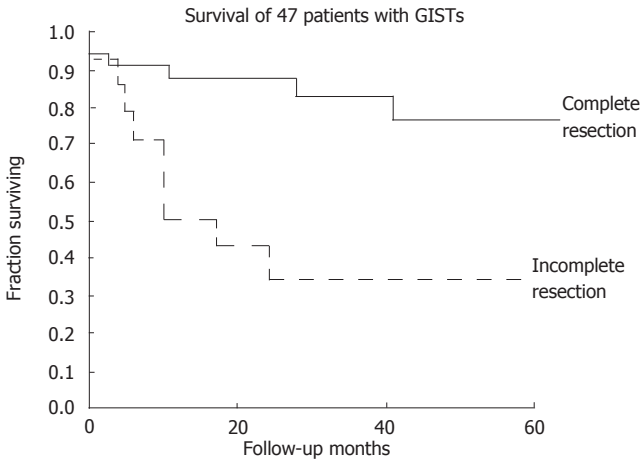

Figure 2 Kaplan-Meier survival curve of GIST patients with complete and incomplete tumor resection.

Survival

Totally 16 deaths were recorded in the study period, and 11 deaths were tumor related. The overall median survival was 26 mo. Five-year survival probability was 61.3% (SE 8.0%). The median survival time for completely resected GISTs was longer than that for incompletely resected or inoperable patients, 37 mo versus 10 mo respectively (log rank test, $P=0.0013$) (Figure 2). Two patients receiving imatinib were still alive at the end of the study, with liver metastatsis. Their survival time censored at the end of the study was 26 mo and 37 mo respectively.

Prognostic factors

By univariate analyses, the significant factors predicting tumor recurrence or tumor related death included tumor size 5 cm or above ($P=0.003$), presence of significant mitotic figures (1/10 HPF or above) ($P=0.021$), presence of necrosis ($P=0.005$), invasion to adjacent organ and/or presence of metastases at the time of diagnosis ($P<0.001$),

Table 3 Univariate analyses of factors predicting GISTs recurrence or tumor related death

Prognostic factors	Hazard ratios	*P* value
Tumor size 5 cm or above	20.5	0.003
Presence of significant mitotic figures (1/10 HPF or above)	3.8	0.021
Presence of necrosis	4.4	0.005
Invasion to adjacent organ and/or presence of metastases at the time of diagnosis	16.5	<0.001
Incomplete tumor resection	4.6	0.002

Table 4 Multivariate analyses of factors predicting GISTs recurrence or tumor-related death

Prognostic factors	Hazard ratios (CI)	*P* value
Tumor size 5 cm or above	9.6 (1.1-86.0)	0.042
Invasion to adjacent organ and/or presence of metastases at the time of diagnosis	14.0 (2.5-78.6)	0.003
Incomplete tumor resection	2.1 (1.1-86.0)	0.032

incomplete tumor resection ($P = 0.002$) (Table 3). By multivariate analyses, tumor size 5 cm or above (hazard ratio = 9.6, $P = 0.042$), invasion to adjacent organ and/or presence of metastases at the time of diagnosis (hazard ratio 14.0, $P = 0.003$), and incomplete tumor resection (hazard ratio = 2.1, $P = 0.032$) remained the significant factors predicting tumor recurrence or tumor related death (Table 4).

DISCUSSION

In this study, we summarized our 8 years' experience in the diagnosis and management of GISTs in a regional hospital in Hong Kong. Stromal tumors of the gastrointestinal tract are rare, accounting for less than 1% of all gastrointestinal tract malignancies. Their presumed origin from smooth muscle cells has led to the use of terms such as "leiomyoma", "leiomyoblastoma" and "epithelioid leiomyosarcoma". However, the exact origin of the tumor was difficult to determine in the early days until discovery of gain-of-function mutations in the *c-KIT* proto-oncogene in GISTs by Hirota and colleagues in 1998[3]. Therefore, the incidence of GISTs was rarely reported in the literature and was not reported in Chinese population.

Our hospital serves a local population of 300 000-350 000. The estimated prevalence of GISTs was 13.4-15.6 per 100 000 people, with an annual incidence of 1.68-1.96 per 100 000 people. This is comparable to that of the United States where the estimated annual incidence is 1-2 cases per 100 000 people, of which 20%-30% are malignant[4]. In contrast, Finland has higher annual incidence of malignant GISTs, 0.4 per 100 000 people[6], i.e. estimated 4 GISTs per 100 000 people.

The true incidence of GISTs could be underestimated before the introduction of CD117. In our hospital, all gastrointestinal tract tumors suspected to be GISTs were routinely tested for CD 117 marker since October 1998.

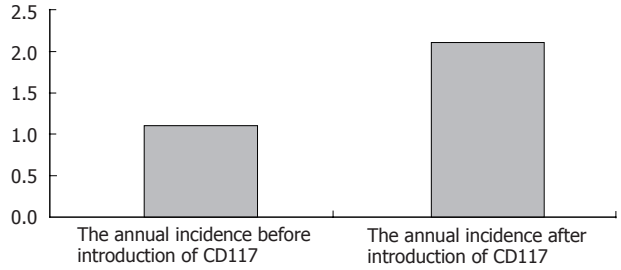

Figure 3 The annual incidence of GISTs before and after the introduction of CD117 was 1.1 per 100 000 people and 2.1 per 100 000 people respectively.

Interestingly, only 10 patients out of 47 (21%) were diagnosed as GISTs before the introduction of CD117. The annual incidence of GISTs after the introduction of CD117 increased from 1.1 per 100 000 people to 2.1 per 100 000 people (Figure 3). Similar trend was also noted in the United States. The estimated incidence of GISTs in the United States was around 0.6 per 100 000 people in the 1980s. The incidence increased to approximately 1-2 patients per 100 000 people after 2 000[4].

There existed some conflicting evidence on male predominance, however, most studies indicated no sex predilection[18, 21, 24, 31]. In our study, the occurrences of GISTs were similar in both sexes (1.2 male to 1 female). The age of presentation had a unimodal distribution, similar to the published data where the majority of patients presents in the fifth to seventh decade of life[4], the mean age of presentation of our patients was 66 years. GISTs are occasionally found in young adults, but they are very rare in children[7].

The vast majority of GISTs arise as a result of somatic mutation, but rare familial cases associated with mutated *c-KIT* have been identified[8, 10-12]. In our study, we could not identify any patient with familial relation. All the patients with GISTs were sporadic, and the predisposing factors were unknown.

Similar to other published data[7,13,14], the stomach was the most frequent site of involvement in our patients (72%), followed by small intestine (17%). The large bowel, esophagus and omentum were least likely involved. Symptomatic lesions have manifestations that depend on tumor size, location and growth pattern[7,13,14]. Ludwig and Traverso reported that GISTs with intraluminal nodule less than 2 cm was generally asymptomatic while tumors >4 cm were associated with symptoms[15]. In the literature approximately 50% of patients presented with acute or subacute gastrointestinal bleeding as the major symptom leading to diagnosis[25]. In our local patients, the most common presenting symptoms were gastrointestinal bleeding (60%), as results of overlying mucosal ulceration, followed by epigastric pain and abdominal mass. Other symptoms included fever, anorexia, dysphagia, obstruction and perforation of bowel were seldom seen in our series. Clinically palpable mass usually implies invasion to adjacent organs or distant metastasis, thus in turn predicts poor outcome of the patients. Surgical resection is the treatment of choice and should be performed with the intention to performing complete en bloc resection of the tumor, as it

is difficult or impossible to differentiate between benign or malignant lesions before or during operation[16]. Tumor size and frozen section during operation are not conclusive [17,18].

Prognostic factors

Gastrointestinal stromal tumors are unique in that their malignant potential is not always predictable. Most GISTs appear relatively low grade histologically, and it has been difficult to distinguish benign from malignant GISTs, especially at the low-grade end of the histological spectrum. Many previous studies suggest a single factor or even combinations of two factors are not sufficient to reliably predict the outcome of GISTs[19]. Currently no accepted staging system exists. Most pathologists use a multiparametric approach to predict the biological behavior of GISTs. The most reproducible predictor of malignancy has been mitotic rate >1-5 mitosis per 10 HPF[20-22]. Other poor prognostic factors include tumor size > 5 cm[23-27], mutation in the c-kit gene[28-30], necrosis[18, 20, 24, 31], infiltration and metastasis to other sites[13]. In our study, significant prognostic factors were tumor size 5 cm or above, invasion to adjacent organ and/or presence of metastases at the time of diagnosis as well as incomplete tumor resection. In contrast to previous studies[20-22], mitotic index did not appear as significant prognostic factor in our cohort. The different approaches to sample tissue from large tumors with considerable heterogeneity for microscopic assessment may explain such discrepancy between different studies. At present, the best method to adequately sample tumor tissue and report mitotic index is still controversial. In our hospital, our pathologists choose random sampling approach and report the highest mitotic index among different tissue samples. From the literatures, approximately 10% to 30% of all GISTs display malignant behavior[4, 14]. Our patients with GIST demonstrated similar ratio regarding malignant GISTs.

Survival

The overall survival appears to reflect the completeness of resection[7, 18, 32]. In Roswell Park Cancer Institute (RPCI), the United States, the median survival rate was significantly higher in those who underwent complete resection (33 mo) as compared to those who underwent palliative surgery (15 mo)[32]. Similarly in our center, the median survival time for completely resected GISTs was significantly longer than incompletely resected or inoperable patients, 37 mo versus 10 mo. The adjuvant therapy appeared to improve the survival and the quality of life in patients with incomplete tumor resections. Despite extensive metastasis, the 2 patients receiving imatinib were still alive at the end of the study. The survival times of 26 mo and 37 mo were much longer than the median 10 mo of other patients with incomplete tumor resection, although the number of patient in this group was too small for statistical analysis.

Recurrence is commonly local and peritoneal, often associated with liver metastasis. Peritoneal metastases are most probably a result of tumor cells seeding from the primary tumor directly into the peritoneal cavity. Liver metastases most probably result from haematogenous seeding into the portal vein[33]. Extra-abdominal disease in the absence of peritoneal involvement is rare[13]. There exist few reports in the literature describing a survival advantage after the resection of abdominal recurrence. In our hospital, local recurrence of GIST was not routinely operated again.

In conclusion, the incidence of GIST in Hong Kong is comparable to that of United States but lower than that in Finland. The true incidence of GISTs could be underestimated before the introduction of CD117. Incomplete resection, tumor size 5 cm or above, invasion to the adjacent organ or presence of metastasis are factors predicting tumor-related death or recurrence. The survival of the completely resected tumor is good. The introduction of medical adjuvant therapy appears to improve the survival and the quality of life in the unresectable and incompletely resected GISTs patients.

Abstract

AIM: To investigate risk factors for pancreatic cancer and establish a risk model for Han population.

METHODS: This population-based case-control study was carried out from January 2002 to April 2004. One hundred and nineteen pancreatic cancer patients and 238 healthy people completed the questionnaire which was used for risk factor analysis. Logistic regression analysis was used to calculate odds ratio (ORs), 95% confidence intervals (Cls) and β value, which were further used to establish the risk model.

RESULTS: According to the study, people who have smoked more than 17 pack-years had a higher risk to develop pancreatic cancer compared to non-smokers or light smokers (not more than 17 pack-years) (OR 1.98; 95% CI 1.11-3.49, $P=0.017$). More importantly, heavy smokers in men had increased risk for developing pancreatic cancer (OR 2.11; 95%CI 1.18-3.78, $P=0.012$) than women. Heavy alcohol drinkers (>20 cup-years) had increased risk for pancreatic cancer (OR 3.68; 95%CI 1.60-8.44). Daily diet with high meat intake was also linked to pancreatic cancer. Moreover, 18.5% of the pancreatic cancer patients had diabetes mellitus compared to the control group of 5.8% ($P=0.0003$). Typical symptoms of pancreatic cancer were anorexia, upper abdominal pain, bloating, jaundice and weight loss. Each risk factor was assigned a value to represent its importance associated with pancreatic cancer. Subsequently by adding all the points together, a risk scoring model was established with a value higher than 45 as being at risk to develop pancreatic cancer.

CONCLUSION: Smoking, drinking, high meat diet and diabetes are major risk factors for pancreatic cancer. A risk model for pancreatic cancer in Chinese Han population has been established with an 88.9% sensitivity and a 97.6% specificity.

Key words: Pancreatic cancer; Risk factor; High-risk model

INTRODUCTION

Pancreatic cancer is one of the most deadly cancers in the world. The mortality over morbidity ratio is 0.99:1. Only 10% patients have cancer cells confined in pancreas at the time of diagnosis, 40% have local invasion and 50% have distal metastasis. Although surgery, radiotherapy and chemotherapy have improved the life quality and survival rate in the cancer patients, only 10% patients show significant improvement. Most patients die from the cancer after 4 to 6 mo from diagnosis. Niederhuber *et al*[1] reported that one-year survival rate was less than 20%, decreasing to 7% for three-year and 3% for five-year. It is proposed that the best way to reduce the mortality is to improve early detection of this deadly cancer. In this paper we analyzed the possible risk factors and symptoms that correlated to pancreatic cancer based on a questionnaire survey among pancreatic patients and control subjects, and established a risk model for cancer estimation with weighted scores of risk factors and symptoms in an attempt to help early detection of pancreatic cancer in Chinese Han population.

MATERIALS AND METHODS

Subjects

A total of 119 cases of pancreatic cancer included in this study were diagnosed by Peking Union Medical College Hospital (PUMCH) between January 2002 and April

Table 1 Diagnostic standards for pancreatic cancer

A. Confirmed diagnosis by pathology
B. A valid confirmation requires at least 2 of the following listed items of imaging tests
(1) Ultrasound indicates there are low-density area in pancreas, as well as pancreatic duct dilation and common bile duct and gall bladder swelling
(2) CT indicates local enlargement and mass occupying lesion in pancreas
(3) ERCP indicates discontinuity of pancreatic duct, having mouse-tail ending, stiff and irregular duct wall, or any pull sign and double-duct sign
(4) MREP indicates there are stenosis and dilation in pancreatic duct and/or bile duct and space-occupying lesion in pancreas
(5) EUS indicates there is low-density, occupying lesion in pancreas
(6) IDUS
(7) Angiography
(8) PET
C. Palpable mass in surgery and at least an item of radiology evidence

ERCP: Endoscopic retrograde cholangiopancreatography
MREP: Magnetic resonance cholangiopancreatography
EUS: Endoscopic ultrasound sonography
IDUS: Intraductal ultrasound sonography
PET: Positron Emission Tomography

2004. The diagnosis was based on pathological, clinical and surgical evidence (Table 1). Among the 119 cases, 42 (35.3%) were confirmed by pathology; 17 (14.3%) by surgical findings; the rest (50.4%) by clinical findings. Those patients with a past history of chronic pancreatitis were diagnosed based on evidence of pancreatic calcification and pancreatic duct dilatation on imaging tests. All patients came from Beijing and its peripheral areas and were Han nationalities. The normal control group was randomly selected from normal general population in the same geographic area. The two groups were matched in gender and age and marriage status (Tables 2 and 3).

Methods

This is a case-controlled epidemiological study. We interviewed each subject in both groups based on a pre-determined questionnaire, which included questions about demographic data, smoking and drinking habits and family history of related diseases with pancreatic cancer. According to World Health Organization's definition of smoking, we defined the smokers as those who have smoked for 12 mo or more continuously or cumulatively in their lives. We measured the smoking history by the unit of pack-year which was defined as smoking of a package (20 pieces) of cigarette per day for one year. The number of pack-year = (the number of cigarette per day/20) × the number of years smoked. Because some persons used the pipe, we converted 50 g of pipe tobacco to 10 pieces of cigarettes. We defined the alcohol drinker as drinking at least twice a week and continuously for at least one year. Regarding the drinking volume, we adopted the unit of "drink", which was commonly used in North America. One drink contains 14 mL or 10.9 g of pure alcohol, which equals to 280 mL of beer (50 mL/L alcohol), 112 mL of wine (125 mL/L alcohol), 70 mL of rice wine (200 mL/L alcohol) or 35 mL of hard liquor (400 mL/L alcohol). In China, one bottle of beer is 640 mL, which is converted to 2.29 drinks. A glass of wine has 50 mL in volume, which is 0.45 drink unit. One cup of hard liquor is 55 mL, which equals to 1.57 drink units. One cup of rice wine having 50 mL in volume is converted to 0.71 drink unit. We assumed the subject drank the same amount of alcohol per day per year. The total drinking volume is calculated by the following formula: Total volume (drink-years) = (Numbers of bottle of beer × 2.29 + Numbers of glass of wine × 0.45 + Numbers of cup of hard liquor × 1.57 + Numbers of cup of rice wine × 0.71) × (Numbers of drinking years). Because a large number of subjects in this study did not drink or only drank once in several weeks or months, we did not adopt the calculating method of gr (alcohol)/per day, which is often used to define heavy drinking.

According to the relative amount of meat and vegetable intake during most time of one's life, diet habit was divided into high meat consumption, high vegetable consumption and equal meat and vegetable consumption.

The high-risk scoring model was established on the basis of multivariate logistic regression analysis. The variables included risk factors and symptoms of pancreatic cancer. Possible risk factors and symptoms described in the questionnaire were compared between two groups with the t test or χ^2 test. The OR value of each factor was also calculated and those with statistical significance were listed. Combined with our clinical findings, significant and borderline risk factors and symptoms were selected as variables. With multivariate logistic regression analysis, we obtained regression coefficient β of each independent variable. Selecting the minimal β value as radix, and through division of every β value by the radix, the weighted numerical scores of each variable were derived. We made small adjustments to some scores based on the suggestions of some experts of epidemiology and gastroenterology and established the risk scoring model. The risk score of each patient could be calculated through simple addition of weighted score of each variable. The risk scores were compared between two groups by the t test. Receiver operating characteristic (ROC) curve was used to set a cutoff value for high cancer risk.

RESULTS

Analysis of risk factors for pancreatic cancer

The body mass index of pancreatic cancer patient was distinctively higher than that of control group. After correction by age and gender, the average weight index of patient group was 24.89 (17.99-36.73), while that of control group was 23.99 (14.53-32.74), with significant difference ($P = 0.033$) between these two groups. A clinical manifestation of pancreatic cancer patient was weight loss in a short term. Among the 109 patients who had weight index, the average weight loss was 6.70 (-5-31) kg during the one-year period before diagnosis. However, among the 197 control subjects who had weight index, their body weight increased by an average of 0.33 (-10.5-5) kg during the same period. The weight changes between the two groups had significant difference ($P < 0.0001$). Therefore, we used the weight index of the subjects one year before they were recruited into the study group.

Heavy smoking was shown as a risk factor for pancreatic cancer. There was no significant difference

Table 2 Inclusion and exclusion criteria for patients and controls

	Inclusion criteria	Exclusion criteria
Patients	(1) The patient voluntarily took part in this research; agreed to take necessary clinical examinations and answer epidemiological questionnaire survey; and give consent to the publication of research data.	(1) The patient did not agree upon the conditions to participate in the study or the patient information was not available at the inclusion time.
	(2) Diagnosed by the pancreatic cancer team from PUMCH.	(2) Not diagnosed by the pancreatic cancer team from PUMCH.
	(3)Clinical examination and epidemiological investigation were acceptable for the patient's condition.	(3) The patient's condition did not allow the clinical examination and epidemiological investigation.
	(4) Patient was diagnosed for pancreatic cancer between 2002 and 2004.	(4) The patient was not diagnosed for pancreatic cancer for the first time between 2002 and 2004.
	(5) Patients did not undergo radiotherapy and anticancer therapy before surgery, and did not have other primary tumors.	(5) Patients whose pancreatic tumor was a metastatic carcinoma or who had other tumors.
	(6) Patients belonged to Han nationality.	(6) Patients were not from Han nationality.
Controls	(1) The person voluntarily took part in this research; agreeed to take necessary clinical examinations and answer epidemiological questionnaire survey; and give consent to the publication of research data.	(1) The person did not agree upon the conditions to participate in the study or the person's information was not available at the inclusion time.
	(2) The person did not have any kind of tumor.	(2) Person had any kind of malignant tumor.
	(3) The person matched with the patients for gender and age (±5 years).	(3) Person suffered from severe coronary heart disease or stroke.
	(4) Being the resident of Beijing or its peripheral area for at least 5 years.	(4) Person did not match with the patient group for gender and age (±5 years).
	(5) Han nationality.	(5) Not from Han nationality.

Table 3 Demographic characters of patients and controls

	Patients		Controls		χ^2	*P*
	n	(%)	*n*	(%)		
Age (yr)						
Male ≤50	16	(20.8)	36	(31.9)		
50-59	17	(22.1)	27	(23.9)	3.6583	0.1606
≥60	44	(57.1)	50	(44.3)		
Female ≤50	9	(21.4	28	(29.5)		
50-59	8	(19.1)	26	(27.4)	3.1297	0.2091

Divorced	0	(0)	7	(3.4)		
Widowed	4	(3.4)	16	(7.7)	8.093	0.082
Separated	0	(0)	1	(0.5)		
Spinsterhood	0	(0)	1	(0.5)		

between patient group (39.5%) and control group (35.92%) in terms of the percentage of smokers. After we divided each group into three subgroups (0, ≤17 package years and ≥17 package years) in terms of smoking history, we found significant differences between the patient group and control group. For those who smoked more than 17 package years (heavy smoker), the percentage of smokers accounted for 30.7% in patient group, which was 10% higher than that of control group. The risk of developing pancreatic cancer in the heavy smoker subgroup was 1.51 times that of the non-smokers (no statistic significance). When we combined the non-smoker and intermediate smoker subgroups (≤17 package years) together, it showed that the heavy smoker had increased risk of pancreatic cancer (OR, 1.98; 95% CI, 1.11-3.49; $P=0.017$). If divided by gender, there were more male heavy smokers in patient group (47.7%) than control group (30.3%). The risk of pancreatic cancer was increased for male heavy smokers (OR, 2.11; 95% CI, 1.18-3.87, $P=0.012$). However, no conclusion for females was made due to the low percentage of smokers within the patient group and control group.

Heavy drinking was shown as a risk factor for pancreatic cancer. According to the median total drinking volume of control group, we divided the drinkers into three subgroups: non-drinking, low-drinking (≤20 drink-years) and heavy-drinking (>20 drink-years). The result indicated that the distribution frequencies of three subgroups in patient group were 74.0% (88/109), 5.9% (7/109) and 20.2% (24/109) respectively, while in control group were 84.5% (175/207), 8.2% (17/207), 7.3% (15/207) respectively. The distribution in patient group had significant difference from control group. After correction of age, gender and smoking factors, the OR value of low-drinking compared to the non-drinking was 1.003, while for the heavy-drinking subgroup, it increased to 3.681. Therefore, heavy-drinking had higher risk to develop pancreatic cancer.

Diet with high meat consumption was shown as a high risk for pancreatic cancer. In this study, we only explored the relationship between dietary habit and pancreatic cancer. The results showed that those who claimed meat as their major daily diet accounted for 31.0% of patient group, while the number dropped significantly to 7.6% in control group. For those who claimed vegetable was their major daily diet accounted for 39.7% (46/116) in patient group and 28.9% (57/197) in control group. The diet containing half meat and half vegetable was reported by 25.9% (30/116) of patient group and 57.9% (114/197)

Table 4 Benign digestive diseases in patients and controls

Diseases	Patients				Controls				*P*
	n	Yes	No	Not stated	*n*	Yes	No	Not stated

Abdominal pain	2	119	38.7	61.3	0	205	4.9	95.1	0	<0.0001
Jaundice	1	119	42.0	58.0	0	205	0.5	99.5	0	<0.0001
Skin itch	1	119	13.5	86.6	0	205	8.7	91.3	0	0.0032
Weight loss	3	119	76.5	22.7	0.8	205	2.4	97.6	0	<0.0001

of control group. Therefore, people who had meat as their major diet faced higher risk of developing pancreatic cancer.

Also we found that 18.5% patients with pancreatic cancer had a history of diabetic mellitus; however this ratio dropped to 5.8% in the control group. There was significant difference between patient group and control group in having chronic pancreatitis, cholelithiasis and cholecystitis (Table 4). Moreover, we asked each subject for any cancer family history among the primary and secondary generation relatives, but no significant differences were found between the two groups. In patient group, those who had a family history of cancer accounted for 26.9%, while in the control group was 31.3% ($P=0.4064$). For those who lost weight in patient group, 48.9% patients lost weight within 3 mo, 33.3% in 4-6 mo, 16.7% in 7-12 mo, and 1.1% in more than 1 year. In addition, 45. 6% of patients had weight lost less than 5 kg, 30.0% between 6 to 10 kg, and 24.4% more than 10 kg (Table 5).

Although most factors had significant difference between two groups, their OR value did not show significance except for smoking and drinking due to relatively small sample of this study.

Establishment of the high-risk scoring model of pancreatic cancer

With multivariable logistic regression and some adjustments, we established the high-risk scoring model (as shown in Table 6).

The score of pancreatic cancer group was 80.6 ± 30.0 (95% CI 74.9-86.3), and the score of normal control group was 7.4 ± 11.9(95% CI 6.0-8.7), ($P<0.001$, Mann-Whitney test). According to the scores of pancreatic group and normal control group, we protracted ROC curve and the area below the curve was 0.981. When selecting $\geqslant 45$ as the differential cutoff between pancreatic cancer and normal control, the sensitivity and specificity of diagnosis were quite ideal, which were 88.9% and 97.6% respectively.

DISCUSSION

Because the two groups in our study were matched according to age and gender, there were no significant differences of the two factors. Based on previous studies on risk factors we included the two factors into high risk model. We have reported earlier that mortality of pancreatic cancer rises with age[2]. In a study involved 1619 cases of pancreatic cancer, 3.95% of the patients died before 40, but the mortality rate between 65 to 80 years was more than 5 times that of the average[2], which is consistent with other reports[3-6]. From 1991 to 2000, the epidemiological data of pancreatic cancer in China showed that the average male's mortality rate, revised mortality and standardized mortality grew 4.23%, 5.1% and 3.1% per year respectively, but the average growth rates for female were 7.7%, 8.6% and 6.74% respectively[2]. Although the gender disparity had been decreasing during this period, the increasing mortality rate in female has outpaced male. The age standardized mortality rate of male and female decreased from 1.97 in 1999 to 1.41 in 2000, which was consistent with report by Zheng *et al*[7].

Smoking is the only widely recognized risk factor for pancreatic cancer. Compared to non-smokers, the mortality rate of pancreatic cancer in smokers increased by 1.2-3.1 fold, and showed a dose-effect relationship. We found that the risk of pancreatic cancer occurrence increased in the heavy-smoking group (OR, 1.98; 95% CI, 1.11-3.49; $P=0.017$), which is consistent with previous literatures[4,8,9]. There was no consistent conclusion drawn for the risk of drinking associated with pancreatic cancer in literatures[4,10-12]. The OR value in the heavy-drinking

Table 6 Risk scoring model for pancreatic cancer

Risk factor	Criteria	Points
Gender	Male	2
Age (yr)	>60	7
Alcohol drinking	>20 drink-yr	4
Smoking	>17 pack-yr	5
Diabetic mellitus history		17
High meat consumption		7
Family history of pancreatic cancer		15
Chronic pancreatitis		12
Cholelithiasis history		8
Cholecystitis history		1
Anorexia		25
Epigastric pain		25
Weight loss		37
Jaundice		30

subgroup was 3.70 (95% CI, 1.604-8.443) compared to non-drinking subgroup. Therefore, we considered the risk of drinking associated with pancreatic cancer mainly existed in the heavy-drinking patients. Immigration epidemiological research showed that the mortality rate of pancreatic cancer among Asian and African populations in their homeland was low. However, for Asians and Africans who lived in western countries and adopted western diet habits, the risk of having pancreatic cancer was similar to or even higher than the Caucasians[13]. From our study, the percentage of people who had high meat consumption in their daily diet was much higher in the patient group than in control group ($P < 0.0001$). Currently, 35% of pancreatic cancers were attributed to the dietary factor. It was reported earlier that the vegetable abundant diet could prevent 33%-50% of pancreatic cancer cases[14].

Whether diabetes is the etiologic factor or the early manifestation of pancreatic cancer is still controversial. When probing into the relationship between them, we cannot draw a conclusion because it is impossible to carry out a randomized prospective research. At the same time, it is difficult to obtain evidence from animal experiments because of lacking credible animal model for type II diabetes. Currently, most investigations have used case-control study and prospective cohort study in general population. In our case-control study, 18.5% of pancreatic cancer patients had diabetes history, while only 5.8% of the control group did. This finding is in accordance with other researches[15-18].

The relationship between chronic pancreatitis and pancreatic cancer is still under debate. Our study showed that 22.5% of pancreatic cancer patients had chronic pancreatitis while only 0.49% of control group did. Karlsen reported that the risk of pancreatic cancer increased 13 times from a follow-up investigation of 715 chronic pancreatitis patients for an average of 10 years during 1971 to 1995[19]. At the same time, the author noticed that the incidence of pancreatic cancer was much higher than non-pancreatic tumors among those patients.

A population based case-control study showed that performing cholecystectomy a year before the diagnosis of pancreatic cancer was related to the occurrence of pancreatic cancer. However, the risk gradually decreased along with the delay of the surgery, but still positively related [11]. Because pancreas and bile duct tumors are difficult to distinguish, some researchers believed that patients with concealed pancreatic tumor were likely to have cholecystectomy performed because of presumed cholelithiasis. However, we did not discover any relation between pancreatic cancer and cholecystectomy in our study. Therefore, it still awaits further clarification.

We established the high-risk scoring model on the basis of the results of case-control study and clinical experience. The risk factors in the high-risk model including smoking, weight loss and diabetes are basically the same as that of overseas studies. For instance, in the cancer risk index established by Harvard University[20], the risk factors for pancreatic cancer are smoking (moderate to high dose), family history of pancreatic cancer, diabetes, chronic pancreatitis and carbohydrate ingestion. In that index, they mainly do allotment of fraction according to the OR value of each risk factor. However, our model is to confirm the fraction of each factor according to the result of logistic multivariate regression, and it reveals the relative contribution of each risk factor to pancreatic cancer. Our risk model is to help clinical diagnosis, which is different from the cancer risk index of Harvard University whose purpose is cancer prevention. So we added the associated symptoms of pancreatic cancer to the risk model. Although the main symptoms of pancreatic cancer such as abdominal pain and jaundice usually appear late when the tumor is already in advanced stage, there are some non-specific symptoms such as anorexia and weight loss which are very obscure and easy to be overlooked by patients and doctors or mistakenly diagnosed as other diseases and functional abnormity[21,22]. So tackling the symptom clues might be helpful for screening and early diagnosis of pancreatic cancer. Our research showed that weight loss, epigastric pain and diabetes all had significant differences in the two groups, but weight loss in mo offers the best indication for diagnosis, so its score is the highest.

In conclusion, we have established a risk factor model for early screening of pancreatic cancer in Chinese Han population through case-control study. In future, we will apply this model in areas that have high incidence of pancreatic cancer in Han population to further improve our model.

Abstract

AIM: To find out whether there is a significant difference in the prevalence of the precore stop codon mutation between HBeAg positive and anti-HBe positive children.

METHODS: We investigated a large pediatric population of 155 European children (mean age 10.9 years) with chronic hepatitis B by PCR and direct sequencing. Ninety were HBeAg positive and 65 had seroconversion to anti-HBe. Additionally genotyping was performed.

RESULTS: Seventy-four (48%) of the sequenced HBV strains were attributed to genotype D and 81 (52%) to genotype A. In the group of 90 HBeAg positive patients, 2 (2.2%) 1896-G-to-A transitions leading to precore stop codon mutation were found, and in the group of 65 anti-HBe positive children, 5 (7.7%) were identified harbouring HBeAg-minus mutants. The difference was not statistically significant ($P = 0.13$).

CONCLUSIONS: HBeAg minus variants as predominant viral HB strains play a minor role in the course of chronic hepatitis B in European children.

Key words: Hepatitis B; Precore mutants; Children; HBeAg minus variants

INTRODUCTION

Chronic hepatitis B (HB)-infection is a serious health problem worldwide and the leading cause of liver cirrhosis and hepatocellular carcinoma (HCC). In Germany 0.3%-0.5% of the population are HBsAg carriers and it is estimated that approximately 5% of them are children. Mutations preventing the expression of HBeAg, so-called precore stop codon mutations, have been reported to aggravate liver disease and to cause fulminant hepatitis in children as well as in adults[1-3]. Currently it is not yet clear whether these mutations influence the response to antiviral treatment. However, a recent study has shown a better outcome after interferon-alpha treatment for chronic hepatitis in individuals without precore mutant strains before treatment[4]. The most common stop-mutation is the G1896A-substitution in the precore region of HB-virus. A guanine (G) to adenine (A) mutation of the HBV precore gene at nucleotide 1896 (numbered from the EcoRI site) leads to a conversion of codon 28 from TGG (tryptophan) to TAG, which is a stop codon, thereby rendering HBV incapable of producing HBeAg[5]. In adults the prevalence of this mutation ranges between 20%-95%, whereas it is more common in HBeAg-negative than in HBeAg-positive patients[6]. Results of a cross-sectional multicenter study of adults with chronic HBV infection in the United States show an association of the presence of precore variants with higher serum HBV DNA levels in HBeAg-negative but not in HBeAg-positive patients[7]. The selection of precore variants is dependent on HBV genotype. It is most common in patients with genotype D and rare in patients with genotype A[8]. This phenomenon is related to base pairing in the stem-loop structure of the pregenome encapsidation sequence[9,10].

Fukuda *et al*[11] have postulated that hepatitis B virus exists mainly as a quasi species. On account of this, a correlation of nucleotide sequences with clinical and serological findings has to be made with caution. Available data about prevalence and significance of precore mutations in childhood are limited. A study of children with chronic HBV infection ($n = 60$) has shown the 1896-G-A-transition in 93% as mixed infection, with a similar prevalence of mixed viral populations in responders and non-responders to interferon treatment[12]. In the course of chronic HBV infection in children the frequency of precore mutant is increased after seroconversion from HBeAg to anti-HBe. It has been postulated that the higher

the aminotransferase levels are, the higher and the earlier the mutant emerges[13].

The aim of this study was to evaluate the prevalence of precore mutations in a large cohort of European children with chronic hepatitis B.

MATERIALS AND METHODS

Patients

A cross sectional testing of sera from 155 randomly assigned HBsAg positive chronic hepatitis B virus carriers was performed. The median age of the children at the time of blood sampling was 10.9 years. Ninety were HBeAg positive and 65 had seroconversion to anti-HBe 1 - 3 years before blood sampling. Fifty-four (35%) were female, 101 (65%) male; 108 (70%) of Caucasian, 42 (27%) of Mediterranean and 5 (3%) of Southeast Asian origin. ALT was elevated in 66 (73%) of HBeAg positive individuals (mean: 1100 nkat/L) and in 18 (28%) of anti-HBe positive individuals (mean: 367 nkat/L; normal <417 nkat/L).

HBV molecular analyses

DNA was extracted from sera with the QiaAmp blood kit (Qiagen, Chatsworth, CA, USA) and eluted with 50 μL distilled water according to the manufacturer's recommendations. The precore region of the HBV genome was amplified and re-amplified with a proof reading of expand-polymerase (Expand High Fidelity PCR System) by nested PCR. The following primers were used for amplification (nucleotide positions are according to the unique EcoRI site[14]: Sense P1: 5' -TGTCAACGACCGACCTTGAG-3' (nt 1683-1702), anti-sense P2: 5'-CAATGCTCAGGAGACTCTAAGGC-3' (nt 2045-2023); nested PCR: sense P3: 5'-GAGGAGT TGGGGTAGGACATT-3' (nt 1736-1756), anti-sense P4: 5'-TAGCTCCAAATTCTTTATA-3' (nt 1936-1918). PCR was performed in a 50-μL mixture with 20 pmol of each primer (Roth, Germany), 100 mmol/L of each dNTP, and 2.5 units of a Taq-Tgo polymerase mixture (Expand High Fidelity PCR System, Roche, Germany) diluted in 10 × expand polymerase buffer (Expand High Fidelity PCR System, Roche, Germany) in a DNA thermal cycler (Eppendorf Mastercycler personal). The amplified products were visualized by 20 g/L agarose electrophoresis and ethidium bromide staining.

Direct sequencing of PCR products

The amplified PCR products were purified by QIA Quick PCR-purification kit (Quiagen, Chatsworth, CA) according to the manufacturer's recommendations and precipitated with isopropanol to remove residual dNTPs and primers and re-suspended in a final volume of 10 μL distilled water. Nucleotide sequences of the PCR products were determined using a dye terminator cycle sequencing kit (big dye vs 3.1) in an automated sequencer (ABI PRISM, Foster City, CA, USA). The sequencing primers were the same as those used for DNA amplification.

Genotyping

The HBV-DNA sequences were assigned to the appropriate genotype based on the restriction fragment length polymorphism (RFLP) created by Ava2 and Dpn2 action on an amplified segment of the pres-S-region according to Lindh *et al*[15]. PCR of certain serum samples was performed under conditions as previously described with the following primers: Sense P1: 5'-CGA GGCAGGTCCCCTAGAAGAAGAA-3' (nt 2356-2380), anti-sense P2: 5'-GTCCTAGGAATCCTGAA-3' (nt 187-171); nested PCR: sense P3: 5'-TCACCATATTCT TGGGAACAAGA-3' (nt 2819-2841), anti-sense P4: 5' -TTCCTGAACTGGAGCCACCA-3' (nt 82-63). The PCR products were incubated with restriction enzymes Ava II and Dpn II (New England Biolabs, Inc., USA) for 3 h at 37 °C in a 15 μL reaction sample according to the manufacturer's recommendations. The products were visualized by 2 g/L agarose electrophoresis and ethidium bromide staining.

Statistical analysis

Fisher's exact test was used for statistical analysis $P < 0.005$ was taken as significant.

RESULTS

A total of 155 patients were enrolled. Seventy-four (48%) of the sequenced HBV strains were attributed to genotype D and 81 (52%) to genotype A. In the group of 90 HBeAg positive patients, 2 (2.2%) 1896-G-to-A transitions leading to precore stop codon were found, and in the group of 65 anti-HBe positive children, 5 (7.7%) were identified harbouring HBeAg-minus mutants. The difference was not statistically significant ($P = 0.13$).

First, all sera were randomly selected for analysis without association with patients' identities. We were then able to additionally investigate four HBeAg positive sera of the five patients who showed precore-mutations in anti-HBe positive status of the disease in order to find out if mutations already emerged in the HBeAg positive status. One of them was also positive for the G1896A-substitution in the HBeAg positive phase. All mutations identified were found in HBV DNA sequences of genotype D (Figures 1, 2).

The ALT levels in the two HBeAg positive sera with precore-mutation were 883 and 2983 nkat/L, reflecting a considerable elevation in one patient compared to the wild type sera of HBeAg positive status (mean: 1100 nkat/L). In the five anti-HBe positive individuals with the G1896A-substitution, the ALT levels were mildly elevated (mean: 467 nkat/L) compared to the group of 60 patients with wild type virus infection (mean: 367 nkat/L).

DISCUSSION

In contrast to previous studies with adults in particular, which reported HBeAg stop codon mutants in 20-95% of investigated patients (6, 16), we found a very low prevalence in children, both in the HBeAg (2.2%) and anti-HBe positive (8%) phase of the disease. However, our results demonstrated consistently that precore variants were more common in anti-HBe positive children, but the difference did not reach statistical significance. We were

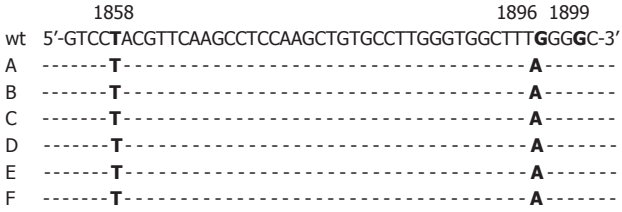

Figure 1 Precore region of HB virus with G1896A-substitution in 6 patients compared to the wild type-sequence (wt). Samples A and B were HBeAg positive. Samples while C-F were anti-HBe positive. All patients belonged to genotype D showing T at nucleotide position 1858.

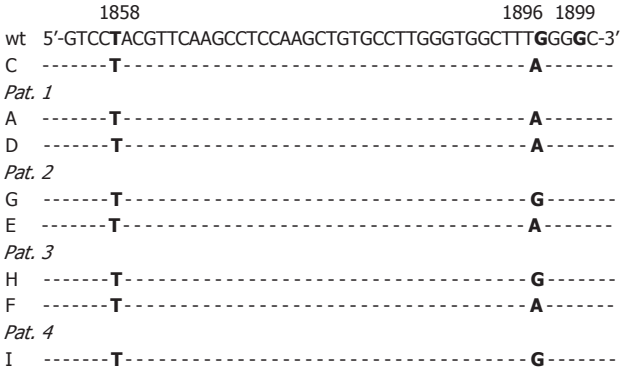

Figure 2 Precore region of HB virus in anti-HBe and HBeAg positive sera of 4 patients compared to the wildtype-sequence (wt). Samples A and C, G and D, H and E, I and F each belonged to one patient respectively. Samples C-F were anti-HBe positive, showing the G1896A-substitution. Samples A, G, H and I were HBeAg positive. All but sample A were negative for the mutant virus strain. Only one patient (No. 1) showed the G1896A-substitution both in anti-HBe and HBeAg positive serum (samples A and C). All patients belonged to genotype D showing T at nucleotide position 1858.

not able to show that mutations in anti-HBe positive sera have necessarily emerged already in the HBeAg positive phase of the disease. Thus, our data suggest that there is at least no strong evidence for the hypothesis that the mutant is selected by host immune pressure[13].

Due to the fact that the occurrence of the G1896A mutation is restricted to HBV genotypes with T at nucleotide position 1858 (genotype D)[17], it was not surprising that no mutations were identified in the group of genotype A virus strains. It has to be conceded that the existence of viral quasi-species including small amounts of precore stop mutations could not be excluded in our survey due to the method of direct sequencing. However, considering the high proportion of genotype D in our survey (48%), the postulation of a high prevalence of the G1896A precore mutation in these HBV strains[16] was not confirmed in chronically infected children.

It was reported that the precore mutation is common in Mediterranean and Asian populations, and two studies have shown a high prevalence of 16%-40% of the HBeAg minus variants in German adult populations as well[18,19]. It seems obvious that the age of the patients is more important than their ethnic origin.

Due to the elevated levels of transaminases in HBeAg positive sera, precore mutations may influence the inflammatory activity of the disease. But indeed, evidence is limited due to the small number of patients. In contrast to former studies, wherein a difference in clinical courses between genotypes B and C was described[20], this seems to be different for the most prevalent genotypes A and D in Europe, because they were equally distributed in our patients.

In summary, HBeAg minus variants as predominant viral HB strains play a minor role in the course of chronic disease in European children. Our results confirm the recent study of Söderström and colleagues who postulated that the most influential factors of HB-infection in childhood are epidemiologic parameters and the route of transmission[21].

Abstract

AIM: To analyze our Wilson disease patient cohort ($n = 106$) for alterations in the gene coding for *MURR1*.

METHODS: Patients with an established diagnosis of Wilson disease but normal ceruloplasmin blood levels were chosen for our study ($n = 14$). Patients with two known disease-causing mutations in the *ATP7B* gene were not included. The three exons of the human *MURR1* gene were sequenced after amplification of the genomic DNA by polymerase chain reaction.

RESULTS: Our study did not reveal any mutations leading to an amino acid change in the *MURR1* sequence of Wilson disease patients. A polymorphism at 472 bp of the coding sequence could be confirmed.

CONCLUSION: The *MURR1* gene plays no role in the pathogenesis of Wilson disease patients with normal serum ceruloplasmin levels.

Key words: Wilson Disease; ATP7B; MURR1; COMMD1

INTRODUCTION

In humans, Wilson disease (WD) is an autosomal recessively inherited disorder of copper metabolism[1, 2] characterized by the impaired biliary excretion of copper. Wilson disease leads to toxic copper accumulation predominantly in the liver and brain, causing liver cirrhosis and severe neurological defects. Common clinical findings in WD are low serum ceruloplasmin (CP) levels, elevated hepatic copper contents, elevated urine 24-h copper excretion and Kayser-Fleischer rings[3]. Homozygous or compound heterozygous mutations in the copper-transporting P-type ATPase ATP7B lead to Wilson disease[4, 5].

The genetic background is highly variable, with more than 300 mutations reported so far[6]. But not all cases are unambiguous because no mutations in the *ATP7B* gene have been found in some WD patients. It is unclear why no *ATP7B* mutations are detectable in a subgroup of patients presenting with typical features of Wilson disease. It might be due to an incomplete analysis of the *ATP7B* gene or due to other yet unidentified defects of genes involved in copper metabolism.

The clinical presentation is highly variable even among patients with the same mutation. In Wilson disease a low serum ceruloplasmin level is a typical finding and can be observed in 80%-90% of the patients. Ceruloplasmin is a copper binding ferroxidase in blood[1]. Today's understanding of the underlying molecular mechanisms[7] is that ATP7B is predominantly localized to the trans Golgi network and transports copper across the membrane to the lumen of the Golgi apparatus where apoceruloplasmin is loaded with copper. In case of a malfunction of ATP7B, apoceruloplasmin can not be loaded with copper and is degraded more rapidly, resulting in reduced blood levels of ceruloplasmin. Under elevated copper conditions, ATP7B translocates from the trans Golgi network to a vesicular compartment where it may facilitate biliary copper excretion[8, 9].

Recently, the autosomal recessively inherited canine copper toxicosis has been described in Bedlington terriers. Like in Wilson disease these dogs develop copper accumulation in the liver due to impaired biliary copper excretion leading to chronic hepatitis and cirrhosis. Neurological abnormalities have not been reported. The genetic basis of this defect is a deletion of the exon2 of the *Murr1* gene[10-12] mapped to 10q26 in Bedlington terriers. The human orthologous gene has been identified on chromosome 2p13-16 and is distinct from the *ATP7B* gene locus[11]. Furthermore, affected dogs present with normal ceruloplasmin serum levels, suggesting that the defect is beyond the trans-Golgi network. A direct interaction be-

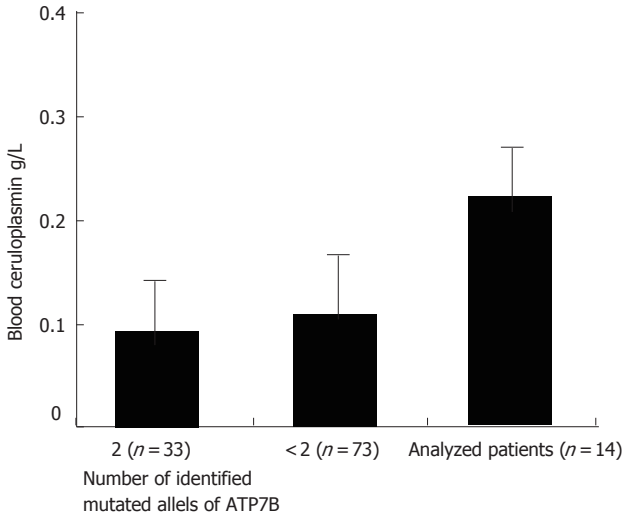

Figure 1 Mean ceruloplasmin blood levels in patients with two or less identified mutated alleles of ATP7B.

tween MURR1 and ATP7B has been reported[13]. There is biochemical evidence that decreased MURR1 levels lead to intracellular copper accumulation[14]. Based on these observations a role of MURR1 in the biliary copper excretion downstream of ATP7B has been suggested[15].

It would be interesting to identify a human disorder caused by defects in the human *MURR1* gene. Recently, a novel protein family (COMMD proteins) of structural and functional homologues of MURR1 (COMMD1) has been identified[16]. Recently, we reported an association between an *MURR1* polymorphism and onset of neurological and hepatic symptoms in WD patients homozygous for the most common *ATP7B* mutation H1069Q. Onset of disease was significantly earlier in patients with a heterozygous state at codon Asn 164 (GAT/GAC) than in patients with wild type (GAT/GAT)[17]. In the former study patients with low ceruloplasmin serum levels were included.

To identify possible disease related mutations in the *MURR1* gene in the current study we focused on patients with Wilson Disease but normal ceruloplasmin serum levels and at least one unknown mutation of *ATP7B*.

MATERIALS AND METHODS

Patients

Data of patients with an established diagnosis of Wilson disease were collected ($n = 106$). The diagnosis of Wilson disease was based on the criteria of the 8th International Conference on Wilson Disease and Menkes disease[19] (Leipzig, Germany April 16-18, 2001). For this study only patients with at least one undetermined mutation of the *ATP7B* gene were selected ($n = 73$), patients with two known disease defining mutations were excluded ($n = 33$). The *ATP7B* gene was sequenced in most patients in cooperation with Professor Ferenci, Department of Gastroenterology and Hepatology, Vienna, including the H1069Q mutation state in all patients. For our investigation out of the subset of WD patients without or with only one disease defining mutation, patients with normal or only slightly reduced ceruloplasmin levels were selected ($n = 14$) at the beginning of the study.

Ceruloplasmin cutoff was defined at a CP level of 0.15 g/L (normal in healthy persons: 0.2-0.6 g/L). Patients were excluded if the finding of a CP level above 0.15 g/L could be explained otherwise (e.g. contraceptive medication, pregnancy, acute phase reaction). A total of 14 patients with a CP level > 0.15 g/L and without any or with only one *ATP7B* mutation could be identified (Figure 1).

Mutation analysis of MURR1

Mutation analysis of *MURR1* was performed as described in detail previously[17]. In short, total DNA from the 14 selected patients was isolated and the three exons of the *MURR1* gene were amplified by polymerase chain reaction. The used primer combinations (exon 1 sense primer 5‘-GGT GGT TTT GCA CAG GCT ATT TAG-3‘, exon 1 anti-sense primer 5‘-GGC TTG TGA GGA CAG GGG AAG G-3‘; exon 2 sense primer 5‘-CAG TGA TTT AAG AGT CAC TC-3‘, exon 2 anti-sense primer 5‘-GCT GAA TAG ACA AGC TAA CAT GTA-3‘; exon 3 sense primer 5‘-GGG TAT TTT GAG TTT GGT CAT GC-3‘, exon 3 anti-sense primer 5’-TGA GAA CCT CTG CAC TGG AAC-3‘) resulted in PCR products covering the exons and parts of the 3` untranslated region and parts of the 5` region upstream of the start codon[17]. Additional putative exons or putative regulatory regions of the *MURR1* gene were not analyzed.

PCR products were purified as described previously[17]. Sequencing reactions were carried out by SEQLAB (Sequence Laboratories, Goettingen, Germany) or by MPI sequencing (Max Planck Institute, Dresden, Germany). For later analysis NM-152516 and AB17881 (NCBI sequence Viewer, http://www.ncbi.nlm.nih.gov/) were used as reference sequence. Nucleotide changes were numbered corresponding to their position in the *MURR1* mRNA beginning with the adenine of the ATG start codon.

RESULTS

The human orthologue of the *Murr1* gene encoded a protein of 190 amino acids. The gene spanned nearly 235 kb. Both introns were about 100 kb each in size (Figure 2). Therefore only the three exonic sequences were analyzed. In this study no mutations changing the amino acid sequence were found in the analyzed patients. A polymorphism at 472 bp of the coding sequence was detected (Table 1). Ten Patients (71%) were homozygous for wild-type GAT, 3 patients (21%) were heterozygous GAT/GAC and 1 patient was homozygous for GAC. The frequency of these variations was in line with previous reports[17]. We already reported a putative association between the GAT/GAC heterozygous state at codon Asn-164 with an earlier onset of disease in H1096Q *ATP7B* homozygous patients [17]. However, in the present study no significant genotype/phenotype correlation could be found, which might be due to the small number of patients.

DISCUSSION

Some patients with Wilson disease show no disease causing mutation in the *ATP7B* gene. Therefore other patho-

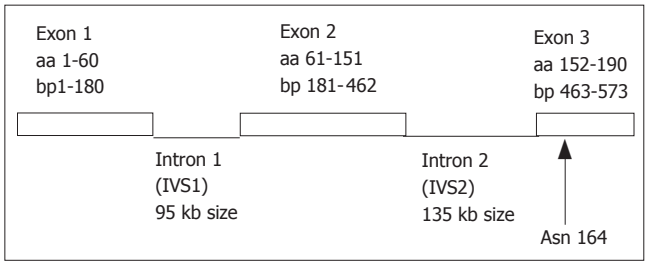

Figure 2 Map of the human *MURR1* gene. Localization of the reported polymorphism (492 T > C) in exon 3 is marked.

genetic factors might be involved. Due to the in part comparable phenotype of canine copper toxicosis and the reported interaction with *ATP7B*, the *MURR1* protein is an interesting candidate.

In this study we focused on Wilson disease patients showing a comparable phenotype to the copper toxicosis in dogs in regard to the normal ceruloplasmin serum level. However, in our group of patients with non-homozygous *ATP7B* mutation, no mutation in the coding sequence of the *MURR1* gene was found. Mutations in other parts of the Murr1 gene were not analyzed but could affect the gene expression and thus affect the phenotype. The finding that copper toxicosis gene *MURR1* is not changed in Wilson disease patients with normal blood ceruloplasmin levels needs to be evaluated in a larger clinical study.

Although our data do not necessarily rule out the possibility that MURR1 is involved in biliary copper excretion under physiological conditions, there is no direct evidence that it is indeed a disease-causing factor in human Wilson disease. This is in agreement with the findings of other investigators[17, 18]. In fact, a homozygous mutation of *ATP7B* resulting in the absence of this protein in the trans-Golgi network may be the only cause of Wilson disease. In our study population with detectable heterozygous or absent mutations of *ATP7B*, the other mutations may have not been identified yet. A low normal ceruloplasmin concentration was also observed in patients with homozygous mutations, suggesting that it may represent an undefined compensatory process by which apoceruloplasmin is loaded with copper by an *ATP7B* independent route, even outside the trans-Golgi network. This route seems to be less efficient but could result in low normal serum coeruloplasmin levels.

Although the possibility that *MURR1* is involved in biliary copper excretion in humans has not been ruled out, *MURR1* does not seem to play a role in the pathogenesis of Wilson disease.

ACKNOWLEDGMENTS

The authors thank the patients for their help and willingness to participate in this study and Dr. Bettina Stuehler for her advice and help with the sequencing reactions.

Abstract

AIM: To assess the actigraphy, an ambulatory and continuous monitoring of wrist motor activity fitted to study sleep/wake patterns in hepatic encephalopathy (HE).

METHODS: Twenty-five cirrhotic patients (17 M, 8 F, mean age 56 ± 11 years, 24/25 alcoholic, Child-Pugh A , B, C: 2, 6, 17) were included. The patients were classified into 3 groups: stage 0 group ($n = 12$), stage 1-2 group ($n = 6$), and stage 3-4 group ($n = 7$) of encephalopathy. Over three consecutive days, patients had clinical evaluation 3 times a day with psychometric test, venous ammoniemia, flash visually evoked potentials (VEP), electroencephalogram and continuous actigraphic monitoring for 3 d, providing 5 parameters: mesor, amplitude, acrophase, mean duration of activity (MDAI) and inactivity (MDII) intervals.

RESULTS: Serum ammonia and VEP did not differ among the 3 groups. Electroencephalography mean dominant frequency (MDF) correlated significantly with clinical stages of HE ($r = 0.65$, $P = 0.003$). The best correlation with HE stage was provided by actigraphy especially with MDAI ($r = 0.7$, $P < 10^{-4}$) and mesor ($r = 0.65$, $P < 10^{-4}$). MDAI correlated significantly with MDF ($r = 0.62$, 0.004) and was significantly shorter in case of HE compared to patients without HE (stage 0: 5.33 ± 1.6 min; stage 1-2: 3.28 ± 1.4 min; stage 3-4: 2.52 ± 1.1 min; $P < 0.05$). Using a threshold of MDAI of less than 4.9 min, sensitivity, specificity, positive predictive value, negative predictive value for HE diagnosis were 85%, 67%, 73% and 80%, respectively.

CONCLUSION: Actigraphy may be an objective method to identify HE, especially for early HE detection. Motor activity at the wrist correlates well with clinical stages of HE. MDAI and mesor are the most relevant parameters.

Key words: Hepatic encephalopathy; Cirrhosis; Actigraphy

INTRODUCTION

Hepatic encephalopathy (HE) diagnosis is based on clinical criteria. Serum ammonia, evoked potentials and electroencephalogram (EEG) have low sensitivity[1-3]. Actigraphy allows ambulatory and continuous monitoring of motor activity and is fitted to study sleep/wake patterns. The actigraph worn on the non dominant wrist is based on a miniaturized acceleration sensor that translates physical motion to a numeric representation. It has already been successfully used in insomnia and extra pyramidal syndrome[4,5]. We assessed the actigraphy in HE.

MATERIALS AND METHODS

Twenty-five cirrhotic patients (17 M, 8 F, mean age 56 ± 11 years, 24/25 alcoholic, Child-Pugh A ,B, C: 2, 6, 17) were consecutively included. Patients with serum sedative or alcohol detection were excluded. Patients were classified into 3 groups: stage 0 group ($n = 12$), stage 1-2 group ($n = 6$), and stage 3-4 group ($n = 7$) of acute encephalopathy. HE causes were alcoholic hepatitis ($n = 5$), severe liver insufficiency ($n = 3$), digestive bleeding ($n = 1$), bacterial infection ($n = 1$), or undetermined ($n = 3$). Over three consecutive days, patients had clinical evaluation 3 times a day with the psychometric test Trail making test A when permitted by consciousness, venous ammoniemia using da Fonseca-Wollheim method, flash visual evoked potentials (VEP) with measurement of latencies of wavex N2, P2, N3, EEG and continuous actigraphic monitoring for 3 d using a small non dominant wrist-worn piezoelectric accelerometer (Gaehwiler electronic actimeter, CH 8634 Hombrechtiken, Switzerland) with a 0.1 G lower limit of sensitivity. Activity (wrist movements) measured at one-min intervals over a period of 24 h, was stored into the actigraph memory. Data downloaded to a compatible computer, were analysed by MONITOR software. The cosinor method or entire data linear adjustment by least-square method, provided 3 parameters: mesor (rhythm-adjusted mean), amplitude (half the variability between peaks to troughs), acrophase (peak time). Mean duration

of activity (MDAI) and inactivity (MDII) intervals independent of recording time, were measured. An activity interval was defined as a period during which the patient had more than 2 movements per minute, and an inactivity interval as a period during which the patient had less than 2 movements per minute. After 3 d, means of pooled data were calculated. Recording was made in hospitalized patients, so that physical activity was standardized.

Statistical analysis

Quantitative data were compared by ANOVA. Correlations were performed by Pearson test ($P<0.05$).

RESULTS

There was no difference between the 3 groups according to venous ammonia (41 ± 17 *vs* 46 ± 33 *vs* 65 ± 50 μmol/L respectively) or VEP (N3 = 201 ± 31 *vs* 205 ± 38 *vs* 227 ± 70 milliseconds). Electroencephalography mean dominant frequency (MDF) correlated significantly with clinical stages of HE ($r=0.65$, $P=0.003$). The best correlation with HE stage was provided by actigraphy especially with MDAI ($r=0.7$, $P<10^{-4}$) (Figure 1) and mesor ($r=0.65$, $P<10^{-4}$). Moreover MDAI correlated significantly with MDF ($r=0.62$, 0.004) and was significantly shorter in case of HE compared to patients without HE (stage 0: 5.33 ± 1.6 min versus stage 1-2: 3.28 ± 1.4 versus stage 3-4: 2.52 ± 1.1; $P<0.05$). In stages 0 and 1-2 of HE, MDAI correlated significantly with Trail making test A ($r=-0.61$; $P<0.05$). Using a threshold of MDAI of less than 4.9 min, sensitivity, specificity, positive predictive value, negative predictive value for HE diagnosis were 85%, 67%, 73% and 80%, respectively.

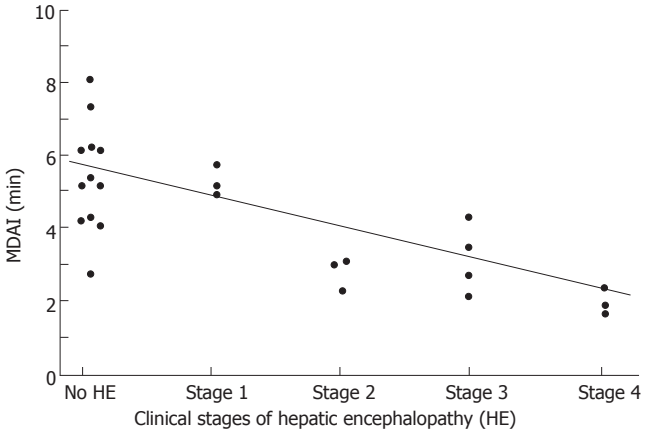

Figure 1 Correlation between clinical stages of hepatic encephalopathy and mean duration of activity intervals (MDAI), $r=0.7$, $P<0.0001$.

DISCUSSION

We suggest for the first time that actigraphy may be an objective method to identify HE. In our study, motor activity at the wrist recorded over three days, correlated well with clinical stages of HE. MDAI and mesor were the most relevant parameters. According to other works, neither serum ammonia[1] nor VEP[2] correlates with HE, contrary to EEG. However, EEG is a hospital procedure which has low specificity[3]. Using actigraphy, Cordoba *et al*[6] have previously shown a decrease of motor activity in cirrhotic patients without clinical evidence of HE. Seven out of 20 cirrhotic patients complained of unsatisfactory sleep, but they did not perform psychometric tests to screen subclinical encephalopathy. Actigraphy[4,5] is non invasive and simple to use. It can provide data under natural conditions over several days, which allows to take into account the oscillations in HE. One limit in our study is the decrease of motor activity due to bed-rest. However, we showed a significant relationship between actigraphy and encephalopathy. Actigraphy exhibits non specific changes in motor activity, but since we standardized physical activity, the observed changes might be due to HE. Our results suggest that actigraphy is especially fitted for early HE detection, since MDAI is significantly shorter in HE stage 1-2 patients compared to HE stage 0 patients. Moreover in cases of HE stages 0 and 1-2, MDAI, mesor, and acrophase correlate significantly with Trail making test A, a psychometric test routinely used to detect sub clinical encephalopathy. Further studies are needed to confirm actigraphy interest in sub clinical encephalopathy, a predictive factor of HE which is reversible by lactulose.

Abstract

AIM: To investigate the hepatoprotective effect of manual acupuncture at Yanglingquan (GB34) on CCl_4-induced chronic liver damage in rats.

METHODS: Rats were injected intraperitoneally with CCl_4 (1 mL/kg) and treated with manual acupuncture using reinforcing manipulation techniques at left GB34 (Yanglingquan) 3 times a week for 10 wk. A non-acupoint in left gluteal area was selected as a sham point. To estimate the hepatoprotective effect of manual acupuncture at GB34, measurement of liver index, biochemical assays including serum ALT, AST, ALP and total cholesterol, histological analysis and blood cell counts were conducted.

RESULTS: Manual acupuncture at GB34 reduced the liver index, serum ALT, AST, ALP and total cholesterol levels as compared with the control group and the sham acupuncture group. It also increased and normalized the populations of WBC and lymphocytes.

CONCLUSION: Manual acupuncture with reinforcing manipulation techniques at left GB34 reduces liver toxicity, protects liver function and liver tissue, and normalizes immune activity in CCl_4-intoxicated rats.

INTRODUCTION

Herbal medicine and acupuncture are the two main methods to treat disease in oriental medicine. Because of chemical residue contamination, there is recent gaining suspicion that herbs may be harmful to the liver. Accordingly, acupuncture is getting more interest these days for the treatment of liver diseases in oriental medical clinics. In the present study, we tried to investigate the effects of manual acupuncture on long-term liver damage. To investigate the effects of manual acupuncture at GB34 on liver damage, we used CCl_4-intoxicated rat model and chose GB34 as an acupoint to protect liver and treat liver damage induced by CCl_4 administration.

GB34 is an acupoint located on the gall bladder meridian. In oriental medical theory, the liver and gall bladder corresponds to each other and their meridians are also closely related with each other in the 'interior-exterior relationship'[1,2]. Gall bladder meridian pertains to the gall bladder organ and connects with the liver organ. The liver meridian pertains to the liver organ and connects with the gall bladder organ. Therefore, the acupoints on the liver meridian are used to treat gall bladder organ diseases as well as liver organ diseases. Consequently, the acupoints on the gall bladder meridian are used to treat liver organ diseases as well as gall bladder organ diseases. Hence, GB34 is closely related with the liver as well as the gall bladder. It explains why GB34 is used to treat liver disease so often. Moreover, GB34 is the *He* (meaning "sea") point of gall bladder. In oriental medical theory, a "sea *He*" point is considered to be the entrance of the meridian energy to the corresponding organ[3]. Therefore, GB34 influences the liver and gall bladder more strongly than other acupoints. The functions of this point are regulating and tonifying the liver, regulating the gallbladder, spreading liver *Qi* (oriental medical term for "vital energy"), subduing liver *Yang*, draining liver pathogens, *etc*. GB34 has been clinically used for hypochondriac pain, jaundice, hepatitis, acute biliary tract diseases, cirrhosis of the liver and hypertension due to liver *Yang* excess, *etc*[1,4].

We presume that neuronal activity is involved in the transmission of acupuncture stimulation, so the animals were not anesthetized during the acupuncture administra-

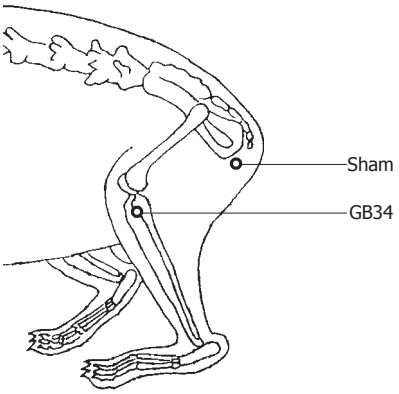

Figure 1 GB34 and sham point for acupuncture.

tion. To keep the animals from moving during the acupuncture administration, they were put in cages with five holes for tail and four limbs. To estimate and exclude the effect of stress from restriction within the cage, the rats in the control group were also kept in the cages in the same manner as the acupuncture group.

The action of acupuncture could be influenced by acupuncture techniques as well as point selection. There are two main categories of acupuncture techniques: reinforcing technique and reducing technique. Clockwise needle rotation, scraping downward of needles, and odd number of manipulating operations are considered as reinforcing techniques. On the other hand, counterclockwise needle rotation, scraping upward of needles, and even number of manipulating operations are considered as reducing techniques. Reinforcing acupuncture manipulation techniques are used for chronic and deficient syndrome, while reducing techniques are used for acute and excess syndrome [1]. Since the animals in the present study were injected with CCl_4 for a long period, we considered it as a chronic and deficient condition, and therefore, we administered acupuncture with reinforcing manipulation techniques.

MATERIALS AND METHODS

Animals

Sprague-Dawley male rats (200-250 g) were purchased from Deahan Biorink Co. The animals were adapted to the environment of 22±2℃ room temperature, 12-h light/dark cycle for 2 wk and had free access to water and food. Our animal experiment has been conducted in accordance with the Use of Laboratory Animals as adopted and promulgated by the U.S. National Institutes of Health.

Experimental design

Experimental animals were randomly divided into four groups: normal; control (CCl_4); Sham (CCl_4 + manual acupuncture at sham point); and GB34 (CCl_4 + manual acupuncture at left GB34). Each group consisted of 7 rats. Liver injury was induced by intraperitoneal injections with 500 mL/L CCl_4 (Sigma, USA) solution in olive oil (1 mL/kg), twice a week for 10 wk. Manual acupuncture was administered 3 times a week during the same period[5].

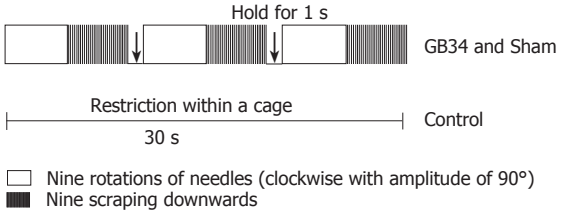

Figure 2 Acupuncture scheme.

Acupuncture

Cages with five holes for the tail and four limbs were manufactured for this study. During acupuncture administration, the animals were kept in the cage with left hind limb fastened to the wall of the cage with tape. Sterilized disposable stainless steel needles (0.25 mm × 30 mm, Dongbang Acupuncture Inc., Korea) were inserted perpendicularly as deep as 2-3 mm at left GB34 or sham point. Rat GB34 was determined according to human GB34 which locates on gall bladder meridian, in the depression anterior and inferior to the head of the fibula[1]. A non-acupoint in the gluteal region was selected as a sham point (Figure 1). After the needles were inserted, they were rotated clockwise with amplitude of 90° nine times, and scraped downward nine times. Nine rotations and nine scrapes constituted one manipulation unit, and three manipulation units constituted one treatment session. After each manipulation unit, there was a hold for about 1 s. The full manipulation took about 30 s. The rats in the control group were kept in a cage for 30 s with the left hind limb tied without acupuncture treatment (Figure 2). All acupuncture was administered by a trained and experienced oriental medical doctor who was unknown about the research protocol except the needle manipulating methods.

Liver index measurement

Rat's body weight was measured before the animals were sacrificed. Rat liver was removed and weighed right after the animal was sacrificed and the liver index (% of liver weight/body weight)[6,7] was estimated.

Biochemical analysis and blood counts

Forty-eight hours after the last administration with CCl_4, the rats were anesthetized with ethyl ether and blood samples were taken from the heart. Blood was centrifuged at 3000 r/min for 15 min and serum was taken. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphotase (ALP), total cholesterol in serum and the populations of RBC, WBC, lymphocytes in plasma were detected.

Histological analysis

The rats were sacrificed and the liver tissues were obtained individually from each group and fixed in 40 g/L formaldehyde. After decalcification in 50 mL/L formic acid, the specimens were processed for paraffin embedding. Tissue sections were obtained and stained with hematoxylin and eosin (HE) or masson's trichrome (MT). Tissue destruction and fatty changes of liver were observed at 400× magnification.

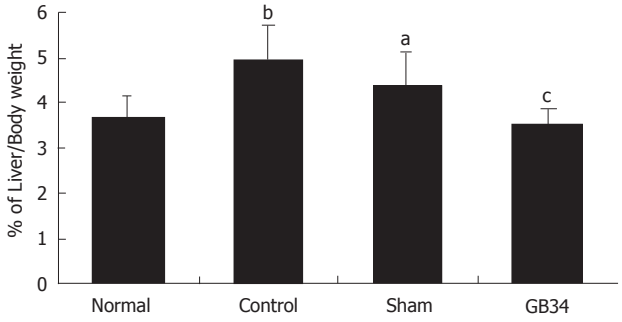

Figure 3 Effect of manual acupuncture at BG34 on liver index of CCl_4-intoxicated rats. [a]$P < 0.05$, [b]$P < 0.01$ *vs* normal group; [c]$P < 0.05$ *vs* control group.

Statistical analysis

Data were obtained from the rats which survived to the end of the experiment. All in normal group, 3 in control group, 3 in sham group and 5 in GB34 group survived to the end of the experiment. Data were expressed as mean ± SD. Statistical significance of difference between groups was determined using ANOVA, followed by *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Liver index

CCl_4 injection induced a significant increase in liver index. On the other hand, manual acupuncture at GB34 lowered it similar to the normal value (Figure 3).

Serum ALT, AST, ALP and total cholesterol

ALT, AST, ALP and total cholesterol in serum were increased remarkably by long-term CCl_4 administration, indicating damage to the liver. Manual acupuncture at GB34 significantly reduced serum ALT, AST and total cholesterol in comparison with the control group. Serum ALP was also reduced by manual acupuncture at GB34 but no statistical significance was found (Figure 4).

Blood cell counts

The number of RBC was slightly reduced by CCl_4 intoxication and restored by manual acupuncture at GB34, though statistical significance was not observed. The number of WBC and the percentage of lymphocytes out of WBC was significantly reduced by CCl_4 intoxication and restored by manual acupuncture at GB34 close to the normal level (Figure 5).

Liver histology

Histological analysis using HE stain showed that necrosis of liver tissue and fatty changes were viciously induced by CCl_4 administration. The group treated with manual acupuncture at GB34 showed reduced feature of hepatocyte necrosis and fatty change compared to the control group and the sham group. In addition, MT staining showed lower accumulation of extracellular matrix in the GB34 group compared to the control group and sham group (Figure 6).

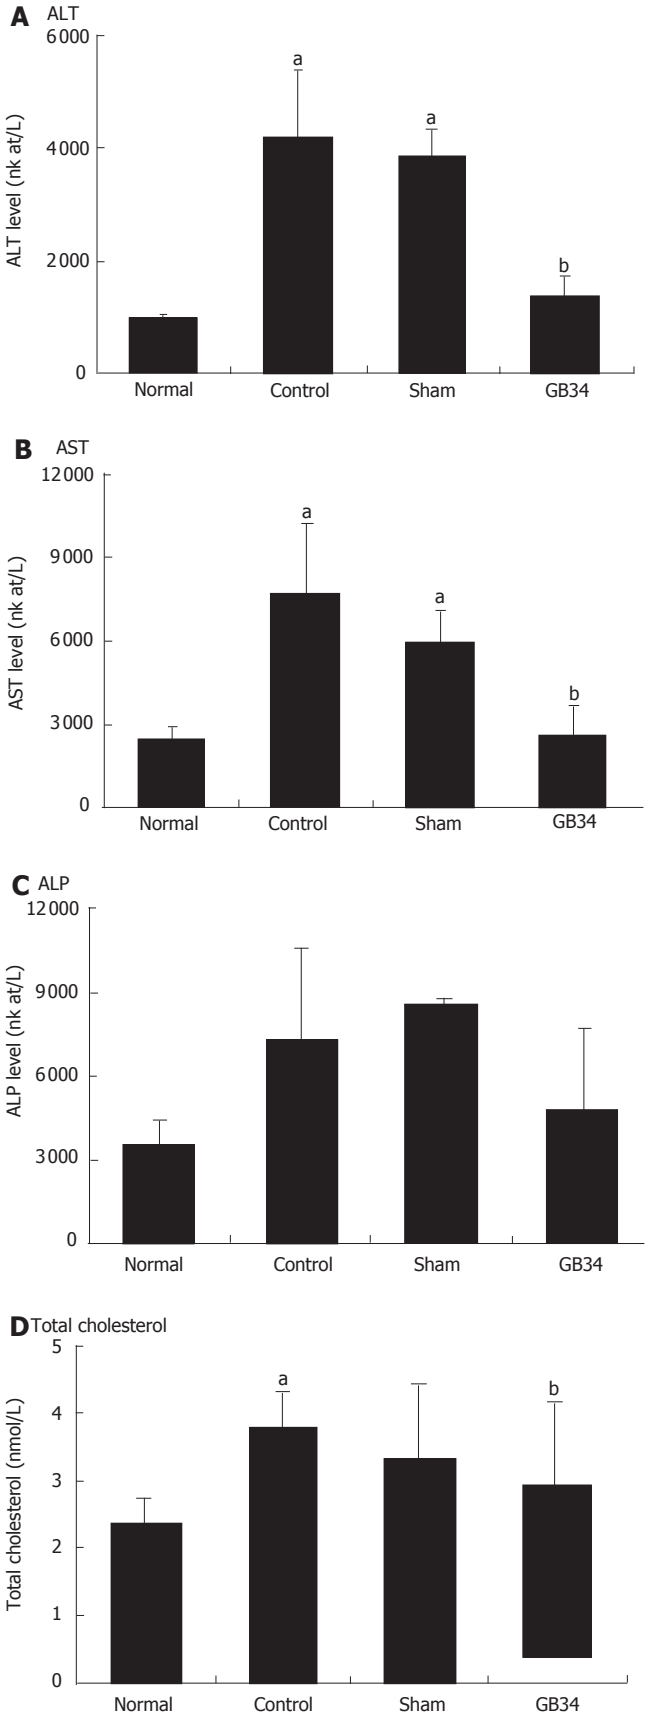

Figure 4 Effect of manual acupuncture at GB34 on serum ALT, AST, ALP and total cholesterol of CCl_4-intoxicated rats. [a]$P < 0.01$ *vs* normal group; [b]$P < 0.05$ *vs* control group

DISCUSSION

CCl_4 has been widely used to induce experimental hepatic

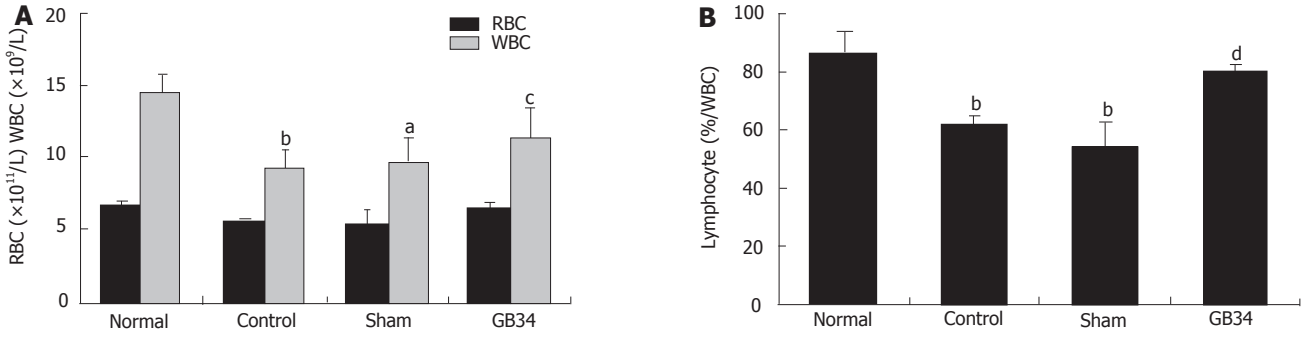

Figure 5 Effect of manual acupuncture at GB34 on RBC, WBC and lymphocytes in blood. $^{a}P<0.05$, $^{b}P<0.01$ *vs* normal group; $^{c}P<0.05$, $^{d}P<0.001$ *vs* control group.

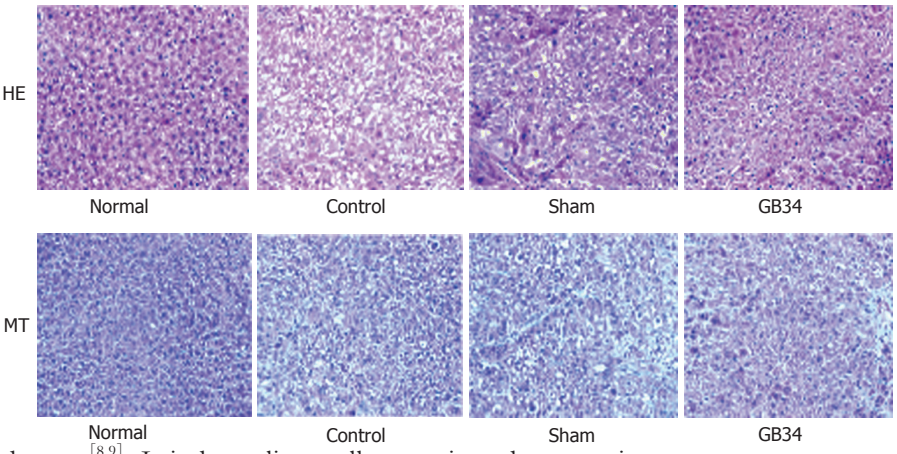

Figure 6 Histological results of liver tissue. Necrosis and fatty change could be found in the control group (top). GB34 group revealed lower accumulation of extracellular matrix compared to the control group and sham group (bottom) (× 400 magnification)

damage[8,9]. It induces liver cell necrosis and apoptosis, and can be used to induce hepatic fibrosis or cirrhosis by repetitive administration[10-12]. Liu *et al*[13] investigated the effect of manual acupuncture at ST36 and LR3 on CCl_4-induced acute liver damage. In the present study, we investigated the effect of manual acupuncture at GB34 on chronic liver damage induced by long-term CCl_4 administration.

ALT and AST are the specific markers to assess hepatocellular damage leading to liver cell necrosis[14]. Slight to moderate increases in ALP (1-2 times normal) occurred in liver disorders[15]. Serum cholesterol is one of the general indications of the synthetic and general metabolic capacity of the liver[16]. In the present study, CCl_4 injection significantly increased serum ALT, AST, ALP and cholesterol levels, indicating induction of hepatic damage. Manual acupuncture at GB34 inhibited the increases of these parameters, indicating that manual acupuncture at GB34 protected liver and reduced liver toxicity. Histological analysis also showed that the acupuncture at GB34 protected liver tissue against CCl_4-intoxication. Our histological analysis in this study was only qualitative. Quantitative assessment of anti-fibrotic effect of acupuncture, such as determination of hepatic hydroxyproline

content, would be meaningful in the next study.

In the present study, long-term CCl_4 administration reduced the population of leucocytes and lymphocytes in blood. We infer that this reduction was due to the decline of immune activity by long-term liver damage. Manual acupuncture at GB34 recovered the population of leucocytes and lymphocytes in blood. Therefore, we presume that manual acupuncture at GB34 restored the immune activity, which is also in agreement with Hau's report on the white cell increase by acupuncture[17]. However, the effect of acupuncture on inflammation in liver is not clear yet. It is known that inflammatory cells are infiltrated in CCl_4-intoxicated liver, and there exists an abnormality of cytokines in liver tissue. For instance, TNF-α and IL-10 are increased, and IL-2 and IFN-γ are reduced in CCl_4-intoxicated liver tissue[18,19]. More profound studies are required on how acupuncture influences the chronic inflammatory conditions of the liver.

Based on the results of the present study, we speculate that manual acupuncture at GB34 is beneficial to protect liver function and tissue, reduce hepatic toxicity and normalize immune activity against CCl_4-intoxication in rats. The hepatoprotective effect of manual acupuncture at GB34 in this study may be related to the immune reinforcing effect of acupuncture or neuro-immune interaction on the pathway of the transmission of acupuncture stimulation.

Abstract

AIM: To investigate whether krÜppel-like factor 6 (KLF6) plays an important role in the development and/or progression of colorectal cancer.

METHODS: A total of 123 formalin-fixed and paraffin-embedded colorectal cancer specimens were analyzed by immunohistochemistry using tissue microarray for the expression of KLF6 protein. The specimens were collected over a 3-year period in the laboratories at our large teaching hospital in Seoul, Republic of Korea. The correlation of KLF6 expression with clinicopathologic parameters was analyzed by χ^2 test and Bartholomew test.

RESULTS: Normal colonic epithelium showed weak to moderate expression of KLF6, whereas reduced KLF 6 expression or loss of KLF6 expression was seen in 45 (36.6%) of the 123 colorectal carcinoma specimens. Interestingly, aberrant expression of KLF6 was detected in 25 (43.1%) of 58 cases with metastasis to regional lymph node and in 31 (47.0%) of 66 tumors more than 5 cm in size. Statistically, loss of KLF6 expression was significantly associated with tumor size ($P < 0.05$). However, there was no significant correlation between KLF6 expression and Dukes' stage (Bartholomew test, $P > 0.05$), tumor location and lymph node metastasis (χ^2 test, $P > 0.05$).

CONCLUSION: Loss of KLF6 expression may be a common and early event in colorectal carcinogenesis.

Key words: KLF6; Mutation; Immunohistochemistry; Aggressiveness; Tumor stage; Colorectal cancer

INTRODUCTION

Colorectal cancer is the second leading cause of cancer-related death in the Western world[1]. In Korea, it accounts for an estimated 11.2% of all malignancies, with 11.6% in the male population and 10.7% in the female population[2]. Thus, colorectal cancer remains a significant contributor to the world's health burden. At a molecular level, great progress has been made in the last two decades in identification and characterization of the genetic changes involved in the malignant colorectal transformation process. Thus, the concept of multistage carcinogenesis is now widely accepted as a consequence of multiple genetic alterations accumulated in cancer cells [3]. However, the molecular mechanisms underlying dysregulated cell growth in colorectal cancer remain the subject of intensive investigation.

Krüppel-like factor 6 (KLF6) is a ubiquitously expressed zinc finger transcription factor that is part of a growing KLF family. The KLF family is broadly involved in growth-related signal transduction, cell proliferation, development and apoptosis, as well as angiogenesis[4, 5]. In functional analysis, wild-type KLF6 up-regulates the cell cycle inhibitor p21 in a TP53-independent manner and suppresses growth, whereas tumor-derived KLF6 mutants fail to upregulate p21 or suppress proliferation in prostatic and non-small cell lung cancer cells[6, 7]. In addition, introduction of KLF6 disrupts cyclin D1-dependent kinase 4 complexes and forces the redistribution of p21, which promotes G1 cell cycle arrest[8]. Furthermore, KLF6 plays

Table 1 Relationship between KLF6 expression and clinicopathologic parameters of colorectal carcinoma

a role as an inhibitor of cell proliferation by counteracting the function of the c-Jun protooncoprotein[9].

Recently, genetic alterations of *KLF6* gene have been identified in several human cancers, including colorectal cancer, hepatocellular carcinoma, prostate and gastric cancer[10-13]. Reduced expression of KLF6 protein has been found in non-small cell lung cancers and glioblastomas[7, 14]. Interestingly, the survey of gene expression in a panel of 60 NCI cancer cell lines showed that expression of KLF6 mRNA was reduced in colon cancer cell lines[15]. However, there is no report describing the expression pattern of KLF6 protein in colorectal cancers.

In the present study, to determine whether altered expression of the KLF6 protein is involved in colorectal cancer development, we analyzed the expression pattern of KLF6 on a series of 123 colorectal cancer specimens.

MATERIALS AND METHODS

Tissue samples

One hundred and twenty-three formalin-fixed and paraffin-embedded colorectal cancer specimens collected between 2002 and 2003 were enrolled in this study. No patient had a family history of colorectal cancer. Tumor stage was classified according to Dukes' criteria. Thirteen patients were classified as Dukes' A, 47 as Dukes' B, 55 as Dukes' C and 8 as Dukes' D[16]. Two pathologists screened histological sections and selected areas of the representative tumor cells. Three tissue cores (0.6 mm in diameter) were taken from each tumor sample and placed in a new recipient paraffin block using a commercially available microarray instrument (Beecher Instruments, Micro-Array Technologies, Silver Spring, MD) as previously described[17]. One cylinder of normal colonic mucosa adjacent to each tumor was also transferred to the recipient block.

Immunohistochemistry for KLF6

The primary polyclonal rabbit anti-KLF6 antibody (Santa Cruz Biotechnology, Santa Cruz, CA) was used. Immunostaining was performed on microarray tissue sections with a tyramide signal amplification kit (NEN Life Science, Boston, MA) for signal intensification. Antigen retrieval was performed by microwave heating in a citrate buffer (pH 6.0). Other procedures were performed as previously described[18]. Reaction products were developed with diaminobenzidine (Sigma, St Louis, MO) and counterstained with hematoxylin. Because all the corresponding normal colonic mucosae showed KLF6 expression, tumors were considered as negative when nuclear and cytoplasmic staining was seen in less than 20% of cancer cells. We calculated the KLF6 positive and negative cancer cells in three representative areas at X200 magnification. We only considered the percentage of stained nuclei in each tumor, independent of the intensity. Three pathologists independently reviewed the results and those cases with discrepant results were discussed until agreement was achieved. As a negative control, we used non-immune rabbit serum instead of the KLF6 antibody.

Statistical analysis

The correlation of KLF6 expression with clinicopathologic parameters, such as tumor site, size, lymph node metastasis and clinical stage, was analyzed by χ^2 test and Bartholomew test. $P < 0.05$ was considered statistically significant.

RESULTS

Expression of KLF6

We assessed the pattern of KLF6 protein expression in 123 colorectal carcinoma specimens by immunohistochemistry using tissue microarray. The KLF6 expression was positive in cytoplasm and nuclei of normal colonic mucosal epithelial cells, but weak to moderate in lymphocytes and fibroblasts. The expression of KLF6 in tumor cells was compared to the expression in their corresponding normal colonic mucosae. Interestingly, reduced KLF6 expression or loss of KLF6 expression was found in 45 (36.6%) of the 123 colorectal carcinoma specimens, in which immunostaining on cytoplasm and nuclei of tumor cells was predominantly (Figure 1). Unexpectedly, overexpression of the KLF6 in cancer was also found in 12 cases. Negative immunoreactivity was seen in 15.4% (2 of 13 cases) of stage A, 38.3% (18 of 47) of stage B, 41.1% (23 of 56) of stage C, and 25.0% (2 of 8) of stage D, respectively (Table 1). Loss of expression was found in 25 (43.1%) of 58 cases with metastasis to regional lymph nodes and 32 (32.7%) of 98 left-side colorectal cancers. In addition, immunostaining was negative in 31 (47.0%) of 66 cases with tumors >5 cm. Statistically, loss of KLF6 expression was closely associated with tumor size (χ^2 test, $P < 0.05$). However, there was no significant correlation between KLF6 expression and Dukes' stage (Bartholomew test, $P > 0.05$), tumor location and lymph node metastasis (χ^2 test, $P > 0.05$).

DISCUSSION

It has been reported that several KLFs play an essential role in maintaining the homeostasis of mammalian cells through the regulation of proliferation and

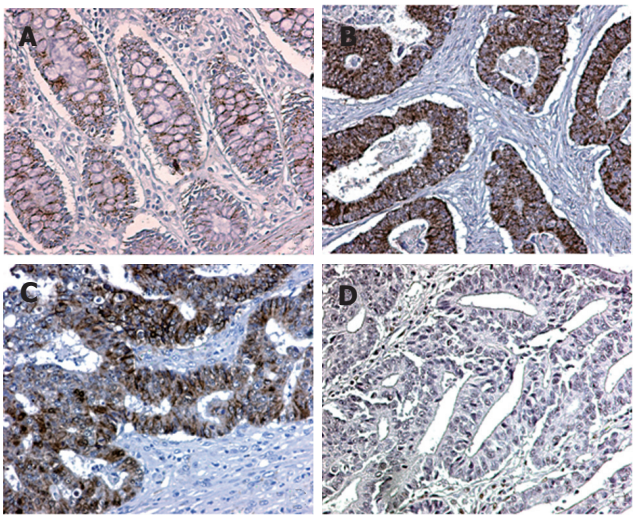

Figure 1 Expression of KLF6 protein in colonic mucosa and cancer. **A:** Positive reaction mainly in colonic glandular epithelial cells; **B:** Predominantly strong immunopositivity in cytoplasm of colon cancer cells; **C**: Predominantly strong immunopositivity in nuclei of colon cancer cells; **D**: Negative staining of KLF6 in cancer cells (original magnifications: X 200).

differentiation[4, 5]. The KLF6 is regulated during mammalian development and tissue regeneration, while its aberrant expression is associated with tumor formation. Recently, KLF6 has been identified as a tumor suppressor gene in several kinds of cancer because of reduced expression and its frequent genetic alterations, such as loss of heterozygosity and mutation, as well as functional suppression of cell proliferation. To further clarify the role of KLF6 in colorectal cancer, we examined loss of expression in 123 colorectal cancer samples.

In this study, reduced KLF6 expression or loss of KLF6 expression was found in 45 (36.6%) of the 123 colorectal adenocarcinoma specimens. Statistically, loss of KLF6 expression was closely associated with tumor size (χ^2 test, $P<0.05$). However, there was no significant correlation between reduced KLF6 expression and other clinicopathologic parameters, including Dukes' stage (Bartholomew test, $P>0.05$), tumor location and lymph node metastasis (χ^2 test, $P>0.05$). It has been reported that the expression of KLF6 protein is frequently down-regulated in non-small cell lung cancer and glioblastoma [7, 14]. Interestingly, down-regulation of KLF6 expression is not associated with the histology or surgical-pathological stages of lung tumors[7]. Taken together, these results further support that down-regulation of KLF6 may contribute to the development of human solid cancers and that inactivation of KLF6 may occur in the development of colorectal cancer as an early event.

Unexpectedly, upregulation of KLF6 was also seen in 14 colorectal cancer cases. Since KLF6 is broadly involved in growth-related signal transduction, cell proliferation, differentiation and apoptosis, upregulation of KLF6 might reflect compensatory mechanisms directed at reestablishing the equilibrium in proliferation, differentiation, and survival characteristics of colonic epithelial cells disrupted during carcinogenesis. Because mutation of the KLF6 is frequently found in colorectal cancer [13], over-expression of KLF6 might be caused by the genetic alteration of the *KLF6* gene. Further studies are necessary to investigate the precise molecular mechanisms underlying its over-expression.

Tissue microarray (TMA) consists of numerous tissues and tumor types. The use of TMA can stain a large number of cases at minimal cost and allow a rapid assessment of the staining profile. However, whether cores of tumor are representative of whole sections remains unclear. It was reported that immunostaining of one to four 0.6-mm cores is correlated with whole sections staining [19], suggesting that the use of small cores is equivalent to whole section immunohistochemistry. Another issue for consideration is that the scoring of TMA immunohistochemistry experiments remains subjective and not easily quantifiable. Significant efforts have been made to quantify protein expression levels on TMA sections [20], but most TMAs are subjectively scored by eyes. In this study, expression of KLF6 in three cores of tumor tissues was compared to their corresponding normal colonic mucosae by three pathologists. Although we did not perform immunohistochemistry on whole section, our results on TMA may be consistent with those of whole section immunohistochemistry.

Generally, the inactivation of a tumor suppressor associated with loss of expression results from genetic or epigenetic alterations, such as mutation, allelic loss or hypermethylation of the promoter region of the genes. Recently, genetic alterations of *KLF6* gene have been identified in several human cancers, including hepatocellular carcinoma, prostate, gastric and colon cancers[10-13]. However, no mutation of KLF6 has been found in human cancer[21-23]. Further studies on a large number of patients are necessary to find out the discrepancy in incidence of *KLF6* mutation. Interestingly, the *KLF6* mRNA is also frequently down-regulated in non-small cell lung cancer, glioblastoma, and colon cancer cell lines[7, 14, http://smd.stanford.edu/cgi-bin]. No mutation has been found in these cancer tissues and KLF6 is down-regulated in all samples with allelic loss[7]. Additionally, the *KLF6* is suggested to be a methylation-silenced gene in esophageal squamous cell carcinoma[24]. In the present study, we found that KLF6 expression was reduced or lost in 36.6% of colorectal cancers (Table 1). Although we did not perform the genetic or epigenetic analysis of the *KLF6* gene, our results suggest that reduced KLF6 expression or loss of KLF6 expression may be a common and early event in colorectal carcinogenesis.

Abstract

AIM: Many cirrhotic patients have muscular symptoms and rhabdomyolysis. However, myopathy associated with liver cirrhosis has not been established as a disease entity. We evaluated the clinical significance of acute myopathy associated with liver cirrhosis.

METHODS: We retrospectively reviewed the medical records of 5440 cirrhotic patients who had been admitted to Gyeongsang National University Hospital from August 1997 to January 2003. Among these, 99 developed acute myopathies, and they were analyzed with respect to clinical and laboratory parameters, and outcomes.

RESULTS: The Child-Pugh classification at the time of myopathy onset was A in 3(3.1%) cases, B in 33(33.3%), and C in 63 (63.6%). Infection was identified as the most predisposing factor to myopathy. Fifty percent of 18 idiopathic cases who were tested for influenza antibody were positive. Forty-two of the 99 cases were complicated by acute renal failure, and 25 (59.5%) of these expired. Apart from 6 cases lost to follow-up, 64 of 93 recovered, giving a mortality rate of 31.2%. Mortality was higher in Child-Pugh class C than in B or A.

CONCLUSION: Acute myopathy can develop as a serious complication in liver cirrhosis. Its frequency, severity and mortality depend on underlying liver function, and are higher in decompensated liver cirrhosis. Influenza should be considered as an etiologic factor in idiopathic cases. It is proposed that acute myopathy associated with liver cirrhosis be called 'hepatic myopathy', and that careful monitoring for hepatic myopathy is necessary in the patients with advanced liver cirrhosis.

Key words: Myopathy; Rhabdomyolysis; Liver cirrhosis

INTRODUCTION

Since many investigators[1-3] had been interested in a causal relationship between alcohol ingestion and acute myonecrosis, Martin *et al*[4] systematically described the clinicopathological features of acute and chronic myopathy associated with alcoholism, and defined this as alcoholic myopathy. Now, it is well known that alcoholism and alcoholic liver diseases can be accompanied by alcoholic skeletal myopathy[5,6]. Moreover, a higher prevalence of muscle cramps was reported in patients with liver cirrhosis than in a matched population without cirrhosis, and it was suggested that muscle cramps be included as a recognized symptom of cirrhosis[7]. Muscular symptoms such as muscle cramps, weakness, aching and tenderness are also common in patients with liver cirrhosis, and even rhabdomyolysis can occur[8-10]. However, myopathy associated with liver cirrhosis has not been established as a disease entity. Here, we investigated the clinical characteristics of acute myopathy, which developed in patients with liver cirrhosis, and evaluated its clinical significance.

MATERIALS AND METHODS

Inclusion criteria

Of the 5440 patients with liver cirrhosis who had been admitted because of various problems related to cirrhosis to Gyeongsang National University Hospital from August 1997 to January 2003, 99 patients who developed acute myopathy were included. We reviewed and analyzed their medical records retrospectively so to find out predisposing or etiologic factors, and possible factors influencing the frequency, severity, and prognosis of acute myopathy associated with liver cirrhosis.

A diagnosis of liver cirrhosis was made based on liver biopsy, or clinical, laboratory and radiological evidence of chronic hepatocellular dysfunction and portal hypertension. Underlying liver function was assessed by Child-Pugh's classification based on laboratory data and physical signs at the time of most recent visit.

Acute myopathy was defined as an elevated serum muscle enzymes, i.e., creatine kinase (CK, 45-390 IU/L), lactate dehydrogenase (LDH, 30-170 IU/L), and aspartate

Table 1 Clinical characteristics of patients with liver cirrhosis who developed acute myopathy

Clinical parameters	Number of cases ($n=99$)
Sex (M:F)	74:25 (2.96:1)
Age (yr) range	27 - 76
mean	51 ± 10
Etiology of LC	
Alcohol	47
CVH (B)	41
CVH (C)	5
Wilson's disease	1
Idiopathic	5
Child-Pugh Class	
A:B:C	3:33:63

LC, Liver cirrhosis; CVH, Chronic viral hepatitis.

Table 2 Predisposing factors of acute myopathy in patients with liver cirrhosis ($n=99$)

Predisposing factors	Number of cases (%)
Infection	46 (46.5)
Respiratory infection	17
Gastrointestinal infection	12
Genitourinary infection	8
Septic shock	5
Alcohol	8 (8.1)
Exercise or trauma	8 (8.1)
Transarterial embolization	4 (4.0)
Herb medicine	3 (3.0)
Dehydration	2 (2.0)
Gastrointestinal bleeding	1 (1.0)
Idiopathic	27 (27.3)

transaminase (AST, 5-45 IU/L), and/or accompanied by acute muscular symptoms, such as muscle cramps, generalized or localized muscle weakness, muscle edema, muscle pain, or tenderness.

Possible predisposing factors were defined as the events occurring within one week prior to the onset time of myopathy.

Acute renal failure was diagnosed when the serum creatinine level increased by more than 50% of the baseline value, to above 1.5 mg/dL[11]. If there was no improvement in serum creatinine despite optimization of intravascular volume in azotemia, hepatorenal syndrome was diagnosed[12].

Exclusion criteria

Exclusion criteria were a history of myocardiac infarction, cardiomyopathy, cerebrovascular accident and other cardiovascular diseases, thyroid disease, peripheral neuropathy, phlebitis, primary muscle disease, heat stroke, and underlying kidney disease, and the ingestion of agents known as triggering agents of myopathy such as digitalis, cimetidine, clofibrate, lithium, opiate, nifedipine, beta 2-agonist, beta-blockers, penicillamine (except for Wilson's disease), cyclosporine, quinidine, antispastic drugs, verapamil, amphetamine, cocaine, vitamin E, or taurine[9,13].

RESULTS

General characterisitics

Ninety-nine (1.8%) of 5440 patients with liver cirrhosis developed acute myopathy. With exception of 4 patients who developed myopathy during hospitalization after transarterial embolization, 95 patients were admitted due to acute myopathy. Seventy-four patients were male, giving a male to female ratio of 2.96. Mean age of patients was 51 ± 10 years (range; 27-76 years), and most were in the 6th decade. The etiology of the liver cirrhosis was alcohol in 47, hepatitis B virus in 41, hepatitis C virus in 5, Wilson's disease in 1, and cryptogenic in 5 (Table 1).

Underlying liver function

Child-Pugh classification at the time of myopathy onset was A in 3 (3.0%), B in 33 (33.3%), and C in 63 patients (63.6%) (Table 1).

Etiologic factors

The most predisposing factor to myopathy was infection (46.5%); respiratory tract infections including common cold in 17, gastrointestinal infections in 12, urinary infection in 8, and septic shock in 5. Alcohol (8.1%), exercise or trauma (8.1%), transarterial embolization (4.0%), herb medicine (3.0%), dehydration (2.0%), and gastrointestinal bleeding (1.0%) were also possible predisposing factors of acute myopathy, and 27 cases (27.3%) were idiopathic (Table 2). In cases of transarterial embolization, acute myopathy developed after hepatic arterial embolization for primary liver cancer in two, and after splenic arterial embolization for splenomegaly with severe pancytopenia in two. Influenza antibody was checked in 18 of the 27 idiopathic cases and 9 (50%) had positive results.

Symptoms and signs

Patients presented with muscle pain (57.6%) and/or generalized muscle weakness (23.2%). However, in 19 patients (19.2%) muscular symptoms were masked with concomitant complications, namely, hepatic encephalopathy (15.2%) or spontaneous bacterial peritonitis (4%).

Muscle enzyme changes

Peak levels of AST, CK, and LDH in serum were 1264.8 IU/L, 20693.2 IU/L, and 1926.7 IU/L, respectively. The intervals from symptom onset to peak levels of these muscle enzymes were 5.1, 5.4, and 6.2 days. According to Child-Pugh class, AST, CK, LDH levels were 925, 6820.7, 1013 IU/L in A, 1359.8, 21083.3, 1991.7 IU/L in B, and 1231.2, 21147.9, 1936.1 IU/L in C, respectively. No statistically significant difference was found in muscle enzymes according to Child-Pugh class (Table 3).

Myoglobin

Sixty cases received a urine orthotolidine test for myoglobin; 38 (63.3%) were negative, and 22 (37.6%) positive. The incidence of myoglobinuria was not different significantly between patients with or without renal failure (41.2% *vs* 33.4%). Serum myoglobin concentrations were high in all patients, but did not differ in myoglobinuria-

Table 3 Muscle enzymes in patients with liver cirrhosis and acute myopathy

	AST (IU/L)	CPK (IU/L)	LDH (IU/L)
Class A	925	6820.7	1013
Class B	1359.8	21083.3	1991.7
Class C	1231.2	21147.9	1936.1
Total	1264.8	20693.2	1926.7
Peak day[a]	5.1	5.4	6.2

[a]The intervals from symptom onset to peak levels.

negative and -positive patients (565 ± 267 *vs* 575 ± 183 mg/dL, $P > 0.05$), or between patients with or without renal failure (616.3 ± 332.1 *vs* 629.9 ± 269.8 mg/dL, $P > 0.05$).

Radionuclide bone scan

A ^{99m}Tc-HDP (hydroxymethylene diphosphonate) radionuclide bone scan was performed in 28 patients, and radionuclide muscular uptake increased in 18 (64.3%) who received the test within a few days of onset. However, it should be noted that all 10 patients who did not show increased muscular uptake received the scan when they showed signs of symptomatic improvement rather immediately after onset.

Hospital course

Guidelines of discharge from hospital were the complete disappearance of muscular symptoms and a normalization or maintenance of muscle enzymes at < 1.5 times the normal value. Mean length of hospital stay was 20.8 ± 14.9 d, and this was longer for Child-Pugh B or C patients than for Child-Pugh A patients (21.6 ± 13.1 d, 20.4 ± 16 d *vs* 12.2 ± 3.1 d). Acute renal failure was a complication in 42 of the 99 (42.4%) acute myopathy patients.

Clinical outcomes

Of the 93 patients followed, i.e., except the 6 lost to follow-up, 64 (68.8%) recovered, and 29 (31.2%) expired. In-hospital mortality was higher in Child-Pugh class C (24/59, 40.7%) than in Child-Pugh class B (5/31, 16.1%) or A (0/3, 0%)(Table 4, Figure 1). Forty of the 93 cases (43.0%) were complicated by acute renal failure, and 25 (62.5%) of these expired. The incidences of renal failure were 0%, 30.3%, and 49.2% in Child-Pugh A, B, and C, respectively. The most common causes of death were hepatic failure (14, 48.3%), renal failure (6, 20.7%), septic shock (6, 20.7%), and upper gastrointestinal bleeding (3, 10.3%).

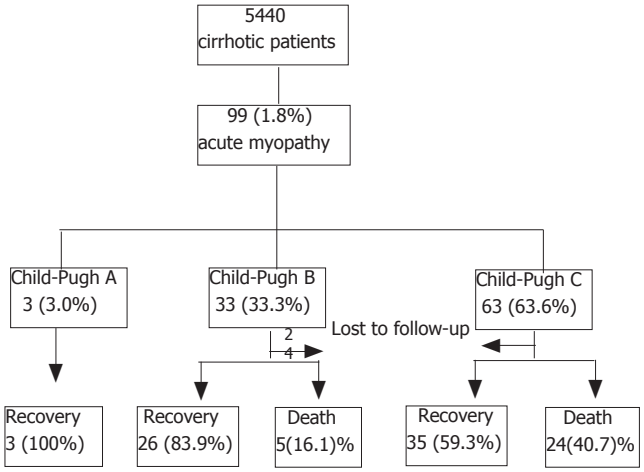

Figure 1 Clinical course of the patients with liver cirrhosis and acute myopathy.

DISCUSSION

Many investigators[7-9] have reported on the high prevalence of muscle cramps in patients with liver cirrhosis. Konikoff *et al*[7] found an 88% incidence of painful cramps in 33 cirrhosis patients, as compared to 21% in a matched population without liver disease. They concluded that the strikingly high incidence and uniformity of the phenomenon might justify the inclusion of painful muscle cramps among the recognized symptoms of cirrhosis. Abrams *et al*[8] suggested that cramps in cirrhotic patients are specifically related to the development of cirrhosis, and that a worsening liver function may be a risk factor for the development of cramps. Angeli *et al*[9] found that the prevalence of cramps was higher in cirrhotic patients than in controls, and that it was related to the duration of recognized cirrhosis and to the severity of liver function impairment. Moreover, they concluded that the pathophysiological link between cirrhosis and cramps may associate with a reduced effective circulating volume, and also indicated that weekly human albumin infusion may be an effective treatment for cramps in cirrhosis. However, these reports focused upon muscle cramps as a symptom observed in liver cirrhosis patients, and not on the clinical and laboratory findings associated with muscular symptoms. Moreover, in addition to muscular symptoms such as muscle cramps, weakness, aching and tenderness, rhabdomyolysis can also occur in liver cirrhosis patients[8-10]. However, no systematic investigation has been conducted on rhabdomyolysis development in cirrhotic patients.

Rhabdomyolysis may be defined as a clinical and laboratory syndrome resulting from skeletal muscle injury with the release of muscle cell contents into the plasma[14]. Increased concentrations of these released substances, such as CK, permit clinicians to diagnose this syndrome[14]. We found an incidence of acute myopathy of 1.8% among hospitalized liver cirrhosis patients. We investigated here cirrhotic patients with elevated muscle enzyme concentrations and/or muscular symptoms, i.e., rhabdomyolysis. And, we described this syndrome as acute myopathy rather than rhabdomyolysis, to better characterize the syndrome and to highlight its significance in liver cirrhosis patients, much like that of the myopathies of alcoholism and alcoholic liver diseases.

We observed that almost all cirrhotic patients who developed acute myopathy had a poor liver function, i.e., Child-Pugh B or C at the time of onset, with exception of 3 cases with Child-Pugh A. Therefore, patients with advanced liver cirrhosis and a poor liver function should be monitored carefully for acute myopathy, in addition to the better known complications of hepatic encephalopathy,

Table 4 Clinical outcome of patients with liver cirrhosis and acute myopathy by Child-Pugh's classification ($n=93$)

Outcome	Child-Pugh class (%)			
	A	B	C	Total
Recovery	3(100)	26(83.9)	35(59.3)	64(68.8)
Death	0(0)	5(16.1)	24(40.7)	29(31.2)
Total	3	31	59	93[a]

[a]Six patients (2 with Child-Pugh B and 4 with C) were lost to follow-up.

gastrointestinal bleeding, or hepatorenal syndrome.

Compared with rhabdomyolysis in the general population, in which drug overdose and septicemia are the most common etiologic factors[15], we found that the most predisposing factor to myopathy development in cirrhotic patients was infection (46.5%), including respiratory, spontaneous bacterial peritonitis (*E. coli*), urinary tract infection, and *Vibrio vulnificus* sepsis. Furthermore, 50% of idiopathic cases were positive for anti-influenza antibody, suggesting that an infectious etiology may account for over 50% of acute myopathy associated with liver cirrhosis, and that influenza should be considered an etiologic factor of acute myopathy developing in cirrhotic patients without a definite etiology. In addition to influenza, various viral and bacterial infections have been reported to be etiologic factors of rhabdomyolysis in the general population[16-20]. Although the precise pathophysiology underlying virus or bacteria-induced rhabdomyolysis is unknown, proposed pathophysiological mechanisms include direct viral or bacterial invasion of skeletal muscle and toxin generation[17]. Muscle biopsies performed on rhabdomyolysis patients found lymphocytic infiltrate or viral inclusions, which support the hypothesis of direct viral invasion[21-23]. Viral DNA PCR analysis of muscle specimens and the identification of viral particles and bacteria in the muscle biopsy specimens, and the isolation of virus by culture from muscle specimens provide more compelling evidence of direct viral or bacterial invasion[22-24].

As 19.2% of our subjects presented with symptoms of concurrent complications other than muscular symptoms, acute myopathy may be difficult to identify in some cirrhotic patients by symptoms alone, i.e., without testing muscle enzymes. Because cirrhotic patients can develop various complications, muscle enzymes investigations are recommended for the detection of acute myopathy. On this point, previous investigations[7-9] were limited because they evaluated only muscular symptoms.

Increased levels of muscle enzymes are the result of skeletal muscle injury and the consequent release of muscle cell contents into the plasma[14]. AST, CK, and LDH peaked 5-6 d after symptom onset, and symptom alleviation was followed by a reduction in muscle enzyme levels (data not shown). The patients with decompensated liver cirrhosis had higher plasma levels of muscle enzymes than cirrhotic patients with a well preserved liver function. These findings represent the natural course of acute myopathy development in cirrhotic patients.

Rhabdomyolysis may or may not result in myoglobinuria, depending on the amount of myoglobin released into plasma, the glomerular filtration rate, and the urine concentration[14]. In the present study, myoglobinuria was present in only 37.6% of subjects who took the urine orthotolidine test; however, serum myoglobin was elevated in all patients. Moreover, myoglobinuria and serum myoglobin levels were unrelated to each other or to the development of renal failure. Different urine sampling times may also have influenced the low incidence of myoglobinuria. Though myoglobinuria is an important clue for the diagnosis of rhabdomyolysis, it cannot be used alone to identify all myopathies. Increased levels of muscle enzymes and serum myoglobin are more sensitive for the diagnosis of rhabdomyolysis, and in particular, CK is a highly sensitive marker of muscle injury[25].

Many case reports have mentioned the usefulness of Tecnetium-99 m bone scintigraphy for the early diagnosis, and for determining the location and extent of the muscle damage in rhabdomyolysis[26-28]. In the present study, a ^{99m}Tc-HDP radionuclide bone scan was diagnostic in 64.3% of the patients evaluated. Patients evaluated within a few days after onset showed increased muscular uptake, but not all patients showing symptomatic improvement who received this test showed increased muscular uptake. Thus, ^{99m}Tc bone agent scintigraphy may be useful for the evaluation of the degree and extent of muscle injury, if it is timely performed.

The length of hospital stay was about 12 d in patients with Child-Pugh A and about 3 wk in the patients with Child-Pugh B or C. Over 40% of cirrhotic cases with acute myopathy were accompanied by acute renal failure. The incidence of renal failure depended on Child-Pugh class, and was highest in patients with Child-Pugh C. Although the pathophysiologic mechanisms of rhabdomyolysis-related acute renal failure are unknown, several mechanisms have been proposed, for example, tubular obstruction by myoglobin plugs and/or urate, renal vasoconstriction caused by the inhibitory effect of myoglobin on endothelial vasodilator production, and toxic free radical produced by ferrous compound, a metabolite of myoglobin[29, 30]. The frequency of acute renal failure in cases of rhabdomyolysis was reported to be 16%-33% in the general population[14,31], and 40.4% in acute myopathy associated with liver cirrhosis. In the present study, among rhabdomyolysis cases complicated by acute renal failure, 62.5% expired, and acute renal failure accounted for 20.7% of these mortalities. Thus, acute renal failure seems to have a prognostic role and its frequency was found to depend on Child-Pugh class. These findings suggest that the status of underlying liver function may be the most important prognostic factor in cases of acute myopathy associated with liver cirrhosis.

The mortality rate reported in the general population was 10%-12%[14, 15, 31], and the overall mortality rate in the present study was 31.2%, which is higher than those reported in cases of rhabdomyolysis in the general population. The mortality rate also depended on the status of underlying liver function. In particular, in-hospital mortality of Child-Pugh C patients was 40.7%. The most common cause of death in cirrhotic patients with acute myopathy was hepatic failure (48.3%).

There are some limitations in this study. First, since the present study was based on retrospective review of medi-

cal records of only symptomatic hospitalized patients, the incidence of acute myopathy was underestimated. In addition, all 5440 cirrhotic patients were hospitalized because of various problems related to cirrhosis so that a majority of them had advanced diseases and the patients with well compensated diseases were not included. Therefore, for all that an analysis of all cirrhotic patients including those without any complication is necessary for defining the predisposing factors for acute myopathy, we could not compare underlying disease function between the patients with myopathy and those without. Thirdly, the diagnosis of myopathy was based on the laboratory and clinical findings, not electromyography or muscle biopsy. However, the decompensated cirrhotic patients can hardly receive electromyography or especially muscle biopsy. Furthermore, the term 'myopathy' was used as rhabdomyolysis in this study.

We found that acute myopathy development is a serious complication in liver cirrhosis patients and that this has several predisposing factors. Moreover, its frequency, morbidity, and mortality were found to depend on underlying liver function and to be higher in decompensated liver cirrhosis. The authors propose that acute myopathy associated with liver cirrhosis be called 'hepatic myopathy' and that careful monitoring is required for its early recognition in the advanced liver cirrhosis patients. The avoidance of predisposing factors by identifying disease mechanisms is certain to reduce the occurrence and mortality of hepatic myopathy. Further studies on the pathophysiologic mechanism and treatment of hepatic myopathy are warranted.

Abstract

AIM: To investigate the mechanism of bombesin-induced circular smooth muscle cell contraction in cat esophagus.

METHODS: Specific G protein or phospholipase C involved in cat esophagus contraction was identified, muscle cells were permeabilized with saponin. After permeabilization of muscle cells, the Gi3 antibody inhibited bombesin-induced smooth muscle cell contraction.

RESULTS: Incubation of permeabilized circular muscle cells with PLC-β3 antibody could inhibit bombesin-induced contraction. H-7, chelerythrine (PKC inhibitor) and genistein (protein tyrosine kinase inhibitor) inhibited bombesin-induced contraction, but DAG kinase inhibitor, R59949, could not inhibit it. To examine which mitogen-activated protein kinase (MAPK) was involved in bombesin-induced contraction, the specific MAPK inhibitors (MEK inhibitor, PD98059 and p38 MAPK inhibitor, SB202190) were used. Preincubation of PD98059 blocked the contraction induced by bombesin in a concentration-dependent manner. However, SB202190 had no effects on contraction.

CONCLUSION: Bombesin-induced circular muscle cell contraction in cat esophagus is madiated *via* a PKC or a PTK-dependent pathway or p44/p42 MAPK pathway.

Key words: Bombesin; G protein; Phospholipase C; Protein kinase C; Protein tyrosine kinase; MAP Kinase; Cell contraction

INTRODUCTION

Bombesin is originally isolated from *Bombina bombina*, a European frog. Utilizing antibodies to amphibian bombesin, bombesin-like immunoreactivity has been identified in mammalian brain, lung, and gut[1]. Bombesin has a wide range of biological effects that include release of hormones, stimulation of pancreatic enzyme secretion, inhibition of gastric emptying, modulation of gastric acid secretion and contractions of various smooth muscle preparations from isolated gut[2]. Until now, four different subtypes of bombesin receptors have been discovered, which can lead to the activation of multiple cell signaling pathways[3]. The primary structures of all these receptor subtypes as deduced from corresponding cDNAs, display seven transmembrane domains coupled to signaling pathways via heterotrimeric G proteins[4-6].

Protein kinase C (PKC) is a family of homologous serine/threonine kinases and presents in cytoplasm. Upon agonist stimulation, it rapidly translocates to the particulate or membrane fraction[7,8]. PKC plays a role in the regulation of sustained agonist-induced contraction of various vascular smooth muscle preparations[9].

Increased protein tyrosine phosphorylation occurs rapidly (within seconds) in response to both polypeptide growth factors and vasoconstrictor hormones[10,11]. Furthermore, epidermal growth factor and platelet-derived growth factor increase vascular tone[12], and are blocked by genistein and typhostins, both of which are inhibitors of tyrosine kinases, indicating that tyrosine phosphorylation is involved in the contractile response[12].

The p44/42 MAP Kinase pathway consists of a protein kinase cascade linking growth and differentiation signals

with transcription in nuclei. Activated p44/p42 MAP kinase translocates to the nuclei and activates transcription by phosphorylation of transcription factors such as Elk-1 and Stat3. A selective and potent inhibitor of the p44/42 MAP kinase cascade, PD98059, has been identified[13]. This compound binds to inactive MEK and prevents phosphorylation and activation by Raf.

To test whether bombesin-induced contraction is mediated via a PKC- or PTK- or MAPK- dependent pathway and which G protein and phospholipase C isozyme is coupled to bombesin, we investigated the signals in mediating contraction induced by bombesin in cat esophageal circular muscle cells.

MATERIALS AND METHODS

Materials

R59949, PD98059 and SB202190 were purchased from Calbiochem (La jolla, CA). G protein antibodies (Gi1, Gi2, Gi3, Gq, and Go), and PLC isozyme antibodies (β1, β3, γ1) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). HEPES, collagenase type F, and other reagents were purchased from Sigma (St Louis, MO).

Preparation of dispersed muscle cells

Single muscle cells were isolated as previously described[14,15]. Muscle strip was incubated overnight in normal potassium HEPES buffer containing 1 g/L papain, 1 mmol/L DTT, 1 g/L bovine serum albumin (BSA) and 0.5 g/L collagenase (type F, Sigma) and equilibrated with 950 mL/L O2 and 5 mL/L CO_2 to maintain a pH of 7.0 at 31 ℃. The normal potassium-HEPES buffer contained 1 mmol/L CaCl2, 250 μmol/L EDTA, 10 mmol/L glucose, 10 mmol/L HEPES, 4 mmol/L KCl, 131 mmol/L NaCl, 1 mmol/L $MgCl_2$ and 10 mmol/L taurine. Next day we warmed up the tissue at room temperature for 30 min and incubated the tissue in water bath at 31 ℃ for 30 min. After incubation, the digested tissue was washed with 50 mL enzyme-free solution on 360 μm Nitex filter and reincubated in enzyme-free solution at 31 ℃ and gassed with 950 mL/L O_2 and 5 mL/L CO_2 and the cells were allowed to disperse spontaneously for 10-20 min. Suspensions of single muscle cells were harvested by filtration through 500 μm Nitex meshes. Before beginning the experiment, the cells were heated at 31 ℃ for at least 10 min to relax the cells. Throughout the entire procedure, care was taken not to agitate the fluid to avoid cell contraction in response to mechanical stress.

Preparation of permeabilized smooth muscle cells

Cells were permeabilized to diffuse the agents such as G protein antibodies or PLC isozyme antibodies. After completion of the enzymatic phase of the digestion process, the partly digested muscle tissue was washed with an enzyme-free cytosolic buffer containing 20 mmol/L NaCl, 100 mmol/L KCl, 5.0 mmol/L $MgSO_4$, 0.96 mmol/L NaH_2PO_4, 1.0 mmol/L EGTA, 0.48 mmol/L $CaCl_2$, and 2% bovine serum albumin. The cytosolic buffer was equilibrated with 950 mL/L O_2 and 5mL/L CO_2 to maintain a pH of 7.2 at 31 ℃. Muscle cells dispersed spontaneously in this medium. The cytosolic buffer contained 0.48 mmol/L $CaCl_2$ and 1 mmol/L EGTA, yielding 0.18 μmol/L free Ca^{2+} calculated as previously described[16]. After dispersion, the cells were permeabilized by incubation for 5 min in cytosolic buffer containing saponin (75 mg/L). After exposure to saponin, the cell suspension was centrifuged at 350 r/min and the resulting pellet was washed with saponin-free modified cytosolic buffer containing antimycin A (10 μmol/L), ATP (1.5 mmol/L) and an ATP-regenerating system consisting of creatine phosphate (5 mmol/L) and creatine phosphokinase (166.7μkat /L). After the cells were washed free of saponin, they were resuspended in modified cytosolic buffer.

Measurement of contraction by scanning micrometry

Contraction of isolated muscle cells was measured by scanning micrometry[17]. An aliquot of cell suspension containing 10^7 muscle cells/L was added to HEPES medium containing the test agents. The reaction was terminated by addition of formalin (10% final concentration). The length of 40-50 muscle cells treated with a contractile agent was measured at random by scanning micrometry, phase contrast microscope (model ULWCD 0.30 Olympus, Japan) and digital closed-circuit video camera (CCD color camera, Toshiba, Japan) connected to a Macintosh computer (Apple, Cupertino, CA) with a software program, NIH Image 1.57 (National Institutes of Health, Bethesda, MD) and compared with the length of untreated cells. Contraction was expressed as the percentage decrease in mean cell length from control.

Statistical analysis

Data were expressed as mean±SE. Data differences between means were determined by Student's *t* test.

RESULTS

Characterization of G protein subtype-coupled receptor of bombesin

Freshly isolated smooth muscle cells were stimulated for 30 s with bombesin (10^{-6}mol/L) and bombesin induced the contraction of smooth muscle cell (24.3%±2.2% decrease in cell length from control). G proteins, Gi1, Gi2, Gi3, G (40 ku), Gq (42 ku), Gs (46 ku) in cat esophagus cells were established as previously described[17,18]. To identify the specific G protein involved in cat esophagus contraction, muscle cells were permeabilized with saponin preincubated in cytosolic medium containing G protein antibody to allow the antibodies to diffuse into the cytosolic region of the cell membrane. These antibodies could block receptor-induced activation of G protein by binding to the terminal peptide region of G protein that could interact with the receptor. After permeabilization, the Gi3 inhibited contraction, but Gi1, Gi2, Go, Gq did not (Figure 1).

PLC-β3 mediated bombesin-induced contraction

We have previously shown that PC-PLC inhibitor D609 could block the bombesin-induced contraction[17]

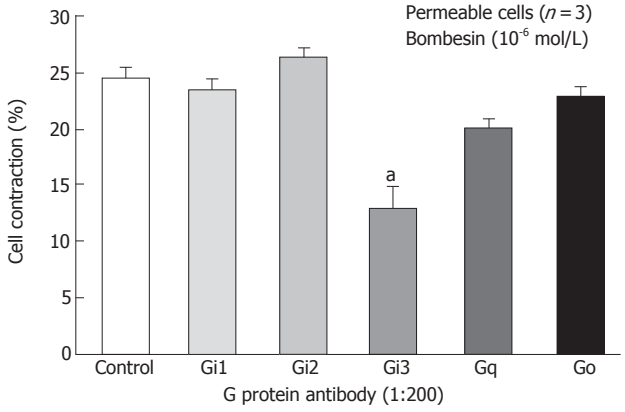

Figure 1 Inhibition of bombesin induced-contraction in permeabilized esophageal circular muscle cells by antibodies to G protein isoforms (Mean ± SE, Student's *t test*, $^aP < 0.05$ *vs* Control).

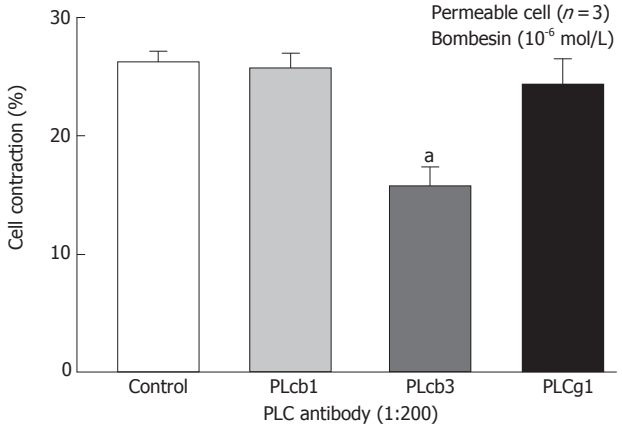

Figure 2 Inhibition of bombesin-induced contraction in permeabilized esophageal circular muscle cells by antibodies to PLC isoforms (Mean ± SE, Student's *t test*, $^aP < 0.05$ *vs* Control).

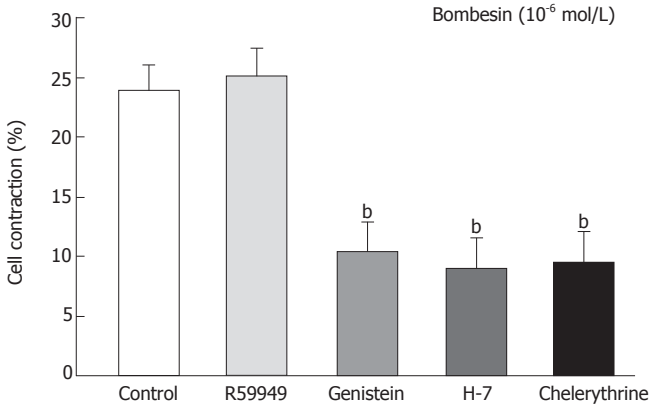

Figure 3 Contractile response of smooth muscle cells from cat esophagus to bombesin in presence of protein kinase C inhibitors (mean ± SE, $n = 4$, Student's *t test*, $^bP < 0.01$ *vs* Control).

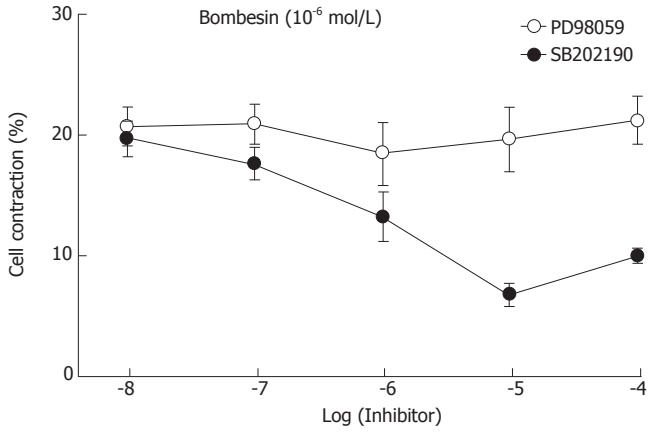

Figure 4 Effect of MEK inhibitor, PD98059 and p38 MAP kinase inhibitor, SB202190 on the bombesin-induced cat esophageal smooth muscle cell contraction (mean ± SE, $n = 4$).

and Western blot analysis of homogenates obtained from dispersed smooth muscle cells using monoclonal antibodies to PLC isozymes could demonstrate the presence of immunoreactive protein bands corresponding to 150 Ku PLC-β1, and PLC-β3 antibody, and 145 Ku PLC-β1 antibody[18]. Incubation of permeabilized circular muscle cells for 1 h with PLC- 3-specific antibody inhibited bombesin- (10^{-6} mol/L) induced contraction ($P < 0.05$). No other PLC-β3-specific antibodies had any significant effect on the contraction (Figure 2).

Role of protein kinase C and tyrosine kinase in bombesin-induced contraction

Cells were preincubated with either the tyrosine kinase inhibitor genistein (10^{-5} mol/L) for 20 min or with the protein kinase C inhibitor H-7 for 15 min (10^{-5} mol/L) or chelerythrine (10^{-5} mol/L) and diacylglycerol (DAG) kinase inhibitor R59949 (10^{-5} mol/L) for 1 min respectively, before the addition of bombesin (10^{-6}mol/L). Bombesin-induced contraction was inhibited by preincubation with genistein as follows: percent age decrease in cell length was 24.3% ± 2.2% *vs* 10.4% ± 2.5% and 9.1% ± 2.5% *vs* 9.5% ± 2.5% in the cells preincubated with H-7 and chelerythrine, respectively (Figure 3).

Role of MAPK in bombesin-induced smooth muscle cells contraction

To examine which MAPK was involved in bombesin-induced contraction, specific MAPK inhibitors were used. Preincubation of PD98059 (the MEK inhibitor) blocked the contraction induced by bombesin in a concentration-dependent manner. The maximal inhibition was observed in 10^{-5}mol/L (Figure 4). However, preincubation of SB202190 (the p38MAPK inhibitor) did not inhibit bombesin-induced concentration, suggesting that bombesin-induced concentration might be mediated via the p44/p42 MAPK pathway.

DISCUSSION

Bombesin is an amidated tetradecapeptide originally purified from the skin of the European frog *Bombina bombina*[1]. Exogenous introduction of this peptide into various organ systems elicits a wide range of responses including secretion of gastrointestinal, adrenal and

pituitary hormones and gastric acid, pancreatic enzyme and mucous, as well as regulation of smooth muscle contraction and modulation of neuronal firing rate[19]. Bombesin receptor is a member of the rhodopsin family of receptors containing seven transmembrane domains coupled to a G protein[20]. Molecular cloning studies have revealed the identity of three mammalian bombesin receptors: gastrin-releasing peptide (GRP receptor)[6], neuromedin B (NMB receptor)[21] and bombesin receptor subtype 3 (BRS-3)[4]. These three receptors share about 50% amino acid sequence identity. In adult animals, GRP-R and NMB-R are widely expressed in the central nervous system[21] and gastrointestinal tract[22,23], whereas BRS-3 shows limited expression in the hypothalamus but is expressed in secondary spermatocytes[4]. Peripheral administration of bombesin produces a variety of effects directly or indirectly linked to the activation of receptors for bombesin-like peptides in the gastrointestinal tract, including exocrine pancreatic secretion, gastrointestinal peptide hormone release, smooth muscle contraction and reduction of food intake. Bombesin receptor is activated after ligand binding and then catalyzes the exchange of GDP bound to the Gα subunit for GTP. After dissociation from Gβγ subunits, functional GTP binds to Gα subunit and activates β isoform of phospholipase C that catalyzes the hydrolysis of phosphatidyl inositol 4,5-bisphosphate (PIP2) in the cell membrane[24]. Gq (42 Ku), Gi1 (40 Ku), Gi2 (40 Ku), Gi3 (40 Ku), Go (40 Ku), Gs (46 Ku) in esophageal circular muscle have been detected by western blot[17]. In addition, when the same G protein antibodies are used to examine which G protein could mediate the contractile response of esophageal muscle, bombesin-induced contraction of esophageal muscles is inhibited by antibodies against the *alpha* subunits of Gi3[17].

We have previously shown that the response of esophageal cells to bombesin is blocked by the inhibitor of specific phosphatidylcholine-phospholipase C (PLC), D609[17] and Western blot analysis can demonstrate the presence of immunoreactive protein bands corresponding to 150 Ku PLC-β1, PLC-β3 antibody, and 145 Ku PLC-γ1 antibody[18]. Permeabilization was used to examine the participation of PLC isozymes in bombesin-induced muscle contraction in this study. Antibodies to PLC-β3, similarly to rabbit intestine[25], could inhibit bombesin-induced contraction. PLC-β1 and PLC-γ1 antibodies had no effect by themselves. The result suggests that PLC-β3 plays a role in mediating esophageal muscle contraction.

Many vasoconstrictor agonists increase protein tyrosine phosphorylation and ERK activity in smooth muscle preparations[26,27]. Furthermore, tyrosine kinase inhibitors block agonist-induced contraction[26,28,29], suggesting that this pathway is important for smooth muscle contraction. In this study, we investigated the regulation of tyrosine phosphorylation following bombesin stimulation and the role of this pathway in the contractile response. Genistein, a tyrosine kinase inhibitor, reduced contraction in response to bombesin in cat esophagus cells, suggesting that tyrosine kinases are involved in bombesin-induced contraction pathway.

Protein kinase C (PKC) is an enzyme activated by DAG, a second messenger produced by the PLC-catalyzed hydrolysis of PIP2. PIP2 hydrolysis produces two signaling molecules, DAG and IP3. DAG is the physiological activator of the classical and novel isoforms of PKC[30], whereas IP3 regulates intracellular Ca^{2+} movements[31]. DAG kinase plays an essential role in attenuation of DAG signals in agonist-stimulated cells. DAG kinase, which phosphorylates DAG to phosphatidic acid, is divided into a membrane bound and a soluble form. DAG kinase inhibitor increases PKC activity by blocking the phosphorylation of DAG to phosphatidic acid[32]. In this study, we showed that R59949 (the DAG kinase inhibitor) did not increase the bombesin-induced contraction. We found that PKC inhibitor, H-7 and chelerythrine, blocked the contraction induced by bombesin. This result is similar to those of Bitar *et al*[33].

MAP kinase is a serine/threonine-specific protein kinase, activation and phosphorylation of which are induced by a variety of extracellular factors such as mitogenic growth factors and neuropeptides[34,35]. In colonic smooth muscle cells[36,37], agonist-induced contraction involves a kinase cascade initiated by PKC and activation and redistribution of MAP kinase. The activation of MAP kinase by bombesin is rapid (within 15 s), reaching a maximum within 30 s, followed by a decline[37]. We found that p44/p42 MAP Kinase was involved in the bombesin-induced contraction in cat esophagus, indicating that the bombesin-induced signaling pathway progresses to p44/p42 MAP kinase to induce contraction.

In conclusion, bombesin induces circular muscle cell contraction in cat esophagus, which is mediated by protein kinase C and tyrosine kinase pathway. Bombesin induces contraction via Gi3 and PLC-β3. The contraction is mediated via p44/p42 MAP kinase pathway. Our findings provide the basic and clinical experimental data on bombesin-induced contraction and its signal transduction in esophagus.

Abstract

AIM: To assess the role of lactase non-persistence/persistence in school-aged children and their milk-related symptoms.

METHODS: The genotypes for the C/T$_{-13910}$ variant associated with lactase non-persistence/ persistence were determined using PCR-minisequencing in a group of 172 children with a mean age of 8.6 years (SE = 0.02, 93 boys) participating in a follow-up study for cow's milk allergy. The parents were asked to assess their children's milk consumption and abdominal symptoms.

RESULTS: The presence of allergy to cow's milk was not associated with the C/C$_{-13910}$ genotype related with a decline of lactase enzyme activity during childhood (lactase non-persistence). The frequency of the C/C$_{-13910}$ genotype (16%) was similar to published figures for the prevalence of adult-type hypolactasia in Finland. The majority of the children (90%) in this series consumed milk but 26% of their families suspected that their children had milk-related symptoms. Forty-eight percent of the children with the C/C$_{-13910}$ genotype did not drink milk at all or consumed a low lactose containing diet prior to the genotyping ($P < 0.004$ when compared to the other genotypes).

CONCLUSION: Analysis of the C/T$_{-13910}$ polymorphism is an easy and reliable method for excluding adult-type hypolactasia in children with milk-related symptoms. Genotyping for this variant can be used to advise diets for children with a previous history of cow's milk allergy.

Key words: Adult-type hypolactasia; Primary lactose malabsorption; Genetic testing; Cow's milk allergy

INTRODUCTION

Lactase deficiency (LD, lactase non-persistence) is the most common cause of milk intolerance in children and adolescents world-wide[1]. It plays a significant role in recurrent abdominal pain in populations with common consumption dairy products[2]. Immunologically mediated adverse reaction to ingested proteins of cow's milk is referred to as cow's milk allergy (CMA), the symptoms of which usually appear under one year of age[3]. CMA affects 1.9%-3.2% of infants[4] though recent studies suggest that allergy to cow's milk protein may have an impact on abdominal symptoms at schoolage also[5]. CMA is easily differentiated from LD if it manifests at an early age with skin and/or respiratory symptoms[6]. In cases of CMA that present with gastrointestinal symptoms, the clinical picture may overlap with symptoms caused by low lactase activity especially at schoolage, when the downregulation of lactase enzyme activity occurs[7].

The differential diagnosis of milk-related symptoms in children is difficult to establish because of the variability of clinical symptoms and inaccurate diagnostic laboratory tests[8]. The diagnosis of lactose malabsorption is based on the measurement of disaccharidase activities in intestinal biopsy specimens, a method which is not suitable for every day clinical practice. The indirect commonly used lactose-tolerance test (LTT) is not reliable in children and results in up to 30% of false positive results, thus reducing its value in clinical use[9]. In addition, children with normal lactose digestion complain of symptoms during LTT[10].

Recently, a C to T single nucleotide polymorphism residing 13 910 base pairs upstream of the lactase-phlorizin

hydrolase (LCT) gene has been shown to associate with lactase persistence/non-persistence, the C/C-13910 genotype defining lactase non-persistence as well as C/T-13910 and T/T-13910 genotype lactase persistence[11]. The association of the C/T-13910 variant with disaccharidase activities and lactase/sucrase ratio (L/S) has been verified in a total of >600 intestinal biopsy specimens[7, 11, 12]. In Finnish children (8-20 years of age) the mean level of lactase activity among subjects with the C/C-13910 genotype is 6.5 U/g protein. The C/T-13910 genotype is 29.9 U/g protein and 50.0 U/g protein respectively, showing a trimodal distribution of the lactase activity[7]. Functional evidence for the C/T-13910 variant in regulation of lactase activity has been obtained in several studies[12-15] and a greater increase in LCT promoter activity was reported for the T-13910 variant[13, 14]. The down-regulation of intestinal lactase varies according to ethnicity but the differences at the timing of down-regulation are not marked and most commonly start to appear around 5-6 years of age[7]. At the age of 12 years, all children with the C/C-13910 genotype have low lactase activity in their intestines[7].

The aim of the present study was to evaluate the role of lactase non-persistence in milk consumption and milk-related clinical symptoms by analysing the C/T-13910 genotypes of lactase persistence/non-persistence in a group of 172 school-aged children from eight to nine years of age with or without a previous history of CMA.

MATERIALS AND METHODS

Subjects

This study was part of a prospective follow-up study of children with a history of CMA diagnosed at a mean age of seven months [16]. The present study group comprised 172 school-aged children (mean age 8.6 years; SE = 0.02, 93 boys, 79 girls) who were clinically examined during August 2003-March 2004 at the Helsinki University Central Hospital, Helsinki, Finland. Ninety-three children (54%) had a previous diagnosis of CMA and 79 children comprised the control group. All these children were subjects in the study by Saarinen and collaborators[17], in which 6209 unselected infants born between August 1994 and November 1995 in the Helsinki region were followed up from birth for the development of CMA. The presence of CMA was confirmed by a challenge test[17]. At the time of the present visit, the families were asked about the children's milk consumption and possible milk-related symptoms and those agreeing to participate in genetic testing of adult-type hypolactasia were included in the study. IgE-mediated hypersensitivity to cow's milk was measured by skin prick test. A diameter >3 mm exceeding the negative control was considered as a positive response[18]. Those children who were still avoiding milk due to previous CMA were re-challenged by cow's milk[16]. A supplementary questionnaire on the amount of milk consumed and possible abdominal symptoms during the preceding week was mailed later. Celiac disease was screened as previously described[19].

Ethics

The study was approved by the Ethical Committee of the Hospital for Children and Adolescents, University of Helsinki. The families/children gave their informed consent.

Genotyping

DNA was isolated from blood by phenol-chloroform extraction as previously described[20] and DNA fragments spanning the C/T-13910 variant were amplified using one biotinylated primer and one unbiotinylated primer (primer sequences available on request). Briefly, PCR amplifications were carried out in a 50-μL volume with genomic DNA (100 ng), primers (20 ng), dNTPs (200 μmol/L), and 0.5 U of Taq polymerase in a standard buffer (Dynazyme, Finnzymes, Espoo, Finland). The PCR cycle conditions were as follows: an initial round of denaturation at 94 ℃, then 35 cycles at 94 ℃ for 30 s, at 53 ℃ for 30 s, at 72 ℃ for 1.25 min and a final extension at 72 ℃ for 10 min. Ten μl of the PCR product was captured in a streptavidin-coated microtiter well (Thermo Electron, Vantaa, Finland) and two parallel minisequencing reactions were carried out for each PCR-product. The minisequencing reaction contained 10 pmoles of the minisequencing primer (primer sequence available on request), 0.1 μL of tritium-labelled dNTP (Amersham Biosciences, Little Chalfont, Buckinghamshire, UK), and 0.05 U of DNA polymerase (Dynazyme, Finnzymes, Espoo, Finland). The microtiter wells were incubated for 15 min at 56 ℃ and finally the wells were washed. The detection primer was eluted and the eluted radioactivity was measured in a liquid scintillation counter (Rackbeta 1209, Wallac, Finland) as previously described [21].

Statistical analysis

The Mann-Whitney *U* test and Spearman's rank correlation test were used for nonparametric comparisons. Fisher's exact 2-sided test was also used.

RESULTS

Twenty-six percent of the families (45/172) suspected that their children had milk-related symptoms at 8-9 years of age at the time of this study. A significantly greater proportion of these came from those diagnosed to have CMA (76%, 34/45) at a mean age of seven months[17] than those serving as controls ($P < 0.003$).

Skin-prick test with cow's milk was positive (> 3 mm) in 12% of the children undergoing these tests (20/168) and all these children had a previous history of CMA (Table 1). At the time of this study, the challenge test with cow's milk was positive in 11 of the 16-challenged children[16].

The frequency of C/C-13910 genotype defining adult-type hypolactasia was 16% in the total study group of 172 children. There was no correlation with the genotype and positive reaction in the skin prick test or food challenge. Of the 27 children with the C/C-13910 genotype, two were challenged with cow's milk at the time of this study and one of them had a positive challenge for cow's milk. The milk consumption of different genotypes is presented in Table 2. Screening for celiac disease was negative in 170/172 of the children. The two children with a positive screening test consumed milk and reported no abdominal symptoms. The genotypes in these two children were C/

Table 1 Milk consumption and abdominal symptoms in school-aged children with a history of cow's milk allergy[1] and their controls

	Previous allergy[1]	Controls
Questionnaire completed	92% (n=86)	97% (n=77)

T-13910 and T/T-13910 (data not shown).

Fifty-two children out of the total study group of 172 children drank less than one dL of milk per day or did not consume milk products. The C/C-13910 genotype defining adult-type hypolactasia was present in 25% (13/52) and CMA in 21% (11/52, confirmed in a challenge test) of these children. Each child with CMA had a previous diagnosis of CMA. Milk consumption did not have any significant effect on body mass index (BMI, kg/m^2) and BMI was similar in children with different genotypes for adult-type hypolactasia (data not shown).

The questionnaire on daily milk consumption and abdominal symptoms was filled in by 95% (163/172) of the families (Table 3). Adult-type hypolactasia was suspected in 9% (15/163) of the children by their parents but was confirmed by genotyping in not more than 20% of these children (3/15 with the C/C-13910 genotype). One of these three children with the C/C-13910 genotype had a diagnosis of lactose malabsorption based on intestinal biopsy at the age of 7 years and the other two were noticed to have lactose-related symptoms at the age of 1.5 and 7 years. Two of the 27 children with the C/C-13910 genotype did not consume milk because of CMA. Eighty percent of the children (20/25) with the C/C-13910 genotype who had no CMA at this age had a low lactose containing diet at home or drank quantities of milk less than one dL/day already prior to the genetic testing (Table 2). A similar diet with milk restriction was practiced more rarely among children with genotypes associated with lactase persistence (31/119 of the children with C/T-13910 or T/T-13910 genotypes who answered the question and did not have allergy to milk, P< 0.004). Children with the C/C-13910 genotype did not report significantly more abdominal pains than children with the C/T-13910 or T/T-13910 genotypes but there was a difference in the presence of flatulence (P< 0.04, Table 3). Among the children with the C/C-13910 genotype, 4/15 children had milk restriction beyond two years of age because of milk allergy. Two of these four children experienced lactose-related symptoms.

The acceptance of genetic testing was good, as only two families did not participate in the study. Based on the interviews of the families among the children with the C/C-13910 genotype, 30% of the families reported to have another family member with symptoms of adult-type hypolactasia. Thirteen percent of the families of the total series and one third of the children with the C/C-13910 genotype reported that the result of the genetic test for adult-type hypolactasia had a probable effect on their milk consumption (Table 4). Of the families with genotypes associating with lactase persistence (C/T-13910 or the T/T-13910 genotype), 10% reported that the result of the genetic test was helpful in avoiding unnecessary restrictions on milk consumption.

DISCUSSION

Our results show that the overlap of IgE-mediated cow's milk allergy, CMA, and lactase non-persistence is unlikely

to occur at schoolage. The prevalence of adult-type hypolactasia in our study was 16% corresponding to the reported frequency in our population[7,11,22,23] and was not associated with CMA but correlated with the consumption of low lactose containing diets and the presence of flatulence. All children with a positive skin prick test for cow's milk at this age (12%) had a previous diagnosis of CMA, settled at a mean age of seven months as previously reported in detail[16]. It is noteworthy that not a single child in the non-CMA group turned IgE-positive for milk at schoolage, further confirming that IgE-mediated reactions with cow's milk develops at an early age. Tolerance to cow's milk develops in the majority of children with CMA (70%) by the age of three and eight to nine years. At the time of the present study, 85% of the children recovered from CMA[16].

It was reported that one third of the Finnish children at the age of eight years with the genotype C/C$_{-13910}$ have a high intestinal lactase activity[7] and are unlikely to develop symptoms caused by adult-type hypolactasia. It should however be borne in mind that in children the decline of intestinal lactase occurs slowly and depends on ethnicity [7]. Based on our previous study about the timing of down-regulation of lactase activity[7], we can estimate that about 10% (0.63 × 16%) of the children being studied have a reduced lactase activity (<10 U/g/protein) and all the others have a high lactase activity (>10 U/g/protein). In the present study, 60% of the children with the C/C$_{-13910}$ genotype consumed a low lactose containing diet or had milk-related symptoms at this age and 40% of those with the C/C$_{-13910}$ genotype were considered milk-tolerant. The avoidance of milk and consumption of low lactose containing diet was much more common among children with the C/C$_{-13910}$ genotype than among those with the genotypes associated with lactase persistence. This confirms our preliminary finding[7] and suggests that the children have experienced milk-related symptoms triggering a reduced lactose intake.

It is common, however, that children with abdominal dysfunction after consuming milk are unaware of its cause[24, 25]. This was also obvious in our series as the suspicion of milk-related symptoms was not increased in the families of the children with the C/C$_{-13910}$ genotype defining adult-type hypolactasia. However, restricted lactose intake was more common in these families. Although this dietary modification, the children with the C/C$_{-13910}$ genotype reported more flatulence when compared to those with the genotype T/T$_{13910}$ associated with lactase persistence ($P < 0.04$). There was no difference in the frequency of abdominal pain between the children with either CMA or lactose malabsorption and the control children.

It is common that only some individuals who self-report them as lactose intolerants are in fact lactose maldigesters when tested objectively[26-30]. The data on children, however, are limited. In our series, every fifth child suspected not to tolerate lactose was confirmed to have the predisposing genotype for adult-type hypolactasia. The lack of awareness of lactose maldigestion may increase abdominal symptoms in children as reported by Webster *et al*[31] who noticed that after a proper diagnosis of lactose malabsorption, the avoidance of milk products is more rigorous and results in a decrease in complaints. It is unclear whether individuals with adult-type hypolactasia and lactose maldigestion but without obvious symptoms of lactose intolerance should avoid milk or not. A recent double-blind study suggested that lactose maldigesters might benefit from lactose avoidance even though the diagnostic criteria for lactose intolerance are not fulfilled[32]. On the other hand, studies in adults reported that as many as 32% of lactose mal-absorbers experience no symptoms from lactose containing milk products[26], but at present there are no means to predict this at an individual level.

In the present study, 10% of the children with the C/T$_{-13910}$ genotype reported symptoms such as flatulence and loose stools suggestive of milk intolerance. One of these children had CMA (milk challenge positive) but in the other cases the causes for these symptoms were unknown. It is possible that some of these children are carriers of a mutation of congenital lactase deficiency (CLD), a rare congenital disorder which may result in low lactase activity but no disease manifestations in heterozygotes[33, 34]. Celiac disease may cause secondary hypolactasia but screening tests for the disease are negative in these children.

Parents easily suspect milk as a causative agent for abdominal symptoms in countries where dairy products are widely used. In the present study, 26% of the families reported a suspicion of milk-related symptoms in their school-aged children. The majority of these children did not drink milk nor had low lactose containing diets. When milk-related symptoms were suspected, the parents recognized CMA easily due to the previous history of CMA but their suspicion of adult-type hypolactasia was seldom confirmed. Accurate diagnosis of possible milk-related symptoms poses a challenge for clinicians as the elimination of milk and a proper challenge test for milk proteins or tolerance test for lactose are both time-consuming and may give unsatisfactory results[8]. The genetic testing of adult-type hypolactasia performed from a drop of blood was accepted well by the families as 99% of the families agreed to test their children. About 10% of the families reported that a negative result for adult-type hypolactasia was helpful as they may now avoid unnecessary restrictions on milk consumption.

In conclusion, a suspicion of milk-related symptoms is common in everyday clinical practice. The genetic test of C/T$_{-13910}$ polymorphism is reliable in excluding adult-type hypolactasia in children with milk-related symptoms. Genotyping for this variant may help in planning the diet for children with a suspicion of milk-related symptoms.

ACKNOWLEDGMENTS

The authors are grateful to the children and their families for their participation in this study. The authors thank Eija Hämäläinen, Hanna Komu and Sirkku Kristiansen for excellent help in performing the laboratory work.

Abstract

AIM: To identify the variants in UDP-glucuronosyltransferase 1 (UGT1A1) gene in Gilbert's syndrome (GS) and to estimate the association between homozygosity for TA insertion and GS in India, as well as the frequency of TA insertion and its impact among normal controls in India.

METHODS: Ninety-five GS cases and 95 normal controls were selected. Liver function and other tests were done. The promoter and all 5 exons of UGT1A1 gene were resequenced. Functional assessment of a novel trinucleotide insertion was done by *in silico* analysis and by estimating UGT1A1 promoter activity carried out by luciferase reporter assay of appropriate constructs in Hep G2 cell line.

RESULTS: Among the GS patients, 80% were homozygous for the TA insertion, which was several-fold higher than reports from other ethnic groups. The mean UCB level was elevated among individuals with only one copy of this insertion, which was not significantly different from those with two copies. Many new DNA variants in UGT1A1 gene were discovered, including a trinucleotide (CAT) insertion in the promoter found in a subset (10%) of GS patients, but not among normal controls. *In-silico* analysis showed marked changes in the DNA-folding of the promoter and functional analysis showed a 20-fold reduction in transcription efficiency of UGT1A1 gene resulting from this insertion, thereby significantly elevating the UCB level.

CONCLUSION: The genetic epidemiology of GS is variable across ethnic groups and the epistatic interactions among UGT1A1 promoter variants modulate bilirubin glucuronidation.

Key words: Unconjugated hyperbilirubinemia; UGT1A1 gene; DNA resequencing; Luciferase reporter assay

INTRODUCTION

Gilbert's syndrome (GS) is generally considered to be an autosomal recessive disorder (OMIM #143500) characterized by mild, chronic, non-hemolytic unconjugated hyperbilirubinemia in the absence of liver disease. Although it has long been perceived to be an innocuous clinical entity with a benign course, recent data suggest that affected individuals may be predisposed to development of liver injury following treatment with various drugs and xenobiotics and that the genetic defect in GS may influence the outcome of liver transplantation and other clinical conditions. The disorder due to a deficiency in bilirubin glucuronidation, is commonly caused by dinucleotide (TA) insertions and [TA $(TA)_7$TAA] alleles in the promoter region of the bilirubin UDP-glucuronosyltransferase 1 (UGT1A1) gene. This dinucleotide insertion reduces the efficiency of transcription of the gene and decreases hepatic UDP-glucuronosyltransferase activity to about 30% of normal levels in homozygous subjects[6-9]. The prevalence of GS, the frequency of the $(TA)_7$TAA allele in the UGT1A1 promoter and the proportion of GS patients who are homozygous for the $(TA)_7$TAA allele vary widely

across populations[10-19]. Recent data have also shown that variants in UGT1A1 gene other than the classical dinucleotide insertion in its promoter, can contribute to hyperbilirubinemia, including the milder form as in GS, although their effects appear to be variable across populations[5,20-24]. Thus, as recently emphasized[20], detailed investigations into genetic polymorphisms of UGT1A1 gene in Asian populations may provide a better understanding of unconjugated hyperbilirubinemia.

The objectives of our case-control study were to estimate the association between homozygosity for the $(TA)_7TAA$ allele and GS in India, to identify and study the impact of this and other polymorphisms in the promoter and exons of the UGT1A1 gene on serum bilirubin levels, and to estimate the frequency of the $(TA)_7TAA$ homozygous genotype in the general population in India.

MATERIALS AND METHODS

Participant recruitment and clinical biochemistry analysis

This study was conducted in 95 consecutive patients presenting to the Liver Clinic at the Department of Gastroenterology of the Institute of Postgraduate Medical Education & Research, Kolkata, India, for evaluation of persistent unconjugated hyperbilirubinemia (serum bilirubin greater than 1.2 mg/dL) documented at least twice over a period of one month. Serum total bilirubin and its unconjugated fraction were estimated in fasting condition. Each of these individuals had a normal finding on physical examination, normal hepatobiliary ultrasound, normal liver function test excluding hyperbilirubinemia and a normal reticulocyte count. A total of 95 adult healthy volunteers from the same ethnic population as the GS patients were included as controls. Each control also underwent the same set of investigations as the patients. Their fasting serum bilirubin level estimated twice at intervals of fifteen days was consistently less than 1.0 mg/dL. Patients were excluded if they were under any medication during the past one month or consumed alcohol regularly or had present or past history of hepatic/hematological disease. Additionally, quantitative estimation of hemoglobin fractions (A_0, A_2 and F) was carried out on each patient and control by cation-exchange HPLC using the Variant™ Hemoglobin Testing System Beta Thalassemia Short Program (Bio-Rad Diagnostics, Hercules, USA). A 5 mL blood sample was collected from each patient by venipuncture and DNA was isolated using a standard protocol[25]. Data and samples were collected with written informed consent of the patients and controls, after the approval was obtained from the Human Research Ethics Committee of the Institute of Postgraduate Medical Education & Research, Kolkata.

DNA re-sequencing and identification of variant alleles

DNA re-sequencing of the promoter and exon 1*1 encoding the substrate-specific region of bilirubin-UGT1 gene as well as the 4 common exons (exons 2-5) was carried out using an automated DNA sequencer (ABI-3100; Applied Bio-systems, Foster City, USA.). DNA samples were first amplified by the polymerase chain reaction technique using an ABI-9700 thermal cycler. PCR products were then cleaned using exonuclease-I (USB. Corporation, Cleveland, USA) and shrimp alkaline phosphatase (Amersham, Freiburg, Germany), and sequencing reactions were carried out. DNA resequencing was carried out in both forward and reverse directions. Raw DNA sequences were analyzed as previously described[26], and variant genotypes were identified.

Functional analysis of a novel trinucleotide insertion by luciferase reporter assay

UGT1A1 promoter fragments, 331-336 bp in length depending on the number of TA repeats and CAT insertion, were amplified using primers (F: 5'-tgtagatcttcct ctctggtaacact-3') and (R: 5'-atgaagctttgctcctgccagaggttc-3') from genomic DNA of individuals homozygous for six and seven TA repeats, and CAT insertion on $(TA)_7TAA$ background. DNA amplification was carried out with polymerase chain reaction (PCR) using FastStart Taq DNA polymerase (Roche, Mannheim, Germany) with an initial denaturation at 95℃ for 10 min, followed by 35 cycles at 94℃ for 1 min, at 56℃ for 45 s and at 72℃ for 30 s on an ABI-9700 (Applied Bio-systems, Foster City, USA.) thermal cycler. To facilitate subcloning of the PCR products in the reporter gene construct, oligonucleotides F and R were designed with a *Bgl* II and a *Hind* III restriction enzyme site at the 5' end, respectively. PCR products were doubly digested with *Bgl* II and *Hind* III, purified by Qiagen gel purification kit (Qiagen, Hilden, Germany) and subcloned into pGL3-basic vector (Promega, Madison, USA). The integrity of the resulting plasmids was confirmed by restriction mapping and sequencing analyses. Promoter activity of each construct was measured in HepG2 cell line. Cells were grown in MEM medium supplemented with 2 mmol/L L-glutamine, 0.1 mmol/L non-essential amino acids, 1 mmol/L sodium pyruvate and 10% fetal calf serum (GIBCO -BRL, Grand Island, USA) at 37℃ with 50 mL/L CO_2. Exponentially growing cells were trypsinized, seeded at 2.5×10^5 cells, and incubated overnight prior to transfection. Transfection was carried out by lipofectamin (Invitrogen, Carlsbad, USA) using 2 μg of each of the constructs (namely $(TA)_6$ TAA, $(TA)_7$ TAA and CAT insertion on $(TA)_7$ TAA background), as well as the pGL3-basic and pGL3-control as positive controls $(TA)_7TAA$, the luciferase gene was under the control of SV40 promoter and enhancer. After 48 h of transfection, the cells were lysed and centrifuged in cell culture lysis buffer (Promega, Madison, USA). Luciferase activity was assayed in the cell lysate by measuring the photoluminescence in a Monolight 2010 single channel luminometer and the total cellular protein content was measured by the standard Bradford's method. Luciferase activity was normalized to total cell protein concentration. Normalized luciferase activity of each construct was expressed as a ratio to that of the pGL3-basic vector. Three independent experiments were performed for each construct and all measurements were determined in duplicate.

Statistical analysis

Equality of proportions was statistically tested by the standard normal test procedure[27]. Equalities of mean

values of various hematological parameters for individuals belonging to different genotypes at various polymorphic loci were statistically tested using the Student *t*-test or the analysis of variance (ANOVA) procedure, as appropriate. Regression analysis was performed to test the significance of dependence of un-conjugated serum bilirubin level on some relevant variables. Allele frequencies were estimated using the gene-counting method.

RESULTS

Characteristics of patients and controls

No statistically significant ($P > 0.05$) differences in the proportions of males and females were observed between the patients (87 males, 8 females) and controls (77 males, 18 females). The mean ages of male and female patients (30.1 ± 1.1 years of males, 26.8 ± 5.1 years of females) and controls (30.2 ± 1.1 years of males, 31.1 ± 2.9 years of females) were not significantly different ($P > 0.05$). Since elevated HbA_2 levels could potentially increase the unconjugated bilirubin level, we tested the significance of the regression coefficient of HbA_2 level on unconjugated bilirubin, separately for patients and controls. In both sets, there was no statistically significant impact of HbA_2 (*P*-values for patients and controls were 0.638 and 0.106, respectively). The difference in the mean values of HbA_2 between patients and controls was not significantly different ($t = 1.76$, d.f. $= 128$, $P > 0.05$). The 8 GS patients, but none of the normal controls, who were habitual smokers were asked to refrain from smoking for 24 h prior to blood collection. We tested whether the inclusion of these 8 GS patients had a significant impact on our findings. We therefore, examined whether the mean value of un-conjugated bilirubin among patients who were smokers ($n = 8$) was significantly higher than that among patients who were not smokers ($n = 87$). No significant difference was found (mean for smoker patients $= 2.67 \pm 0.33$, mean for non-smoker patients $= 3.38 \pm 0.30$, $t = 0.696$, d.f. $= 93$, $P = 0.488$). We have performed all analyses that were reported below with and without the inclusion of the 8 GS patients who were habitual smokers. No differences in inferences were found (results not shown). Therefore, we presented all results including these 8 GS subjects.

UGT1A1 sequence variants and their relation with bilirubin level

Eleven sequence variants in UGT1A1 gene was observed, of which 3 each were in the promoter, 3 in exon 1, 2 in exon 2, 1 in exon 3 and 2 in exon 4. No variant was found in exon 5. The genotype and variant allele frequencies at these positions in patients and controls are given in Table 1. Of these 11 variant sites, 2 were non-polymorphic (frequency of the rarer allele $< 1\%$), while the remaining 9 sites were polymorphic either among patients or among controls or in both. One of the polymorphic sites was the TA insertion [$(TA)_7TAA$ allele] in the TATA box of the UGT1A1 promoter[2,3]. The frequencies of the $(TA)_7TAA$ allele (0.879) and the 7/7 genotype (80%) among the patients were significantly higher ($P < 0.005$) than those among the controls (0.384 and 10%, respectively). The un-conjugated serum bilirubin values for GS patients belonging to the 6/6, 7/6 and 7/7 genotypes are presented in Figure 1. The mean values of un-conjugated bilirubin for GS patients and normal controls were 2.5 ± 0.25 mg/dL and 0.61 ± 0.09 mg/dL respectively. The mean±SE value of un-conjugated bilirubin among patients with the 7/6 genotype was 3.46 ± 0.54 mg/dL, which was not significantly different ($P = 0.05$) from patients with the 7/7 genotype (3.31 ± 0.33 mg/dL). The mean un-conjugated serum bilirubin values for these genotypes among controls were only 0.59 ± 0.10 mg/dL and 0.64 ± 0.15 mg/dL, respectively.

No significant differences ($P = 0.05$) were found in the mean bilirubin levels among individuals belonging to the various genotypes at the remaining single nucleotide polymorphic loci. With respect to the C6844G polymorphism resulting in a non-synonymous amino acid change (A321G), all patients were CC homozygotes, while about 30% of the controls were CG heterozygotes (Table 1). We did not find any significant effect of the G71R polymorphism on un-conjugated bilirubin level. This polymorphism also showed no significant interaction with the TATA box insertion polymorphism (results not shown). These findings are discordant with those reported among the Japanese[19].

A novel human-specific trinucleotide insertion in Gilbert's syndrome patients and its impact on bilirubin level

Among the polymorphic variants described in Table 1, aside from the familiar TA insertion, the most striking was the CAT insertion (nucleotide positions -85 to -83) in the CAAT box of UGT1*1 promoter. Normally, there is one copy of the CAT trinucleotide present in human Genbank (http://www.ncbi.nlm.nih.gov/Genbank/). We found two copies of this trinucleotide in some GS patients. To confirm that this was an insertion we searched the chimpanzee (gi|6456543|gb|AF135463.1|AF135463) and gorilla (gi|6456545|gb|AF135464.1|AF135464) databases. In both species there is only copy, confirming that the single copy is the ancestral state. This CAT insertion was found only among nine (10%) GS patients, who were all homozygous for the TA insertion. We found that GS patients with the CAT-insertion had a significantly ($P < 0.001$) elevated mean level (6.13 ± 1.61 mg/dL) compared to those without the insertion (2.93 ± 0.28 mg/dL). Individuals who possessed the CAT insertion did not consistently possess a variant allele at any of the other sites. One individual who was heterozygous for the CAT insertion was also heterozygous for the I322V variant, and other three CAT-insertion heterozygotes were also heterozygotes for the H376R variant.

Functional analysis of CAT insertion

Since about 10% of the $(TA)_7TAA$ homozygotes carried the CAT insertion and the insertion significantly elevated the bilirubin level, we postulated that the insertion had a functional impact. To examine this, we studied the change in DNA-folding of the promoter region caused by this insertion. The most stable structures, namely those with lowest free energy (dG) values, are given in Figure 2 for the UGT1A1 promoter region without (dG = -14.4) and

[1]Amino acid changes resulting from nucleotide changes in the exons are indicated in parentheses.

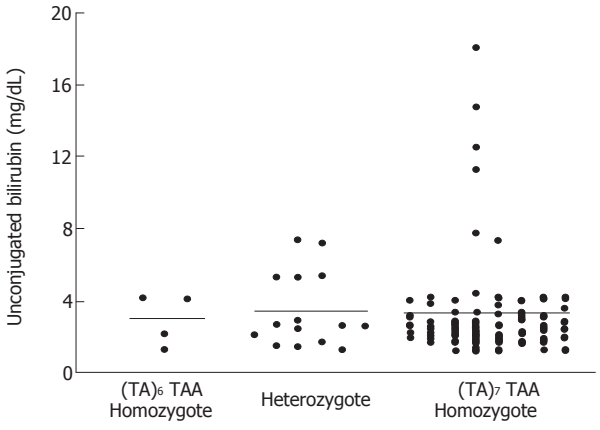

Figure 1 Distributions of un-conjugated serum bilirubin values among Gilbert's syndrome patients classified by the genotype of the common TA insertion in the TATA box of the UGT1A1 promoter.

with (dG = -14.8) the additional CAT insertion. A striking structural change was found around the region of the insertion, the loops were converted to stems. It is well known that formation of stems in the promoter could reduce transcription of the gene. A detailed functional analysis of the UGT1A1 promoter by luciferase reporter assay confirmed that there was a two-fold decrease in transcription efficiency for the variant $(TA)_7$TAA promoter allele, and a 20-fold decrease when there was a CAT insertion in the promoter on the background of the $(TA)_7$TAA allele compared to the normal $(TA)_6$TAA promoter allele (Figure 3).

DISCUSSION

Genetically determined un-conjugated hyperbilirubinemia constitutes a spectrum of clinical entities characterized by incremental serum bilirubin values related to graded reduction of UGT1A1 enzyme activity. The most novel finding of our study is that a trinucleotide (CAT) insertion in the nucleotide positions -85 to -83 of the UGT1A1 promoter was present in GS patients who were homozygous for the causal TA insertion, but not in other GS patients or in controls. This insertion significantly ($P < 0.001$) elevated the un-conjugated bilirubin level (mean = 6.13 mg/dL) in the patients to the range usually seen in Crigler-Najjar (CN) II syndrome. We have

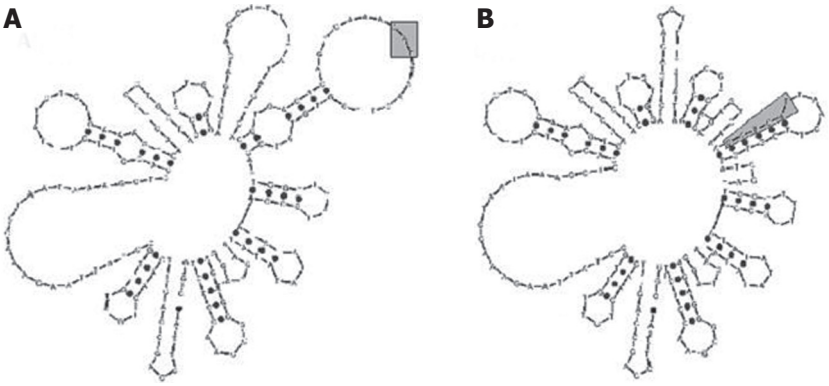

Figure 2 Folded DNA structures of the UGT1A1 promoter region with one copy of the CAT trinucleotide (shaded region) (**A**) and two copies of the CAT trinucleotide (CAT insertion allele, shaded region) (**B**).

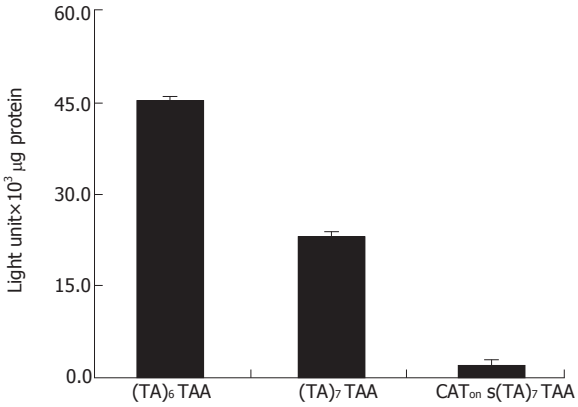

Figure 3 Transcriptional activities of the (TA)$_6$TAA, (TA)$_7$ TAA and CAT alleles as assessed by a luciferase reporter assay.

demonstrated that this insertion in the background of the (TA)$_7$ allele classically described in GS, diminishes UGT1A1 transcriptional activity to about 5% (2.4 light units/10^3 μg protein) of the normal (44.9 light units/10^3 μg protein), much lower than the 50% reduction (22.9 light units/10^3 μg protein) observed for (TA)$_7$ alone. Thus the combined biological effect of the CAT and TA insertions is a further elevation in the un-conjugated bilirubin level compared to that of the TA insertion alone, which is exactly what we have observed in the GS patients carrying the CAT insertion. This initial description of the interactive influence of a novel trinucleotide insertion and the GS-type abnormality in the promoter region alone, in the absence of a consistent exonic mutation, to quantitatively elevate un-conjugated bilirubin to levels observed in Crigler-Najjar II (CN II) provides further evidence of genetic heterogeneity and overlap of the clinical syndromes of un-conjugated hyperbilirubinemia. Thus, Gilbert's, Crigler-Najjar I (CN I) and CN II syndromes may not be mutually exclusive clinical-genetic entitities but are different windows of the quantititative spectrum of elevated serum unconjugated bilirubin levels.

The association (80%) between homozygosity for the (TA)$_7$TAA allele and GS is much stronger in India than reported earlier from most other ethnic groups[14,15,16,20]. Graded reduction of UGT1 activity has been demonstrated with increasing length of the TA repeats in a recent study[28]. It was demonstrated that 7/7 homozygotes and 7/6 heterozygotes have, respectively, a 52% and a 37% reduction of UDP glucuronyl transferase activity in liver tissue homogenates. In our study, serum un-conjugated bilirubin values among 7/6 heterozygote GS patients were high but not significantly different from the 7/7 homozygotes. The finding of increased serum bilirubin values among the 7/6 heterozygote GS patients to the same extent as those homozygous for the classically described 7/7 genotype, even in the absence of any other consistent change in the UGT1A1 gene, is intriguing. We could not explain this finding, but speculate the role of other interacting non-UGT1A1 genetic variants.

Although the insertion of additional TA repeats in the (TA)$_6$ TAA promoter, sequence of the UGT1A1 gene is the most common variation associated with Gilbert's syndrome, (TA)$_5$ and (TA)$_8$ sequences in the TATAA box have also been found[4,14]. We did not find (TA)$_5$ and (TA)$_8$ alleles in our study participants. Moreover, several mutations in the exons have been found in other populations, particularly from Asia, in association with GS and hyperbilirubinemia, either as the only abnormality or in addition to the more common promoter defect[20-22,29-31]. We have identified several promoter and coding region (all non-synonymous) variants of the gene (Table 1). The G71R variant has been reported earlier[19, 22-24], and the P364L variant has recently been reported in one Japanese GS patient[19]. Contrary to the finding among the Japanese[32], the G71R change had no impact on un-conjugated bilirubin level in our samples, nor did it interact with the dinucleotide (TA) insertion in the TATA box of the UGT1A1 gene. Many variants discovered in this study have not been reported earlier and many variants reported earlier were not found in the present sample. Although all the observed variations in exons could result in amino acid substitutions, none of these significantly altered the mean bilirubin level. Thus, the UGT1A1 gene appears to tolerate a large number of mutations without any significant deleterious effect. None of these was strongly associated with the (TA)$_7$TAA allele in our study. However, the amino acid change from isoleucine to valine at the amino acid position 322 was only found among the controls and not among the GS patients. Further studies are necessary to test whether this change helps bilirubin glucuronidation by the UGT1A1 gene.

The UGT1A1 polymorphisms have recently acquired significance because they predispose individuals to altered metabolism and enhanced toxicity of several drugs like paracetamol, propofol, irinotecan, indinavir, *etc*, which are

substrates for glucoronidation by UGT1A1[33-36]. Exons 2-5 are shared by other UGT1A transcripts and isozymes that mediate metabolism of xenobiotics apart from A1 involved in bilirubin glucuronidation[37]. The new variants in these exons may be relevant to drug metabolism, but we have not tested this. Our findings reveal that it is crucial to carry out detailed surveys on genetic variations in and around the UGT1A1 gene and functional studies on these variants for a deeper understanding of quantitative anomalies of bilirubin.

Abstract

AIM: To study the relation between acoustic parameters and histological structure of biological tissue and to provide the basis for high-resolution image of biological tissues and quantitative ultrasonic diagnosis of liver disease.

METHODS: Ultrasonic imaging and tissue characterization of four normal porcine liver and five cirrhotic liver tissue samples were performed using a high frequency imaging system.

RESULTS: The acoustic parameters of cirrhotic liver tissue were larger than those of normal liver tissue. The sound velocity was 1577 m/s in normal liver tissue and 1631 m/s in cirrhotic liver tissue. At 35 MHz, the attenuation coefficient was 3.0 dB/mm in normal liver tissue and 4.1 dB/mm in cirrhotic liver tissue. The backscatter coefficient was 0.00431 dB/Srmm in cirrhotic liver tissue and 0.00303 dB/Srmm in normal liver tissue. The backscatter coefficient increased with the frequency. The high frequency images coincided with their histological features.

CONCLUSION: The acoustic parameters, especially the sound backscatter coefficient, are sensitive to the changes of liver tissues and can be used to differentiate between the normal and pathological liver tissues. High frequency image system is a useful device for high-resolution image and tissue characterization.

INTRODUCTION

Ultrasonic diagnosis has been widely used in the clinical medicine. However, contemporary ultrasonic diagnosis technique is limited to the qualitative description at frequency ranging between 0.5-10 MHz based on the gray scale presentation in ultrasonic image. Due to the longer wavelength at a low frequency, the image resolution is not very high. Besides, the physical quantity using the ultrasonic image is the amplitude of the echo while the spectrum of the echo is overlooked.

The research on the ultrasound scatter spectrum has begun since 1970s. Shung and Reid[1] conducted an experimental study of ultrasound backscatter in calf liver and muscle using the pulse insert-substitution method. The backscatter coefficients for calf heart, kidney, pancreas and spleen were studied by Ten and Shung[2] at frequency between 2-7 MHz using bandwidth pulse insert-substitution measurement system. The ultrasound backscatter in myocardial muscle of dog was studied by Donnell *et al*[3]. The anisotropy for ultrasound backscatter in myocardial muscle was reported by O'Mottley and Miller[4], which coincides with the theoretical prediction. The backscatter coefficient for human brain was studied at frequency between 0.5-1.5 MHz by Barger[5], who successfully differentiated the white from the gray matters in the brain. Nicholas[6] studied the backscatter coefficient of human tissues using spectrum technique. However, the frequency used in these researches is below 10 MHz. To increase the resolution of imaging, the frequency of ultrasound must be increased. D'Astous *et al*[7] and Foster *et al*[8] have achieved the high frequency imaging of breast. Turnbull[9-12] studied mouse embryos using ultrasound backscatter microscopy. Ye *et al*[13] and Pavlin *et al*[14,15] studied the ocular tissue using high frequency imaging. The ultrasonic properties of vascular tissues and blood were measued from 35 to 65 MHz by Lockwood *et al*[16] and Meyer *et al*[17]. Yano *et al*[18] and Liu *et al*[19] studied the high frequency imaging of skin and thyroid. Ultrasound backscatter microscopy images of the internal structure of living tumor spheroids have been

obtained[20,21].

Liver is the important organ for metabolism. Hepatic lobule is the basic element in liver, and is surrounded by connective tissue. Most blood capillaries pass through the boundary of its connective tissues. Hepatic tissue regeneration and connective tissue hyperplasia induce change of the normal structure of hepatic lobule. The liver becomes deformed and stiff, known as hepatocirrhosis. Common liver diseases can be diagnosed by B- ultrasound. However, it is difficult to diagnose diffuse diseases of liver.

The present study was to investigate the relation between acoustic parameters and histological structure of biological tissue and to provide the basis for high-resolution image of biological tissues and quantitative ultrasonic diagnosis of liver disease.

MATERIALS AND METHODS

Experimental system

High frequency imaging system was set up in our laboratory. The sample was fixed in the sample-holder between quartz and a thin plastic membrane and then mounted in water bath. The focused ultrasound transducer (center frequency 35 MHz, -3dB bandwidth from 25 MHz to 55 MHz, f-number 1.6, focus depth 1 mm, beam width 70 μm) was excited with a pulse (300 Vpp in amplitude, 15 ns in width). The ultrasonic pulse passing through the membrane, sample reflected from the quartz flat was received by the same transducer. The transducer and the step motor were carefully moved, the region of interest in the sample was located in the focus area and in the focal depth of the transducer. The scan parameters for raster motion were downloaded by MTM2500 pp (Newport Co, USA). The attenuation signal and backscatter signal were recorded by a 400 MHz digital scope (HP54502A, USA). The information about the C-scan imaging was acquired by sampling the backscatter signal after a specified delay corresponding to the focus and stored in a hard disk for software scan conversion after data collection was completed. An IEEE-488 bus transferred the digitized signals to the control computer for further processing

The transducer in a raster fashion over a 3 mm × 5 mm area was removed and a backscatter image of the sample was generated using C-scan mode. The region of homogenous tissue was selected for quantitative measurement. The incident direction of the sound beam was perpendicular to the surface of the sample during the measurement. The interest region containing 16 points in 4 by 4 grids was selected to measure the velocity of sound, 64 points in 8 by 8 grids were selected to measure the attenuation and backscatter coefficients of the sample and each grid was separated by 80 μm.

Sample preparation

Liver tissue samples were obtained from the Meat Processing Plant. In the experiment, the sample was clamped between plastic membrane and reflector quartz flat in a specially designed sample holder and both sides of the sample were cut at -10℃ using Cryostat 2700 (Frigocut, Reichert-june, Germany) to make the surface with a homogenous thickness between 0.5-1.5 mm. Then the sample was thawed in saline solution and sealed with a thin plastic membrane. In the study, four normal liver tissue samples and five cirrhotic liver tissue samples (hepatocirrhosis) were used. A slice from each sample was stained. The corresponding histological diagram and ultrasound image were obtained.

Table 1 Sound speed and attenuation and acoustic backscatter coefficient (mean ± SD)

		Normal liver	Cirrhotic liver
Sound speed (m/s)		1577 ± 7	1631 ± 5
Attenuation	α_1	0.121 ± 0.045	0.082 ± 0.023
(dB/mm)	α_{35}	3.0 ± 0.6	4.1 ± 0.8
	m	0.9	1.1
Backscatter coefficient	μ_1	$2.66 \times 10^{-6} \pm 1.43 \times 10^{-6}$	$4.85 \times 10^{-6} \pm 1.52 \times 10^{-6}$
(1/Srmm)	μ_{35}	0.00303 ± 0.00015	0.0043 ± 0.00025
	n	1.98	1.91

RESULTS

Images

The ultrasound imaging of normal and cirrhotic liver tissues and their corresponding pathological slices are shown in Figure 1A-1D. From the images, some microstructures of the tissue could be observed. However, the image of normal liver tissue (Figures 1A, 2B) was different from that of cirrhotic liver tissue (Figures 1C, 1D). The image of normal liver tissue was ultrasonically homogenous while the image of cirrhotic liver tissue was contrary to that of normal liver tissue. From the imaging, we could see the hyperecho of the cirrhotic liver. Some short and strong echoes caused by hyperplasia of connective tissue occurred.

Sound velocity, attenuation and backscatter coefficient

A summary of the acoustic parameters measured in the liver are listed in Table 1.The experimental results showed that the acoustic parameters from cirrhotic liver were larger than those from normal liver. The sound velocity in normal liver was 1 577 m/s and 1 631 m/s in cirrhotic liver, which coincides with the sound velocity (1 600 m/s) in bovine liver[22]. At 35 MHz, the attenuation coefficient was 3.0 dB/mm in normal liver and 4.1 dB/mm in cirrhotic liver. However, it has been reported to be 9.73 dB/mm at 70 MHz[22] and 0.89 dB/mm at 10.0 MHz respectively in liver[23]. The backscatter coefficient was 0.00431/Srmm at 35 MHz in cirrhotic liver and 0.00303/Srmm in normal liver. The power-law fits with the backscatter coefficient in normal liver as a function of frequency. However, it has been reported to be $(2.66\times10^{-6}\pm1.43\times10^{-6})^{f1.98}$/Srmm) and $(4.85\times10^{-6}\pm1.52\times10^{-6})^{f1.91}$/Srmm in cirrhotic liver[24]. The increase of backscatter coefficient is caused by hyperplasia of the connective tissue in cirrhotic liver (Figure 2). The backscatter occurs when the size of backscatter structure is similar to the wavelength of the sound beam, suggesting that the size of backscatters is within the wavelength of the ultrasound wave and the size of porcine liver lobules may be similar to it. The frequency-dependent decrease in cirrhotic liver reflects the increase of scattering elements

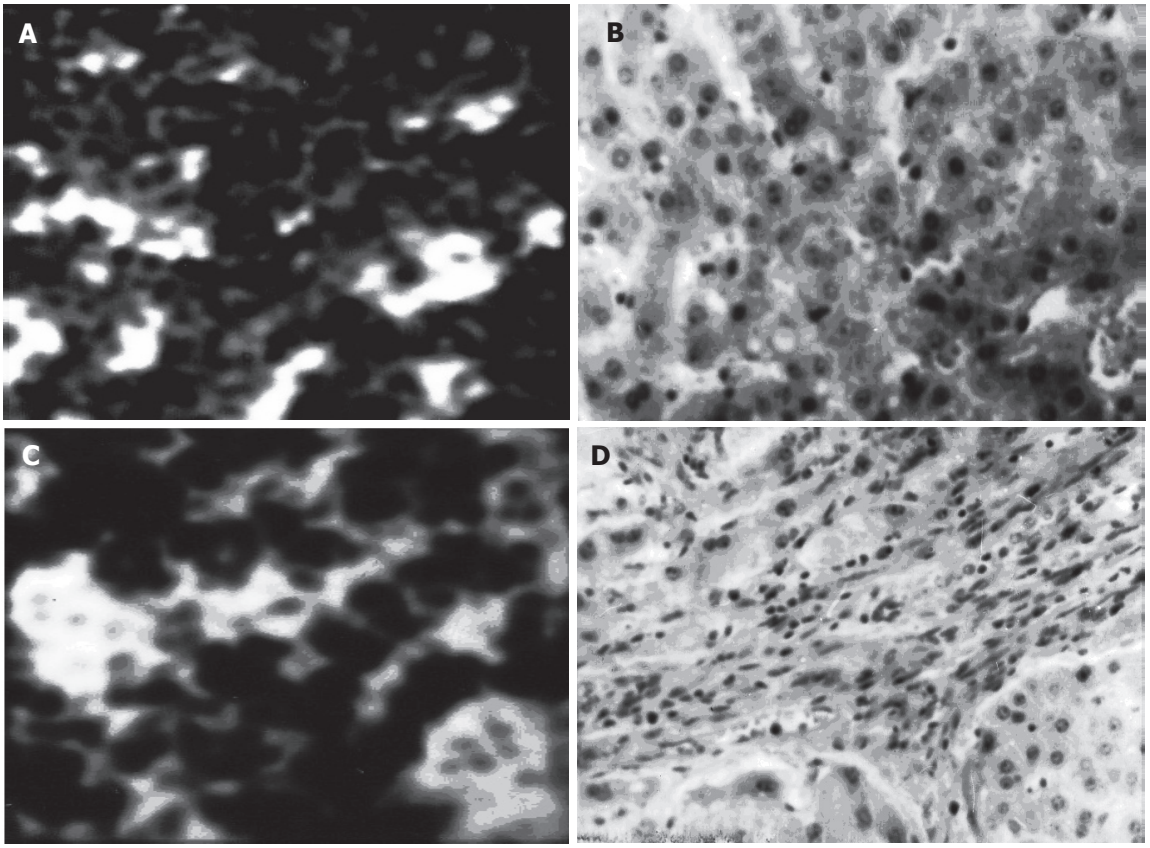

Figure 1 Ultrasound images of normal and cirrhotic liver and their corresponding pathological slices **A:** ultrasound imaging of normal liver; **B:** pathological slice of normal liver; **C:** ultrasound imaging of cirrhotic liver; **D:** pathological slice of cirrhotic liver.

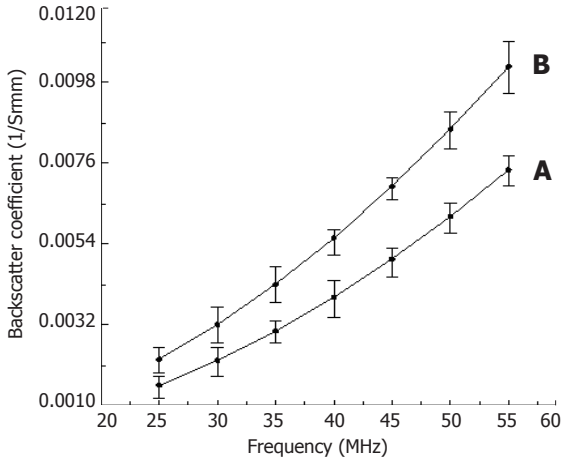

Figure 2 Backscatter coefficients changing with frequency in normal liver (**A**) and cirrhotic liver (**B**).

in the liver.

DISCUSSION

Ultrasonic tissue characterization based on spectrum analysis of backscattered radio frequency (RF) echo signals provides information regarding the acoustic properties of tissue, such as the size, concentration, and acoustic impedance of scatterers that are not available by conventional imaging methods[25,26]. The ultrasonic backscatter coefficient in human liver was measured in the range of 2.0-4.0 MHz[24]. The ultrasonic propagation properties at 100 MHz in excessively fatty rat liver were studied[27]. Strong correlation of ultrasonic speed with both water concentration and fat concentration in the liver was observed. The ultrasonic attenuation and velocity in rat liver as a function of fat concentration at 100 MHz were investigated[28] and the acoustic properties of freshly excised bovine liver were characterized at the frequency range between 20-200 MHz by the ultrasonic spectroscope system[22].

On the other hand, ultrasonic imaging systems in medicine depend fundamentally upon analysis of the ultrasonic scattering properties of the soft tissues investigated. However, the mechanism governing ultrasonic scattering within most soft tissues have not been delineated. In many cases the absolute magnitude of the scattering process has not been accurately quantified. The relationship between collagen and ultrasonic backscatter in myocardial tissue was evaluated[3]. The dependence of the ultrasonic scatter coefficient on collagen concentration in mammalian tissues was addressed[29]. And the mean-scatter spacing estimated with spectral correlation was used for tissue characterization[30]. However, there is little report on tissue characterization of hepatic tissues in the range between 25-55 MHz.

In this study, ultrasound images and sound parameters for hepatic tissues were studied by using C-scan ultrasound system at the frequency between 25-55 MHz. The above experimental results indicate that the resolution of high frequency image is much better than that obtained at low ultrasound frequency because some microstructure of the tissue can be seen. The information obtained from the ultrasound image is coincided with the histological feature of the sample. Furthermore, the samples need not to be stained. The acoustic parameters especially the sound backscatter coefficient are sensitive to the changes of the

tissues and can be used to differentiate between the normal and pathological tissues, the frequency dependence of backscatter coefficient could be reflected by the change of scattering elements and may be employed as a parameter for characterizing tissues and their physiological states. Therefore the high frequency image system is a useful device for high-resolution image and tissue characterization within the high frequency range.

Abstract

AIM: To study the antiviral effect of Chinese medicine jiaweisinisan (JWSNS) on hepatitis B virus (HBV) infection in transgenic mice (TGM).

METHODS: Twenty two 6-8 wk old HBV TGM in the third generation were divided into TGM control group and TGM treated group randomly. The normal control group included ten normal BC 57L/6 mice at the same age. The mice in treated group were administrated with JWSNS at the concentration of 4 g/mL and the dosage of 50 g/kg per d for 30 d, while the mice in TGM control group and normal control group were administrated with normal saline at the same dosage and the same time. Polymerase chain reaction (PCR) was used to assess the contents of HBV DNA in serum of HBV TGM before and after treatments, whereas blot hybridization was utilized to measure the contents of HBV DNA in the liver of both HBV TGM and normal BC 57L/6 mice.

RESULTS: The levels of serum HBV DNA in TGM treated group were remarkably decreased after the treatment of JWSNS (7.662 ± 0.78 *vs* 5.22 ± 3.14, $P < 0.05$), while there was no obvious change after administration of normal saline in TGM control group (7.125 ± 4.26 *vs* 8.932 ± 5.12, $P > 0.05$). The OD values of HBV DNA in the livers of the mice in TGM treated group were significantly lower than those of TGM control group (0.274 ± 0.096 *vs* 0.432 ± 0.119, $P < 0.01$).

CONCLUSION: JWSNS exerts suppressive effects on HBV DNA in the serum and liver of TGM.

INTRODUCTION

In this *in vivo* study, HBV transgenic mice (HBV TGM) models were established to detect the antiviral effects of traditional Chinese medicine, jiaweisinisan (JWSNS) on HBV TGM, so to further confirm the inhibitory effects of this traditional Chinese herb on HBV infection.

MATERIALS AND METHODS

Experimental animals

Normal C57BL/6 mice and the HBV transgenic mice, living in the same cote, were provided by Department of Transgenic Engineering in Hepatopathy Research Center of Guangzhou Military Hospital. All the non-transgenic mice were under close surveillance to ensure the HBV DNA in serum and tissue to be negative.

Traditional Chinese herbs

JWSNS, including buplerum chinense DC, flea body, prunus persica (L.) batsch, of 10 grams each, and radix paeoniae alba, fructus aurantii immaturus, dipsacus asper wall, rhizoma dryopteris crassirhizomae, eupatorium adenophorum sprengel, of 12 grams each, as well as 5 grams of glycyrrhizaglabral, and 30 grams of loranthus parasiticus, was prepared according to the traditional procedures. Five compounds of drugs were mixed together, 141 grams per compound, and dissolved into the water to distil twice, yielding 1500 mL distillation solution, followed by inspissation of the distillation to 180 mL. The final concentration was 4 g/mL, stored in refrigerator for use.

PCR primer and reagent

PCR primers and relevant reagents were provided by

Shanghai Bioengineering Research Center of Chinese Academy of Sciences. The sequence of PCR primer one is 5'-TGGCACTAGTAAACTGAGCC-3' and that of PCR primer two is 5'-ACATCAGGATTCCTAGGACC-3'. Other reagents such as $MgCl_2$, dNTP, buffer, Tag enzyme, and paraffin oil were purchased from Promega Company (Madison, USA). Quantitative diagnostic kit (batch number 1000-902-1) for HBV DNA was provided by Biotromcs Technological Company (San Francisco, USA).

DNA extraction kit

DNA extraction kit was obtained from Maikang Biotechnological Company of Zhongshan Medical University.

Recombinant plasmid PBR322-2.0 HBV rapid extraction reagents

The reagents included host strain, antibiotics, peptone, yeast extract, gelose, buffer Ⅰ (50 mmol/L glucose, 25 mmol/L Tris HCl, 10 mmol/L EDTA), buffer Ⅱ (0.2 mol/L NaOH, 1% SDS), and buffer Ⅲ (5 mol/L potassium acetate 60 mL, iced acetic acid 11.5 mL, water 28.5 mL).

α-^{32}P-DNA probe labeled reagents

It included NEN kit (Promega Co., Madison, USA), Sephaclex G-50 columniation, purified recombinant plasmid PBR322-2.0 HBV (100 ng/μL), 0.5 mol/L EDTA.

Blot hybridization reagents

It included nitrate fibrous membrane (aperture 0.45 μm, Amersham Co., Buckinghamshire, UK), Formamide 20×SSC buffer, 37% formaldehyde, dyestuff (25% Bromophenolblue dissolved into Ficoll), TE buffer.

Apparatus

Gene amp PCR system (Techne, England), AG-9600 equipment for analytical fluorescence microscope (USA), low-temperature freeze centrifuge (Biofuge 22R, Germany), water bath, pH meter, magnetic shaker, vacuum pump, refrigerator, balance (China), constant temperature rocker, constant temperature incubator, superclean working table (China), ZXZ-4 gyral vacuum pump (Zhejiang Linhai Vacuum Apparatus Factory), 721 spectrophotometer (The Third Spectrophotometry Factory, Shanghai) were used.

Establishment of HBV TGM model

P2.0 HBV plasmid passed through a series of *Eco*RI/*Sal*I restriction enzyme digestion, and electrophoresis, followed by the collection of 7.0 kb DNA fraction, which contained two end-to-end 3.2 kb HBV entire genes, and 0.6 kb PBR322 DNA vector. After electrophoresis quantitative analysis, the collected DNA fractions were dissolved in TE buffer under bioclean condition to ensure the concentration to be 1 mg/L, then respectively packed and stored at -20 ℃ to wait for micro- injection. C57BL/6 mice injected entire genome plasmid which contained HBV were identified to be G0 generation. Positively integrating male mice of G0 generation were selected to hybridise with infraspecific normal female mice, producing G1 generation. In similar manner, positively integrating male mice of G1 generation were selected to copulate with infraspecific normal female mice, producing G2 generation. Mice of G3 generation were produced in the same way[1].

Selecting procedures of HBV TGM

A total of one hundred and fifteen 6-8 wk old mice of G3 generation, weighing 20 g, were provided by Department of Transgenic Engineering in Guangzhou Military Hospital. HBV DNA detection kit was purchased from Baosheng Bioengineering Company (Dalian). Tissues were firstly detected to select HBV DNA positive mice, followed by serum detections. Twenty-two serum HBV DNA positive mice were eventually selected from 115 mice of G3 generation to be labeled as HBV DNA transgenic mice.

Grouping

Twenty-two HBV TGM, whose serum HBV DNA was positive, and 10 normal C57BL/6 mice were grouped into TGM treated group, 12 TGM mice; TGM control group, 10 TGM mice; normal control group, 10 normal C57BL/6 mice; and then registered. Additional six 6–8 wk old C57BL/6 mice, weighing (20 ± 2) g, whatever male or female, were also prepared. All the mice were fed in Experimental Animal Center of Guangzhou Military Hospital. Auto-supply of water and standard food were offered as well as air condition to maintain the constant temperature during the whole experimental procedures.

Administration

Mice in TGM treated group were administrated with JWSNS at 50 g/kg per d, in 0.3-0.4 mL JWSNS solution (about 4 g/mL, ig) once a day for four weeks, while the mice in the other two control groups were administrated with the same dosage of normal saline at the same time.

Sample collection

Two hours after the last administration, eyeballs were extirpated to collect peripheral blood before the execution of the mice followed and sera were then separated for detection of HBV markers. Promptly, livers were removed and broken, frozen by liquid nitrogen and stored at -70 ℃ for detection.

Detection method

PCR quantitative analysis[2, 3] was used to detect the serum contents of HBV DNA of TGM at the moment when the total contents had reached up to 1.0×10^5 kb/mL, while blot hybridization[4, 5] was utilized to analyze the contents of HBV DNA in liver of mice. The extraction of DNA in liver tissue was processed according to the instruction provided by the manufacturer of the kit. The rapid extraction of recombinant plasmid PBR322-2.0 HBV was performed by alkali fission method[6]. α-^{32}P-DNA probe was labeled according to instructions of Promega Co. reagent kit. Blot hybridization was performed as follows: 40 μL α-^{32}P-DNA probe labeled solutions was used

Table 1 Changes of serum levels of HBV DNA in HBV TGM before and after treatment of JWSNS (mean±SD)

Group		*n*	Serum HBV DNA	
			Case transformed from DNA positive to negative	Content of HBV[1]
TGM controlled group	Prior to administration of normal saline	10	0	7.125±4.26
	After administration of normal saline	10	0	8.932±5.12
TGM treated group	Prior to JWSNS treatment	10	0	7.662±0.78
	After JWSNS treatment	10	3	5.122±3.14

[1]Analyzed by *t*-test. TGM treated group, [1]$P<0.05$ *vs* TGM controlled group, [1]$P>0.05$.

Table 2 Effect of JWSNS on levels of HBV DNA in the liver of HBVTGM (mean±SD)

Group	*n*	HBV DNA blot hybridization
Normal control group	9	0
TGM control group	9	0.432±0.119
TGM treated group	9	0.274±0.096[b]

[b]$P<0.01$ *vs* TGM control group.

to dot on the membrane, which was then dipped in the metamorphic solution, and baked in the oven at 80 ℃ for two hours. After pre-interaction, membrane washing, slice nipping, the positive degree was justified according to the OD value of each blot.

Statistical analysis

Statistical data was analyzed by SPSS software. The comparability prior to and after disposal of the same sample was verified by paired-samples *t*-test, whereas the difference of the mean value among various groups was analyzed by χ^2 test. *P* less than 0.05 was taken as significant.

RESULTS

Effects of JWSNS on serum contents of HBV DNA in HBVTGM

The levels of serum HBV DNA in TGM treated group displayed considerable distinction before and after treatment of JWSNS ($P<0.05$), compared with those in TGM controlled group in which no significant difference was shown before and after administration with normal saline ($P>0.05$) (Table 1).

Effect of JWSNS on levels of HBV DNA in the liver of HBV TGM

HBV DNA blot hybridization was positive in HBV TGM both before and after treatment. The OD value showed extremely significant difference between TGM controlled group and TGM treated group ($P<0.01$), whereas blot hybridization in normal control group appeared to be negative (Table 2).

DISCUSSION

Value of HBV TGM model in the study of inhibitory effect of the traditional Chinese medicine on HBV

The host infected by HBV showed violent phyletic and tissue specificity, resulting in the remarkable restriction in the establishment of the animal model infected by HBV and anti-HBV study. In the past, data related to anti-HBV entirely came from HBV-infected patients, orangutan or cell *in vitro*. In addition, significant distinction existed between experimental data of other hepatophilic DNA virus such as duck or groundhog HBV and those of human HBV[7,8].

In 1980, microinjection HBVTGM model was successfully established which obviously overcame the limitation described above. Chissari [9] established TGM model and claimed that HBV DNA and HBsAg granules were detected in TGM blood and congregated in a fraction of hepatocyte, inducing tumefaction and dysfunction of the endoplasm as well as the ground glass hepatocytes, besides enhancing the sensitivity of hepatocytes to the lipopolysaccharide and IFN-γ, resulting in the damnification, necrosis and regeneration of the hepatocyte, or even the occurrence of hepatocarcinoma. Thus, HBVTGM model was, to a great extent, similar to the immune interaction between virus and host during natural infection of HBV[10].

HBVTGM is viewed as an immune tolerance condition. Despite limited damnification of hepatocytes in some mice, inflammation was not obvious, which is consistent with the pathologic change in human beings infected with HBV. The objective of our study emphasized on suppressive effect of JWSNS on HBV including the change of HBV contents in blood and tissue rather than the inflammatory level in liver. Thus, it is appropriate that HBVTGM served as the anti-HBV model.

Anti-HBV effect of traditional Chinese medicine and significance of HBV DNA detection

The symptom in different stage of HBV persistent infection varies from chronic asymptomatic HBV carrier and chronic hepatitis to hepatocirrhosis and hepatocarcinoma[11,12]. According to modern medicine chronic asymptomatic HBV carrier is viewed as the earlier stage of chronic persistent infection of HBV, in which the immune system is inhibited, leading to the inefficacy of interferon and lamivudine, the traditional antivirus drugs. Thus it is a widespread viewpoint that there is no effective treatment for earlier stage of HBV infection. However, it does not mean that there is no need for treatment[13,14]. Of note, at this stage, viruses copy themselves constantly, accompanied with the obvious viraemia, and approximately

normal liver function. However, as the copying process continues, a series of immune reaction of the host would be triggered to damage the liver and other organs. This stage may be a chance for traditional Chinese medicine to act as antivirus agent[15]. Pioneering clinical experiences indicated that traditional Chinese medicine such as phyllanthus urinaria L., matrine could endow the host in immune tolerance condition advantage in antivirus effect and protective effect on liver, and the detection of HBV DNA contents could help evaluate the antivirus effect of traditional Chinese medicine.

Theoretic basis for treatment of HBV infection by JWSNS

The treatment regimen of chronic hepatitis B by JWSNS is rooted in pathologic hypothesis of traditional Chinese medicine proposed by Bao Yi Liu, a famous doctor in ancient China who stated that whenever the *nephric qi* is inadequate, the protective function of human body against disease would decline, whereas *sick qi* would take the chance to invade the human body, weakening the *hepatic qi*, inducing the damp and the heat, which then attack the spleen and stomach, leading to the disfunction of both liver and spleen. This main pathologic process persists during the whole course of disease. According to this pathologic hypothesis, nothing but nourishing *nephric qi* is the key step to cure chronic hepatitis B. JWSNS, a famous compound, is used to enrich *nephric qi,* thus to reinforce the protective effect of the human body, and to overcome the state of immune tolerance.

Inhibitory effect of JWSNS on HBV of HBVTGM

In this study, HBVTGM model was used to observe the change of HBV DNA content both in serum and in hepatic tissue before and after the JWSNS treatment. The contents of HBV DNA in liver reflect the contents of HBV in hepatocyte. HBV, a hepatophilic virus, invades into the hepatocyte, in which they copy themselves, and then migrate into the peripheral circulation, inducing the diffuse chronic infection of HBV. The contents of HBV DNA reflect the level of virus copy. In the study, hepatocellular DNAs were extracted, and with the probe of P^{32} labeled plasmid P2.0 HBV, blot hybridization proceeded in nitrate fibrous membrane. The results of blot hybridization showed that no blot could be seen in normal control group, in striking contrast with the obvious blot appearing in both TGM control group and TGM treated group. The measurement of OD value of the blot demonstrated that the contents of HBV DNA in hepatocyte dramatically decreased four weeks after JWSNS treatment, compared with HBVTGM control group ($P < 0.01$).

PCR, a comparatively sensitive method was utilized in detecting the change of serum HBV DNA before and after JWSNS treatment in treated group or before and after administration of normal saline in control group. Four weeks later, no significant change could be seen in TGM control group administrated with normal saline, whereas HBV DNA of three mice was converted from positive to negative after treatment with JWSNS, and the serum contents of HBV DNA showed significant decline before and after treatment ($P < 0.05$).

The detection of HBV DNA contents in both liver tissue and serum shows that JWSNS could, to certain extent, inhibit HBV DNA, which provides the experimental proof for treatment of chronic hepatitis B with JWSNS.

Abstract

AIM: To investigate the effect of firing noise on gastrointestinal transit and probe its mechanism by measuring the levels of plasma polypeptide hormones.

METHODS: A total of 64 SD rats were randomly divided into a control group and three stimulating groups. Firing noise of different intensity by sub-machine guns was used as inflicting factor. The effect of firing noise on liquid substance gastrointestinal transit and solid substance gastrointestinal transit was observed by measuring the ratio of carbon powder suspension transmitting and barium sticks transmitting respectively. Plasma levels of polypeptide hormones were measured by radio-immunoassay.

RESULTS: The noise accelerated gastrointestinal transit of solid food by more than 80 db;and accelerated gastrointestinal transit of liquid food significantly by more than 120 db. Meantime, plasma levels of plasma motilin (MTL)(157.47±16.08; 151.90±17.08), somatostatin (SS)(513.97±88.77; 458.25±104.30), substance P (SP)(115.52±20.70; 110.28±19.96) and vasoactive intestinal peptide (VIP) (214.21±63.17; 251.76±97.24) remarkably changed also.

CONCLUSION: Within a certain intensity range, the firing noise changes the levels of rat plasma gastrointestinal hormones, but the gastrointestinal transit is still normal. Beyond the range, the noise induces plasma hormone levels disturbance and gastrointestinal transit disorder.

http://www.wjgnet.com/1007-9327/12/2284.asp

INTRODUCTION

Explosive noise may produce an adverse effect on gastrointestinal tract, and there is higher incidence of digestive system disease in war time. Current studies mainly focus on morphological changes of gastrointestinal tract[1], and there is little information available in literature about the effect of firing noise on the gastrointestinal transit. The aim of this study was to show the effects of explosive noise on gastrointestinal transit, and probe its mechanism by measuring the levels of plasma polypeptide hormones.

MATERIALS AND METHODS

Materials

Healthy SD rats were purchased from Animal Center of the Fourth Military Medical University (FMMU). The ND2 volume level meter was provided by the School of Aerospace Medicine of FMMU. Radioimmunoassay kits were supplied by Naval Radioimmunoassay Technology Center. An FJ-2003/8PS radioimmunity counter and a high-speed and low-temperature centrifuge were used in this experiment.

Experimental procedures

After an adaptive phase of 7 d, 64 SD male rats were randomly divided into 4 groups: Group A, consisting of 16 rats, which were not stimulated; Group B, which were stimulated with 40 dB noise; Group C, which were stimulated with 80 dB noise; and Group D, which were stimulated with 120 dB noise. Different groups received different intensity noise stimulations respectively. Then 8 rats of each group (including Group A) were intragastricly administrated with carbon powder suspension[2,3], anesthetized 20 min later, and then decapitated. Blood was sampled and the ratio of carbon powder suspension transmitting measured. The other 8 rats were intragastricly administrated with barium small sticks[4], anesthetized 10 h later, and decapitated. Blood was sampled in the same way and the ratio of barium sticks transmitting observed under X-ray.

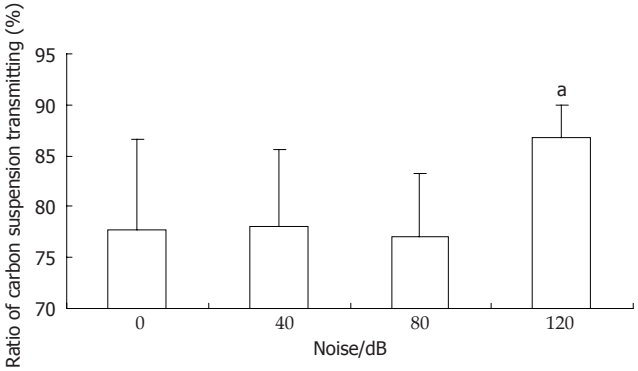

Figure 1 Effect of explosive noise on liquid substance gastrointestinal transit ($n=8$, *vs* 0 dB), $^aP<0.05$.

Noise stimulation

After 12-h abrosia, rats were put into sound-proof room. Firing noise of submachine guns acted as an inducing factor which had been recorded and was played to rats through a loudspeaker at a distance of 20-30 cm for 12 h. Examined with ND2 volume level meter and frequency spectrum analyzer, the intensity of the firing noise was measured as 0 dB (Group A), 40 dB (Group B), 80 dB(Group C) and 120 dB(Group D) respectively and their frequency as 0.25-4.00 kHz.

Liquid substance gastrointestinal transit

Rats were intragastricly administrated with 1 mL carbon powder suspension, consisting of carbon powder (50 g/L), gum arabic (100 g/L) and water(850 g/L), then anesthetized and dissected 20 min later. Small intestine was taken out of abdomen and tiled on the bench. The distance of carbon powder transmission from pyloric sphincter to the end of small intestine was measured, and the ratio of carbon powder suspension transmitting calculated [5,6] (distance of carbon powder transmission/ total length of small intestine ×100%).

Solid substance gastrointestinal transit

Rats were intragastricly administrated with 10 barium small sticks (length: 5 mm, diameter: 1 mm), then anesthetized and dissected 10 h later. The sticks were taken out of gastrointestinal tract. Barium small sticks which remained in each segment of the gastrointestinal tract were counted.

Measurement of plasma MTL, SS, VIP and SP

Rats were decapitated to sample the blood. Blood plasma was separated by centrifugation at 3500 r/min at 4 ℃, then concentrations of MTL, SS, SP and VIP were tested by radio-immunoassay[7], according to instruction of RIA kits strictly.

Statistical analysis

Analysis of variance was performed to investigate the effects of firing noise on gastrointestinal transit and plasma polypeptide hormone level in rats of four groups. All data were presented as mean ± SD. $P<0.05$ was taken as significant.

Table 1 Plasma polypeptide hormones after noise stimulation (mean ± SD, $n=8$, μg/L)

Noise/dB	MTL	SP	SS	VIP
0	128.0±5.1	52.5±20.1	184.6±49.6	254.3±129.1
40	130.6±15.6	74.4±17.4	382.8±79.1^b	471.1±145.4^a
80	133.2±30.5	86.6±15.2^b	386.6±59. 6^b	460.6±173.8^a

$^aP<0.05$. $^bP<0.01$ *vs* 0 dB(control).

RESULTS

Liquid substance gastrointestinal transit and plasma peptides levels

Ratios of carbon powder suspension transmitting in groups B and C were 78.1%±7.6% and 77.1%±6.1% respectively, and were not significantly different from that of group A (control group, 77.8%±8.8%). Ratio of carbon powder suspension transmitting in group D was 86.7%±3.3%, significantly higher than that of group A ($P<0.05$). The liquid substance gastrointestinal transit of group D (120 dB noise stimulated group) was accelerated significantly (Figure 1).

At the same time, all of the plasma MTL, SS, SP and VIP concentrations in groups B and C were increased compared with that of group A. In group D, plasma MTL, SS and SP concentrations were increased, but plasma VIP concentration decreased to some extent (Table 1). It could be seen that plasma peptides in groups B and C were increased gradually, but plasma peptides in group D were changed irregularly.

Solid substance gastrointestinal transit and plasma peptides levels

Percentage of barium sticks remained in the gastrointestinal tract in group A was 40.6%±25.4%, and that of group B was 36.9%±22.1%. There was no significant difference between groups A and B. Percentage of barium sticks remained in groups C and D was 16.2%±10.8% and 22.5%±16.1% respectively, significantly lower than that of group A(control group) ($P<0.05$) (Figure 2). There was smaller percentage of barium sticks remained in the gastrointestinal tract, indicating that barium sticks gastrointestinal transmit was faster. So the solid substance gastrointestinal transit of groups C and D (80,120 dB noise stimulated group) was accelerated.

All of the plasma peptide concentrations in group B was increased compared with that of group A. In groups C and D, plasma MTL, SS and SP concentrations were increased, but plasma VIP concentration decreased to some extent(Table 2). It could be seen that plasma peptides in group B were increased stepwise, but plasma peptides in groups C and D were irregularly disturbed.

DISCUSSION

There is a higher incidence of digestive system disease in war time than in peace time. Explosive noise is one of important factors that induce human body stress

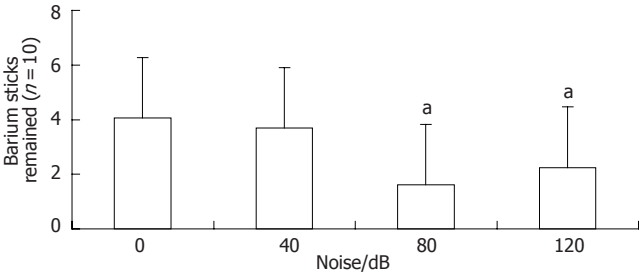

Figure 2 Effect of explosive noise on gastrointestinal transit $^{a}P<0.05$ *vs* 0 dB.

Table 2 Plasma polypeptide hormones after noise stimulation (mean ± SD, $n = 8$, μg/L)

Noise/dB	MTL	SP	SS	VIP

in war time, and it may produce an adverse effect on gastrointestinal tract[8-10]. Liu found that explosive noise could injure gastric mucosa. Our results indicated that explosive noise could accelerate gastrointestinal transit, and that the effect was related to the intensity of the noise. There was no apparent change in gastrointestinal transit ($P>0.05$), after stimulated with lower intensity noise; however, not only solid substance but also liquid substance gastrointestinal transits were accelerated significantly ($P<0.05$), after stimulated with high level noise.

Gut hormone is a main factor in regulatory mechanism of gastrointestinal motility, and plays an important regulatory role in gastrointestinal function in stress state[11-13]. Gut hormone is generally divided into two categories, erethitic hormone and inhibitive hormone. They are contradictory regulating factors in the blood. When balance between them is lost, the disturbance of gastrointestinal motility occurs[14]. We observed plasma concentrations of two kinds of erethitic braingut peptides and two kinds of inhibitive braingut peptides, after stimulation of rats with different intensity noise, so as to probe the mechanism of explosive noise impacting gastrointestinal transit.

We found that concentrations of all four plasma peptides were increased, when rats were stimulated by low level noise, and the balance between stimulatory and inhibitory gut hormones was normal. When rats were stimulated with high level noise, three of peptides (including MTL, SS and SP) were increased in comparison with normal controls, but plasma VIP was decreased.

It is well known that MTL and SP are erethitic gut hormones. They could promote GI transit[15,16]. Our results showed that plasma MTL and SP concentration increased after stimulation with firing noise. After lower intensity sound stimulations, their plasma levels increased to some extent and after high intensity sound stimulations, their plasma levels increased obviously. In all, we found that plasma erethitic gut hormones concentration was increased and was positively correlated with intensity of noise.

SS exerts depressive effect on GI motility[17]. Previous findings showed that plasma SS level was higher in stress state[18,19]. Similarly, we found that plasma SS concentration increased along with the augmentation of the sound intensity. VIP is another kind of inhibitive gut hormone[20]. In our study, after lower intensity sound stimulation, plasma VIP concentration increased also; but it declined after stimulation by high intensity noise.

Rats, after stimulation by low intensity noise, could keep the GI transit normal, and the balance between the erethitic and inhibitive gut hormones was kept under moderate stress still, which helped to keep GI transmission function normal. At same time, we found that disturbance of GI transmission function occurred after stimulation with high intensity noise, and that the balance between the erethitic and inhibitive gut hormones was lost because of severe stress, which induced GI transmission function disorder. Therefore we presumed that changes of plasma gut hormone level were related to GI transmission function disorder induced by explosive noise and were one of the important underlying reasons.

In summary, our results indicate that explosive noise could induce stress in rats and exert some negative effect upon gastrointestinal transit. After explosive noise stimulation, secretion of many kinds of gut hormone is chaotic, which plays an important role in occurrence of gastrointestinal transmission disorder.

Abstract

AIM: To study the expressions of gastrin (GAS) and somatostatin (SS) in gastric antrum tissues of children with chronic gastritis and duodenal ulcer and their role in pathogenic mechanism.

METHODS: Specimens of gastric antrum mucosa from 83 children were retrospectively analyzed. Expressions of GAS and SS in gastric antrum tissues were assayed by the immunohistochemical En Vision method.

RESULTS: The expressions of GAS in chronic gastritis Hp+ group (group A), chronic gastritis Hp- group (group B), the duodenal ulcer Hp+group (group C), duodenal ulcer Hp- group (group D), and normal control group (group E) were 28.50+4.55, 19.60+2.49, 22.69+2.71, 25.33+4.76, and 18.80+2.36, respectively. The value in groups A-D was higher than that in group E. The difference was not statistically significant. The expressions of SS in groups A-E were 15.47+1.44, 17.29+ 2.04, 15.30+1.38, 13.11+0.93 and 12.14+1.68, respectively. The value in groups A-D was higher than that in group E. The difference was also not statistically significant.

CONCLUSION: The expressions of GAS and SS are increased in children with chronic gastritis and duodenal ulcer.

Key words: Chronic gastritis; Duodenal ulcer; Gastrin; Somatostatin

INTRODUCTION

Infantile chronic gastritis and peptic ulcer are frequently encountered in children. The gastroscopic diagnostic rate accounts for 85%-94.5% for chronic gastritis and 8%-22% of peptic ulcer. The causes of these diseases and pathogenic mechanisms are not completely clear. The digestive tract is the largest and most complicated secretory organ in human bodies. Gastrointestinal hormones not only play an important regulatory role in secretory and motor functions of the digestive tract, but also have an important effect on its growth, development and damage repair. It has been shown that abnormity of GAS and SS plays an important role in causing chronic gastritis and duodenal ulcer in children[1]. We examined the expression of GAS and SS in gastric antrum tissues from 83 children with chronic gastritis and duodenal ulcer using immunohistochemical method (Table 1). The changes in GAS and SS and Hp infection and their effect on chronic gastritis and duodenal ulcer in children were studied, in order to provide a theoretical basis for the gastrointestinal hormone drugs used in the treatment of chronic gastritis and duodenal ulcer in children.

MATERIALS AND METHODS

Materials

Paraffin specimens of gastric antrum mucosa were obtained from the children during the period of 2002-2003 in our hospital. All the subjects did not receive gastrointestinal kinetic drugs and H2 receptor agonists. The biopsy tissues were fixed in 10% neutral formalin, routinely dehydrolyzed, paraffin-embedded and cut into sections which were stained with HE. Hp infection was diagnosed by rapid urease test and microscopy. The cases were regarded as strongly positive when the test paper of urease test became cherry-red from yellow within 1 min, weakly positive when the test paper turned cherry-red and negative when the test paper did not change color. The weakly positive specimens were excluded from the study. Microscopy at 400 × magnification revealed positive rod-shaped bacteria in the gastric pit and body (Figure 1). A case was considered Hp+ when it was positive in the two methods and Hp- when it was negative in the two methods. The experimental samples were divided into group A: chronic superficial gastritis, Hp+; group B: chronic superficial gastritis, Hp-; group C: duodenal ulcer, Hp+; group D: duodenal ulcer, Hp-; and group E: normal gastric antrum tissues with no obvious pathologic

Table 1 Expression of GAS and SS in gastric antrum mucosa from children with chronic gastritis and duodenal ulcer (mean ± SD)

Groups	*n*	GAS	SS
Chronic gastritis Hp+ group	20	28.50±4.55	15.47±1.44
Chronic gastritis Hp- group	19	19.60±2.49	17.29±2.04
Duodenal ulcer Hp+ group	21	22.69±2.71	15.30±1.38
Duodenal ulcer Hp- group	12	25.33±4.76	13.11±0.93
Normal control group	11	18.80±2.36	12.14±1.68

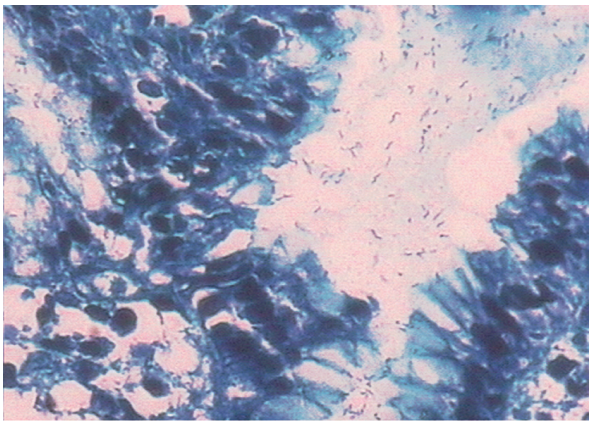

Figure 1 *Helicobacter pylori* in gastric pit (Giemasa ×400).

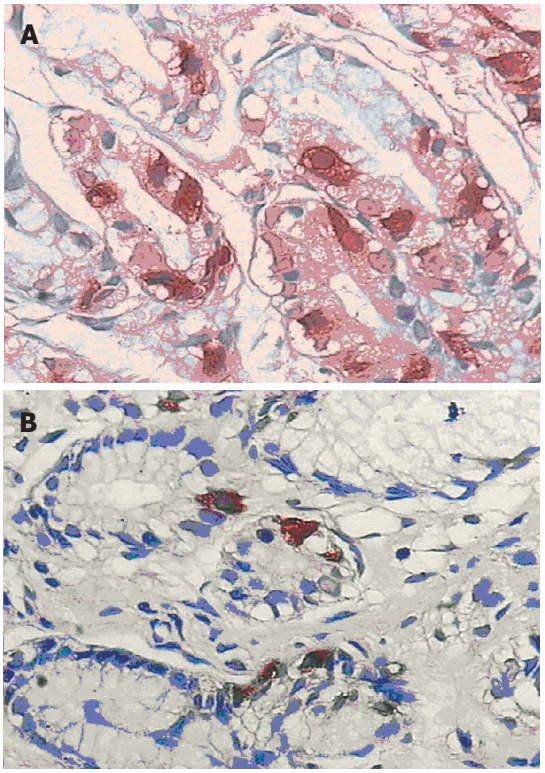

Figure 2 Expression of GAS (**A**) and SS (**B**) in glands. Brown particles were identified in cytoplasm (En Vision ×400).

changes, Hp-. Patients with other diagnoses such as chronic atrophic gastritis were excluded from the study. Thirty experimental samples were then randomly taken from each group. After specimens from patients with intestinal metaplasia or superficial specimens and very tiny specimens were excluded, the exact number of samples used in groups A-E was 20, 19, 21, 12 and 11, respectively.

Methods

Immunohistochemical method (En Vision method) was used and each paraffin sample was labeled with GAS and SS, respectively. When GAS and SS were located in cytoplasm, samples displaying brownish yellow particles or balls were regarded as positive. Positive cell bands of each sample were observed and lymph follicle areas were avoided. The number of positive cells within a sample was counted.

Statistical analysis

Statistical analysis was carried out with SPSS10.0 software package. The count of GAS and SS was in conformity with a normal distribution and expressed as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

GAS and SS expression was higher in groups A-D than in group E with no significant difference (Figures 2A, 2B).

DISCUSSION

GAS is a kind of peptides secreted by G cells located in the gastric antrum and duodenal mucosa, whose main function is to stimulate gastric acid secretion. It is of physiopathologic importance in occurrence of duodenal diseases. Since Levi *et al*[2] found that Hp could lead to increase in serum GAS of Hp-infected persons, a flood of studies have found that the level of serum GAS is higher in Hp positive children with chronic gastritis than in Hp negative children. After anti-Hp treatment, the level of GAS in children decreases[3]. It is held that Hp infection may lead to increase in GAS released by G cells, making damages to gastric and duodenal mucosa. Hp stimulates inflammatory cell factors such as IL-21, IL-28, TNF, IFN and G cells to release GAS[4]. SS secretion is reduced by the inhibition of D cell functions by Hp infection, which results in decrease in inhibition of G cells by SS[5]. The increased Hp level on surface of the gastric antrum by ammonia interferes with the normal feedback mechanism of inhibition of GAS secretion by acids in the stomach, which results in increase in GAS secretion. Hp or its products (ammonia or peptides) have direct effects on G cells[6]. The present study showed that the expression of GAS in chronic gastritis Hp+ group (group A) and chronic gastritis Hp- group (group B) was higher than that in the normal control group (group E) and the expression of GAS in chronic gastritis Hp+ group (group A) was higher than that in chronic gastritis Hp- group (group B), indicating that chronic inflammation, especially Hp infection, can result in increase in GAS, which may be one of the pathogenic mechanisms underlying chronic gastritis.

The causes of duodenal ulcer are associated with various factors. Digestion of local mucosal tissues by gastric acid and peptase is an important cause of ulcer occurrence. Therefore, ulcer is closely associated with

GAS. Smith *et al* [7] reported that the basal and postprandial concentrations of serum GAS are increased in adults with duodenal ulcer. Wu *et al* [8] reported that the level of serum GAS in children with duodenal ulcer was much higher than that in the control group. Increased GAS release, which results in increased secretion of gastric acid and occurrence of ulcer, is one of the mechanisms underlying duodenal ulcer in children.

SS widely exists in the gastrointestinal tract, with its highest concentration in the gastric pylorus area. D cells in the gastric pylorus secrete SS. SS has an inhibitory effect on secretion of gastrointestinal hormones such as GAS, motilin and gastric acid. Therefore, SS is regarded as a defensive factor for local mucosa.

Geller *et al*[9] showed the level of fasting serum SS was higher in DU patients than in normal persons, suggesting that the increased level of SS in DU patients is a compensatory mechanism caused by the feedback stimulation with high concentrations of acids. Lucey *et al* [10] showed hydrochloric acid can increase the level of SS in DU patients. Erton *et al*[11] found that high concentrations of acids could stimulate SS release. Mihaljevic *et al*[3] showed that the level of serum SS in Hp+ patients was lower than that in Hp- patients. Zavros *et al*[12] found that the content of SS in specimens of gastric mucosa from chronic gastritis Hp+ patients was 6 times lower than that in chronic gastritis Hp- patients. Chavialle *et al*[13] showed that the content of SS in gastric antrum mucosa of DU patients was lower than that in the control group. However, Jensen *et al* [14] reported that the content of SS in bulb mucosa of DU patients was higher than that in the control group. Therefore, the true meaning of changes in the content of SS in gastroduodenal mucosal tissues of DU patients and their role in the pathogenic mechanism of DU are unclear. The extent of various damages and regulating function may be different in human tissues during different phases. Our study showed that the number of SS positive cells in groups A-D was higher than that in group E, indicating that inflammation, especially Hp infection, can stimulate release of GAS and SS as well as secretion of gastric acid under high concentrations of acids. The reason why there was no significant difference may be the insufficient cases of experiment. Due to relatively small amount of biopsy tissues from superficial or relatively superficial mucosa and the abandoned sections whose immunohistochemical staining was not clear, the valid cases for the experiment were greatly reduced. Besides, because the size of biopsy tissues from children was smaller than that from adults, the observed number of cells was also smaller. Therefore, our studies necessitate further efforts to perfect them.

Abstract

Cholelithiasis occurs infrequently in the paediatric age group. Hereditary spherocytosis, sickle cell anaemia and thalassemia are the haemolytic disorders most commonly associated with development of gall stones in paediatric age group. The question is whether an isolated episode of haemolysis can cause gallstones.

Key words: Cholelithiasis; Haemolytic anaemia; Haemolytic uraemic syndrome

Kejariwal D. Cholelithiasis associated with haemolytic-uraemic syndrome. *World J Gastroenterol* 2006; 12(14): 2291-2292

http://www.wjgnet.com/1007-9327/12/2291.asp

INTRODUCTION

Haemolytic uraemic syndrome (HUS) is characterised by acute haemolytic anaemia, thrombocytopenia and acute oliguric renal failure. Often the patient has a prodrome of gastroenteritic bloody diarrhoea caused by *Escherichia coli* (*E. coli*). We report a patient who presented with biliary colic four months after recovery from HUS and her abdominal ultrasound revealed gallstones.

CASE REPORT

A 15-year-old girl presented with a 10-day history of watery diarrhoea, oliguria, haematuria and vomiting. A diagnosis of HUS was made based on renal failure, anaemia, thrombocytopenia and the presence of schistocytes on peripheral smear. Stool culture grew *E. coli* O157, phage type 21. She received packed cell transfusion, but did not need any dialysis. Following satisfactory clinical and biochemical improvement, she was discharged a week after admission. On follow-up, she was doing well.

Four months after admission, she presented with an episode of intermittent colicky right upper quadrant abdominal pain and nausea. Clinical and biochemical examination was normal. An ultrasound examination revealed marginally dilated common bile duct (diameter 9 mm) and common hepatic ducts. Gall bladder contained a small amount of sludge, but was otherwise normal. She was treated conservatively with analgesics and intravenous fluids and was doing well at discharge, a couple of days later.

She was readmitted 2 mo later for another episode of colicky right upper quadrant abdominal pain and nausea. A repeat abdominal ultrasound revealed multiple small gall bladder calculi. Rest of the ultrasound examination was normal. She had a magnetic resonance cholangiopancreatography (MRCP), which revealed a normal biliary duct and a common bile duct, besides gallstones. She had an elective laparoscopic cholecystectomy 6 wk later. Multiple pigment gallstones were found. On follow-up, she remained asymptomatic and was doing well.

DISCUSSION

Gallstones are classified into three types according to their chemical composition, namely cholesterol, pigment and mixed stones. Mixed and cholesterol gallstones usually contain more than 70% cholesterol monohydrate plus an admixture of calcium salts, bile acids and bile pigments, proteins, fatty acids and phospholipids. Pigment stones are composed primarily of calcium bilirubinate containing less than 10% cholesterol.

Although cholelithiasis occurs infrequently in the paediatric age group, its incidence has increased during the last few decades. The reason why gall stones are not considered as a possible cause of jaundice or right upper quadrant discomfort in the past is the emphasis placed on the belief that haemolytic disease is a necessary prerequisite for gall stone formation in children[1].

Currently only about 20% of cholelithiasis cases in children are attributed to haemolytic conditions. Hereditary spherocytosis, sickle cell anaemia and thalassemia are the haemolytic disorders most commonly associated with development of gall stones. The question is whether an isolated episode of haemolysis can cause gallstones. The answer is yes because there are many reports in the literature.[2, 3] while the answer is no because none of the textbooks mentions it as a cause of gallstones. Hence, there is relatively low awareness that self-limiting haemolytic episodes can predispose to gall stones.

There are a few case reports of gall stones associated with HUS[2, 3]. Brandt *et al*[4] reported a high incidence of

gastrointestinal sequelae following typical HUS. Cholelithiasis might be related to haemolysis during the acute phase of HUS leading to pigment gall stones or to the use of parenteral nutrition. Parenteral nutrition was not used in the case presented.

In conclusion, neither is cholelithiasis mentioned as a complication of the HUS, nor is an acute haemolytic process listed as aetiology of gallstones. But gallstones should be suspected in both settings. An abdominal ultrasound examination can easily and readily confirm the diagnosis.

Abstract

Xanthogranulomatous cholecystitis (XGC) is a destructive inflammatory disease of the gallbladder, rarely involving adjacent organs and mimicking an advanced gallbladder carcinoma. The diagnosis is usually possible only after pathological examination. A 46 year-old woman was referred to our center for suspected gallbladder cancer involving the liver hilum, right liver lobe, right colonic flexure, and duodenum. Brushing cytology obtained by endoscopic retrograde cholangiography (ERC) showed high-grade dysplasia. The patient underwent an en-bloc resection of the mass, consisting of right lobectomy, right hemicolectomy, and a partial duodenal resection. Pathological examination unexpectedly revealed an XGC. Only six cases of extended surgical resections for XGC with direct involvement of adjacent organs have been reported so far. In these cases, given the possible coexistence of XGC with carcinoma, malignancy cannot be excluded, even after cytology and intraoperative frozen section investigation. In conclusion, due to the poor prognosis of gallbladder carcinoma on one side and possible complications deriving from highly aggressive inflammatory invasion of surrounding organs on the other side, it seems these cases should be treated as malignant tumors until proven otherwise. Clinicians should include XGC among the possible differential diagnoses of masses in liver hilum.

INTRODUCTION

The term xanthogranulomatous cholecystitis (XGC) describes a rare inflammatory lesion of the gallbladder, characterized by marked proliferative fibrosis and infiltration of macrophages and foam cells involving the wall of the gallbladder[1]. Although a fair number of cases of this pathological condition have already been described, so far very few reports have described XGC with aggressive tumor-like inflammation pattern directly involving adjacent structures and organs[2-7].

We herein report a case of XGC presenting as advanced gallbladder carcinoma with involvement of liver, common bile duct, duodenum and transverse colon, review the characteristics of patients with XGC involving adjacent organs who underwent extended surgery, and discuss the different diagnostic and surgical options in cases of massive extra-gallbladder involvement.

CASE REPORT

A 46-year-old woman with no prior medical history was admitted to a local hospital due to progressively increasing upper abdominal discomfort for some weeks, lately associated with jaundice. No weight loss was reported. No mass was palpable at the physical examination. Ultrasound showed a gallbladder hydrops with gallstone in the infundibulum and bilateral dilation of intrahepatic bile ducts. An endoscopic retrograde cholangiography (ERC) demonstrated a filiform stenosis of the proximal common bile duct and the bifurcation with upstream intrahepatic bile duct dilation, and no visualisation of cystic duct and

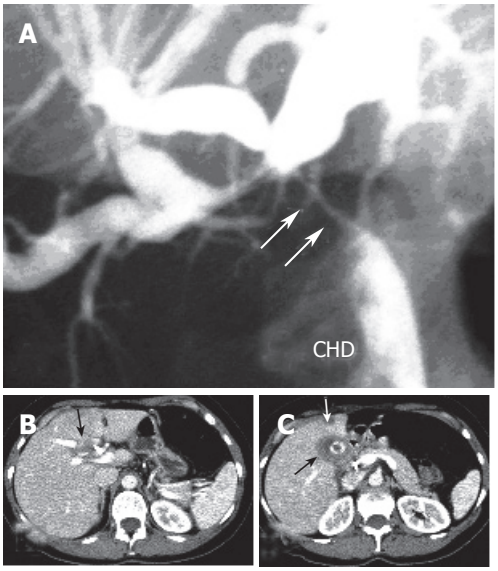

Figure 1 Proximal obstruction (arrows) of the common hepatic bile duct (CHD) with upstream dilatation of both left and right intrahepatic bile ducts (**A**), a soft tissue mass at the hepatic hilum (**B**), and thickened gallbladder wall (black arrow) with a concretion and hepatic lesion in liver segment 4 (**C**).

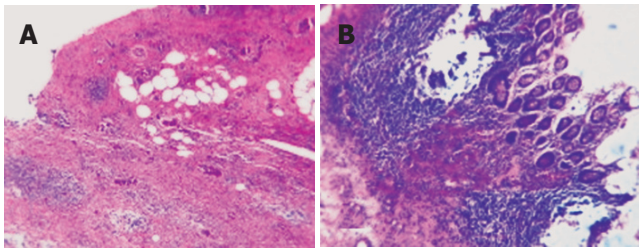

Figure 3 Xanthogranulomatous cholecystitis (**A**) and xanthogranulomatous cholecystitis involving the wall of the transverse colon (**B**). There is destruction of the submucosa and muscular coat of the transverse colon by extensive macrophage infiltrates, the mucosa is intact and exhibits no cellular atypia (HE, 200x).

gallbladder. A complete sphincterotomy was performed with insertion of an internal stent draining the left main bile duct. Magnetic resonance imaging (MRI) confirmed the presence of a hilar mass with two liver lesions in the right lobe of the liver, suspicious of metastases. MRI-vascular reconstruction excluded an infiltration of the portal vein and the hepatic artery. The patient was then transferred to our clinic with the diagnosis of advanced gallbladder cancer with differential diagnosis from Mirizzi's syndrome type I (i.e., secondary stenosis of the common hepatic duct caused by inflammatory fusion of gallbladder infundibulum and common bile duct due to gallstone impaction, without presence of a fistula). On admission to our centre, the patient was icteric after internal drainage of the left and common bile duct. Serum concentrations of total bilirubin (4.2 mg/dL, ref <1.1 mg/dL), alkaline phosphatase (325 U/L, ref <170 U/L), gamma glutamyl transpeptidase (55 U/L, ref <18 U/L), were all elevated. The tumor marker carbohydrate antigen 19-9 (CA19-9) was 42 U/mL (ref <33 U/mL) while carcinoembryonic antigen (CEA) was normal. We repeated ERC (Figure 1A) to attain cytological material and removed the internal stent. Brushing cytology revealed atypical epithelial cells with high-grade dysplasia. Computed tomography (CT-scan) with liver volumetry (Figures 1B, 1C) confirmed the presence of two hypodense lesions in the right liver lobe, suspicious of metastases, already detected by the MRI performed in the first hospital. Clinical, serological, cytological and imaging data were highly indicative of malignancy. Surgical exploration confirmed the diagnostic findings (Figure 2A): the mass completely involved the hepatic hilum, the transverse colon and the second duodenal portion, seeming to originate from the gallbladder bed, since the gallbladder itself was not distinguishable from the surrounding inflammatory tissue. The preoperatively suspected liver metastases were intraoperatively identified as hemangiomas. Assuming an advanced gallbladder carcinoma, we performed an anatomic right lobectomy en-bloc with gallbladder and extrahepatic bile duct resection, segmental duodenal resection, right hemicolectomy and partial omentectomy. Reconstruction was achieved by a hepaticojejunostomy protected by transhepatic drainage through the left biliary system, and an ileotransversostomy. Gross examination of the specimen (Figure 2B) demonstrated a bright white, hard mass, inseparable from the adjacent structures. A 2.5 cm × 3 cm × 2.5 cm biliary stone was packed in the infundibulum of the gallbladder. Histological examination unexpectedly revealed a xanthogranulomatous cholecystitis (Figure 3A), with tumor-like inflammatory tissue invading the liver as well as the proximal common bile duct, the right flexure of the colon (Figure 3B) and the second duodenal portion, with no evidence of malignancy.

The postoperative course was completely uneventful and the patient was discharged on the 15th postoperative day. One year after surgery, the patient was asymptomatic and in good health.

DISCUSSION

XGC is found after approximately 1.46% of cholecystectomies and affects men and women equally[8], almost always in presence of gallstones (91%-100%)[1]. Even if aetiology is unknown, some authors suggest that in the presence of gallstones, obstruction, and cholestasis, XGC results from the extravasation of bile into the gallbladder wall. With involvement of Rokitansky-Aschoff sinuses[8], the process is supposed to start as an initial inflammatory process, followed by a granulomatous reaction, similarly to the aetiopathogenesis of xanthogranulomatous pyelonephritis, in which chronic infection and calculi are common findings. Macroscopically, XGC is characterized by formation of multiple yellowish nodules within the gallbladder wall. Histologically, abundant so-called foam-cells (histiocytes)

Table 1 Characteristics of the patients with XGC who underwent extended surgical resections

Author Year	Age (Sex)	Symptoms	Tumor markers	Involvement of	Performed resection	Follow-up
Okamoto 1990	70 (F)	Fever, general malaise	CA19.9 ↑, CEA normal	Liver, bile duct, transverse colon	Cholecystectomy, local atypical liver resection, bile duct resection and transverse colectomy	Uncomplicated postoperative course, alive 6 mo after surgery
Maeda 1994	75 (F)	No complaints	CA19.9 ↑, CEA normal	Liver bed and transverse colon	Cholecystectomy with local atypical liver resection and transverse colectomy	Uncomplicated postoperative course, follow-up not reported
Furuta 1996	46 (M)	Epigastric pain	CA19.9 and CEA normal	Liver, bile duct, duodenum, right hepatic artery, right portal vein	Right hepatectomy and pancreatoduodenectomy	-
Natori 1997	55 (M)	No complaints	CA19.9 normal, CEA ↑	Liver (gallbladder bed) and bile duct	Cholecystectomy with local atypical liver resection and bile duct resection	-
Enomoto 2003	64 (M)	High fever, hypochondralgia	CA19.9 and CEA normal	Liver, bile duct, duodenum, transverse colon, right hepatic artery and right portal vein	Right hepatectomy, pancreatoduodenectomy and transverse colectomy	Uncomplicated postoperative course, alive 4 yr after surgery
Pinocy 2003	64 (M)	Hypochondralgia, fever	-	Right colonic flexure	Cholecystectomy and resection of the right colonic flexure	-
Present case 2005	46 (F)	Epigastric pain, sense of fullness, jaundice	CA19.9 ↑, CEA normal	Right liver, right colonic flexure, second duodenal portion	Right hepatectomy, partial duodenectomy and right hemicolectomy	Uncomplicated postoperative course, alive 1 yr after surgery

are mixed with chronic and acute inflammatory cells[9]. With regard to imaging of a liver hilar mass, ultrasound, CT, MRI and ERC can be considered. In the case of XGC, ultrasound can detect focal or diffuse thickening of the hyperechoic gallbladder wall[10] with the presence of characteristic intraluminal hypoechoic nodules in 35-73% of the cases[11]. Other commonly reported findings are cholecystitis-like fluid collections near the gallbladder and dilation of intra- and extra hepatic bile ducts in case of choledocolithiasis. Chun *et al*[12] analyzed CT-patterns of XGC in a series of patients, with emphasis on differential diagnosis of gallbladder carcinoma and stated that intramural hypodense nodules occur more often in XGC than in cancer patients. However, these characteristic findings are inconstant in patients with XGC, as highlighted by more recent studies[11, 13-14]. Visualisation of the biliary anatomy through direct (percutaneous or endoscopic) cholangiography or magnetic resonance cholangiopancreatography (MRCP) is particularly important if a direct involvement of the common bile duct is suspected. Furthermore, ERC allows brushing cytology. The potential role of positron emission tomography in the differential diagnosis of cholecystitis from gallbladder carcinoma is unclear, because only a few studies in small series are available up to now[15,16] with a patient with XGC being the only false positive case in one study[15].

Concerning tumor markers, our patient had only a slightly elevated (42 U/mL) serum level of CA 19.9 (reference = 33 U/mL), which persisted even after resolution of jaundice through placement of an endoscopic stent preoperatively. Adachi *et al*[17] argued that serum-CA 19.9 may be elevated even greatly in both carcinoma and XGC patients, thus being not helpful in the differential diagnosis between the two conditions. Even in cases of XGC with extended involvement of other organs[3,5] elevations of tumor markers concentrations (CA 19.9, CEA) are inconsistent.

Although XGC is not an exceptional finding, a direct involvement of extra-gallbladder organs and structures is very rare. To the best of our knowledge, only six cases of extended surgical resections for XGC have been reported so far. In these cases (Table 1), additional procedures such as bile duct resections, segmental resections of colon or duodenum, partial pancreatoduodenectomies have been performed. It can be discussed if such extended surgical procedures could be avoided in presence of a benign disease. Our patient exhibited severe, destructive, tumor-like xanthogranulomatous inflammation, with extensive invasion of adjacent organs (right lobe of the liver, extrahepatic bile ducts, colon and duodenum). The clinical and radiological findings were suggestive of a gallbladder carcinoma. ERC was indicative of hilar cholangiocarcinoma (Klatskin tumor). However, after confrontation with CT findings (gallbladder hydrops, gallbladder wall thickened over 1.8 cm, presence of suspect lesions in the right liver lobe, suspected infiltration of adjacent organs- all uncharacteristic findings in cases of Klatskin tumors), the most probable diagnosis was a locally advanced gallbladder cancer, with infiltration of the proximal common bile duct and the bile duct bifurcation. In addition, cytology obtained during ERC showed high-grade dysplasia and CA 19.9 was slightly but persistently elevated after stenting. Under these conditions, a radical resection of the mass was the only reasonable option. According to the published data on gallbladder cancer and hilar cholangiocarcinoma, radical surgery offers the only chance to achieve long-term survival[18-23]. The necessity of radical surgery in those cases of XGC with extensive extra-gallbladder involvement is not cleared. We agree with Houston *et al*[24] emphasizing the necessity of a complete resection of the involved structures in order to treat symptoms like jaundice and cholangitis and to prevent possible complications like bowel obstruction and perforation, potentially life threatening.

Intraoperative frozen section investigation or fine needle aspiration cytology has been suggested to confirm the

diagnosis. In cases with no invasion of adjacent organs these tools are indicated because they can change the surgical strategy (e.g, simple cholecystectomy versus associated liver resection). Nevertheless, in cases of extensive invasion of other organs, like in our patient, it can not alter our approach. Even in the case of a negative or inconclusive result, radical surgery can be performed since gallbladder carcinoma and XGC may coexist [24-26] and the patient had jaundice and cholangitis, which needed a treatment. Furthermore, even assuming an advanced gallbladder carcinoma, we believe it is essential to minimize the intraoperative tumor cell spread by avoiding any unneeded manipulation or dissection in the liver hilum.

Two different risks are linked to misjudgement of this pesudotumoral condition. On the one hand, excessive surgical resection is inevitably linked with a certain perioperative mortality and morbidity. On the other hand, this condition may be misinterpreted as not being radically operable. Especially in this latter case, before deciding for inoperability, it is essential to gain specimens for frozen section biopsy.

In conclusion, preoperative or intraoperative differential diagnosis of XGC from gallbladder carcinoma remains a challenge, especially in patients with extensive pseudotumoral involvement of surrounding structures and organs. From our point of view, radical resection is mandatory as long as malignancy can not be ruled out after a complete preoperative diagnostic examination. Preoperative fine needle aspiration biopsy and intraoperative frozen section are valuable tools for differential diagnosis when there is no invasion of adjacent organs, otherwise they would not influence the surgical strategy. The presence of symptoms such as jaundice and cholangitis, as well as the potential risk of life-threatening complications like bowel obstruction and subsequent perforation, supports a radical surgical approach.

Abstract

An association between chronic hepatitis C virus (HCV) infection and essential mixed cryoglobulinaemia and non-Hodgkin lymphoma (NHL) has been suggested. However, a causative role of HCV in these conditions has not been established. The authors report a case of a 50 year-old woman with chronic hepatitis C (CHC) who has been followed up since 1998 due to a high viral load, genotype 1b and moderately elevated liver function tests (LFTs). Laboratory data and liver biopsy revealed moderate activity (grade: 5/18, stage: 1/6). In April 1999, one-year interferon therapy was started. HCV-RNA became negative with normalization of LFTs. However, the patient relapsed during treatment. In September 2002, the patient was admitted for chronic back pain. A CT examination demonstrated degenerative changes. In March 2003, multiple myeloma was diagnosed (IgG-kappa, bone marrow biopsy: 50% plasma cell infiltration). MRI revealed a compression fracture of the 5th lumbar vertebral body and an abdominal mass in the right lower quadrant, infiltrating the canalis spinalis. Treatment with vincristine, adriamycin and dexamethasone (VAD) was started and bisphosphonate was administered regularly. In January 2004, after six cycles of VAD therapy, the multiple myeloma regressed. Thalidomide, as a second line treatment of refractory multiple myeloma (MM) was initiated, and followed by peginterferon-α2b and ribavirin against the HCV infection in June. In June 2005, LFTs returned to normal, while HCV-RNA was negative, demonstrating an end of treatment response. Although a pathogenic role of HCV infection in malignant lymphoproliferative disorders has not been established, NHL and possibly MM may develop in CHC patients, supporting a role of a complex follow-up in these patients.

INTRODUCTION

Numerous clinical syndromes have been reported in association with hepatitis C virus (HCV) infection. Some are well established while others remain a speculation (Table 1)[1], Fourteen to seventy percent of patients with HCV have detectable cryoglobulins in their serum even in the absence of rash, weakness or arthralgias[1], whereas 50-90% of patients with mixed cryoglobulinaemia are reported to have HCV infection[2]. It is suggested that approximately 10% of type II mixed cryoglobulinaemiae can evolve into malignant lymphoma several years after diagnosis.

Epidemiological studies from Europe, Japan and North America also implicate that HCV plays a role in the pathogenesis of non-Hodgkin lymphomas (NHL)[3-7]. HCV infection is detectable in a significant proportion of NHL (14%-52%), nonetheless, it has not been confirmed[8]. A 50-fold elevation in the risk for NHL of the liver or salivary glands has been reported in an Italian case-control study, which is greater than the relative risk of hepatocellular carcinoma. The relative risk for NHL of other sites is increased about 4-fold[9]. An association between multiple myeloma (MM) and chronic HCV infection has been suggested by some epidemiological studies[2,9].

CASE REPORT

The authors report a case of a 50 year-old woman with chronic HCV infection who has been followed up since 1998 due to high viral load (13.47 MEq/mL), genotype 1b and moderately elevated liver function tests (LFTs). The patient received treatment of chronic backache and tonsillectomy prior to admission to our hospital. Laboratory data and liver biopsy revealed moderate activity (grade 5/18, stage I). In April 1999, one-year interferon therapy (3x3ME/wk) was initiated. HCV-RNA became negative with normalization of the LFTs. However, the

patient relapsed in the 7th mo of treatment (HCV-RNA became positive, LFTs increased). The liver function tests are summarized in Figure 1. In February 2000, hypothyroidism was diagnosed, substitution was initiated and follow-up was scheduled.

In September 2002, the patient was admitted for chronic backpain. CT examination revealed degenerative changes of the 5th lumbar vertebral body. Subsequently, the patient was not monitored until March 2003, when she was again hospitalized due to chronic backache and weakness of the right lower limb. Based on laboratory results, IgG-κ multiple myeloma was diagnosed (erythrocyte sedimentation rate; ESR): 104 mm/h, IgA: 0.18 g/L, IgG: 41.86 g/L, IgM: 0.29 g/L and 12.8% M-component on serum immunoelectrophoresis; bone marrow biopsy: 50% plasma cell infil). Mixed cryoglobulins were detected in the serum. Anemia, low platelet count or hypercalcaemia did not occur during follow-up. Serum IgG was elevated from 1998. However, monoclonality was not detected prior to March 2003. The serum immunoglobulin data and ESR are presented in Figure 2. MRI revealed a compression fracture of the 5th lumbar vertebral body and an abdominal mass in the right lower quadrant, infiltrating the canalis spinalis, ileum and sacroiliac joint (osteolytic lesions).

An aggressive treatment regimen was implemented with vincristine, adriamycin and dexamethasone (VAD). From April to October 2003, she received six cycles of VAD therapy followed by multiple myeloma's regression. The presence of compression fracture also prompted the regular adminis of bisphosphonate (Aredia). In January 2004, 22.2% M-components were detected by immunoelectrophoresis, yet the ESR was normal (17mm/h). Methyl prednisolone (100 mg b.i.d) and cytoxane (100 mg o.d.) p.o. therapy was started.

In April 2004, she was admitted to the Haematological Department for paraparesis. Laminectomy (Th VII-IX) with myelin decompression and tumor resection was performed. Therapy was amended with thalidomide (100mg o.d.) orally. In August, repeated CT scans demonstrated compression fractures at L5 and S2 accompanying narrowing of the spinal canal at L5. In September, due to worsening of the paraparesis, a second laminectomy was performed (L5-S1) followed by insertion of a stabilizing prosthesis (L4-S1).

In June 2004, weekly peginterferon-α2b (1.5 μg/kg) and 800 mg ribavirin (daily) were prescribed (HCV PCR 145000 IU/mL, Roche TaqMan). No further dose adjustment was necessary. The LFTs became normal and PCR returned negative after three months of therapy, indicating an early viral response (EVR). In June 2005, the LFTs were normal with a negative HCV-PCR, demonstrating an end of treatment response (ETR).

DISCUSSION

In recent years, major advances have been made in the treatment of HCV infection with the sustained response rate of 52%-63% achieved[11-13]. A major disadvantage in Hungary is that the hard-to-treat genotype 1 is almost universal (90%-95%) and occurs much more frequently compared to that in other European countries[13, 14].

Apart from hepatocellular carcinoma, HCV infection is also associated with various extrahepatic diseases, including mixed cryoglobulinaemia and NHL. Fourteen to seventy percent of patients with HCV have detectable cryoglobulins in their serum[1, 2], while 50%-90% of patients with mixed cryoglobulinaemia are reported to have HCV infection.

Epidemiological case-control studies from the 1990s suggest that chronic HCV infection is associated with the development of NHL. It was reported that 9% and 11.5% of NHL patients are HCV-antibody positive[15,16]. Germanidis *et al*[4] investigating 201 NHL patients found that the prevalence of HCV infection was 2-fold higher

than that in controls[4]. More recent studies have further confirmed this finding. A Japanese study showed that 17% of patients with B-cell NHL were HCV-antibody positive compared to 6.6% of controls[6]. Moreover, an East European study[7] reported that 6 out of 42 (24.3%) NHL patients were HCV-antibody positive. In contrast, Rabkin *et al*[8] investigated the stored sera of 57 NHL patients, 24 MM patients and fourteen Hodgkin's disease patients, and found that only four patients were HCV-antibody positive.

An association between chronic HCV infection and MM was also found in epidemiological studies. Gharagozloo *et al*[2] showed that HCV antigens were detectable in 11% of patients with MM, 69% of patients with essential mixed cryoglobulinaemia and 4.3% of patients with NHL, using recombinant immunoblot assay (RIBA) and enzyme-linked immunosorbent assay (ELISA). Another study revealed that HCV infection was found in 32% of MM patients[10]. The former was associated with 4.3-fold risk for MM.

The possible mechanism by which HCV infection leads to stimulation of B cells is starting to unravel. It is well documented that HCV infection, as observed in our case, usually precedes NHL by many years[9]. Hepatitis C is lymphotropic and may replicate in lymphocytes and hepatocytes[17]. The second portion of the HCV envelope (E2 protein) binds to CD81[18], suggesting that this phenomenon is associated with CD19 and CR2 as well as MHC class II molecules on lymphocytes. The binding of CD81 to B cells can activate this complex, which lowers the antigen threshold necessary for antibody stimulation, thus rendering the B cell hyper-responsive. Sequencing of the antigen-binding region of immunoglobulin produced by malignant lymphocytes demonstrates that it has a high degree of homology to both antibodies specific for E2, as well as the antibodies produced by B cells that secrete RF. Furthermore, 88% of patients with HCV infection and cryoglobulinaemia demonstrate over-expression [t(14,18)translocation] of the anti-apoptotic *bcl-2* gene, compared with 8% of patients with HCV infection, 2% of patients with other liver diseases, and 3% of individuals with other rheumatoid disorders, which cause enhanced B cell survival[19]. In addition, over-expression of NF-kB has been reported in lymphocytes and liver samples of patients with chronic HCV infection and those with NHL[20, 21]. This is an important finding, as NF-kB plays a key role in virus-induced lymphomagenesis. Mutations of the NF-kB gene are common in lymphoid malignancies[22] and alterations of NF-kB could initiate changes in downstream regulatory pathways. A second mutation (e.g. myc, NF-kB) could possibly initiate the progression to lymphoma[23].

In conclusion, although a pathogenic role of HCV infection in malignant lymphoproliferative disorders has not been established, NHL and possibly MM may develop in cases of CHC, supporting the need for a complex follow-up in these patients.

Abstract

Enteropathy-associated T-cell lymphoma (EATCL) is a high grade, pleomorphic peripheral T-cell lymphoma usually with cytotoxic phenotypes. We describe a first case of patient with EATCL that is remarkable for its fulminant course and invasion of both kidneys manifested as acute renal failure. The patient was a 23 year old woman with a long history of celiac disease. She was presented with acute renal failure and enlarged mononuclear infiltrated kidneys. Diagnosis of tubuloi-nterstitial nephritis and polyserositis was confirmed with consecutive pulse doses of steroid therapy. After reco-very, she had disseminated disease two months later. Magnetic resonance imaging showed thickened intestine wall, extremely augmented kidneys, enlarged intra-abdominal lymph nodes with extra-luminal compression of common bile duct. Laparotomy with mesenterial adipous tissue and lymph glands biopsy was done. Consecutive pathophysiological and immunohistochemical analyses confirmed the diagnosis of EATCL: CD45RO+, CD43+, CD3+. The revision of renal pathophysiology sub-stantiated the diagnosis. The patient received chemotherapy, but unfortunately she died manifesting signs of pulmonary embolism caused by tumor cells.

Key words: EATCL; Acute renal failure; Celiac disease; Anti-endomisial antibodies

INTRODUCTION

Intestinal enteropathy associated T-cell lymphoma (EATCL) is highly aggressive, pleomorphic peripheral T-cell lymphoma (PTL), usually with cytotoxic immunological phenotypes (TdT-, CD3+, CD5-, CD7+, CD4-, CD8±, CD45RO+, CD103+, HLA-DR-)[1-3]. This type of PTL originates from intraepithelial T-lymphocytes of small intestine mucosa and is associated with celiac disease (CD) in about 50% of the time[4,5]. Intestinal lymphoma develops in 7%-12% of CD cases[6]. It may even occur without any previous CD[6]. Infiltration of the kidneys is commonly found in disseminated lymphoma but rarely in primary renal lymphoma[7]. Acute renal failure (ARF) arising from bilateral renal infiltration is also uncommon[8,9]. Primary renal failure may occur and is usually of B-cell lineage[7]. It is rare for patients with lymphoma to develop ARF as their initial clinical presentation. The first report in which the phenotype of non-Hodgkin's lymphoma was established using renal biopsy was published by Miyake *et al*[10]. Renal lymphoma is commonly secondary due to lymphomatous infiltration of the kidneys in disseminated lymphoma and advanced stage IV of the disease. Different pathophysiological aggressive types of B-cell lymphoma such as Burkitt[11], precursor B-lymphoblastic lymphoma/leukemia[12], mantle cell lymphoma, diffuse large B-cell lymphoma[13] as well as PTL[14,15], T-cell rich B-cell lymphoma[8], make parenchymal neoplastic invasion of the kidneys. We present, as far as we know for the first time, ARF as the initial manifestation of EATCL.

Nevertheless, the intestinal lymphomas account for 20%-35% of non-Hodgkin's lymphomas (NHL) of the gastrointestinal tract (GIT) and serological screening for CD is not recommended generally in people with lymphoma[16]. In patients with primary small intestinal disease, 9% are found to have small intestinal lymphoma[17]. Lymphomas involving the small intestine represent a heterogenous group with diverse pathogenic mechanisms[18] and high-risk MALT lymphoma is most frequently considered for differential diagnosis. EATCL, a type of PTL is most commonly localized in jejunum (70% of cases) but rarely in the colon and stomach. Gross examination can reveal multiple ulcers of jejunal

mucosa frequently associated with perforation of intestinal wall or solitary lymph nodes[19]. Microscopy can show solitary epithelial lesions in the form of microabscess or lymphoepithelial lesions. In the adjacent mucosa, alterations are seen in CD such as crypt elongation, flattened mucosa and villi which are shortened, blunted or missing[2]. Tumor cells of the respective immunological phenotype have genetic characteristics as clonally rearranged TCR β and γ[5,6] can be arrested in varying stages of activation[1].

CASE REPORT

We report a case of female patient who was 23 years old with CD diagnosed at her age of 3 and had regular gluten-free diet regime. In March 1999, she was admitted to the Institute of Nephrology due to anemia and ARF. Clinical examination revealed excessive pallor of the skin and apparent mucous membranes with fever, splenomegaly +1 cm and ascites. A history was negative for exposure to nephrotoxins and hereditary renal diseases. Laboratory tests showed Hb = 65 g/L (120-170), WBC = 5.3×10^9/L (4-10), Platelet = 401×10^9/L (150-450), MCV = 90 fl (80-100), Hct = 0.34 (0.36-0.42), and normal differential count. In biohumoral status, the following pathological values were found: ESR = 90 mm/h, urea = 17.9 mmol/L (2.5-7.5), Cr = 476 μmol/L (53-106), ClCr = 13.3mL/min, tubular proteinuria=0.82 g/24h without erythrocyturia, total protein = 60 g/L (62-81), albumin = 6 g/L (40-55), Fe = 4.6 μmol/L (7-26), TIBC = 36.3 μmol/L (44.8-75.1), LDH = 590 IU/L(160-320). Immunological analyses showed CRP 28.9 mg/L (<9), ANA negativity, RF 37.3 IU/mL (<25) WR 1:40+. Virusological and bacteriological analyses were normal. Hemostasis screening did not display any detectable abnormalities. X-ray of the lungs and heart was normal, too. Abdominal echosonography showed craniocaudal splenomegaly of 14 cm, ascites and enlarged kidneys, the right of 14.5 cm and the left of 13.7 cm, without corticomedullary border. Echosonography of the heart showed pericardial effusion. Thereupon, ultrasound-guided biopsy of kidneys was performed and pH finding indicated tubulointerstitial nephritis (TIN). There were no criteria for connective tissue disease, drug-or infection-induced acute TIN**.** The diagnosis of idiopathic acute TIN with polyserositis was made and urbason at pulse doses of 3×1 g/d was administered, followed by prednisolone 45 mg/d for another month. After a short recovery, in May 1999, the patient was rehospitalized for jaundice, pains under the right costal arch, nausea and vomiting. Endoscopic retrograde cholangiopancreatography showed extra-luminal compression of ductus pancreaticus and ductus hepaticus which was moved to the right, while choledochus was filamentary narrowed distally from the site of compression. Proximal of stricture was a huge biliary duct dilatation with changes of intrahepatical biliary ducts [as in cholangitis]. Magnetic resonance imaging of the abdomen and small pelvis revealed the enlarged retroperitoneal and mesenterial lymph glands, thickened small intestine wall, extremely augmented kidneys with destroyed corticomedullary structure, as well as infiltration of the right sacral bone (Figure 1). Choledochotomy and cholecystectomy with choledochojejunostomy and biopsy of mesenterial lymph glands and adipous tissue were performed. Pathohistological (PH) and immunohistochemical (IHC) analyses of mesenterial lymph nodes and adipous tissue from transfersal mesocolon showed the PTL infiltration (anti-CD45RO+, anti-CD43+, CD3+ as well as anti-EMA- /epithelial membrane antigen/, anti-vimentin-) (Figure 2). The revision of renal PH findings substantiated the diagnosis (Figure 3). Neoplastic lymphoid cells were also found in the ascites (Figure 4). Antiendomysial serum IgA antibodies (EmA) in high titer +++ were (Figure 5) detected by indirect immunofluorescence on monkey oesophagus. Anti-nuclear, anti-microsomal, anti- tireoglobulin antibodies were negative and serum levels of IgM, IgG and IgA were normal. Upon complete staging of the disease, it was

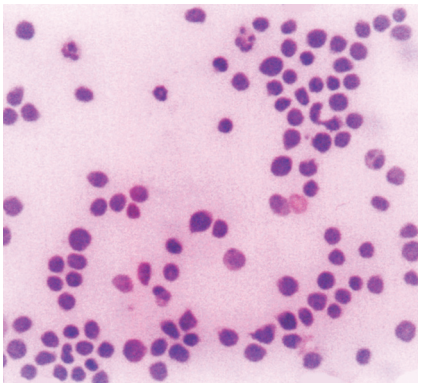

Figure 4 Neoplastic lymphoid cells in ascites (MGG, x100).

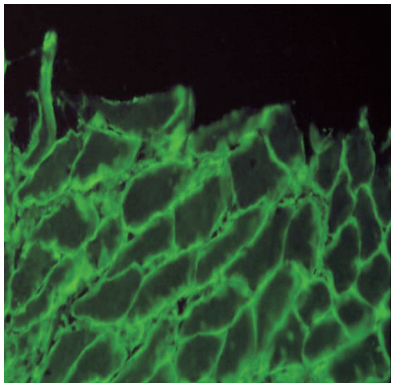

Figure 5 IgA antiendomysial antibodies surrounding sarcolemma of smoth muscle fibers in lamina muscularis mucosae of monkey esophagus (IIF, x 400).

verified that it was EATCL with infiltration of intestines, intraabdominal lymph glands, kidneys and sacral bone (CS IVB). The patient was transferred to the Institute of Hematology, where she received chemotherapy with cyclophosphamide (1200 mg, D1), doxorubicin (90 mg, D1), vincristine (2 mg, D1), prednisolone (100 mg, D1-5. On the second day of therapy, the patient died manifesting the signs of cardiorespiratory insufficiency and picture of pulmonary embolism, most probably caused by tumor cells.

DISCUSSION

EATCL is a relatively rare disease with the incidence rate less than 1% of all NHL[20]. By nature, it is aggressive whether it occurs as de novo disease or results from long-term untreated or refractory CD. Usually, the jejunum is involved with presence of multiple circumferential ulcerations but without formation of homogenous tumor mass. In addition, the involvement of mesenterial lymph glands is frequently seen. In fact, refractory CD is considered as lymphoma of low grade malignancy resulting from clonal expansion of intraepithelial lymphocytes and represents an intermediate stage between CD and EATCL[21,22].

The moment when CD converts to intestinal lymphoma is sometimes difficult to recognize. Diffuse bilateral infiltration of the kidneys by lymphoma cells is a rare but well documented cause of ARF[23]. The diagnosis should be suspected in a patient with ARF, bilateral enlargement of the kidneys, minimal proteinuria, non-specific findings on urine analysis, and absence of other features (fever, skin rush, eosinophilia) typical of drug-induced TIN. Renal imaging techniques may suggest the possibility of lymphomatous infiltration, but only renal biopsy or autopsy can provide a definitive diagnosis[24]. Diffuse bilateral renal cell lymphoma sometimes presents as ARF of unknown cause. Signs of extrarenal lymphomatous involvement were detected in 44% patients at the time of kidney biopsy or shortly thereafter[25] and often clinically mimic primary renal disease or systemic connective disease.

In our patient who was diagnosed with CD 20 years prior to the development of lymphoma, CD was in subclinical form for years. This is a key point for misdiagnosis of TIN instead of lymphoma renal infiltration. At the time of aggravation of general condition, renal failure with signs of TIN and polyserositis predominated in the clinical picture of disease. Short-term improvement after the corticosteroid treatment was followed by stasis icterus but without any symptoms typical of intestinal lymphoma. Diagnostic dilemma was resolved by complete PH and IHC examinations of bioptic specimens of mesenterial lymph glands and mesocolic adipous tissue tumor. Time loss due to unrecognized intestinal lymphoma, and dissemination into abdominal organs and small pelvis, brought about the extreme progression of the disease. Because of huge tumor mass, it led to lethal outcome with pulmonary embolism by tumor cells after the chemotherapy. Actually, this was a long-term CD, which like the premalignant condition gave rise to highly aggressive T-cell lymphoma with striking propagation and short survival median.

Our case demonstrated that in this point of view, serological follow-up was very useful and could reduce the time of possible subclinical or refractory CD. It is necessary to determine serum IgA EmA not only to monitor the activity but also to predict the gluten-free diet compliance. IgA EmA should disappear after a gluten free diet is started and about 90% of patients who have characteristic findings of CD respond to complete dietary gluten restriction[26]. In the early stages of EATCL, serological, immunohistochemical and molecular biological analyses may lead to the correct diagnosis and better prognosis[27].

The target cells in EATCL as a member of uniform subclass T-cytotoxic lymphocytes are also target cells in the intestinal lesion in CD patients, indicating that the evolution of genetically controlled autoimmune disease as pre-malignant condition to highly risk and aggressive lymphoma of small intestine is the evidence confirming that autoimmunity is a risk factor for malignancy.

Our case revealed very aggressive atypical clinical onset of EATCL patient, which was presented as ARF without intestinal symptoms at presentation. This is a first case in published literature, which describes ARF as an initial manifestation of EATCL. Although it was a case of misdiagnosis of idiopathic TIN with polyserositis instead of lymphoma, our study has confirmed that subjects with persistent high IgA EmA should be regularly re-examined concerning possible evolution of CD towards EATCL. Although good serological predictors are not yet available, IgA EmA assessment may help to detect individuals at higher risk to develop EATCL.

Abstract

Multiple myeloma is a neoplasm of mature and immature plasma cells. A 50-year-old woman with lumbago, dysphagia, and left arm pain was presented. Upper endoscopical examination was performed. There was an exudate-covered ulcer in the distal esophagus, located at 30-32 cm from the incisors, covering the whole mucosa. Histopathological examination of the specimens obtained from the lesion showed the involvement of plasma cells consistent with multiple myeloma of IgG kappa subtype. Esophageal involvement of multiple myeloma should be kept in mind in patients presenting with dysphagia.

Key words: Multiple myeloma; Esophageal ulcer; Dysphagia; Endoscopy

INTRODUCTION

Multiple myeloma (MM) is a plasma-cell neoplasm characterized by skeletal destruction, renal failure, anemia and hypercalcemia. The most common symptoms at presentation are fatigue, bone pain and recurrent infections. New diagnostic criteria require the presence of at least 10% plasma cells on examination of the bone marrow (or biopsy of tissue with monoclonal plasma cells), monoclonal protein in the serum or urine, and evidence of end-organ damage[1].

Apart from the bone marrow, MM may involve any part of the body including spleen, liver, lymph nodes, thyroid, adrenal glands, ovary, testis, lung, pleura, pericardium, skin, pancreas and intestinal tract. Esophageal involvement by multiple myelomas is uncommon in the English literature. Here we report an extremely rare involvement in MM.

CASE REPORT

A 50-year-old woman was admitted to Gaziantep University Hospital with lumbago, dysphagia and left arm pain. She complained of lumbago in the last 3 mo, which deteriorated but was relieved by non-steroid anti-inflammatory drugs (NSAIDs). Dysphagia was particularly associated with solid foods over a period of month. Her severe arm pain began after lifting a heavy weight. She also complained of fatigue.

Her medical history revealed a 10-year history of hypertension and one year of type 2 diabetes mellitus. No abnormal signs were detected apart from the pale conjunctivas and the left arm pain during physical examination. She was taking gliclazide 3 mg/d and amlodipine 10 mg/d.

Biochemical examination and complete blood count showed (normal reference ranges are given in parenthesis) hemoglobin:102 g/L (110-180 g/L); hematocrit: 0.32 (0.35-0.60); ESR: 110 mm/h (1-18 mm/h); glucose: 160 mg/dL (70-110 mg/dL); total serum protein: 144 g/L (64-82 g/L); albumin: 22 g/L (34-50 g/L); globulin: 122 g/L (14-30 g/L); calcium: 12.6 mg/dL (8.5-10.1); (BUN, Cr, Na, Cl, and P were in the normal limits). IgG: 46.7 g/L (7-16); IgA:0.29 g/L (0.7-4); IgM:0.171 IU/mL (0.4-2.3); and IgE:184 g/L (0-100). Bone marrow aspiration and biopsy confirmed multiple myeloma (30% plasma cells) besides hyperglobulinemia, hypercalcemia, anaemia, elevated ESR, and bone pain. Multiple lytic lesions were encountered on radiographic examination of the arms, the vertebras, and the cranium. Endoscopic examination showed exudate-covered ulcer in the distal esophagus located at 30-32 cm from the incisors, covering the whole mucosa (Figure 1) and no pathological finding in the stomach. Histopathologic examination of the specimens obtained from the lesion showed the involvement of plasma cells in the ulcerated esophageal mucosa (Figure 2). Immunohistochemically, plasma cells revealed positive reaction with CD38, CD56, and kappa light chain and (Figure 3)

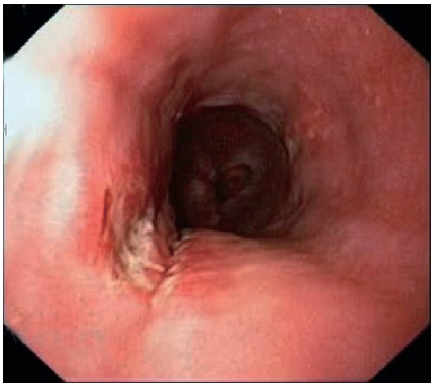

Figure 1 Exudate-covered ulcer in distal esophagus.

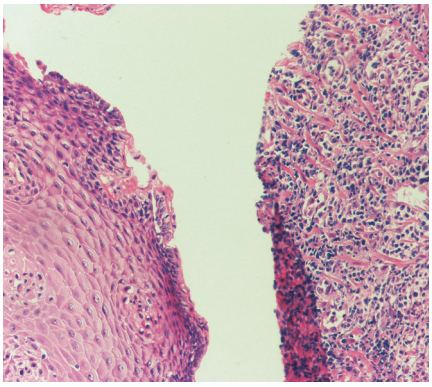

Figure 2 Plasma cells infiltrating esophageal mucosa (hematoxylin & eosin staining, x 200).

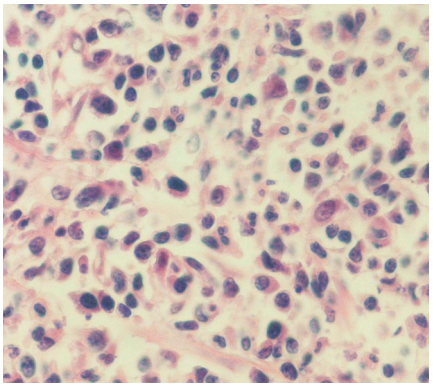

Figure 3 Myeloma cells in lamina propria of esophagus (hematoxylin & eosin staining, x 400).

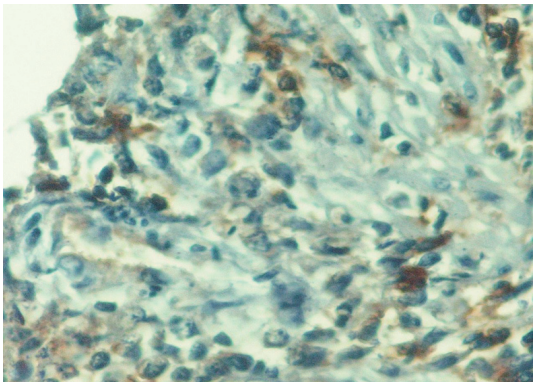

Figure 4 Immunohistochemically stained kappa light-chain showing monoclonality of plasma cells (x400).

negative reaction with CD20 and lambda light chain both in the bone marrow and in the esophagus (Figure 4). It was consistent with MM of IgG kappa subtype. Left upper extremity MRI revealed an irregularly shaped 5 cm × 4 cm × 6 cm mass on the humeral head. Total excision of the mass in the left arm was performed. It was also consistent with MM.

The patient was diagnosed with MM of IgG kappa subtype, and chemotherapy regimen of VAD was applied (vincristine 0.4 mg for 24 h infusion on days 1-4, adriablastina 9 mg/m^2 for 24 h infusion on days 1-4, dexamethasone 40 mg po on days 1-4, 9-12, 17-20). Dysphagia was relieved after administration of the chemotherapy regimen. Control endoscopical examination revealed that the formerly detected ulcers on admission were improved.

DISCUSSION

Multiple myeloma is a neoplastic proliferation of monoclonal plasma cells that can result in osteolytic bone lesions, hypercalcemia, renal impairment, bone marrow failure, and the production of monoclonal gammopathy. Although it is usually restricted to the bone marrow, extramedullary involvement can occur in the form of plasmacytomas in up to 20% of cases. The most common site of extramedullary involvement is the upper respiratory tract, including the oropharynx, nasopharynx, nasal cavity, paranasal sinuses, and larynx[1,2]. Gastrointestinal involvement by plasma cells is rare, representing less than 5% of all extramedullary plasmacytomas. Presentation may be either primary or secondary. Before a diagnosis of multiple myeloma is made it is mandatory to exclude primary extramedullary plasmacytoma (PEMP) by performing the necessary investigations. The differential diagnosis of PEMP from multiple myeloma is important because these two entities are thought to be biologically different and their prognoses are not the same.

Most of the reported cases represent involvement of the gastrointestinal tract by solitary plasmacytomas. All segments of the gastrointestinal tract may be involved by plasma cell infiltration. Small bowel is the most common site of involvement, followed by stomach, large bowel and esophagus[2-5]. Esophageal involvement by multiple myeloma is uncommon (Figure 3). A search of the English literature for plasmacytoma of the esophagus has revealed only four previous reports. The case reported by Morris and Pead[6] occurred in a 59-year old woman who presented with weight loss and intermittent dysphagia that progressively worsened over a 4- 5-mo period. Plasmacytoma is a protuberant mass occurring in the lower esophagus and involving the full thickness of the wall. Ahmed *et al*[7] encountered an esophageal PEMP in a 67-year-old man who, in addition to dysphagia, had weakness and weight loss. The lower third of the esophagus was invaded by an 8 cm tumour that extended to the gastric cardia and penetrated the entire thickness of the esophageal wall. Davis and Boxer[8] described a PEMP of esophagus in a 69-year-old man who only had a two-week history of dysphagia. Furthermore, this patient did not have weight loss, malaise or constitutional symptoms. The tumour was polypoid,

measured 4 cm in diameter, and involved the distal third of the esophagus. Recently, Chetty *et al*[9] described a PEMP of esophagus in a 58-year-old man. Dysphagia occurs particularly with consumption of solid foods over a period of 2 mo. Gross examination of esophagus can reveal large polypoid tumour. In the present case, however, dysphagia was particularly with solid foods over a period of one month. The lesion was in the form of ulcer and was probably induced by impairment of the esophageal mucosa due to replacement of the stromal tissue by the plasma cells (Figure 4).

The presenting features of esophageal plasmacytoma are similar to esophageal carcinoma, i.e., progressive dysphagia, profound weight loss, signs of malnutrition, and anemia. Diagnosis on clinical grounds alone is impossible and the radiologic appearance does not seem distinctive. Endoscopic biopsy is the earliest opportunity for diagnosis.

Diffuse plasma cell infiltration may also be seen in Barrett's esophagus that should be ruled out in the differential diagnosis. Plasma cells are positive for monoclonal light chain in MM as in the present case, but they are polyclonal in Barrett's esophagus. Additionally, there was no intestinal glandular metaplasia in the present case.

In conclusion, multiple myeloma is a systemic disease which may be rarely presented with esophageal involvement. It should be kept in mind that esophageal ulcers in patients diagnosed with MM may be related to the myeloma involvement and these patients should be examined further.

World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

Abstract

H pylori gastric infection is one of the most prevalent infectious diseases worldwide. The discovery that most upper gastrointestinal diseases are related to *H pylori* infection and therefore can be treated with antibiotics is an important medical advance. Currently, a first-line triple therapy based on proton pump inhibitor (PPI) or ranitidine bismuth citrate (RBC) plus two antibiotics (clarithromycin and amoxicillin or nitroimidazole) is recommended by all consensus conferences and guidelines. Even with the correct use of this drug combination, infection can not be eradicated in up to 23% of patients. Therefore, several second line therapies have been recommended. A 7 d quadruple therapy based on PPI, bismuth, tetracycline and metronidazole is the more frequently accepted. However, with second-line therapy, bacterial eradication may fail in up to 40% of cases. When *H pylori* eradication is strictly indicated the choice of further treatment is controversial. Currently, a standard third-line therapy is lacking and various protocols have been proposed. Even after two consecutive failures, the most recent literature data have demonstrated that *H pylori* eradication can be achieved in almost all patients, even when antibiotic susceptibility is not tested. Different possibilities of empirical treatment exist and the available third-line strategies are herein reviewed.

Key words: *Helicobacter pylori*; Third-line rescue therapy; Antimicrobial resistance; Levofloxacin; Rifabutin; Furazolidone; Doxycycline

Cianci R, Montalto M, Pandolfi F, Gasbarrini GB, Cammarota G. Third-line rescue therapy for *Helicobacter pylori* infection. *World J Gastroenterol* 2006; 12(15): 2313-2319

http://www.wjgnet.com/1007-9327/12/2313.asp

INTRODUCTION

Helicobacter pylori (*H pylori*) is a spiral-shaped bacterium that is attached to or just above the gastric mucosa. The organism can persist in the stomach indefinitely and may not cause clinical illness for many years after infection. Indeed, a large number of infected patients never develop any symptoms. However, a large body of literature has associated *H pylori* infection with gastritis and gastric malignancies (gastric adenocarcinoma and MALT-lymphoma)[1]. Chronic *H pylori* infection has also been associated with several extra intestinal diseases, such as autoimmune thrombocytopenia, sideropenic anemia and chronic urticaria but the pathogenesis is still not known [2].

H pylori gastric infection is one of the most prevalent infectious diseases worldwide with an estimation of 40%-50% of the world population. Remarkable differences are due to geographical, socio-economical and demographic factors [3, 4]. *H pylori* transmission is still not completely understood. In addition, among infected patients, the reasons why only some develop symptoms is still a matter of speculations. The more generally accepted point of view is that bacteria are likely spread from person to person by fecal or oral transmission. Humans are the primary reservoir of *H pylori* infection [5].

Several tests are available to detect *H pylori* in patients with ulcer or dyspepsia. The more commonly used tests are the evaluation of bioptic specimens during upper GI endoscopy, the detection of serum anti *H pylori* antibodies and breath tests with ^{13}C-labeled urea [6].

The discovery that most upper gastrointestinal diseases are the consequence of *H pylori* infection and can be treated with antibacterials is an important medical advance [7]. In the last few decades, *H pylori* eradication has been standardized. The occurrence of resistance to therapeutic regimens is a growing problem.

Selection of papers was based on those papers thought to be more relevant to the authors based on two criteria: larger studies and novel studies even if based on limited series of patients, in which case this limit was stated.

FIRST-LINE THERAPY

The first-line therapy protocol is now generally accepted [8-12], which consists of proton pump inhibitor (PPI) (b.i.d.) or ranitidine bismuth citrate (RBC) plus two antibiotics: clarithromycin (500 mg, b.i.d.) and amoxicillin (1 g, b.i.d.) administered for 7 d. Metronidazole (500 mg, b.i.d.) can be used as an alternative to amoxicillin. However, even with

the correct use of these drug combinations, infection is not eradicated in 10%-23% of patients [13].

FACTORS DETERMINING PRIMARY ERADICATION FAILURE

H pylori may develop resistance to the prescribed antibacterials and may acquire resistance by acquisition and recombination of genes from other bacteria [14]. Chromosomic mutations can also induce resistance [15]. Gene acquisition is unlikely because *H pylori* lives alone in a unique ecological niche and is equipped with multiple restriction systems to avoid the introduction of hexogenous DNA [16]. Therefore, resistance is generally thought to be the consequence of point mutations. Indeed metronidazole targets DNA and a high mutation rate is observed [15].

After the development of eradication therapies, *H pylori* resistant strains have rapidly disseminated [17-21]. Several mechanisms are involved in the development of resistance. First, the lack of patient compliance is assumed to be a key factor in eradication failure, which occurs because adverse events are relatively frequent and lead to treatment discontinuation [22, 23]. Second, insufficient antibiotic concentration at the site of infection contributes to the spreading of resistant strains [22, 23].

An emerging problem is that general practitioners prescribe treatments without adequate diagnosis and do not adhere to eradication guidelines [24, 25]. Given the importance of host immune response in *H pylori* infection, the role of immunity in eradication failure can be hardly argued. However, data are anecdotal. Borody *et al* [26] suggested that IL-4 is important in *H pylori* eradication and hypothesized that IL-4 defect contributes to eradication failure.

Cytochrome P450, isoenzyme 2C19 [27] and interleukin-1-beta polymorphisms can interfere with acid secretion and have the activity of antimicrobial agents [28].

Finally, socio-economic factors (smoking habit), geographical factors, gender, histological changes also affect the eradication success [23-25]. Disease phenotypes also contribute to eradication failure. In fact, the failure rate in duodenal ulcer is 21.9%, lesser than in nonulcer dyspepsia (33.7%). In addition, the presence of histological fibrosis and lympho-epithelial lesions leads to poor eradication rates [23, 29].

Large studies on all these possible mechanisms of failure are lacking, but clarithromycin resistance appears to be the most important mechanism [30, 31].

SECOND-LINE THERAPY

Second-line therapy has been extensively reviewed by several authors[30, 32-34]. Therefore, we herein only discuss the Maastricht guidelines and some of more recently proposed protocols using new antimicrobial drugs, such as levofloxacin, rifabutin and furazolidone.

Most authors concord that culture after a first eradication failure is not thought to be necessary to start the second-line therapy. The assessment of *H pylori* sensitivity to antibiotics may be useful only after failure of the second-line therapy [8, 9, 35]. As second-line therapy, the Maastricht 2-2000 Consensus Report suggests a quadruple therapy based on bismuth (120 mg, q.i.d.), tetracycline (500 mg, q.i.d.), metronidazole (500 mg, t.i.d.) and antisecretive agent (PPI, b.i.d.) for a minimum of 7 d [12].

Further trials have shown that replacing the proton pump inhibitor and the bismuth compound of the quadruple therapy by RBC also achieves good results, with an eradication rate ranging between 57%-95% [36-39]. The failure of second line quadruple therapy is associated with its discontinuation because of the high incidence of side effects (6%-68%) [40]. Low compliance for the high number of pills to be taken each day also affects the clinical results [24]. However, in second-line regimens, new combination of drugs has been used. A triple therapy with the combination of levofloxacin, rabeprazole and tinidazole or amoxicillin has been proposed as an alternative to Maastricht [41]. This protocol shows an eradication rate higher than 90% compared to quadruple therapies given for 7 d (63%) with a lower incidence of side effects [42].

Rifabutin has been shown to have a good eradication rate (87%), if administered at a high dose (300 mg) in combination with amoxicillin and PPI, as compared to quadruple therapy [43-47]. Rifabutin shows an important side effect (mielotoxicity) [46]. Wong *et al* [43] showed that a combination of levofloxacin, rifabutin and rabeprazole has a high efficacy with an eradication rate >90% [43].

Furazolidone is also used to replace metronidazole in quadruple therapy [48-51]. Different *in vivo* studies have confirmed the efficacy of regimens containing a high-dose furazolidone [200 mg, b.i.d.] as the second-line therapy in patients with metronidazole-resistance [48-51]. Many other combinations have been used [31] with various rates of success. Bacterial eradication may fail in up to 40% of cases after the suggested second-line regimens. As a consequence, to treat patients who have already undergone the first- and second-line therapies is a common challenge.

THIRD-LINE RESCUE THERAPY

Currently, a standard third-line therapy is lacking. Different groups have tested various therapeutic protocols [33, 52, 53]. When available, endoscopy with culture and consequent antibiotic susceptibility testing remains the most appropriate option for patients with two eradication failures [54-56] to avoid a widespread use of expensive antibiotics such as rifabutin. The use of these drugs may also induce severe side-effects and development of *H pylori* resistant strains [30]. However, systematic use of culture is questionable [57]. Culture implies general endoscopic risks and is expensive as well as time-consuming due to *H pylori* difficult growth and not always available on a routine basis [58].

The sensitivity of bacterial culture is not 100% even in expert hands [6]. Moreover, amoxicillin and tetracycline rarely induce resistance [58, 59]. On the other hand, most of *H pylori* isolates after two eradication failures are resistant to metronidazole and clarithromycin, respectively [55]. Therefore, these two drugs are not recommended for third-line therapy [22, 56]. Our own previous data also show high resistance rates to metronidazole and clarithromycin even if the previously used regimens did not include either

of these two drugs [55]. In addition, *in vitro* susceptibility cannot predict eradication success [60-62]. Taken together, these data suggest that cultures are not strictly necessary to decide upon a third-line protocol.

The third-line therapy should avoid metronidazole and clarithromycin and antibiotics that are likely to have contributed to development of resistance. A consensus for third-line therapies has not been presently reached. Herein we discuss those based on levofloxacin, rifabutin, furazolidone and doxycycline.

Levofloxacin-based therapy

Levofloxacin is a broad-spectrum fluoroquinolone, active against Gram-positive and negative bacteria and atypical respiratory pathogens [63]. Levofloxacin inhibits the DNA synthesis, has a good oral absorption and is well tolerated [64]. Fluoroquinolones are active against *H pylori in vitro* [65] and have a synergistic effect with PPIs [66]. Primary resistance to levofloxacin ranges between 8%-31% in different countries or regions [55, 67, 68].

Recently, Gatta *et al* [69] have proposed a third-line treatment after two eradication failed courses without fluoroquinolones, with standard dose of PPIs (b.i.d.), levofloxacin (250 mg, b.i.d.) and amoxicillin (1 g, b.i.d.) for 10 d. The eradications rates of 76.2% and 84.6% according to ITT and PP analysis, respectively, have been achieved in 151 enrolled patients in a prospective open study. The levofloxacin-based treatment could eradicate most of the strains (92.3%) which are resistant *in vitro* to both clarithromycin and metronidazole, but susceptible to levofloxacin. The primary resistance to levofloxacin found in this study was 14%. Furthermore, this drug combination, successfully employed as rescue therapy [70], is well tolerated and has no major side-effects [71].

A more recent prospective multicentric study [72] reports data of 100 patients who have failed two eradication courses without fluoroquinolones. This study demonstrated that a regimen of levofloxacin (500 mg, b.i.d.), amoxicillin (1 g, b.i.d.) and omeprazole (20 mg, b.i.d.) for 10 d can achieve an eradication rate of 60% or 66% according to ITT and PP analysis. The treatment was given without previous sensitivity test.

Low compliance with the current regimens is one of the main causes of failures [24]. Therefore, Coelho *et al* [73] have proposed a combination of rabeprazole (20 mg), levofloxacin (500 mg) and furazolidone (200 mg) (two tablets) administered at a single dose for 10 d. Twelve patients who failed at least two eradication courses are successfully treated. Per-protocol and intention-to-treat eradication rates were 100% and 83.3%, respectively. However, because of the paucity of patients in third-line therapy, these data have to be confirmed in larger series. Furthermore, cultures obtained before treatment from some patients show no resistance to furazolidone, while 87% of the samples analyzed are sensitive to levofloxacin. No severe adverse effects are observed [73]. Therefore, the results after the levofloxacin-based triple therapy for ten days in patients with two eradication failed courses with amoxicillin, clarithromycin, metronidazole, tetracycline and bismuth, are encouraging. However, the resistance to quinolones is easily acquired, and the resistance rate is relatively high in countries with a high consumption of these drugs [55, 68]. Therefore, it seems advisable to reserve levofloxacin to third-line rescue treatment to avoid the increase of the resistance phenomenon [72].

Rifabutin-based therapy

Rifabutin is a spiropiperidyl derivative of rifamycin-S, an antitubercolar compound. Rifabutin inhibits the beta-subunit of *H pylori* DNA-dependent RNA polymerase encoded by the rpoB gene [74]. Rifabutin is expensive and unavailable in various countries and has side effects (leukopenia and thrombocytopenia, with myelotoxicity) [46]. It has been suggested to reserve the use of rifabutin for the treatment of multiresistant *Mycobacterium tuberculosis* strains [53, 75]. *H pylori* is highly susceptible *in vitro* to rifabutin and no resistant strains have been isolated from patients treated or untreated for *H pylori* infection [74, 75]. Furthermore, rifabutin is chemically stable at a wide pH range [76].

Three different trials have shown that rifabutin (300 mg o.d. or 150 mg b.i.d)-based therapies in combination with amoxicillin (1 g, b.i.d.) and standard dose of PPIs (b.i.d.) are a good third-line strategy, achieving the eradication rate of at least 70% [46, 47, 53]. On the other hand, Qasim *et al* [77] have achieved only a 38% eradication rate [77].

A more recently single centre prospective study [78] studied 67 patients who failed to respond to two or more courses. The result showed that when the rifabutin dose is reduced from 300 mg to 150 mg, it results in a signficant drop in eradication rate from 86.6% to 66.6% [45]. Borody *et al* [78] have shown that a 12 d regimen with low-dose rifabutin (150 mg a day) in combination with increased frequency of amoxicillin (1 g, t.d.s.) and pantoprazole (80 mg, t.d.s.) could achieve an overall eradication rate of 92.1% in patients harbouring double resistance strains to metronidazole and clarithromycin, with an eradication rate of 95.7%. Mild side effects are found in 40% of patients. Unlike regimens which use higher doses of rifabutin, no patients develop drug-related neutropenia or thrombocytopenia after treatment. Nevertheless, the main problem with a widespread use of rifabutin is the concern that antibiotic resistance may develop against *Mycobacterium avium* in HIV-infected patients. Therefore, the use of this drug for *H pylori* is questionable.

Furazolidone-based therapy

Furazolidone is a broad-spectrum nitrofuran, active against Gram-negative and positive bacteria and protozoa by inhibiting bacterial enzymes [79]. It is widely used in low income populations because it is inexpensive. It kills *H pylori* [80,81]. Strains resistant to furazolidone are rare [82, 83] and its potential to develop resistance is as low as bismuth compounds or amoxicillin [84]. Furthermore, it has no cross-resistance to metronidazole [83] and is effective in populations with a high prevalence of metronidazole resistance [85]. It has poor oral absorption and presents some side effects, especially gastrointestinal ones [79]. Concomitant intake of alcohol and MAO-inhibitors should be avoided as other interacting drugs. Furazolidone may induce a disulfiram-like reaction to alcohol and is an MAO-inhibitor. One week quadruple regimen with lansoprazole (30 mg, b.i.d), bismuth (240 mg, b.i.d.), tetracycline (1g, b.i.d.) and fura-

zolidone 200 mg (b.i.d.) has shown an eradication rate of 90% as third-line therapy in 10 patients with metronidazole resistance by culture [48]. Furthermore, 7 d triple-regimen comprising of furazolidone (200 mg, b.i.d), amoxicilin 1 g (b.i.d.) and standard dose of PPI (b.i.d.), achieves an eradication rate of 60% in 10 patients who failed first-line, second-line and rifabutin-based triple therapy [77].

In conclusion, in developing countries where resistance to metronidazole is usually very high [12], furazolidone in combination with tetracycline, bismuth and PPI for one week is very effective, safe and cost effective against *H pylori* as the third-line therapy.

Doxycycline-based therapy

Doxycycline is a widely used tetracycline antibiotic for several infections. With respect to tetracycline, doxycycline requires the administration of only two tablets per day, leading to a better compliance in patients undergoing eradication therapies. Furthermore, Heep *et al* [19] have found no secondary resistance to doxycycline in *H pylori* isolates from patients who failed one or more eradication therapies.

Quadruple regimens represent the most widely used rescue therapy. Yet, it is limited by lack of patient compliance due to the large number of tablets and by several side-effects. The classic quadruple therapy includes bismuth salts which have a synergistic effect on antibiotics possibly by decreasing the bacterial load, PPI which facilitates antibiotic activity by increasing the gastric pH, tetracycline with a low rate of resistance in *H pylori* isolates, and metronidazole [58, 59]. Induction of metronidazole resistance has suggested a new protocol, namely replacing tetracycline with doxycycline (because it requires the administration of only two tablets per day) and metronidazole with amoxicillin (because its resistance is less 1%), 1-week-quadruple therapy with doxycycline (100 mg, b.i.d.), amoxicillin (1 g, b.i.d.), omeprazole (20 mg, b.i.d.) and bismuth salts (120 mg, two tablets b.i.d). This treatment has proved to be a highly effective third-line 'rescue' therapy, achieving 91% eradication rate in patients harbouring metronidazole and clarithromycin resistant *H pylori* strains (by ITT analysis) [55]. This regimen, showing excellent compliance (99%) and mild side-effects, may well constitute the test available option for the third-line rescue treatment.

Rifampicin-based therapy

Rifampicin is a semisynthetic derivative of rifamycin B. The target is the DNA-dependent DNA polymerase, mainly the beta subunit [86]. Rifampicin inhibits the growth of most Gram-positive and negative microorganisms. The clinical efficacy of rifampicin against *H pylori* has been discovered by the observation of the decrease of anti-*H pylori* antibodies in patients on rifampicin-containing antitubercular therapy [87]. Rifampicin has an excellent *in vitro* efficacy against *H pylori* [88, 89] and a favorable pharmacokinetics. Less-expensive rifabutin is available in many countries. A single-center study has shown that 10 d rifampicin (450 mg o.d.)-triple therapy in combination with esomeprazole (40 mg b.i.d.) and tetracycline (1 000 mg b.i.d.) can achieve an eradication rate of 32.1% and 31.6% (by ITT analysis), if given as second-line or third-line therapy, respectively. Side effects are common but minor.

In conclusion, rifampicin-based rescue therapy is not as effective as a salvage-based therapy for *H pylori* eradication [86].

CONCLUSION

An undisputed third line strategy to cure *Helicobacter pylori* is still lacking. Eradication rates >90% can be achieved following the Maastricht guidelines for first- and second-line therapies. New first-line alternative strategies are needed, considering the development of primary and secondary resistances. Second-line therapy depends on which regimen is used initially, the re-administration of any antibiotics against which *H pylori* has probably become resistant, as metronidazole and clarithromycin or drugs with cross-resistance to these or previously used antimicrobial are not recommended. To face treatment failures, several third-line 'rescue' therapies have been tested, achieving good eradication rates. In our opinion, levofloxacin-triple (eradication rate of 92%) [69] and doxycycline-quadruple (eradication rate of 91%) [55] are more active on resistant strains. They are safe, better tolerated and less expensive than rifabutin-based regimen. Moreover, the widespread use of rifabutin may be a major concern due to the possible development of antibiotic resistance. We believe that the worldwide aid tubercular emergency and the risk to develop *Mycobacterium*-resistant strains strongly suggest a conservative approach reserving rifabutin to antitubercular therapy. This is especially recommended in countries where alternative drugs are available. In developing countries where resistance to metronidazole is usually very high, the 7 d furazolidone-quadruple third-line therapy is effective against *H pylori* (with eradication rates of 90%), safe and cost-effective.

In conclusion, our review shows that *Helicobacter pylori* eradication can be eventually obtained even in the few patients who experience up to 8 consecutive failures [78, 90, 91]. This can be done by different drugs as reported in the different protocols discussed above.

Abstract

Primary biliary cirrhosis (PBC) is a disease of unknown etiology leading to progressive destruction of small intrahepatic bile ducts and eventually to liver cirrhosis and failure. It is characterised by female predominance and serum auto-antibodies to mitochondrial antigens targeting the E2 components of the 2-oxoacid dehydrogenase complex. Although they are associated with disease pathogenesis, no concrete evidence has been presented so far. Epidemiological data indicate that a geographical clustering of cases and possible environmental factors are implicated in pathogenesis. A number of genetic factors play a role in determining disease susceptibility or progression, although no definitive conclusion has been reached so far. A key factor to immune pathogenesis is considered to be the breakdown of immune tolerance, either through molecular mimicry or through the so called determinant density model. In this review, the available data regarding the pathogenesis of primary biliary cirrhosis are described and discussed. A new unifying hypothesis based on early endothelin overproduction in primary biliary cirrhosis (PBC) is presented and discussed.

Key words: Primary biliary cirrhosis; Pathogenesis

INTRODUCTION

Primary biliary cirrhosis (PBC) is a chronic cholestatic disease of unknown aetiology characterized by progressive destruction of small intrahepatic bile ducts eventually leading to cirrhosis. It is considered to be an autoimmune disease due mostly to the presence of well characterized auto-antibodies. These auto-antibodies target the components of 2-oxoacid dehydrogenase complexes. Antibodies against components of the nuclear pore complex have also been described. The disease may be considered as an example of the vanishing bile duct syndrome.

Although auto-antigens have been molecularly identified and epitope-mapped and auto-reactive T and B cells have been characterized, the exact mechanism of liver tissue damage remains unclear. Recent reviews have summarised the present theories of PBC pathogenesis [1,2]. In this review, we first examined the evidence and then the current models concerning disease pathogenesis. Finally, a unifying hypothesis based on recent observations is proposed.

PRIMARY BILIARY CIRRHOSIS AS A GENETIC AND ENVIRONMENTAL DISEASE

Following earlier case reports of familial cases of PBC, a more comprehensive cohort study has estimated the sibling relative risk for PBC at 10.5, similar to other classical autoimmune diseases [3]. Recently, a pairwise concordance rate of 0.63 for PBC in monozygotic twin pairs has been published [4], which is one of the highest reported in autoimmunity. Taken together these reports indicate a significant genetic contribution to the disease pathogenesis. However, studies on specific genes have provided only weak associations. Extensive reviews on genetic factors in PBC have been recently published [5, 6].

Geographical disease clusters have been reported [7-9] and provide evidence for an as yet unidentified environmental factor in PBC pathogenesis. Although these studies are criticized and the case control studies are not able to identify putative environmental factors [10,11], there is enough evidence that environmental susceptibility does play a role.

PRIMARY BILIARY CIRRHOSIS AS A HUMORAL IMMUNE RESPONSE DISEASE

High titers of antibodies against mitochondrial elements are characteristic of the disease. Anti-mitochondrial antibodies (AMA) target the E2 component of the

pyrurate dehydrogenase complex (PDC-E2), which belongs to the family of the 2-oxoacid dehydrogenase complexes (2-OADC) [12]. The main epitopes have been localised within the inner lipoyl-binding domain of the subunit overlapping amino acids 212-226. The AMA response is polyclonal and these antibodies also react with the dihydrolipoamide dehydrogenase binding protein [13].

Based on the in vitro fact that 2-OADC activity is inhibited by AMA and 10% of the portal B cells produce antibodies reactive with PDC [14,15], a pathogenetic role of AMA has been proposed.

Sera from over 50% of patients do contain AMA with a different specificity. They react with the E1α component of PDC [16]. Their reactivity is directed to the C-terminus of the molecule which contains the active site of the enzyme and therefore these antibodies are also inhibitory of PDC activity [17,18]. Antibodies against the branched chain of 2-oxoacid dehydrogenase complex E1α have also been identified [19]. Auto antibodies against the nuclear pore proteins gp210 and p62 are associated with more active or severe disease [20]. Perhaps the best evidence for the pathogenetic role of auto antibodies in PBC comes from the description of secretory IgA anti-PDC in saliva, bile and urine of patients which retain their enzyme inhibitory capacity [21-24].

In PBC, both biliary epithelial cells and salivary epithelial cells (the main targets of the disease process) demonstrate an apical surface up-regulation of PDC or an antigen cross reacting with it [25]. This expression appears earlier than the reported up-regulation of other surface molecules like MHC class II, or ICAM-1 [26]. It seems, however, that PDC is released from apoptotic mitochondria to the cytoplasm within six hours of the induction of apoptosis and that auto-reactive epitopes are present on the still intact cell surface at later time points during the process of apoptosis [27]. However, convincing evidence for a role of AMA in the pathogenesis of PBC has yet to be produced [28]. Moreover, the very existence of the so called autoimmune cholangitis or AMA-negative PBC, a disease similar in every aspect to PBC but without detectable AMA, strongly argues against a pathogenetic role of AMA.

T CELL RESPONSES IN PBC

CD4 and CD8 T-cells reactive with PDC have been identified in the peripheral blood and liver of PBC patients [29-31]. These cells are reactive with the native human antigen [32, 33]. PDC- E2 specific T-cells are present in the liver of PBC patients [29, 34], mostly during the earliest disease states [30, 31]. Epitope mapping studies have identified HLA DR4*0101-restricted T cell epitope, spanning residues 163-176 of PDC-E2 [35, 36]. Recently HLA-A2-restricted CD8 T cell lines reactive with PDC-E2 residues 159-167 have been characterised [37, 38]. Interestingly, CD8 T cells from livers of PBC patients demonstrate cytotoxicity against PDC-E2 159-167 pulsed autologous cells [39].

APOPTOSIS IN PBC

There is concrete evidence that apoptosis is possibly the most important mechanism of biliary epithelial cell loss. Markers of ongoing apoptosis have been reported within affected portal tracts [40,41], including down regulation of the anti-apoptotic protein bcl-2 [42]. Apoptosis is considered the result of the attack of effector cells like CD8 T cells [39]. Interestingly, *in vitro* caspase cleavage of PDC-E2 has been shown to generate immunologically active protein fragments [43].

ROLE OF REACTIVE OXYGEN SPECIES (ROS) in PBC

Data on the role of oxidative stress in the pathogenesis of PBC are scarce. In the damaged bile ducts of PBC, glutathione-S-transferase expression is markedly reduced, reflecting reduction of intracellular glutathione, while perinuclear expression of 4-hydroxynonenal is increased, reflecting active lipid peroxidation associated with biliary epithelial damages [44]. Levels of the antioxidant vitamin E have been found to be decreased in PBC, together with other fat soluble vitamins [45-47], while serum total antioxidant capacity (measured with an enhanced chemiluminescent technique) is significantly reduced in PBC patients [48].

A number of antioxidant substances including retinol, alpha-tocopherol, total carotenoids, lutein, zeaxanthin, lycopene, alpha and beta-carotene are reduced in PBC patients compared to normal controls [49]. However, we have reported highly corrected total antioxidant capacity in PBC [50], a fact that may reflect a compensatory but probably not sufficient increase to counteract an increased ROS production.

Evidence for a role of ROS in the liver damage of PBC is provided by *in vitro* reports that ursodeoxycholic acid (UDCA), a drug commonly used in PBC, has extensive ROS scavenging properties and prevents mitochondrial oxidative stress and lipid peroxidation in a dose-dependent manner [51-53]. Finally, evidence from the rat bile duct-ligated model may have relevance to PBC.

Lipid peroxidation is a relatively late event in this model and a close link seems to exist between lipid peroxidation and the activation of inflammatory cells [54,55]. Free radicals triggering hepatic injury in this model, involve overproduction of the pro-inflammatory cytokines TNFα, IL-6 and IL-1b via enhanced activation of nuclear factor kB [56]. Moreover, *in vitro* experiments have shown that several bile acids including taurochenodeoxycholic acid and taurocholic acid cause hepatocyte injury with a concomitant generation of hydroperoxide by mitochondria [57,58] and also induce hepatocyte apoptosis in a time- and concentration-dependent manner via ROS generation by mitochondria [59]. An increased bile acid concentration is a feature of at least late PBC.

CURRENT VIEWS ON THE PATHOGENESIS OF PBC

There are two fundamental facts that should be interpreted in every model trying to explain the pathogenesis of PBC. First, the PBC auto-antigen PDC is located on the inner surface of the inner mitochondrial membrane and is therefore normally separated from the extra-cellular immune system by three membranes. It is difficult to understand how such an antigen is exposed to antigen presenting cells, eliciting an autoimmune reaction. Second, PBC is a disease with very limited tissue distribution, yet the putative autoimmune response is directed at an antigen with an extremely widespread localization.

So far, the models developed to explain the pathogenesis of PBC suggest that the key step in disease pathogenesis is the breakdown of T cell self-tolerance to PDC, since the induction of anti-PDC antibodies is not enough by themselves to produce liver disease [60]. The mechanisms of the disease pathogenesis have been elegantly reviewed elsewhere [61].

Molecular mimicry model of self-tolerance breakdown

Infection, either viral or bacterial, can either directly induce apoptosis of biliary epithelial cells or more probably trigger an immune attack on epithelial cells as a result of molecular mimicry. A T-cell response is initiated and mediated by toll-like receptor interaction with a pathogen epitope cross-reactive with a self-PDC epitope. An immune attack on biliary epithelial cells is mediated by these T-cells leading to apoptosis. However, the evidence for the initiating micro-organism is conflicting. Studies implicating mycobacteria as the source of cross-reactive targets are not reproducible and recent reports on Chlamydia pneumoniae as the potential microbial factor require confirmation [62].

Non PDC-E2 microbial sequences with a high degree of similarity to PDC-E2 212-226 epitope, mostly *E coli* mimics, are described as the major targets of cross-reactivity with human PDC in the sera of PBC patients [63]. Recently, the cross-reactive target has been reported to be the myobacterial hsp65 sharing a common motif with PDC-E2 212-226 epitope [64]. IG G3 antibodies to mimics from Lactobacillus delbrueckii with the same motif cross-reactive target can react with the PDC-E2 212-226 epitope in PBC sera [65]. Therefore, this motif may be a candidate epitope in the molecular mimicry model.

An alternative explanation for the molecular mimicry model would be a retroviral infection. The retroviral etiology of PBC has been recently reviewed in detail [28], but still remains controversial [66].

Determinant density model

This model has been described in detail by Jones [1]. According to this model, potentially self-PDC reactive T cells survive negative selection in the thymus, because their T cell receptor (TCR) shows low affinity for the complex of self-peptide and MHC. Sporadic self-PDC-derived epitopes presented by antigen presenting cells (APC) to these low TCR affinity T-cells, are unable to activate T cells. However, enrichment of APC presentation of self-PDC-derived epitopes could give sufficient low affinity presentation to overcome a triggering threshold and induce a proper CD4 T-cell activation.

In this model also, the initial trigger of antibody response cross-reaction with self-PDC could be either viral or bacterial epitopes with a structural homology to PDC. An interesting feature of this model is that the state of activation of APC mediated through toll-like receptors may determine the efficacy of antigen presentation and promote tolerance breakdown [67]. Peripheral blood monocytes from PBC patients produce higher levels of pro-inflammatory cytokines (TNFα, IL1b, IL-6, IL-8) when they are challenged with specific ligands for TLR2, TLR3, TLR4, TLR5 and TLR9. These findings indicate that monocytes in PBC (and possibly APC) are hyper-responsive to signalling through TLRs, a fact that may help in tolerance breakdown.

PATHOGENESIS OF PRIMARY BILIARY CIRRHOSIS: A UNIFYING HYPOTHESIS

We recently reported a significant increase of endothelins, particularly ET2 (and to a lesser extent of ET1) both in peripheral blood and in the hepatic vein, occurring at an early stage of the disease. Moreover, UDCA treatment caused a significant reduction of all three endothelins, its effect being most pronounced in early stage PBC.

Based on our observations, a new unifying hypothesis for the pathogenesis of PBC is proposed (Figure 1). In this model, there is a primary dysfunction of endothelial cells overproducing ET-2 (and to a lesser extent ET-1). This could be a primary genetically determined event. Endothelial cells express scavenger receptor type B [68] and internalise foreign antigens. Indeed lipoteicholic acid, a strongly antigenic component of gram positive bacteria, has been found in endothelial cells [68], while Helicobacter and lipopolysaccharide have also been described in PBC livers [69, 70]. ET2 may in turn stimulate Kupffer cells to produce pro-inflammatory cytokines, such as IL-1 and IL-6 from mouse peritoneal macrophages (but not TNFα or NO in this particular model) [71]. ET2 is also a potent macrophage chemoattractant [72] via the ETB receptor. ET2 shares the similar peptide sequence with CXC chemokines.

In accordance with this hypothesis, macrophages constitute 30% of the cellular infiltrate on portal areas and around damaged bile ducts [73]. Activated macrophages have also been observed by electron microscopy near epithelial cells of the bile ductules and seem to develop into epitheliod cells [74]. Epitheliod granulomata of PBC patients contain most MCP2 and MCP3 positive cells at their edge and more than 60% of them co-express CD68, indicating that they are derived from macrophages [75].

In stages 3 and 4, PBC Kuppfer cells and myofibroblasts are increased in periportal and periseptal areas, possibly indicating that Kupffer cells interact with stellate cells and lead to fibrosis [76], thus forming the connecting element to the development of cirrhosis.

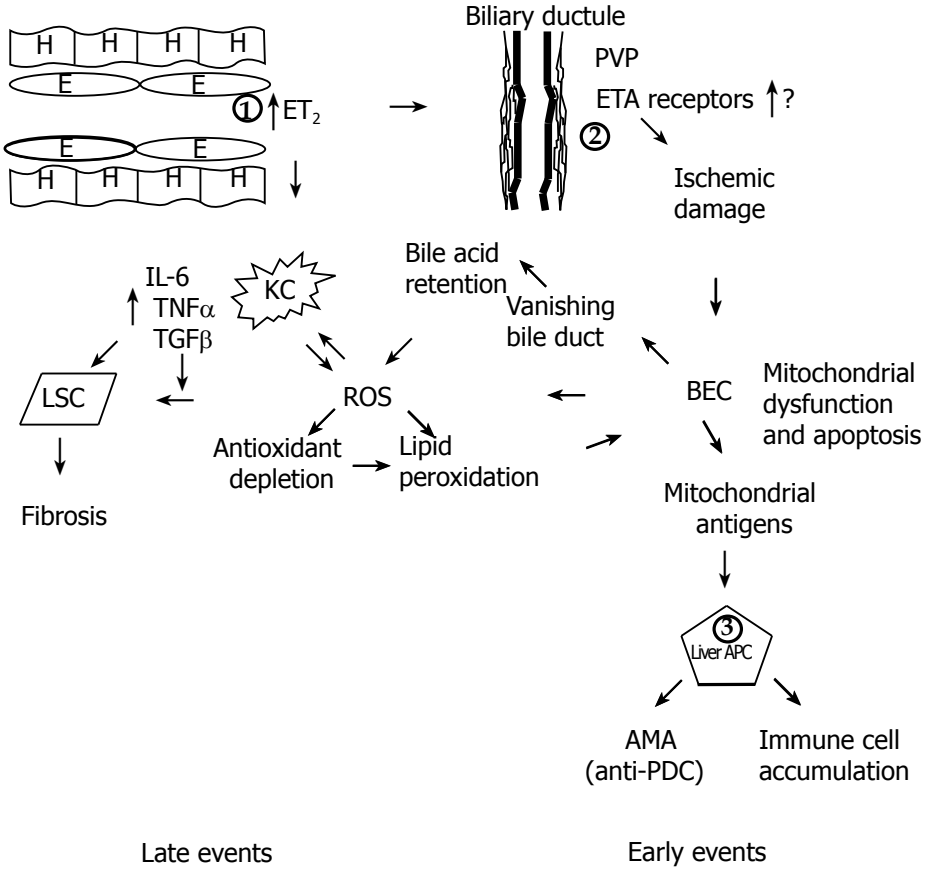

Figure 1 Figure 1 Occurrence of late and early events in the unifying model. The fundamental early defect in PBC is the overproduction of ET2 by endothelial cells (1) possibly driven by virus [95-98] or other microbial pathogens in genetically predisposed individuals. ET2 is a chemoattractant for Kupffer cells and also causes contraction of stellate cells leading to early portal hypertension. ET2 leads to ischemic damage of BEC (2) through constriction of the PVP with resultant BEC mitochondrial dysfunction and membrane disruption by ROS generation and eventually apoptosis leading to the vanishing bile duct syndrome. Mitochondrial antigens possibly generated through caspase cleavage, are presented by hyper-responsive liver dendritic cells (APC) (3) and lead to immune cell accumulation and AMA production. The second fundamental defect occurring later in the disease process is the production of ROS. Together with ingestion of BEC apoptotic bodies, ROS drives the accumulated Kupffer cells to produce more ROS and pro-inflammatory cytokines and TGFβ, which in turn leads to fibrosis. ROS is also produced after development of the vanishing bile duct syndrome as a result of bile acid retention. Finally through antioxidant depletion or through an insufficient increase of antioxidants ROS leads to lipid peroxidation and further BEC apoptosis and mitochondrial dysfunction. Genetically determined control may be exercised at levels 1,2 and 3.

Endothelins also cause contraction of stellate cells [77] and possibly help their differentiation to myofibroblasts. This contradiction may play an important role in the development of early portal hypertension in PBC as has been suggested in rats with biliary cirrhosis [61, 76-78].

Intrahepatic bile ducts receive their blood supply from a periductal network of minute vessels, known as the peribiliary vascular plexus (PVP). This plexus originates from hepatic artery branches accompanying its intrahepatic bile duct [79] and drains mostly into the sinusoids [80]. The peribiliary space also contains dendritic cells and stellate cells. Insufficient perfusion of this system can cause profound bile duct damage [81]. ETs and NO seem to be the principal molecules that regulate circulation of the PVP [82]. It is suggested in our model that patients with PBC have damage to the biliary endothelium as an initiative event caused by ischaemia due to ET-2 driven vasoconstriction. There is direct evidence that the peribiliary capillary plexus is indeed damaged in PBC. It was reported that the peribiliary plexus is significantly reduced in PBC (and interestingly also in auto-immune hepatitis), while there is proliferation of the plexus in other liver diseases [83]. There are also other reports indicating vascular impairment in PBC [61,78]. The increased circulating ET-2, observed both in early and late stage PBC seems to be specific for this disease, since it has not been found in the disease control groups of cirrhotics and patients with chronic viral liver disease.

Biliary ischemia might then lead to apoptosis of biliary epithelial cells, which is indeed a mechanism proposed for biliary epithelial destruction in PBC [84, 85]. Moreover biliary epithelial cells (BEC) undergoing apoptosis release the pyruvate dehydrogenase complex (PDC) from mitochondria into the cytoplasm as early as 6 hours after induction of apoptosis and auto-reactive epitopes are present in BEC, while other cells efficiently delete cytoplasmic PDC by glutathione [43,86]. Such a mechanism may also explain the similarities between PBC and graft *vs* host disease (GVHD) [87-90]. GVHD is associated with endothelial cell injury [91] and IL-1 has been implicated in its pathogenesis [92]. More importantly, in GVHD after small bowel transplantation, ET1 levels are increased before the induction of GVHD and have been histochemically shown to be increased in endothelial and epithelial cells some days before GVHD, implicating a pathogenetic significance [93]. Immunoreactive epitopes, self-PDC generated during apoptosis, possibly through the action of caspase 3 [43] are taken up by either the peribiliary dendritic cells or by BEC expressing MHC II (this could be either genetically determined or alternatively be caused by pro-inflammatory cytokines [94]). In the first instance this leads to the production of auto-antibodies and possible the determinant density model as elegantly described by Jones [1].

There are many questions that have yet to be answered regarding the above suggested model of liver injury in PBC. The most important issue is that the increased concentration of ET-2 has been found in

systemic circulation. This means that the vasoconstriction and the consequent ischemic injury ought to happen in many organs apart from liver and PVP. A possible explanation for this selectivity is an increased expression of ET receptors in the PVP of PBC patients but this suggestion needs to be further studied.

The suggested model is diagrammatically outlined in Figure 1. However, the proposed model has the following advantages. It implicates both innate and adaptive immunity. The former is the initiating event while the latter is the element that causes perpetuation of the disease even after disappearance of the initial event (if this is environmental infections). It explains the role of infective agents and the similarity of PBC with graft vs host disease. Interaction of endothelial and Kupffer cells with stellate cells explains the progress to fibrosis and cirrhosis. It predicts that most infiltrating cells should be CD4 helper T cells participating in B cell differentiation as it is indeed the case [31-35] but the role of CD8 is limited [37,38]. Since AMA production is a secondary phenomenon rather than pathogenetically related to liver damage, the presence of AMA negative PBC is also explained. Ursodeoxycholate (UDCA) may act mostly as an R0S scavenger preventing the mitochondrial oxidative stress. Most importantly, it offers 3 levels for a genetically determined control, namely the level of endothelial cells (and possibly Kupffer cells), the level of perivascular plexus and ET receptor expression, and the level of peribiliary dendritic cells that might be genetically hyper-responsive. All of them may well be estrogen dependent, thus explaining the extreme female prevalence of the disease, but this requires further research.

Abstract

Eosinophilic esophagitis has rapidly become a recognized entity causing dysphagia in young adults. This review summarizes the current knowledge of eosinophilic esophagitis including the epidemiology, clinical presentation, diagnostic criteria, pathophysiology, treatment, and prognosis. An extensive search of PubMed/Medline (1966-December 2005) for available English literature in humans for eosinophilic esophagitis was completed. Appropriate articles listed in the bibliographies were also attained. The estimated incidence is $43/10^5$ in children and $2.5/10^5$ in adults. Clinically, patients have a long history of intermittent solid food dysphagia or food impaction. Some have a history of atopy. Subtle endoscopic features may be easily overlooked, including a "feline" or corrugated esophagus with fine rings, a diffusely narrowed esophagus that may have proximal strictures, the presence of linear furrows, adherent white plaques, or a friable (crepe paper) mucosa, prone to tearing with minimal contact. Although no pathologic consensus has been established, a histologic diagnosis is critical. The accepted criteria are a dense eosinophilic infiltrate (>20/high power field) within the superficial esophageal mucosa. In contrast, the esophagitis associated with acid reflux disease can also possess eosinophils but they are fewer in number. Once the diagnosis is established, treatment options may include specific food avoidance, topical corticosteroids, systemic corticosteroids, leukotriene inhibitors, or biologic treatment. The long-term prognosis of EE is uncertain; however available data suggests a benign, albeit inconvenient, course. With increasing recognition, this entity is taking its place as an established cause of solid food dysphagia.

Key words: Eosinophilic esophagitis; Allergy; Dysphagia

INTRODUCTION

The esophagus normally is rather devoid of eosinophils. Not merely a simple conduit for swallowing food and liquids, the esophagus is being recognized as an immunologically active organ that can respond to a variety of stimuli like gastric acid and allergens by recruiting eosinophils and eliciting an inflammatory response. Eosinophils, for example, commonly infiltrate the lower esophagus in conjunction with gastroesophageal reflux disease (GERD)[1] A relatively new entity, eosinophilic esophagitis, with more extensive eosinophilic infiltration, particularly in the proximal esophagus[2] possesses clinical features that differ from GERD[3]. This entity is becoming increasingly recognized as a cause of dysphagia, often with a history of food impaction[4]. Since its original description in 1978[5], EE has exploded onto the clinical scene, becoming a recognized cause of solid food dysphagia, first identified in the pediatric and now the adult population[6-8]. Eosinophilic esophagitis is a disorder in which eosinophils infiltrate the superficial mucosa of the esophagus. Previously thought to be a rarity, case reports of eosinophilic esophagitis are rapidly accumulating in the literature[3,7]. Clinical presentation and the endoscopic-[7] and histological[7] features have become more firmly established, although a consensus is still lacking for an absolutely clear-cut diagnosis. Eosinophilic esophagitis has been associated with food allergies and atopic conditions such as asthma and atopic dermatitis[6,8-10].

Eosinophilic esophagitis is better known in the pediatric population through several published studies and reviews[11-14]. Infiltration of eosinophils into the esophagus may result from conditions such as food allergy, infection, gastroesophageal reflux disease (GERD), or systemic eosinophilic conditions. The mechanism of dysphagia from eosinophilic esophagitis has yet to be defined.

This review summarizes the epidemiology, clinical presentation, possible pathophysiological mechanism, diagnosis, treatment, and prognosis for eosinophilic esophagitis, primarily focusing on adults with this condition.

Table 1 Clinical features of eosinophilic esophagitis

	Adult	Pediatric
Common	Dysphagia Food impaction/foreign body Esophageal stricture Nausea/vomitting/regurgitation Heartburn Food allergy	Abdominal pain Failure to thrive Nausea/vomitting Dysphagia Food allergy Heartburn
Uncommon	Hematemesis Globus Waterbrash Weight loss Chest pain Abdominal pain	Food impaction
Associated Conditions	History of atopy Asthma Allergic rhinitis	Asthma Allergic rhinitis Eczema Atopic dermatitis Strong family history of atopy

EPIDEMIOLOGY

Epidemiological studies on eosinophilic esophagitis are lacking, likely from inadequate recognition and a paucity of established diagnostic criteria. Most publications are case reports or case series. Information is more widely available for the pediatric population compared to adults. This may be due to increased aggressiveness in investigating children with GI symptoms, or practice habits of pediatric gastroenterologists performing random biopsies in all cases. Fox *et al*[15] estimated that 6.8% of children with esophagitis had eosinophlic esophagitis, while Liacouras *et al*[16] indicated 3.4% of such children experienced reflux symptoms. A previous estimate of frequency was 1 per 100 000[17]. A recent population based study by Noel *et al*[13] in Ohio based on 103 children suggested a much higher figure: an annual incidence of 1 per 10 000 and a prevalence of 4.296 per 10,000 children, which rose over the period of the study - from 2 000 to 2003. Whether this represented a true increase in the entity or bias from improved detection is unknown. A strong familial pattern was evident. In Italy the prevalence was reported to be 3.5%[18]. A worldwide pediatric registry has been established[19].

Population-based data is lacking in the adults. Croese *et al*[20] identified eosinophilic esophagitis in 19 adult patients from a population of 198 000 over a 21 months period. The study, however, used 30 eosinophils per high power field as its criteria for diagnosis, a value higher than in most studies (usually >20/high power field). Therefore the incidence may be underestimated. The study also included both pediatric and adult populations with an age range of 14-77. Nevertheless, eosinophilic esophagitis appears to be an increasingly recognized entity with an accelerating frequency[13,21,22].

DIAGNOSIS

The diagnosis of eosinophilic esophagitis is based on clinical presentation, endoscopic or radiographic features, and histopathological criteria.

Clinical features

Clinical features (Table 1) of eosinophilic esophagitis have been previously well defined[13,20,22,23]. There is a male predilection and a wide range of ages from pediatric to adult populations. Mean age in children ranges from 7-10 years, and 30-40 years in adults. Dysphagia is the most common symptom in adults and is usually longstanding. Food impaction, reflux symptoms, vomiting or regurgitation, and food allergy are also common. Abdominal pain (30%), vomiting (30%) and failure to thrive (20%) are more common in the pediatric population compared to only 3% adults with abdominal pain, however there may be a selection bias based on more aggressive evaluation of these symptoms in children compared to adults. The majority of the pediatric population will have a history of atopic conditions, such as asthma, allergic rhinitis, eczema, or atopic dermatitis[24]. Noel *et al*[13] found 57.4% of children with eosinophilic esophagitis had a history of rhinoconjunctivitis, 36.8% wheezing, 46% possible food allergy, and 73.5% a family history of atopy. Adults also may have a history of atopy, but this is not as prevalent as in children. Croese *et al*[20] found that 46% of adults with eosinophilic esophagitis had a history of atopy, and only 25% food allergy. No relation has been found to connective tissue diseases such as scleroderma, rheumatoid arthritis, or lupus. Uncommon symptoms include hematemesis, globus, and waterbrash.

Laboratory features have not been extensively reported in eosinophilic esophagitis, therefore sensitivity and specificity of laboratory tests are unknown. Peripheral blood eosinophilia range from 5%-50% in the adult population with eosinophilic esophagitis. Increased serum IgE, positive skin prick or radioallergosorbent test (RAST) may be found in 40%-73% of patients[6,20]. In a study of 26 children, 19 tested positive for skin prick testing, and 21/26 had positive patch testing[25]. Skin testing may therefore help to identify causative food agents. These cases of rather overt immediate hypersensitivity are often not apparent in the adult patient. Indeed, food allergies in childhood may not persist to adulthood. Limited studies are available on the use of these laboratory values for the diagnosis of eosinophilic esophagitis.

Radiological features

The most common diagnostic imaging test that to date has detected eosinophilic esophagitis is a barium study[26,27]. Zimmerman *et al* retrospectively assessed 14 patients with confirmed eosinophilic esophagitis and found 10 with strictures (mean length 5.1 cm), of whom 7 had multiple fixed ring-like indentations. Four patients had esophagitis, 10 hiatus hernia, and 9 with evidence of reflux[27].

Endoscopic features

The "feline esophagus", also known as the "corrugated esophagus", "ringed esophagus", or "concentric mucosal rings", is the classic endoscopic description of eosinophilic esophagitis (Table 2, Figure 1)[7,20]. A small caliber esophagus with a narrow fixed internal diameter, with or without a proximal esophageal stenosis, may also be the major feature[28,29]. Adherent white exudates, vesicles, or papules along with loss of vascular pattern may indicate focal areas

Table 2 Endoscopic features of eosinophilic esophagitis

Endoscopic feature	Description
Feline esophagus (corrugated, ringed esophagus)	Multiple concentric rings, may be fine in nature, web-like or thickened
Small calibre esophagus	Narrow, fixed internal diameter Featureless, unchanging column Poor expansion on air insufflation Proximal and/or distal stenosis
Adherent white papules	White exudates 1-2 mm in diameter which do not wash off (similar to candidiasis) Speckled patches Vesicles Loss of vascular pattern
Esophageal furrows	Vertical esophageal lines
Crêpe paper mucosa	Fragile esophageal mucosa Delicate, inelastic Mucosal abrasions or tear with minimal contact

Table 3 Histopathology of eosinophilic esophagitis

	GERD	Eosinophilic esophagitis
Eosinophilic infiltration (squamous epithelium)	<10/hpf	>20/HPF
Other features	Esophagitis (usually distal)	Esophagitis (proximal and/or distal, may be patchy or segmental)
	Intestinal metaplasia	Basal zone hyperplasia
		Increased papillary size
		Superficial eosinophilic layering or aggregates
		Microabscesses

GERD: Gastroesophageal reflux disease; HPF: high power field.

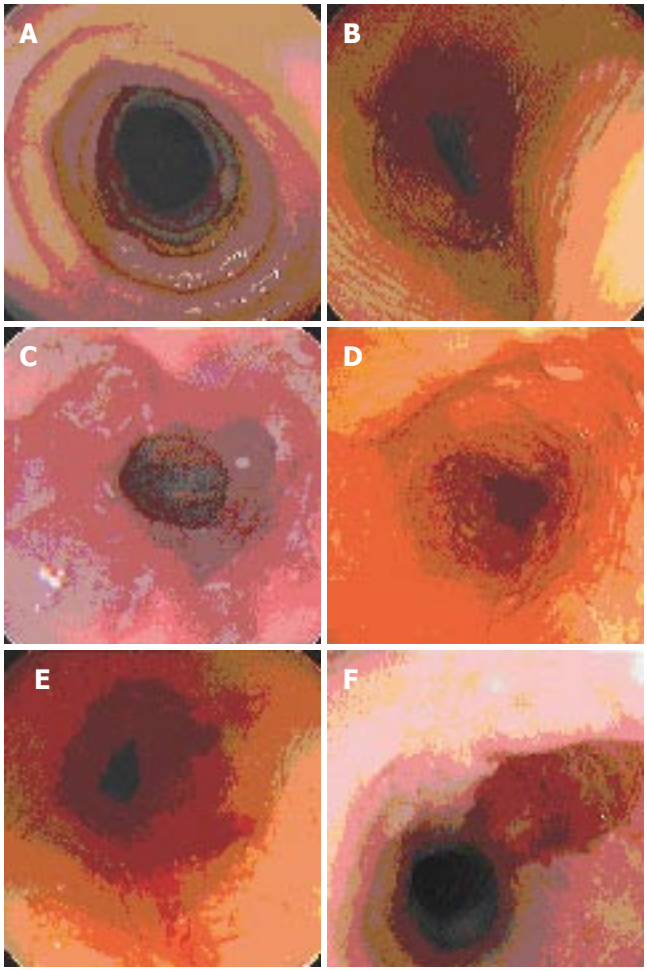

Figure 1 Classic endoscopic features of EE. **A**: Coarse, corrugated, narrow esophagus with papules; **B**: Fine feline esophagus; **C**: Distal esophageal stricture; **D**: Diffusely narrow esophagus with adherent white papule; **E**: Friable, crêpe paper mucosa with linear furrows; **F**: Large esophageal tear after biopsy.

of eosinophilic infiltration[30,31]. Vertical esophageal lines also may indicate eosinophilic esophagitis[32]. Finally, the esophageal mucosa may be fragile, or the so called "crêpe paper mucosa"[33]. This would explain the frequency of esophageal tears following dilation when treating the dysphagia associated with an apparently narrowed esophagus or its ringed structure (appearing like stricture). Thus the fragile esophagus is also characteristic. Endoscopic ultrasound, when performed, will show circumferential but asymmetric thickening of the muscularis propria[34]. The most common endoscopic findings in one relatively large series[35] were, in order of frequency: mucosal rings (81%), furrows (74%), strictures (31%), exudates (15%), small caliber (10%) and edema (8%). The endoscopic appearance is helpful but not diagnostic without a confirmatory biopsy. All patients with endoscopic features of eosinophlic esophagitis should have distal and proximal eosophageal biopsies to confirm eosinophilic esophagitis. Furthermore, this should be assessed prior to mechanical dilatation of strictures, as medical treatment for eosinophilic esophagitis should be the initial treatment. There have been no studies assessing the histopathological diagnosis of eosinophilic esophagitis in those with dysphagia and normal endoscopy. Therefore, it is unclear whether all these patients should have the proximal esophagus biopsied.

Histopathology

The diagnosis of eosinophilic esophagitis is dependent on eosinophilic infiltration of the squamous epithelium (Table 3). Although there is no consensus statement, most studies agree that >20 eosinophils per high power field (HPF) are diagnostic of eosinophilic esophagitis[6,36,37]. GERD can increase eosinophilic infiltration in the distal esophagus and therefore, mid or upper esophageal biopsies with increased eosinophils is more specific for eosinophilic esophagitis. Nevertheless, increased tissue eosinophils associated with GERD occur at a lower density <10/HPF[36,37] (Table 4).

Other features that are helpful but not essential for the diagnosis include basal zone hyperplasia, increased papillary size, and superficial layering of eosinophils with aggregates or microabscesses (aggregate of 4 or more contiguous eosinophils).

PATHOPHYSIOLOGY

Eosinophils originate in the bone marrow. When mature, only a small number circulate in the peripheral blood; rather they are predominantly tissue-dwelling cells. In health, other than hematopoietic sites, eosinophils only reside in the lamina propria of the gastrointestinal tract, the exception being the esophagus. Resident in the

Table 4 Differential diagnosis [40]

Primary	Idiopathic eosinophilic esophagitis Familial eosinophilic esophagitis Atopic esophagitis
Secondary: Eosinophilic related	Eosinophilic gastroenteritis Hypereosinophilic syndromes
Secondary: Non – eosinophilic related	GERD Recurrent vomitting Infection (helminth, parasitic, fungal) Esophageal GI stromal tumor Myeloproliferative disorders Carcinomatosis Allergic vasculitis Scleroderma Drugs/Iatrogenic

Table 5 Treatment regimens for eosinophilic esophagitis

Treatment option	Protocol
Elimination Diet	Avoidance of allergen depending on results of food allergy testing Oligoantigenic diet: Eliminate large number of suspected foods and allow limited nutritionally balanced diet Elemental diet: Various formulas such as Neocate (free amino acids, corn syrup solids, medium chain triglycerides)
Topical corticosteroids: Mayo Clinic protocol	Fluticasone 220 μg puffer 4 puffs BID x 6 wk, swallowed, no spacer Rinse mouth with water and spit out No food or drink for 3 h after dose
Systemic (oral) corticosteroids	Methylprednisolone 1.5 mg/kg per day (or equivalent dose prednisone) Divide into bid dosing for 4 wk then taper over 6 wk
Montelukast	Initial dose: 10 mg *po* daily Titration: Dose up to 100 mg/d depending on symptoms and tolerance Maintenance: Once symptoms relieved titrate down to minimal dose to maintain remission (usually 20 - 40 mg/d)
Mepolizumab	10 mg/kg *iv* infusion q 4 wk x 3 doses

BID: twice daily; PO: oral; IV: intravenous.

gastrointestinal tract, eosinophils normally do not evoke either an inflammatory reaction or tissue damage[38]. Under inflammatory conditions, eosinophils can infiltrate several organs (e.g., lung, esophagus and GI tract, and skin), playing a major role in causing tissue damage and organ dysfunction, and being mediators of allergic responses such as atopic dermatitis, allergic rhinitis, and asthma. Eosinophilic esophagitis characteristically has a dense eosinophilic infiltrate confined to esophageal tissues[21,36]. Activation of eosinophils results in degranulation, upregulated cytokine production, and IgE production. Recruitment and activation is regulated by cytokines including interleukin 5 (IL-5), eotaxin, interleukin 13 (IL-13), and interleukin 4 (IL-4)[38,39,40].

IL-5 is a critical cytokine for the differentiation and activation of eosinophils[38,41]. In eosinophilic esophagitis, a Th2 allergic response and production of IL-5 is key in recruitment of eosinophils to the esophagus. Mice devoid of IL-5 or lacking the receptor for IL-5 have a significant reduction in GI eosinophils. Overexpression of IL-5 can promote eosinophilic accumulation[38]. Eotaxin is constitutively expressed in the GI tract and has a critical role in eosinophilic recruitment[38]. Transgenic IL-5 mice deficient in eotaxin fail to recruit eosinophils to the GI tract. It seems to be more important for chemotaxis to the stomach and intestine[40,42]. Fujiwara, however, showed significant staining of eosinophils with anti-eotaxin-antibodies in patients with EE[43].

IL-13 is a profibrotic cytokine and its production has been demonstrated in eosinophils. Likely Th2 mediated, IL-13 contributes to an inflammatory response and bronchial hyperreactivity[10,44]. Intratracheal IL-13 was shown to induce eosinophilic esophagitis, linking pulmonary to esophageal eosinophilic inflammation[45]. It appears that IL-13 is a key mediator of eosinophilic inflammatory pathways and in the recruitment of eosinophils to the esophagus[10,45]. IL-13 may be a serologic indicator of systemic inflammation[46]. IL-13 induction of eosinophilic esophagitis seems to be dependent on IL-5, eotaxin, and STAT-6[45]. Interestingly, mepolizumab, an anti-IL-5 antibody, was shown to be beneficial for symptomatic and histologic improvement in eosinophilic esophagitis[47]. It is possible that the interaction of IL-13, IL-5 and eotaxin may be a component to the development of eosinophilic esophagitis. IL4 and IL-13 share a signal transduction pathway involving IL-4 receptor α chain and STAT-6[43]. IL-4 has been implicated in eosinophilic accumulation, regulating trafficking, and promoting adhesion to endothelial surfaces. Increased IL-4 secreting T cells in esophageal lesions were evident in one trial of patients with secondary eosinophilic esophagitis[48], but do not induce eosinophilic infiltration into the murine esophagus[43].

The net result of such chronic inflammation is irreversible structural change with loss of mucosal elasticity and the development of fibrosis in the subepithelial layers[21].

TREATMENT

The majority of reports on eosinophilic esophagitis are case reports or series. Therefore, randomized controlled trials (RCTs) for eosinophilic esophagitis treatment are not available. Indeed, a recent Cochrane review did not yield any RCTs, nor were the authors able to make any conclusions on benefits and harms of treatment regimens[49]. Treatment falls into two categories: (1) avoidance/removal of stimulation and (2) immune modulation. The majority of studies have been published in pediatric literature (Table 5). Avoidance of stimulation involves dietary changes with the elimination of foods or an elemental diet. Given that skin testing may help identify causative foods[25,27], this may help in avoidance of the specific culprit in some cases. Skin prick and skin patch testing may be more effective than skin prick testing alone. As shown by Spergel *et al*[25] in 26 children with documented eosinophilic esophagitis, 68 foods were identified in 19/26 by skin prick testing, and 67 foods in 21/26 by skin patch testing, for an average

of 2.7 foods per patient. With specific food avoidance, 18 had complete resolution and 6 partial improvement. Kelly *et al*[50] used an elemental diet in 10 children with eosinophilic esophagitis, and showed partial or complete resolution of symptoms in all 10. Markowitz *et al*[51] conducted a study in 346 children with chronic GERD symptoms of which 51 were eventually diagnosed with eosinophilic esophagitis. They were then given an elemental formula (Neocate 1+, SHS Northa America, Gaithersburg, MD) consisting of free amino acids, corn syrup solids, and medium chain triglyceride oil. Forty-eight patients were fed via a nasogastric tube, 49/51 patients improved symptomatically and there was a significant decrease in the number of eosinophils in the distal esophagus. Average time to improvement was 8.5 d. Unknown is if any of these measures of food avoidance or elemental diets are effective in adults.

Topical steroid therapy has been shown to be helpful in a number of uncontrolled case series reports for both the pediatric[52,53] and adult populations[54]. Arora *et al* treated 21 adult patients with eosinophilic esophagitis (diagnosed via solid food dysphagia, ringed esophagus, and eosinophils >20/hpf in mid to distal esophagus) with a 6 wk regimen of fluticasone 220 μg 4 puffs swallowed twice daily. All patients had complete symptomatic relief for at least 4 mo. The only side effect was dry mouth, with no oral candidiasis reported. Three out of 21 patients had relapse at 4 months and 50%-60% of patients had recurrence of symptoms at 1 year[6,54]. Systemic steroid therapy was first reported by Liacouras *et al* in the pediatric population[16]. Of 1809 patients with reflux, 20 had documented eosinophilic esophagitis and were treated with 1.5 mg/kg oral methylprednisolone divided twice daily for 4 wk. Steroids and anti-reflux medications, such as proton pump inhibitors, were then tapered and withdrawn after 6 wk. Thirteen out of 20 patients had a complete response and 6/20 marked clinical improvement (total 19/20 responders). Average time to improvement was 8 d. All had histologic evidence of improvement and a significant decrease in peripheral eosinophil counts and quantitative IgE levels. At 1-year follow-up, 10/20 were asymptomatic and 9/20 relapsed. Relapsers were treated with dietary changes, of which two required a second course of oral steroids. A randomized controlled trial comparing oral to inhaled corticosteroids is ongoing.

Leukotrienes promote eosinophilic trafficking, smooth muscle constriction, and mucous hypersecretion. Eosinophils generate large quantities of leukotriene C4, which is then metabolized to leukotriene D4 and E4 (LTD4 and LTE4 respectively). Montelukast is a selective inhibitor of the LTD4 receptor. Attwood *et al* reported 12 adult patients with dysphagia secondary to eosinophilic esophagitis and investigated the use of montelukast in 8/12 [55]. Patients were given an initial dose of montelukast 10 mg orally once daily and titrated up to a total of 100 mg daily. Once symptoms were relieved, dose was reduced to a "maintenance level" (20-40 mg/d). All patients were previously treated with proton pump inhibitors and 2 previously responded to corticosteroid treatment. All patients had symptomatic improvement, with only 2 having residual discomfort. Patients have been treated for a median of 14 months with no relapse. Six out of 8 experienced recurrence of symptoms within 3 wk of dose reduction or cessation. Important side effects were nausea and myalgias. Treatment did not change the density of eosinophils on repeat biopsy.

The central role of IL-5 in eosinophilic regulation and activation makes it a viable target for therapy. Mepolizumab is a humanized anti-IL-5 monoclonal antibody shown to be safe and effective in reducing sputum eosinophils in asthma but ineffective in outcome measures[56]. Garrett *et al*[47] performed an open label pilot study on 4 patients with hypereosinophilic syndromes, of which 3 had idiopathic hypereosinophilic syndrome and only 1 patient had eosinophilic esophagitis. This patient had dysphagia, esophageal narrowing on endoscopy with marked eosinophilia on biopsy, and was unresponsive to dietary elimination, topical, and oral corticosteroid treatment. Three doses of mepolizumab (10 mg/kg intravenous) infused at 4 wk intervals were given and patients followed for 18 wk after first infusion. Remarkable symptomatic improvement was achieved. Endoscopic and histologic improvement was seen at 4 wk after the last infusion. Peripheral eosinophils were reduced immediately after the first infusion and continued to the end of follow up. No serious adverse events were noted. No larger trials have been published. Other medications successfully used in eosinophilic gastroenteritis such as cromolyn and ketotifen (mast cell stabilizing medications), and suplatast tosilate (selective Th2 IL-4 and IL-5 inhibitor) have not been studied in eosinophilic esophagitis[19].

PROGNOSIS

Esposito *et al*[18] followed 7 children with eosinophilic esophagitis for 4 years, ages ranging from 6 months to 14 years old. All were treated with inhaled fluticasone. Two children experienced relapse at 1 year and 4 years post treatment, respectively, which improved with a second course of inhaled corticosteroid. Compliance was low in 2 patients and both had poor clinical and histologic response. Repeat treatment with appropriate dosing cured their symptoms. All children had normal growth after treatment. Interestingly, density of eosinophilic infiltrate was inversely proportional to age, and progressively reduced with time. This may explain the higher incidence in children compared to adults. Liacouras *et al*[16] found a 50% one year relapse rate after a course of oral steroids. Finally, Orenstein *et al*[14] found that 1/3 of patients were asymptomatic without any therapy.

Straumann *et al*[21] documented the natural history of eosinophilic esophagitis in 30 adult patients. Mean age was 40.6 and mean follow up time was 7.2 years. None were treated with dietary changes or medical therapy. Only those with severe and frequent attacks were treated with dilatation. No patients died and all were in "good health" with maintenance of body weight. Twenty-nine of 30 (96.7%) patients had dysphagia throughout follow up: 7 experienced increasing dysphagia, 11 persistent but stable dysphagia, 11 decreasing dysphagia, and 1 complete resolution. Eleven out of 30 required dilatation, of which 10 had reduction or cure of dysphagia. In terms of the impact of

dysphagia on quality of life, 1/30 reported a significant negative impact on socioprofessional activities, 15/30 minor, and 14/30 reported no significant impact. No increased risk of malignancy was found and no eosinophilic gastroenteritis was documented. It appears that in the adult population disease tends to be stable with no significant effect on morbidity or mortality, at least for up to 11 years' follow up. Whether a persistent inflammatory state will affect motility, mechanical obstruction, inflammatory bowel disease, malignancy, or mortality in the long term has yet to be seen.

SHORTFALLS

A lack of consensus for diagnosis hinders research progress in eosinophilic esophagitis. Case descriptions to date have used variable cutoffs for eosinophilic infiltration ranging from >15/HPF to >30/HPF. This not only affects the epidemiological data for incidence and prevalence, but also affects the inclusion/exclusion into trials and histological response to therapy. Furthermore, no distinction is made between proximal and distal esophageal biopsies, which might influence the pathologist into the diagnosis of esophagitis secondary to reflux rather than idiopathic eosinophilic esophagitis. Biopies are essential for the accurate diagnosis of eosinophilic esophagitis and are best taken from the proximal esophagus to better distinguish this entity from reflux esophagitis, even though the latter has a less dense eosinophilic infiltrate.

No objective criteria have been developed to assess the response to treatment. All studies to date have employed subjective improvement in symptoms, which is prone to bias. No randomized controlled trials to date have validated the efficacy of any treatment regimen. Elimination diets are inconvenient and result in low compliance. Topical steroid treatment seems safe[54] and may be the most convenient and effective therapy in adults, though technique may be an issue. Oral corticosteroid has its myriad of side effects and complications. Montelukast may be effective but would be long-term treatment given its relapse rates off treatment. Given its benign natural history in which the majority of patients have minor or no impact on quality of life, these therapies should be validated with vigorous clinical trials that include an analysis of cost effectiveness.

Finally, what should be done with the non-responsive patient? Compliance should definitely be confirmed. Repeat treatments may be beneficial. Combination therapy has yet to be explored. New biologic agents may be beneficial, but efficacy needs to be confirmed, and cost will be a limiting factor.

CONCLUSION

Since its original description, most publications have emphasized the clinical and histopathological presentation of eosinophilic esophagitis. The epidemiology is being better understood as clinicians are recognizing this unique disease entity. Diagnostic criteria are evolving which will improve the quality of future research. A consensus on the diagnosis of eosinophilic esophagitis is urgently needed. Despite a plethora of case reports, case series, case cohorts and reviews, randomized placebo-controlled trials are needed to confirm the efficacy of treatment regimens. In adult patients, topical corticosteroid appears to be the most convenient and efficacious treatment. As the pathophysiology of eosinophilic recruitment and activation in the esophagus is further elucidated, future treatment targets are possible. The long term natural history and response to treatment is awaited. Eosinophilic esophagitis may be a relatively new entity, undoubtedly overlooked in the past but this disease is here to stay. With better recognition, it has moved into the forefront of esophageal diseases.

Abstract

AIM: To investigate whether *Helicobacter* species (*Helicobacter* spp.) could be detected in hepatocellular carcinoma (HCC) tissue.

METHODS: Liver samples from 28 patients with hepatocellular carcinoma (HCC) diagnosed by histopathology were studied. Twenty-two patients with other liver diseases (5 with liver trauma, 7 with cavernous liver hemangioma, 6 with liver cyst and 4 with hepatolithiasis), 25 patients with gastric cancer, 15 with colonic cancer and 15 with myoma of uterus served as controls. Two pieces of biopsy were obtained from each patient. One was cultured for *Helicobacter* spp. and extraction of DNA, the other was prepared for scanning electron microscopy (SEM) and *in situ* hybridization. The samples were cultured on Columbia agar plates with microaerobic techniques. *Helicobacter* spp. in biopsy from the studied subjects was detected by polymerase chain reaction (PCR) with *Helicobacter* spp. 16S rRNA primers. Amplified products were identified by Southern hybridization and sequenced further. Besides, other genes (*vacA, cagA*) specific for *Helicobacter pylori* (*H pylori*) were also detected by PCR. *Helicobacter* spp. in biopsies was observed by SEM. Transmission electron microscopy (TEM) was performed to identify the cultured positive *Helicobacter* spp. The presence of *Helicobacter* spp. was detected by *in situ* hybridization to confirm the type of *Helicobacter*.

RESULTS: The positive rate of *Helicobacter* cultured in HCC and gastric cancer tissue was 10.7% (3/28) and 24%(6/25), respectively. *Helicobacter* microorganisms were identified further by typical appearance on Gram staining, positive urease test and characteristic colony morphology on TEM. The bacterium was observed in adjacent hepatocytes of the two HCC samples by SEM. The number of cocci was greater than that of bacilli. The bacterium was also found in four gastric cancer samples. PCR showed that the positive rate of HCC and gastric cancer samples was 60.7% and 72% respectively, while the controls were negative ($P < 0.01$). The PCR-amplified products were identified by Southern hybridization and sequenced. The homology to 16S rRNA of *H pylori* was 97.80%. The samples were verified by *in situ* hybridization for *Helicobacter* spp. 16S rRNA–mRNA and proved to be *H pylori* positive. There was no statistical significance between HCC and gastric cancer ($P > 0.05$), but the positive rate of HCC and controls had statistical significance ($P < 0.01$). Only 3 HCC samples and 2 gastric cancer samples of the cagA genes were detected. None of the samples reacted with primers for vacA in the two groups. As for the genotype of *H pylori*, type II had preference over type I.

CONCLUSION: *Helicobacter* infection exists in liver tissues of HCC patients. *Helicobacter* spp. infection is related with HCC, which needs further research.

Key words: Hepatocellular carcinoma; *Helicobacter* infection

INTRODUCTION

The profound impact of HCC on human health is known worldwide[1]. In China, the death rate ranks the third in malignant tumors. Persistent hepatitis B virus (HBV) and hepatitis C virus (HCV) infection and aflatoxins are the main causes of HCC[2]. The real risk factors for HCC may be far more than the known causes. A new infectious agent, *Helicobacter hepaticus* (*H hepaticus*) causing chronic active hepatitis and associated liver tumors has been described by Ward *et al*[3]. Recently, other *Helicobacter* species (*Helicobacter* spp.), including *H pylori* and other bacteria associated with the pathogenesis of gastric[4-7] and extradigestive manifestations[8,9], have been detected in the liver of patients suffering from cholestatic diseases and HCC arising from non-cirrhotic liver[10,11]. We have previously reported a high frequency of *Helicobacter* spp.

in the liver of patients with HCC[12]. *Helicobacter* spp. DNAs have been detected in paraffin-embedded tissue sections of HCC by PCR[13]. Whether *Helicobacter* spp. promotes liver tumors or acts as a cofactor in the process of carcinogenesis in humans with hepatitis virus needs further research. This study was to determine whether *Helicobacter* spp. could be detected in HCC tissue and to investigate the potential significance of *Helicobacter* in HCC carcinogenesis.

MATERIALS AND METHODS

Samples

All samples were immediately frozen in liquid nitrogen and stored at -80℃ before testing. Liver samples from 28 patients with HCC (25 males, 3 females, mean age 54 years) were studied. Twenty patients (18 males, 4 females, mean age 48 years) with other liver diseases (5 with liver trauma, 7 with cavernous liver hemangioma, 6 with liver cyst and 4 with hepatolithiasis), 25 with gastric cancer (20 males, 5 females, mean age 61 years), 15 with colonic carcinoma (9 males, 6 females, mean age 55 years) and 15 with myoma of uterus (mean age 49 years) served as controls. Two pieces of biopsy were obtained from each patient, one was cultured for *Helicobacter* spp. and extraction of DNA, the other was prepared for scanning electron microscopy (SEM) and *in situ* hybridization.

Germ culture

To culture *Helicobacter* spp., the diluted homogenates of biopsy specimens were smeared on the surface of Columbia agar plates (Oxoid Company, France) supplemented with 7% sheep erythrocytes, 6 μg/mL vancomycin, 2 μg/mL amphotericin B and 0.32 μg/mL polymyxin B. The plates placed in an anaerobic jar together with a GENbox microaer paper sachet (Biomerieux, Marcy l'Etoile, France) were incubated to generate a microaerophilic environment containing 5 mL/L oxygen, 10 mL/L CO_2, and 85 mL/L N_2), then the biopsy specimens were incubated at 37℃ for 7 d under a humid condition. *Helicobacter* colonies were identified further by their typical morphology, characteristic appearance on Gram staining, positive urease test. PCR was performed to examine the 16S rRNA, cagA and vacA genes of *Helicobacter* spp. The PCR products were sequenced.

Detection of 16S rRNA, vacA and cagA genes

Approximately 5 mm × 5 mm × 5 mm of tissue was cut and lysed in 0.25% pancreatic RNase, 0.2% collagen enzyme and 0.1 mg/mL proteinase K (Sigma, St Louis). The proteins were extracted with phenol:chloroform, and the genomic DNA was recovered by precipitation with ethanol. Initially, the samples were amplified by *Helicobacter* spp. 16S rRNA primers as previously described[13]: sense primer: 5'-AAC GAT GAA GCT TCT TCT AGC TTG CTA G-3' (28 bp); antisense primer: 5'-GTG CTT ATT CGT TAG ATA CCG TCA T-3' (25 bp) (Shanghai BioAsia Biotechnology Co., Ltd, China). The forward and reverse primer amplified a product of approximately 400 bp. Thirty-five cycles of amplification were performed, each consisting of an initial denaturation at 94℃ for 4 min, followed by denaturation at 94℃ for 1 min, primer annealing at 55℃ for 1.5 min, extension at 72℃ for 2 min, and a final extension step at 72℃ for 10 min. *H pylori* (NCTC11637) was used as the positive control and double-distilled water was used as the negative control. The samples generated a positive result in *Helicobacter* spp. PCR was subsequently performed with another two different sets of primers. A primer pair amplifying a 352-bp product, based on the partial DNA sequence of a species-specific gene encoding *vacA* of *H pylori* was previously described elsewhere[14]. Primers based on *cagA*, amplifying a 297-bp product, were used as previously described [15], including sense primer: 5'-GGA GCC CCA GGA AAC ATT G-3'; antisense primer: 5'-CAT AAC TAG CGC CTT GCA C-3'; sense primer: 5'-ATA ATG CTA AAT TAG ACA ACT TGA GCG A-3'; antisense primer: 5'-TTA GAA TAA TCA ACA AAC ATC ACG CCA T-3'. The *vacA* and *cagA* genes of *H pylori* (NCTC11637) were used as the positive control and double-distilled water was used as the negative control.

Southern hybridization

In order to prove the characteristics of *Helicobacter* spp. 16S rRNA, Southern hybridization was carried out using probes for *Helicobacter* spp., *H pylori*, *H hepaticus*, and *H fennellia* (Beijing AoKe Biotechnology Co. Ltd, China). These probes were designed using Battle software: *Helicobacter* spp. 16S rRNA-cDNA probes: 5'-CGC CGC GTG GAG GAG GAT GAA GGT TTT AGG ATT GTA-3' (36bp): *H pylori* 16S rRNA-cDNA probes: 5'-GAG GGC TTA GTC TCT-3' (15bp); *H hepaticus* 16S rRNA-cDNA probes: 5'-CCT TGC TTG TCA GGG -3' (15bp); and *H fennellia* 16S rRNA-cDNA probets: 5'-CCT TGC TTG ACA GGG-3'(15bp). Hybridization was performed by the above-mentioned probes using the digoxygenin DNA labeling kit (Boehringer Mannheim Company) according to the manufacturer's instructions, then the PCR products were transferred to a nylon membrane (Amersham, Buckinghamshire, United Kingdom) with the capillary blotting technique. The membrane was prehybridized, hybridized, then anti-digoxin (1:5000) and CSPD were added. The bound probes were finally detected by autoradiography after 2 h at room temperature (Kodak Scientific Imaging Film, XK-1 REF 6535009, Rochester, New York).

Sequence analysis of PCR products

The PCR products were purified from agarose gels by the JETsorb DNA extraction kit (Genomed, GmbH, Bad Oeynhausen, Germany). The purified products were sequenced and analysed (Dalian Bao biotechnology Co., Ltd, China). The sequences were compared with the known 16S rRNA of *Helicobacter spp.* and the other bacteria using the GenBank.

Scanning microscopy and in situ hybridization

The appropriate specimens were examined by SEM (JEOL JSM-840). For each hybridization reaction, the biopsy specimens were frozen, cut into 4 μm thick sections using

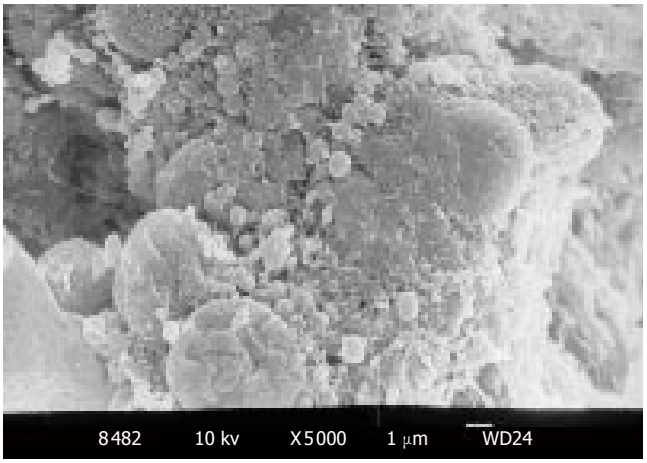

Figure 1 Cocci in adjacent hepatocytes (SEM × 5000).

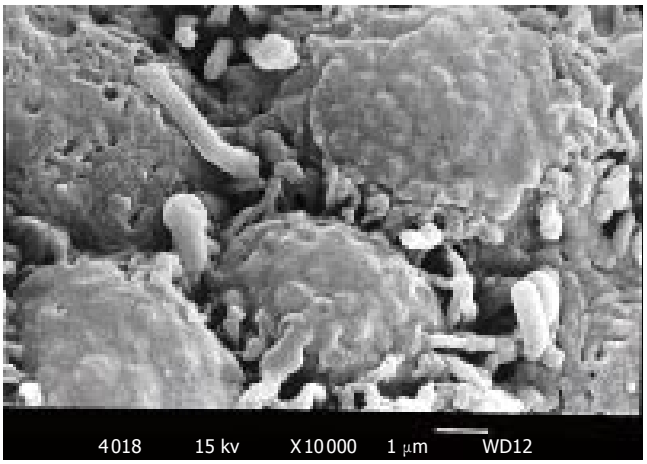

Figure 2 Spiral-shaped bacteria in vicinity of pit cell lineage (SEM × 10 000).

a cryomicrotome (Leica, Wetzlar, Germany) and placed on glass slides. The slides were placed in 4% polyformaldehyde for 20 min, washed and treated with proteinase K (100 μg/mL) at 37℃ for 30 min, washed again and marinated with 0.2% glycin for 10 min, and finally washed with 2 × SSC for 5 min. The sections were covered with 20 μL of 4 kinds of probes mentioned above. The slides were then hybridized overnight at 60 ℃ in a humid chamber and washed with SSC. The sections were incubated in protein blocking buffer. After washed, the slides were incubated with anti-digoxin-alkaline phosphatases complex (1:3000) for 1 h at 37 ℃ and marinated with buffer. After marinated, the slides were counterstained with DAPI overnight, marinated with double-distilled water for 5 min, dehydrated in a graded series of ethanol, hyalined with xylene, covered with balata and observed under microscope.

Statistical analysis

The results of PCR and hybridization were analyzed. $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of germ culture

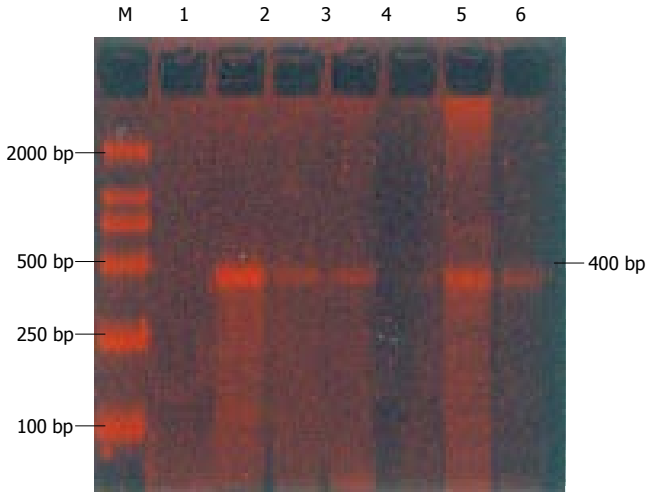

Figure 3 Analysis of *Helicobacter* spp. PCR products from HCC samples. The 400-bp fragments were analyzed by 1.5% agarose gel electrophoresis. Lane M: nucleotide marker; lane 1: negative control (double-distilled water); lane 2: positive control (*H pylori* DNA); Lanes 3, 4, 6: positive samples.

Helicobacter microorganisms were identified by typical appearance on Gram staining, positive urease test and characteristic colony morphology on TEM. After cultured for 48 h, the small and grey colonies were detected in Columbia agar plates, and the mean colony diameter was 1 mm. *Helicobacter* was cultured in 3 HCC and 6 gastric cancer tissue specimens. The positive rate was 10.7% and 24%, respectively. The bacterium was positive in urease test. TEM showed that the bacterium could be divided into two types, one was bacillus with flagellum, the other was coccus with flagellum. All the flagelli were located in one side.

Scanning microscopy

The cocci were observed by SEM in adjacent hepatocytes of 28 HCC samples, and the mean diameter cocci was 0.7 - 0.8 μm (Figure 1). In the 25 gastric cancer samples, 4 were found to have spiral-shaped bacteria (2.0-4.0 μm in length and 0.5-1.0 μm in width). The spiral-shaped bacteria partly adhered to the surface of gastric epithelial cells (Figure 2).

PCR of 16S rRNA,vacA and cagA

The positive rate of HCC and gastric cancer tissue samples was 60.7% and 72%, whereas no sample was positive in the other groups. The size of PCR products corresponded to the expected 400 bp (Figure 3). The positive rate of HCC and gastric cancer tissue samples had no significant difference ($P > 0.05$). Amplified products were identified by Southern hybridization. Besides, the other genes (vacA, cagA) specific for *H pylori* were also detected. The sizes of PCR fragments generated with the vacA (352 bp) and *cagA* primers (297 bp) corresponded to the expected sizes. The cagA gene was detected only in 3 HCC and 2 gastric cancer samples (Figure 4). None of the samples reacted with primers for *vacA* in the two groups.

Sequence analysis and in situ hybridization

The amplified products were sequenced (Figure 5) and compared with *Helicobacter* spp. The *Helicobacter* spp.

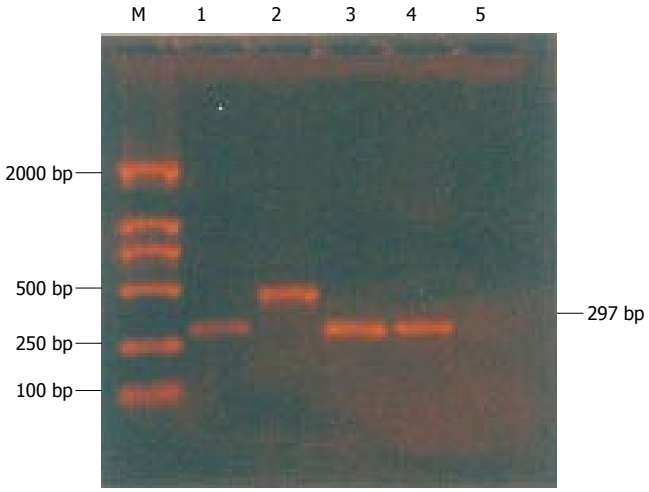

Figure 4 Analysis of *vacA* and *cagA* PCR products from HCC samples. The 352-bp and 297-bp fragments were analyzed by 1.5% agarose gel electrophoresis. Lane M: nucleotide marker; lane 1: positive control (*cagA* DNA); lane 2: positive control (*vacA* DNA); Lanes 3, 4: *cagA* positive samples; lane 5: negative control (double-distilled water).

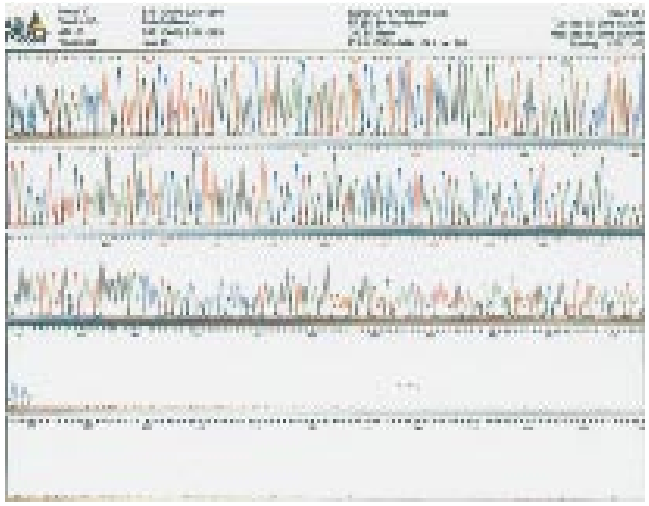

Figure 5 Sequencing results of 16S rRNA in *helicobacter* genus-positive products from HCC.

searched from the GenBank, includeed *H hepaticus, H bilis, H felis, H canis, H muridarum, H mustelae, H nemestrine, H fennelliae, H cinaedi, H acinoyx* (Figure 6). The homology of base pair and amino acid sequence was 97.8% between the amplified products and *H pylori* and 80.9% in *H fennelliae*.

In situ hybridization showed that *Helicobacter* spp. 16S rRNA-mRNA was positive in 17 patients with HCC-with a positive rate of 60.7%. The black-brown granules distributed in cholangioles of hepatocytes were positive hybridization signal. The positive signal was also found in intracellular fluid close to the hepatocyte membrance. All the granules were dispersedly distributed. The number of granules was not different in carcinoma and its adjacent tissues. Seventeen patients with gastric cancer were positive and the positive rate was 68%. The positive granules residing within the epithelium plasma membrane were symmetrically distributed and the number of the granules was not different in carcinoma and its adjacent tissues. *Helicobacter* spp. was negative in patients with colonic cancer (except for one case) and in those with other liver diseases and myoma of uterus.

Table 1 *Helicobacter* detection by different probes

Group	cDNA probes				
	Helicobacter spp.	*H pylori*	*H hepaticus*	*H fennellia*	*P*
HCC	17/28	17/28	0	0	
Gastric cancer	17/25	17/25	0	0	0.40[a]
Other liver diseases	0/22	0	0	0	0
Colonic cancer	1/15	1	0	0	0
Myoma of uterus	0/15	0	0	0	0

[a]$P > 0.05$ *vs* HCC group and gastric cancer group.

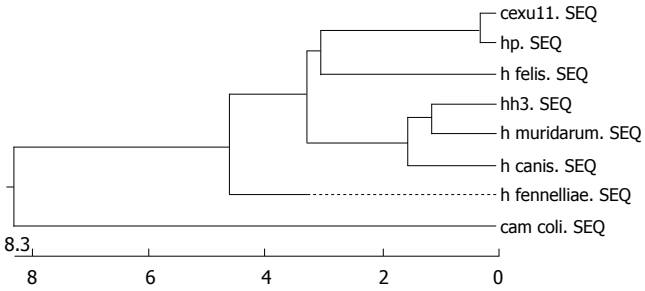

Figure 6 Genic phylogenetic tree of *Helicobacter* spp. and deduced protein.

The positive rate of *Helicobacter* spp. 16S rRNA-mRNA was comparable in HCC and gastric cancer patients with no statistical significance ($P > 0.05$). When HCC and gastric cancer patients were compared with those with other liver diseases, there was a statistical significance($P < 0.01$, Table 1).

In order to confirm the type of *Helicobacter*, the probes for *H pylori*, *H hepaticus* and *H fennellia* were used to detect the positive samples of *Helicobacter* spp. 16S rRNA-mRNA by *in situ* hybridization. The result revealed that the hybridization by *H pylori* probe was consistent with that by *Helicobacter* spp. probe. The positive rate was 60.7% in HCC patients and 68% in gastric cancer patients while being negative in patients with other liver diseases.

DISCUSSION

H pylori is one of the most common bacteria worldwide found in more than 50% of human population[16]. The presence of *H pylori* is the main cause of several gastroduodenal diseases, including peptic ulcer[4,6], gastric cancer[17], and gastric MALT lymphoma[18], and has been designated as class I carcinogen by the World Health Organization[19]. Chronic *H pylori* or *Helicobacter* spp. infection is related with a variety of extragastric diseases, including ischaemic heart disease, liver disease, skin disease, blood disorder and others[8]. The relationship between *Helicobacter* spp. infection and liver disease in humans needs to be further studied. Fan *et al*[20] demonstrated that the seroprevalence of *H pylori* is high in Chinese

patients with HBV-related chronic hepatitis. Experimental infection with *H hepaticus* in mice causes chronic hepatitis and HCC[3]. Thus *H hepaticus* infection of mice provides a uniquely valuable animal model for exploring the mechanisms underlying liver cancer[21]. Avenaud *et al*[11] have demonstrated the presence of genomic sequences of *Helicobacter* spp. in patients with HCC. Ponzetto *et al*[22] reported that the *cagA* gene can be obtained from liver tissue of cirrhotic patients with HCC. By PCR, hybridization and partial DNA sequencing, Nilsson *et al*[10] found that *Helicobacter* genus-specific primers are positive in patients with PBC or PSC. Furthermore, the gene sequence obtained from positive PCR of *Helicobacter* spp. 16S rRNA is usually analogous to *H pylori*. *Helicobacter* spp. has been successfully cultured in liver samples from patients with Wilson's disease by Queiroz and Santos[23]. The isolate is closely related to *H pylori* by biochemical and 16S rRNA analysis. There is evidence that hepatobiliary *Helicobacter* spp. may exist in liver of severe HCV-infected and HCC patients[19]. High rates of human HCC are reported in Southeast Asia, which are caused by hepatobiliary *Helicobacter* spp. and other environmental agents[24]. Pellicano *et al*[25] reported that the presence of genomic sequences of *H pylori* is infrequent in patients who have undergone surgery for metastasis of colon cancer to the liver. In contrast, the presence of genome of *Helicobacter* spp. is higher in patients with HCV-related cirrhosis and HCC. Huang *et al*[26] reported that *Helicobacter* spp. 16S rDNA can be found in patients with primary liver carcinoma. Verhoef *et al*[27] found that gastric colonization with a specific subset of *Helicobacter* strains is associated with the induction of HCC, either directly via colonization of the liver or indirectly via secretion of specific toxins by *Helicobacter* residing in the stomach. Rocha *et al*[28] reported that the presence of *Helicobacter* species DNA in liver is associated with hepatitis C. These observations prompted us to explore a possible association between *Helicobacter* spp. and HCC in Chinese patients.

In this study, the relationship between *Helicobacter* spp. and HCC was investigated by isolation and culture of strains from biopsies, electron microscope, PCR, hybridization techniques and partial DNA sequencing assay. The potential significance of *Helicobacter* spp. in HCC carcinogenesis was investigated. *Helicobacter* spp. was 10.7% (3/28) and 24% (6/25) cultured in HCC and gastric cancer tissue samples, respectively. *Helicobacter* microorganisms were identified by their typical appearance on Gram staining, positive urease test and characteristic colony morphology on transmitting electron microscopy. The bacterium was observed by SEM in the adjacent hepatocytes of HCC samples. The number of cocci was greater than that of bacilli. Our study showed that *Helicobacter* spp. DNA could be found in liver tissue from 60.7% patients with HCC, which might be related to a variety of environmental factors, host characteristic bacteria virulence determinants, and the small size of samples. Eighteen of 25 (72%) liver samples from patients with gastric cancer were positive by PCR analysis using *Helicobacter* spp. primers. Patients with HCC and gastric cancer had a higher positivity with no statistical significance ($P > 0.05$), suggesting that *Helicobacter* spp. infection is closely related with diseases of the digestive system. Amplified products were identified by Southern hybridization, suggesting that *Helicobacter* spp. infection might occur in HCC patients. Sequencing showed that PCR-amplified products and *H pylori* had a 97.8% homology. To make sure that the bacteria was *H pylori*, the vacuolating cytotoxin gene A (*vacA*) and cytotoxin-associated gene A (*cagA*) specific for *H pylori* were also detected by PCR. *H pylori* can be divided into $cagA^+$- *H pylori* and $cagA^-$-*H pylori* in clinical medicine, leading to a different result in gastrointestinal disease. $CagA^-$-*H pylori* usually colonizes the mucous gel or the apical epithelial surface, whereas $cagA^+$- *H pylori* colonizes the immediate vicinity of epithelial cells or the intercellular spaces[29]. Strains possessing the *cag* pathogenicity island are more likely to cause disease rather than those lacking this locus[30]. The *vacA* and *cagA* help gastric epithelial cells to form vacuolation, injury, necrosis, ulcer, etc. *H pylori* strains possessing *cagA* are associated with the development of peptic ulcer, gastric cancer and extragastric diseases. Most of the strains could be divided into two major types. Type Ⅰ bacteria have the gene coding for cagA and express CagA and VacA. Type Ⅱ bacteia do not express either cagA or vacA[11]. Therefore, the difference between type Ⅰ and type Ⅱ bacteria is due to toxicity. In our study, the cagA gene was detected in only 3 HCC and 2 gastric cancer samples (Figure 4). None of the samples reacted with primers for vacA in the two groups. As for the genotype of *H pylori*, type Ⅱ bacteria have preference over type Ⅰ, which is consistent with the report of Avenaud *et al*[11].

To confirm the *Helicobacter* spp. distribution in HCC patients, *Helicobacter* spp. 16S rRNA-mRNA was detected by *in situ* hybridization with a positive rate of 60.7%, which was coincident with the result by PCR. Besides, the positive rate in gastric cancer patients was 68%. The positive granules residing within the epithelium plasma membrane were distributed symmetrically. *Helicobacter* spp. was negative in patients with colonic cancer except for one case and those with other liver diseases and myoma of uterus. The positive rate in HCC and gastric cancer patients had no statistical significance ($P > 0.05$). When HCC patients were compared with those with other liver diseases, there was no statistical significance ($P < 0.01$).

In conclusion, *Helicobacter* spp. infection is related with diseases of the digestive system, especially HCC and gastric cancer. Further studies are needed to establish the role of *H pylori* in HCC.

Abstract

AIM: To investigate the selective cytotoxic effect of constructed hybrid protein on cells expressing granulocyte macrophage colony stimulating factor (GM-CSF) receptor.

METHODS: HepG2 (human hepatoma) and LS174T (colon carcinoma) were used in this study. The fused gene was induced with 0.02% of arabinose for 4 h and the expressed protein was detected by Western blotting. The chimeric protein expressed in *E.coli* was checked for its cytotoxic activity on these cells and apoptosis was measured by comet assay and nuclear staining.

RESULTS: The chimeric protein was found to be cytotoxic to the colon cancer cell line expressing GM-CSFRs, but not to HepG2 lacking these receptors. Maximum activity was observed at the concentration of 40 ng/mL after 24 h incubation. The IC_{50} was 20 ± 3.5 ng/mL.

CONCLUSION: Selective cytotoxic effect of the hybrid protein on the colon cancer cell line expressing GM-CSF receptors (GM-CSFRs) receptor and apoptosis can be observed in this cell line. The hybrid protein can be considered as a therapeutic agent.

INTRODUCTION

Although systemic treatment of colon cancer including combination of surgery, hormone therapy, chemotherapy is commonly believed to be effective in prolonging patient survival, colon cancer remains one of the principal cancer-related deaths[1]. Human cancer is becoming more definable by cell surface proteins. One of these molecules is GM-CSF receptor that expresses in several tumors including colon cancer[2].

GM-CSF is used to attenuate the myelosupressive effects of chemotherapy in the treatment of hematologic malignancies and solid tumors, but GM-CSF usually does not stimulate growth of solid tumors[2]. It was reported that GM-CSFR is absent on most immature hematopoietic progenitors but increases expression during maturation[3]. This finding strongly suggests that GM-CSFR may be a useful target for recombinant toxins or immunotoxins.

Immunotoxin comprises cells targeting and killing moieties. Therefore, bacterial or plant toxins are used as the killing moieties. Shiga and Shiga-like toxins (STX, SLTs) are ribosome-inactivating proteins (RIPs) produced by *Shigella* and *E.coli*, composed of an enzymatic A subunit non-covalently associated with a pentamer receptor-binding subunit. SLTs inhibit protein synthesis in eukaryotic cells by releasing adenine residue from the highly conserved aminoacyl-tRNA-binding site which exists on large subunit of ribosome [4]. In this study, the catalytic domain of Shiga toxin (StxA1) and hGM-CSF were genetically fused and expressed in *E.coli*. Then, the function of recombinant protein was assessed on colon cancer cell line.

MATERIALS AND METHODS

Preparation of purified recombinant chimeric protein (StxA1-GM-CSF)

The catalytic domain of Shiga toxin, StxA1, was fused

teria with 0.02% arabinose for 4 h incubation. The expressed protein was purified following the manufacturer's instructions (Invitrogen, USA). The amount of protein was estimated by Bio-Rad protein assay kit (Bio-Rad, USA).

Cell culture

HepG2 cell line derived from human hepatoma and LS174T cell line derived from colon carcinoma were provided by Cell Bank of Institute of Development, Aging and Cancer, Tohoku University, Japan. These cell lines were kept in RPMI-1640 medium (Gibco-BRL, Germany) supplemented with 10% fetal bovine serum (Gibco-BRL , Germany) at 37 ℃ in 50 mL /L CO_2 atmosphere.

Cytotoxicity assay

The cytotoxic effect of SltxA1-GM-CSF was determined by trypan blue exclusion assay and MTT[5] assay. For trypan blue dye exclusion assay, 2.5×10^4 cells were seeded in one well of 96-well plates and different concentration (10-160 ng) of SltxA1-GM-CSF was added to each well. After incubation for 24, 48, and 72 h, the number of viable cells was determined.

For MTT assay, HepG2 and LS174T cell lines were cultured and StlxA1-GM-CSF was added as described above. After 24, 48 or 72 h incubation, 10 μL of 0.5 mg/mL of 3-(4, 5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT; Sigma, Japan) was added to each well and further incubated at 37 ℃ in 50 mL/L CO_2 atmosphere for 4 h to allow MTT to be converted to formazon crystals by reacting with metabolically active cells. Reactions were stopped by addition of 10% SDS in 0.01 mol/L HCl and absorbance at 570 nm was determined.

Neutral comet assay

Neutral comet assay was carried out as previously described[6] with some modifications. Briefly, freshly prepared cell suspension (2×10^3 / 10 μL) was mixed with 150 μL of 1% low-melting agars. The mixture was layered on top of the microscopic slide coated by 1% agarose. After low melting agarose was solidified in a refrigerator for 10 min, the slide was gently immersed in a freshly prepared lysing solution (2% SDS, 0.03 mol/L EDTA) for 30 min protected from light. After the slides were washed with TBE buffer, electrophoresis was carried out at 25 V for 25 min. Then, comets were visualized with 1 mmol/L propodium iodide. One hundred and fifty cells per slide were analysed under fluorescent microscope.

Hoechst staining

After administration of SltxA1-GM-CSF, cells were fixed with 1% paraformaldehyde for 30 min, washed with PBS and stained with 1mmol/L Hoechst 33342 (Sigma, Japan) for 10 min. Nuclear morphology of at least 400 cells was randomly observed under fluorescent microscope.

Statistical analysis

The results were expressed as mean ± SD and each value represented the mean of three experiments. Differences between groups were compared using the Student's *t* test. $P < 0.05$ was taken as significant.

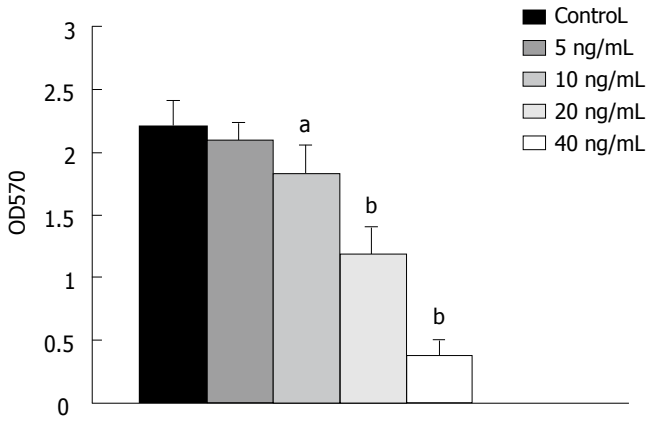

Figure 1 Effect of different concentrations of StxA1-GM-CSF on LS174T cell line by MTT assay. ($^aP < 0.01$, $^bP < 0.001$ *vs* trypan blue exclusion assay).

RESULTS

Expression and characterization of StxA1-GM-CSF

The fusion protein consisting of 1-255 a.a. of A1, the catalytic domain of Shiga-toxin and 1-127 a.a. of hGM-CSF was observed. The recombinant was analysed by SDS-PAGE and Western blot as previously described[7].

Cytotoxicity

Cytotoxicity of hGM-CSF to cells was analysed by both trypan blue exclusion assay and MTT assay. LS174T cells showed the extreme susceptibility to StxA1-GM-CSF (Figure 1), while HepG2 cells lacking GM-CSFR showed very poor susceptibility to StxA1-GM-CSF. Maximum activity was observed at the concentration of 40 ng/mL ($P < 0.001$) after 24 h incubation. Higher concentration and longer treatment time did not show any profound effect. The IC_{50} was 20 ± 3.5 ng/mL.

Apoptosis

We next examined death of LS174T cells induced by the StxA1-GM-CSF by comet assay. In comet assay apoptotic cells after treatment showed puffy tails and pin heads while normal cells had spherical heads but no tails (Figure 2). To verify the apoptotic results obtained by comet assay, cells were analyzed by Hoechst 33342 staining. Apoptotic cells with nuclear condensation and fragmentation were analyzed (Figure 3). The results indicated that the apoptotic cells were effectively induced by the toxin (Figure 4).

DISCUSSION

In this study we constructed the recombinant protein of StxA1-GM-CSF by overlap extension PCR, which was expressed in pBAD/gIIIA system[7]. Al-Jaufy *et al*[8] have also made the recombinant protein genetically. They fused StxA with HIV gp120-binding domain of CD4 by restriction enzyme sites. However, some limiting factors like incomplete digestion, absence of suitable restriction sites for genes of interest and appropriate vector have limited the

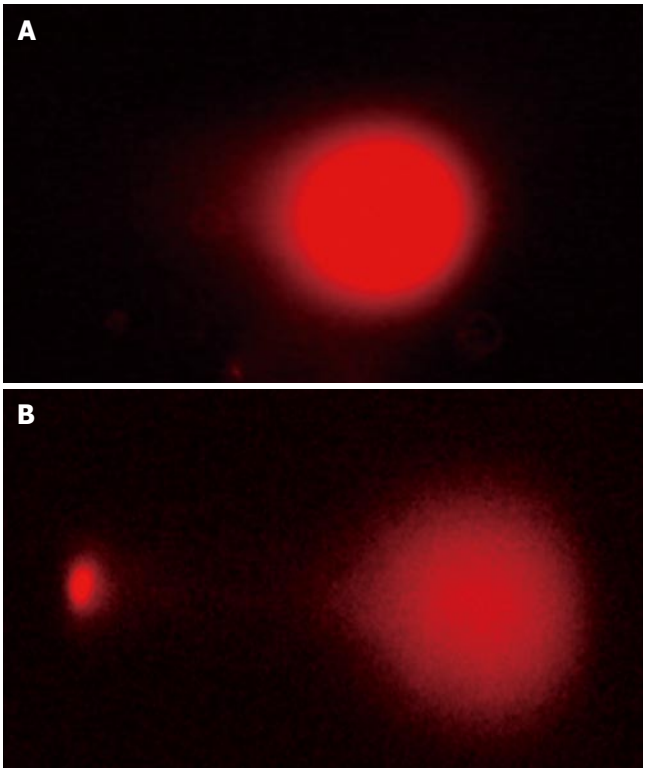

Figure 2 Morphology of normal cells (**A**) and apoptotic cells (**B**) after treatment with hybrid protein.

application of this method. Accuracy and ease of manipulation, are likely the advantages of PCR technique.

StxA is an established inhibitor of eukaryotic translation and more potent than ricin[9]. No reduction in its enzymatic inhibitory activity has been reported when it is genetically fused with HIV gp120-binding domain of CD4[8]. Similarly in our study, fusion of StlxA1 with hGM-CSF caused no reduction in its inhibitory effect. In addition, the enzymatic domain of diphtheria toxin has been fused to hGM-CSF using recombinant DNA techniques and is under clinical trial[10]. Our results suggest that StxA1-GM-CSF is more toxic than DT-GM-CSF, since IC_{50} is 20 ± 3.5 ng/mL for StxA1-GMCSF and 70 ± 18 ng/mL for DT-GM-CSF[8]. In this study, LS174T showed very obvious cytotoxic effect and changes characteristic of apoptosis were observed. A close correlation between protein synthesis inhibition and apoptosis induction has also been reported for DT-GM-CSF in which LS174T is not sensitive to apoptosis while other cell lines are more sensitive to cytotoxicity and apoptosis[11].

Agarose gel electrophoresis is one of the commonly used techniques for the detection of apoptotic cells. This technique usually involves a DNA isolation procedure from millions of cells and obtained results can not be quantified[12]. TUNEL assay is an established method for the detection of apoptotic cells, but this method is associated with a number of artefacts[13]. Annexin V labelled with fluorescent protein like FITC is used for rapid cytofluorometric analysis of apoptosis, but this method can produce false positive results when membrane is damaged[14]. Comet assay is sensitive, simple and fast. Usually this method is used to detect DNA damage like single or double strand breaks. On the other hand, this method also can detect single apoptotic cells in a large number of cells[15]. A few studies have tried to delineate the mechanism of apoptosis induction by Stx[16-18]. More knowledge about its mechanism can help us prevent shigellosis and enable us to tackle the problem of resistance to cancer therapy. Induction of apoptosis by hybrid protein indicates that catalytic domain of Shiga toxin in hybrid protein can not activate the cellular apoptosis machinery directly since the toxin inactivates ribosomes that inhibit protein synthesis.

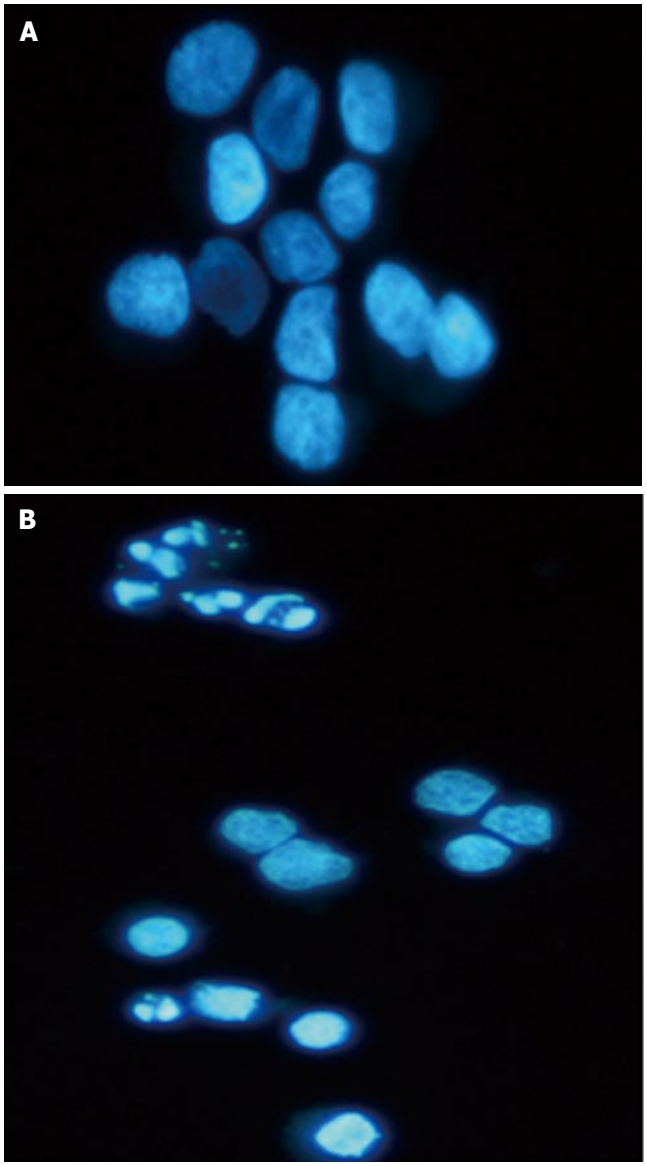

Figure 3 Hoechst 33342-staining of LS174T cells treated with StxA1-GM-CSF. **A**: control; **B**: cells after treatment.

In conclusion, more investigations are required to clarify how StxA1-GMCSF induces apoptosis. Our results reveal that the hybrid protein is toxic to the colon cancer cell line and can be considered as a therapeutic agent.

ACKNOWLWLEDGMENTS

The authors thank Li Li for his technical assistance.

Abstract

AIM: To evaluate the sensitivity and specificity of MR colonography (MRC) and CT performance in detecting colon lesions, and to compare their sensitivity and specificity with that of conventional colonoscopy.

METHODS: Forty-two patients suspected of having colonic lesions, because of rectal bleeding, positive fecal occult blood test results or altered bowel habits, underwent the examinations. After insertion of a rectal tube, the colon was filled with 1000-1500 mL of a mixture of 9 g/L NaCl solution, 15-20 mL of 0.5 mmol/L gadopentetate dimeglumine and 100 mL of iodinized contrast material. Once colonic distension was achieved, three-dimensional gradient-echo (3D-GRE) sequences for MR colonography and complementary MR images were taken in all cases. Immediately after MR colonography, abdominal CT images were taken by spiral CT in the axial and supine position. Then all patients were examined by conventional colonoscopy (CC).

RESULTS: The sensitivity and specificity of MRC for colon pathologies were 96.4% and 100%, respectively. The percentage of correct diagnosis by MRC was 97.6%. The sensitivity and specificity of CT for colon pathologies were 92.8%, 100%, respectively. The percentage of correct diagnosis by CT was 95.2%.

CONCLUSION: In detecting colon lesions, MRC achieved a diagnostic accuracy similar to CC. However, MRC is minimally invasive, with no need for sedation or analgesics during investigation. There is a lower percentage of perforation risk, and all colon segments can be evaluated due to multi-sectional imaging availability; intramural, extra-intestinal components of colonic lesions, metastasis and any additional lesions can be evaluated easily. MRC and CT colonography are new radiological techniques that promise to be highly sensitive in the detection of colorectal mass and inflammatory bowel lesions.

Key words: MR colonography; CT colonography; Colorectal mass; Inflammatory bowel disease; Conventional colonoscopy

INTRODUCTION

The colon is the end part of the gastrointestinal tract from the ileocecal valve to the anal region. For many years, barium examination and endoscopy were the only proven diagnostic methods for evaluating diseases of the colon. In the last 15-20 years, however, spiral computed tomography (CT) has also been shown to be an essential tool in radiological evaluation of the gastrointestinal tract. CT and MRI can be used to evaluate diseases of the colon. They can show the colon wall, colon lumen and the adjacent tissues and organs. CT and MRI are particularly useful in the initial staging of colon neoplasms, assessing the response of colon tumors to therapy and postoperative recurrence of gastrointestinal tumors, evaluating possible causes for gastrointestinal organ displacement and extrinsic impressions detected by barium studies or endoscopy. Moreover, CT and MRI are useful for the detection of inflammatory bowel disease[1-5]. Selective three-dimensional (3D) imaging of the colon was first described in 1994 by Vinning *et al*[6] as a method using spiral CT to provide a computer-simulated endoluminal perspective of the air distended colon. In 1997, Luboldt *et al*[8] first described 3D imaging of the colon filled with paramagnetic contrast as MR colonography[6-8].

Colorectal cancer is the third most common cancer and the second leading cause of cancer-related death in western countries. Most colorectal cancer evolves from pre-existing adenomatous polyps. The incidence of

colorectal cancer could be considerably reduced if polyps and small tumors were detected and eliminated prior to their malignant degeneration[9-11]. There is ongoing research for a colorectal cancer screening test that is cost-effective, safe, and acceptable to patients. Current screening methods for colorectal polyps and colonic cancer include fecal occult blood testing, sigmoidoscopy, colonoscopy and double contrast barium enema examination. The effectiveness of each modality as a screening tool remains controversial, and each method has inherent limitations. MR colonography based on MR imaging is a relatively new diagnostic modality for diagnosing colon pathology.

The purpose of this prospective study was to evaluate the sensitivity and specificity of MR colonography and CT in 42 patients who were suspected of having colonic lesions. Standard colonoscopy and histopathologic examination were accepted as the reference standard.

MATERIALS AND METHODS

Patients

A total of 42 patients (25 men, 17 women; mean age 59.3, range 2-85 years), who were suspected of having colonic lesions because of rectal bleeding, positive fecal occult blood test results or altered bowel habits, underwent MR colonography and CT examination, followed by a conventional colonoscopy (CC). All patients underwent standard bowel preparation 24 h before examination. All patients gave written informed consent, and the procedures were approved by the Local Ethics Committee.

Methods

MR colonography was performed on a 1.5T MR system (Edge, Picker, USA). No sedative or analgesic agents were used. Patients were placed in a supine position on the MR table. After insertion of a rectal tube, the colon was filled with 1000-1500 mL of a mixture of 0.9 g/L NaCl solution (1000 mL) and 0.5 mmol/L gadopentetate dimeglumine (15-20 mL) and 300 g/mL iodinized contrast material (100 mL). When the contrast material reached the cecum, the 3D colon imaging data were acquired using a T1W 3D Gradient-Echo Sequence (GRE) (TE: 2.49 ms, TR: 6 ms, flip angle: 10, thickness: 2.5 mm, FOV: 40 cm-43 cm, matrix: 128 × 192). Further sequences were performed on all patients of axial spin-echo (SE) T1W (TE: 10 ms, TR: 130 ms, flip angle: 90, thickness: 8 mm, FOV: 40 cm-43 cm matrix: 192 × 256), and fatsat SE T1W (TE: 20 ms, TR: 749 ms, flip angle: 90, thickness: 7 mm, FOV: 40 cm-43 cm, matrix: 192 × 256).

Immediately after the MR colonography, abdominal CT images were taken on the spiral CT (PQS, Picker, USA) in the axial planes (kV: 130, mA: 175, thickness: 5 mm, matrix: 512 × 512) and supine position. The three-dimensional MR data sets were analyzed in the multiplanar reformation and evaluated completely and separately and independently by two experienced radiologists. The CT axial plane images were evaluated by both the experienced radiologists. Each radiologist recorded the location and the size of colorectal masses or defined the colon lumen, wall and adjacent tissues to lesions of the large bowel, respectively. If their interpretation of the MR colonography and CT images differed, consensus was reached by review and discussion of the controversial images.

All patients were examined with the same endoscopist video (Pentax EC 38 40 TL, Tokyo, Japan) colonoscope. The location and size of any endoluminal lesions were identified and the colon wall pathologic appearance was recorded. All lesions found by CC were biopsied or removed by polypectomy. All specimens were examined histologically for differential diagnosis of inflammatory disease, hyperplastic polyps, adenomatous polyps, and cancers.

Standard colonoscopy and histopathologic examination were accepted as the references, so the MR colonography and CT were being evaluated for sensitivity, specificity and correct diagnosis ratio in the detection of colonic lesions. Each MRC examination lasted about 20-30 min, CT examination about 10-15 min and CC examination about 20-30 min. MR colonography and CT were well tolerated by all patients with no post-procedural complications after MR colonography, CT or CC.

RESULTS

A total of 42 patients suspected of having colonic lesions underwent MR colonography and abdominal spiral CT. Colonic lesions were identified by MR colonography in 26 patients. MR colonography was normal in 16 patients. On the basis of MR colonography and CT, 17 colon carcinoma (65.3%), 2 invasion to rectum (7.7%), 1 recurrent colon tumor (3.8%), 4 inflammatory bowel disease (15.3%), 1 hirschsprung disease (3.8%), and 1 diverticulosis (3.8%) were determined and these lesions were confirmed by conventional colonoscopy and histopathologic examination.

MR colonography and CT identified colorectal cancer in 17 patients. Malignant tumors of the colon were located in the rectum (6), rectosigmoid region (3), caecum (2), ascending colon (1) (Figure 1), descending colon (1) and sigmoid colon (4) (Figure 2). Malignant tumors of the colon appeared on MR colonography and CT as a tumor mass projecting into the lumen of the colon or as an asymmetrical or circumferential thickening of the bowel wall with deformation and narrowing of the lumen. Fourteen adenocarcinoma, two mucinous adenocarcinoma and one tubulovillous adenoma (carcinoma *in situ*) were confirmed by histopathologic examination. Seventeen patients with colon tumors underwent CC. A complete CC was achieved in 14 patients. In three patients, CC could not be evaluated completely due to occlusive carcinoma. However, in these patients, all of the colon segments were examined by MR colonography. The results of the MR colonography and CT were compared with the colonoscopy, histopathologic examination and surgery results. All patients with colon tumors had been correctly identified on MR colonography and CT.

Four patients with inflammatory bowel disease were correctly identified on MR colonography and CT. These were identified by histopathologic examination as ulcerative

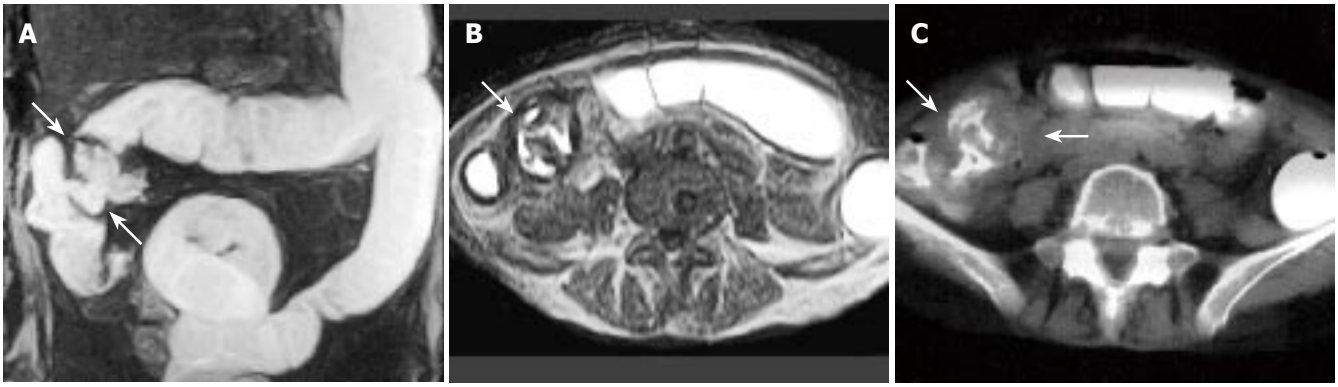

Figure 1 A 59-year-old woman with cecum and ascending colon carcinoma. **A**: MR colonography MIP (maximum intensity projection) image showing asymmetrical, irregular wall thickening at the cecum and ascending colon segments (arrows); **B**: SE T1W axial image; **C**: axial CT image showing asymmetrical, irregular wall thickening of the ascending colon (arrows).

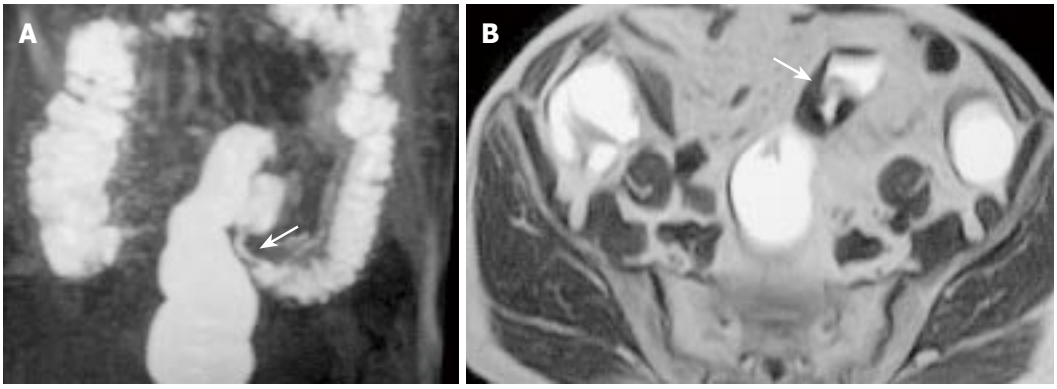

Figure 2 A 77-year-old man with sigmoid carcinoma. **A**: MR colonography MIP (maximum intensity projection) image showing asymmetrical, annular wall thickening at the sigmoid colon segment (arrow); **B**: SE T1W axial image showing asymmetrical, irregular wall thickening of the sigmoid colon (arrow).

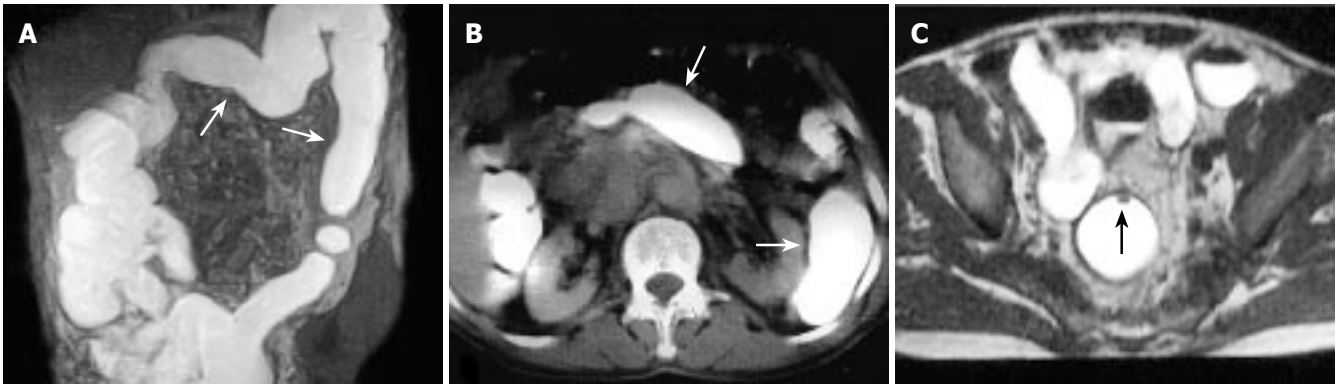

Figure 3 A 63-year-old man with ulcerative colitis. **A**: MR colonography MIP (maximum intensity projection) image; **B**: axial CT image showing haustral flattening at transverse and descending colon segments (arrows); **C**: SE T1W axial image showing a 0.5-cm polyp at the rectosigmoid junction (arrow).

colitis (Figure 3), non-specific colitis and ileocaecal region inflammatory disease (Figure 4). In one patient non-specific colitis was evaluated by histopathologic examination and colonoscopy, but it was not identified by MR colonography and CT. Thus MRC and CT failed to identify 20% (1/5) patients with inflammatory colon disease. In 2 patients with colon carcinoma, the colonoscopy detected polyps (size: 3 mm in one patient and 7 mm in the other) which had not been diagnosed with MR colonography. In one of them, the MR examination had been insufficient because of technical reasons. In the other patient, the small polyp was not identified from the adjacent mass. In the 2 patients with colon carcinoma and one patient with ulcerative colitis, colonoscopy detected polyps (size: 3 mm in 1 patient, 5 mm in 1 patient and 7 mm in the other) which had not been diagnosed with CT. In all three cases, the CT examination had been insufficient because of technical reasons and the small polyps had not been identified from the adjacent mass.

MR colonography and CT identified invasion to the rectum in two patients. In one case where there was bladder cancer invasion to the rectum, both the MR colonography and CT examinations identified invasion to the rectum and further MR colonography showed the

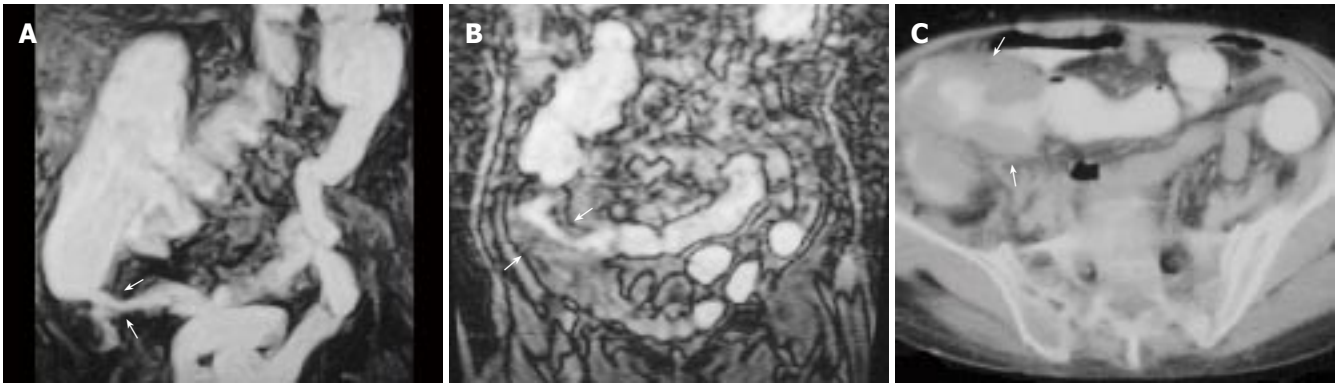

Figure 4 A 70-year-old man with inflammatory disease in the ileocaecal region. **A**: MR colonography MIP (maximum intensity projection) image; **B**: coronal plane MR colonography raw data image; **C**: axial CT image showing asymmetrical, irregular wall thickening of the ileocaecal region (arrows) and serpiginous strands extending into soft tissue due to inflammatory disease.

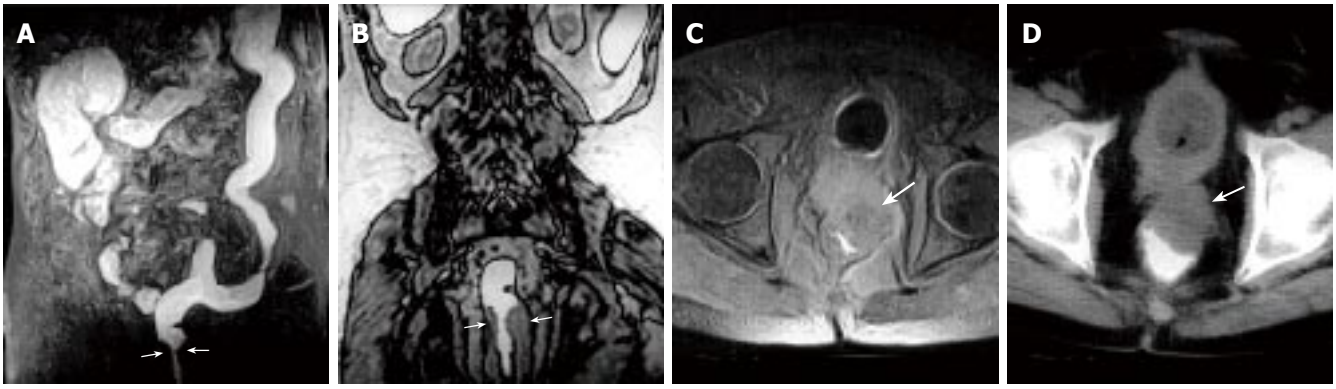

Figure 5 A 63-year-old man with rectum carcinoma invasion to prostate. **A**: MR colonography MIP (maximum intensity projection) image showing luminal narrowing at rectum (arrows); **B**: MR colonography raw data coronal image showing luminal narrowing due to annular thickening of the rectum wall (arrows); **C**: SE axial T1W image; **D**: axial CT image showing asymmetric wall thickening at rectum (arrows), and invasion to the fatty tissue arround the mass.

presence of rectovesical fistula due to bladder cancer. In the other patient, an invasion to the rectum due to prostate cancer was detected (Figure 5). The sensitivity and specificity of MR colonography for colon pathologies were 96.4% and 100%, respectively. The percentage of correct diagnosis of MR colonography was 97.6%. The sensitivity and specificity of CT for colon pathologies were 92.8% and 100%, respectively. The rate of correct diagnosis of CT was 95.2%. The MR colonography was well tolerated without sedation or analgesia and no complications were observed. MR colonography and CT identified 19 extracolonic lesions in 12 of 42 patients. These lesions were liver metastases, hydatic cyst of the liver, simple cyst of the liver, mesenteric cyst, gallbladder carcinoma, duodenum carcinoma, renal cyst, gastric tumor, multiple lymphadenopathy, intraperitoneal lipoma, hiatal hernia, subcapsular hematoma of the spleen and pleural effusion.

DISCUSSION

Colorectal cancer is the second leading cause of cancer-related death. Most colorectal cancer evolves from adenomatous polyps and screening for colorectal polyps with subsequent polypectomy has been shown to constitute an effective approach to decreasing its incidence[9,10]. However, as evidenced by disappointing participation in colorectal screening and the continuing high incidence of colorectal cancer, new screening strategies may prove beneficial. To prove effective in reducing mortality from colorectal cancer, new screening methods must demonstrate a high diagnostic accuracy at a low cost, and be proven safe and highly acceptable to patients[12].

Fecal occult blood testing has a sensitivity of less than 10% for adenomatous polyps, and a sensitivity of less than 15% for the detection of polyps under 2 cm in size[13]. In contrast, the promise of MR colonography is to detect malignant and premalignant polyps with a sensitivity rivaling colonoscopy.

Flexible sigmoidoscopy allows for the examination of only the distal 60 cm of the colon which limits evolution to the descending colon, sigmoid, and rectum; inevitably, lesions are missed in more than half the subjects who have advanced colonic adenoma located proximal to the splenic flexure but who do not have a distal index polyp[14,15]. Colonography, in contrast, images the entire colorectum and may be able to decrease the mortality by detecting more right-sided lesions. In retrospective evaluations of double-contrast barium enema examination, investigators have found sensitivities of 71%-95% for the detection of colorectal cancer[16]. However, in prospective studies of double-contrast barium enema examination, data have

shown the sensitivities as low as 50%-75% for colorectal cancer detection in asymptomatic patients with positive fecal occult blood test[17]. A recent study in which double-contrast barium enema examination was compared with colonoscopy for colonic surveillance after polypectomy found a poor detection rate of 48% for polyps ⩾10 mm in size, as well as a poor overall detection rate of only 39% for adenomas[18]. Unlike barium enema, MR colonography does not suffer from superimposition and can explain the attenuation characteristics of suspicious lesions, as well as allowing for the evaluation of pericolonic tissues.

In most centers, colonoscopy has emerged as the principal means of examining the colon. Although standard colonoscopy is a total colonic examination that allows lesion biopsy and resection, it fails to demonstrate the entire colon in up to 5% of cases examined by an experienced gastroenterologist[19], and up to 20% of all adenomas are missed[20].

Furthermore, there is a risk of complications associated with diagnostic and therapeutic colonoscopy, including perforation (1 in 1000), major haemorrhage (3 in 1000), and death (1 in 30 000)[12,20]. In addition, colonoscopy is limited by poor patient acceptance, which is a most important variable for a screening test[21,22]. Rex *et al*[23] have shown that even when it is offered free of charge, most patients refused to undergo colonoscopy for primary colorectal cancer screening.

In colorectal cancer screening, MR colonography can play an important role for patients who have undergone incomplete endoscopic colonoscopy. Common reasons for incomplete colonoscopy are redundant bowel loops and occlusive carcinoma. MR colonography can achieve a complete examination of the colon in these patients. In patients with occlusive carcinoma, the evaluation of the proximal colon is necessary to exclude a secondary neoplasia, which occurs in 5% of these cases[24]. MR colonography is available for detecting colorectal masses. Luboldt *et al*[25] performed MR colonography in 132 patients referred for CC, showing a sensitivity of 93% and specificity of 99% of MR colonography. A similar study by Pappalardo *et al*[26] compared MR colonography with conventional colonoscopy in 70 patients. All patients who underwent MR colonography had satisfactory studies and MR colonography achieved a diagnostic accuracy similar to that of conventional colonoscopy (sensitivity of 96%, specificity of 93%).

MR colonography techniques have recently been introduced as potential methods for colorectal screening. MR colonography may have a role in accurately staging colorectal cancers, in particular if combined with state-of-the-art MR imaging of the liver. In the same manner as for staging, MR colonography can also be used for post-operative surveillance[27]. Besides the detection and assessment of neoplastic disease, MR colonography can also be employed for the evaluation of inflammatory bowel disease. Over the past decade, several authors have found that MR imaging is a useful, non-invasive tool in patients with Crohn's disease, regardless of whether it is manifested in the small bowel, large bowel, or in the perianal region[28-30]. MR imaging can be used to assess disease activity and may help distinguish reversible inflammatory changes from irreversible fibrostenosis[31-33]. In contrast to double-contrast barium enema or conventional colonoscopy, MR colonography might be used to distinguish the Crohn's strictures that require surgery from those that might benefit from anti-inflammatory therapy, in addition to visualizing the colon proximal to a narrowing, and assessing extracolonic complications of the disease, including fistula and abscesses[34].

An enema with dilute iodinated contrast material can be administered well by the rectal tube in advance of the CT study, just prior to imaging. CT can also be used to evaluate the colon wall. In its characterization of colon neoplasms, CT is useful to categorize the extent of tumor as follows: intraluminal mass without wall thickening; wall thickening focal or diffuse with no extramural tumor extension; invasion of contiguous mesenchymal tissue; invasion of adjacent organs or other anatomic structures; involvement of regional lymph nodes; or metastatic spread to distant organs, lymph nodes or other structures[1-3]. CT colonography is available for detecting colorectal masses. Pickhardt *et al*[35] performed CT colonography in 1233 asymptomatic adults referred for CC, and found the sensitivity of virtual colonoscopy for adenomatous polyps was 93.8% for polyps at least 10 mm in diameter, 93.9% for polyps at least 8 mm in diameter, and 88.7% for polyps at least 6 mm in diameter. The specificity of virtual colonoscopy for adenomatous polyps was 96.0% for polyps at least 10 mm in diameter, 92.2% for polyps at least 8 mm in diameter, and 79.6% for polyps at least 6 mm in diameter. CT virtual colonoscopy with the use of a three-dimensional approach is an accurate screening method for the detection of colorectal neoplasia in asymptomatic average-risk adults and compares favorably with optical colonoscopy in terms of the detection of clinically relevant lesions[35].

CT can show diverticulosis and inflammatory bowel disease. CT findings in inflammatory disease include circumferential wall thickening, serpiginous soft-tissue strands extending into the mesenteric fat, and enlarged lymph nodes in the same region[5].

MR colonography and CT were used on 5 patients with inflammatory bowel disease, and 4 of 5 were correctly identified. MR colonography and CT failed to correctly identify in one patient who was diagnosed to have non-specific colitis by histopathologic examination. Currently, colonoscopy is generally reserved for patients with positive results from screening tests or those with a higher than average-risk of colorectal cancer, rather than applying it for routine screening. In the search for an adequate screening method, MR colonography has emerged relatively strongly. MR colonography possesses unique advantages over existing screening tests in that it is quick, less invasive, with no need for sedation or analgesics during investigation and with a lower percentage of perforation complications. Moreover, it enables evaluation of all colon segments because of multi-sectional imaging availability, thus enabling to evaluate intramural, extra-intestinal components of colonic lesions, metastasis and additional lesions. MR colonography is a fundamentally new imaging technique with the potential to alter current clinical approaches in the detection of colorectal neoplasms and

inflammatory bowel disease.

In conclusion, in the search for a rapid, less invasive, accurate, and well-tolerated colorectal examination method, magnetic resonance colonography can be an effective method.

Abstract

AIM: To investigate the effects of verapamil on nitric oxide (NO) synthesis in a portal vein-ligated rat model.

METHODS: Systemic and splanchnic hemodynamics were measured by radiolabeled microspheres in portal hypertensive rats after acute administration of verapamil (2 mg/kg) on chronic treatment with N^{w}–nitro-L-arginine (NNA)(80 mg/kg) and/or indomethacin (2 mg/kg) .

RESULTS: Verapamil (2 mg/kg) caused a marked fall in both arterial pressure and cardiac output accompanied by an insignificant change in the portal pressure and no change in portal venous inflow. This result suggested that verapamil did not cause a reduction in portal vascular resistance of portal hypertensive rats, which was similar between N^{w}- nitro–L-arginine-treated and indomethacin-treated groups.

CONCLUSION: In portal hypertensive rats pretreated with NNA and/or indomethacin, acute verapamil administration can not reduce the portal pressure, suggesting that NO and prostaglandin play an important role in the pathogenesis of splanchnic arterial vasodilation in portal hypertension.

INTRODUCTION

Verapamil, a calcium entry blocker, in addition to its inhibiting action on the contraction of rat portal vein[1,2], can decrease hepatic venous pressure gradient[3,4] and is proposed as a drug in the treatment of variceal bleeding in patients with HBsAg-positive cirrhosis[4,5]. It was reported that verapamil reduces the intrahepatic shunting in cirrhotic rat- perfused liver[6]. Furthermore, verapamil can also reverse the altered microvascular exchange caused by sinusoidal capillarization in cirrhotic rats when given acutely or chronically[6,7]. However, studies testing verapamil, nifedipine and nicardipine in patients with cirrhosis have failed to show any reduction in hepatic vein pressure gradient, but increase in portal collateral blood flow, an effect that may be dangerous in patients with esophageal varices[8-10]. So far, the mechanism responsible for the effect of verapamil on splanchnic circulation in the rat model of pre-hepatic portal hypertension is still unknown.

Nitric oxide (NO) and prostacyclin (PGI2) are endogenous vasodilators synthesized by the vascular endothelium[11-13]. In fact, both can modulate the mesenteric vascular tone and are important contributors to splanchnic arterial vasodilation in portal hypertensive rats[12,13]. In addition, some investigators have reported that NO plays a major role in modulating collateral vascular resistance[14-16]. Increased PGI2 activities have been observed in the splanchnic vascular bed of portal hypertensive rat model[17-19]. However, it is unknown whether both vasodilators modify the response of splanchnic arterial vasodilation to verapamil in portal hypertensive rats. Thus, we aimed to identify any unique advantageous or deleterious haemodynamic effect of acute verapamil on nitric oxide synthese in a pre-hepatic portal hypertensive rat model. In addition, the influence of NO and prostaglandin on the responsiveness of splanchnic arterial vasodilation to verapamil was also evaluated.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats weighing 280-340 g at the time of surgery were used for experiments. The rats were housed in a plastic cage and allowed free access to food and water. All rats were fasted for 12 h before operation. In all experiments, the investigators followed the American Physiological Society Guiding Principles for the Care and Use of Laboratory Animals.

A prehepatic portal hypertensive animal model was induced by partial portal vein ligation (PVL) as previously described[20]. Anesthesia was performed with ketamine HCl (100 mg/kg body weight, intramuscularly). In brief, the portal vein was isolated and a 3-0 silk ligature was tied around the portal vein and a 20-gauge blunt-tipped needle. The needle was then removed and the vein allowed to reexpand. A second loose ligature was left around the portal vein with the 2 ends of the ligature placed on each side in the abdominal cavity. The abdomen was then closed and the animal was allowed to recover. Perfusion studies were performed on overnight-fasted rats 10-13 d after the operation, at which time an extensive collateralization of the portal system was fully established.

Experimental design

Rats with a ligated portal vein were divided into three groups. In each group of PVL rats, verapamil (Isoptin Knoll AG, Ludwigshafen, Germany) was given at a dose of 2 mg/kg parenterally, which decreased the mean arterial pressure (MAP) by more than 10%. One group of sham-operated rats received sterile saline (1 mL/kg) only. A group of PVL rats were also studied after the administration of sterile saline (1 mL/kg) alone to ensure that the hyperdynamic state could be achieved. Pressure dose-response curves were constructed for each group of rats 15 min after the administration of each dose. Seven doses were used at the concentration ranging from 0.02 to 2.0 mg/kg body weight. Verapamil was administered through a venous catheter. In the first group, sham-operated and PVL rats were treated daily following the ligation with one ip injection of N^{w}–nitro-L-arginine (NNA) (80 mg/kg). In the second group, sham-operated and PVL rats were treated daily following the ligation with one ip injection of indomethacin (INDO) (2 mg/kg). In the third group, sham-operated and PVL rats were treated daily following the ligation with ip injection of both NNA (80 mg/kg) and indomethacin (2 mg/kg).

Experiment preparation

All animals were anaesthetized with pentobarbital (50 mg/kg) and fastened on an animal board in dorsal recumbency. Both femoral vein and artery were cannulated with a polyethylene catheter (PE-50). The mean arterial blood pressure (MAP) was measured with a strain-gauge transducer (Statham P23 Db) connected to the femoral artery cannula and recorded continuously on a Grass polygraph (Grass Apparatus, Quincy, MA, USA). The skin over the left upper abdominal quandrant was shaved, a small (1.0 cm-2.0 cm) parasagittal incision was made at the level of the left anterior axillary line and the muscles were gently separated with forceps. The spleen was exposed by pulling it away from the perisplenic fat and then covered with a piece of warm Ringer-lactate moist gauze. Special care was taken to avoid any unnecessary manipulation of the spleen. The jejunal vein was cannulated with a PE-50 catheter for the continuous monitoring of portal pressure. Catheters were also placed in the left femoral artery and right carotid artery. The right carotid artery catheter was carefully advanced into the left ventricle under continuous pressure. Heart rate measurement was used to radiolabel the microsphere injection for the determination of portal venous inflow (PVI). All catheters were connected to Statham P-23-Db strain gauge transducers (Statham), and continuous pressure recordings of left ventricular and portal pressures (PP) were printed on a Grass model ID inscription recorder (Grass, Quincy, MA, USA). Baseline pressure and heart rate measurement were recorded in each animal.

Systemic and splanchnic hemodynamics

Splanchnic organ blood flow and cardiac output were determined twice (before and 15 min after administration of the drug) according to the reference sample method with intracardiac injection of isotope-labelled microspheres (15±3 μm in diameter)[21]. 「^{57}Co」 and 「^{113}Sn」-labelled microspheres (New England Nuclear, Boston, MA, USA) suspended in Tween 80 (0.05%) were used for the first or second injection. Approximately 180 000 「^{57}Co」 and 「^{113}Sn」-labelled microspheres were aspirated into plastic 1.0 mL syringes (volume 0.3-0.4 mL) and mixed in a vortex for 5 min. An additional 0.2 mL sample containing approximately 30 000 「^{46}Sc」-labelled microspheres was also placed into a 1.0 mL plastic syringe until injection.

Ten seconds after withdrawal of a blood sample from the left femoral artery for reference, microspheres were injected into the left ventricle over 10-15 s. Catheters were flushed with 0.2 Ml of 0.9% NaCl. Blood was withdrawn from the left femoral artery over 90 s at an approximate rate of 1 mL/min using a Harvard pump (Harvard Apparatus, Millis, MA, USA). Once withdrawal was complete, a volume of 0.9% NaC1 equal to the sample volume was withdrawn and reinfused, arterial blood pressure was monitored to ensure stability during microsphere distribution. As soon as the spleen was exposed, the 「^{46}Sc」-labelled microspheres were injected through a 23-gauge needle into the splenic pulp over a period of 20 s. The animals were then killed with an injection of bolus of saturated KC1 into the carotid artery catheter.

The liver, lungs, stomach, intestine, spleen, pancreas, mesentery and kidneys were dissected and weighed. The radioactivity of the organs was determined in a scintillation counter (Packard, Downers Grove, IL, USA) with an energy window set at 50-200 KeV for ^{57}Co, at 300-500 KeV for ^{113}Sn and at 800-1200 KeV for ^{46}Sc, respectively. At least 300 microspheres were trapped in the reference sample and organs to ensure validity of the measurement. The error in the measurement of radioactivity induced by spillover of each radioactive microsphere channel was corrected using ^{57}Co, ^{113}Sn and ^{46}Sc standards. Each standard was checked by a multichannel analyzer (Series

Table 1 Baseline characteristics in different study groups (mean ± SD)

Groups	*n*	Body weight (g)	Mean arterial pressure(mmHg)	Heart rate (beat/min)
Vehicle	8	326.7±10.6	98.6±3.6	296±18
Verapamil	8	332.6±11.8	96.5±4.8	320±16
Verapamil+vehicle	8	321.5±9.8	99.5±5.2	318±20
Verapamil+NNA	8	330.8±9.6	97.4±3.8	317±17
Verapamil+INDO	7	327.8±8.5	94.2±6.2	328±14
Verapamil+INDO+NNA	8	319.8±7.9	96.2±4.8	308±15

NNA: N^{ω}-nitro-L-arginine; INDO: indomethacin.

35 PLUS). Adequate microsphere mixing was assumed at a difference < 20% between the left and right kidneys. Any animal not meeting this requirement was rejected from the analysis. Cardiac output was calculated according to the following formula:

Cardiac output (mL/min) = (injected radioactivity (cpm) × reference sample blood flow (mL/min)) / reference sample radioactivity (cpm).

Injected radioactivity was calculated on the basis of the difference between the initial and residual radioactivity in the syringe. Organ blood flow was calculated as follows:

Organ blood flow (mL/min) = (organ radioactivity (cpm) × reference sample blood flow (mL/min)) / reference sample radioactivity (cpm).

Vascular resistance of different organs in the portal venous system was calculated according to the following formula:

Resistance (dyn.s.cm^{-5}×10^5) = (mean arterial pressure (mmHg) - portal venous pressure (mmHg)) × 80/organ blood flow (mL/min)

Portal tributary blood flow was calculated as the sum of the blood flow in the spleen, stomach, colon, mesentery and pancreas. The hepatic arterial blood flow was taken to be equal to the liver blood flow.

Portal systemic shunt (PSS) % was calculated as:

[ct/min in lung/ct/min in (lung + liver)] x 100

Drugs

Verapamil, NNA, INDO, and reagents for preparing Krebs' solution were purchased from Sigma. All solutions were freshly prepared on the day the experiment was conducted.

Statistical analysis

Results were expressed as mean ± SD. The concentration of verapamil at 50% of the maximal response (EC_{50}) in each preparation was calculated from sigmoid logistic curves and expressed as negative log molar (-log mol/L). Statistical analyses were performed by the paired or unpaired Student's *t* test and one-way analysis of variance with Tukey's test when appropriate. $P<0.05$ was considered statistically significant.

RESULTS

Systemic and splanchnic hemodynamics

No differences were observed in body weights, mean arterial pressures and heart rates among the three groups (Table 1). The PVL rats exhibited a hyperdynamic state of splanchnic circulation with a high cardiac index. The pressure-dose-response curves of the sham-operated and PVL rats after acute verapamil administration in different groups were similar to the curves previously reported by us[20](Figure 1).

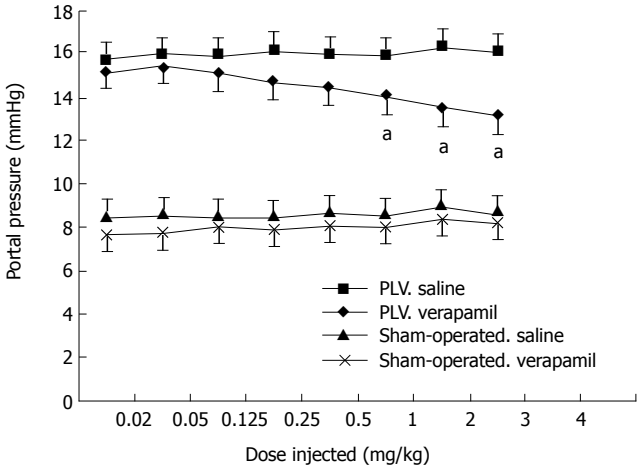

Figure 1 Portal pressure responses to verapamil in four groups of rats: $^aP<0.05$ *vs* sham-operated control. PVL: portal vein ligated.

No significant change of the portal pressure (PP) was noted when verapamil (2 mg/kg) was given to PVL rats by early chronic administration of NNA, INDO, or both in all three groups. The results of this study also indicated that acute verapamil administration could reduce the PP in different study groups of PVL rats in a hyperdynamic state. In all three groups of rats, the mean arterial pressure (MAP) significantly decreased following administration of verapamil compared to the control group. In contrast, the portal pressure, portal venous inflow (PVI) and hepatic arterial flow (HAF) were maintained, while cardiac output (CO) decreased significantly compared to the control group (Table 2, Figure 2). Thus, the effect of verapamil on chronic treatment with NNA (80 mg/kg), INDO (2 mg/kg), and both on splanchnic organ blood flow in sham-operated and PVL rats after 15 d from the control are shown in Figure 3. At a dose of 2 mg/mL verapamil, there was also no significant decrease in total peripheral resistance (TPR), splanchnic arterial resistance (SAR) and portal venous resistance (PVR) in all three groups of PVL rats (Table 3).

Portal-systemic shunting

After PVL rats were pretreated with either NNA or indomethacin for 15 d, acute verapamil (2 mg/kg) administration did not induce any significant reduction in the portal-systemic shunting. Furthermore, the portal pressure in both NNA- and indomethacin-pretreated PVL rats was also not significantly different from that in the control group. The portal pressure reduction was not correlated with portal-systemic shunting reduction in either NNA- or indomethacin-pretreated PVL rats (r = 0.05, NS; r = 0.03, NS).

DISCUSSION

The results of the present study showed that verapamil administration did not favorably influence splanchnic arterial vasodilation in portal vein-ligated rats pretreated with NNA and indomethacin as expected.

These findings are not consistent with those of a previous study in rats with carbon tetrachloride-induced cirrhosis[6], in which rat model it was demonstrated that verapamil reduces hepatic resistance, exerts beneficial effect on the hepatic microvascular exchange, improves liver function and reduces portal pressure if chronically administered. It was reported that verapamil is a useful therapeutic agent for patients with cirrhosis[4]. In a small group of patients, Freeman *et al*[3] demonstrated that verapamil administered intravenously, decreases the hepatic venous pressure gradient (HVPG). Furthermore, we

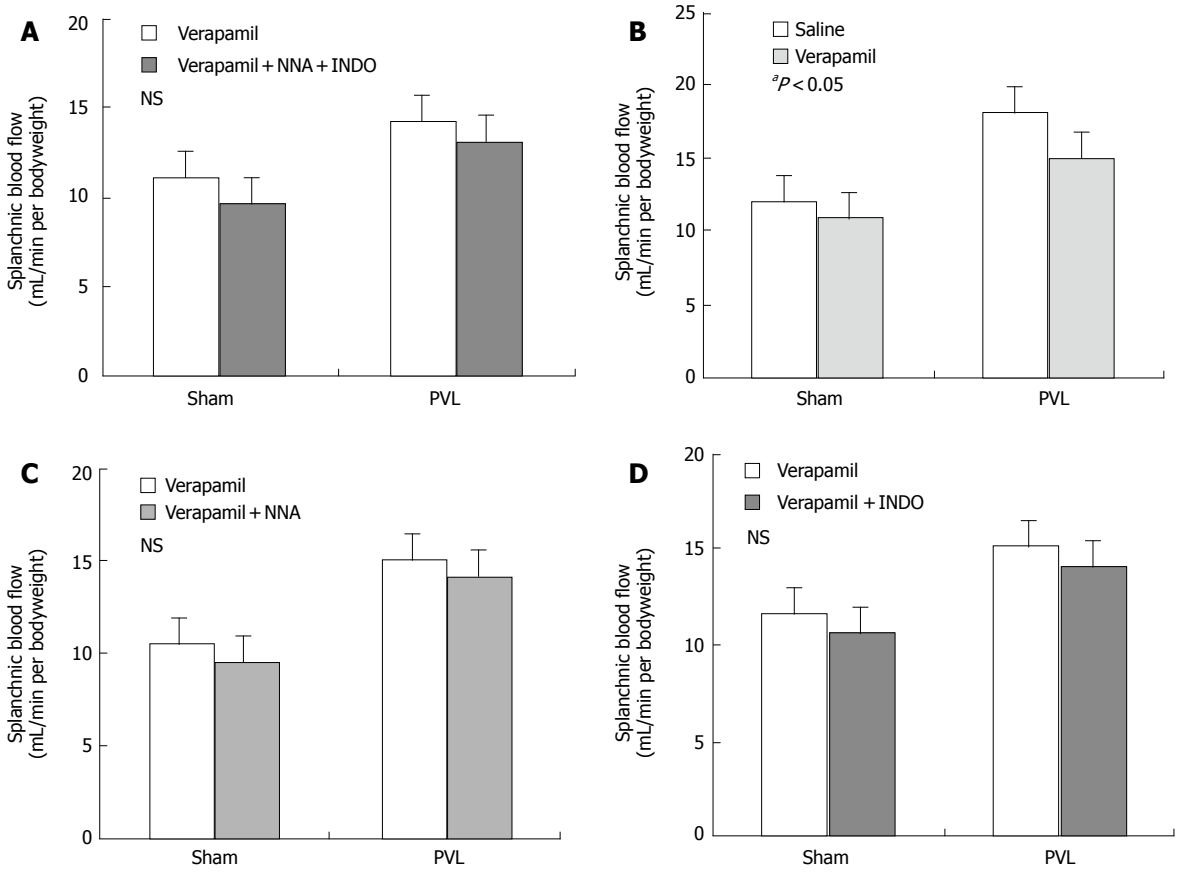

Figure 3 Effects of verapamil in combination with NNA (80 mg/Kg), INDO (2 mg/Kg) and NNA plus INDO on splanchnic blood flow in sham-operated and PVL rats after 15 days. **A**: verapamil plus NNA plus INDO; **B**: verapamil alone; **C**: verapamil plus NNA; **D**: verapamil plus INDO. $^aP < 0.05$ *vs* control group.

have obtained similar results in patients with postnecrotic cirrhosis after both acute and chronic administration of verapamil[4,5].

The present study failed to document any beneficial effect of verapamil in portal hypertensive rats pretreated with NNA and indomethacin. This might not be due to a low dose or a poor absorption of verapamil, as documented by the dose response curve which was well within the therapeutic range. Pharmacodynamic efficacy was also manifested by the observed systemic effects of verapamil, including increased HR and peripheral vasodilation as well as decreased arterial pressure and SVR. Verapamil did not exert any noticeable effect on portal pressure, PVI and HAF. Accordingly, the hepatic vascular resistance did not decrease in our study. Because of this lack of effect on the splanchnic and hepatic arterial vasodilation, verapamil failed to influence liver perfusion. Thus, our results do not support the use of verapamil in the treatment of cirrhosis and portal hypertension pretreated with NNA and indomethacin. Further evidence against the use of verapamil in portal hypertension has been demonstrated by Narasa *et al*[8] who in accordance with our findings have failed to document any decrease in portal pressure following verapamil administration in portal hypertensive patients.

The reason for the discrepancies between the current results and previous studies is not clear. It may be related to the fact that our rat model was produced by portal vein ligation, causing presinusoidal portal hypertension, and these rats were pretreated with NNA and indomethacin. It is also possible that in this kind of animal model, verapamil cannot reduce portal pressure by decreasing intrahepatic portal resistance, and improve hepatic function by affecting the apparent hepatic blood flow[22]. So far, the effect of verapamil on rat hepatic stellate cells is still unknown[23]. The structural changes have not been observed and within the liver the hepatic microcirculation cannot be pharmacologically altered because verapamil has a high first-pass effect[1,24]. However, we have previously documented in a similar model of portal hypertensive rats that the hepatic vascular resistance and portal pressure can be lowered by verapamil[4]. Although animal experiments have demonstrated that verapamil can produce a complex interplay of alterations in preload (splanchnic venodilatation), afterload and myocardial contractility by inhibiting the constrictor responses of the splanchnic capacitance vessels of small resistant arterioles and arteries to the sympathetic nervous outflow[1,6,7], this finding indicates that the effect of verapamil on splanchnic arterial vasodilation can be pharmacologically modified by pretreatment with NNA and indomethacin.

Nitric oxide and prostaglandin are endogenous vasodilators produced by vascular endothelial cells[11-15]. Non-specific inhibition of NO synthesis can restore mesenteric vascular responsiveness[25] and normalize splanchnic vascular resistance[26], thus ameliorating portal-systemic shunting and hyperdynamic circulation[27,28]. Both NO and prostaglandin participate in the regulation of

vascular tone in different vascular beds of normal and portal hypertensive animals[15-18]. It has been shown that in portal hypertensive rats, inhibition of nitric oxide synthesis increases not only intrahepatic and splanchnic vascular resistance but also portal-collateral resistance[11,15,29]. Recently, increased prostacyclin (PGI 2) activities have been observed in systemic circulation and portal vein segments of portal hypertensive rats[18]. In addition, prostaglandin is involved in the modulation of collateral vascular tone in portal hypertensive rats and can modify the vasoconstrictive effect of vasopressin[25]. Nitric oxide and PGI 2 produce relaxation of the vascular smooth muscle by different mechanisms. Nitric oxide works by activating guanylate cyclase which increases the intracellular levels of guanosine 3, 5-cyclic monophosphate[12].

In conclusion, acute verapamil administration does not increase the splanchnic arterial vasodilation in pre-hepatic portal hypertensive rats pretreated with NNA and /or indomethacin. In conjunction with our previous reports[20], these findings indicate that both NO and prostaglandin can modulate the splanchnic vascular response to verapamil and may therefore participate in the development and maintenance of portal hypertension.

Abstract

AIM: To study the effect of interleukin-10 (IL-10) on the expression of transforming growth factor β1 (TGF-β1) in hepatic fibrosis rats and the anti-fibrotic role of exogenous IL-10.

METHODS: Hepatic fibrosis was induced by carbon tetrachloride administered (CCl_4) intraperitoneally. The experiment was performed in two stages. In the first stage, 60 SD rats were divided randomly into normal control group 1 (GN_1, n = 8), hepatic fibrosis group (GC, n = 28) and IL-10 intervened group (GI, n = 24). At the beginning of the 7th and 11th wk, hepatic stellate cells (HSCs) were isolated, reverse transcription-polymerase chain reation (RT-PCR) and immunocytochemistry were performed to detect the expression of TGF-β1 in HSCs. Histological examination was used to determine the degree of hepatic fibrosis. In the second stage, 47 SD rats were divided randomly into normal control group 2 (GN_2, n = 6) and CCl_4 group (GZ, n = 41). At the end of the 9th week, rats in GZ group were allocated randomly into model group (GM, n = 9), IL-10 treatment group (GT, n = 9) and recovered group (GR, n = 9). At the end of the 12th week, all rats were sacrificed. RT-PCR and immunohistochemistry were performed to detect the expression of TGF-β1 in liver tissue. ELISA was used to assay serum TGF-β1 levels.

RESULTS: Hepatic fibrosis developed in rats with the increase of the injection frequency of CCl_4. In the first stage, hepatic fibrosis developed and HSCs were isolated successfully. At the 7th and 11th week, TGF-β1 mRNA in GC group increased significantly compared with that in GN_1 (P = 0.001/0.042) and GI groups (P = 0.001/0.007), whereas there was no significant difference between the two groups. The levels of TGF-β1 at the beginning of the 7th wk was higher than that of the 11th wk (P = 0.049). Immunocytochemistry results of TGF-β1 were consistent with the above findings. In the second stage, TGF-β1 increased significantly in GM group compared to GN_2. After treatment with IL-10, TGF-β1 declined obviously. The expression of TGF-β1 decreased in GR group but was still higher than that in GT group.

CONCLUSION: The levels of TGF-β1 are increased in hepatic fibrosis rats and decreased after treatment with exogenous IL-10. IL-10 may play an anti-fibrotic role by suppressing TGF-β1 expression.

Key words: Hepatic fibrosis; Hepatic stellate cells; Interleukin-10; Transforming growth factor-β1

INTRODUCTION

Hepatic fibrosis, which represents the wound healing response of the liver, is a common sequel of liver injury characterized by increased deposition and altered composition of extracellular matrix (ECM) [1-2]. Hepatic stellate cells (HSCs) are the major source of ECM and regarded as the principle cell type in the development of hepatic fibrosis [3-5]. TGF-β1 appears to be the main fibrogenic mediator and exerts its effects through autocrine or paracrine on HSCs [6]. Hepatocytes also express TGF-β1 when isolated and cultured *in vitro* as a response to an altered extracellular environment. It has been reported that interleukin-10 (IL-10) could relieve the degree of rat hepatic fibrosis induced by carbon tetrachloride (CCl_4) [7]. In the present study, we isolated HSCs and detected the expression of TGF-β1 in HSCs and liver tissues, and explored the relationship between TGF-β1 and hepatic fibrosis in an attempt to explain the possible mechanisms of the antifibrotic activities of exogenous IL-10 *in vivo*.

MATERIALS AND METHODS

Establishment of models

All rats were bred under routine conditions (at room temperature of 22 ℃ ± 2 ℃, a humidity of 55% ± 5%) with a light/dark cycle and free access to drinking water and food (BK Company in Shanghai, China). In the first stage, 60 clean male SD rats were divided randomly into normal control group 1 (GN_1, n = 8), hepatic fibrosis group (GC, n = 28) and IL-10 intervened group (GI, n = 24). Rats in GN_1 group were injected intraperitoneally with saline at a dose of 2 mL/kg twice a week. Rats in the other two groups received intraperitoneal injection of 50% CCl_4 dissolved in castor oil (2 mL/kg) twice a week as described previously[8]. From the third week, rats in GI group were injected intraperitoneally with IL-10 dissolved in saline (4 μg/kg) 20 min before CCl_4 administration as previously described[9]. The intervention lasted to the end of the experiment. In the second stage, 47 SD rats were divided randomly into normal control group 2 (GN_2, n = 6) and CCl_4 group (GZ, n = 41). Rats in the GN_2 group were injected intraperitoneally with saline at a dose of 2 mL/kg, twice a week. Rats in the GZ group received intraperitoneal injection of 50% CCl_4 dissolved in castor oil (2 mL/kg) twice a week. At the end of the 9th week, rats in the GZ group were divided randomly into model group (GM, n = 9), IL-10 treatment group (GT, n = 9) and recovered group (GR, n = 9). Rats in the GM group were injected with CCl_4 continuously: Rats in the GT group received intraperitoneal IL-10 dissolved in saline (4 μg /kg) after injection of CCl_4 for 9 weeks and rats in the GR group were not treated. Three rats in the GN_2 group were executed at the 9th week and the other rats were sacrificed at the 12th week.

Histological examination

In the first stage, at the beginning of the 7th and 11th week, 2 rats from each group were chosen randomly for histological examination. Liver tissues were fixed in 10% formalin and embedded with paraffin. Sections were stained with hematoxylin and eosin (HE) and examined under a light microscope.

Isolation, incubation and identification of HSCs

Isolation, incubation and identification of HSCs were performed as previously described[10]. Briefly, at the beginning of the 7th and 11th week, 5 rats from each group were chosen randomly to perfuse with 0.13% pronase E and 0.025% type-IV collagenase through a portal vein catheter. The liver tissue suspension was incubated with 0.02% pronase E and 0.025% type-IV collagenase under agitation. The suspension obtained from the digested liver tissue was centrifuged with 11% Nycodenz density gradient to purify HSCs. Then, the HSCs were seeded at the concentration of 1×10^6 cells /mL of Dulbecco's modified Eagle's medium (DMEM) supplemented with 20% fetal calf serum in 96-well plates and kept at 37 ℃ in a 50 mL/L CO_2 atmosphere for 72 h. The HSCs were identified by their typical phase-contrast microscopic appearance and immunocytochemistry using antibody directed against desmin. Cell vitality was checked by trypan-blue exclusion.

RNA extraction and RT-PCR

Total RNA was extracted from freshly isolated HSCs and liver tissues according to the instructions of the RNA isolation kit (Jingmei Biotechnology Company, Shenzhen). Its quantity and purity were assessed by measuring the optical density at 260 nm and 280 nm. After measurement of RNA amount, samples were either used immediately for RT or stored at -70 ℃.

For RT, 1 μg total RNA was transcribed following the instructions of the first strand cDNA synthesis kit (Jingmei Biotechnology Company, Shenzhen). Twenty μL reaction mixture was transcribed at 42 ℃ for 60 min, at 99 ℃ for 5 min and stored at -20 ℃.

For PCR, primers coding for the house-keeping gene-β-actin were added into the reaction mixture to standardize the results. Fifty μL aqua was added into the reactive system containing 2 μL cDNA, 5 μL 10×buffer, 5 μL 25 mmoL/L $MgCl_2$, 1 μL 10 mmoL/L dNTP, 1 μL 20 mmoL/L up stream and down stream primer of target gene, 1 μL 20 mmoL/L β-actin primer pairs, 3U Taq DNA polymerase. Then PCR was performed with predenaturation at 94 ℃ for 5 min followed by 30 cycles at 94 ℃ for 45 s, at 55 ℃ for 30 s, at 72 ℃ for 60 s and a final extension at 72 ℃ for 7 min. Primers were designed according to the reference of GenBank (Table 1). PCR products were immediately analyzed by 20 g/L agarose gel electrophoresis and the density of resultant bands was semi-quantified by scanning densitometry using the ratio of TGF-β1 to β-actin to assess the relative level.

Table 1 Primer sequences used in the study

mRNA	Upstream primer	Downstream primer	Product length (bp)
TGF-β1	CTC TGC AGG CGC AGC TCT G	GGA CTC TCC ACC TGC AAG AC	392
β-actin	CCA ACC GTG AAA AGA TGA CC	CAG GAG GAG CAA TGA TCT TG	660

Immunocytochemistry

Most of HSCs attached to the dishes after 72 h of primary culture. The 96-well plates were washed twice with 0.1 moL/L PBS and cells were fixed with poly-formaldehyde at 4 ℃ overnight. The following procedures were performed according to the instructions of streptavidin/peroxidase (S-P) kit (Beijing Zhongshan Company). Briefly, cells were washed with PBS, incubated with bovine serum albumin in PBS, reacted with primary antibody dissolved in PBS, washed, incubated with peroxidase-conjugated second antibody, washed again and reacted with S-P for 20 min. Color reaction was developed by incubation with DAB. In negative controls, the primary antibody was replaced by PBS.

Immunohistochemistry of hepatic TGF-β1

After dewaxed with xylene and rehydrated through a graded alcohol series, sections were digested with 4 g/L trypsin. The following procedures were similar to the steps of immunocytochemistry. Slides were then analyzed with an image analyzing system to obtain the relative contents of hepatic TGF-β1. The characteristics of the antibodies used in this study are summarized in Table 2.

Table 2 Antibodies used for immunocytochemistry and immunohistochemistry

Antibody	Type	Source	Working solution
Desmin	Polyclonal, mouse	Beijing Zhongshan Co.	1:100
TGF-β1	Polyclonal, rabbit	BOSTER Co.	1:20/1:25
Antibody to rabbit IgG	Goat	Beijing Zhongshan Co.	Ready to use
Antibody to mouse IgG	Goat	Beijing Zhongshan Co.	Ready to use

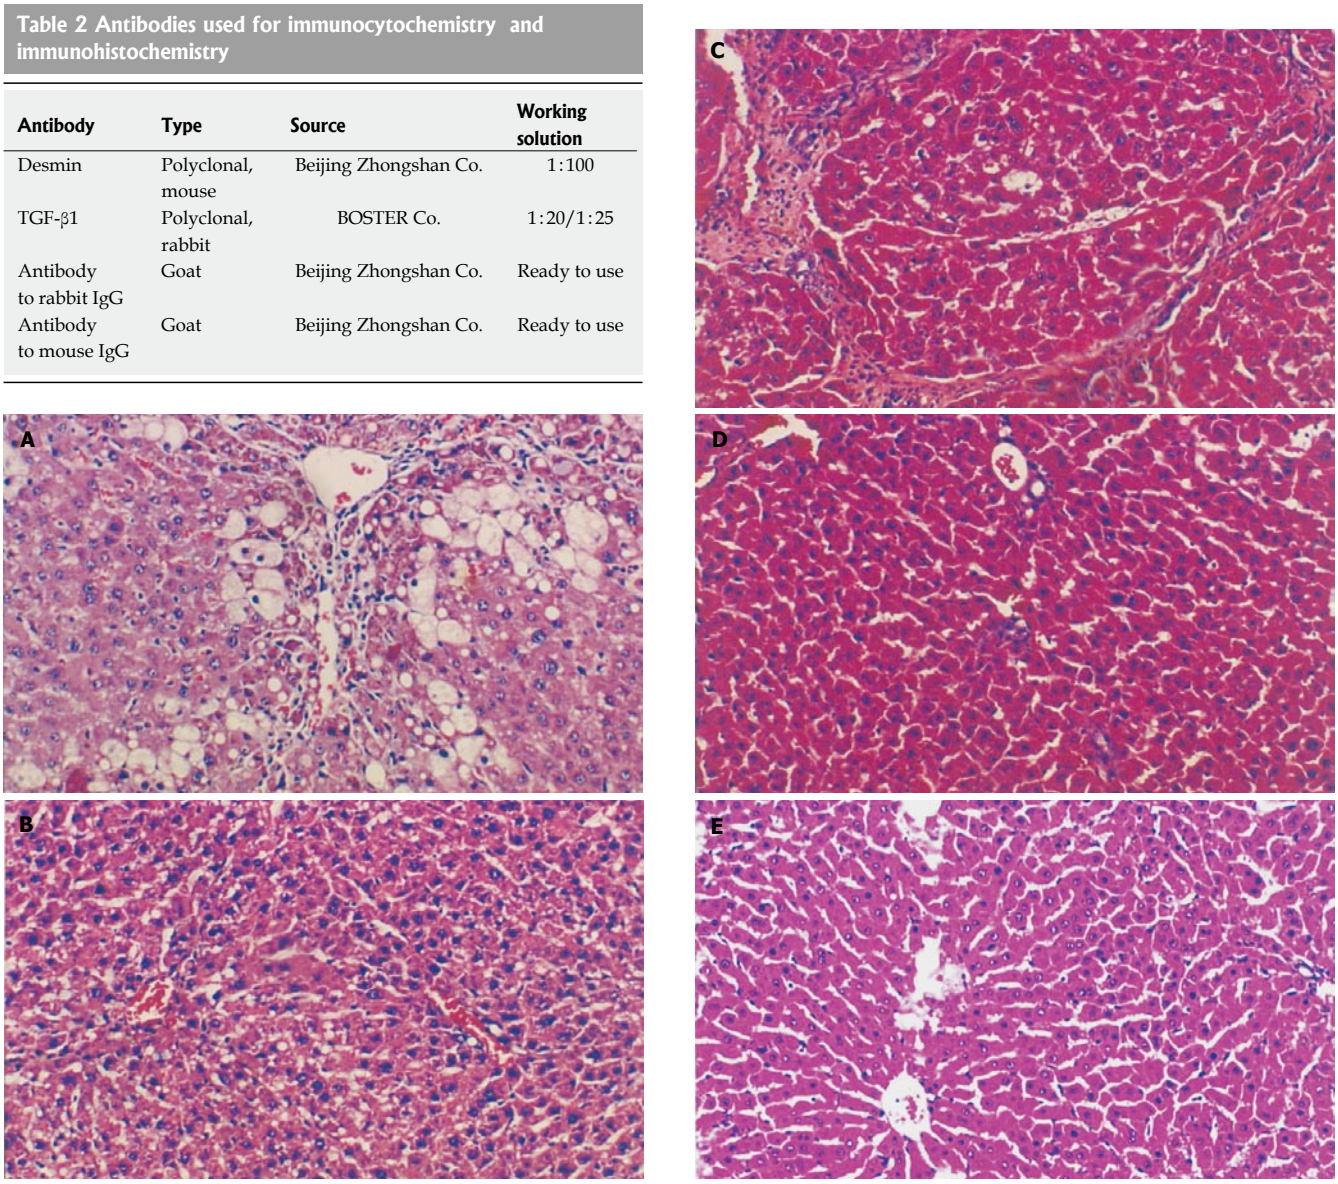

Figure 1 Effect of IL-10 on liver histological change in group C at the 7th wk (**A**), group I at the 7th wk (**B**), group C at the 11th wk (**C**), group I at the 11th wk (**D**), and group N (**E**).

ELISA of serum TGF-β1

Assay of serum TGF-β1 content was performed with double antibody ABC-ELISA method according to the ELISA kit instructions (Maoyuan Science Technology Limited Company, Shanghai).

Statistical analysis

All data were expressed as mean±SE. The significance for the difference between the groups was studied with SPSS11.0 by one-way ANOVA. $P < 0.05$ was considered statistically significant.

RESULTS

Histological examination

Hepatic fibrosis became remarkable after the treatment with CCl_4. At the 7th wk, specimens from the GC group showed steatosis and ballooning degeneration, the collagen fibers increased and began to extend to the parenchyma, many mononuclear cells and unusual neutrophils surrounded the centrilobular veins and fibrotic septa (Figure 1A), while only a few inflammatory cells infiltrated around the centrilobular veins without evident changes of lobular structure in the GI group (Figure 1B). At the 11th week, the reticular fiber extended into the hepatic plate and full delimitation was developed (Figure 1C), while less fibrosis septa and inflammatory infiltration were seen in the GI group (Figure 1D). Specimens from the GN_1 group showed normal lobular structure (Figure 1E). Due to the limit of samples, no statistical data presented disparity between the two groups, but fibrogenesis in the GI group was much less severe than that in the GC group.

Isolation and identification of HSCs

A total of $2–4.5\times10^7$ cells were harvested from each rat. HSCs were identified by immunoreaction with desmin (Figure 2). The mean purity of freshly isolated HSCs was 95% ± 5%. The cell vitality checked by trypan-

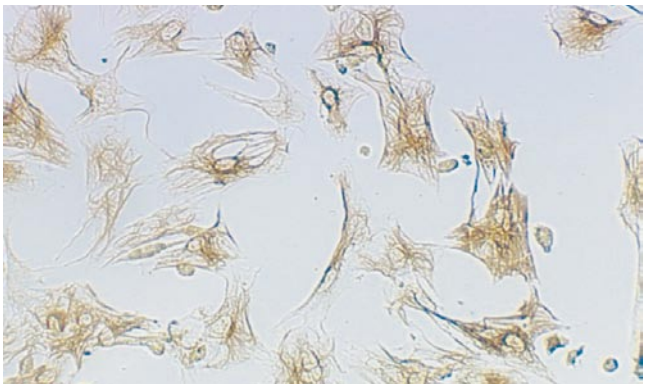

Figure 2 Desmin expression in freshly isolated HSCs (SP × 100).

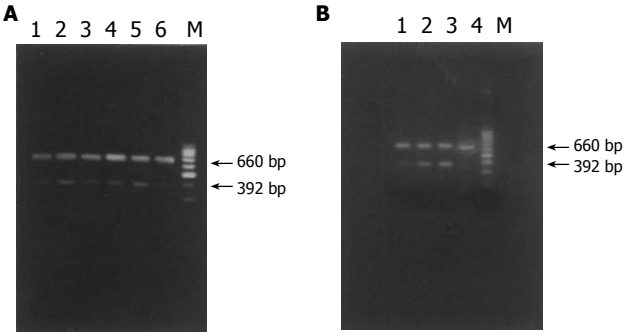

Figure 3 Expression of TGF-β1 in HSCs the first (**A**) and the second stage (**B**).

blue exclusion was higher than 95%.

Expression of mRNA

The purity of RNA was determined by the ratio of OD260 and OD280 ranging between 1.8-2.0. In the first stage, at the 7th and 11th wk, TGF-β1 mRNA in the GC group increased obviously compared to the GN_1 and GI groups ($P < 0.01$), but no difference was seen between the two groups. TGF-β1 expression at the 7th wk was higher than that at the 11th wk ($P < 0.05$, Table 3, Figure 3A). In the second stage, TGF-β1 mRNA in the GM group increased notably compared to the GN_2 group ($P < 0.01$) and declined obviously after treatment with IL-10 ($P < 0.01$). Its expression in the GR group was lower than that in the GM group ($P < 0.01$) but still higher than that in the GT group ($P < 0.05$, Table 4, Figure 3B).

Immunocytochemistry and immunohistochemistry

In the first stage, TGF-β1 positive expressions were localized in cytoplasm and nuclei of HSCs in all groups by immunocytochemistry after 72 h of primary culture. Most of the cells attached to and spread over the plastic substratum. At the 7th wk, the size of HSCs in the GC and GI groups was a little larger than that in the GN_1 group. At the 11th wk, cell phenotype in the GI group showed circle or ellipse and was a little smaller than that in the 7th wk, no obvious change of phenotype was seen in the GC group. Although the number of samples was limited, the expression of TGF-β1 in the GC group was higher than that in the GN_1 group and decreased after treatment with IL-10 (Figures 4A-4D). In the second stage, TGF-β1 positive expressions in the GM group were localized in most

of the liver tissues, appearing brown. After treatment with IL-10, the distributing area was smaller and the color was lighter. TGF-β1 expression in the GR group was lower than that in the GM group but still higher than that in the GT group (Table 4, Figures 5A-5D).

Expression of serum TGF-β1

The expression of serum TGF-β1 detected by ELISA in different groups had the same tendency as that detected by RT-PCR and immunohistochemistry in the second stage (Table 4).

DISCUSSION

Although significant progress has been made in understanding the pathogenesis of hepatic fibrosis, a rational therapy that prevents the progression or even reverses fibrosis remains elusive[11-13]. IL-10 is produced mainly by TH_2 cells and inhibits the functions of TH_1 cells. It down-regulates pro-cytokines synthesis and is associated with amelioration of the inflammatory response[14-16] and fibrosis[17-18]. The present study also found the trend from the pathological sections that IL-10 could relieve the degree of inflammation. In this experiment, we detected TGF-β1 in hepatic fibrosis group as well as in IL-10 treatment group.

TGF-β1 is a multi-functional cytokine in the liver involved in regulation of liver growth and induction of hepatocyte apoptosis, and is the most important medium involved in fibrotic and cirrhotic liver[19-22]. It can promote the development of liver fibrosis by inducing the synthesis of ECM proteins and down-regulating the expression of matrix, thus degrading enzymes and stimulating synthesis of their respective inhibitors[23-26]. The present study showed that, with the development of hepatic fibrosis, TGF-β1 increased in hepatic fibrosis rats and decreased after treatment with IL-10. TGF-β1 mRNA level in HSCs did not run parallel with the progression of hepatic fibrosis in the first stage. TGF-β1 protein level detected by immunohistochemistry and ELISA in IL-10 treatment group was lower than that in normal control group in the second stage. These results suggest that TGF-β1 is closely correlated with hepatic fibrosis and that the improvement of hepatic fibrosis is related with the decreasing expression of TGF-β1. These results also suggest that the expression of TGF-β1 of HSCs cannot be regarded as a predictable factor for the degree of hepatic fibrosis and that the ability of HSCs to produce TGF-β1 is declined when fibrosis develops. While the results of ELISA proved that IL-10 exerted its inhibitory effects on the expression of TGF-β1 not only in liver but also in serum, suggesting that IL-10 can inhibit the expression of TGF-β1. However, further studies are needed to confirm whether the expression of TGF-β1 in normal liver inhibited by IL-10 has any adverse effects and whether the effect of IL-10 on TGF-β1 is modulated by weakening the signal transduction.

Abstract

AIM: To analyze the biological role of the surface antigen of *Toxoplasma gondii (T gondii)* in development of vaccine.

METHODS: The surface antigen of *T gondii* (SAG1) was expressed *in vitro*. The immune response of the host to the antigen was investigated by detection of specific antibody reaction to SAG1 and production of cytokines. Mice were immunized with recombinant SAG1 and challenged with lethal strain of *T gondii* RH. The monoclonal antibody to r-SAG1 was prepared and used to study the effects of SAG1 on *T gondii* tachyzoites under electromicroscope.

RESULTS: The mice immunized with recombinant SAG1 delayed death for 60 h compared to the control group. The recombinant SAG1 induced specific high titer of IgG and IgM antibodies as well as IFN-γ, IL-2 and IL-4 cytokines in mice. In contrast, IL-12, IL-6 and TNF-α were undetectable. When *T gondii* tachyzoites were treated with the monoclonal antibody to r-SAG1, the parasites were gathered together, destroyed, deformed, swollen, and holes and gaps formed on the surface.

CONCLUSION: SAG1 may be an excellent vaccine candidate against *T gondii*. The immune protection induced by SAG1 against *T gondii* may be regulated by both hormone- and cell-mediated immune response.

Key words: *Toxoplasma gondii;* Recombinant SAG1; Monoclonal antibody; Cytokines; Morphology change

INTRODUCTION

Toxoplasma gondii (T gondii) is an intracellular coccidian parasite and causes the most common parasitic disease of animals and human beings[1]. The definitive hosts for the parasite are members of the Felidae family. The clinical manifestations associated with feline toxoplasmosis are anorexia, weight loss, lethargy, dyspnoea, ocular signs, pyrexia, vomiting and diarrhea, jaundice, myositis and abortion. Humans become infected when they ingest the Toxoplasma at infective stages (oocysts and tissue cysts) found in some cat feces and in raw meats. People weak in immune function may develop severe diseases such as encephalitis, pneumonia or other life-threatening conditions. Infants born with congenital toxoplasmosis may develop permanent diseases such as mental retardation or eye, liver and brain diseases. In cirrhotic patients, Toxoplasma IgG and IgM antibody positivity is as high as 68.5%[2]. In patients with AIDS, *T gondii* colitis can occur[3]. In veterinary medicine, *T gondii* infection may influence economics due to neonatal loss in sheep and goats[4], or as a source of transmission to humans[5]. Thus, it is of great value to develop an effective vaccine against *T gondii*.

The characterization of the molecules which play the role in the pathogenesis and immune protection is the important step in vaccine development. The surface of *T gondii* is the first component to contact with the host cells and the surface antigen of the parasite is recognized as the major study target. It was reported that there are 5 proteins in the superfamily of the surface antigens (SAG) of *T gondii*, including SAG1, SAG2 (22 Ku), p23, p35, and SAG3 (43 Ku). SAG1 is a 30 Ku glycoprotein and is therefore designated as SAG1/P30[6] and can be detected in the tachyzoite and sporozoite stages[7,8]. It was reported that SAG1 can elicit a lethal inflammatory process in mouse model of pathogen-driven ileitis[9]. However, the biological role of this surface protein remains unclear.

In the current study, the biological function of SAG1 was studied through the analysis of the induction of specific antibody, elicitation of specific cytokines by the recombinant protein for SAG1 (r-SAG1 or r-P30) of *T gondii*. The immune protection ability of SAG1 was studied by challenging experiments. The results show that SAG1 is a very important protein and its biological function is regulated by multiple mechanisms.

MATERIALS AND METHODS

Parasites and antigens

T gondii RH tachyzoites were maintained by two weekly passages of tachyzoites to peritoneum of BALB/C mouse. Four days later parasites in the peritoneal fluid were collected and the cavity was washed with 5 mL of phosphate buffered saline (PBS). The total tachyzoite crude antigen was obtained from washed and pelleted tachyzoites, resuspended in PBS and freeze-thawed three times, then subjected to 2 cycles of ultrasound disruption (UTR200) for 10 min and incubated at 37 ℃ for 2 h with 1% decanoyl-N-methylglucamide (MEGA 10, Sigma). After centrifugation at 36 000 r/min for 30 min, the pellet was discarded and the supernatant was aliquoted and stored at -70℃. The protein concentration was determined by BCA assay (Pierce) using BSA as standard.

Cloning and expression of SAG1 gene in E. coli

About 5×10^7 *T gondii* RH strain tachyzoites were concentrated by centrifugation, washed with PBS, then lysed in 0.1 mol/L Tris-HCl (pH 8.0) containing 1% sodium dodecyl sulphate (SDS), 0.1 mol/L NaCl and 10 mmol/L EDTA and then treated with proteinase K (100 μg/mL) at 55℃ for 2 h. The genomic DNA was extracted by phenol/chloroform method followed by ethanol precipitation. After centrifugation the pellet was dissolved in TE buffer (10 mmol/L Tris-HCl, pH 8.0 and 1 mmol/L EDTA) and used as a template for polymerase chain reaction (PCR) amplification, which used the primers (5' TGGtttcactcttaagtgccctaaaacagc-3'and 5' ctgcattaacctgc agccccggcaaactc-3') together with PCR buffer, dNTP and Taq polymerase. The amplified SAG1 gene was inserted into the *Nco*I and *Hind*III sites of the plasmid pET-30a, and expressed as a His-tag fusion protein in *E. coli* BL21 (DE3) strain according to the manufacturer's instructions. The transformed bacteria were centrifuged and lysed by a combination of detergent Triton X-100, lysozyme and ultrasonication. The suspension was centrifuged and the pellet was dissolved in 8 mol/L urea solution containing 50 mmol/L Tris-HCl (pH 8.0), 1 mmol/L dithiothreitol (DTT) and 1 mmol/L EDTA. One hour after incubation at room temperature (RT), the supernatant was contrifuged and dialyzed at 4℃ followed by 2 mol/L urea solution at 4℃ for 1 h each. Dialysis was done twice in 50 mmol/L Tris-HCl (pH 8.0) with 1 mmol/L DTT at 4℃ and each lasting for 1 h. This was followed by overnight dialysis at 4℃ in the same buffer. The dialyzed sample was centrifuged and the supernatant was recovered and used as antigen.

Immunization and challenge

Five to 7-wk-old female BALB/c mice (purchased from Shandong University) housed under approved conditions of the animal research facility, were used in this study. Twenty-one BALB/c mice were immunized at two locations at the base of the tail with 30 μg of *T gondii* recombinant SAG1 in 0.1 mL of saline, which was emulsified with an equal volume of complete Freund's adjuvant (CFA) (Sigma, USA). Sixteen mice were injected with PBS. Booster was done 2 wk after the first injection using Freund's incomplete adjuvant for the r-SAG1 group. Sera were collected at 3 wk post immunization for antibody test. For cytokine test, mice were killed at 6 wk post immunization. The mice inoculated with r-SAG1 of *T gondii* were challenged intraperitoneally with 1×10^5 tachyzoite forms of *T gondii* RH strain 9 wk after the first immunization.

ELISA

To measure antigen-specific antibodies, plates were coated overnight at 4℃ with 10 μg/mL solution of antigen in 0.05 mol/L potassium phosphate buffer pH 8 (50 μL per well). Blocking was carried out with 2% BSA in PBS (pH 7.2) for 2 h at RT. After washed with PBS containing 0.05% Tween 20 (PBST20), sera were diluted in 1% BSA-PBST20 (50 μL per well) and incubated for 1 h at RT. After washed, bound antibodies were detected by incubation at RT for 1 h with horseradish peroxidase-labeled goat anti-mouse immunoglobulins at 1:2 000 dilution in 1% BSA-PBST20 (50 μL per well). Peroxidase activity was revealed by adding 50 μL per well of a solution containing 12.5% H_2O_2, 0.1 mol/L citrate-phosphate pH 4 and 10 mg/mL of TMB. The reaction was stopped by adding 50 μL of 2 mol/L H_2SO_4 and the absorbance (A) was read at 450 nm in an ELISA microplate reader (Bio-Rad, USA). A sample was considered positive when A > A mean + 3 SD (cut off), where A is that of the tested sample, and A mean and SD are the mean and the standard deviation of the A of the sample from PBS, respectively.

SDS-PAGE and immunoblotting

SDS-PAGE was performed on 12% polyacrylamide gels according to the procedure of Laemmli[10] using a total tachyzoite extract or r-SAG1. Gels were transferred to nitrocellulose membranes as previously described[11] and blocked in PBS containing 5% nonfat dry milk. Membranes were incubated with primary Abs and then with anti-species alkaline phosphatase conjugates, both were diluted in PBS containing 1% nonfat dry milk. The alkaline phosphatase activity was detected with the ProtoBlot nitroblue tetrazolium and 5-bromo-4-chloro-3-indolyl phosphate color development system (Promega, Madison, WI).

Cytokine determination

At 6 wk post immunization, mice were sacrificed and single-cell suspension was prepared as previously described[12]. A volume of 10 μg/mL of r-SAG1 of *T gondii* was added and the supernatants were collected from cultures after 72 h and assayed by ELISA for cytokines.

The monoclonal antibody (mAb) was used for assay of IL-6 (MP5-20F3), IL-2 (JES6-1A12), IL-12 (9A5), IL-4 (BVD4-1D11), TNF-α (TN3-19.12), IFN-γ (AN-18) (BD Pharmingen).

Preparation of monoclonal antibodies

Monoclonal antibodies against recombinant SAG1 of *T gondii* were obtained by fusion of SP2/0 myeloma cells with the spleen cells of BALB/c mice immunized with r-SAG1 in the presence of polyethylene-glycol (Sigma) according to standard protocols. Hybrid cells were cultured in hypoxantine, aminopterin and thymidine (HAT) in DMEM/20% FBS medium. Clones growing in selected media were expanded and tested for antibody production. Positive clones were cloned twice by limiting dilution. Hybridomas were screened for specific antibody production by ELISA and immunoblot against the *T gondii* antigen. The identification of mAb isotype was made by ELISA using goat anti-mouse IgG subclasses (Nordic) appropriately diluted in PBS containing 0.1% Tween-20, 2% normal goat serum, followed by incubation with alkaline phosphatase conjugated rabbit anti-goat IgG (Sigma). Hybrid cells producing mAbs were injected to mouse intraperitoneally and after 2 wk ascites fluid was collected.

Electron microscopy

T gondii strains were harvested from BALB/C mice and washed twice with 0.05 mol/L pH7.2 PBS. The ascites fluid mAb against r-SAG1 was added (1:100) to the parasites. After incubation at 37℃ for 1h, the parasites were washed 3 times with PBS and fixed in 4% paraformaldehyde, 0.05% glutaraldehyde in cacodylate buffer+3% sucrose for 2 h at RT. After dehydration and embedding, the slides were observed under electron microscope (Hitachi 600, Hitachi, Japan).

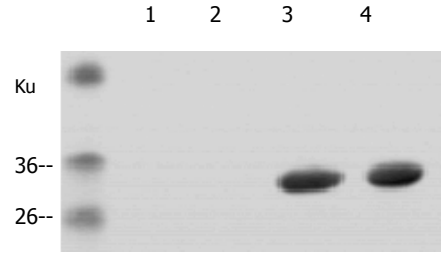

Figure 1 A strong band at 30 ku position after reaction with serum from mice infected with T. r-SAG1 of *Toxoplasma gondii* tachyzoites. The band was electrophoresed on SDS-12% polyacrylamide gel and then transferred onto a nitrocellulose membrane probed with sera (diluted at 1:100) from PBS-inoculated mice (lanes 1 and 2) or from mice infected with crude antigens of *T. gondii* (lanes 3 and 4). Bound antibodies were detected using anti-mouse-alkaline phosphatase conjugate. The positions of molecular masses are shown on the left.

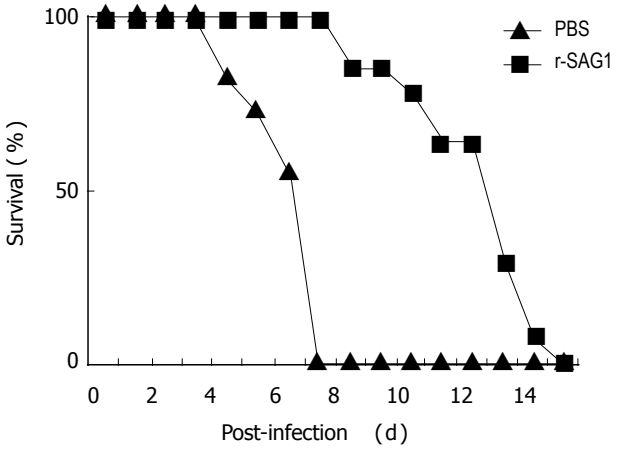

Figure 2 Protection of r-SAG1 against infection with tachyzoites of *Toxoplasma gondii*. Sixteen BALB/C mice were immunized with r-SAG1 of *T. gondii* and 11 mice were injected with PBS as a control. The mice were challenged with $1X10^5$ tachyzoites of *Toxoplasma gondii* RH at 9 wk post immunization. The number of the dead mice was counted.

RESULTS

Characterization of SAG1 recombinant protein

To study the biological function of the *P30* gene encoding SAG1, the *P30* gene of *T gondii* RH strain was amplified by PCR, the PCR product was subcloned into bacterial expression vector pET-30a and SAG1 was expressed as Histidin-fusion protein in *E. coli*. The gene was sequenced and the recombinant SAG1 was analyzed by Western blotting. A strong band at 30 Ku position was found after reaction with serum from mice infected with *T gondii* (Figure 1), indicating that the *P30* gene could encode a functional protein.

Immunization with r-SAG1 protein could protect mice from a lethal T gondii challenge

To test whether r-SAG1 could afford protection against a lethal *T gondii* RH strain infection, BALB/c mice were immunized with r-SAG1 as described in the methods. Nine weeks after the first injection, the animals were intraperitoneally infected with 1×10^5 tachyzoites of the highly virulent RH strain. The death number of the mice was counted after challenge. It was found that after challenge with RH tachyzoites, mice started to die on day 4 in PBS-inoculated control group. On day 7, all the mice in control group were dead. However, mice immunized with r-SAG1 delayed death for 60 h compared to those in the control group (Figure 2).

r-SAG1 induced specific antibody response

To investigate whether r-SAG1 could induce humoral immune response, the sera from mice were collected 3 wk after the last immunization. The titer and classes of immunoglobulin were tested by ELISA. It was obvious that vaccination of the mice with r-SAG1 induced a strong antibody response. The highest reaction antibody was immunoglobulin G (IgG). IgM was detected with a lower titer than that of IgG. IgA antibody response to r-SAG1 was very weak (Figure 3).

To test the specificity of the reaction of the antigen and antibody, the crude antigen of *T gondii* tachyzoites was separated on 12% SDS-PAGE and reacted with one of the mouse sera immunized with r-SAG1 by Western blotting.

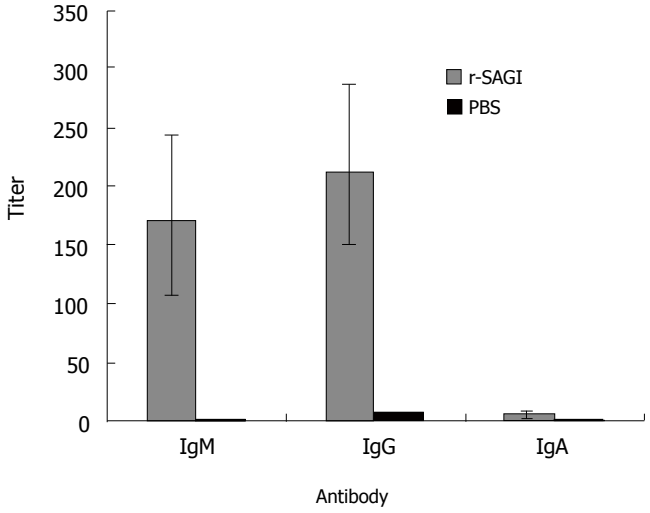

Figure 3 Antibody responses to r-SAG1. BALB/C mice were immunized with 30 μg r-SAG1 of *T gondii* or with PBS as a control. Booster was done with Freund's incomplete adjuvant 2 wk after the first injection. Three weeks post-immunization, sera were collected from 5 mice of each group. Antibodies were tested individually by ELISA.

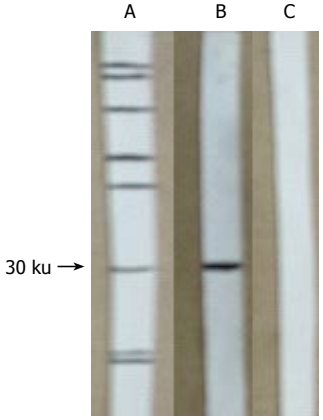

Figure 4 Profile of cytokines induced by r-SAG1 in PBS-inoculated mice (**A**) or r-SAG1 of *T gondii* immunized mice (**B**). Crude antigens of Toxoplasma gondii tachyzoites were electrophoresed on SDS-12% polyacrylamide gel and then transferred onto a nitrocellulose membrane probed with sera (diluted at 1:100). Bound antibodies were detected using anti-mouse-alkaline phosphatase conjugate. The positions of molecular masses are shown on the left.

A strong band was present on the 30 Ku position (Figure 3), corresponding to the predicted size from amino acid sequence.

Profile of cytokines induced by r-SAG1

To investigate the possibility of cell immune response induced by r-SAG1, the spleens of the mice immunized by r-SAG1 were isolated and the cytokines in the spleen cell suspensions were detected by ELISA. Compared to the control group, the spleen cells from r-SAG1-vaccinated BALB/c mice produced significant high levels of IFN-γ, IL-2 and IL-4, while IL-12, IL-6 and TNF-α were undetectable in splenocyte supernatants from all experimental and control animals analyzed (Figure 4).

Morphology change of T. gonddi tachyzoites caused by r-SAG1 antibody

To further elucidate the biological function of r-SAG1, monoclonal antibodies against r-SAG1 were prepared. Two specific clones against r-SAG1 were obtained and

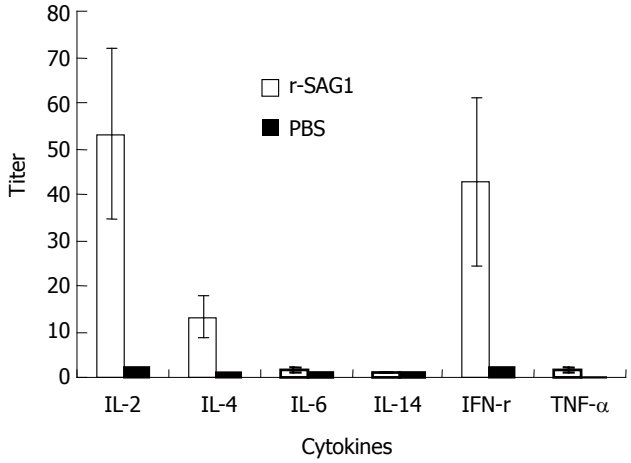

Figure 5 Production of cytokines induced by r-SAG1. BALB/C mice were immunized with r-SAG1 of *T gondii* or with PBS as a control. Six weeks after immunization, cytokines were tested individually by ELISA in 5 mice of each group.

designated as mAb2B3 and mAb1H6, respectively. Both clones were IgM isotype. The antibody produced a specific band at 30 Ku in Western blotting with *T gondii* crude antigens and r-SAG1 antigen.

To study the morphology effects of r-SAG1 antibody on *T gondii*, *T gonddi* tachyzoites were treated with specific antibody mAb2B3 and the morphology was observed under electron microscope. Compared to the PBS-treated control group, *T gondii* tachyzoites were gathered together and some tachyzoites were destroyed, some parasites were deformed(Figure 5). The holes and gaps on the surface of tachyzoites as well as the swollen parasites were observed (Figure 6).

DISCUSSION

In the current study, the recombinant protein for SAG1 of *T gondii* was prepared and the biological function of SAG1 was studied through the investigation of the lethal protection of mice. The possible mechanism was studied by the observation of the induction of specific antibody, elicitation of specific cytokines and the reaction of SAG1 specific antibody with *T gondii* tachyzoites. The study showed that SAG1 elicited a strong immune protective reaction which might be controlled by multiple mechanisms.

This study showed that the mice immunized with r-SAG1 delayed death for 60 h when challenged with *T gondii* RH tachyzoites, demonstrating that SAG1 is an important antigen of *T gondii*. The protection of the host against organism infection may involve many factors including specific antibody. It was reported that antibodies can regulate toxoplasma tachyzoites and thereby promote their killing by normal macrophages[13]. Kang *et al*[14] have proved that antibodies can block infection of host cells. In addition, antibodies in the presence of complement can kill extracellular toxoplasmas[15]. In the present study, the morphology changes of the parasite, such as agglutination, deformation, swelling hole and gap formation on the

Figure 6 Effects of monoclonal antibody to r-SAG1 on tachyzoites of *Toxoplasma gondii*. **A:** Agglutination of the parasites, hole and gap formation on the surface, destroyed parasites and membrane thickness; **B:** Deformed parasite; **C:** Swollen parasites. *Toxoplasma gondii* tachyzoites were collected from mice and washed with PBS. Monoclonal antibody mAb2B3 to r-SAG1 from mouse ascites fluid was diluted and reacted with the parasites and observed under electro-microscope at 6800 x.

surface, corresponding to SAG1 antibody treatment indicated that antibody might play an important role in the protection. The inference was verified further by the specific antibody production following the immunization of r-SAG1. After three weeks of vaccination with r-SAG1, high titer specific IgG and IgM were detected and the high titer of the antibodies was detected (data not shown). IgM antibodies could persist for at least 50 d and IgG could persist for an even longer time[16]. Therefore, when the mice were challenged at 9 wk, both IgG and IgM could contact with parasites to destroy the parasites, inhibit the infection of host cells, and thereby protect the mice from death.

In this study, the expression of cytokines such as IFN-γ, IL-4 and IL-2 was up-regulated in SAG1 immunized mice compared with control group. It was reported that IFN-γ induces inflammatory responses, thus limiting parasite proliferation[17]. In patients with alveolar echinococcosis, IFN-γ is higher, which might play a role in immunological defense against the parasite infection[18]. IL-2 (-/-) mice are unable to generate a protective IFN-γ response following infection with *T gondii* while IL-2 (-/-) mice have an intrinsic defect in their ability to activate and expand IFN-γ, producing T cells required for resistance to *T gondii*[19]. The production of IL-4 and IFN-γ allows identification of the Th0, Th1, or Th2 orientation of helper T cell clones. The production of antigen-specific cytokines suggests that SAG1 is able to elicit anti-SAG1 specific CD4+T-cells. Cell immune response is involved in the protection of the parasites. In addition, IFN-γ producs CD8+CTL which plays a prominent role in controlling *T gondii* infection[20]. It is possible that at least part of the detected IFN-γ can lead to CD8+CTL activation. However, further experiments are required to elucidate this question.

In conclusion, SAG1 induces dominant antibody response and a strong Th1-like T cell response characterized by high titer IFN-γ production during infection. The protective role of SAG1 may be controlled cooperatively by humoral and cellular immune response. The evidence of SAG1 protection against challenge of the parasite proves that SAG1 is a good vaccine candidate for the control of toxoplasmosis.

Abstract

AIM: To investigate the effects of filtrate of fermented mycelia from *Antrodia camphorata* (FMAC) on liver fibrosis induced by carbon tetrachloride (CCl_4) in rats.

METHODS: Forty Wistar rats were divided randomly into control group and model group. All model rats were given 200 mL/L CCl_4 (2 mL/Kg, po) twice a week for 8 wk. Four weeks after CCl_4 treatment, thirty model rats were further divided randomly into 3 subgroups: CCl_4 and two FMAC subgroups. Rats in CCl_4 and 2 FMAC subgroups were treated with FMAC 0, 0.5 and 1.0 g/kg, daily via gastrogavage beginning at the fifth week and the end of the eighth week. Spleen weight, blood synthetic markers (albumin and prothrombin time) and hepatic malondialdehyde (MDA) and hydroxyproline (HP) concentrations were determined. Expression of collagen I, tissue inhibitor of metalloproteinases (TIMP)-1 and transforming growth factor β1 (TGF-β1) mRNA were detected by RT-PCR. Histochemical staining of Masson's trichrome was performed.

RESULTS: CCl_4 caused liver fibrosis, featuring increased prothrombin time, hepatic MDA and HP contents, and spleen weight and decreased plasma albumin level. Compared with CCl_4 subgroup, FMAC subgroup (1 g/kg) significantly decreased the prothrombin time (36.7 ± 7.2 and 25.1 ± 10.2 in CCl_4 and FMAC groups, respectively, $P < 0.05$) and increased plasma albumin concentration (22.7 ± 1.0 and 30.7 ± 2.5 in CCl_4 and FMAC groups, respectively, $P < 0.05$). Spleen weight was significantly lower in rats treated with CCl_4 and FMAC (1 g/kg) compared to CCl_4 treated rats only (2.7 ± 0.1 and 2.4 ± 0.2 in CCl_4 and FMAC groups, respectively, $P < 0.05$). The amounts of hepatic MDA and HP in CCl_4 ± FAMC (1 g/kg) subgroup were also lower than those in CCl_4 subgroup (MDA: 3.9 ± 0.1 and 2.4 ± 0.6 in CCl_4 and CCl_4 + FMAC groups, respectively, $P < 0.01$; HP: 1730.7 ± 258.0 and 1311.5 ± 238.8 in CCl_4 and CCl_4 + FMAC groups, respectively, $P < 0.01$). Histologic examinations showed that CCl_4 + FMAC subgroups had thinner or less fibrotic septa than CCl_4 group. RT-PCR analysis indicated that FMAC (1 g/kg) reduced mRNA levels of collagen I, TIMP-1 and TGF-β1 (collagen I: 5.63 ± 2.08 and 1.78 ± 0.48 in CCl_4 and CCl_4 + FMAC groups, respectively, $P < 0.01$; TIMP-1: 1.70 ± 0.82 and 0.34 ± 0.02 in CCl_4 and CCl_4 + FMAC groups, respectively, $P < 0.01$; TGF-β1:38.03 ± 11.9 and 4.26 ± 2.17 in CCl_4 and CCl_4 + FMAC groups, respectively, $P < 0.01$) in the CCl_4-treated liver.

CONCLUSION: It demonstrates that FMAC can retard the progression of liver fibrosis induced by CCl_4 in rats.

INTRODUCTION

Antrodia camphorata is a new species of the genus *Antrodia* (*Polyporaceae*) parasitic in the inner cavity of the endemic species *Cinnamomum kanehirai* Hay[1]. Traditionally, it has been used as a remedy for food-, alcohol-, drug-intoxication, diarrhea, abdominal pain, hypertension, skin itching, and liver cancer among Chinese. The growth rate of natural *A. camphorata* in the wild is very slow, and it is difficult to cultivate in a green house, thus, it is expensive to obtain fruiting bodies. Therefore, using a submerged culture method to obtain useful cellular materials, or to produce effective substances from cultured mycelia might be a possible way to overcome the disadvantage of the retarded growth of fruiting bodies. In Taiwan, several biotechnology companies have developed the submerged culture method for *A. camphorata*. In the market of Taiwan, the yield of mycelia or culture filtrate of fermented mycelia

is dependent on the different biotechnology companies. Preliminary pharmacological studies revealed that the antioxidant abilities of the culture filtrate of fermented mycelia from *Antrodia camphorata* (FMAC) were correlated with their total polyphenols content based on the evaluation of different antioxidant system[2].

Liver fibrosis is the common end stage of most chronic liver disease regardless of the etiology[3], and its progression leads to cirrhosis and liver cancer. Although the exact mechanisms of pathogenesis in liver cirrhosis are still obscure, the role of the free radical and lipid peroxides has attracted considerable attention[4]. It has been found that the metabolism of CCl_4 involves the production of free radicals through its activation by drug metabolizing enzymes located in the endoplasmic reticulum[5]. CCl_4 is capable of causing liver lipid peroxidation, resulting in liver fibrosis[6]. Hsiao *et al*[7] reported that *A. camphorata* extract exerted protection against chronic chemical-induced hepatic injury in mice. In addition, Song *et al*[8] showed that FMAC possessed a protective activity against acute liver injury induced by CCl_4. However, the effect of FMAC in chronic liver disease is still unknown. In the present study, we attempted to assess the effect of FMAC on chronic CCl_4-induced liver fibrosis in rats.

MATERIALS AND METHODS

Preparation of test substance

FMAC was provided by Food Industry Research & Development Institute, Hsinchu, Taiwan. Culture of *Antrodia camphorata* BCRC 930032 was inoculated onto potato dextrose agar (PDA) and incubated at 30 ℃ for 15 to 20 d. The whole colony was then cut and put into the bottle with 50 mL sterile water. After homogenization, the fragmentated mycelia suspension was used as inoculum. The seed culture was prepared in a 20 L fermentor (BioTop) agitated at 150 r/min with aeration rate of 0.2 vvm and temperature of 30 ℃. A 5-d culture of 15 L mycelia inoculum was inoculated into a 250 L agitated fermentor (BioTop). The fermentation condition was the same as the seed fermentation but operating with an aeration rate of 0.075 vvm. The deep red culture filtrate was separated from the broth harvested at the 331st hour and poured through the non-woven fabric on a 20-mesh sieve. FMAC was concentrated about 20 fold (450 g/L) under reduced pressure at 50 ℃, and stored at -30 ℃ until use. FMAC was suspended in distilled water and administered orally to each rat at a volume of 10 mL/kg body weight.

Since antioxidant and anti-radical properties of plant extracts have been attributed to most phenolic compounds, it is expected that the effectiveness of the extracts is related to their phenolic content[9]. To guarantee the reproducibility of pharmacological experiments, the phenolic compounds in FMAC were determined by a modification of the method of Barness *et al*[10] using catechin as the standard. The concentration of phenolic groups in FMAC was 39.71 μg/mg.

Animals

Male Wistar rats were obtained from the National Laboratory of Animal Breeding and Research Center, National Science Council, and fed with a standard laboratory chow and tap water *ad libitum*. The experimental animals were housed in air-conditioned room of 21-24 ℃ with 12 h of light. The rats were allowed free access to powdered feed, and main water that was supplied through an automatic watering system. When they reached 250-300 g, the rats were used for experiments. Rats were divided randomly into control and model groups according to the body weight in proper range one day before administration of the test substance. All animals received humane care and the study protocols were in compliance with our institution's guidelines for use of laboratory animals.

CCl_4-induced liver fibrosis

Fibrosis was induced in thirty rats by an oral administration of 2 mL/kg body weight of 200 mL/L CCl_4 (diluted in olive oil) twice a week for 8 wk. At the end of 4 th wk after CCl_4 treatment, the CCl_4-treated rats were further divided into 3 subgroups based on the plasma alanine aminotransferase (ALT) level, since the plasma ALT is the major parameter for liver injury. The plasma ALT levels for normal control and 3 CCl_4-treated subgroups were 675 ± 62, 8856 ± 1321, 9005 ± 1659 and 8208 ± 1324 (nkat/L), respectively. The animals received CCl_4 with distilled water or FMAC (0.5, 1.0 g/kg; *po*, daily) which was added at the last four wk of the treatment. The time interval between CCl_4 and FMAC administrations were 5 h to avoid the disturbance of absorption of each other. After blood was drawn from rats at the eighth week, the animals were sacrificed at the same time and the liver and spleen were quickly taken off. They were then weighed after being clearly washed with cold normal saline and sucked up of the moisture. The largest lobe of liver was divided into four parts, and the same parts were 1) submerged in 40 g/L neutral formaldehyde for the preparation of pathological section; 2) after weighed, the liver was completely dried at 100 ℃ for the determination of collagen content; 3) the samples for RT-PCR analysis were kept in liquid nitrogen; 4) other sample was stored at -80 ℃ until assay.

Assessment of liver functions

The blood was centrifuged at 4700 r/min (Jouan BR4i, France) at 4 ℃ for 15 min to separate the plasma. The levels of plasma ALT and albumin were assayed using clinical test kits (Roche Diagnostics) spectrophotometrically (Cobas Mira; Roche, Rotkreuz, Switzerland). Prothrombin time was measured using a coagulation analyzer (Sysmex-CA1000) and reagent (Dade thromboplastin C plus).

Assays of hepatic lipid peroxidation and hydroxyproline

Livers were homogenized in nine volumes of ice-cold 0.15 mol/L KCl, 1.9 mmol/L ethylenediaminetetraacetic acid. The homogenate was used for the determination of lipid peroxidation. Lipid peroxidation was measured by the methods of Ohkawa *et al*[11] using 2-thiobarbituric acid. The lipid peroxidation was expressed as malondialdehyde (MDA) μmol/g protein. Protein was measured by the method of Lowry *et al*[12] using bovine serum albumin as the standard. Hydroxyproline (HP) determination fol-

lowed a method designed by Neuman *et al*[13]. Dried liver tissue after hydrolysis was oxidized by H_2O_2 and colored by p-dimethylaminobenzoaldehyde and absorbance was determined at 540 nm. The amount of HP is expressed in mg/g wet tissue.

RNA extraction and RT-PCR analysis

Total RNA was isolated from livers of the rats using the acid guanidum thiocyanate-phenol-chloroform extraction methods as described by Chomczynski *et al*[14]. Five micrograms of total RNA from each liver sample were subjected to reverse transcription (RT) by MMuLV reverse transcriptase in a 50 μL reaction volume. Aliquots of the reverse transcription mix were used for amplification by polymerase chain reaction (PCR) of fragments specific to collagen I, transforming growth factor (TGF)-β1 and tissue inhibitor of matrix metalloproteinase (TIMP)-1 using the primer pairs listed in Table 1. The levels of expression of all the transcripts were normalized to that of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA in the same tissue sample. PCR product was run on a 20 g/L agarose gel recorded by polarid film; bands were quantitated by densitometer.

Pathological examinations

For histopathological examination, the formalin-fixed liver was embedded in paraffin, cut into 4-5 μm thick sections, stained with Masson's trichrome. Fibrosis was graded according to the method of Ruwart *et al*[15], grade 0: normal liver; grade (1) increase of collagen without formation of septa; grade (2) formation of incomplete septa from portal tract to central vein (septa that do not interconnect with each other); grade (3) complete but thin septa interconnecting with each other, so as to divide the parenchyma into separate fragments; grade (4) as grade 3, except with thick septa (complete cirrhosis). To avoid sampling error, all biopsies were obtained from the same lobe and these semi-quantitative grades were performed without knowledge of sample treatment.

Statistical analysis

Data were presented as mean ± SD. All other experimental data, except the pathological findings, were treated by one-way analysis of variance using the Dunnett's test. Liver histopathological examination data were analyzed by the Kruskall-Wallis non-parametric test, followed by a Mann–Whitney *U*-test. The significance level was set at $P < 0.05$.

RESULTS

Concentrations of plasma albumin and prothrombin time

The plasma albumin concentrations were lower in rats given CCl_4 than that in the control group (Table 2). While in the rats treated by FMAC (1 g/kg), the levels of plasma albumin was markedly higher than that in the CCl_4 model group. The prothrombin time in the CCl_4 model group was much longer than that in control group. FMAC (1 g/kg) significantly shortened the prothrombin time.

Weights of spleen

Marked splenomegaly was caused by CCl_4 treatment; the weight of spleen in the CCl_4-treated group was about 245% of the control group (Table 3). The increase of spleen weight by CCl_4 treatment was significantly reduced by FMAC (1 g/kg).

Liver MDA and HP contents

CCl_4 induced liver fibrosis to the rats resulting in a marked increase of hepatic MDA and HP contents (Table 3). FMAC (1 g/kg) treatment significantly reduced the increase of hepatic MDA and HP contents caused by CCl_4.

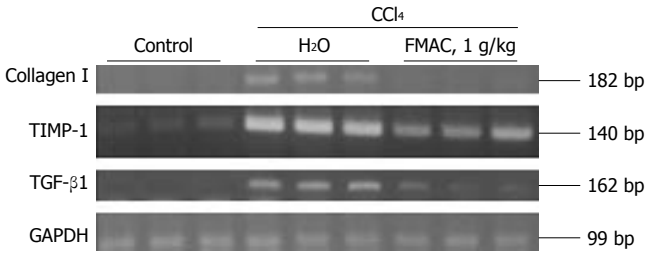

Figure 1 Effect of FMAC on the hepatic mRNA expressions of collagen I, TIMP-1 and TGF-β1 in CCl_4-treated rats.

Table 4 Effect of FMAC on hepatic mRNA expressions of collagen I, TIMP-1 and TGF-β1 in CCl_4-treated rats

RT-PCR analysis of liver tissue

Fragments specific to collagen I, TIMP-1 and TGF-β1 were amplified by RT-PCR (Figure 1). The values from densitometric analysis, after normalization against the corresponding GAPDH transcript were expressed as the collagen I/GAPDH, TIMP-1/GAPDH and TGF-β1/GAPDH ratios. The levels of collagen I, TIMP-1 and TGF-β1 mRNA in rat liver were significantly increased by CCl_4 treatment (Table 4), while the administration of FMAC (1 g/kg) significantly decreased the levels of collagen I, TIMP-1 and TGF-β1 mRNA.

Pathological examination

CCl_4 induced liver damage of the rats. Masson's stain showed clear nodular fibrosis at the central vein and the portal vein area (Figure 2B). Treatment of FMAC (1 g/kg) showed marked improvement of these pathological changes of the tissues (Figure 2C and Table 5).

DISCUSSION

The results of the present study indicate that even after the initiation of hepatic fibrosis in a rat model of CCl_4-induced liver damage, FMAC administration reduced liver fibrosis, as demonstrated by smaller increases in hepatic collagen and lower mRNA expression of collagen I compared with CCl_4 model group. These effects were mainly observed when FMAC was administered from wk 5 to wk 8 of CCl_4 treatment. Both plasma albumin and blood clotting factors were mainly synthesized in the liver. When the chronic liver damage led to fibrosis, the albumin contents dropped and prothrombin time prolonged[16,17]. In this experiment, CCl_4 induced chronic liver lesions in rats and there appeared a decrease of plasma albumin and an increase of prothrombin time. FMAC clearly counteracted both the decrease of albumin content in the plasma and the prolongation of prothrombin time. These results showed that FMAC ameliorated the decline of liver synthetic functions caused by chronic liver injuries.

Liver fibrosis or cirrhosis leads to blockage of blood flow into the liver and causes portal hypertension and it also influences the blood flow of spleen and gives rise to splenomegalia[18]. CCl_4 in this experiment induced chronic

hepatic fibrosis as well as splenomegalia. FMAC could improve splenomegalia, indicating that it might ameliorate portal hypertension.

It is well known that liver fibrosis is a result of increased collagen synthesis[19], and HP is the unique component in collagen[19]. The amount of collagen can be reflected by the contents of HP and can be used to express the extent of fibrosis[19]. When CCl_4 was applied in this experiment to induce liver fibrosis, the content of HP in liver obviously increased. FMAC could reduce the content of HP, which was confirmed by the histopathological examinations. Many studies have shown that level of collagen I increases during liver fibrosis[20]. Therefore, we also investigated the effect of FMAC on the mRNA expression of collagen I. Treatment with FMAC was effective in reducing the amount of collagen I mRNA expression. This result further confirmed that FMAC could remit hepatic fibrosis.

Regardless of the etiologic factors, gross remodeling of extracellular matrix in the fibrotic liver is regulated by a balance of synthesis and enzymatic degradation of extracellular matrix[21]. Matrix degradation is catalyzed by the activity of matrix metalloproteinases. The activities of matrix metalloproteinases are inhibited by tissue inhibitors of metalloproteinases (TIMPs). The expression of TIMPs drastically increased or decreased with time during liver fibrogenesis and fibrosis resolution, respectively[22]. Four members of the TIMP family have been characterized so far and designated as TIMP-1 to TIMP-4[23]. It has been suggested that TIMP-1 plays an important role in the pathogenesis of liver fibrosis[24]. Consistent with previously published work[25], we observed elevated levels of TIMP-1 upon treatment with CCl_4. Treatment with FMAC was effective in reducing the level of TIMP-1 expression, indicating liver fibrosis resolution might be enhanced. This result supported that FMAC could suppress liver fibrotic progression caused by CCl_4.

TGF-β1 is a profibrogenic cytokine, because it directly stimulates extracellular matrix production by both Kupffer cells and stellate cells[26,27]. Increased levels of TGF-β1 mRNA expression have been found in patients with liver fibrosis as well as in experimental models of liver fibrosis[28,29]. Blockade of TGF-β1 synthesis or signaling is a primary target for the development of antifibrotic approaches and modern hepatology has facilitated the design of drugs removing this causative agent[30]. In this experiment, CCl_4 treatment increased, while FMAC significantly reduced TGF-β1 mRNA expression. This result suggested that FMAC ameliorated liver fibrosis perhaps by reducing TGF-β1 secretion.

Increased free radical production and lipid peroxidation have been proposed as a major cellular mechanism involved in CCl_4 hepatotoxicity[5]. Furthermore, a close relationship has been reported between lipid peroxidation and fibrogenesis in rats, in which fibrosis was induced by CCl_4 administration[6]. Our results confirmed these findings that hepatic lipid peroxidation is increased during hepatic fibrogenesis. We also found that FMAC inhibited CCl_4-induced hepatic lipid peroxidation. These results indicated that FMAC might inhibit lipid peroxidation, and consequently attenuate the development of liver fibrosis. A large number of studies indicated that FMAC is a good free radical scavenger[3, 31].

In conclusion, the present study has demonstrated that FMAC retards the progression of liver fibrosis in CCl_4-treated rats possibly by scavenging free radicals formed in the liver. It may be expected that FMAC has preventive potentials in liver fibrosis.

Abstract

AIM: To study the expression and activity of inducible nitric oxide synthase (iNOS) and endothelial nitric oxide synthase (eNOS) in rats with ethanol-induced liver injury and their relation with liver damage, activation of nuclear factor-κB (NF-κB) and tumor necrosis factor-α (TNF-α) expression in the liver.

METHODS: Female Sprague-Dawley rats were given fish oil (0.5 mL) along with ethanol or isocaloric dextrose daily via gastrogavage for 4 or 6 wk. Liver injury was assessed using serum alanine aminotransferase (ALT) activity and pathological analysis. Liver malondialdehyde (MDA), nitric oxide contents, iNOS and eNOS activity were determined. NF-κB p65, iNOS, eNOS and TNF-α protein or mRNA expression in the liver were detected by immunohistochemistry or reverse transcriptase-polymerase chain reaction (RT-PCR).

RESULTS: Chronic ethanol gavage for 4 wk caused steatosis, inflammation and necrosis in the liver, and elevated serum ALT activity. Prolonged ethanol administration (6 wk) enhanced the liver damage. These responses were accompanied with increased lipid peroxidation, NO contents, iNOS activity and reduced eNOS activity. NF-κB p65, iNOS and TNF-α protein or mRNA expression were markedly induced after chronic ethanol gavage, whereas eNOS mRNA expression remained unchanged. The enhanced iNOS activity and expression were positively correlated with the liver damage, especially the necro-inflammation, activation of NF-κB, and TNF-α mRNA expression.

CONCLUSION: iNOS expression and activity are induced in the liver after chronic ethanol exposure in rats, which are correlated with the liver damage, especially the necro-inflammation, activation of NF-κB and TNF-α expression. eNOS activity is reduced, but its mRNA expression is not affected.

INTRODUCTION

Nitric oxide (NO) has been recognized as an important mediator of physiological and pathophysiological processes. It is produced by at least two isoforms of nitric oxide synthase (NOS) in the liver, such as eNOS and iNOS. eNOS is a Ca^{2+}- and calmodulin-dependent constitutive isoform and plays an important role in vasorelaxation, whereas iNOS is not a constitutive enzyme and its expression may be induced by stimuli such as lipopolysaccharide or proinflammatory cytokines[1,2].

The role of NO in alcohol-induced liver injury still remains controversial. Nanji *et al*[3] reported that arginine, a substrate for NO, can significantly attenuate ethanol-induced liver injury. Treatment with N-nitro-L-arginine methyl ester (L-NAME), a nonselective NOS inhibitor, enhances alcohol-induced liver injury in the Tsukamoto-French enteral rat model[4]. However, iNOS knockout mice or wild-type mice treated with N-(3-aminomethyl) benzyl-acetamindine (1400W), a highly selective iNOS inhibitor, are protected against liver damage caused by alcohol[5]. Uzun *et al*[6] showed that L-NAME might produce a restorative effect on ethanol-induced liver damage.

Nuclear factor-κB (NF-κB) is a ubiquitous transcription factor that plays an important role in regulation of inflammatory responses. NF-κB is composed of homo- and hetero-dimers of five members of the Rel family, including NF-κB1 (p50), NF-κB2 (p52), Rel A (p65), Rel B, and Rel C. The most prevalent activated form of NF-

κB is a heterodimer consisting of a p50 or a p52 subunit and p65. NF-κB exists in cytoplasm in an inactive form associated with regulatory proteins called IκB. After stimulation, it is translocated to the nuclei and bound to decameric DNA sequences, and activates transcription of target genes[7]. NF-κB has been shown to be functionally important for iNOS induction[8]. In the present study, we used fish oil plus ethanol gavage model of alcoholic liver disease, and examined the expression and activity of iNOS and eNOS in the liver, and their relation with liver damage, activation of NF-κB and TNF-α expression.

MATERIALS AND METHODS

Chemicals and reagents

Polyclonal rabbit anti-iNOS and anti-NF-κB p65 were obtained from Santa Cruz Biotechnology, Inc. Biotinylated goat-anti-rabbit IgG was purchased from Beijing Zhongshan Reagent Corp. TRIzol reagent was purchased from Invitrogen. DL2000 DNA ladder marker was from TaKaRa Biotech Co., Ltd. M-MLV reverse transcriptase and its buffer, deoxyribonucleotide (dNTP, 10 mmol/L) and oligo(dT)$_{15}$ primer were from Promega Corp. Taq DNA polymerase and its buffer, rRNasin ribonuclease inhibitor was from Biostar. Polymerase chain reaction (PCR) primers for eNOS, iNOS, TNF-α and GAPDH, were synthesized by Sai-Bai-Sheng Biocompany (Shanghai, China). Malondialdehyde (MDA), nitric oxide (NO) and nitric oxide synthase (NOS) activity assay kits were purchased from Nanjing Jiancheng Bioengineering Co.Ltd, China.

Animal model

Female Sprague-Dawley rats weighing 200-250 g, were obtained from the Experimental Animal Center of Wuhan University. After acclimation for 6-7 d, animals were randomly divided into 4-wk dextrose group (n = 5), 6-wk dextrose group (n = 5), 4-wk ethanol group (n = 8), and 6-wk ethanol group (n = 8). Rats were given 0.5 mL fish oil along with ethanol or isocaloric dextrose intragastrically by gavage. The initial dose of ethanol was 6 g/kg per day (solutions maximally containing 56 mL/100 mL alcohol), and the dose was progressively increased during wk 1 to a maintenance dose of 8 g/kg per day that was continued for another 3 or 5 wk. All rats had free access to regular standard rat chow throughout the experiment. The animals were weighed three times per wk. At the end of the experiment, the animals were anaesthetized with urethane (20%, 1.0 g/kg) and sacrificed by bleeding from femoral arteries and veins. Blood samples were collected. Immediately after exsanguination, the livers were harvested. Small portions of the liver were kept at -70 ℃ for reverse transcriptase-polymerase chain reaction (RT-PCR) analysis, whereas another portion was separated and immersed in 10% buffered formalin solution for histological and immunohistochemical examination. All animals were given humane care in compliance with the institutional guidelines.

Pathological evaluation

Liver specimens, 1.0 cm×0.5 cm×0.3 cm in size, were processed for light microscopy. This processing consisted of fixing the specimens in 10% formaldehyde for 12-24 h, embedding them in paraffin, slicing sections of 5 μm in thickness and staining the sections with hematoxylin and eosin. Histological assessment was performed by a pathologist unaware of the study. The severity of liver pathology was assessed as follows[9]: steatosis (the percentage of liver cells containing fat), 1+, <25% of cells containing fat; 2+, 26%-50% of cells containing fat; 3+, 51%-75% of cells containing fat; and 4+, >75% of cells containing fat. Necrosis was evaluated as the number of necrotic foci/mm^2 and inflammation was scored as the number of inflammatory cells/mm^2.

Serum alanine aminotransferase assay

Blood samples were allowed to clot, and the sera were isolated by centrifugation at 1000 r/min for 10 min and kept at -20 ℃ before determination. Enzymatic activity of alanine aminotransferase (ALT) was measured using a commercial kit by an RA 1000 automatic biochemical analyzer (Japan).

Liver MDA contents and NOS activity assay

Liver samples were thawed, weighed and homogenized 1 : 9 w:v in 0.9% saline. Then the homogenates were centrifuged at 3 000 r/min for 10 min at 4 ℃ and the supernatant was taken for the assays of MDA contents, NOS activity and total protein.

MDA was assayed by measuring the thiobarbituric acid-reactive substances (TBARS) levels spectrophotometrically at 532 nm. Results were expressed as nmol.mg^{-1} protein.

NOS catalyzed the formation of NO and L-citrulline from L-arginine and molecular oxygen, and NO reacted with a nucleophile to generate color compounds. The absorbance at 530 nm NOS activity was calculated and expressed as U/mg protein. One unit of NOS activity was defined as the production of 1 nmol nitric oxide per second per mg tissue protein. Total NOS activity was measured as follows: 10% tissue homogenate (100 μL) was incubated with 200 μL substrate buffer, 10 μL reaction accelerator and 100 μL color development reagent at 37 ℃ for 15 min after mixing. Then 100 μL clearing reagent and 2 mL stop solution were added, mixed and absorbances were read at 530 nm. For measuring iNOS activity, an inhibitor was added before incubation according to the manufacturer's instructions.

Total protein concentration was determined using the Coomassie blue method with bovine serum albumin as standard.

Liver NO assay

Liver samples were thawed, weighed and homogenized 1 : 9 w:v in 0.9% saline. The homogenates were then centrifuged at 1 000 r/min for 5 min at 4 ℃, the supernatant was taken for NO assay and total protein determination.

NO was assayed spectrophotometrically by measuring total nitrate plus nitrite (NO_3^- plus NO_2^-) and the stable end products of NO metabolism. In the procedure nitrate was enzymatically converted into nitrite by the enzyme nitrate reductase, followed by quantitation of nitrite using

Table 1 PCR primers used for iNOS, eNOS, TNF-α and GAPDH

Name	Sense	Antisense	Product length (bp)
iNOS	TTCTTTGCTTCTGTGCTAATGCG	GTTGTTGCTGAACTTCCAATCGT	1061
eNOS	TGGGCAGCATCACCTACGATA	GGAACCACTCCTTTTGATCGAGTTAT	202

GAPDH	TCCCTCAAGATTGTCAGCAA	AGATCCACAACGGATACATT	309

Griess reagent at the absorbance of 550 nm as previously described[10]. Results were expressed as μmol/g protein.

Immunohistochemical detection of iNOS and NF-kB p65 in liver

Five μm thick sections were prepared from paraffin-embedded tissues. After deparaffinization, endogenous peroxidase was quenched with 3% H_2O_2 in deionised water for 5-10 min. Nonspecific binding sites were blocked by incubating the sections in 10% normal rabbit serum for 10-15 min. The sections were then incubated with polyclonal rabbit anti-iNOS (dilution 1:25) or anti-NF-kB p65 (dilution 1:100) overnight at 4 ℃, followed by incubation with biotinylated goat-anti-rabbit IgG at room temperature for 10-15 min. After 3×3 min PBS rinses, the horseradish-peroxidase-conjugated streptavidin solution was added and incubated at room temperature for 10-15 min. The antibody binding sites were visualized by incubation with a diaminobenzidine-H_2O_2 solution. The sections incubated with PBS instead of the primary antibody were used as negative controls. Brown-yellow granules in cytoplasm or nuclei were recognized as positive staining for iNOS or NF-kB p65 respectively. NF-kB immunoreactivity was expressed as the number of positive cells/high-power field (× 400).

RT-PCR analysis of iNOS, eNOS and TNF-α mRNA expression in liver

Total RNA was isolated from approximatively 50-100 mg snap-frozen liver tissue using the TRIzol protocol as suggested by the supplier. Following precipitation, the RNA was resuspended in RNAse-free buffer, the concentration was assayed by measuring ultra-violet light absorbance at 260 nm and purity was estimated from the ratio of A_{260}/A_{280}.

Single-stranded complementary DNA (cDNA) was synthesized from the total RNA using the following method. In brief, 2 μg RNA was preincubated with 0.5 μg oligo(dT)$_{15}$ primer and diethylpyrocarbonate (DEPC)-treated water was added to a total volume of 15 μL at 70 ℃ for 5 min, then rapidly chilled on ice. To the annealed primer/template 5 μL M-MLV 5×reaction buffer, 1.25 μL dNTP (10 mmol/L, each), 25 units of rRNasin ribonuclease inhibitor, 200 units of M-MLV RT and DEPC-treated water were added to a final volume of 25 μL. The reaction was incubated at 42 ℃ for 60 min and terminated by placing it on ice after deactivation at 85 ℃ for 5 min. The resulting cDNA was used as a template for subsequent PCR.

The PCR mixture contained 5 μL of 10×Taq buffer, 1 μL of dNTP (10 mmol/L, each), 1 μL of gene specific primers (Table 1, sense and anti-sense primers, 25 pmol/μL, each), 2.0 units of Taq DNA polymerase and 1 μL of cDNA in a total volume of 50 μL. Thirty-five cycles of amplification were performed with initial incubation at 94 ℃ for 3 min and a final extension at 72 ℃ for 7 min, each cycle consisted of denaturation at 94 ℃ for 45 s, annealing at 54 ℃ for 45 s and extension at 72 ℃ for 1 min. To ensure the use of equal amounts of cDNA from each group samples in PCR, the aliquots of the reverse transcription products were used in PCR with the primers for house-keeping gene GAPDH. The quantities of cDNA producing equal amounts of GAPDH-PCR-product were used in PCR with the primers for iNOS, eNOS and TNF-α. Following RT-PCR, 5 μL samples of amplified products was resolved by electrophoresis on 2% agarose gel and stained with ethidium bromide. The level of each PCR product was semi-quantitatively evaluated using a digital camera and an image analysis system (Vilber Lourmat, France), and normalized to GAPDH.

Statistical analysis

Results were presented as mean ± SD unless otherwise indicated. Differences between groups were analyzed using analysis of variance with *post hoc* analysis using LSD test. The correlation was analyzed with Spearman's correlation coefficients. $P < 0.05$ was considered statistically significant.

RESULTS

In each of the four groups, the rats increased their weight at a constant rate. There was no difference in weight gain among the groups.

Pathological changes and serum aminotransferase activity

The animals given fish oil plus dextrose developed slight steatosis in the liver, but no obvious inflammation or necrosis was observed (Figure 1A). However, chronic ethanol gavage for 4 wk caused steatosis, minimal to mild inflammation and necrosis in the liver (Figure 1B). Prolonged ethanol administration (6 wk) enhanced the liver damage. Pronounced macrovesicular and microvesicular steatosis as well as spotty necrosis and mild inflammation were observed (Figure 1C, Table 2).

Consistent with the histological changes, serum ALT levels, an index of liver cell injury, were significantly increased in 4-wk ethanol group, and further increased in 6-wk ethanol group as compared with dextrose groups (Table 2).

Liver MDA and NO contents

Liver contents of MDA, a marker of lipid peroxidation, were significantly increased after 4 wk ethanol gavage

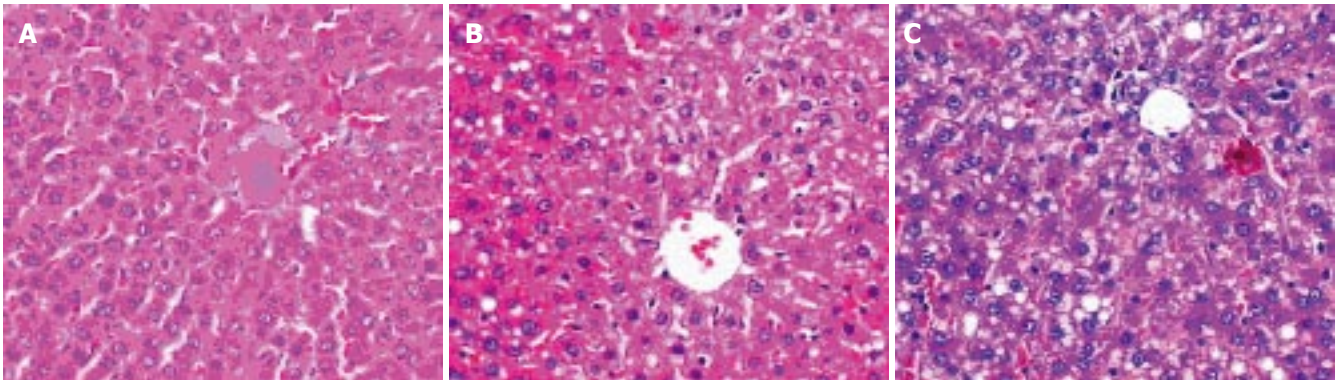

Figure 1 Representative pathologic changes in 4-wk dextrose group (**A**), 4-wk ethanol group (**B**), and 6-wk ethanol group (**C**). Original magnification, ×200.

Table 3 Liver NO contents, iNOS and eNOS activity in different experimental groups (mean ± SD)

Groups	NO (μmol/g^{-1} protein)	iNOS (U/mg^{-1} protein)	eNOS(U/mg^{-1} protein)
4-wk dextrose	0.75±0.14	0.27±0.07	0.64±0.06
4-wk ethanol	1.67±0.15[a]	0.60±0.07[a]	0.48±0.03[a]
6-wk dextrose	0.87±0.07	0.35±0.06	0.58±0.04
6-wk ethanol	1.84±0.12[b]	0.70±0.09[b]	0.43±0.05[b]

[a]$P<0.05$ *vs* 4-wk dextrose group; [b]$P<0.05$ *vs* 6-wk dextrose group.

compared with dextrose groups. Prolonged ethanol exposure (6 wk) led to a further increase in MDA contents (Table 2).

Levels of NO in the liver of two dextrose groups were 0.75 ± 0.14 and 0.87 ± 0.07 μmol/g protein, respectively. Chronic ethanol gavage-induced NO level was two-fold higher in 4-wk ethanol group and further higher in 6-wk ethanol group (Table 3).

Liver NOS activity

The isoforms of NOS present in the liver were mainly eNOS and iNOS as previously reported[2]. The amount of total NOS activity minus iNOS activity might represent the activity of eNOS. Chronic fish oil plus ethanol gavage led to a marked elevation in iNOS activity with further elevation in 6-wk ethanol group compared with 4-wk ethanol group. In contrast, the eNOS activity was significantly reduced compared with dextrose groups (Table 3).

Expression of NF-κB p65 in liver

NF-κB p65 staining was present in cytoplasm and nuclei, but only nuclear staining was considered positive. There was no positive staining in two dextrose groups, whereas following chronic ethanol administration, remarkable enhancement in the positive staining was observed (Figures 2A and 2B). The number of positive cells in 4-wk and 6-wk ethanol groups was 8.0 ± 1.1 and 10.0 ± 1.9 /high-power field, respectively (Figure 2C). The NF-κB p65 positive cells were primarily Kupffer cells and hepatocytes.

iNOS, eNOS and TNF-α expression in liver

Only faint immunoreactive staining of iNOS was detected in the liver from dextrose groups (Figure 3A). However, intense staining of iNOS was observed in 4-wk ethanol group (Figure 3B), and more intense staining was found in 6-wk ethanol group (Figure 3C). The staining was mainly present in both severely damaged and perivascular areas.

iNOS mRNA was barely detectable in the liver of dextrose groups, but after chronic ethanol gavage (4 wk), iNOS mRNA was markedly induced. Prolonged ethanol gavage (6 wk) was associated with more intense bands (Figure 4). In dextrose groups only faint bands for TNF-α were detected. After chronic ethanol gavage, similar

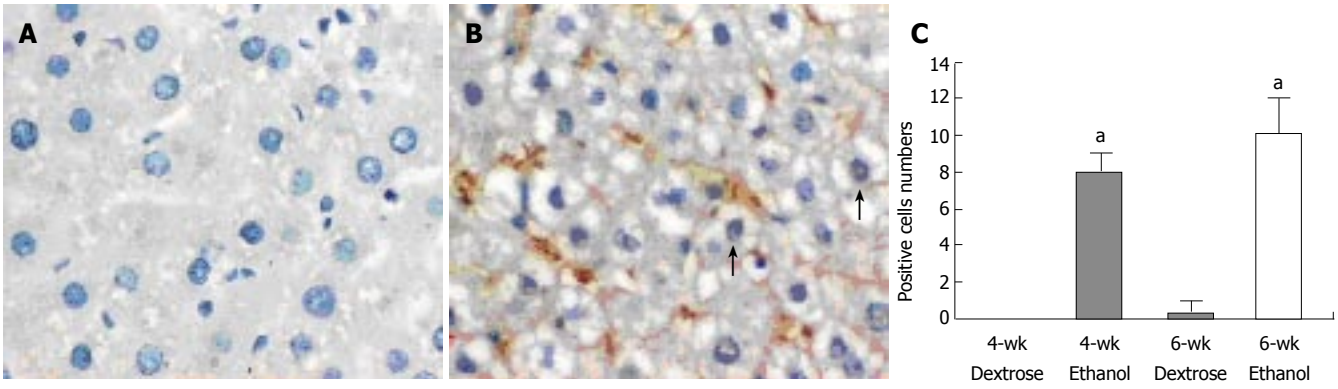

Figure 2 Expression of NF-κB p65 in 6-wk dextrose group (**A**), 6-wk ethanol group (**B**) and the number of positive cells in high-power fields (**C**). [a] $P < 0.01$ *vs* dextrose group. Original magnification, ×400.

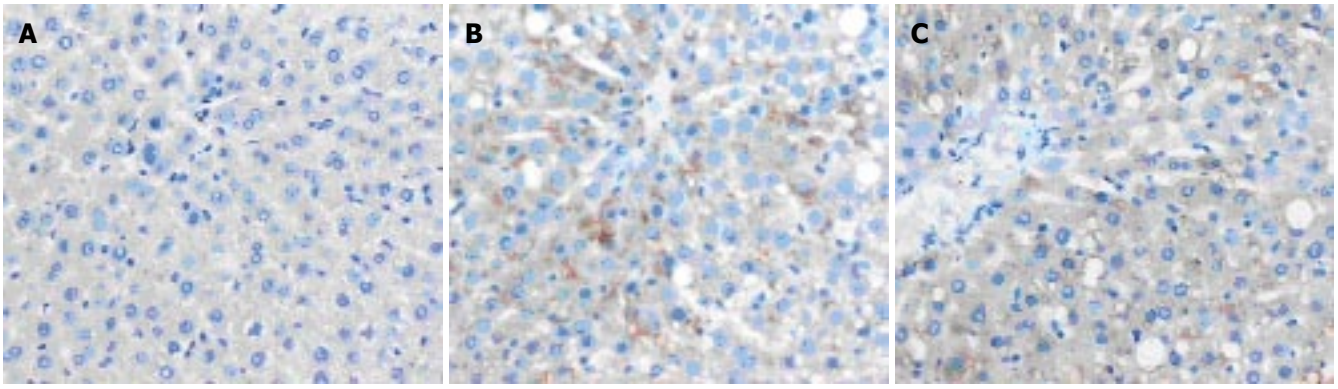

Figure 3 Immunohistochemical detection of iNOS in 6-wk dextrose group (**A**), 4-wk ethanol group (**B**), and 6-wk ethanol group (**C**). Original magnification, ×200.

expression pattern of iNOS was also observed in TNF-α mRNA expression (Figure 4).

In contrast, there was no significant change in eNOS mRNA expression between dextrose and ethanol groups (Figure 4).

Relationship between liver iNOS activity, expression and other parameters

Correlation analysis showed that liver iNOS activity was positively correlated with the severity of liver damage (steatosis, necroinflammation) ($r = 0.71$ and 0.93, respectively, $P < 0.05$), especially the necroinflammation. iNOS expression was only detected in rats with liver damage, activation of NF-κB and intense TNF-α mRNA expression. The intensity of the former paralleled that of the latter.

DISCUSSION

It has been reported that dietary fatty acids play an important role in the pathogenesis of alcoholic liver disease[11,12]. Polyunsaturated fatty acids enriched in fish oil promote alcoholic liver injury and pathological changes occur only in rats fed with ethanol containing polyunsaturated fatty acids[13]. Alcoholic liver injury is more severe and develops rapidly in women than in men[14]. Our study employed female rats and used fish oil plus ethanol gavage to make an animal model of alcoholic liver injury. The rats developed pathological changes in the liver after 4 or 6 wk, such as steatosis, spotty necrosis and inflammation, all of which resemble alterations found in clinical alcoholic liver disease. This chronic gavage of alcohol in rats is a simple experimental model that mimics key aspects of alcoholic liver disease in humans, and is useful for exploring the mechanism and treatment of alcoholic liver disease.

NO is an important biological mediator and has been shown to be involved in diverse physiological as well as pathological processes[1]. In our study, chronic ethanol gavage led to a significant elevation of liver NO contents compared to dextrose groups. NO is generated by NOS. We assayed the activity of total NOS and iNOS in liver. Because the main isoforms of NOS in the liver are eNOS and iNOS[2], the amount of total NOS activity minus iNOS activity may represent the activity of eNOS. Our study showed that iNOS activity was significantly elevated after chronic ethanol consumption in rats, whereas eNOS activity was markedly reduced as compared with dextrose groups. Accompanying the enhanced activity, iNOS expression detected by immunohistochemistry and RT-PCR in the liver was significantly increased in ethanol groups compared to dextrose groups. However, the eNOS mRNA expression was comparable between these groups. The results suggest that the elevated NO release in the liver is attributable to the enhanced activity and expression of iNOS. Relationship analysis showed that enhanced

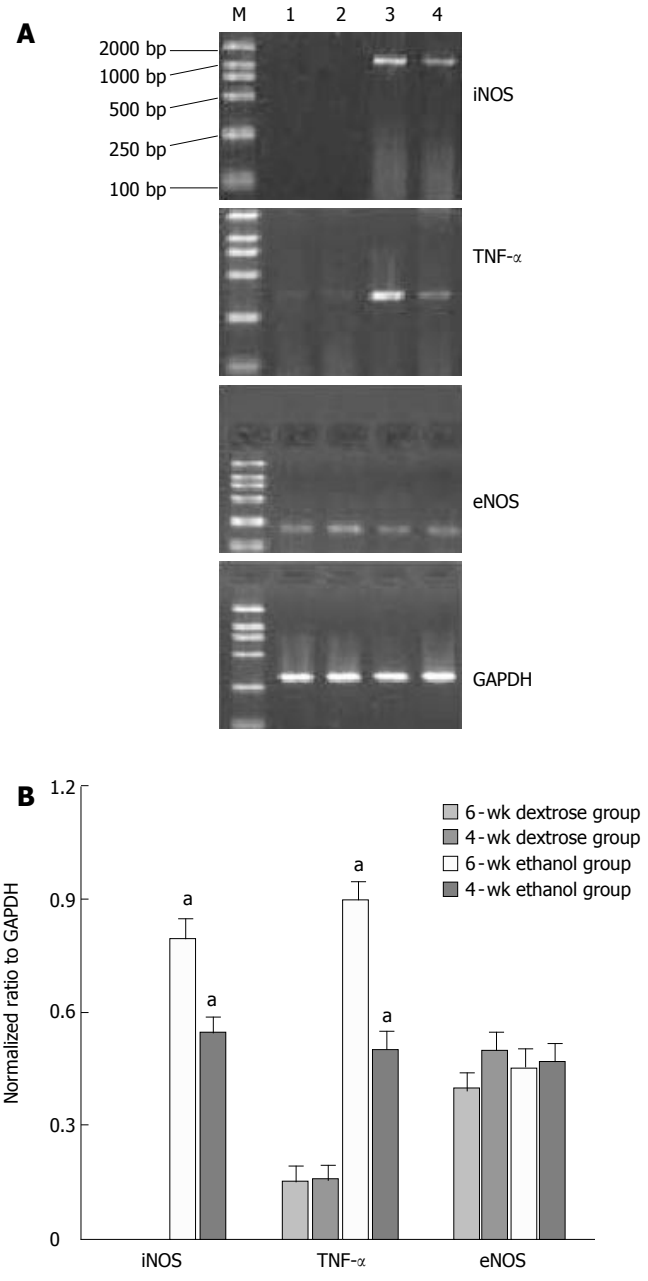

Figure 4 RT-PCR analysis of mRNAs for iNOS, eNOS and TNF-α in the liver. **A**: representative bands for iNOS, TNF-α, eNOS and GAPDH transcripts (lane 1: 6-wk dextrose group, lane 2: 4-wk dextrose group, lane 3: 6-wk ethanol group, lane 4: 4-wk ethanol group); **B**: normalized densitometric ratios of iNOS, TNF-α and eNOS transcripts to GAPDH. [a] $P<0.01$ *vs* dextrose group.

iNOS activity and expression were associated with the severity of liver damage, especially the necroinflammation, suggesting that iNOS contributes to alcohol-induced liver injury. It was reported that iNOS knockout mice or wild-type mice treated with 1400W, a highly selective iNOS inhibitor, are protected against alcohol-induced liver injury[5]. In contrast with iNOS, eNOS activity is reduced after treatment with ethanol. A recent report showed that chronic alcohol intake attenuates hepatic eNOS activity by increasing the expression of the inhibitory protein caveolin-1 and enhancing its binding to eNOS[15]. Treatment with L-NAME, the stronger eNOS inhibitor, exacerbates alcohol-induced liver injury[4]. These facts suggest that the role of NO in ethanol-induced liver injury may be dependent on the isoforms of NOS.

Oxidant stress has been reported to play a role in the pathogenesis of alcohol-induced liver injury[16]. In this study, liver contents of MDA, a marker of lipid peroxidation, were significantly elevated in the ethanol groups as compared with dextrose groups. Oxidant stress can result in degradation of the cytoplasmic NF-κB inhibitor, IκB, allowing translocation of NF-κB to nuclei[17]. Our study showed that chronic ethanol gavage significantly enhanced the expression of active NF-κB in the liver, as evidenced by the increased number of NF-κB p65 positively stained (in nuclei) cells. Furthermore, TNF-α mRNA expression in the liver was markedly increased. These results are consistent with the report of Nanji *et al*[18], who showed that NF-κB is activated during alcoholic liver disease in the presence of pro-inflammatory stimuli, resulting in increased expression of pro-inflammatory cytokines and chemokines. In our study, correlation analysis showed that iNOS expression was positively associated with NF-κB p65 expression, suggesting that increased iNOS expression may be caused by the activation of NF-κB. Activated NF-κB, a transcription factor, may bind to the specific DNA sequence of iNOS to promote its expression[19].

In conclusion, iNOS expression and activity induced in ethanol-induced liver injury are responsible for the elevated NO production. The induction of iNOS is associated with liver damage, especially necroinflammation, activation of NF-κB and elevated TNF-α mRNA expression in the liver.

Abstract

AIM: To correlate the clinical features of treated and untreated patients with irritable bowel syndrome (IBS) to the results of skin prick test (SPT) for food and inhalant allergens.

METHODS: We recruited 105 subjects to form three different target groups: treated group ($n = 44$) undergoing treatment for IBS, untreated group ($n = 31$) meeting the Rome II criteria without treatment for IBS, control group ($n = 30$) with no IBS symptoms.

RESULTS: SPT results were different among the three groups in which SPT was positive in 17 (38.6%) treated patients, in 5 (16.1%) untreated patients and in 1 (3.3%) control ($P < 0.01$). The number of positive SPTs was greater in the IBS group than in the control group ($P < 0.001$). The number of positive food SPTs was higher in the treated IBS group than in the untreated IBS group ($P = 0.03$).

CONCLUSION: Positive food SPT is higher in IBS patients than in controls.

Key words: Irritable bowel syndrome; Skin prick test; Food allergy

INTRODUCTION

Irritable bowel syndrome (IBS) is common. Depending on the studies, the prevalence (using Rome II criteria) varies between 9%-22% among Caucasians[1-3]. In Korea, the prevalence of IBS has been reported to be 6.6% and there is no difference in the prevalence between men and women[4].

In patients with IBS, postprandial worsening of symptoms as well as food-related reactions to one or more foods is very common[5]. In published data, speculation of an immunological reaction to foods in IBS has been reported[6,7]. Data from dietary elimination and food challenge studies support the role of diet in the pathogenesis of IBS[8-10]. This hypothesis is supported by the response to disodium cromoglycate in such patients[11,12]. Although well designed randomized controlled studies are scarce, milk, wheat, egg and foods high in salicylates or amines are consistently a problem among the studies[13,14]. Recently, Dainese *et al*[7] have indicated discrepancies between reported food intolerance and skin prick test (SPT) findings in IBS patients, suggesting that the SPT used to identify food sensitization mediated by the IgE mechanism is inappropriate. IBS is a heterogeneous disease having various symptoms and severity. So in our study, IBS patients were divided into treatment and untreated groups. Moreover, to clarify the possible role of food hypersensitivity in IBS, we used both common food and inhalant antigens. The results of SPT for food allergens were compared to the SPT for inhalant allergens.

The aim of this study was to correlate the clinical features of treated and untreated IBS patients to the results of the skin prick test for food and inhalant allergens, total IgE level, and radio- allegro-sorbent test (RAST)

for IBS and 35 randomly selected healthy undergraduate students were recruited in the study. After giving their informed consent, all volunteers underwent a physical examination and laboratory screening (upper gastrointestinal endoscopy, colonoscopy, routine red and white blood cell count, and biochemical examinations). Subjects receiving any medication (antihistamines, steroids, H_2 receptor antagonist, anti-inflammatory drugs, and herb medications) over a two-week period prior to study and those with current severe allergic disease identified by interview were excluded from the study (n = 9). Therefore, out of 70 students, 31 untreated IBS students and 30 healthy students participated in the trial. Forty-four consecutive patients with IBS referred to our institution for evaluation and treatment served as positive controls. Standard workup included upper gastrointestinal endoscopy, laboratory testing and colonoscopy.

The enrolled patients were divided into three groups after clinical evaluation and the application of Rome II criteria. Group I consisted of 44 patients with IBS referred to our institution for evaluation and treatment. All treated patients were selected from a single tertiary outpatient clinic (treatment group). Group II consisted of 31 untreated IBS patients meeting the Rome Ⅱ criteria but not treated for IBS (untreated group). Group III consisted of 30 healthy undergraduate students (control group).

Questionnaire and clinical measurements

To assess abdominal symptoms and intensity, all study participants were given a questionnaire. A modified WHO-QOL (WHOQOL-BREEF) method validated by Min *et al*[15] was used to measure the quality of life in the IBS and control groups. The questionnaire consisted of 26 items measuring four dimensions of health: physical health, psychological health, social relationships and environmental health. Each item asked the respondents to indicate the extent to which their IBS interfered with their health during the previous four weeks.

Skin prick test and RAST

SPT was carried out on all subjects on the upper back involving the application of 70 fresh food extracts using the prick-by-prick method. Some of the fresh food extracts used were saury, mackerel, beef, pork, chicken, milk, egg white, egg yolk, wheat flour, buckwheat, rice, beans, apples, peaches, tomatoes, celery, carrots, onions, peanuts, chocolate, and coffee. A doctor carried out an additional SPT involving the application of inhalant allergens. The 11 commercial allergens tested for D-pteronyssinus, D-farinae, alternaria alternata, grass pollen, tree pollen, mugwort pollen, willow pollen, ragwort, dog hair, cat fur, and cockroaches mix. In both SPTs, one drop of the extract was placed on the skin, and a disposable syringe needle was placed into the drop and then into the skin until a small puncture was visible. A histamine control was employed. SPT was considered positive if the net wheal diameter was significantly greater than the net wheal diameter of the histamine reaction. The reaction to the extract was measured 15-20 min after application. Discomfort and bleeding were not evident.

Serum samples for total IgE and total eosinophil count were collected by trained phlebotomists. Two 10 mL blood samples from an antecubital vein were taken. IgE measurement was determined by the paper radioimmunosorbent test (PRIST, Pharmacia Laboratories, USA) using a Phadebas IgE kit. The total IgE test provided evidence for IgE sensitivity to antigens because the IgE antibody resulted in mast cell activation and release of histamine. Also, total eosinophils were stained with a Hinkelman solution, and the eosinophil count provided immediate hypersensitivity to IgE antibody.

Statistical analysis

Tables were constructed for frequency and percentage. Categorical data were analyzed using the chi-square test or Fisher's exact test. Continuous data were analyzed using the Student's t-test and one-way ANOVA or Scheffe's test. To minimize type I errors, $P < 0.05$ was considered statistically significant. Exact P-values are listed in the tables and text. All statistical analyses were performed using the SPSS 11.0 statistical package.

RESULTS

Patient population

In the study population, 44 treated IBS patients had a mean age of 38 years (37.9±13.2), 31 untreated IBS patients had a mean age of 27 years (27.2±1.9), and 30 controls had a mean age of 26 years (25.8±1.7). There were no statistically significant differences in gender ratio, height, weight, alcohol and coffee intake, and smoking habits among the three groups (not shown). In the treated group, the number of females (56.8%, n = 25) was greater than that of males (43.2%, n = 19). In this group, the most subtype IBS was found in 19 patients. The subtype constipation dominant IBS was found in 12 patients of untreated group. Subjects in the treated group mainly sought for a primary care setting as the first visit due to

abdominal pain (15 patients), stool pattern change (13 patients) and abdominal bloating (13 patients) (Table 1).

Subgroup analysis and scores of quality of life (WHOQOL-BREEF)

We utilized a questionnaire to compare and estimate the onset, duration and severity of symptoms between the two IBS groups. More than half of the treated IBS patients (59.1%) reported that the symptoms lasted for more than 24 h, but only 29.0% of untreated IBS patients reported that the symptoms lasted for more than 24 h. Five IBS patients (11.4%) in the treated group complained of abdominal symptoms almost all day for more than one month. Subjective severity score of symptoms was also higher in the treated IBS patients than that of the untreated IBS patients ($P = 0.001$). But there was no significant difference in the onset of the disease between the two groups ($P = 0.065$) (Table 2).

Modified WHOQOL (WHOQOL-BREEF) questionnaire validated by Min *et al*[15] was used. It consisted of 26 items measuring four dimensions of health. All dimensions including overall quality of life scores were significantly lower in IBS patients than in controls (Table 3).

History of allergies and food intolerance

There was no significant difference in the reported food intolerance among the three groups. However, among the treated and untreated IBS patients, dairy products were reported to cause most of the intolerance. Of the treated and untreated IBS patients, 25 (56.8%) and 21 (67.7%) had an allergic condition and only 9 (30%) of the controls had an allergic condition ($P = 0.008$). However, no difference in the number of allergic conditions was found between the treated and untreated IBS patients. Rhinitis was the most common condition, and five patients had a history of asthma in the IBS patients (Table 4).

Skin prick test and IgE level

Seventy fresh food extract allergens were used to identify the cause of food hypersensitivity. SPT results were different among the three groups. SPT was positive in 17 (38.6%) treated IBS patients, in 5 (16.1%) untreated IBS patients, and in 1 (3.3%) control ($P < 0.01$). The number of positive SPTs was greater in the IBS patients than in the controls ($P < 0.001$). The number of positive food SPTs was greater in the treated patients than in the untreated patients ($P = 0.03$). The most frequent SPT positive food allergen was saury among the different groups. Five IBS patients had positive SPT for rice (Table 5). Eleven treated and untreated IBS patients and four controls had positive SPT for inhalant allergens. No significant difference in SPT inhalant allergens was noted among the three groups. The most common reactive inhalant allergens were D-farinae and D-pteronyssinus.

There were no significant differences in IgE and total eosinophil counts among the three groups. Also, no significant differences in IgE and total eosinophils were noted between the treated and untreated IBS patients (Table 6).

QOL: quality of life. [a]$P < 0.05$ by χ^2-test; [c]$P < 0.05$ by χ^2-test between IBS patients and control.

Characteristics according to the food SPT in treated and untreated groups

When SPT for food allergen and gender ratio were compared between those with a positive and negative SPT, no difference was noted. Also, there were no significant differences in positive SPT between IBS subtype and current allergy history. However, food intolerance and positive inhalant allergen were much higher in SPT positive food allergens ($P = 0.013$, $P = 0.006$). Twenty-two IBS patients had one or more skin positive tests. Serum samples were taken for RAST in order to compare the SPT results. Only three treated IBS patients had a positive RAST for beans, pork, and beef (Table 7).

DISCUSSION

The term "adverse food reaction" or "food-related symptoms" encompasses immunological responses and non-immunological responses to food. Food hypersensitivity/ allergy is used to describe conditions in which an immunological mechanism may be demonstrable[16,17]. In contrast, food intolerance is a non-immunological response to proteins that may result from particular constituents of foods such as toxins (e.g., food poisoning) or pharmacological agents (e.g., caffeine or tyramine) or from host factors such as lactase deficiency. However, food hypersensitivity

resulting in food intolerance in the cause of gastrointestinal problems is much harder. Niec *et al*[18] reported that milk, wheat, eggs, potatoes, and celery are the most commonly identified factors causing gastrointestinal symptoms. Locke *et al*[19] reported that beans and legumes, chocolate, dairy products, and nuts are the most common foods causing hypersensitivity. It was reported that patients with IBS reveal intolerance to foods such as milk, bread, pizza, apple, hazelnut, tomato, egg, peach, and greens[7]. In our study, dairy products, coffee, alcohol, raw food, and spicy food were the most common foods causing problems. However, SPT was positive for saury, rice, mackerel, buck-

wheat, sweet potatoes, celery, onions, and trumpet shell. The results of different studies are inconsistent, which poses the question of the population specificity of such studies.

No correlation between SPT and patient's intolerance to certain foods was noted. There are several explanations for the discrepancies between reported food intolerance and SPT results. First, SPT is generally considered the most convenient and least expensive screening method for detecting allergic reactions in most patients. However, until the diagnostic efficacy of SPT is fully established with standardized allergens and methods, a positive skin test alone cannot confirm a definite clinical sensitivity to an allergen. Second, clinicians consider cross-reactions among various plants and animal allergens[20, 21]. The conservation of these proteins across biologic substances affects cross-reactivity in several ways. Certain foods (e.g., peanut) are able to sensitize and elicit reactions after oral exposure (type 1 allergy) and can trigger responses to related foods (e.g. legumes). Other foods (e.g., apples) containing labile proteins are not strong oral sensitizers. Helbling *et al*[22] have reported the clinical cross-reactivity to most fish species and several *in vitro* studies have demonstrated the existence of common allergens between different fish species[23-26]. The third explanation is that food allergies are localized at the intestinal mucosa and specific IgEs are primarily present in intestinal mucosa but not systemically. For this reason, Andre *et al*[27] have indicated the importance of stool IgE rather than serum IgE. Bischoff *et al*[28] have also stressed the importance of stool eosinophil counts and mast cell mediators.

Both SPT and RAST are for IgE-mediated disease, but there is no correlation between the two methods. However, RAST is not as sensitive as the skin test. As a result, in patients with a history of reactions to foods, insect stings, drugs, or latex, skin testing is still required because of its higher sensitivity even if the RAST is negative. The primary advantage of RAST over SPT is safety with the results not influenced by skin disease or medication[29].

In our study, the IBS patients showed much higher positive SPT rates than the controls ($P < 0.001$). The treated IBS patients were more likely to have a positive SPT than the untreated IBS patients ($P = 0.03$). The untreated IBS patients defined by fulfillment of the Rome IBS criteria complained of severe symptoms ($P < 0.05$) (Table 2), suggesting a possible relationship exists between IBS and allergic diathesis. Further studies are needed to explore this relationship. In addition, we also used common inhalant allergens to compare with the food allergens and did not find any difference in positive SPT between inhalant allergens among the three groups (25%, 35% and 13% respectively). White *et al*[30] reported that increased airway responsiveness to inhaled methacholine can be demonstrated in irritable bowel syndrome patients with no clinical evidence for atopic disease[31]. These findings are in contrast to the previous hypothesis that IBS is a generalized immune hypersensitivity state. These findings also suggest that food allergens may play a certain role in IBS patients. However, well designed dietary elimination and food challenge studies are needed to document the food hypersensitivity in IBS patients.

In this study, the untreated IBS patients were older than the treated patients ($P = 0.005$). Because age could affect SPT, it may confound our results. But the number and size of prick skin reactions increase throughout childhood until twenty years of age and then gradually decline until age fifty[32]. Even if age is considered, more treated patients were positive for SPT in our study.

In conclusion, more IBS patients are positive for SPT and food allergens than healthy controls. However, the IBS patients present more severe symptoms, lower overall quality of life, and higher positive SPT compared to the untreated IBS patients even though the history of allergies is not different.

Abstract

AIM: Positioning of interventional devices in liver lesions is a challenging task if only CT is available. We investigated the potential benefit of combined PET/CT images for localization of interventional devices in interventional liver studies.

METHODS: Thirty lesions each of hyperdense, isodense and hypodense attenuation compared to normal liver parenchyma were injected into 15 *ex-vivo* pig livers. All lesions were composed of the same amounts of gelatine containing 0.5 MBq of ^{18}F-FDG. Following lesion insertion, an interventional needle was placed in each lesion under CT-guidance solely. After that, a PET/CT study was performed. The localization of the needle within the lesion was assessed for CT alone and PET/CT and the root mean square (RMS) was calculated. Results were compared with macroscopic measurements after lesion dissection serving as the standard of reference.

RESULTS: In hypo- and isodense lesions PET/CT proved more accurate in defining the position of the interventional device when compared with CT alone. The mean RMS for CT and PET/CT differed significantly in isodense and hypodense lesions. No significant difference was found for hyperdense lesions.

CONCLUSION: Combined FDG-PET/CT imaging provides more accurate information than CT alone concerning the needle position in FDG-PET positive liver lesions. Therefore combined PET/CT might be potentially beneficial not only for localization of an interventional device, but may also be beneficial for guidance in interventional liver procedures.

INTRODUCTION

Treatment of liver lesions may be performed either surgically or interventionally. Surgery still represents the treatment of choice in solitary liver lesions or in patients with a limited number of lesions confined to a specific liver segment. However, certain cardiovascular or pulmonary risk factors may prevent patients from undergoing surgery with a curative intent [1,2]. In some patients minimally invasive interventional approaches may serve as an option for patient treatment. Interventional procedures for treatment of liver lesions include procedures such as radiofrequency ablation, laser induced ablation or chemoembolization [3-5]. Except for chemoembolization, all other therapeutic interventional procedures include placement of an interventional needle transcutaneously within the liver lesion. In most procedures, the needle is placed under CT, MRI, or ultrasound guidance. However, localization and guidance of an interventional device on morphological imaging can be challenging, particularly in selected cases where differentiation of the tumor from adjacent liver parenchyma may be difficult. These circumstances occur especially in tumors with only little or no contrast enhancement [6,7]. On the other hand, functional imaging has proved to be superior to morphological imaging in detection and characterization of these tumors, but is known for only limited anatomical information.

In any case accurate placement of an interventional device is indispensable for complete tumor treatment in every interventional method. In cases of equivocal findings on morphological imaging procedures, additional functional data can provide information about viable tumor parts. Combined PET/CT imaging systems provide accurate morphological and functional data sets within a single operation [8].

The aim of this study was to evaluate a potential benefit of combined PET/CT imaging concerning mor-

phology and complementary functional information when assessing the position of an interventional needle within an isolated liver without breathing. This might potentially improve the accuracy of localization of interventional devices compared with morphological imaging alone.

MATERIALS AND METHODS

Lesion model

Ninety artificial lesions, two hypodense, two isodense, and two hyperdense were placed in each of 15 *ex-vivo* pig livers by needle injection. The injected substances consisted of the following ingredients: Hypodense lesions: gelatine (9 g), sodium chloride (NaCl: 20 mL). Isodense lesions: gelatine (9 g), NaCl (20 mL), iodine-based contrast agent (0.2 mL/300 mg/mL Xenetix 300, Guerbet GmbH, Sulzbach, Germany). Hyperdense lesions: gelatine (9 g), NaCl (20 mL), iodine-based contrast agent (0.4 mL/300 mg/mL). Additionally 0.5 MBq ^{18}F in form of [^{18}F]-2-Fluoro-2-deoxy-D-glucose (FDG) were administered to all mixtures, thus 0.5 MBq FDG, 20 mL sodium chloride, 9 g of gelatine and the different amounts of contrast agents were used per lesion.

The concentration of FDG was chosen based on previous measurements of differences between tumor and liver background in 75 patients with liver malignancies. A ratio using the differences of Standard Uptake Values (SUV) between the tumor and the liver background was established. Based on this ratio, the amount of FDG was chosen to establish the same ratio between the artificial lesions and the liver background. Seventy-five consecutive patients with metastases of colorectal carcinoma, 25 patients with metastases of NSCLC (non small cell lung cancer) and 10 patients with hepatocellular carcinomas (HCC) were chosen from the local PACS. Patients with HCC were only partly PET-positive tumors or had only low values (SUV), but were chosen to define a broad spectrum of liver malignancies.

Lesion injection and interventional procedure

First, the artificial lesions were injected into the liver with a 7-gauge needle (Figure 1). After injection of the artificial lesion into the *ex-vivo* pig livers, the gelatine mixture hardened as it cooled. Lesion injection and the subsequent interventional device placement were carried out by different physicians. Thus, one physician injected the artificial lesions, while another physician inserted the biopsy needles in the following step.

Second, 18 gauge biopsy needles were inserted (by the second physician) in each liver, one needle in each lesion for a total of 6 needles per *ex-vivo* liver under strict CT-guidance. The needles were only inserted in lesions with favourable shape (round, oval or elliptic) to guarantee reproducible measurements. Lesions which partly dropped away through bile ducts and veins were excluded from the measurements. Additionally, before needle placement, each liver was covered by a thin, non-transparent sheet before needle placement to hide the injection sites.

CT and PET/CT imaging

CT and PET/CT imaging were performed with a Biograph™ system (Siemens Medical Solutions, Hoffman Estates, IL).

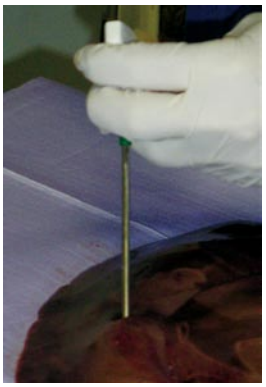

Figure 1 A 7-gauge biopsy needle and a syringe were used for insertion of the gelatine/FDG mixture into the liver. The mixture hardened as it cooled in the *ex-vivo*-liver.

The system consists of two components: a dual-slice CT scanner (Somatom Emotion, Siemens Medical Solutions, Erlangen, Germany) with a minimum gantry rotation time of 800 ms and a full ring PET tomograph (ECAT HR+, Siemens Medical Solutions, Hoffman Estates, IL). The PET system has an axial field of view of 15.5 cm per bed position and an in-plane spatial resolution of 4.6 mm. CT and PET images were acquired consecutively. Repetitive CT scans were carried out for needle positioning with a field-of-view focused on the interventional region. Acquisition parameters for the interventional CT were 120 mAs, 130 kV, 1 mm slice thickness and 1.5 mm table feed.

Following needle placement under strict CT guidance (without using any PET information) a combined PET/CT study was conducted with all needles in position covering the whole *ex-vivo* liver (CT: 120 mAs, 130 kV, 1 mm slice thickness with a 0.5 incremental reconstruction, 1.5 mm table feed, 1 mm collimation, PET: scan time 4 min, 3D data acquisition). CT and PET data sets from the combined imaging approach can be viewed separately or in fused mode on a commercially available computer workstation, which also allows distance measurements on fused images in all three dimensions. Thus, CT images and combined PET/CT images were evaluated separately while all needles inserted within the artificial lesions.

Image evaluation

CT images, either viewed alone or in fused mode (PET/CT), were adjusted to the soft tissue window (center: 50 Hounsfield Units (HU), width: 350 HU). PET images were adjusted to Full Width at Half Maximum (FWHM).

The lesions' width and height were measured in the coronal plane on the commercially available computer workstation and the length was measured in the same way using MPR (multi planar reformatting) in the sagittal direction. The accuracy of CT data alone and combined PET/CT data for determining the needles' position was assessed by measuring the distance (in the horizontal direction) of the needle tip to the lesions' margins on both imaging procedures (CT alone and combined PET/CT) with an electronic calliper in the coronal, transverse and sagittal planes. Imaging measurements from the workstation were correlated with macroscopic measurements after liver lesion dissection, which served as the standard of reference. For this purpose, the liver, with all needles still in place, was finely sliced to measure the distance from the needles' tip to the lesion's margins macroscopically.

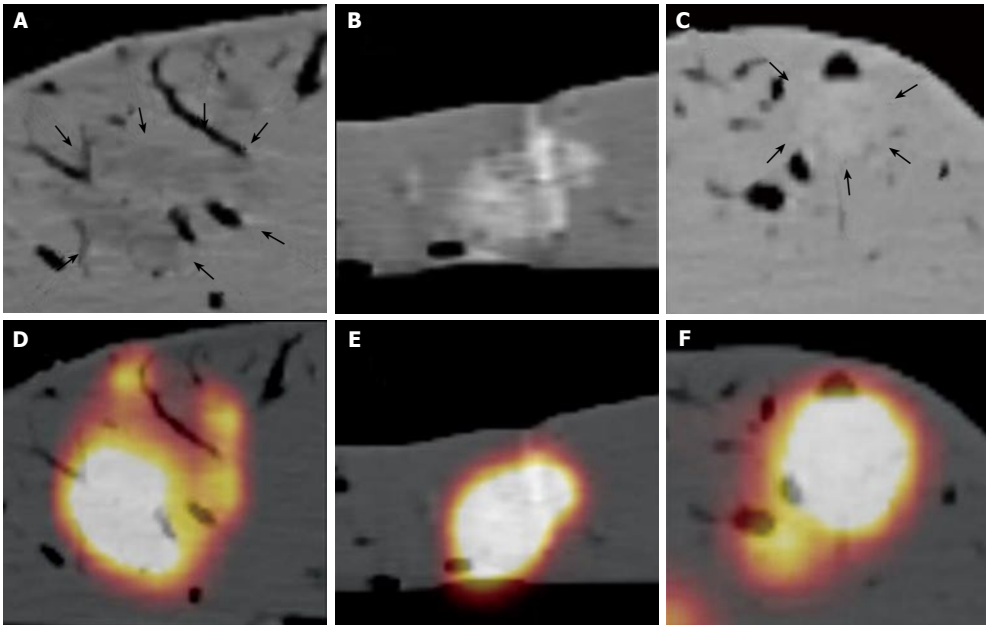

Figure 2 **A**: This shows a hypodense lesion. The margins of the hypodense lesion are barely seen (fine black arrows). In comparison, the combined PET/CT image of the same lesion shows exactly the margins of the lesion (Figure 2D). Furthermore, the combined PET/CT suggests a different location and extent of the lesion, which was confirmed by the standard of reference. **B**: This shows a hyperdense lesion. The margins of the lesions are well seen. The combined PET/CT shows the same location and extent of the lesion within the liver tissue (Figure 2E). Thus, in hyperdense lesions, a high correlation of CT and combined PET/CT measurements was found. **C**: This shows a nearly isodense lesion. The margins of the lesions can only be anticipated (fine black arrows). The corresponding PET/CT (Figure 2 F) of the same lesion shows a different extent of the same lesion with well defined and sharp margins.

All measurements concerning the position of the needle within a single lesion (distances to lesion margin) were compared separately, and the root mean square (RMS) was calculated. The RMS was chosen as a standard description to compare the mean values of different group measurements. The Root Mean Square is calculated as follows:

$$RMS = \sqrt{(x-x_0)^2+(y-y_0)^2+(z-z_0)^2}$$

In this formula, x, y and z are defined as the values derived from the macroscopic measurements, serving as the gold standard. In comparison, x_0, y_0 and z_0 are the values from CT measurement or PET/CT measurement. Therefore, in this formula, the values of the gold standard and the values of CT and PET/CT are already compared by calculating the deviation of measurements from CT or PET/CT compared with the macroscopic standard of re-ference. Thus, greater deviations (meaning less exact definition of the needles' tip on CT or combined PET/CT compared to the standard of reference) will be represented by higher RMS values. In comparison, lower RMS values are calculated based on less deviation of the needles' tip compared to the standard of reference. Values (mean values) were calculated for every lesion based on CT and PET/CT measurements.

Additionally, Hounsfield Units (HU) of every lesion and their surrounding liver tissue was measured and mean values for surrounding tissue and every lesion type were calculated to compare the lesions densities in relation to the liver background. Wilcoxon test for comparing two paired groups was used for statistical analysis.

RESULTS

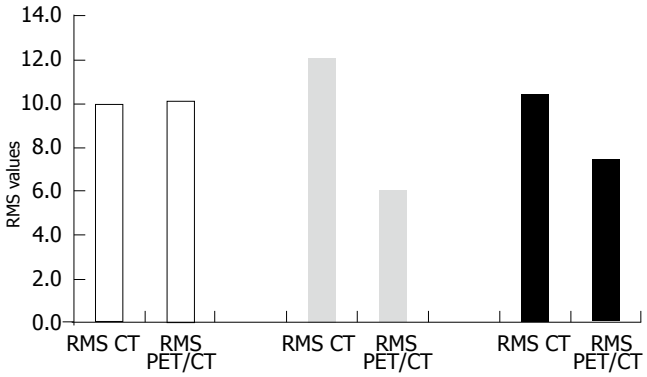

Figure 3 This shows the different mean RMS values for hyper-, iso-, and hypodens lesions. A statistically significant difference was found between the mean RMS values in CT and PET/CT in isodense lesions ($P < 0.05$, grey bars). Additionally, a statistically significant difference was found between the mean RMS values of CT and PET/CT in hypodense lesions ($P < 0.05$, black bars). No difference was found in hyperdense lesions (white bars).

In 90 lesions placed in 15 ex-vivo pig livers, 77 were left in favourable shape for needle intervention (Figure 2). Since several lesions dropped away through bile ducts and veins, 23 hyperdense, 28 isodense, and 26 hypodense lesions were left for measurement.

The mean width was 20.2 (standard deviation (SD): 9 mm) mm, length and height of these lesions were 18.6 (SD: 6 mm) mm, and 16 (SD: 5 mm) mm, respectively, according to the macroscopic standard of reference. Two isodense lesions were missed based on CT data due to poor visibility on the CT images only, whereas both lesions were clearly seen on combined PET/CT images only. The lesions were confirmed by liver dissection. There were no failed punctures in hypo- and hyperdense lesions. The mean RMS for the CT measurements and the combined

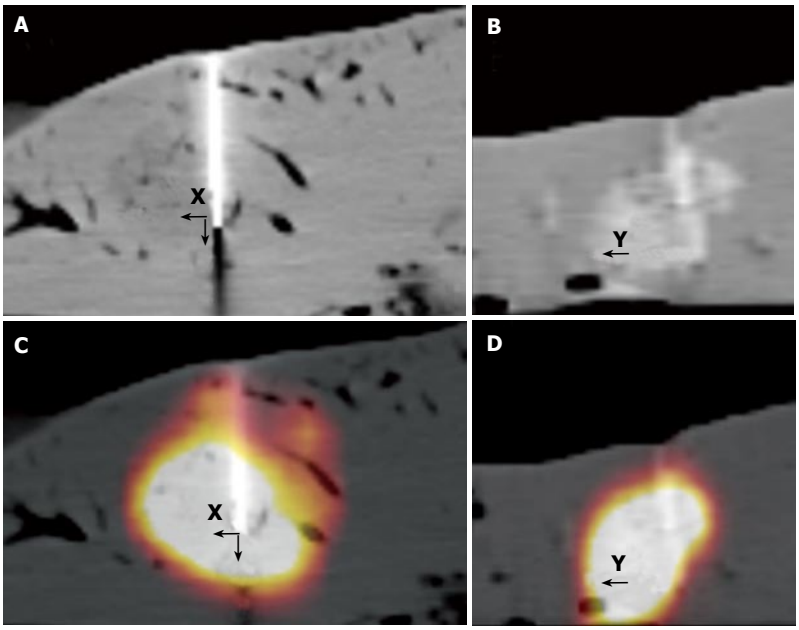

Figure 4 It shows the measurements on the commercially available computer workstation for CT alone (**A**/**B**) and combined PET/CT (**C**/**D**). The lesions´ width and height was measured in coronal direction (Figure 4**A** and **C**, X/Z), the lesions´ length in sagittal direction (black arrow (Y) in Figure 4 **B** and **D**).

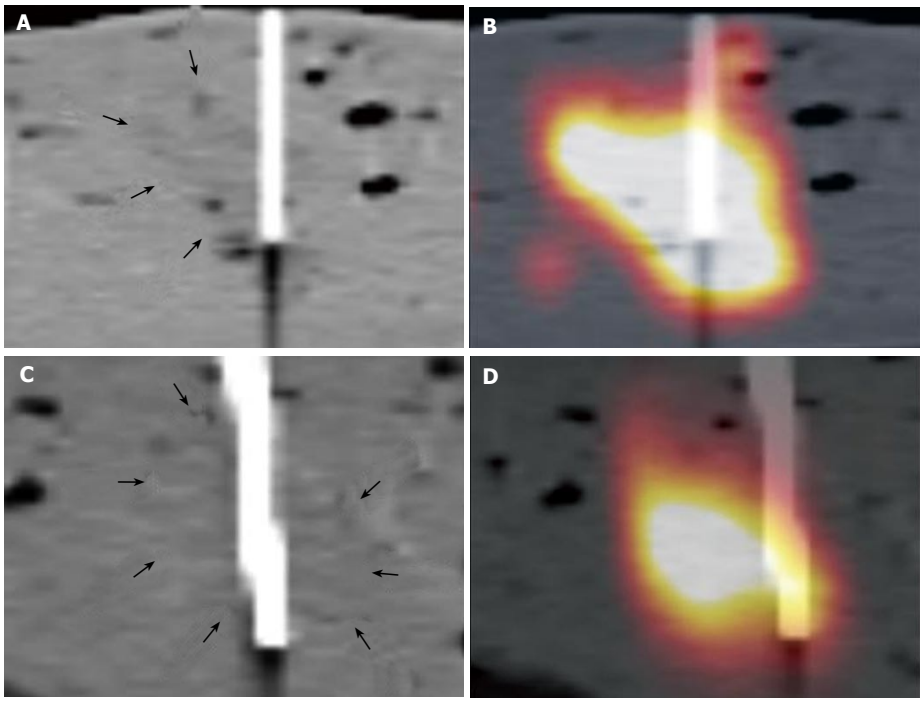

Figure 5 It shows an example of two isodense lesions on CT alone and combined PET/CT with the inserted biopsy needles. The lesions margins are barely seen on CT images alone (fine black arrows, **A** and **C**). In comparison, the true extent and localisation of the lesion are well shown on the combined PET/CT images. Based on poor visibility on CT alone, the lesion in the bottom row was nearly missed (**D**).

PET/CT in hyperdense lesions showed nearly identical values (mean RMS for CT: 10, mean RMS for PET/CT: 10.1) (Figure 3). On the other hand, significant differences were found for the comparison of isodense lesions (mean RMS for CT: 12.1, mean RMS for PET/CT: 6.1). The values for hypodense lesions were less different, however, a significant difference was found here as well (mean RMS for CT: 10.4, mean RMS for PET/CT: 7.4) (Figure 3). Differences between CT and PET/CT were statistically significant in hypodense and isodense lesions ($P < 0.05$ for hypo-, and isodense lesions). Thus, the definition of the needles' position within the lesion on combined PET/CT images was significantly more accurately defined than on CT images alone in hypodense and isodense lesions (Figure 4 and Figure 5). No statistically significant difference between CT-based and PET/CT-based measurements in hyperdense lesions was found. The distribution of mean Hounsfield Units (HU) for hypodense lesions, isodense lesions and hyperdense lesions, as well as for the surrounding liver tissue with corresponding standard deviation was measured and calculated as well (Figure 6).

The difference between mean values for hypodense lesions compared to the liver background was less than the difference of mean values of hyperdense lesions compared to liver background. Mean values of isodense lesions were only slightly different compared to mean values of the liver background, thus the model of artificial lesions met the requirements of the study.

DISCUSSION

PET/CT imaging proved more accurate when assessing

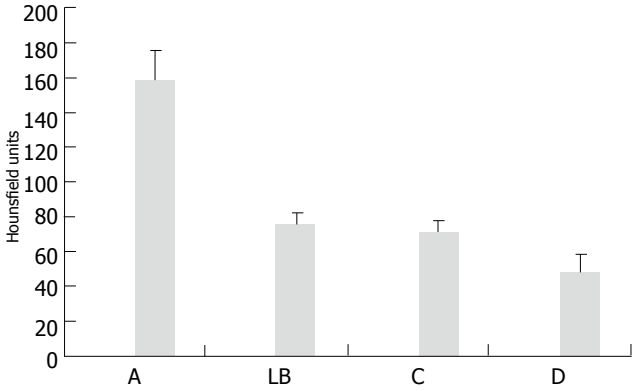

Figure 6 This shows the mean Hounsfield Units (HU) of all measured lesion types, the compared liver background and the corresponding standard deviation. **A**: hyperdense lesions; **LB**: liver background; **C**: isodense lesions; **D**: hypodense lesions.

the position of an interventional device within a liver lesion than imaging analysis based on morphological data alone. Hence, based on the option of more accurate detection of viable tumor tissue, PET/CT promises to add substantial information in selected liver interventions in which equivocal findings on morphologic imaging procedures complicate accurate determination of the interventional needle within the tumour.

Exact positioning of different interventional devices is indispensable for appropriate results in different interventional procedures. In cases of radiofrequency ablation (RFA), complete tumor necrosis is required, because inaccurate position of the ablation device will lead to much higher recurrence rate [9-11]. In biopsy procedures, however, differentiation of viable tumor tissue and necrosis might sometimes be difficult based on only slight differences in density. Furthermore, exact positioning may sometimes be problematic due to unfavourable shape, size, position and visibility of the lesions.

Although CT is a widely used tool for guidance of interventional procedures [12-14], even contrast-enhanced CT images may sometimes not be able to distinguish, both the margin of the lesion and the necrotic region from viable tumor fractions. Lesion attenuation values may differ after i.v. contrast enhancement depending on the tumour entity. Thus, metastases of colorectal cancer appear as hypodense lesions within a contrast enhanced liver, whereas HCC as a contrast-enhancing lesion appears with a higher attenuation than the surrounding liver tissue in the arterial phase. However, some lesions may not show lesion to background contrast after i.v. contrast enhancement, they appear isodense. Therefore a lesion model with different densities, representing several contrast enhancing patterns was chosen.

PET/CT provides additional data by adding functional information to morphology and may be of benefit in cases with impaired visibility and only partly viable lesions [15, 16]. In our study, the needles' positions were significantly better determined on combined PET/CT data sets in hypodense and isodense lesions than with CT alone. Two advantages may arise from these methods from the clinical point of view: first, the placement of the needle may be performed more accurately in cases with impaired visibility. Although PET/CT puncture itself was not performed in this study, these results are suggesting that the use of the additional functional information can possibly lead to the correct position of the ablative device within the lesion. Thus complete tumour ablation in RFA can be achieved. Second, the assessment of the positioning of interventional devices may be more accurate as well.

Needle positioning was significantly more accurate in hypodense and isodense lesion. While this result may be expected for isodense lesions, it seems rather surprising for hypodense lesions. After all, the needle position in hyperdense lesions was assessed equally well with CT alone and combined PET/CT. These results may be explained by attenuation values of the different lesions types. Differences between attenuation values of hypodense lesions and liver background were less than the difference between the mean Hounsfield Units of hyperdense lesions and liver background. Thus, lesion to background contrast was substantially higher for hyperdense lesions than for hypodense lesions (Figure 6). A further decrease in CT attenuation of hypodense lesions may lead to similar results as detected for hyperdense lesions in this study.

Additionally, two isodense lesions were missed by needle placement based on CT images alone. Primary puncture based on PET/CT images might presumably bring an advantage in visibility and might lead to a successful puncture in these cases.

The study has different limitations. Since it was conducted as an *ex-vivo* trial, patient-induced organ movement was excluded and unfavourable tumor sites close to the diaphragm or the liver hilum could be disregarded. Furthermore, this *ex-vivo* model did not include any background activity which may lead to an increased lesion detectability when assessing the needles' position on combined PET/CT. However, the concentration of FDG injected was chosen based on the described ratio calculated on measurements in patients with different liver malignancies. Thus, we tried to come close to a lesion to background ratio similar to those of patients with a broad average of liver malignancies.

Clinical disadvantages are the small size of the evaluated lesions less than 4 cm in diameter. However, small lesions are the ones most difficult to place an ablative device in. Thus, these are the ones in which CT or other morphological imaging procedures may fail. In addition, interventional procedures with a curative intent are limited to smaller lesions. For example, in RF-ablation the maximal diameter that may successfully be treated is 5 cm. Therefore, the lesion size chosen here met the requirements to simulate clinically often difficult procedures.

Additionally, effective treatment (especially in RFA) can particularly be delivered only to lesions with an appropriate, more or less round, shape. However, primary liver tumors for example can grow beside vessels and bile ducts. In these cases, other therapeutic options have to be considered. Since several lesions in our study setting drained away through bile ducts or veins, these unfavourable lesions were excluded from the evaluation as well.

A general consideration when implementing PET/CT-guided interventions in clinical practice will be its com-

plexity and additional cost compared to CT-guided liver interventions. This approach will be more time-consuming, based on patient preparation with FDG administration one hour prior to the intervention and a substantially longer scan time based on the PET component. Hence, this approach should be limited to cases in which CT alone is not able to accurately assess lesion size, shape and location. A possible clinical procedure when evaluating patients for (diagnostic or therapeutic) interventions could be to conduct a contrast enhanced CT scan first. If the target is well visualized and the lesions' margins are clearly defined on non-enhanced or contrast-enhanced images, a conventional CT-guided intervention might be performed. If the lesion is not clearly defined (hypodense or isodense), a separate PET/CT might be performed to identify the exact localisation and margins of the lesions. The combined PET/CT image then can possibly serve as a landmark tool for the CT-guided intervention. Another step further can be the direct, PET/CT-guided intervention. In this case, the interventional procedure has to be performed directly within the PET/CT system. However, the PET component will require, compared to CT alone, significantly more time, which presumably will be one limiting factor in this scenario. To date, there is no software available where the needle's position can be defined online under combined PET/CT-guidance. Hence, further studies with new technologies have to address the feasibility of this approach. In our opinion, this should be furthermore chosen with focus on cases in which a curative approach is aspired, based on the additional complexity, duration and costs of this procedure.

We conclude that combined PET/CT adds substantial additional information to CT alone when assessing the position of an interventional device within a liver lesion. Thus, co-registered PET/CT can be recommended to date for planning selected liver interventions but, based on its additional complexity and cost, should be limited to those procedures where CT alone is not able to accurately delineate the lesion in question.

Abstract

AIM: To investigate the hepatocytic differentiation of mesenchymal stem cells (MSCs) in co-cultures with fetal liver cells (FLC) and the possibility to expand differentiated hepatocytic cells.

METHODS: MSCs were marked with green fluorescent protein (GFP) by retroviral gene transduction. Clonal marked MSCs were either cultured under liver stimulating conditions using fibronectin-coated culture dishes and medium supplemented with stem cell factor (SCF), hepatocyte growth factor (HGF), epidermal growth factor (EGF), and fibroblast growth factor 4 (FGF-4) alone, or in presence of freshly isolated FLC. Cells in co-cultures were harvested, and GFP+ or GFP- cells were separated using fluorescence activated cell sorting. Reverse transcription-polymerase chain reaction (RT-PCR) for the liver specific markers cytokeratin-18 (CK-18), albumin, and alpha-fetoprotein (AFP) was performed in different cell populations.

RESULTS: Under the specified culture conditions, rat MSCs co-cultured with FLC expressed albumin, CK-18, and AFP-RNA over two weeks. At wk 3, MSCs lost hepatocytic gene expression, probably due to overgrowth of the cocultured FLC. FLC also showed a stable liver specific gene expression in the co-cultures and a very high growth potential.

CONCLUSION: The rat MSCs from bone marrow can differentiate hepatocytic cells in the presence of FLC *in vitro* and the presence of MSCs in co-cultures also provides a beneficial environment for expansion and differentiation of FLC.

INTRODUCTION

The existence of putative liver stem cells in the bone marrow was first described by Petersen *et al*[1] who showed that bone marrow cells transplanted into lethally irradiated mice could engraft in the recipient's liver and differentiate into hepatic stem cells (oval cells) or hepatocytes. First *in vitro* data suggest that several types of bone marrow cells / stem cells can differentiate towards hepatocytic cells under the appropriate culture conditions[2-5]. Oh *et al*[6] found that the liver specific proteins alpha-feto protein (AFP) and albumin are expressed in cultures of unsorted rat bone marrow cells after 21 d. Furthermore, several recent *in vitro* studies indicate the possibility of hepatocytic differentiation of MSCs *in vitro*[7-9]. Kang *et al*[7] reported that MSCs from the rat bone marrow can express the liver specific marker AFP, and produce albumin and urea *in vitro* when cultured in the presence of cytokines, fibroblast-growth factor (FGF-4) and hepatocyte growth factor (HGF). Hong *et al*[8] demonstrated that the liver specific genes cytokeratin (CK) 18, AFP, and albumin are expressed in cultures of human umbilical cord-blood derived MSCs. Furthermore, Lee *et al*[9] also showed liver specific functions of cytochrome P450 activity, urea and albumin-production, and glycogen storage in hepatocytic differentiated umbilical cord blood-derived MSC cultures. We had also shown that rat MSCs have a differentiation potential towards hepatocytic cells when co-cultured with adult rat liver cells[10,11]. The fetal milieu, however, might permit a more suitable environment for rapid MSC-maturation into hepatocytic cells.

In this study, we investigated the potential of rat mesenchymal stem cells derived from adult bone marrow to differentiate into hepatic cells *in vitro* under the direct influence of fetal liver cells for the initiation of liver specific gene expression.

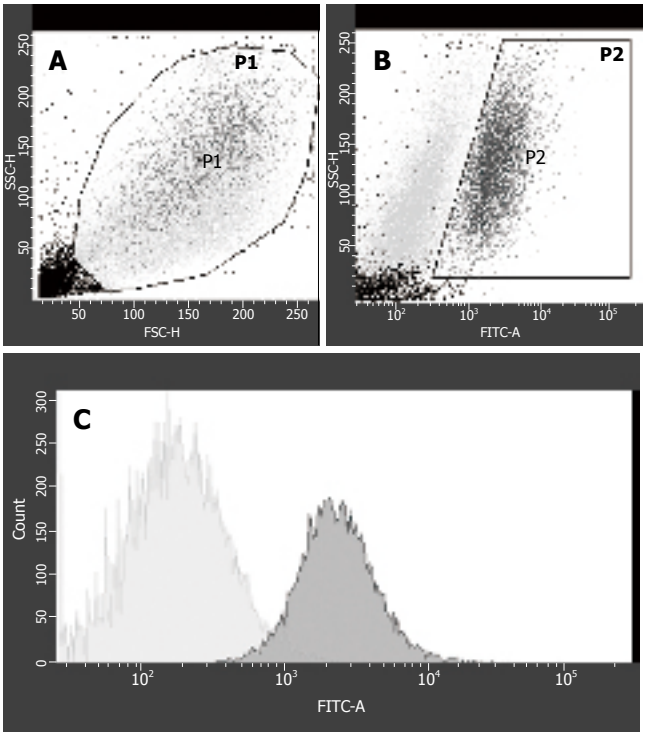

Figure 1 FACS sorting of GFP+ and GFP- cells of co-cultures at wk 1. **A**: Viable cells were gated as P1 cells; **B**: P1 cells were gated in GFP- or GFP+ (P2); **C**: For the highest purification of GFP+ cells, P2 cells were analyzed and only GFP+ cells were sorted for PCR-analysis (light grey peak), 34.5 % of cells from P2 were GFP+ and 65.5 % were GFP-.

MATERIALS AND METHODS

Rat mesenchymal stem cells and fetal liver cells

Isolation, transduction and cloning of rat mesenchymal stem cells were carried out as described previously[10]. Rat embryos of embryonal/ fetal day (ED) 16 were harvested by section after the mother was sacrificed by an overdose of ether-anesthesia. Fetuses were dissected under the dissection microscope. Fetal livers were harvested and liver cells were isolated by a collagenase digestion using collagenase type IV (Sigma, St. Louis, USA) as described previously[12]. A Percoll (P = 1 124 g/mL, Biochrom, Berlin, Germany) gradient centrifugation was used to enrich the viable cell fraction. The Percoll concentration used was 76%. Magnetic cell sorting was used for the removal of fetal OX-43 and OX-44 positive hematopoietic cells from the freshly isolated cells as described elsewhere[13]. In brief, isloated cells were marked with mAb OX-43 and mAb OX-44 (both Serotec, Eching, Germany). Unbound antibodies were removed and secondary marking was done with goat-anti-mouse IgG bound magnetic microbeads (Miltenyi Biotec, Bergisch-Gladbach, Germany). Positive cells were absorbed in a magnetic field by Vario-MACS columns, the depleted cell fraction was collected in a tube.

Co-culture of rMSCs with fetal rat liver cells

Cultures were performed according to our protocol published previously[10]. In brief, cells were seeded on culture wells coated with fibronectin (Sigma) on 24-well plates (Greiner). rMSCs (9×10^4) per well were seeded for MSC-controls, or 6×10^4 fetal liver cells per well for controls. For co-cultures of rMSCs with fetal rat liver cells, 9×10^4 rMSCs per well were preceded in 24-well plates for 2 - 3 h. Then, 6×10^4 fetal rat liver cells per well were added to the cultures. Medium was changed twice a week. Stem Span SFEM (Stem Cell Technologies, St. Katherinen, Germany) medium was supplemented with penicillin/streptomycin (Gibco), dexamethasone (Sigma), 100 ng/mL human recombinant stem cell factor (SCF), 20 ng/mL hepatocyte growth factor (HGF) (both Immunotools, Friesoythe, Germany), 50 ng/mL epidermal growth factor (EGF), and 10 ng/mL fibroblast growth factor-4 (FGF-4) (both R&D, Wiesbaden, Germany). Cultures were analyzed on d 7, 14, and 21.

Separation of GFP positive and negative cells in co-cultures by fluorescence activated cell sorting (FACS)

After the culture period, cells from co-cultures were trypsinized, counted with trypan blue, and re-suspended in 3mL PBS. To get single cell suspension, cells were filtered through a 35 μm filter (BD, Heidelberg, Germany). Cells were sorted using the FACS Aria™ Cell Sorter (BD) into GFP-positive (GFP+) or GFP-negative (GFP-) cells, focussing on the highest possible purity of GFP+ cells.

RNA extraction from cells by RT-PCR

RNA was extracted using the Invisorb Spin Cell-RNA™ Mini-kit (Invitek, Berlin, Germany) according to the manufacturer's instructions and stored at -80℃. Reverse transcription (RT) of extracted RNA was performed using the bulk first-strand c-DNA synthesis kit (Amersham, Freiburg, Germany). The cDNA was stored at -20℃. For PCR, 5 μL of cDNA-template was mixed with 2.5 μL of 10× PCR-buffer, 0.5 μL of 10 mmol dNTP´s, 0.5 μL of each primer (50 ng/μL), and 0.5 μL of polymerase (AmpliTaq., Gibco) in a total volume of 25 μL for each probe. PCR was carried out in a programmable Biometra Uno-Thermobloc (Biometra, Göttingen, Germany) using the primers for albumin, AFP, and CK-18 as described previously[10]. Negative controls were performed for each set of primers. Samples were analyzed on 1% agarose gels. The size of the PCR-fragments was estimated using the 100-base-pair ladder (Gibco BRL).

RESULTS

FACS of co-cultured cells

The sorting strategy concentrated on maximal purity of GFP+ cells to exclude contamination with FLC-derived RNA. A typical example for FACS 1 wk after co-culture is shown in Figure 1. The viable cells were gated according to forward and side scatter properties (Figure 1A). Two populations varied in size and granulation. GFP-expression of the gated cells was investigated in two populations, differing in granulation (Figure 1B) and gated as P2 cells. From these P2-cells, the contaminating GFP- cells were sorted out (Figure 1C). All non-P1, non-P2 and non-GFP cells were collected as GFP- cells. When the number of viable cells (gate P1) was set as 100%, the fraction of GFP positive cells decreased from 24.2 % of viable cells at wk 1 to 1.3 % of viable cells at wk 3 (Table 1). This was also con-

Table 1 Fractions of FAC-sorted cells (%)

	Wk 1	Wk 2	Wk 3
Viable Cells	70.2	79.1	77
GFP-positive cells	34.5	5.6	1.7
GFP-negative cells	65.5	94.4	98.3

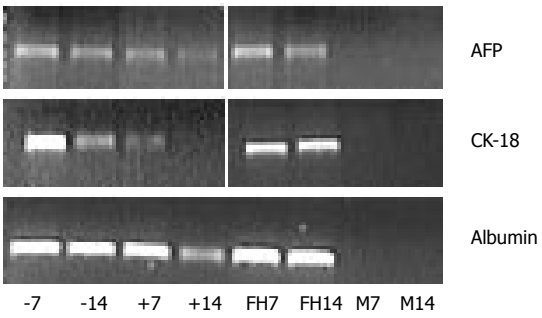

Figure 2 Expressions of the liver specific markers (AFP, CK-18, or albumin) of cultured rMSCs (M), fetal liver cells (FH), and GFP+ (+) or GFP- (-) cells of the co-cultures on d 7 or 14. Cultured rMSCs lacked expression of AFP, CK-18, or albumin on d 7 or 14 (lanes M7 and M14). Cultured fetal liver cells showed expression of AFP, CK-18 and albumin on d 7 or 14 (lanes FH7 and FH14). The GFP+ cells (lanes +7 and +14) showed clear expression of albumin and AFP, and lower expression of CK-18. The GFP- cells (lanes -7 and -14) showed a stable expression of AFP, CK-18, and albumin.

sistent with the morphological findings in the co-cultures, where a massive overgrowth of the adherent MSCs to the fetal liver cells was observed.

Liver specific geneexpression (AFP, CK-18, albumin)

Glyceraldehyde phosphate dehydrogenase (GAPDH) expression in cultured rMSCs, fetal liver cells, or GFP+ and GFP- FACS cells was equal at all time points (data not shown). Cultured rMSCs showed no expression of AFP, CK-18, or albumin on d 7 or 14 (Figure 2, lanes M7 and M14). Cultured fetal liver cells showed expression of AFP, CK-18 and albumin over the two wk culture period (Figure 2, lanes FH7 and FH14). The GFP+ cells (Figure 2, lanes +7 and +14) showed a strong expression of albumin and AFP, and a declining expression of CK-18. The GFP- cells (Figure 2, lanes -7 and -14) showed a stable expression of AFP, CK-18, and albumin. Negative controls without template were negative at all time points and probes (data not shown). On d 21, no liver specific genes were detected in the GFP+ cells (data not shown) probably due to the small cell number.

DISCUSSION

In this study, cloned GFP+ rMSCs from passage ⩾9 were used for the differentiation analysis towards liver cells. For liver specific differentiation, cells were cultured on a fibronectin matrix in serum free medium containing the liver growth factors: HGF, EGF, FGF-4, and the stem cell growth factor: SCF. The impact of FLC on hepatic differentiation was assessed in co-cultures of GFP+ rMSCs with freshly isolated fetal rat liver cells (GFP-negative), and compared to cultures with rMSCs or FLC alone. For gene-expression analysis, cells from co-cultures were separated in GFP+ or GFP- cells by fluorescence-activated cell sorting before RT-PCR analysis.

Albumin is a typical marker of mature hepatocytes, whereas CK18 is expressed in several liver cell types, including biliary epithelial cells and hepatic oval cells[14]. AFP in the liver is a marker of immature (e.g. fetal) liver cells or oval cells in the adult liver[15]. Our data indicate that rMSCs possess a differentiation potential towards hepatocytic cells *in vitro*. Expression of the liver specific genes CK-18, albumin, and AFP was demonstrated in GFP+ cells of the cocultures for two weeks. Additionally, we found that liver specific gene expression in mesenchymal stem cells was induced by the coculture with isolated FLC. Cultured rMSCs alone did not express any of the liver specific genes studied in the presence of fibronectin (FN)-coating and liver-differentiation stimulating growth factors. Avital *et al*[16] have highlighted the effects of co-cultured hepatocytes (separated by a PTFE-membrane) for β2m-negative thy1-positive stem cells from rat bone marrow expressing the liver marker albumin[16]. An important influence of hepatocytes on the differentiation of stem cell-enriched bone marrow has also been highlighted by Okumoto *et al*[17] who found that MSCs-enriched bone marrow stem cells cultured in the presence of HGF and fetal bovine serum (FBS) express the markers: hepatic nuclear factor 1 (HNF1-α) and CK-8 only after 7 d. In co-cultures with hepatocytes separated by a semi-permeable membrane the stem cells additionally express the liver specific markers: AFP and albumin. We found a beneficial effect for differentiation and growth of the co-cultured fetal liver cells (GFP-), which also showed a stable liver specific gene expression and viability over the whole observation period. This is consistent with findings of Hoppo *et al*[18] who showed a positive influence of MSCs on cultured endodermal fetal liver cells of the mouse in culture. However, the FLC tended to overgrow the adherent layer of MSCs at the end of the culture period. Thus, we could not detect any liver specific gene expression in the few remaining GFP+ MSC-derived cells in the co-cultures at wk 3. Our results support the notion of a faster differentiation of MSCs into hepatocytic cells under the influence of fetal liver cells compared to adult hepatocytes. The growth potential of MSCs seems to be impaired by the huge overgrowth of FLC, thus limiting the desired expansion of differentiated MSCs. Based on the declined GFP-positive fraction of cells and the decreased intensity of semi-quantitative PCR-signals over the experimental time of 3 wk, differentiation of rMSCs into hepatocytic cells could be suggested. However, fusion events can not be ruled out by our data.

Our *in vitro* data indicate that mesenchymal stem cells from rat bone marrow possess a differentiation capacity towards hepatocytic cells *in vitro*. Furthermore, we showed a strong influence of co-cultures with fetal liver cells on the induction of liver specific gene expression of cultured stem cells. However, fetal liver cells tended to overgrow the adherent MSCs in the co-cultures.

In conclusion, the co-culture of MSCs and FLC is a feasible culture model which might provide more insights into the relationship between fetal hepatopoietic cells during liver development.

Abstract

AIM: To compare peptic ulcer prevalence in patients referred for upper gastrointestinal endoscopy in two Italian hospitals in pre-*Helicobacter* era and ten years after the progressive diffusion of eradication therapy.

METHODS: We checked all the endoscopic examinations consecutively performed in the Gastroenterology Unit of Padova during 1986-1987 and 1995-1996, and in the Gastroenterology Unit of Parma during 1992 and 2002. Chi Square test was used for statistic analysis.

RESULTS: Data from both the endoscopic centers showed a statistically significant decrease in the prevalence of ulcers: from 12.7% to 6.3% ($P < 0.001$) in Padova and from 15.6% to 12% ($P < 0.001$) in Parma. The decrease was significant both for duodenal (from 8.8% to 4.8%, $P < 0.001$) and gastric ulcer (3.9% to 1.5%, $P < 0.001$) in Padova, and only for duodenal ulcer in Parma (9.2% to 6.1%, $P < 0.001$; gastric ulcer: 6.3% to 5.8%, NS).

CONCLUSION: Ten years of extensive *Helicobacter pylori* (*H pylori*) eradication in symptomatic patients led to a significant reduction in peptic ulcer prevalence. This reduction was particularly evident in Padova, where a project for the sensibilization of *H pylori* eradication among general practioners was carried out between 1990 and 1992. Should our hypothesis be true, *H pylori* eradication might in the future lead to peptic ulcer as a rare endoscopic finding.

Key words: Ulcer prevalence; *H pylori*

INTRODUCTION

It is now well established that *Helicobacter pylori* (*H pylori*) eradication can significantly modify the natural history of peptic ulcer disease. Marshall *et al* first demonstrated in 1988 that when *H pylori* was cleared 92% of ulcers healed and only 21% relapsed during a 12 mo follow-up period[1]. Several studies have then confirmed these data over the years. Follow-up studies have in fact shown lower relapse rates of both gastric and duodenal ulcers after successful *H pylori* eradication, in the short term as in the long term[2-4]. So by the end of the eighties *H pylori* was generally accepted as a causal factor in the pathogenesis of chronic gastritis and peptic ulcer. Between the end of the eighties and the beginning of the nineties eradication of *H pylori* has become a widespread approach for acid-related disorders, first among GI specialists, then among general practitioners.

Leerdam *et al* (2003) described a reduction in the incidence of upper gastrointestinal bleeding between 1993/94 and 2000[5]. They hypothesized that the decrease in incidence might partly be explained by the fact that *H pylori* is more often eradicated in patients with dyspeptic complaints and peptic ulcer disease, thus reducing the possibility of development of complications as bleeding. Furthermore, it is often reported as an impression by endoscopists that we see fewer ulcers than we did years ago, but data on the real prevalence are still scanty. Xia *et al* (2001) studied the prevalence of *H pylori* infection, peptic ulcer disease and reflux esophagitis in consecutive patients referred for upper GI endoscopy in an endoscopy unit in Sydney in a three-month period in different years (1990, 1994 and 1998), reporting a decrease in peptic ulcer disease

(22%, 15% and 13%, respectively, $P = 0.003$). They also described a lower prevalence of *H pylori* infection as well as a significant decrease in NSAIDs consumption, leading to the hypothesis that both these two risk factors likely contributed to the reduction of peptic ulcer disease[6].

Therefore, the aim of this study was to compare the prevalence of peptic ulcer disease among patients referred for upper GI endoscopy between the eighties and the nineties and after a period of 10 years, in two Italian GI units of two hospitals.

MATERIALS AND METHODS

Patients

We retrospectively analyzed all the upper GI endoscopies performed in the Gastroenterology Unit of Parma in two different years (1992 and 2002), and in the Gastroenterology Unit of Padova in two periods: from Feb 1, 1986 to Dec 31, 1987 and from Feb 1, 1995 to Dec 31, 1996. We selected the patients with a diagnosis of gastric or duodenal ulcer. Both the endoscopic units of Parma and Padova serve in-patients and out-patients, and are the major endoscopy centers of the area. Out-patients are directly sent by general practitioners or by specialists. Both the units have an informatic database (DB3 engine). We searched for gastric and duodenal ulcers both manually and informatically, with the strings "(gastrica or gastriche or angolare or antrale or del corpo-fondo) and/or (duodenale/i or bulbare or bulbari or del duodeno) and (ulcera or ulcere)".

Between 1990 and 1992 a project was performed in Padova in order to stimulate the aptitude towards the *Helicobacter pylori* (*H pylori*) eradication among physicians. It involved both specialists and general practitioners.

H pylori status was obtained for all patients accessing the hospital, through the dosage of serum antibodies. Data about upper GI symptoms and history of acid-related disorders were also collected. All patients positive for *H pylori* infection were treated with a triple one week therapy ("ulcer-free hospital" project).

Several meetings were held by the Gastroenterology Clinic of Padova between 1990 and 1992, with the participation of groups of 30 general practitioners. Statements discussion and interactive clinical case analysis were conducted, with initial and final testing of *H pylori* . General practitioners were sensibilized to test all patients suffering from upper GI symptoms or with a history of gastritis or peptic ulcer, diagnosed with a structured questionnaire ("ulcer-free ambulatory") and eradicate *H pylori*, when positive.

Statistical analysis

Chi Square test was applied on the changes of prevalence of peptic ulcers (total), gastric and duodenal ulcers after a decade. $P < 0.05$ was considered as significant.

RESULTS

In Parma we analyzed a population of 3779 subjects in 1992 (2185 out-patients and 1594 in-patients), with a mean age of 69.4 years (range 5-94 years) and a sex distribution of 54.4% males and 45.6% females, as well as a population of 3828 subjects in 2002 (1985 out-patients and 1843 in-patients), with a mean age of 62.3 years (range 12-97 years) and a sex distribution of 53.4% males and 46.6% females. We found 588 ulcers in 1992 (239 GU and 349 DU), 459 ulcers in 2002 (223 GU and 236 DU). *H pylori* status was evaluable only for 28.7% of patients with peptic ulcer in 1992 and 47.7% in 2002, so it could not be useful for statistical analysis. Among gastric ulcers, we found neoplastic lesions in 56 subjects in 1992 and 20 subjects in 2002.

In Padova we analyzed a population of 3703 subjects during 1986-1987, with a mean age of 54 years (range 15-91 years) and a sex distribution of 53.5% males and 46.5 females, as well as a population of 5727 subjects during 1995-1996, with a mean age of 51 years (range 14-98 years) and a sex distribution of 39.7% males and 60.3% females. We found 470 ulcers during 1986-87 (144 GU and 326 DU), 361 ulcers during 1995-1996 (86 GU and 275 DU). *H pylori* status was available only for patients with peptic ulcer during 1995-1996 and showed a prevalence of 83.6% (68.6% for GU and 88.4% for DU). It was determined by histology of mucosa, with appropriate staining.

Table 1 and Table 2 summarize the changes in prevalence of peptic ulcer after ten years in Parma and in Padova. Table 3 and Table 4 describe the epidemiological characteristics of the populations we studied.

Both the endoscopic centers showed a statistically significant decrease in the prevalence of ulcers: 12.7% to 6.3% ($P < 0.001$) in Padova, 15.6% to 12% ($P < 0.001$) in Parma. The decrease was greater for duodenal ulcer (8.8% to 4.8%, $P < 0.001$ in Padova, 9.2% to 6.1%, $P < 0.001$ in Parma) than for gastric ulcer (3.9% to 1.5%, $P < 0.001$ in Padova, 6.3% to 5.8%, NS in Parma).

Table 1 Changes in prevalence of peptic ulcer after ten years in Padova

Padova	1986-1987 *n* (%)	1995-1996 *n* (%)	*P*
Population	3703	5727	
Total of ulcers	470 (12.7)	361 (6.3)	< 0.001
Duodenal ulcer	326 (8.8)	275 (4.8)	< 0.001
Gastric ulcer	144 (3.9)	86 (1.5)	< 0.001

Table 2 Changes in prevalence of peptic ulcer after ten years in Parma

Parma	1992 *n* (%)	2002 *n* (%)	*P*
Population	3779	3828	
Total of ulcers	588 (15.6)	459 (12)	< 0.001
Duodenal ulcer	349 (9.2)	236 (6.1)	< 0.001
Gastric ulcer	239 (6.3)	223 (5.8)	NS

Table 3 Characteristics of the population from Parma

	1992	2002

Origin	2185 out-patients, 1594 in-patients	1985 out-patients, 1843 in-patients
Age (yr)	69.4 (range 5-94)	62.3 (range 12-97)
Sex (M/F)	54.4%/45.6%	53.4%/46.6%

Table 4 Characteristics of the population from Padova

	1986-1987	1995-1996
Population (*n*)	3703	5727
Age (yr)	54 (range 15-91)	51 (range 14-98)
Sex (M/F)	39.7%/ 60.3%	53.5%/ 46.5%

DISCUSSION

The study suggests that the incidence of peptic ulcer among patients referred for upper GI endoscopy significantly decreased through the years. Our hypothesis is that *H pylori* eradication could have changed the natural history of peptic disease. Eradication of the bacterium by the general practitioners in symptomatic subjects has become a common approach through the nineties. So we identified those patients who have not been eradicated or who were still symptomatic after the therapy.

One limit of the present study is the examination of a selected population, which was referred for upper GI endoscopy and probably had been given antisecretory drugs during the weeks preceding the access to the endoscopy. We have asked ourselves if the reduced prevalence of ulcer after ten years could be related with differences in drug prescription of anti-secretive agents among general practitioners. We did not collect data on drug intake, however, we thought this finding might only play a secondary role in the observed trend. In fact, significant differences in drug prescription could be seen when comparing the early eighties to the nineties, and since the late eighties histamine H2-receptor antagonists (anti-H2s) and proton pump inhibitors (PPIs) have been widely used in both the Italian areas we examined.

Capurso *et al* (1996)[7] retrospectively analysed upper gastrointestinal endoscopies performed in their center in Rome between January 1981 and December 1991. They reported an incidence of 4.1%±0.6% and a mean annual prevalence of 6.9%±0.7%. These data are quite similar to those in our center at the beginning of the observation period.

Data in Parma for peptic ulcer prevalence are quite similar to those reported by Xia *et al* in Sidney during the same decade. The authors concluded that both the decreased use of NSAIDs and the decline of *H pylori* infection have likely contributed to the reduction of peptic ulcer disease. Regretfully we did not have data about the *H pylori* status and the NSAIDs use of the population we examined. A reduced use of NSAIDs during the last decade has, however, not been reported in our areas, so we do not think it could have played a significant role.

The two populations examined in the present study showed different prevalence of both duodenal and gastric ulcer. We are not sure if this reflected a really different prevalence in the general populations of Parma and Padova, since no available data were collected on this subject. On the other hand, it must be underlined that the organization of both endoscopic units was similar; they tested both in-patients and out-patients, directly sent by general practitioners or by specialists.

Padova showed a greater significant decrease in the prevalence of ulcers through the decade. This might be due to the fact that the Gastroenterology Department of the University of Padova performed during those years a diffuse sensibilization of general practitioners about the eradication of *H pylori*, by means of the so called "Ulcer Free Project", as above described.

The decrease in prevalence was greater for duodenal ulcer than for gastric ulcer in both the studied populations. This is probably related to the different role played by *H pylori* in gastric and duodenal ulcer pathogenesis: it is known that more than 90% of duodenal ulcers but only 70% of gastric ulcers are associated with *H pylori* infection. This is in line with the results of the meta-analysis conducted by Ford *et al*[8]. They showed a reduction of relative risk of 54% in the recurrence of duodenal ulcer after *H pylori* eradication, and a still significant but smaller reduction of relative risk of 37% for gastric ulcer.

Additionally, it must be stressed that the role of anti-inflammatory drugs in the pathogenesis of gastric ulcer could be important in trying to correctly explain these data, but as previously mentioned, we lack at present epidemiological data on this subject.

In conclusion, we think *H pylori* eradication may in the future lead to peptic ulcer as a rare endoscopic finding, particularly in areas where a diffuse information program among general practitioners is performed. By now, the absolute number of ulcers we have diagnosed is still high, and there is need for more prevention strategies.

Abstract

AIM: To accurately differentiate the adenomatous from the non-adenomatous polyps by colonoscopy.

METHODS: All lesions detected by colonoscopy were first diagnosed using the conventional view followed by chromoendoscopy with magnification. The diagnosis at each step was recorded consecutively. All polyps were completely removed endoscopically for histological evaluation. The accuracy rate of each type of endoscopic diagnosis was evaluated, using histological findings as gold standard.

RESULTS: A total of 240 lesions were identified, of which 158 (65.8%) were non-neoplastic and 82 (34.2%) were adenomatous. The overall diagnostic accuracy of conventional view, and chromoendoscopy with magnification was 76.3% (183/240) and 95.4% (229/240), respectively ($P < 0.001$).

CONCLUSION: The combination of colonoscopy and magnified chromoendoscopy is the most reliable non-biopsy method for distinguishing the non-neoplastic from the neoplastic lesions.

Key words: Colorectal polyps; Colonoscopy; Chromoendoscopy; Magnifying endoscopy

INTRODUCTION

Recently, colorectal polyps have been identified with increasing frequency as a result of the wide use of colonoscopy for screening. The detection and subsequent removal of neoplastic colorectal lesions, including adenomatous polyps and early cancers can reduce the incidence and mortality of colorectal cancers. Although initial data suggest that 80%-90% of diminutive colorectal polyps (≤5 mm) are histologically hyperplastic, more recent data indicate that 40%-60% of such polyps are neoplastic [1-5]. The ability to accurately differentiate the adenomatous from the non-adenomatous polyps is useful because it obviates the need for biopsies during colonoscopy and for removal of all diminutive polyps[6-8]. Some investigators suggest that the combination of magnified chromoendoscopy and colonoscopy can make the histopathological diagnosis of colorectal polyps. However, how this technique increases the accuracy of differential diagnosis of adenomatous from non-adenomatous polyps over conventional colonoscopy is unclear.

This study was to compare the observations by conventional colonoscopy to these obtained by magnified chromoendoscopy in a group of patients with diminutive colorectal polyps (≤5 mm), using histopathology as a "gold standard".

MATERIALS AND METHODS

Patients and exclusion criteria

Patients were eligible to participate in the study if they were scheduled to undergo flexible colonoscopy in our center. Patients with polyps larger than 5 mm were excluded from this study. Patients with inflammatory bowel disease (IBD), hereditary non-polyposis colorectal cancer (HNPCC) and familial adenomatous polyposis (FAP) were also excluded.

The study protocol was approved by the institutional review board of our hospital. An informed consent was

obtained from each patient for the inclusion in the study.

Diagnostic procedures

A zoom-colonoscope (Olympus CF-Q160ZL, Olympus Optical Co., Ltd., Tokyo, Japan) providing both conventional and magnified images was used. The colonoscope was introduced up to the cecum. Subsequently, while the instrument was retracted, the colorectal mucosa was scrutinized in detail. When a polyp was detected, the mucus on the surface of the lesion was washed away and the polyp was first examined with the conventional view. Then 0.5% indigo carmine dye was sprayed over the lesion with a special catheter and observation was carried out. On conventional view, the key endoscopic findings for distinguishing non-neoplastic from neoplastic lesions were based on the gross appearance at visual inspection, namely the size, shape, overlying mucus, and color of the lesions. Macroscopic appearance was reported according to the Paris endoscopic classification of superficial neoplastic lesions[9].

The polyps were categorized as neoplastic or non-neoplastic as previously described[10]. The diagnosis at each step was recorded consecutively and all polyps were completely removed endoscopically. The accuracy rate of each type of endoscopic diagnosis was evaluated, using histological findings as gold standard. Morphology, size, and anatomical location of all lesions were documented. The diameter of each lesion was estimated using standard fully open biopsy forceps (4 mm) with the height estimated by placing the closed forceps tip adjacent to the lesion (2 mm). A single colonoscopist who was well trained in magnified colonoscopy, performed all procedures.

Statistical analysis

The number of patients in each group to demonstrate statistical significance with 5% alpha error and 90% power was estimated to be 47 and calculated on the basis of previous data[11-14], assuming a 25% difference in negative predictive value (NPV) for adenomatous polyps between the two groups. A chi-square analysis was performed for comparisons. $P < 0.05$ was considered statistically significant.

RESULTS

Of the 1982 consecutive patients attending for routine colonoscopy, 150 (93 men and 57 women with a mean age of 58.9 years) with polyps smaller than 5 mm in diameter were recruited between December 2004 and July 2005. Characteristics of the patients enrolled and indications for endoscopy are shown in Table 1. Total colonoscopy and histological evaluation were carried out in all patients without complications. A total of 240 lesions were identified. A single lesion was found in 101 (67.3%) cases, and 35 (23.3%) and 14 (9.3%) patients had two or more than three lesions, respectively.

A total of 158 lesions (65.8%) were non-neoplastic (including hyperplastic polyps, inflammatory polyps, and lymphoid aggregates) and 82 (34.2%) were adenomatous. Of these lesions, 194 (80.8%) were located in the distal colon (below the splenic flexure) and 46 (19.2%) in the proximal colon. The mean size of the non-neoplastic and neoplastic lesions was 3.46 mm and 3.83 mm, respectively. Although the neoplastic lesions might be larger than the non-neoplastic ones, the difference was not significant. The characteristics and distribution of colonic lesions are shown in Table 2.

The surface pattern of the lesion could be obtained and interpreted adequately in all cases. The overall diagnostic accuracy for distinguishing the neoplastic from the non-neoplastic lesions at each step (that is, conventional colonoscopy and magnified chromoendoscopy) was 76.3% (183/240), and 95.4% (229/240), respectively. The method of magnified chromoendoscopy with indigo carmine dye was significantly better for distinguishing the neoplastic from the non-neoplastic lesions, compared with conventional colonoscopy ($P < 0.0001$).

Fifty-seven of 240 lesions were misdiagnosed by conventional colonoscopy, including 38 hyperplastic polyps, 8 inflammatory polyps and 4 lymphoid aggregates which were overdiagnosed and 7 adenomas with mild atypia which were underdiagnosed. For the detection of adenomatous and non-adenomatous polyps, conventional colonoscopy had a sensitivity of 91.4%, specificity of 68.3%, NPV of 93.9% and PPV of 60.0% (Table 3). Eleven of 240 lesions were misdiagnosed by magnified chromo-

endoscopy, including 5 hyperplastic polyps, 2 inflammatory polyps and 2 lymphoid aggregates which were overdiagnosed and 2 adenomas with mild atypia which were underdiagnosed. For the detection of adenomatous and non-adenomatous polyps, high-resolution chromoendoscopy had a sensitivity of 97.5%, specificity of 94.3%, NPV of 98.69% and PPV of 89.9% (Table 4).

DISCUSSION

Given the incidence of colorectal cancer in the Western population and the recent thrust to implement broad-based screening methods, the issue of endoscopic resection of potentially cancerous or precancerous lesions assumes immense practical importance. It has been estimated that approximately two thirds of colorectal cancers arise from adenomatous polyps. The endoscopic detection and removal of polypoid tumors, therefore, have been emphasized to prevent the development of advanced colorectal cancers[2,15,16]. Since 10%-30 % of all colorectal polyps are non-neoplastic, it is very important to distinguish non-neoplastic from neoplastic lesions by colonoscopy, because removal or biopsy of non-neoplastic lesions would not only waste time and money but may also increase procedure-associated complications[6-8]. In particular, since reported data suggest that 80%-90% of diminutive colorectal polyps ($\leqslant$5 mm) are histologically hyperplastic, the ability to establish an immediate endoscopic diagnosis that is virtually consistent with the histology would be useful because it would obviate the need for biopsies during colonoscopy and also the need to remove all diminutive polyps, which is time consuming, expensive, and associated with risk.

Various data have been reported on the diagnostic abilities of conventional colonoscopy and magnified chromoendoscopy for such differentiation[11-15]. However, to the best of our knowledge, there is no prospective study on the accuracy for the differential diagnosis of non-neoplastic from neoplastic colorectal lesions using conventional colonoscopy and high-resolution chromoendoscopy consecutively.

In the present study, the diagnostic accuracy by conventional endoscopy and magnified chromoendoscopy using indigo carmine was 72.0% and 95.6%, respectively, with statistically significant difference ($P < 0.0001$). Fifty-seven of 240 lesions were misdiagnosed by conventional endoscopy, including 38 hyperplastic polyps, 8 inflammatory polyps and 4 lymphoid aggregates which were over-diagnosed and 7 adenomas with mild atypia which were underdiagnosed. For the detection of adenomatous and non-adenomatous polyps, conventional colonoscopy could show over 90% of the neoplastic lesions, but less than 70% of the non-neoplastic lesions, suggesting the possibility of excessive treatment, waste of time and resources (Table 3). Eleven of 240 lesions were misdiagnosed by magnified chromoendoscopy, including 5 hyperplastic polyps and 2 inflammatory polyps, 2 lymphoid aggregates which were over-diagnosed and 2 adenomas with mild atypia which were underdiagnosed. Magnified chromoendoscopy displayed 97.5% of the neoplastic lesions and 94.3% of the non-neoplastic lesions. Two (0.8%) false negative cases due to mixed polyps were diagnosed by magnified ehromoendoscopy.

Because the NPV was 98.6% indicating that some polyps were overlooked, it could be argued that high-resolution chromoendoscopy is not completely useful in clinical practice. Since no screening tests currently used have a NPV of 100%, the combination of magnified colonoscopy and dye spraying is the most reliable non-biopsy method for distinguishing the non-neoplastic from the neoplastic lesions at present. Moreover, with improved dyes and higher resolution chromoendoscope, better results might be obtainable. In this study all procedures were performed by a single operator who was well trained in magnified chromoendoscopy. The problem of a single operator study can represent the difficulty in deciding whether such results can be generalized. The time necessary for learning to recognize the mucosal crypt patterns is important, but has not been precisely reported. The endoscopist in this study had 5 years of experience in magnified endoscopy. In our previous experience, a foreign doctor without knowledge of pit patterns took only 3 months to acquire a differential diagnostic accuracy of over 90 %, which was similar to that of the well-trained endoscopists in this study (unpublished data). We believe that the time for learning could be shortened by showing trainees numerous typical endoscopic pictures of pit patterns before they perform the diagnostic procedure. However, this should be confirmed by future prospective studies including a large number of endoscopists.

Further questions include whether magnified endoscopy is as effective as total colonoscopy, how much time this adds to per case, and what is the cost associated with this procedure. In this study, with an instrument that was slightly more difficult to handle, intubation of the cecum was achieved for all patients without complications. Therefore, our results support the conclusion that magnified endoscopy is safe and can be used routinely. In our experience, the procedure usually only takes about 10-20 seconds for one polyp, and is less troublesome and time-wasting than colonoscopy.

In conclusion, the combination of colonoscopy and magnified chromoendoscopy is the most reliable nonbiopsy method for distinguishing non-neoplastic from neoplastic lesions. The use of this technique could decrease the time and resources required during colonoscopy by reducing the need for biopsy and resection of non-neoplastic polyps.

Abstract

AIM: To assess whether portacaval anastomosis (PCA) in rats affects the protein expression and/or activity of glutaminase in kidneys, intestines and in three brain areas of cortex, basal ganglia and cerebellum and to explain the neurological alterations found in hepatic encephalopathy (HE).

METHODS: Sixteen male Wistar rats weighing 250-350 g were grouped into sham-operation control ($n = 8$) or portacaval shunt ($n = 8$). Twenty-eight days after the procedure, the animals were sacrificed. The duodenum, kidney and brain were removed, homogenised and mitochondria were isolated. Ammonia was measured in brain and blood. Phosphate-activated glutaminase (PAG) activity was determined by measuring ammonia production following incubation for one hour at 37℃ with O-phthalaldehyde (OPA) and specific activity expressed in units per gram of protein (μkat/g of protein). Protein expression was measured by immunoblotting.

RESULTS: Duodenal and kidney PAG activities together with protein content were significantly higher in PCA group than in control or sham-operated rats (duodenum PAG activity was 976.95±268.87 μkat/g of protein in PCA rats *vs* 429.19±126.92 μkat/g of protein in sham-operated rats; kidneys PAG activity was 1259.18 ± 228.79 μkat/g protein in PCA rats *vs* 669.67± 400.8 μkat/g of protein in controls, $P < 0.05$; duodenal protein content: 173% in PCA *vs* sham-operated rats; in kidneys the content of protein was 152% in PCA *vs* sham-operated rats). PAG activity and protein expression in PCA rats were higher in cortex and basal ganglia than those in sham-operated rats (cortex: 6646.6 ± 1870.4 μkat/g of protein *vs* 3573.8 ± 2037.4 μkat/g of protein in control rats, $P < 0.01$; basal ganglia, PAG activity was 3657.3 ± 1469.6 μkat/g of protein in PCA rats *vs* 2271.2 ± 384 μkat/g of protein in sham operated rats, $P < 0.05$; In the cerebellum, the PAG activity was 2471.6 ± 701.4 μkat/g of protein *vs* 1452.9 ± 567.8 μkat/g of protein in the PCA and sham rats, respectively, $P < 0.05$; content of protein: cerebral cortex: 162% ± 40% *vs* 100% ± 26%, $P < 0.009$; and basal ganglia: 140% ± 39% *vs* 100% ± 14%, $P < 0.05$; but not in cerebellum: 100% ± 25% *vs* 100% ± 16%, P = ns).

CONCLUSION: Increased PAG activity in kidney and duodenum could contribute significantly to the hyperammonaemia in PCA rats, animal model of encephalopathy. PAG is increased in non-synaptic mitochondria from the cortex and basal ganglia and could be implicated in the pathogenesis of hepatic encephalopathy. Therefore, PAG could be a possible target for the treatment of HE or liver dysfunction.

INTRODUCTION

Hyperammonaemia plays a major role in the pathogenesis of hepatic encephalopathy (HE). Phosphate-activated glutaminase (PAG) catalyzes the hydrolysis of glutamine (Gln) to yield glutamate (Glu), energy, nucleotide synthesis and ammonia. Two main isoforms of PAG have been described: the kidney-type (K-PAG) and the liver type (L-PAG). The K-PAG has been found in kidney, brain and villi enterocytes, while L-PAG is restricted to the liver. Hyperammonaemia is largely considered to be derived from urea breakdown by intestinal bacteria, thus most treatments have been focussed on reducing ammonia production from colon bacteria[1]. However, some data suggest that small intestine plays an important role in ammonia production during the pathogenesis of hepatic encephalopathy[2]. Indeed, duodenal PAG activity has been found to be nearly four times higher in cirrhotic patients than in healthy controls, and moreover it is closely related to minimal hepatic encephalopathy[3]. In rats, the highest PAG activity along the length of gastrointestinal tract has been measured in the small intestine[4]. Lower but still substantial activity (15% of total PAG activity) has been found in large intestine. PAG activity distribution along the gastrointestinal tract in humans is similar to that in rats[5]. PAG plays another important role at renal level. Glutamine is filtered and reabsorbed in the proximal convoluted tubule where it is deamidated by PAG. Two thirds of this ammonia production is excreted in urine. This process is pH sensitive and helps to maintain acid-base homeostasis and to excrete nitrogen[6]. However, PAG activity in kidney remains largely unexplored in portacaval shunted rats. Distribution and location of PAG in brain as well as its role in the pathogenesis of HE, are widely controversial, while PAG activity in portacaval shunted rats still remains unknown. Portacaval anastomosis (PCA; or portacaval shunt PCS) in rats is widely accepted as a model of type B hepatic encephalopathy that mimics minimal hepatic encephalopathy in humans. The aim of this study was to assess whether portacaval anastomosis in rats affects the expression and/or activity of glutaminase in kidney, intestines and the astrocytes of three brain areas (cortex, basal ganglia and cerebellum) involved in the neurological alterations of hepatic encephalopathy.

MATERIALS AND METHODS

Animal surgery

Sixteen male Wistar rats (n = 16) weighing 250-350 g were randomly allocated into sham operation controls (n = 8) or portacaval shunt (n = 8). All animals were pair fed two weeks before and four weeks after operation and kept under standard laboratory conditions. Both PCA and sham-operated rats were fasted overnight in single wire-net floor cages with free access to tap water. All animal procedures were approved by our institution and met the guidelines of Spain (RD 223 erased 14th March 1998) and European (Directive 86/609/CEE) Union for care and management of experimental animals.

Rats were operated under general anaesthesia with isofluorane to avoid liver metabolism of intravenous agents and end-to-side portacaval shunt was performed as previously described[7]. Briefly, after middle laparotomy for viscera exteriorization, inferior vena cava and portal veins were exposed, dissected and clamped laterally together with a Satinsky clamp. Longitudinal incisions in both veins and lateral anastomosis with running suture as usual were performed. Finally, portal trunk was tied and cut next of liver hilum, turning the portacaval lateral shunt in functionally terminal. Sham-operation was performed following laparotomy, the inferior vena cava was isolated and clamped for 30 s. Sham-operated animals served as controls.

Determination of ammonia in brain and blood

Ammonia was measured in cerebral cortex and blood as previously described[8]. Cerebral cortex was homogenized and deproteinised in 5 volumes of ice-cold 100 g/L trichloroacetic acid, and kept on ice for 15 min. After centrifugation at 12 000 r/min for 10 min at 4 ℃, the supernatants were collected, neutralized with 2 mol/L $KHCO_3$ and centrifuged at 12 000 r/min for 10 min at 4 ℃. The neutralized supernatants were used to measure ammonia in μmole/g tissue. Blood (150 μL) was taken from the tail vein the third week after surgery. Blood samples were deproteinized with one volume of ice-cold 100 g/L trichloroacetic acid and kept on ice for 15 min. After centrifugation at 12 000 r/min for 10 min at 4 ℃, the supernatants were collected, neutralized with 2 mol/L $KHCO_3$ and centrifuged at 12 000r/min for 10 min at 4 ℃. The neutralized supernatants were used to measure ammonia. In a final volume of 100 μL, the reaction mixture contained 50 μL or 60 μL of sample, 30 mmol/L α-ketoglutarate, 0.5 mmol/L nicotinamide adenine dinucleotide (reduced form) in potassium phosphate buffer (pH 8.0). After recording of the initial fluorescence, reactions were started by the addition of 5 μg of glutamate dehydrogenase (Boehringer Mannheim, Germany) and monitored by the fluorimeter (Fluoroskan Ascent; Labsystems; Oy, Helsinki, Finland) for at least 70 min. Standards containing up to 25 nmol of ammonia were included in each assay. Assays were performed in Costar 96-well UV plates (cat. No. 3635; Corning Costar Corporation, Cambridge, MA).

Animal handling and brain tissue preparation

All procedures were carried out in the cold room at 2℃-4℃. The rats were killed by cervical dislocation. The skull of each rat was opened to remove blood from the surface of the tissue and this procedure needed to be performed in <30 s. The tissue was placed in 5 mL of isolation medium in a Petri dish maintained in an ice bath. The brain was chopped with fine scissors and the chopped material was washed frequently with isolation medium to remove blood. Meanwhile, the first portion of small intestine (3 cm of length) was removed and placed in 5 mL of isolation medium in Petri dish maintained in an ice bath. The duodenum was washed and mucosa was removed by glass film and quickly frozen in liquid air. Samples of kidney were similarly obtained. Tissue samples were then homogenized manually in 1 mL of isolation medium per 100-150 mg of tissue using a Dounce

homogenizer fitted with a Teflon pestle having a total clearance of 0.1 mm. Usually, six up- and down-strokes were sufficient to generate a rough homogenate which was then diluted with isolation medium to a final volume of 1.2 mL and homogenized further with four up- and down-strokes.

Preparation of mitochondria

The procedure for isolation of brain mitochondria was based on previously reported methods[9] except for 1 mmol/L ethylene glycol-bis (β-aminoethyl ether) tetra-acetic acid (EGTA) being used in the homogenisation medium instead of EDTA. The homogenate was centrifuged at 2 000 r/min for 3 min, the pellet was washed with 400 μL of homogenisation medium and re-centrifuged at 2 000 r/min for 3 min. Both supernatants were pooled and centrifuged for 8 min at 12 000 r/min to obtain the crude mitochondrial pellet. The pellet was suspended in 300 μL of the 30 g/L Ficoll medium (see below) and layered onto 1.2 mL of 60 g/L Ficoll medium and centrifuged at 12 000 r/min for 30 min. The 60 g/L Ficoll medium contained 6% (w/w) Ficoll, 0.24 mol/L mannitol, 0.06 mol/L sucrose, 0.05 mmol/L K-EDTA and 10 mmol/L Tris-HCl, pH 7.4. The 30 g/L Ficoll medium was the 60 g/L Ficoll medium diluted 1:1 with glass re-distilled water. The loose, fluffy, white upper layer of the pellet was removed, the remaining brown pellet was re-suspended in isolation medium without EGTA and the suspension was centrifuged at 12 000 r/min for 10 min. The pellet was re-suspended in incubation medium (isolation medium with 2.5 mL/L buffer containing protease inhibitor, 7 g/L Triton X-100, 5 mmol/L β-mercapto-ethanol) to obtain a protein concentration in the range of 5-10 g/L. After incubation on a mixing wheel for 30 min at 4 ℃, the samples were frozen at -80 ℃ for batched activity measurement.

PAG activity assay

Mitochondrial protein was measured by the method of Bradford *et al*[10] with bovine serum albumin (BSA) as standard. Briefly, 25 μL of mitochondrial solution was added to 35 μL of reaction medium (150 mmol/L K_2HPO_4, pH 8; 171 mmol/L L- GLn; 1 mmol/L NH_4Cl; pH 8). After incubation for 60 min the reaction was stopped with 10 μL of 100 g/L trichloroacetic acid (TCA). Blanks were prepared separately following the incubation of the reaction medium and samples were mixed before the addition of TCA. When the sample-mixture reaction was stopped, the reaction mixture was placed in ice for 15 min and then centrifuged at 12 000 r/min for 5 min at 4 ℃. The micro-titre plate was loaded with 5 μL of supernatant and 150 μL of OPA reagent (0.2 mol/L K_2HPO_4, pH 7.4; 56 mL/L ethanol; 10 mmol/L *O*-phthaldialdehyde; 0.4 mmol/L *β*-mercapto-ethanol). The plate was incubated in dark at room temperature for 45 min. Standards of NH_4Cl were prepared to concentrations of 50-300 mg/L. Absorbance was measured at 405 nm with a spectrophotometer (R&D System, Palo Alto, USA). Specific activities of enzymes were expressed in international units per gram (μkat/mg) of mitochondrial homogenate protein.

Analysis of glutaminase protein content by immunoblotting

Samples from sham-operated rats or rats with PCS were homogenized in medium containing 66 mmol/L Tris-HCl (pH 7.4), 10 g/L SDS, 1 mmol/L EGTA, 100 ml/L glycerol, 1 mmol/L sodium orthovanadate and 1 mmol/L sodium fluoride and the protein concentration was determined by the bicinchonic acid method (Pierce, Rockford, IL, USA). Samples were subjected to gel electrophoresis and immunoblotting as previously described[11] using isoform-specific polyclonal antibodies raised in rabbits against K- glutaminase proteins diluted at 1:1000. After incubation with anti-rabbit IgG conjugated with alkaline phosphatase (Sigma, Germany) and development with alkaline phosphatase colour developer (Sigma, Germany), the image was captured using the Gel Printer Plus System (TDI, Madrid, Spain) and the densities of the spots were measured using the Intelligent Quantifier ™ software Version 2.5.0 (BioImage®, Madrid, Spain). Results were relativized to the optical density respect to controls.

Statistical analysis

Data were expressed as mean ± SD. Statistical analyses were performed using the SPSS 11.0 software (spss, Chicago, IL). Differences in glutaminase activity or protein content were analysed by Student *t*-test. $P \leqslant 0.05$ was considered statistically significant for all tests applied.

RESULTS

Ammonia measurement

Ammonia was significantly higher in PCA group than in control rats. Plasma ammonia level was 166 ± 51 μmol/L in PCA rats and 83 ± 12 μmol/L in control rats ($P < 0.05$). In the cortex, brain ammonia was 0.9±0.4 μmol/g of tissue in PCA rats and 0.3 ± 0.1 μmol/g of tissue in sham operated rats ($P < 0.05$).

PAG activity in duodenum and kidneys

Duodenal and kidney PAG activities were significantly higher in PCA group than in control rats. In the duodenum, PAG activity was 976.95 ± 268.87 μkat/g of protein in PCA rats and 429.19 ± 126.92 μkat/g of protein in sham-operated rats ($P < 0.05$). In mitochondria from kidneys, PAG activity was 1259.18 ± 228.79 μkat/g protein in PCA rats and 669.67 ± 400.8 μkat/g of protein in controls ($P < 0.05$).

Glutaminase protein content in intestine and kidneys

There was a significant effect of PCA on PAG protein in duodenum. The content of protein was 173% in PCA compared to sham-operated rats and in kidneys the content of protein was 152% in PCA compared to sham-operated rats (Figure 1).

PAG activity in brain

The PAG activity was 6646.6 ± 1870.4 μkat/g of protein in the cortex of PCA rats and 3573.8 ± 2037.4 μkat/g of protein in that of control rats ($P < 0.01$). The PAG activity was 3657.3 ± 1469.6 μkat/g of protein in basal ganglia

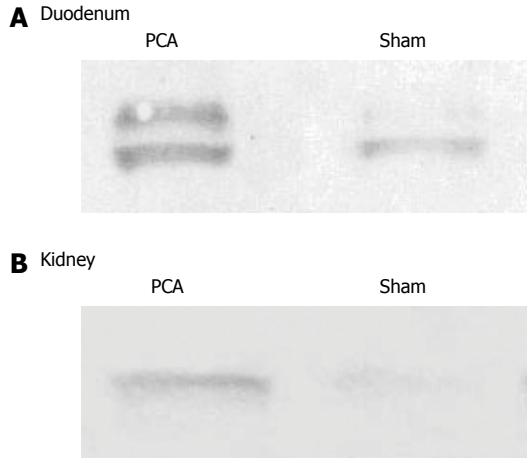

Figure 1 Representative immunoblotting from duodenum (**A**) and kidneys (**B**). Glutaminase content in enterocytes from rats with portacaval shunt (PCA) and 6 control rats (sham) homogenised and subjected to immunoblotting, 10 μg of protein applied in each lane.

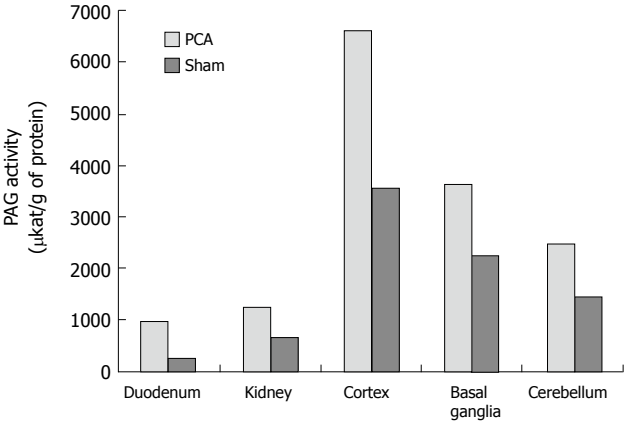

Figure 2 PAG activity (kat/g of protein) in duodenum, kidneys and brain of PCA and control rats (sham).

of PCA rats and 2271.2 ± 384 μkat/g of protein in that of sham-operated rats ($P < 0.05$). In the cerebellum, the PAG activity was 2471.6 ± 701.4 μkat/g of protein and 1452.9 ± 567.8 μkat/g of protein in the PCA and sham-operated rats, respectively ($P < 0.05$). In PCA rats, the PAG activity was increased up to 186% in cortex, 161% in basal ganglia and 170% in cerebellum compared to sham-operated rats. The highest activity was found in the cortex (Figure 2).

Glutaminase protein content in cerebral cortex and basal ganglia

The content of glutaminase was significantly increased in cerebral cortex of PCA rats compared to sham-operated animals (162% ± 40% and 100% ± 26%; $P < 0.009$) and the content of glutaminase was significantly higher in basal ganglia of PCA rats than in that of sham-operated animals (140% ± 39% and 100%±14%; $P < 0.024$), but there was no significant difference between the groups after PCA in cerebellum (100% ± 25% and 100% ± 16%; P = NS) (Figure 3).

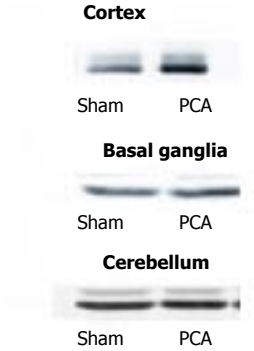

Figure 3 Glutaminase content in cerebral cortex and basal ganglia. Cerebral cortex basal ganglia or cerebellum from 7 rats with portacaval shunt (P) and 6 control rats (C) was homogenised and subjected to immunoblotting, 10 μg of protein was applied in each lane. The codes under the bands of representative blots indicate the different rats with portacaval shunt (P) or control rats (C).

DISCUSSION

The PCA performed in rats is widely accepted as a model of liver dysfunction. In this study, PAG activity was increased in kidney and duodenum, which could contribute significantly to systemic hyperammonaemia. PAG activity was increased in cortex and basal ganglia, which might be responsible for brain hyperammonemia and intra-mitochondrial ammonia levels derived from glutamine hydrolysis that are maintained because successful detoxification by glutamine-synthetase is precluded.

During the 2nd half of the 20th century, hyperammonaemia was considered to be derived from urea breakdown by intestinal bacteria and the majority of treatments are targeted against bacteria-derived ammonia from the colon[1]. However, the hypothesis was not universally accepted[12]. Hyperammonaemia following portacaval shunting in rats has been found to be similar in germ-free as well as in non-germ-free animals [13, 14], providing support to the concept that hyperammonaemia and encephalopathy could develop without participation of bacteria[15]. The highest hyperammonaemia has been found in portal-drained viscera and derived mainly from glutamine deamidation[16]. Hence, increased PAG activity in small intestine could explain these observations at least in part. Moreover, increased PAG in duodenum has been demonstrated in cirrhotic patients suffering from minimal hepatic encephalopathy[3].

Recently, renal ammoniagenesis has been implicated in several forms of hepatic encephalopathy. In patients suffering from hepatic encephalopathy due to variceal bleeding or overdose of diuretics, ammonia production from kidney seems to be the main factor involved in the development of hepatic encephalopathy[17]. Glutamine is filtered in the glomeruli and enters the lumen of the nephron. The filtered glutamine is reabsorbed in the proximal tubule where glutamine is deamidated by PAG. The main factor in the regulation of kidney PAG activity seems to be pH. During metabolic acidosis, PAG activity increases which induces higher excretion of ammonia[18]. In hepatic encephalopathy, metabolic alkalosis is observed more frequently than acidosis and increased PAG activity in kidney could be a protective mechanism. This PAG increase could be even more protective than the event associated with the systemic hyperammonaemia. However, this possibility needs to be explored in greater detail in future studies.

Ammonia reaching the brain can be detoxified to

glutamine only in astrocytes due to the predominance of glutamine synthetase in these cells. Glutamine accumulation as a by-product of ammonia metabolism has been implicated in the pathogenesis of hepatic encephalopathy[19]. Glutamine is an osmotic amino acid and plays a major role in the regulation of cell volume. A raised peak of glutamine-glutamate/creatine ratio is a typical feature of brain spectroscopic magnetic resonance imaging in hepatic encephalopathy. However, glutamine synthetase has not been found to be increased in brain of portacaval shunted rats[20]. Indeed, administration of amino acid mixtures induces hyperammonaemia, raises glutamine peak in the brain and is associated with impairment in neuropsychological function[21]. Also, use of methionine-sulfoxamine blocks the activity of glutamine synthetase and improves abnormalities induced by ammonia, such as seizures or astrocytes swelling[22]. Nevertheless, accumulation of glutamine following treatment with drugs that are able to block N-methyl-D-aspartate (NMDA)-receptors has not been shown to be associated with neurological impairment[23]. Indeed, in astrocyte culture, glutamine metabolism is linked to free radical production and oxidative stress and this may represent a key mechanism in ammonia neurotoxicity [24]. Thus, glutamine accumulation in the brain is neither a pathological event *per se* nor a safe ammonia detoxification pathway. Glutamine accumulating in the astrocytes can be considered as a "Trojan horse" leading circuitously to neurological impairment. In cultured astrocytes, glutaminase inhibitors such as 6-diazo-5-oxo-L-norleucine (DON) induce a complete blockade of glutaminase activity and preempt free radical production and neurotoxicity induced by ammonia[25]. Most of the glutamine in astrocytes is metabolized by mitochondrial PAG[26]. Since ammonia induces free radical production, the PAG can be implicated in free radical production. The inhibition of this enzyme could be a new therapeutic target. However, DON has also been reported to inhibit γ-glutamyl-transpeptidase, increase glutamine release, inhibit transport of glutamine into cells and block the transport of glutamine into mitochondria. All these mechanisms could induce a decrease in the amount of glutamine available for hydrolysis[27]. The distribution of K-type PAG in the brain has been strongly debated. Some studies have reported that PAG is absent in astrocytes of cerebellum[28]. In the current study, PAG activity in non-synaptic mitochondria from the cerebellum showed the lowest activity in the brain and no differences were observed between PCA and sham-operated rats using immunoblotting. Thus, PAG could be detected in cerebellum, but at a low-level in comparison to other areas such as basal ganglia or cortex.

In summary, PAG is enhanced in the intestine and kidney of PCA rats and induces hyperammonaemia and hepatic encephalopathy. Furthermore, PAG activity and glutaminase content are increased in astrocytes from cortex and basal ganglia. Mitochondrial glutaminase activity in astrocytes could be implicated in the production of ammonia. The induction of the mitochondrial permeability transition and free radicals production as the end product of glutamine metabolism could be responsible at least in part for the pathogenic effect observed in hepatic encephalopathy. Hence, PAG might be a new therapeutic target in the management of hepatic encephalopathy. Further studies using PAG inhibitors or PAG knock-out mice help clarify the role of increased PAG expression in the pathophysiology of hepatic encephalopathy.

Abstract

AIM: To assess the effectiveness and side-effects of lamivudine therapy for children with chronic hepatitis B (CHB) who fail to respond to or have contraindications to interferon-α (IFN-α) therapy.

METHODS: Fifty-nine children with CHB were treated with 100 mg lamivudine tablets given orally once daily for 12 mo. Alanine aminotransferase (ALT) activity was evaluated monthly during the therapy and every 3 months after its discontinuation. HBe antigen, anti-HBe antibodies, HBV DNA level in serum were evaluated at baseline and every six months during and after the lamivudine therapy. Sustained viral response (SVR) to lamivudine therapy was defined as permanent (not shorter than 6 mo after the end of the therapy), namely ALT activity normalization, seroconversion of HBeAg to anti-HBe antibodies, and undetectable viral HBV-DNA in serum (lower than 200 copies per mL). The analysis of the side-effects of the lamivudine treatment was based upon interviews with the patients and their parents using a questionnaire concerning subjective and objective symptoms, clinical examinations, and laboratory tests performed during clinical visits monthly during the therapy, and every 3 mo after the therapy.

RESULTS: ALT normalisation occurred in 47 (79.7%) patients between the first and 11th mo of treatment (mean 4.4 ± 2.95 mo, median 4.0 mo), and in 18 (30.5%) of them after 2 mo of the therapy. There was no correlation between the time of ALT normalization and the children's age, the age of HBV infection, the duration of HBV infection, inflammation activity score (grading), staging, ALT activity before treatment, serum HBV DNA level, and lamivudnie dose per kg of body weight. HBeAg/anti HBe seroconversion was achieved in 27.1% of cases. The higher rate of seroconversion was connected with lower serum HBV DNA level and longer duration of HBV infection. There was no connection between HBeAg/anti HBeAb seroconversion and the children's age, age of HBV infection, grading, staging, ALT activity before treatment, and lamivudnie dose per kg of body weight. No complaints or clinical symptoms were observed during lamivudine therapy. Impairment of renal function or myelotoxic effect was noted in none of the patients.

CONCLUSION: One year lamivudine therapy for children with chronic hepatitis B is effective and well tolerated. Seroconversion of HBeAg/HBeAb and SVR are connected with lower pre-treatment serum HBV DNA level.

INTRODUCTION

Hepatitis B virus (HBV) infection is still an important problem due to its high incidence and may lead to chronic hepatitis[1]. Up to 90% of infected children develop chronic hepatitis[2]. Chronic hepatitis B greatly increases the risk of liver cirrhosis or hepatocellular carcinoma[3]. Spontaneous seroconversion of HBeAg/HBeAb during the course of chronic hepatitis B is observed only in less than 10% of children, and total recovery with the elimination of all virus antigens and the presence of anti-HBs occurs in approximately 2% of cases[4]. In recent years lamivudine treatment for chronic hepatitis B has been recommended for patients who fail to respond to IFN-α therapy or have contraindications for this therapy[5]. However clinical data concerning nucleotide analogue treatment for CHB children are lacking.

The aim of the present study was to analyze prospectively the results, tolerance, and side-effects of lamivudine therapy for children with chronic hepatitis B who fail to respond to or have contraindications for IFN-α treatment.

Table 1 Characteristics of the patients

	n (%)	Mean	Median
Sex			
Boys	48 (81.4)		
Girls	11 (18.6)		
Age (yr)	6-18	10.5±3.24	10
Age of HBV infection (yr)	1-14	3.7±3.09	3
Duration of HBV infection (yr)	1-16	6.8±3.09	6
Completed previous IFN-α treatment			
Yes	51 (86.4)

Lamivudnie dose (mg per kg of body weight)	1.3-4.1	3.0±0.85	2.9

MATERIALS AND METHODS

Fifty-nine children, 48 boys and 11 girls, aged 6 - 18.0 years were included in the study. The age of HBV infection varied from 1 to 14 years and the known duration of infection was 1-16 years (Table 1). The precise route of infection was not determined. Most of the children had a history of multiple hospital admissions. None of these children suffered from onco-hematological disorders. Fifty-three children were previously treated with recombinant (3 million units) IFN-α given subcutaneously, three times a week for 20 wk, recommended by the Polish Working Liver Group[6]. Fifty-one of them completed the therapy, in 2 cases the therapy was discontinued at the 8th and 12th wk due to repeated seizures. Interferon therapy was completed 1 - 7.5 years before the present study (mean 4.0 ± 1.8 years, median 4.0 years). Six patients (10.2%) were not previously treated because of relative contraindications for IFN-α therapy, including high grade fibrosis on liver biopsy in 3 cases and epilepsy in 1 case.

The inclusion criteria for lamivudine treatment were increased aminotransferase activities in serum noted at least three times during the last six months before therapy, the presence of HBsAg and HBeAg in the blood, measurable (above 200 genome copies/mL) HBV-DNA in serum for at least six months prior to the study, negative HCV-RNA and anti-HCV antibodies in serum, and evidence of inflammation on liver biopsy performed within 24 mo before the study.

Patients with coexisting clinically significant illness or other types of liver disease, or having received antiviral agents, immunomodulatory drugs within the previous 6 mo were excluded from the study. The teenage pregnant girls were excluded and advised not to get pregnant during and after 6 mo after the lamivudine therapy.

ALT activity as well as total and direct bilirubin, alkaline phosphatase (ALP) and gammaglutamyl-transpeptidase (GGT) activity in serum were measured before treatment, monthly during and every 3 mo after the therapy by routine laboratory method. Serological markers of HBV infection were analyzed before and every six months during and after the therapy by immunoenzymatical methods: HBeAg, anti-HBe and anti-HBs by Roche's diagnostics tests while HBsAg by Micro Elisa tests. HBV-DNA serum concentration was measured in all patients before and every six months during and after the lamivudine therapy by quantitative PCR method using the Roche Cobas Amplicor HBV Monitor Assay (Roche Diagnostics, Pleasanton, USA). Activity of inflammation (grading) and fibrosis (staging) of liver biopsy was classified according to Scheuer's scale modified by International Working Party in 1995[7].

All patients were treated with 100 mg lamivudine tablets given orally once daily for 12 mo (Zeffix, GlaxoSmithKline Pharmaceuticals, SA). A single dose of lamivudine varied from 1.3 mg/kg to 4.1 mg/kg (Table 1)

The analysis of the side-effects of the lamivudine treatment was based upon interviews with the patients and their parents using a questionnaire concerning subjective and objective symptoms, clinical examinations, and laboratory tests (level of hemoglobin, blood cell count, urea and creatinine level) performed monthly during and every 3 mo after the therapy. The duration of clinical observation was at least 6 mo after the therapy in all cases.

Sustained viral response (SVR) to lamivudine therapy was defined as permanent (not shorter than 6 mo after the end of the therapy): ALT activity normalization, seroconversion of HBeAg to anti-HBe antibodies, and undetectable viral HBV-DNA in serum (lower than 200 copies per mL).

In patients with ALT elevation during the lamivudine therapy mutations in the YMDD (tyrosine, methionine, aspartate, and asparate) motif of the reverse-transcriptase domain in the HBV polymerase gene were assessed by polymerase chain reaction and restriction-fragment-length polymorphism assay. Analysis of HBV genotype was performed only in these patients because of economical reasons.

The results of the study were statistically analyzed using Statistica 5.77 (StatSoft, Inc., Tulsa, OK, USA). The differences in frequency were analyzed using χ^2 test with Yate's correction if necessary. The differences between groups were achieved using U Mann-Whitney's test. $P < 0.05$ was considered statistically significant.

Children over 12 years of age and their parents or legal guardians provided their written informed consent. The study was approved by the Ethics Committee of the Medical University of Gdańsk.

Table 2 Statistical analysis of factors predicting response to lamivudine treatment

Factors that may predict response	ALT normalisation	HBe/anti-HBe seroconversion	Sustained viral response
Sex	$\chi^2_{(Y)}$=0.37, P=0.54	$\chi^2_{(Y)}$=0.13, P=0.72	$\chi^2_{(Y)}$=0.01, P=0.76
Previous IFN-α treatment	$\chi^2_{(Y)}$=0.70, P=0.76.	$\chi^2_{(Y)}$=3.29, P=0.07	$\chi^2_{(Y)}$=4.42, P=0.04
Children's age	Z=0.10, P=0.92	Z=1.83, P=0.07	Z=2.28, P=0.02
Age of HBV infection	Z=0.70, P=0.49	Z=-1.49, P=0.14	Z=-1.40, P=0.15
Duration of HBV infection	Z=0.13, P=0.89	Z=2.99, P=0.002	Z=3.33, P<0.001
Inflammation activity score (grading)	Z=0.23, P=0.82	Z=1.56, P=0.12	Z=1.76, P=0.08
Staging	Z=0.88, P=0.38	Z=1.46, P=0.14	Z=1.69, P=0.09
ALT activity before treatment	Z=-0.48, P=0.63	Z=1.49, P=0.14	Z=1.23, P=0.23
Serum HBV DNA level	Z=-0.80, P=0.07	Z=-3.29, P=0.001	Z=-3.22, P=0.001
Lamivudnie dose per kg of body weight	Z=-0.46, P=0.64	Z=-1.75, P=0.08	Z=-1.59, P=0.11

RESULTS

ALT activity before the lamivudine therapy varied from 20 to 664 IU/L (Table 1). The ALT level was lower than 100 U/L in 42 (71.2%) patients and higher than 100 U/L in 17 (28.8%) patients. All 59 children who completed the 12-mo therapy had normal serum, total and direct bilirubin, and ALP. GGT level in serum was slightly elevated only in 3 (5.1%) patients.

Inflammation activity in liver biopsy specimens was found at either low or medium levels in 96.6% of patients: grade 1 in 24 and grade 2 in 33 children. Only in 2 patients grade 3 inflammation activity was observed (Table 1). No liver fibrosis was found in 7 patients. Fibrosis of stages 1-4 was found in 37, 12, 2, and 1 patient, respectively (Table 1).

Before lamivudine treatment HBV-DNA serum level ranged between 200-200 000 copies/mL. HBV-DNA level was over 200 000 copies/mL in 33 children (55.9%), 10 000-200 000 copies/mL in 16 (27.1%) children, and below 10 000 copies/mL in 10 (16.9%) children (Table 1).

ALT normalization was achieved in 47 (79.7%) patients at the end of therapy. It occurred mostly between the first and the 11th mo of treatment (mean 4.4 ± 2.95 mo, median 4.0 mo). ALT normalization was observed in 37 of 48 boys and 10 of 11 girls, in 43 of 53 children previously treated and 4 of 6 not treated with IFN-α. There was no connection between the rate of ALT normalization and the children's age, age of HBV infection, duration of HBV infection, inflammation activity score (grading), staging, ALT activity before treatment, serum HBV DNA level, and lamivudnie dose per kg of body weight. Statistical results are shown in Table 2.

HBeAg/anti-HBeAb seroconversion was achieved in 16 cases (27.1%) at the end of therapy. It occurred mostly after 12 mo of treatment. This seroconversion was observed in 13 of 48 boys and 3 of 11 girls, in 12 of 53 children previously treated and 4 of 6 not treated with IFN-α. The higher rate of seroconversion was connected with longer duration of HBV infection (median 9 *vs* 5 years) and lower serum HBV DNA level (median 50 000 *vs* 200 000 copies/mL). There was no connection between HBeAg/anti-HBeAb seroconversion and the children's age, age of HBV infection, inflammation activity score (grading), staging, ALT activity before treatment, and lamivudnie dose per kg of body weight. Statistical results are shown in Table 2. HBsAg/anti-HBsAb seroconversion was observed six months after the end of the therapy only in one child (1.7%). In 14 patients (23.7%) with ALT normalization and HBeAg/anti-HBeAb seroconversion, sustained viral response (SVR) was achieved at the end of therapy. In these cases HBV DNA level in serum was lower than 200 copies/mL. In two patients with ALT normalization and HBeAg/anti-HBe seroconversion, the serum HBV DNA level remained high (14 400 and 145 000 copies/mL). SVR was observed in 11 of 48 boys and 3 of 11 girls, and more frequently achieved in children previously treated with IFN-α. The rate of SVR was connected with older children's age (median 12 *vs* 9 years), longer duration of HBV infection (median 9 *vs* 5 years), and lower serum HBV DNA level (median 50 000 *vs* 200 000 copies/mL). There was no connection between SVR and the age of HBV infection, inflammation activity score (grading), staging, ALT activity before treatment, and lamivudnie dose per kg of body weight. Statistical results are also shown in Table 2.

No complaints or clinical symptoms were observed during the lamivudine therapy. Slight and transient increase of ALT activity was observed in 4 children (6.8%) between the 3rd and the 12th mo of treatment. No association with hyperbilirubinemia or other signs of hepatic decompensation was found in all cases. Mutations in the YMDD were detected in 2 of 4 patients with ALT elevation during the lamivudine therapy.

Lamivudine did not show myelotoxic effect in treated children. There were no significant differences between erythrocyte or leukocyte peripheral blood count, platelet count, and hemoglobin level during or after the therapy.

Impairment of renal function was observed in none of the patients.

DISCUSSION

This study presented an analysis of the outcome, tolerance and side-effects of lamivudine therapy for children with chronic hepatitis B, who failed to respond to or had contraindications for IFN-α treatment. Up till now IFN-α is the therapy of first choice for children with chronic hepatitis B in Poland. However the treatment with IFN-α is uncomfortable (especially in children) and has many different side effects[8].

Lamivudine is the first oral antiviral therapy for chronic hepatitis B. Positive results of this treatment in adult patients have made lamivudine therapy possible in children with chronic hepatitis B[9-11].

The results of international research conducted in children with chronic hepatitis B have proved that a 52-wk course of lamivudine therapy results in the significantly higher rate of viral response. Furthermore, SVR with HBs Ag/HBsAb seroconversion and ALT normalization has also been observed[12]. There are also some other data confirming positive biochemical and viral response in children with chronic hepatitis B treated with lamivudine[13,14].

This study demonstrated that 100 mg lamivudine treatment for 12 mo resulted in a 23.7% sustained virologic response. Special stress must be put on the fact that 86% of patients did not respond to IFN-α therapy.

Lamivudine therapy is mainly used for children with chronic hepatitis who fail to respond to IFN-α[11-15].

Other nucleoside analogues (like adefovir) used in the treatment of adult patients with chronic hepatitis, are not widely accessible for pediatric patients[16,17]. Data on the results of combined IFN-α and lamivudine therapy vary[18-21], seem no more effective than monotherapy with either IFN-α or lamivudine.

Lamivudine has been proved to be more effective than IFN-α for chronic hepatitis HBeAg-minus[22,23]. Most trials on the effectiveness of lamivudine therapy in both adults and children with chronic hepatitis B showed that ALT normalization is significantly more frequent even though it is often not associated with the viral response[10-16].

In the present group of children, ALT normalization within the first 11 mo of therapy was observed in almost 80% of patients and in 30% of children in the first 2 mo. No connection was noted between the time of ALT normalization and clinical data, biochemical tests, histopathological changes in the liver tissue, viral load, or lamivudine dose per kg body weight. Jonas *et al*[12] showed that the median time of ALT normalization was 24 wk.

In our group of patients, HBeAg/HBeAb seroconversion was observed in 27.1% of children and after 12 mo of treatment in most cases. Only in one patient, HBsAg/HBsAb seroconversion took place 6 mo after the lamivudine therapy. The low rate of positive response to lamivudine therapy expressed by HBsAg/HBsAb seroconversion is consistent with other reports[12,13,15]. SVR was noted in 23.7% of patients. ALT normalization and HBeAg/HBeAb seroconversion were still accompanied with high viral load. The results of lamivudine therapy are similar to other reports[12,24]. Some authors investigating lamivudine therapy effectiveness demonstrated a higher viral response rate of 36-44%[13,14]. However, Kocak *et al*[11] observed HBeAg/HBeAb seroconversion only in 5% of cases while viral load significantly decreased in 90% of cases[11].

In the analyzed group of patients the positive response to the lamivudine treatment was connected with the older age of patients and lower serum DNA level before therapy. The similar connection between SVR and the pretreatment viral load has also been observed by other authors[12,13]. On the contrary to the published data[9,25], no connection between SVR and pretreatment ALT activity or grading was noted in our study.

Special attention must be paid to the histopathological improvement within the liver tissue and in ALT activity in patients with no viral response after lamivudine therapy[9].

Liver biopsy after lamivudine therapy was performed only in a few patients. No consent of patients and their parents for invasive diagnostic procedure was available at that time. Control liver biopsy has not been performed by other researchers[11].

Due to the limited number of data on representative groups of patients, establishing the optimal dose especially for children under the age of 12 years appears still problematic. It appears that increase in daily dose or in frequency of lamivudine administration does not improve the results[12,13,15,26]. The recommended dose of lamivudine results in the same serum concentration of the drug in children as in adults receiving 100 mg per 24 h[26]. The experiences with treatment of chronic hepatitis B in adult patients suggest that this dose of lamivudine seems to be satisfactory.

In our group of patients, 100 mg lamivudine tablets were administered, and the dose per kilogram of body weight varied from 1.3 to 4.1 mg/kg per d, mean 3.0 mg/kg per d. Lamivudine in suspension is not widely available. The average dose of lamivudine in our group is comparable with that recommended by other authors[12,13,15,26].

Based upon interviews with the patients and their parents using a questionnaire concerning subjective and objective symptoms, clinical examinations, and monthly laboratory tests during and every 3 mo after the therapy, no particular side-effects were observed in our group of children.

Lebensztejn *et al*[27] reported a case of a child with chronic hepatitis B treated with lamivudine who developed thrombocytopenia and found that withdrawal of lamivudine could normalize platelets count, while reintroduction of the drug results in relapse of thrombocytopenia.

Slight and transient increase of ALT activity during lamivudine therapy (between the 3rd and the 12th mo) was noted in 4 children of our group of patients. YMDD mutation was detected in 2 of them. Termination of lamivudine therapy after 12 mo did not result in any increase of ALT activity or any other symptoms of liver impairment in the follow-up. Some authors have reported the risk of liver dysfunction and even acute liver failure after cessation of lamivudine therapy especially in patients with advanced liver fibrosis or cirrhosis[9]. Advanced fibrosis (stages 3 and 4) could be detected only in 5.1% of children with chronic hepatitis B, which may be the reason for no complications in our group of patients.

Because of economical reasons, only patients with ALT increase were evaluated for YMDD mutation and thus no conclusions about the incidence of YMDD mutation in children with chronic hepatitis B treated with lamivudine can be established. Thus, it can not be ruled out that mutation in the YMDD motif is responsible for the development of resistance to lamivudine in non-responders.

Duration of lamivudine therapy increases not only the rate of positive viral response, but also the risk of YMDD mutations[9], which appears to rise up to 60% in patients treated with lamivudine for more than 4 years[16,24,28]. How-

ever, besides the high percentage of viral mutants, lamivudine is still capable of inducing HBeAg/HBeAb seroconversion and improving histopathological changes within liver tissue in the treated patients[29,30].

In conclusion, one year lamivudine therapy for children with chronic hepatitis B is effective and well tolerated. Seroconversion of HBeAg/HBeAb and SVR are connected with lower pre-treatment serum HBV DNA level.

Abstract

AIM: To investigate the role of pegylated-interferon (IFN) α-2b in the management of patients with lamivudine-resistant chronic hepatitis B.

METHODS: Twenty consecutive anti-HBe positive patients were treated with pegylated IFN α-2b (100 μg sc once weekly) for 12 mo. There was no interruption in lamivudine therapy. Hematology, liver biochemistry, serum HBV DNA levels were detected by PCR, and vital signs were also assessed. Liver histology was assessed in some patients at entry and at wk 52 for comparison.

RESULTS: Nine patients (45%) had a partial virological end-treatment response; seven patients (35%) showed complete virological end-treatment response. Eight patients (40%) showed biochemical end-treatment response. There was a trend for higher virological response rates in patients who had previously responded to IFN and relapsed compared to IFN non-responders (four out of seven patients *vs* none out of six patients, respectively; $P = 0.1$). Patients without virological end-treatment response showed significant worsening of fibrosis [median score 2 (range, 1 to 3) *vs* median score 3 (range, 1 to 4)], in the first and second biopsy respectively ($P = 0.014$), whereas necroinflammatory activity was not significantly affected. Patients with complete or partial virological end-treatment response did not show any significant changes in histological findings, possibly due to the small number of patients with paired biopsies ($n = 5$). Nevertheless, after 12 mo of follow-up, only one patient (5%) showed sustained virological response and only 2 patients (10%) showed sustained biochemical response. Two patients (10%) discontinued pegylated IFN both after 6 mo of treatment due to flu-like symptoms.

CONCLUSION: Pegylated IFNα-2b, when added to ongoing lamivudine therapy in patients with lamivudine-resistant chronic hepatitis B, induces sustained responses only in a small minority of cases.

Key words: Pegylated interferon; Lamivudine resistance; HBeAg negative chronic hepatitis B; Adefovir

INTRODUCTION

Lamivudine has been a major breakthrough in the care of patients with chronic hepatitis B (CHB). Nevertheless, almost all patients with HBeAg-negative CHB, which accounts for the majority of patients in Greece, require long-term therapy with lamivudine to maintain a response[1,2]. This strategy is associated with the frequent emergence of viral resistance with reported rates of 10%-27% at 1 year, 40%-56% at 2 years and 67% at 3 years of treatment[3-7]; in a previous study in 77 patients with anti-HBe-positive CHB we have found resistance rates of 1.6% at 9 mo, 3.3% at 12 mo, 12.7% at 15 mo, 15% at 18 mo and 31% at 48 mo[8]. Once lamivudine resistance occurs, patients may experience an attenuation of the initial clinical, virologic and histologic benefits of therapy[9]. The wide use of lamivudine in CHB during the last 5-6 years has resulted in the constant increase of patients with lamivudine-resistant mutants. Their treatment may be the most pressing task for the current anti-HBV strategies in clinical practice[10]. Adefovir dipivoxil is the only approved agent that has been

shown to be effective in this setting, whilst entecavir is also a potential candidate[11-13]. The efficacy of interferon-α (IFN) therapy has not yet been evaluated in any well-designed study in these patients, and therefore no conclusions can be drawn.

IFN-α has a dual mode of action, antiviral via inhibition of viral replication, and immunomodulatory via enhancement of the immunological response of the host against the virus[14]. Pegylation of interferon leads to improved pharmacokinetic and pharmacodynamic profiles, which translated to superior efficacy, compared with conventional, nonpegylated IFN, in the treatment of chronic hepatitis C, and more recently, CHB[15-20]. Two modulations of pegylated IFN (PEG-IFN) are currently being used in clinical practice, namely PEG-IFN-α 2b and PEG-IFN-α 2a. This study was designed to explore the role of PEG-IFN-α 2b in the management of patients with CHB with lamivudine-resistant HBV.

MATERIALS AND METHODS

Subjects

Between November 1999 and February 2003, a total of 20 consecutive anti-HBe positive patients [18 males (90%)], with a median age of 54 (range, 38-66) years, were enrolled in this prospective study. Patients eligible for the study were aged 18 years and older, hepatitis B surface antigen (HBsAg) positive, and receiving ongoing lamivudine therapy for CHB for at least 6 mo at the time of screening; median duration of prior lamivudine therapy was 20 (range, 8-41) mo. All patients were HBeAg negative and antiHBe positive (both at the beginning of prior lamivudine therapy and at the beginning of the present study), genotype D, and had confirmed HBV polymerase gene mutation within the YMDD motif by DNA sequencing (Trugene HBV genotyping, Visible Genetics Inc); lamivudine resistance mutations are shown in Table 1. Patients were required to have a screening HBV DNA level $>10^9$ copies/L (Amplicor HBV-DNA Monitor Test; Roche Diagnostics, Branchburg, NJ, USA, with a sensitivity of 400×10^3 copies/L) as well as elevated serum alanine aminotransferase (ALT) levels >1.2 times the upper limit of normal (ULN) on at least 2 occasions at least 1 mo apart within the preceding 6 mo. The exclusion criteria are as follows: absolute neutrophil count $\leqslant 10^9$ cells/L; hemoglobin $\leqslant 100$ or $\leqslant 90$ g/L (males or females, respectively); platelet count $< 50 \times 10^9$/L; prior treatment with interferon or other immunomodulatory therapies within the 6 mo preceding study screening; serious concurrent medical conditions, including other concurrent liver diseases; coinfection with hepatitis C virus or hepatitis delta virus or human immunodeficiency virus; current alcohol or substance use; and pregnancy and/or lactation. None of the patients had liver cirrhosis.

Amongst the 20 patients enrolled, 7 (35%) were naive to IFN and 13 (65%) had been previously treated with IFN 5 MU sc three times weekly for at least 12 mo (before receiving lamivudine); six of the latter had shown no response and seven had responded to IFN (i.e. had shown both reduction in serum HBV DNA level to $<10^8$ copies/L and normalization of ALT level at the end of IFN administration) but relapsed after discontinuing therapy.

Methods

Patients were treated with pegylated interferon α-2b (100 μg sc once weekly) for 12 mo. There was no interruption in lamivudine therapy, even after the cessation of PEG-IFN-α 2b. Patients were evaluated every month. At each visit, any untoward medical occurrences, regardless of causality, were recorded as adverse events. Hematology, liver biochemistry, serum HBV DNA levels, and vital signs were also assessed. Liver histology was assessed in 13 patients at entry and at wk 52 for histological comparison; the rest of the patients denied a liver biopsy. A single pathologist, who was blinded to the sequence of the biopsies, evaluated all

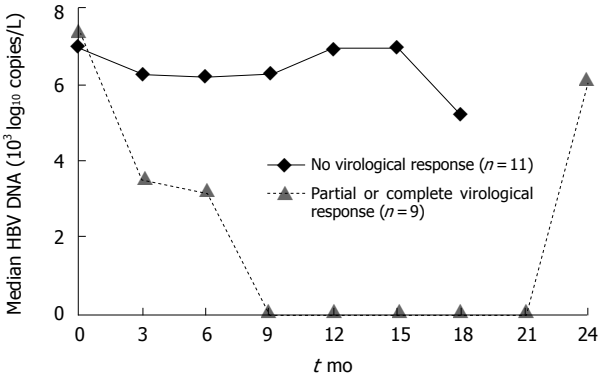

Figure 1 Median HBV DNA titers during PEG-IFN-α 2b therapy and during follow-up.

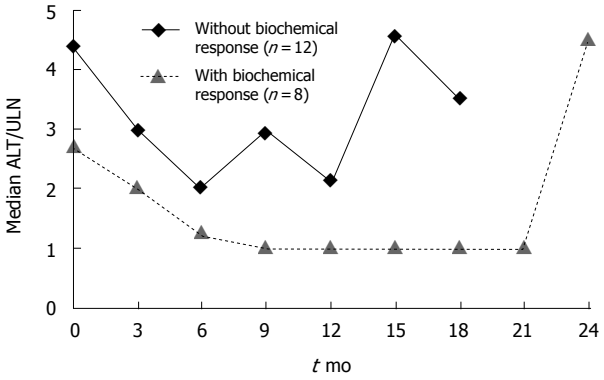

Figure 2 Median ALT values, expressed as multiples of ULN, during PEG-IFN-α 2b therapy and during follow-up.

specimens. Inflammation and fibrosis were each classified into 4 stages according to the Scheuer system.

After the cessation of PEG-IFN-α 2b, adefovir dipivoxil, 10 mg once daily, was given to patients who did not show a reduction in serum HBV DNA level to below 10^8 copies/L at wk 52 and to patients who demonstrated virologic breakthrough during follow-up (defined as reappearance of serum HBV DNA on two consecutive occasions, at least 3 mo apart, after its initial disappearance). The primary end point of the study was a reduction in serum HBV DNA level (partial virological end-treatment response). This was assessed as the proportion of patients with HBV DNA level $<10^8$ copies/L at wk 52. Secondary end points included the proportion of patients with undetectable HBV DNA at wk 52 (complete virological end-treatment response), the percentage of patients with normalization of ALT level at wk 52 (biochemical end-treatment response) and undetectable HBV DNA by PCR and normalization of ALT level after 12 mo of follow-up (virological and biochemical sustained response, respectively).

The study was approved by the ethics committee of our institution, and all patients provided written informed consent before screening. The study was performed in accordance with the principles of the Declaration of Helsinki.

Statistical analysis

All data were analyzed using the statistical package SPSS (version 10.0; SPSS Inc., Chicago, IL). The population analyzed included all patients who received at least one dose of study medication. The Mann-Whitney and Chi-square tests were used for comparisons of quantitative and qualitative variables respectively. The Wilcoxon Signed rank test was used to test the effect of PEG-IFN-α 2b on histological findings in the patients who underwent paired liver biopsies. In all cases, a 2-tailed *P* value less than 0.05 was considered statistically significant.

RESULTS

Baseline demographic and clinical features of the study population are presented in detail in Table 1. At baseline, median HBV DNA level was 7230 log_{10} copies/L (range, 6 000-9 360 log_{10} copies/L) and median ALT level was 3.5 (range, 1.3-10) times the ULN. Changes in median HBV DNA titers during PEG-IFN-α 2b therapy are shown in Figure 1. After 52 wk of treatment, 9 patients (45%) had a partial virological end-treatment response. The median change from baseline in serum HBV DNA levels was -7000 (range, -9 400 to 7 600) log_{10} copies/L. Seven patients (35%) showed complete virological end-treatment response. In these patients HBV DNA became undetectable after a median of 9 (range, 3 to 12) mo. Eight patients (40%) showed biochemical end-treatment response. In these patients normalization of ALT levels occurred after a median time of 9 (range, 3 to 12) mo (Figure 2). Overall, serum ALT level decreased over 52 wk in 16 patients (80%). The median ALT level at baseline was 3.5 times the ULN; by wk 52, this had declined to 2.2 times the ULN.

None of the baseline demographic and clinical features predicted virological (partial or complete) or biochemical end-treatment responses. Nevertheless, it should be noted that none of the six patients who had not responded to prior IFN treatment showed complete virological end-treatment response, while four out of the seven patients who had relapsed after an initial response to IFN showed complete virological end-treatment response ($P = 0.1$). The findings in the 13 patients in whom biopsies were performed are shown in Table 2 and in Figure 3. Patients without virological end-treatment response showed significant worsening of fibrosis ($P = 0.014$) in the second biopsy, whereas necroinflammatory activity was not significantly affected. Patients with complete or partial virological end-treatment response did not show any significant changes in histological findings, possibly due to the small number of patients with paired biopsies ($n = 5$). Likewise, patients without biochemical end-treatment response showed significant worsening of fibrosis ($P = 0.014$) in the second biopsy, whereas necroinflammatory activity was not significantly affected. Also, patients with biochemical end-treatment response did not show any significant changes in histological findings, possibly due to the small number of patients with paired biopsies ($n = 3$).

During follow up, HBV-DNA reappeared in six out of the seven patients who had shown complete virological end-treatment response, giving an overall sustained virological response rate of 5%. The median time to HBV-DNA re-emergence was 5 (range, 1 to 12) mo. Changes in median

Table 2 Histological findings in 13 patients with biopsy performed [median (range)]

	Baseline biopsy		End of treatment biopsy	
Virological end-treatment response	Necroinflammatory activity	Fibrosis	Necroinflammatory activity	Fibrosis
None (n=8)	3 (1-3)	2 (1-3)	2 (1-4)	3 (1-4)
Partial (n=2)	2.5 (2-3)	2.5 (2-3)	2.5 (2-3)	2.5 (2-3)
Complete (n=3)	2 (2-3)	2 (2-2)	1 (1-2)	1 (1-2)

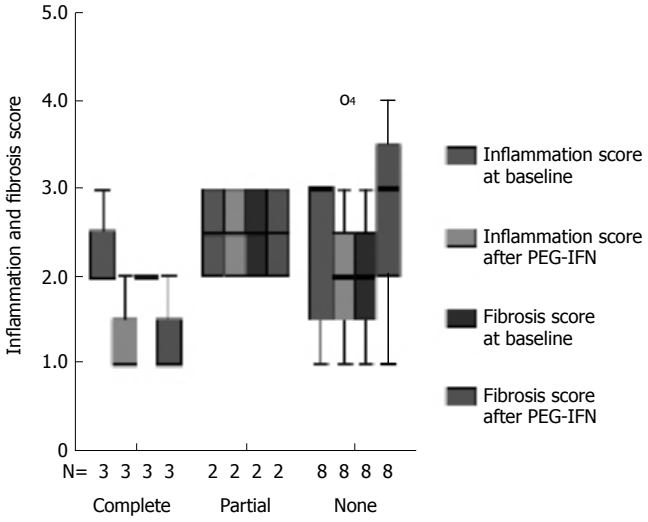

Figure 3 Changes in median inflammation and fibrosis scores according to end of treatment virological response.

HBV DNA titers during follow-up are shown in Figure 1 (patients' data are censored at the time of commencement of treatment with adefovir dipivoxil). Two patients (10%) had a sustained biochemical response while in the remaining 6 patients with biochemical end-treatment response, ALT became abnormal after a median of 4 (range, 1 to 12) mo. Changes in median ALT levels during follow-up are shown in Figure 2 (patients' data are censored at the time of commencement of treatment with adefovir dipivoxil). Two patients (10%) discontinued PEG-IFN both after 6 mo of treatment and both due to flu-like symptoms (fatigue, low-grade fever, arthralgia and headache). Neither of these patients showed virological or biochemical end-treatment response; in fact, one of them showed a rise in HBV-DNA levels and both showed a rise in ALT levels at 52 wk. PEG-IFN was well-tolerated in all other patients and none of them required dose reduction or interruption of therapy. There were instances of hepatic decompensation during the study.

DISCUSSION

Richman[21] has recently defined an antiviral drug as one that selects for resistance. Antiviral drug resistance depends on the viral mutation frequency, intrinsic mutability of the antiviral target site, the selective pressure exerted by the drug, and the magnitude and rate of virus replication. In particular, lamivudine resistance is due to mutations within the YMDD motif in the major catalytic region C of the HBV polymerase gene[22]. Viral resistance is clinically expressed by the virological breakthrough phenomenon, defined as the reappearance of serum HBV DNA after an initial clearance of viraemia despite the continuation of therapy[10]. The emergence of resistance has a negative impact on the efficacy of therapy in CHB patients, since virological breakthroughs are almost invariably followed by increasing viraemia levels, culminating in biochemical breakthroughs, which ultimately have an adverse effect on liver histology[6].

It is clear that the possible adverse effects of YMDD mutants do cast a concern. Rescue therapies for patients with worsening liver disease caused by lamivudine-resistant mutants are being evaluated. Until recently, treatment options for these patients have been limited to continuation or cessation of lamivudine therapy. Continuation of lamivudine aims to further suppress or to prevent the return of wild-type HBV which is more replicative competent than the YMDD mutant[23]. However, this strategy seems ineffective. Lamivudine withdrawal results in re-emergence of wild-type HBV within 3–4 mo[24]. Therefore, acute exacerbations of liver disease might ensue and could, although uncommon, result in hepatic decompensation or acute liver failure[25]. Adefovir dipivoxil effectively inhibits replication of YMDD mutants resistant to lamivudine and hence averts the resultant disease; entecavir has also shown promising results[11-13]. Nevertheless, neither of these novel nucleoside analogues was licensed in Greece during the study period.

There is a paucity of data regarding the role of IFN in the treatment of lamivudine-resistant HBV. Interferon-α has multiple sites of action in the viral life cycle and may be effective against lamivudine-resistant virus[26]. Recently, lamivudine was found to restore cytotoxic T-cell responses in patients with CHB, and, therefore, it may augment the immunomodulatory activity of IFN[27]. Hence, there would be a rationale in treating patients with lamivudine-resistant HBV mutants with IFN. Pegylation is the attachment of a polyethylene glycol (PEG) molecule to the base IFN molecule resulting in effective concentrations of IFN throughout the dosing interval and substantially reduced peak-to-trough ratio, in contrast to conventional IFN, which yields only intermittent drug exposure; pegylation also allows for once weekly frequency of administration[14]. Pegylated IFN has been shown to be highly active against wild-type HBV infection, both HBeAg-positive[15,17-19] and HBeAg-negative[20]. Complete virological end-treatment response was achieved by 35% of our patients. Therefore, this study confirms that PEG-IFN-α 2b is also active against lamivudine-resistant HBV. Of note, complete virological end-treatment response was achieved by 63% of patients with wild-type HBeAg-negative CHB in a recent landmark study[20]. The small number of patients included in the present report might *per se* preclude direct comparisons of efficacy between these two studies; however, different patients' characteristics might have also accounted for the apparently inferior results of PEG-IFN therapy in our study. Even though no pretreatment factor

has been found to be reliably associated with a response to IFN in HBeAg-negative CHB[1], it must be mentioned that our patients were older and had higher ALT and lower HBV-DNA levels at baseline than the patients in the aforementioned study[20]. Of course, it is also possible that PEG-IFN might not be as effective in lamivudine-resistant as in wild-type HBV strains, but this has to be investigated further in large-scale studies.

Patients with HBeAg-negative CHB receiving IFN retreatment respond as well as naive ones, irrespective of the outcome of the initial treatment[28]. In accordance with this, in our study, prior IFN treatment, as well as its outcome, was not associated with the efficacy of PEG-IFN-α 2b. Nevertheless, this could be attributed to the limited number of patients studied, since there was a trend for higher virological response rates in patients who had previously responded to IFN and relapsed compared to IFN non-responders ($P = 0.1$).

In patients with HBeAg-negative CHB, the 12 mo sustained response rates to IFN treatment vary from 10% to 47% (average 24%)[1]; sustained 6 mo biochemical and complete virological response rates with PEG-IFN rise up to 59% and 19%, respectively[20]. The low percentage of sustained biochemical and complete virological response (10% and 5% respectively) in our patients is of concern and renders PEG-IFN-α 2b rather unattractive for patients with lamivudine-resistant CHB. Nevertheless, the already mentioned differences in patients' characteristics between studies and the inherent limitation of the small number of patients included in our report might have contributed to these discrepant findings. Furthermore, it must be pointed out that the time point of evaluation of the sustained response in our study was at 12 mo after treatment completion compared to 6 mo in the wild-type HBV study[20], and this should be taken into account when comparing our results with the latter ones. However, the issue of differing activity of IFN in lamivudine-resistant compared to wild-type HBV strains definitely needs to be addressed.

In conclusion, this study shows that, 52 wk of treatment with PEG-IFN-α 2b, when added to ongoing lamivudine therapy in patients with lamivudine-resistant CHB, induces sustained responses only in a small minority of cases. Therefore, other treatment strategies should be considered for these patients, possibly including more prolonged or earlier (when the viral load is less than 10^6 copies/L) administration of PEG-IFN-α 2b.

Abstract

AIM: To describe a simple one-step method involving percutaneous transhepatic insertion of an expandable metal stent (EMS) used in the treatment of obstructive jaundice caused by unresectable malignancies.

METHODS: Fourteen patients diagnosed with obstructive jaundice due to unresectable malignancies were included in the study. The malignancies in these patients were a result of very advanced carcinoma or old age. Percutaneous transhepatic cholangiography was performed under ultrasonographic guidance. After a catheter with an inner metallic guide was advanced into the duodenum, an EMS was placed in the common bile duct, between a point 1 cm beyond the papilla of Vater and the entrance to the hepatic hilum. In cases where it was difficult to span the distance using just a single EMS, an additional stent was positioned. A drainage catheter was left in place to act as a hemostat. The catheter was removed after resolution of cholestasis and stent patency was confirmed 2 or 3 d post-procedure.

RESULTS: One-step insertion of the EMS was achieved in all patients with a procedure mean time of 24.4 min. Out of the patients who required 2 EMS, 4 needed a procedure time exceeding 30 min. The mean time for removal of the catheter post-procedure was 2.3 d. All patients died of malignancy with a mean follow-up time of 7.8 mo. No stent-related complication or stent obstruction was encountered.

CONCLUSIONS: One-step percutaneous transhepatic insertion of EMS is a simple procedure for resolving biliary obstruction and can effectively improve the patient's quality of life.

Key words: Expandable metallic stent; Bile duct carcinoma; Gall bladder carcinoma; Pancreatic carcinoma; Gastric carcinoma; Obstructive jaundice

INTRODUCTION

The incidence of biliary obstruction resulting from malignancies is increasing. As operative techniques and diagnostic imaging have advanced, more and more patients undergo resection. However, in cases where operation is not possible, prognosis remains poor often because of the presence of obstructive jaundice.

Palliative treatment with a biliary stent is carried out in patients with inoperable malignancies in order to relieve symptoms related to obstructive jaundice, prevent cholangitis and prolong survival. In addition, the biliary insertion procedure only requires a short time of hospitalization, which is especially important for patients with unresectable malignancies because of their poor prognosis.

When first introduced, stent insertion is performed using polyethylene endoprosthese. However, the expandable metallic stent (EMS) has also been available for a number of years [1, 2]. EMSs have advantages over plastic stents in that they can be introduced through a smaller delivery catheter, have a larger inner diameter and remain fixed in position after

release [3-6].

It was previously reported that one-step method of percutaneous transhepatic insertion of EMSs can be used for obstructive jaundice due to unresectable common bile duct carcinoma[7], further supporting the one-step method of percutaneous transhepatic insertion of EMS to treat obstructive jaundice caused by unresectable malignancies.

MATERIALS AND METHODS

Patients

This study comprised 14 patients with obstructive jaundice caused by unresectable malignancies, who were admitted into Nippon Medical School or Uchida Hospital from 2002 to 2004. Of the 14 patients (6 men and 8 women), 1 suffered from gastric carcinoma, 3 from recurrence of gastric carcinoma, 4 from pancreas carcinoma, 3 from bile duct carcinoma, 1 from gall bladder carcinoma, and 2 from recurrence of gall bladder carcinoma. The age distribution of the patients ranged between 65-90 years, with a mean age of 77.1 years.

The diagnosis was confirmed by ultrasonography and computed tomography. All patients were diagnosed before cholangiography as having obstructive jaundice caused by unresectable malignancies as a result of very advanced carcinoma or old age.

This study was performed according to the principles of the Declaration of Helsinki, and informed consent was obtained from the patients and/or their families.

Methods

The procedure was performed single-handedly (Hiroshi Yoshida). The portion of the procedure was consistent for all the patients. Following pre-medication with an intravenous injection of pentazocine (15 mg) and hydroxyzine (25 mg), the patient was given a local anesthetic consisting of 1% xylocaine. The appropriate intrahepatic bile duct of the lateral segment or right lobe of the liver was punctured with a sheath needle (19 gauge × 150 mm; Hakko, Tokyo, Japan) under ultrasonographic guidance. Percutaneous transhepatic cholangiography was then performed (Figure 1A).

The bile duct obstruction was cleared using a guide wire (RADIFOCUS GUIDE WIRE M, 0.035 inch × 150 cm; TERUMO, Tokyo, Japan). After a catheter with an inner metallic guide (EV drainage catheter, 17 gauge × 270 mm; Hakko, Tokyo, Japan) was advanced into the duodenum, a contrast material was injected to determine the overall length of stenosis (Figure 1B). The guide wire was reinserted and the EV drainage catheter was substituted with an EMS (SMART stent, 10 mm in diameter × 80 mm long; Cordis Endovascular, Warren, NJ) system. In cases where it was difficult to advance the EMS system into the duodenum, a dilatation catheter (PTCS catheter, 9 Fr × 60 cm; Sumitomo Bakelite, Akita, Japan) was inserted prior to insertion of the EMS system. The EMS was then placed in the common bile duct between a point 1 cm beyond the papilla of Vater and the entrance to the hepatic hilum, irrespective of the size of stenotic lesion present (Figure 2A). Where it was difficult to span the distance between the above points with a single EMS, an additional EMS SMART stent (10 mm in diameter × 60 mm long) was inserted connecting lengthways to the first stent. The EV drainage catheter or PTCS catheter was left in place to act as a hemostat at the site of insertion to the liver (Figure 2B). The patient received antibiotics following the stent insertion procedure. As an additional measure, saline was injected daily into the catheter to flush out the bile duct. The catheter was removed after resolution of cholestasis and stent patency was confirmed 2 or 3 d post-procedure.

Figure 1 Insertion procedure of EMS (**A**) and the overall length of stenosis (**B**). Appropriate intrahepatic bile duct of the lateral segment of the liver was punctured with a sheath needle under ultrasonographic guidance. Percutaneous transhepatic cholangiography was performed. The bile duct obstruction was cleared using a guide wire. After a catheter with an inner metallic guide was advanced into the duodenum, contrast material was injected to determine the overall length of stenosis.

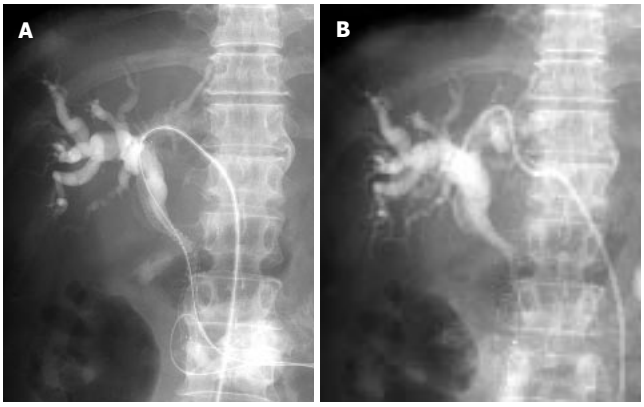

Figure 2 Placement of EMS (**A**) and EV drainage(**B**). The guide wire was reinserted and the EV drainage catheter was substituted with an EMS system. The EMS was placed in the common bile duct between a point 1 cm beyond the papilla of Vater and the hepatic hilum, irrespective of the size of the stenosis lesion present. The EV drainage catheter was left in place to act as a hemostat at the insertion site of the liver.

RESULTS

One-step insertion of the EMS was achieved in all patients. The procedure time ranged between 15-42 min with a mean time of 24.4 min. A single EMS was required in 7 patients, while two EMSs were needed in the other 7.

Table 1 Outcome after insertion EMS

Patient No.	Age	Sex	Disease	Procedure time (min)	No.of EMS	Days[2]	Outcome
1	90	F	Bile duct ca.	32	2[1]	3	death after 8 mo
2	72	F	Bile duct ca.	35	2[1]	2	death after 5 mo
3	87	F	Bile duct ca.	20	2	3	death after 7 mo
4	72	M	Gastric ca.	31	2	2	death after 5 mo

9	84	F	Recurrence of GB ca.	20	1	3	death after 17 mo
10	65	F	Recurrence of GB ca.	28	1	2	death after 11 mo
11	82	M	Pancreas ca.	20	1	2	death after 8 mo
12	76	M	Pancreas ca.	18	1	2	death after 5 mo
13	72	M	Pancreas ca.	22	1	2	death after 6 mo
14	84	F	Pancreas ca.	22	2	2	death after 6 mo
Mean	77.1			24.4	1.5	2.3	7.8

EMS:expandable metallic setent ca:carcinoma. GB:gall bladder. 1: Dilation catheter was used before insertion of EMS. 2: Postprocedure d of catheter removed.

In 2 patients, a PTCS catheter was used because of prior difficulty in inserting the EMS system. Out of the patients who required 2 EMSs, 4 of these needed a procedure time exceeding 30 min.

After successful insertion of the stent, cholestasis rapidly resolved itself in all the patients. The catheter was removed after a mean post-procedure time of 2.3 d. All patients died of malignancy with a mean follow-up time of 7.8 mo. No stent-related complication or stent obstruction was encountered (Table 1).

DISCUSSION

Long-term survival is poor in patients with malignant bile duct obstruction and in those who are not candidates for surgical resection. The objective of palliation with a biliary stent is to relieve symptoms related to obstructive jaundice, prevent cholangitis and prolong survival. Stenting has also been shown to improve patient quality of life[8].

Since the development of suitable metallic stents, a debate has arisen regarding when to use a metallic stent in preference to a plastic one. Randomized studies comparing metallic and plastic endoprostheses demonstrated that the metallic stent is associated with a lower incidence of complications, remains patent longer and is more cost-effective, although it is initially more expensive[5,6, 9-11].

Complications arising from metal stent placement for malignant bile duct obstruction, including tumor ingrowth or overgrowth[4,12], viscus perforation [13, 14], fracture[15], and stent migration[16] have been reported. The early occlusion rate ranges between 7%-42% and the late occlusion rate ranges between 12%-38%, with a mean time to stent failure of 6-9 mo[5,6,10,11,17] . In this study, no EMS-related complication or obstruction was encountered. A possible reason is that all the patients suffered from very advanced carcinoma and could not undergo surgery before cholangiography. Therefore, the prognosis of the patients was poor and patients died due to malignancy after just 7.8 mo. A further possible reason is that the EMS was placed in the common bile duct between a point 1 cm beyond the papilla of Vater and the hepatic hilum, irrespective of the size of stenotic lesion, therefore the stenosis was not completely covered to avoid overgrowth. In addition, saline was injected into the catheter on a daily basis to flush out the bile duct and stent.

In this study, percutaneous transhepatic insertion of the EMS was conducted. A different approach is to insert the EMS endoscopically. Recently, it was reported that the EMS can be inserted from the papilla of Vater under endoscope[18-20]. The success rate is below 100% and the time of procedure is relatively long[18-21]. This is because dilation of the stenotic lesion and control of a long EMS system are difficult in this approach. For high-risk patients with very advanced carcinoma or old age, it is imperative to keep operative procedures as straightforward and short as possible. In the endoscopic approach, the lengthy time of procedure is too invasive to be carried out on high-risk patients. With the percutaneous transhepatic insertion in this study, the distribution of the procedure time ranged between 15 - 42 min, with a mean time of 24.4 min. The EMS insertion could be performed single-handedly, easily, and quickly.

A disadvantage of the percutaneous transhepatic approach is that the catheter must be left in place to act as a hemostat at the insertion site of the liver. However, this is also a benefit as the catheter could then be used to confirm the stent patency and to flush the EMS free from coagula or debris for 2 or 3 d post-procedure.

In conclusion, the one-step percutaneous transhepatic insertion of EMS is a simple procedure for resolving biliary obstruction and can effectively improve the patient's quality of life.

Abstract

AIM: To study the effect of oral garlic on arterial oxygen pressure in children with hepatopulmonary syndrome.

METHODS: Garlic powder in a capsule form was given to 15 children with hepatopulmonary syndrome (confirmed by contrast echocardiography) at the dosage of 1 g/1.73 m^2 per day. Patients were evaluated clinically and by arterial blood gas every four weeks.

RESULTS: The garlic capsule was administered to 15 patients with hepatopulmonary syndrome. There were 10 boys and 5 girls with a mean age of 9.4 ± 3.9 years. The underlying problems were biliary tract atresia (4 patients), autoimmune hepatitis (4 patients), cryptogenic cirrhosis (4 patients) and presinusoidal portal hypertension (3 patients). Eight patients (53.3%) showed an increase of 10 mmHg in their mean arterial oxygen pressure. The baseline PaO_2 was 65.6 ± 12.1 mmHg in the responder group and 47.1 ± 11.2 mmHg in non-responder group. At the end of treatment the mean PaO_2 in responders and non-responders was 92.2 ± 7.75 mmHg and 47.5 ± 11.87 mmHg, respectively ($P < 0.01$).

CONCLUSION: Garlic may increase oxygenation and improve dyspnea in children with hepatopulmonary syndrome.

Key Words: Hepatopulmonary syndrome; Garlic; Arterial oxygen pressure; Pediatric

INTRODUCTION

In 1995, Lange *et al* [1] introduced the term "hepatopulmonary syndrome" for those patients with pulmonary vasodilatation associated with chronic liver disease and cyanosis. Hepatopulmonary syndrome is defined by an arterial oxygen pressure < 70 mmHg in room air. In adults, the prevalence is 5%-29% and the overall mortality is 41% in hospitalized patients. In children, the prevalence ranges from 0.5% in those with portal vein obstruction to 20% in children with biliary atresia and polysplenia syndrome. In other causes of childhood cirrhosis, the prevalence is 2% -4%. Hepatopulmonary syndrome has been described in children as young as 6 months. Generally, hepatopulmonary syndrome is seen in chronic liver disease, but it has also been described in acute liver failure and extrahepatic portal venous obstruction [2].

A right to left pulmonary shunt due to intrapulmonary vascular dilation characterizes this syndrome. Blood flowing through the dilated capillaries is less exposed to oxygen contained in the alveoli, resulting in a ventilation-perfusion mismatch [3-6]. In animal models, elevated levels of nitric oxide have been detected in the lung homogenates of animals with the clinical features of hepatopulmonary syndrome. This finding appears to be supported by reports documenting increased exhaled nitric oxide concentration in patients with hepatopulmonary syndrome [7, 8].

The best method to evaluate the shunt in hepatopulmonary syndrome is the contrast-enhanced echocardiogram [1, 2, 9, 10]. Technetium 99m-labeled macroaggregated albumin scanning is a second method of detecting intrapulmonary vascular dilatations. Pulmonary arteriography can suggest two angiographic patterns [1]. Schneck *et al* [13] have reported the beneficial effect of methylene blue on this syndrome [13]. The transjugular intrahepatic portosystemic shunt (TIPS) [14], cavoplasty [15], octreotide [16], indomethacin [17, 18] and embolization [19] in the management of this syndrome have been assessed.

In 1992, clinical improvement in a case report was

Table 1 Baseline characteristics of children with hepatopulmonary syndrome

achieved following the use of garlic [20]. In a study by Abrams *et al* [21] the use of garlic in adults in treatment of this syndrome was evaluated and garlic was found to be an effective therapy for this syndrome especially in young groups. Ku *et al* [22] revealed that active garlic metabolites are capable of pulmonary vasodilatation in rats. In 1997 Battaglia *et al* [23] reported an improvement in right to left shunt and arterio-alveolar gradient in such patients after liver transplantation. Further studies have confirmed the beneficial effect of liver transplantation on this syndrome [24, 25]. In our country, liver transplantation has a long waiting list. If the oral garlic can improve the arterial oxygenation and dyspnea, it may represent a palliative therapy for patients with hepatopulmonary syndrome awaiting liver transplantation.

MATERIALS AND METHODS

Patients

Fifteen patients (aged 6 months - 14 years) suffering from chronic liver disease, portal hypertension or cirrhosis and intrapulmonary shunt which were confirmed by saline contrast echocardiography were enrolled in this pilot study. Patients with congenital heart diseases, acute and chronic lung diseases and symptoms of severe gastritis, were excluded from the study. This study was performed at Children's Medical Center Hospital of Tehran University from 2002-2003.

Methods

Arterial blood gases were obtained from the radial artery in a sitting position at the same time and in the same room. Echocardiography with saline contrast was performed as previously described [13]. The presence of air bubbles in the left heart between 3 and 6 cardiac contractions indicated intrapulmonary shunt. Garlic was administered to the patients at the dose of 0.5-2 g/1.73 m^2 per day. We obtained a special kind of dried garlic (Hamedan city garlic), which was prepared in the form of 250 mg capsules by the hospital pharmacy.

The parents were asked to add the capsule or its content to their food once or twice a day at the recommended dose. We evaluated the patients every month. Clinical symptoms and signs, probable drug complication, and patient's compliance to the drug were asked in each visit. Arterial blood gas (ABG) was taken in the same condition as mentioned above. During the study we provided some facilities such as free contact if needed.

Response to garlic was defined as a 10 mmHg increment in the PaO_2 or when PaO_2 was more than 70 mmHg. Baseline and monthly data between responders and non-responders were analyzed statistically.

The Ethics Committee of Tehran University approved the protocol. The parents of the children gave their informed consent.

Stastistical analysis

The results were expressed as mean ± SD. Differences between two groups were evaluated by Fisher's exact test, Mann Whitney U and Wilcoxson rank-sum tests. $P < 0.05$ was considered statistically significant.

RESULTS

The baseline data of patients are summarized in Table 1. Fifteen patients with hepatopulmonary syndrome were treated with garlic. One child expired after one month of treatment.

At the end of the first month arterial O_2 pressure was increased significantly ($P = 0.004$). The mean of arterial O_2

Table 2 PaO_2 values of responders and non-responders in relation to dyspnea after treatment

Responders	Baseline	1st mo	2nd mo	3rd mo	4th mo	5th mo	Dypnea after Rx

Total	57 ± 14.7	66.5 ± 19.7	69.4 ± 22	72.1 ± 22.6	72.1 ± 24	73 ± 24.7[d]

[b]P <0.01 *vs* non-responders, [d]P <0.01 *vs* baseline.

pressure increment at the end of the second month was higher than 10 mmHg and over 70 mmHg at the end of the third month. At the end of the fifth month, the mean increment in the arterial O_2 pressure was 15 mmHg (Table 2).

Eight patients (53.3%) were considered as responders. The baseline PaO_2 was 65.6 ± 12.1 mmHg in the responder group and 47.1 ± 11.2 mmHg in non-responder group. There was a statistically significant difference in the initial O_2 pressure between the responders and non-responders (P = 0.009). At the end of treatment the mean PaO_2 in responders and non-responders was 92.2 ± 7.75 mmHg and 47.5 ± 11.87 mmHg, respectively (Table 3).

Dyspnea (including shortness of breath at rest or exercise, orthopnea and platypnea) occurred in 5 responders and 6 non-responders. Four out of these 11 patients had their dyspnea improved after treatment (Table 2).

According to the Child score, 5 patients (33.3%) were in group A, 4 (26.6%) in group B, and 6 (40%) in group C. The mean of arterial oxygen pressure in groups A, B and C, at the beginning of therapy was 56.4 ± 15.6 mmHg, 68.7 ± 11.2 mmHg and 49.6 ± 12.8 mmHg, respectively. At the end of therapy the mean PaO_2 in A, B and C groups was 79.4 ± 19.6 mmHg, 88.2 ± 13.3 mmHg and 53.6 ± 26 mmHg, respectively. No statistical difference in the mean PaO_2 was noted between groups A, B, and C.

DISCUSSION

The role of garlic in the management of hepatopulmonary syndrome is controversial. In 1992, clinical improvement was reported following the use of garlic [20]. In 1998 Abrams *et al* [21] studied the effects of garlic on hepatopulmonary syndrome in adults [21]. Chan *et al* [26] showed that garlic has no effect on the improvement of PaO_2 and hypoxemia as well as clinical status, suggesting that deteriorating oxygenation in patients with chronic liver disease may be an indication for liver transplantation. Abrams *et al* [21] showed that 40% of patients have at least an increase of 10 mmHg in their arterial oxygen pressure after treatment with garlic. They also studied the dyspnea index in these patients and reported that all patients responding to therapy have an improvement in dyspnea [21]. In the present study, 53.3% of patients following the use of garlic had an arterial oxygen pressure > 70 mmHg or an increment > 10 mmHg. Four out of the 8 patients responding to the therapy had an improvement in dyspnea, but non-responders did not show any improvement in their respiratory symptoms.

It was reported that the clinical response is better in younger patients [21]. The results of the present study are consistent with those of Abrams *et al* [21]. We showed an improvement rate of 53.4% in children and Abrames *et al* showed 40% in adults. Nevertheless, no statistically significant differences were noted between responders and non-responders with respect to age.

It is interesting to note that responders had a higher baseline PaO_2, suggesting that non-responders have a severe and profound disease and that medical management can be effective when baseline PaO_2 is higher. Since TC-99 macro-aggregated albumin scan was not performed in the present study, there was a possibility of selection bias, because anatomic shunt failing to respond to medical therapy was not excluded.

The exact mechanism of garlic therapy for hepatopulmonary syndrome is not known. Garlic appears to cause pulmonary vasodilatation [22] and increases the rate of NO synthesis [25, 27,28]. Thus one can conclude that garlic worsens hepatopulmonary syndrome. Garlic causes reduced NO synthesis in macrophages, resulting in reduced concentration in hypoxic tissue [29].

Intrapulmonary vasodilatation occurs primarily in the bases of the lungs, resulting in significant V/Q mismatch in this region. Abrams *et al* [21] speculated that if garlic results in uniform vasodilatation throughout the lung, then a redistribution of pulmonary blood flow to apical and mid lung fields could significantly improve V/Q ratios in these regions. Therefore, garlic may improve V/Q and reduce NO synthesis in the lung bases. Also garlic is known as a hepatoprotective agent and protects liver against tissue and chemical injures. If this is the case, it is probable that garlic might improve liver function and hepatopulmonary syndrome. Garlic might also reduce portal hypertension, indirectly resulting in an improvement in hepatopulmonary syndrome. Additionally, Allicin, Ajoene, and diallyl sulfur may be beneficial for hepatopulmonary syndrome treatment. These ingredients are present in dried garlic in sufficient amount [22]. However, the amounts of these ingredients vary depending on different types of garlic [29].

In children with chronic cholestasis, repeated transcutaneous bedside measurements are a rapid and reliable noninvasive test for characterizing the severity of abnormal oxygenation, and may prove useful also in post liver transplantation monitoring [30]. Although the existence of hypoxemia and hepatopulmonary syndrome has a prognostic value in patients with chronic liver disease [31], controlling the oxygen pressure, is not recommended as a screening tool [9, 10]. Therefore disease in diagnosis and control echocardiography with contrast should be more exact.

In conclusion, garlic can reduce the severity of hepatopulmonary syndrome. Arterial oxygen pressure is increased after treatment with garlic. Further studies are needed to evaluate the garlic therapy for hepatopulmonary syndrome in children.

ACKNOWLEDGEMENTS

The authors thank nurses of Gastroenterology and Cardiology Wards in Children's Medical Center Hospital and also Miss. Khaef and Miss. Javadzadeh for their kind assistance in this study.

Abstract

AIM: To describe the prevalence of transfusion-transmitted virus (TTV) infection in association with hepatitis A-E viral infections in different forms of liver diseases in North India.

METHODS: Sera from a total number of 137 patients, including 37 patients with acute viral hepatitis (AVH), 37 patients with chronic viral hepatitis (CVH), 31 patients with cirrhosis of liver and 32 patients with fulminant hepatic failure (FHF), were analyzed both for TTV-DNA and hepatitis A-E viral markers. Presence of hepatitis B virus (HBV), hepatitis C virus (HCV) and hepatitis E virus (HEV) infections was detected in different proportions in different groups. Moreover, TTV-DNA was simultaneously tested in 100 healthy blood donors also.

RESULTS: None of the patients had hepatitis A virus (HAV) and hepatitis D virus (HDV) infections. Overall prevalence of TTV-DNA was detected in 27.1% cases with AVH, 18.9% cases with CVH, 48.4% cases with cirrhosis and 9.4% cases with FHF. TTV-DNA simultaneously tested in 100 healthy blood donors showed 27% positivity. On establishing a relation between TTV infection with other hepatitis viral infections, TTV demonstrated co-infection with HBV, HCV and HEV in these disease groups. Correlation of TTV with ALT level in sera did not demonstrate high ALT level in TTV-infected patients, suggesting that TTV does not cause severe liver damage.

CONCLUSION: TTV infection is prevalent both in patients and healthy individuals in India. However, it does not have any significant correlation with other hepatitis viral infections, nor does it produce an evidence of severe liver damage in patients with liver diseases.

INTRODUCTION

In 1997, a novel DNA virus was identified in serum of a Japanese patient (TT) having post-transfusion hepatitis[1]. This virus was designated as transfusion-transmitted virus (TTV). Later studies demonstrated TTV to be a non-enveloped single-stranded DNA virus, whose genome consists of 3739 bp and two large overlapping open reading frames (ORF-1 and ORF-2) encoding 770 and 202 amino acids and several small ORFs (22-105 amino acids)[2]. The virus has little sequence similarity with any known virus and so, it is presently not clear to which family it belongs. It is likely that TTV represents a new family. These are dense and 40-nm diameter particles. Individual genome sequences vary by up to 40%. Comparison of the genomic sequence, encoded proteins and the biophysical characteristics of the virus suggests that TTV is closely related to the Circoviridae. The genome exhibits high diversity and is classified into 6 genotypes[3]. As the prevalence of TTV in populations that require frequent transfusion of blood products is higher than that in healthy blood donors, TTV was supposed a parenterally transmissible virus. However, since TTV has been reported to be excreted in feces[4] also, it was felt that virus might also be transmitted non-parenterally. Using PCR with a new set of primers derived from a highly conserved region of the TTV genome, TTV DNA was detected in 92% of the general population in Japan[5], demonstrating that TTV is indeed a common virus.

Since its discovery, it has become clear that TTV infection is present worldwide among blood donors and is common in patients with liver diseases, including cryptogenic cirrhosis and fulminant hepatic failure. In one study, TTV DNA was detected in 46% and 12% of non-A to G hepatitis patients and healthy blood

donors, respectively[4], and it was initially suggested that TTV was a new hepatitis virus. The association of TTV with cryptogenic chronic liver diseases, post-transfusional hepatitis[1] and acute hepatitis of unknown etiology suggested an etiological role of this agent in the development of both acute and chronic hepatitis. Preliminary data from Japan and the United Kingdom indicated that TTV sequences were detectable in 25%-47% of patients with fulminant or chronic hepatitis of unknown origin, 27%-68% of hemophiliacs, and 1.9%-22% of apparently healthy blood donors[6-10]. Moreover, TTV-DNA titres were found to be 10- to 100-fold greater in liver tissue than in serum. All these findings have been interpreted as demonstrating its hepatotropism. Evidence for potential hepatotropism of TTV was supported by the presence of high TTV-DNA concentration in liver[7] and by a correlation between TTV-DNA titres and aminotransferase levels in post-transfusional non-A-G hepatitis patients[11]. In some studies, TTV-DNA has been found more frequently in patients with liver cirrhosis and hepatocellular carcinoma than in those with chronic hepatitis. However, virus DNA is not integrated in tumor cells, which may suggest that the virus is a passenger rather than a cause of the tumor. And therefore, further studies are required to determine the role of TTV. In fact, the significance of TTV infection in liver disease is, at present, analogous to that of HGV.

The aim of this study was to evaluate the prevalence of TTV-DNA in patients with different liver diseases in north India, and at the same time, find out the possible relation between TTV and other hepatitis viral infections in causation or progression of different liver diseases.

MATERIALS AND METHODS

Patients and blood samples

One hundred and thirty seven patients of both sexes and in adult age group were included in the present study. The patients consisted of 37 patients with acute viral hepatitis (AVH, age range: 21-48 years), 37 patients with chronic viral hepatitis (CVH, age range: 19-48 years), 31 patients with liver cirrhosis (age range: 34-57 years) and 32 patients with fulminant hepatic failure (FHF, age range: 28-46). All these patients attended either Outpatient Department or were admitted to the Liver Unit of All India Institute of Medical Sciences, New Delhi, from June 2001 to February 2004. They were evaluated clinically and biochemically and their sera were tested for hepatitis viral markers. The diagnosis of different types of liver diseases was based on accepted clinical, biochemical and histological criteria as outlined elsewhere[12]. AVH was diagnosed when patients exhibited overt jaundice and/or increased alanine aminotransferase levels (at least 3 times above the normal value) documented at least twice at a 1-week interval without any history of pre-existing liver disease. None of the patients had a past history of alcohol intake or using any drug. We also could not find any clinical or serological evidence of autoimmune diseases or biliary infection in these patients. The patients with CVH and cirrhosis of liver were diagnosed by histopathological criteria laid down by International Study Group on Chronic Hepatitis[13]. All these CVH patients had persistent elevation of transaminases level (at least twice the upper limit of normal range) for more than six months and histologic evidence of chronic hepatitis on liver biopsy at the beginning of follow-up. Fulminant hepatic failure was diagnosed if the patients developed hepatic encephalopathy within 4 wk of the onset of acute hepatitis as outlined elsewhere[12]. One hundred age- and sex-matched healthy subjects were used as controls.

From each of the above patients, 6-10 mL of venous blood was drawn and aliquoted in plain tubes without anticoagulant. Serum was separated after centrifugation and then stored at -70℃ until further analysis. Repeated freezing and thawing of serum was avoided as far as possible. These sera samples were used to analyze various hepatitis markers, liver function tests and hepatitis C virus (HCV) core protein.

Hepatitis viral markers

Sera were investigated for hepatitis B surface antigen (HBsAg) and IgM antibodies to hepatitis A virus (IgM anti-HAV), hepatitis B core antigen (IgM anti-HBc), hepatitis D virus (IgM anti-HDV) and hepatitis E virus (IgM anti-HEV). Similarly, all these sera were also tested for total antibodies against hepatitis C virus (anti-HCV). The serological analysis was done using enzyme immunoassay kits of high sensitivity and specificity. Kits for HBsAg, IgM anti-HBc and IgM anti-HAV were purchased from Abbot Laboratories, USA. Anti-HCV was tested using highly sensitive third generation ELISA kit from Ortho Diagnostics. This anti-HCV kit used peptides *versus* core, NS3, NS4 and NS5 regions of HCV genome, as antigen to coat the ELISA plate. IgM antibody to hepatitis D virus (HDV) was tested using an enzyme immunoassay kit from Wellcome, UK. Similarly, IgM anti-HEV was tested using third generation ELISA kit from Genelabs and Diagnostics, Biotechnology, Singapore.

Detection of HCV-RNA by RT-PCR

Total RNA was isolated from 100-μL serum or plasma using High Pure Isolation kit from Roche, Germany according to manufacturer's instructions. Five micrograms of the isolated RNA were applied to reverse transcription and nested PCR with primers located in the highly conserved 5' noncoding region (5' NCR) using BIOHCV kit (B&M Labs., Madrid, Spain). The reverse transcription mixture was incubated for 1 min at 85℃, followed by 30 min at 60℃. First PCR was performed in whole content after adding 40 μL of HCV amplification mixture. Thermal cycler was programmed as follows: 85℃ for 30 s, 94℃ for 2 min, followed by 40 cycles of 94℃ for 30 s, 55℃ for 30 s and 72℃ for 30 s and then further incubation of samples for 5 min at 72℃. Five microliters of first PCR product were subjected to nested PCR using nested PCR mixture containing second round primer and enzymes. The protocol on thermo cycler was the same as mentioned in first PCR. The PCR product was electrophoresed on 20 g/L agarose containing ethidium bromide and visualized under UV. A positive control provided in the kit was used as control. All positive and negative controls were tested in parallel with test samples throughout the entire procedures,

Table 1 Prevalence of TTV-DNA in different liver diseases

Liver disease	*n*	Presence of TTV-DNA *n* (%)
Acute viral hepatitis	37	10 (27.0)
Chronic viral hepatitis	37	7 (18.9)
Cirrhosis	31	15 (48.4)
Fulminant hepatic failure	32	3 (9.4)
Control	100	27 (27.0)

starting with RNA extraction.

Detection of TTV-DNA

Total DNA was extracted from 200 μL of serum using DNA isolation kit from Roche Diagnostics GmbH, Germany. This isolation method utilizes the ability of nucleic acids to absorb to silica (glass) in the presence of a chaotropic salt. Serum sample was treated with buffer containing proteinase K and silica particles where nucleic acids are bound to silica surface of magnetic particles. Since the binding process is specific for nucleic acids, the bound nucleic acids are purified from salts, proteins and other impurities by washing. A low salt buffer is used to elute the DNA. Using 5 μL of the DNA solution as a template, TTV DNA of the open reading frame (ORF-1) sequence, was detected by PCR employing the semi-nested primers reported by Okamoto *et al*[2]. The first-round PCR was carried out for 35 cycles, each cycle consisting of denaturation at 94℃ for 45 s, primer annealing at 60℃ for 45 s and extension at 72℃ for 60 s, followed by an additional extension at 72℃ for 7 min, using the primers NG059 (sense: 5'-ACAGACAGAGGAGAAGGCAAC ATG-3') and NG063 primer (antisense: 5'CTGGCATT TTACCATTTCCAAAGTT-3'). Thereafter, the second-round PCR was carried out using 1 μL of the first-round PCR product, NG061 primer (sense: 5'-GGCAACATG YTRTGGGATAGACTGG-3', where Y=T or C; R=A or G), and NG063 primer for 25 cycles under the same aforementioned conditions. The PCR product (10 μL) was electrophoresed on 20 g/L agarose gel containing ethidium bromide, and observed under ultraviolet light. The product of the first-round PCR was of 286 bp and that of the second-round PCR was of 271 bp.

Diagnosis of viral hepatitis

Liver function tests, including transaminase levels (AST and ALT) in serum, were performed on autoanalyser Hitachi-917 using the established techniques. Similarly, hemogram and coagulation profiles were performed using routine assays established in our laboratory. The diagnosis of different types of viral hepatitis was established as follows: The diagnosis of hepatitis A virus (HAV) infection was confirmed by the presence of IgM anti-HAV in serum. Hepatitis B virus (HBV) infection was established by presence of IgM anti-HBc in sera of AVH and FHF patients and by the persistent HBsAg antigenemia in sera of CVH and cirrhosis cases. Similarly, anti-HCV and IgM anti-HDV in sera samples were used for the diagnosis of HCV and HDV infections, respectively. All anti-HCV sera were also tested for HCV-RNA using nested PCR as described above. However, final diagnosis of HCV was based on anti-HCV antibodies in serum. Active or recent hepatitis E virus (HEV) infection was diagnosed by the presence of IgM anti-HEV in serum. Sera positive for HBsAg but negative for all other viral markers were labeled as HBV-carriers. Absence of all the markers including HBsAg labeled the patients with hepatitis non-ABCDE infection. HCV-RNA in serum was used to confirm active HCV infection.

RESULTS

Analysis of sera for different hepatitis viral markers demonstrated the presence of hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis E virus (HEV) infections in these patients. None of the sera analyzed could demonstrate the presence of markers related to hepatitis A virus (HAV) and hepatitis D virus (HDV) infections. HBV infection was detected in 19 of 37 (54.1%) patients with AVH, 30 of 37 (80.1%) with CVH, 18 of 31 (58.1%) with cirrhosis and 13 of 32 (40.6%) with FHF. HCV infection, as indicated by the presence of anti-HCV in serum, was detected in 8 of 37 (21.6%) patients with AVH, 15 of 37 (40.5%) with CVH, 5 of 31 (16.1%) with cirrhosis and 2 of 32 (6.3%) with FHF. All anti-HCV-positive sera were also tested for HCV-RNA which was found positive in 96-98% sera samples. The percentage of HCV infection was based on anti-HCV positivity in these cases. HEV infection was observed in 14 of 37 (37.8%) cases with AVH and 5 of 32 (15.6%) cases with FHF.

Presence of TTV-DNA was detected in 10 of 37 (27.0%) cases with AVH, 7 of 37 (18.9%) cases with CVH, 15 of 31 (48.4%) cases with cirrhosis and 3 of 32 (9.4%) cases with FHF (Table 1). TTV-DNA was also detected in 27 of 100 (27%) healthy blood donors. In order to investigate TTV coinfection with different hepatitis viral infections, we observed TTV-DNA with IgM anti-HBc in 16.2% cases with AVH and none with FHF. TTV-DNA with HBsAg, indicating TTV-HBV co-infection in CVH and cirrhosis, was observed in 13.5% and 32.3% cases, respectively. TTV-HCV coinfection, indicated by simultaneous presence of TTV-DNA and anti HCV, was present in 10.8% case with CVH, 6.5% with cirrhosis and 3.2% cases with FHF. None of AVH patients had TTV-HCV coinfection. TTV-HEV coinfection could be demonstrated in 2.7% cases with AVH only. No other disease group had HEV-TTV coinfection (Table 2).

When TTV-DNA positive cases were analyzed for ALT level in sera, we found that 60% AVH patients had ALT level up to 3 334 nkat/L, 30% up to 6 668 nkat/L and only 2.7% more than 10 002 nkat/L. In CVH, all TTV-positive cases had ALT level less than 3 334 nkat/L. Similarly, in cirrhosis patients, ALT level was found up to 3 334 nkat/L in 93.3% cases and up to 6 668 nkat/L in 6.7% cases. In FHF, all three cases had ALT level more than 10 002 nkat/L. ALT level in serum was used as an index of liver damage in different disease groups (Table 3).

DISCUSSION

To investigate the status of TTV coinfection in relation

Table 2 Presence of TTV-DNA in relation to other viral hepatitis markers in liver diseases

Liver disease	*n*	*n* (%) TTV-DNA with HBsAg/IgM anti-HBc	TTV-DNA with anti-HCV/HCV-RNA	TTV-DNA with IgM anti-HEV
Acute viral hepatits	37	6 (16.2)	0 (NIL)	1 (2.7%)
Chronic viral hepatitis	37	5 (13.5)	4 (10.8)	-
Cirrhosis	31	10 (32.3)	2 (6.5)	-
Fulminant hepatic failure	32	0 (NIL)	1 (3.2)	0 (NIL)

NIL: 0%. - : Not done, as HEV is not present in chronic and cirrhosis cases.

Table 3 Relation between TTV-DNA and ALT levels in different liver disease groups

Liver disease	No. of TTV-DNA + patients	*n* (%)[ALT (nkat/L)] 833.5 - 3334	3335 - 6668	6669 - 10002	>10002
Acute viral hepatitis	10	6 (60)	3 (30)	0 (NIL)	1 (10)
Chronic viral hepatits	7	7 (100)	0 (NIL)	0 (NIL)	0 (NIL)
Cirrhosis	15	14 (93.3)	1 (6.7)	0 (NIL)	0 (NIL)
Fulminant hepatic failure	3	0 (NIL)	0 (NIL)	0 (NIL)	3 (100)

Present value was computed in comparison to total number positive for TTV-DNA. Nil : 0%.

to other hepatitis infections in different liver diseases, we tested TTV-DNA simultaneously with markers related to hepatitis A-E infections. Results are shown in Table 2. Analysis of data showed that TTV-HBV coinfection was detected in all the groups except FHF. Similarly, TTV-HCV coinfection was also recorded in all except AVH group. TTV-HEV coinfection was found in a minor proportion of AVH group. Attempts were also made to study the impact of TTV infection on liver damage both with or without other hepatitis viral infections. For this, serum level of ALT was tested in all the cases. The results showed that TTV infection did not cause severe liver necrosis in these groups of patients. This was indicated by a very moderate elevation in ALT level in the disease groups except FHF, which otherwise always showed a high ALT level.

While reviewing our findings in reference to various other studies, we found that our data are in agreement with several other reports. Earlier reports indicate that a majority of individuals who become TTV-DNA-positive after blood transfusion usually have normal ALT level and do not develop chronic hepatitis, although TTV viremia persists for years[9,19-20]. We found TTV-DNA in 27% normal population with normal ALT level and at the same time no significant increase in ALT in hepatitis A-E, TTV-positive patients, thereby suggesting that TTV alone does not cause much change in ALT level. This raises the possibility that TTV is merely an innocent bystander, both with and without non A-E hepatitis viral infections, and does not add to the damage caused by other hepatotropic viruses. Also, as such it does not appear to be the primary cause of hepatitis, though many more studies are still needed to prove this theory. The results by Vimolket *et al*[21] demonstrated that in non A-E hepatitis cases, mean ALT level was comparable among TTV-positive and negative cases. There was no consistent relationship between ALT and TTV-DNA level among these patients. These results also support our findings.

In conclusion, TTV infection is prevalent both in normal as well as patients populations in India. It shows its presence in all types of liver diseases, though comparable to the normal population and presenting no evidence of increasing liver damage both with or without other hepatitis viral infections. TTV infection has been found to be coinfected with HBV, HCV and HEV infections, but does not significantly increase ALT level in these patients. It appears as if TTV is a benign virus acting as a bystander in the body without causing any damage of the liver.

Abstract

AIM: To define the common deleted region on the long arm of haman chromosome 7q linked to primary gastric carcinomas in Chinese by loss of heterozygosity (LOH) and its clinical significance.

METHODS: Nine microsatellite markers distributed over chromosome 7q with an average marker density of 10cM were used to examine 70 primary gastric carcinomas for LOH by PCR amplification. The PCR products were separated by electrophoresis on polyacrylamide gel. Genescan and Genotyper softwares were used to analyze LOH.

RESULTS: LOH with at least one marker on 7q occurred in 34.3% (12/50) of the tumors. Among them, LOH at D7S486 and D7S798 was higher in 24.0% (24/70) and 19.2% (5/26), respectively. By statistical analysis we also observed an obvious genotype-phenotype correlation on 7q ($P < 0.05$). The frequency of LOH at D7S486 in patients with lymph node metastasis was significantly higher than that in those without lymph node metastasis ($P = 0.015$).

CONCLUSION: The high incidence of LOH at D7S486 and its correlation with poorer prognosis suggest that there might be putative tumor suppressor genes in this region involved in the tumorigenesis and progression of gastric carcinoma.

Key words: LOH; Chromosome 7; Gastric cancer

INTRODUCTION

Gastric carcinoma is one of the most common malignancies in the digestive system. Generally, the incidence and mortality vary greatly depending on the region. The highest incidence is found in Japan and China in comparison with other regions of the world. It is one of the leading causes of cancer-related death[1]. Multi-gene and multi-step changes are involved in the occurrence and progression of tumors, including activation of oncogenes and inactivation of tumor suppressor genes (TSG). However, the vital genetic alterations remain uncertain. Previous genetic researches have demonstrated highly frequent amplifications of 1q, 2q, 6q, 7q, 8q, 17q, 20q and deletions of 1p, 1q, 2p, 3p, 4q, 5q, 6p, 7q, 9p, 11p, 11q, 12q, 15q, 17p, 17q, 18q, 19p, 21q in primary gastric cancers[2-5], indicating that these genetic alterations might relate to the occurrence and progression of gastric carcinoma. We used direct G-banding analysis and FISH on de-colored G-banding to study chromosome aberrations in primary gastric carcinoma and detected the deletion of 7q, 3p, 1p and 17p. The frequency of 7q deletion was particularly high[6], suggesting that there might be a potential TSG on the long arm of chromosome 7 involved in the progression of gastric carcinoma. Given the high rate of morbidity and mortality associated with GC, any means of reducing the occurrence of the disease or increasing its early detection is most desirable. In this study we examined the loss of heterozygosity (LOH) in microsatellite locus on human chromosome 7q of primary gastric carcinoma and corresponding non-tumor gastric mucosa tissues in order to narrow the oriented region of related TSG on 7q.

Table 1 Distribution and frequency of LOH at 9 microsatellite loci in primary gastric carcinomas

Microsatellite loci	Location on chromosome	LOH cases	Heterozygous cases	Positive rate of LOH (%)
D7S515	7q22.1	6	53	11.3
D7S486	7q31.1	12	50	24
D7S530	7q32.1	4	50	8
D7S640	7q33	3	63	4.8
D7S684	7q34	4	58	6.9
D7S661	7q35	3	27	11.1
D7S636	7q36.1	3	60	5
D7S798	7q36.2	5	26	19.2
D7S2465	7q36.3	5	52	9.6

MATERIALS AND METHODS

Materials

Primary gastric cancer and its corresponding normal tissue were obtained from 70 patients resected at the Affiliated Cancer Center of Zhongshan University during December 2000 to January 2002. All the patients did not receive any radiotherapy or chemotherapy before operation. The tissues were taken immediately after excision. One part of the samples was preserved at -80℃ for DNA extraction, the others were treated with routine protocol, embedded with paraffin and stained with HE.

Seventy patients (52 men and 18 women) aged 19 - 76 years (mean age 52.9 years) were enrolled in this study. The histological types included 1 papillary adenocarcinoma, 15 tubular adenocarcinomas, 25 poorly-differentiated adenocarcinomas, 2 mucinous adenocarcinomas, 20 signet-ring cell adenocarcinomas, 6 undifferentiated adenocarcinomas and 1 adenosquamous carcinoma, which were diagnosed according to the WHO classification of gastric carcinoma (1990). Based on the UICC TNM classification of gastric carcinoma, the patients were divided into 7 cases of stage Ⅰ (3 of ⅠA and 4 of ⅠB), 13 cases of stage Ⅱ, 24 cases of stage Ⅲ (14 of ⅢA and 10 of ⅢB) and 26 cases of stage Ⅳ.

DNA extraction

Genomic DNA samples of cryo-preserved gastric carcinomas and matched normal gastric mucosa were isolated by phenol chloroform extraction using standard protocols. DNA purification and concentration were detected by gel electrophoresis.

Selection of microsatellite markers and PCR amplification

A total of 9 microsatellite markers distributed over the whole chromosome 7q were selected from Genethon human genetic linkage map: D7S515, D7S486, D7S530, D7S640, D7S684, D7S661, D7S636, D7S798 and D7S2465. The frequencies of heterozygosity of the markers were over 75% and the average marker density was about 10cM. Synthesized microsatellite primers were respectively labeled with three different color fluorescent dyes: FAM, NED and HEX (purchased from PE Company). DNA samples were divided into 2 groups according to molecular size of the products and color of the fluorescent dyes. Primers (including 4 to 5 pairs) of each group were mixed in a tube for amplification. Each multiplex PCR reaction volume (5 μL in total) contained 0.5 μL 10×buffer, 0.2 μL 10 mmol/L dNTP, 0.3 μL 25 mmol/L $MgCl_2$, 0.05 μL 10 pmol/L primers, 0.2 U hot star Taq™ DNA polymerase (Gene Company, USA) and 45 ng genomic DNA. PCR amplifications were carried out in Gene Amp PCR system 9700 thermal cycler (Perkin-Elmer Co, Norwalk, USA). The reactive conditions were as follows: initial denaturation at 95℃ for 12 min followed by 10 cycles at 94℃ for 30 s, at 63℃ for 60 s (decreasing by 0.5℃ per cycle), at 72℃ for 90 s, and 26 cycles at 94℃ for 30 s, at 58℃ for 60 s, at 72℃ for 90 s and a final extension at 72℃ for 15 min.

Genomic scanning and analysis of microsatellite instability

PCR products (0.5μL) were diluted with 1.0 μL electrophoresis loading buffer containing 70% formamide, 3.75 mmol/L EDTA, 7.5 mg/ml blue dextran, 1.2 nmol/L Genescan 350. Mixture (1.0 μL) was loaded in urea-containing denaturing Sequagel Tm polyacrylamide gel (Gene Company, USA), and subjected to electrophoresis on a 377 DNA sequencer (ABI PRISM, PE Applied Biosystems). The automatically collected data were analyzed with Genescan Version 3.0 and Genotyper Version 2.0 software. Genotype for a given locus with two peaks of PCR fragments was defined as heterozygosity, and genotype with a single peak was regarded to be homozygosity. Only patients heterozygous for a given locus were regarded to be informative. Comparison of the ratios between tumors (T) and their controls (N) was made using the following formulas for calculations:

$(T_1/T_2)/(N_1/N_2)$ (1)

$(T_2/T_1)/(N_2/N_1)$ (2)

where T_1 and N_1 are the peak height of the smaller allele, while T_2 and N_2 are the peak height of the larger allele. Formula (1) was used to calculate the ratio of the smaller allele while formula (2) was used to calculate the ratio of the larger allele. For ratios greater than 1, the reciprocal of the ratio was calculated to give a value between 0.00 and 1.00. A value <0.67 was assigned as indicative of LOH[10-12].

Statistical analysis

The data of two-sample ratio were evaluated by chi-square test and Fisher's exact test. $P<0.05$ was considered statistically significant.

RESULTS

Distribution and frequency of LOH in primary gastric carcinoma

Genomic DNA was extracted from 70 primary gastric carcinomas and paired normal gastric mucosa tissues, 9 microsatellite fragments were amplified. Subsequent genotype analysis of the reliable amplification fragments was performed. LOH at all 9 loci was found in 70 primary gastric carcinoma cases (Table 1). The highest frequency of LOH was 24.0% at D7S486 and 19.2% at D7S798, respectively. LOH was detected in 24/70 (34.3%) of

Table 2 Correlation between frequencies and clinicopathology of LOH in primary gastric carcinomas

Clinicopathological variables		LOH frequency of chromosome 7 (%)	χ^2	*P* value	LOH frequency of D7S486 (%)	χ^2	*P* value
Gender	Male	17/52 (32.7)	0.22	0.636	7/35 (20)	1	0.317
	Female	7/18 (38.9)			5/15 (33.3)		
Age (yr)	>53	14/37 (37.8)	0.43	0.51	7/26 (26.9)	0.25	0.618
	≤53	10/33 (30.3)			5/24 (20.8)		
Clinical stage	I-II	3/20 (15)	6.16	0.046	1/13 (7.7)	2.63	0.268
	III	8/24 (33.3)			5/18 (27.8)		
	IV	13/26 (50)			6/19 (31.6)		
T stage	T1-2	3/13 (23.1)	0.88	0.349	1/8 (12.5)	0.68	0.411
	T3-4	21/57 (36.8)			11/42 (26.2)		
Lymph node metastasis	No	4/19 (21.1)	2	0.158	0/13 (0)		0.015
	Yes	20/51 (39.2)			12/37 (32.4)		
Distance metastasis	No	20/60 (33.3)	0.17	0.683	9/42 (21.4)		0.379
	Yes	4/10 (40)			3/8 (37.5)		
Histopathological type	Tubular adenocarcinoma	5/15 (33.3)	2.79	0.425	2/9 (22.2)	0.12	0.989
	Poorly- differentiated carcinoma	9/25 (36)			6/22 (27.3)		
	Signet-cell adenocarcinoma	6/19 (31.6)			3/12 (25)		
	Undifferentiated adenocarcinoma	4/6 (66.7)			1/4 (25)		

primary gastric carcinomas, 15/24 cases (62.5%) showed LOH at only one locus, 9/24 (37.5%) cases had LOH at two loci, and LOH occurred at more than three loci in 5/24 cases (25.0%).

Correlations between LOH and clinicopathology

Relations between LOH frequency and clinicopathology in 70 primary gastric carcinomas are shown in Table 2. There were statistical correlations between LOH frequencies at 7q and clinical stages. The frequency increased with poorer clinical stages ($P=0.046$). LOH at all 9 loci was detected in 13/26 (50.0%) cases with clinical stage Ⅳ, of which 6 cases (46.1%) were found to have LOH at D7S486. Five cases with LOH at more than 3 loci were all in stage Ⅳ. The frequency of LOH at D7S486 was related with lymph node metastasis. It was significantly higher in cases with lymph node metastasis than in those without metastasis ($P=0.015$).

However, frequencies of LOH showed no statistically differences in tubular adenocarcinomas, poorly-differentiated adenocarcinomas, signet-cell carcinomas and undifferentiated adenocarcinomas. Four cases showed LOH in 6 undifferentiated adenocarcinomas.

DISCUSSION

In our previous study, chromosome aberrations and their roles in the genesis and development of primary gastric cancer were investigated using direct G-banding analysis and FISH[7]. The deletion of chromosome 7q is the most consistent aberration, and 7q31-qter is the commonly lost segment[7-9]. LOH of this region is a very common occurrence in many kinds of human malignancies including cancers of breast[10], prostate[11], colon[12] and ovary[13], as well as primary squamous cell carcinoma of the head and neck[12]. Taken together, a critical TSG probably exists in this region with activation in a broad range of tissues. Some putative TSGs in this region such as ST7, Caveolin-1, ING3, and PPP1R3 have been reported[7,9,14,15]. However, no further researches provide reliable evidence for the correlation between these candidate genes and primary gastric carcinomas.

Tumor occurrence and progression involve multi-genes and multi-steps. Different genetic alterations participate in tumor occurrence and progression, and genetic alteration plays a vital role in different tumors. Several chromosomal amplifications and deletions have been reported in primary gastric carcinomas[2-5]. Kuniyasu *et al*[16] have reported LOH at 5 microsatellite markers on 7q in 32% (26/82) of 98 gastric carcinomas. D7S95 on 7q31-35 is the most frequent change locus. Similar results were also reported by Nishizuka *et al*[17]. Our findings are consistent with these previous studies. In our study, the total LOH at 7q was 34.3% in gastric carcinomas, and the frequency of LOH at D7S486 reached 24.0%. The higher frequencies of LOH at D7S486 and D7S798 than at the other 7 loci indicate the presence of tumor suppressor genes in these regions, particularly near D7S486.

Different results about correlations between LOH and clinical factors of chromosome 7q have been reported in various studies. Kuniyasu *et al*[16] found that LOH at D7S95 on 7q31-35 is much higher in stage Ⅳ gastric carcinomas and that patients with LOH at D7S95 show celiac metastasis compared with those without LOH ($P<0.05$). Moreover, patients of stage Ⅲ-Ⅳ with LOH at D7S95 survive shorter than those without LOH ($P<0.05$). Thus, LOH at D7S95 is likely involved in gastric carcinoma progression and prognosis. In our 70 gastric carcinomas, the frequency of LOH at any locus on 7q increased obviously with the rising of clinical stage ($P=0.046$), and reached 50.0% (13/26) in patients with clinical stage Ⅳ. Moreover, 5 cases with LOH at more than 3 loci were all in stage Ⅳ. The frequency of LOH at D7S486 in patients with lymph node metastasis was obviously higher than that in those without lymph node metastasis ($P=0.015$). There was no significant correlation between LOH and histological types. This lack of correlation may be related to the small number of undifferentiated tumors. Our results suggest

that one or more tumor suppressor genes associated with gastric carcinomas might situate on chromosome 7q and D7S486. Loss of restraining effects on tumor proliferation, infiltration and metastasis of these candidate genes might promote gastric carcinoma progression.

The region around the marker D7S486 may contain a fragile site. In fact, a 7q31.2 fragile site (FRA7G) of 300 kb is located between markers D7S486 and D7S522[18]. FRA7G is a common aphidicolin-inducible fragile site at 7q31.2, showing LOH in human malignancies. Common fragile sites are specific regions in mammalian chromosomes that are prone to breakage and rearrangements. This genetic instability can lead to disease manifestations and may play a role in oncogenesis[19]. The present study delineated a breakpoint of putative TSG near the marker D7S486. Tatareli *et al*[20] investigated the structure of FRA7G spanning the region between marker D7S486 and Met H and have identified a gene encoding a 421-amino-acid protein with three LIM domains with 89% identity to murine Testin. These findings suggest that TESTIN may represent a candidate tumor suppressor gene at 7q31.2.

The genetic intervals of microsatellite markers in our study were relatively wide (10cM). Additional studies are needed to narrow these regions on D7S486 and identify potential tumor suppressor genes.

Abstract

AIM: To investigate the potential role of perioperative nutrition in reducing complications and mortality in malnourished gastrointestinal cancer patients.

METHODS: Four hundred and sixty-eight elective moderately or severely malnourished surgical patients with gastric or colorectal cancers defined by the subjective global assessment (SGA) were randomly assigned to 7 d preoperative and 7 d postoperative parenteral or enteral nutrition *vs* a simple control group. The nutrition regimen included 24.6±5.2 kcal /kg per d non-protein and 0.23±0.04 g nitrogen /kg per d. Control patients did not receive preoperative nutrition but received 600±100 kcal non-protein plus or not plus 62 ± 16 g crystalline amino acids postoperatively.

RESULTS: Complications occurred in 18.3% of the patients receiving nutrition and in 33.5% of the control patients ($P = 0.012$). Fourteen patients died in the control group and 5 in those receiving nutrition. There were significant differences in the mortality between the two groups (2.1% *vs* 6.0%, $P = 0.003$). The total length of hospitalization and postoperative stay of control patients were significantly longer (29 *vs* 22 d, $P = 0.014$) than those of the studied patients (23 *vs* 12 d, $P = 0.000$).

CONCLUSION: Perioperative nutrition support is beneficial for moderately or severely malnourished gastrointestinal cancer patients and can reduce surgical complications and mortality.

INTRODUCTION

Malnutrition is common in gastrointestinal cancer patients and the causes are often complex and multi-factorial. Although it is widely accepted that malnutrition adversely affects the postoperative outcome of patients, there is little evidence that perioperative nutrition support can reduce surgical risk in malnourished cancer patients. Early retrospective studies suggested that perioperative nutrition support may effectively reduce postoperative complications[1,2]. Subsequent prospective, randomized clinical trials (RCTs) demonstrated that the benefits of perioperative nutrition support are limited to severely malnourished patients undergoing major surgery[3,4]. Most RCTs of perioperative nutritional support in patients with gastrointestinal cancer have shown that the degree of malnutrition varies considerably, ranging from no weight loss to weight loss exceeding 10 % and the results obtained by these studies are different in malnourished and non-malnourished patients[1-4]. Unfortunately, studies in really malnourished gastrointestinal cancer patients are not available. Meanwhile, parenteral and enteral nutrition is till controversial in perioperative malnourished gastrointestinal cancer patients[5].

The aim of this study was to evaluate the efficacy of optimal perioperative nutrition support in reducing complications and mortality in malnourished gastrointestinal cancer patients.

MATERIALS AND METHODS

This prospective study was carried out from May 2002 to July 2004 at the General Surgical Department of Zhongshan Hospital. All patients who underwent surgery for gastrointestinal (stomach, colon and rectum) malignancies were eligible for inclusion. Patients were excluded if they were admitted for emergency surgery. Within 48 h of admission, patients underwent nutritional assessment by the subjective global assessment. (SGA) performed with a standardized questionnaire including the patient's history (weight loss, changes in dietary intake, gastrointestinal symptoms, and functional capacity), physical examination (muscle, subcutaneous fat, sacral

and ankle edema, ascites) and the clinician's overall judgment of the patient's status (normal, moderately or severely malnourished). On the basis of these data, the patients were classified as well-nourished, moderately- or severely-malnourished. A total of 512 moderately- and severely-malnourished gastrointestinal cancer patients were included in this study. The Ethical Committee of the Institution approved this clinical study.

After stratified for age, sex and tumor localization (gastric, colorectal), patients were randomly divided into study group ($n=257$, 95 women, 162 men) and control group ($n=255$, 89 women, 166 men). The mean ages were 57.3 years (range 21 - 84 years) and 56.5 years (range 24 - 86 years) in the study group and control group, respectively.

Perioperative nutrition was administered in the study group by parenteral or enteral route or a combination of the two based on a clinical assessment of intestinal function. Patients due to permanent or temporary intestinal failure were given parenteral nutrition (PN). If the clinician felt that the patients had a functioning gastrointestinal tract, they received enteral nutrition (EN).

Most patients (68%) received PN support during the preoperative and postoperative periods. The PN regimen consisted of 25 kcal/kg per d non-protein and 0.25 g nitrogen /kg per d. The non-protein calorie source included glucose and fat, accounting for 60% and 40% respectively of the energy intake. The protein source was supplied by crystalline amino acid solutions. Electrolytes, vitamins, and trace elements were administered according to the current recommendations. PN mixture was delivered through a central venous catheter or peripheral veins using an "all in one" bag. In addition, the patients receiving preoperative PN had free access to food they preferred.

EN was given to 75 patients (32%) in whom GI function was adequate through a fine bore silicone feeding tube. Where appropriate, EN was alternatively administered via a nasogastric tube or a feeding jejunostomy catheter. Similar target intake of non-protein (25 kcal/kg per d) and protein (0.25 g nitrogen/kg per d) was provided using commercially available enteral formulas. The initial rate of delivery was 40-60 mL/h, increasing stepwise to full intake for 48 h according to patient tolerance. Foods were usually given as a continuous infusion using a volumetric pump for 24 h. Nutritional support was started 8-10 d before surgery and continued for more than a week after surgery.

Patients in the control group were given a standard hospital oral diet before surgery and a hypocaloric parenteral solution (600 kcal non-protein and 60 g amino acid) in the postoperative period until gastrointestinal function recovered completely.

After surgery, patients were monitored daily for postoperative complications including septicemia, intra-abdominal abscess, wound infection, wound dehiscence, fistula formation, urinary tract infection, pneumonia, respiratory insufficiency and phlebitis. Rigid objective criteria were established defining each complication to avoid subjective bias. A diagnosis of septicemia was based on a positive blood culture, hypotension and hypoperfusion. An intra-abdominal abscess was defined as an intra-abdominal purulent collection requiring operative drainage. Fistulae were radiographically documented. A diagnosis of urinary tract infection required a quantitative culture of greater than 100 000 organisms. Pneumonia was documented by an abnormal chest x-ray, positive sputum culture, and treatment with antibiotics. The presence of a wound infection was defined by culture and operative or spontaneous drainage of purulent materials. A wound dehiscence required operative re-closure of the wound. The occurrence and cause of death during hospitalization and the length of hospitalization were recorded.

Statistical analysis

Data were analyzed using standard statistical software (SPSS 10.0). For normally distributed data, a paired Student's t test was used for statistical analysis. $P \leqslant 0.05$ was considered statistically significant. Data were expressed as mean $\pm$ SE.

RESULTS

A total of 512 malnourished patients gave their consent to participate in the study and 16 declined. Of the 512 patients, 28 were not randomized after surgery because of un-resectability. Four hundred and sixty-eight patients were assigned at random to study group ($n=235$, 87 women, 148 men) and control group ($n=233$, 90 women, 143 men). Patient demographics and preoperative parameters of the two groups are presented in Table 1. There were no significant differences in mean age, sex distribution and nutrition status between the two groups. Operative data are listed in Table 2. The mean length of the surgical procedure and the volume of intraoperative blood transfusions were similar in two groups. The volume of postoperative blood transfusions was larger in control group. However, none of these differences was statistically significant. The number of patients requiring albumin infusions and the volume of infused albumin were comparable between the groups.

The number of postoperative complications per study group is shown in Table 3. Forty-three complications occurred in 31 patients in the study group, and five patients died due to major complications. Seventy-eight complications occurred in 64 patients of the control group, and 14 patients died. There were significant

differences in the mortality and complications between the two groups (2.1% *vs* 6.0%, $P = 0.003$ for mortality; 18.3% *vs* 33.5%, $P = 0.012$ for complications). In both groups, the most frequent complication was infection related to muscle weakness and/or prolonged immobilization (respiratory insufficiency, phlebitis).

Table 4 summarizes the incidence of septic complications between PN and EN groups. No significant differences were found in the incidence of septic complications between the two groups of nonrandomized patients. In addition, there was no significant difference in the number of septic complications between the two groups.

The total perioperative and postoperative median length of hospitalization was 22 *vs* 29 d in the study group and 12 *vs* 23 d in the control group, respectively. The total length of hospitalization and postoperative stay of the control patients were significantly longer than those of the study patients ($P = 0.014$, $P = 0.000$).

DISCUSSION

Malnutrition in hospitalized patients is a critical issue associated with a significant increase in morbidity and mortality. Recent surveys have demonstrated that 30 - 50% of hospitalized patients have a certain degree of malnutrition[6,7]. Malnutrition is closely associated with increased morbidity and mortality after major gastrointestinal surgery. Perioperative nutrition support can restore many of biochemical and immunologic abnormalities in malnourished or normal state. However, it is difficult to demonstrate that perioperative nutrition support can significantly reduce surgical complications except in the most severely malnourished patients[8]. Early retrospective studies from 1970s to 1980s suggested that perioperative nutrition support can reduce surgical complications. Subsequent prospective, randomized trials demonstrated that the benefits of perioperative nutrition support are limited to severely malnourished patients undergoing major surgery[3,4]. Most RCTs of perioperative nutritional support in patients with gastrointestinal cancer have shown that the degree of malnutrition varies considerably, ranging from no weight loss to weight loss exceeding 10%, and that the complication rate decreases from 56% in the control arm to 34% in the TPN arm, with no deaths in the latter group[4,9]. Because nutrition support can only ameliorate but not reverse the catabolic response to trauma, it may effectively improve nutritional state and reduce postoperative complications when started preoperatively[10].

This study represented a large randomized clinical trial to explore the role of perioperative nutrition support in moderately- and severely-malnourished gastrointestinal cancer patients. In these patients nutritional support was started 8 ± 10 d before surgery and continued for more than a week after surgery. Nutrition was given by parenteral or enteral routes or a combination of these two. Postoperative complications were defined by rigid objective criteria to avoid subjective bias. This prospective study demonstrated that adequate perioperative nutritional support could effectively reduce the incidence of postoperative complications in moderately- and severely-malnourished gastrointestinal cancer patients. In perioperative nutrition support patients, there was a two-fold reduction in complications ($P = 0.012$) and a three-fold reduction in death ($P = 0.003$). The most dramatic decrease was noted in major septic complications (14.9% *vs* 27.9%, $P = 0.011$) such as pneumonia and wound infection. In addition, the mortality was statistically lower in artificial nutrition support group than in the control group (2.1% *vs* 6.0%, $P = 0.003$). As a consequence of the lower infection rate, the length of hospital stay of the study group was shorter. These results indicate that malnutrition has a negative impact on postoperative outcomes, which may be efficiently controlled by a perioperative nutrition support

that is adequate in quality, quantity, and duration.

Perioperative nutritional support can be administered by PN or EN or their combination. PN has the advantage of easy administration and essentially immediate provision of optimal nitrogen and caloric requirements once the central venous access is established. A major concern with PN in hospitalized patients is the increased risk of septic complications related to immune dysfunction after PN. Unlike PN, EN is not associated with increased infectious complications. In fact, enteral feeding can maintain structural and functional integrity of the gastrointestinal tract and reduce septic complications in critically ill patients. The major disadvantages of EN support are the time delay when attempting to provide complete nutrition by the enteral route and the inability of patients with postoperative abdominal complications to tolerate enteral feeding. Early postoperative EN has fewer septic complications compared to early postoperative PN [11, 12]. Unfortunately, studies in really malnourished cancer patients are not available. The present prospective study demonstrated that there was no statistically significant difference in the incidence of septic complications between PN and EN (15.6% *vs* 13.3%, $P = 0.36$). In addition, there was no significant difference in the number of septic complications per patient or complications per infected patient between PN and EN between the two groups. The results of our study are different from other prospective randomized trials[13-15]. There are several possible explanations for the discrepancies. First, patients are quite different in terms of age, physiologic and nutritional status. Second, the relative protein and energy intake in previous studies are often not comparable, usually being much higher in patients receiving PN than in those receiving EN[16,17]. Excessive energy intake may result in hyperglycaemia and lead to increased septic complications and mortality[18,19]. In the present study, the prescribed target intake for both PN and EN patients was the same (25 kcal /kg per d and 0.25 g N/kg per d). Third, in previous studies, all patients were randomized to receive either PN or EN, with no consideration given to the issue of gut function. Therefore some patients able to tolerate EN were given PN. In the present study, the route of feeding was dictated by an assessment of gut function, ensuring EN was administered only to patients with adequate intestinal function. The results of this study are in accord with the recent studies[20, 21].

In conclusion, perioperative nutrition support can decrease the incidence of postoperative complications in moderately- and severely-malnourished gastrointestinal cancer patients. In addition, it is effective in reducing mortality. Both parenteral support and enteral nutrition support, or their combination can be used in the management of malnourished patients undergoing gastrointestinal surgery.

Abstract

AIM: To observe the effects of acid and bile acid exposure on cell proliferation and the expression of extracellular signal-regulated protein kinase (ERK) and peroxisome proliferator-activated receptor γ (PPARγ) in normal human esophageal epithelial cells *in vitro*.

METHODS: *In vitro* cultured normal human esophageal epithelial cells were exposed to acidic media (pH 4.0-6.5), media containing different bile acid (250 μmol/L), media containing acid and bile acid, respectively. Cell proliferation was assessed using MTT and flow cytometry. The expressions of phosphorylated $ERK_{1/2}$ and PPARγ protein were determined by the immunoblotting technique.

RESULTS: Acid-exposed (3 min) esophageal cells exhibited a significant increase in proliferation ratio, S phase of the cell cycle ($P < 0.05$) and the level of phosphorylated $ERK_{1/2}$ protein. When the acid-exposure period exceeded 6 min, we observed a decrease in proliferation ratio and S phase of the cell cycle, with an increased apoptosis ratio ($P < 0.05$). Bile acid exposure (3-12 min) also produced an increase in proliferation ratio, S phase of the cell cycle ($P < 0.05$) and phosphorylated $ERK_{1/2}$ expression. On the contrary, deoxycholic acid (DCA) exposure (> 20 min) decreased proliferation ratio. Compared with bile acid exposure (pH 7.4), bile acid exposure (pH 6.5, 4) significantly decreased proliferation ratio ($P < 0.05$). There was no expression of PPARγ in normal human esophageal epithelial cells.

CONCLUSION: The rapid stimuli of acid or bile acid increase proliferation in normal human esophageal epithelial cells by activating the ERK pathway.

INTRODUCTION

The incidence of esophageal adenocarcinoma has been rapidly increasing in western countries. With the improvement of investigation devices, reflux esophagitis and Barrett's esophagus (BE) have also been reported in more and more cases in China. In these diseases, duodenogastroesophageal reflux has been established as a strong risk factor[1]. The main components of refluxates are acid and bile acid, whose potential contributions to the esophageal diseases have widely been discussed. However, the effects of acid and bile acid on esophageal cell proliferation and the related signal transduction mechanisms remain unknown. The mitogen-activated protein kinase (MAPK) family, also known as extracellular signal-regulated kinase (ERK), c-Jun-N-terminal kinase (JNK), and p38 pathways, transmit extracellular growth-regulating signals to effector genes in the nucleus, the activation of the ERK pathway is usually associated with pro-proliferative and antiapoptotic effect[2]. Peroxisome proliferator-activated receptor γ (PPARγ), a member of the nuclear hormone receptor superfamily, has recently been shown to be implicated in the development of many digestive tumors[3], with the potential role in the downstream of ERK pathway[4].

In the present study, we examined the effects of acid and bile acid on cell proliferation in normal human esophageal epithelial cells *in vitro*, in association with ERK signaling pathway and PPARγ expression.

MATERIALS AND METHODS

Antibodies and reagents

Monoclonal antibody raised against human cytokeratin 14 (CK14) was purchased from Changdao Biotech Company, Shanghai. Polyclonal antibodies raised against human ERK$_{1/2}$ and phospho-ERK$_{1/2}$ were purchased from Cell Signaling Technology, USA. Monoclonal antibody raised against human PPARγ was purchased from Santa Cruz, USA. Keratinocyte serum-free media (K-SFM) supplemented with bovine pituitary extract (BPE) and recombinant epithelial growth factor (rEGF) were from Gibco, USA. Hydrochloric acid (1 mol/L) was from Sanpu Pure Chemical Industries, Xi'an. Sodium glycocholate (GC), sodium glycodeoxycholate (GDC), sodium glycochenodeoxycholate (GCDC), sodium taurocholate (TC), sodium taurodeoxycholate (TDC), sodium taurochenodeoxycholate (TCDC), and cholic acid (CA), deoxycholic acid (DCA) were purchased from Sigma, USA, and dissolved in K-SFM to 250 μmol/L. Histostain kit was purchased from Zhongshan Golden Bridge Biotech Company, Beijing. RIPA cell lysis kit was purchased from Shenergy Biocolor BioScience Technology Company, Shanghai. BCA protein assay kit and ECL kit were purchased from PIERCE, USA.

Cell culture

Normal esophageal mucosa samples were obtained from surgically resected esophagus with esophageal carcinoma, then confirmed by an experienced pathologist to contain neither macroscopic tumor tissue nor histologically detectable metaplastic cells or cancer cells. Samples were acquired with the signed informed consent from the patient. Samples were collected aseptically, stored in sterile K-SFM at 4℃, and processed within 4 h. Primary culture of normal esophageal epithelial cells was undertaken according to the method described elsewhere[5]. The collected cells were suspended in K-SFM supplemented with BPE and rEGF, and seeded into 75-cm uncoated plastic culture flask in humidified air containing 50 mL/L CO_2 at 37℃. After the initial subculture, an aliquot of cells was grown on coverslips for immunocytochemical stain with CK14 antibody.

Experimental groups

Equally seeded epithelial cells were cultured in K-SFM without BPE and rEGF for 48 h, then divided into 3 groups, acid exposure group: cells were exposed to the acidified medium (pH 4.0-6.5) for 3-60 min; bile acid exposure group: cells were exposed respectively to the medium containing different bile acid (250 μmol/L) for 3-60 min; and mixed exposure group: cells were exposed to the medium containing different bile acid (250 μmol/L) with different pH (4.0 and 6.5) for 3 min. Cells of control group were cultivated in normal media (pH 7.3).

Cell proliferation and cell cycle determination

For cell proliferation assay, 5×10^3 cells/well were plated in 96-well plates. Using MTT assay, changes in cell number were measured 24 h after different exposures. Then 10 μL MTT solution (5 mg/mL) was directly added to the cell cultures. After 4 h, media were removed and cells were lysed with 100 μL of dimethyl sulfoxide. Absorbance at 490 nm was read and data were presented as ratio to control (proliferation ratio).

For cell cycle determination, cells were seeded at 5×10^5/well in 6-well dishes. After 24 h of different exposures, cells were trypsinized and washed in PBS. A pellet of 1×10^6 cells was fixed in 750 mL/L ice-cold ethanol and stored at 4℃ until analyzed. Before flow cytometric analysis, cells were stained with 50 μg/mL RNase and 50 μg/mL propidium iodide. Cells in the G1, S, and G2 phase of the cell cycle and cell apoptotic percentage were determined using flow cytometer (FACSCalibur, Becton Dickinson, USA).

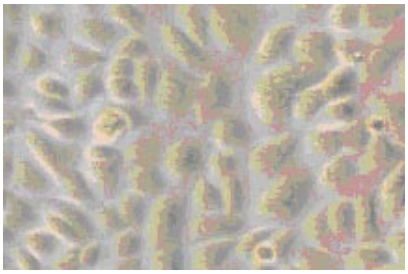

Figure 1 A phase-contrast micrograph of normal human esophageal epithelial cells (× 250).

Immunoblot analysis

After exposure to acid or bile acid for 3 min, cells were immediately treated with cold RIPA cell lysis buffer, followed by centrifugation at 10 000 *g* for 20 min at 4℃ to remove the cell debris. Total protein of the supernatant was measured using a BCA protein assay kit. Protein electrophoresis was performed on a 100 g/L SDS- polyacrylamide gel with 50 μg protein added to each lane. The proteins were then transferred onto a PVDF membrane. The membrane was incubated overnight at 4℃ with the various primary PPARγ (1:100), ERK$_{1/2}$ and anti-phospho ERK$_{1/2}$ (1:1000) antibodies, and then incubated with corresponding secondary antibodies conjugated to horseradish peroxidase for 2 h at room temperature. The protein bands were visualized by ECL and exposed to X-ray film. The relative density of the protein bands was quantified by densitometry using Electrophoresis Documentation and Analysis System.

Statistical analysis

All experiments were performed in triplicate. The data were expressed as mean ± SD. Statistical analysis between two groups was carried out using Student's *t*-test, for comparison of three or more groups using ANOVA test. $P < 0.05$ was considered statistically significant.

RESULTS

Growth characteristics of normal human esophageal epithelial cells

Epithelial monolayer cultures were successfully established with the appearance of cobblestones (Figure 1). As a cytoskeleton protein of esophageal epithelial cells, CK14 was expressed in all secondary cultures using immunocytochemical stain.

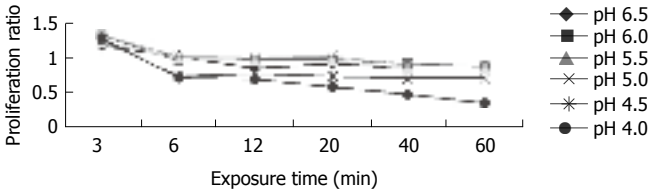

Figure 2 Effect of acid exposure on cell proliferation.

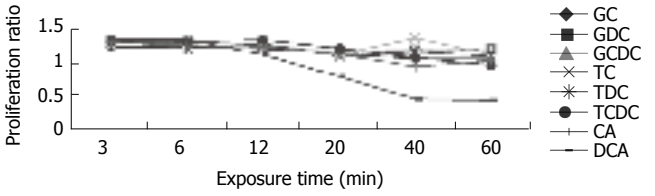

Figure 3 Effect of bile acid exposure on cell proliferation.

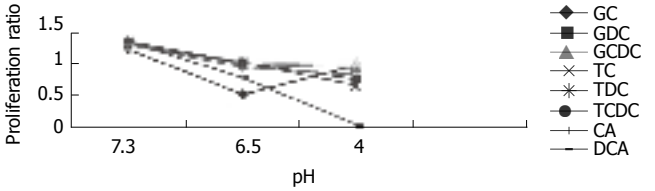

Figure 4 Changes in proliferation of cells exposed to bile acid with different pH for 3 min.

Measurement of cell proliferation and cell cycle

For cells exposed to acid (Figure 2), proliferation ratios were above 1 at 3 min, then decreased gradually to below 1 with prolongation of exposure time, especially when pH < 5.0. For cells exposed to bile acid (Figure 3), proliferation ratios of GC, GDC, GCDC, TC, TDC, TCDC, and CA groups were all above 1 or near 1 with the exposure time of 3-60 min. For DCA group, proliferation ratios were above 1 at 3-12 min, then decreased to below 1 with prolongation of exposure time. For mixed exposure group (Figure 4), proliferation ratios of cells exposed to bile acid with pH 6.5 or 4 for 3 min were markedly less than that of bile acid group (pH 7.4) (P <0.05), for most groups the proliferation ratios dropped to the lowest at pH 4, yet for GC the lowest proliferation ratio was seen at pH 6.5.

The results of cell cycle determination are summarized in Table 1. Compared with the control (pH 7.3), a short-period exposure to acid (3 min) produced an obvious increase of cells in S phase (P < 0.05), and a similar apoptosis percentage. In contrast, longer exposure to acid (6, 12 min) significantly decreased the cell proportion in S phase accompanied by an increased apoptosis percentage (P <0.05). Similarly, a brief exposure to bile acid (3-12 min) also produced an increase of cells in S phase (P<0.05), and a similar apoptosis percentage.

Expression of ERK1/2 and PPARγ

The expression of phospho-ERK1/2 was significantly increased in cells exposed to pH 4.0, 5.0 and 6.0 for 3 min (Figure 5) compared to control (pH 7.3) (P < 0.05). ERK

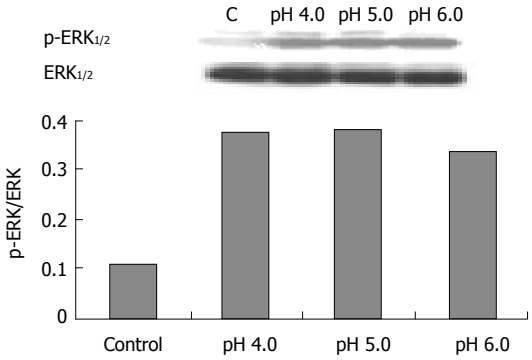

Figure 5 Effect of acid exposure (3 min) on ERK.

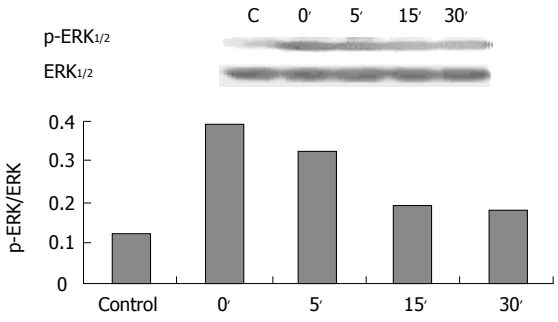

Figure 6 Expression of ERK in 30 min after acid exposure (pH 4.0, 3 min).

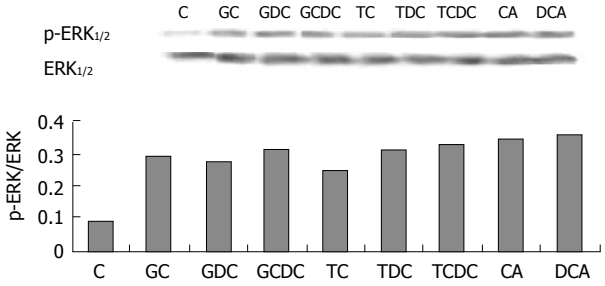

Figure 7 Effect of bile acid exposure (3 min) on ERK.

activity increased immediately after acid exposure (pH 4, 3 min), approximate to the level of control after 15 min (Figure 6). There were also increased expressions of phospho-ERK1/2 in cells exposed to different bile acid for 3 min (P <0.05) (Figure 7). No expression of PPARγ in normal human esophageal epithelial cells, either exposed to acid/bile acid or not, was observed.

DISCUSSION

Increased cell proliferation has been shown in reflux esophagitis and BE[6]. Episodic exposure to acid has been found to increase *in vitro* cell proliferation in organ culture of BE[7] and in Barrett's-associated adenocarcinoma cell line (SEG-1)[8]. Moreover, it was reported the exposure to GCDC for 20 min also increased cell proliferation in SEG-1 cell line[9]. These results suggest that the refluxates probably result in the development of esophageal inflammation, intestinal metaplasia and malignant

progression by inducing abnormal proliferation. Since there have been some problems unsettled in the primary culture of human normal esophageal epithelial cells, the previous studies were mainly limited to the cells in pathologic status. Based on the newly-established primary culture technique of human normal esophageal cells[5], we observed, probably for the first time, the effects of acid and bile acid on cell proliferation in human normal esophageal cells.

We found an acid-pulse (3 min) enhanced proliferation in normal esophageal epithelial cells, whereas continuous acid exposure blocked cell proliferation. A brief acid exposure (3 min) increased proliferation ratios at 24 h, yet longer exposure (>6 min) led to decreased cell number, which was more significant at pH<5.0. This was further confirmed by the results of cell cycle determination, a brief exposure (3 min) to acid produced an increase of cells in S phase, while longer exposure (6, 12 min) decreased the cell proportion in S phase accompanied by an increased apoptosis percentage.

The above results show that the effects of acid on esophageal cells are time-dependent, the brief exposure has pro-proliferation effect and longer exposure can induce apoptosis. Previous reports have showed the effect of acid on apoptosis, exposure to pH 3.5 for 2 d led to a decreased cell number in mouse esophageal keratinocytes[10], and normal human esophageal epithelial cells could not survive in media below pH 5.5 for 12 h[11]. Esophageal acid reflux is judged clinically by pH < 4. Since cells are cultured *in vitro* with a neutral pH of 7.2-7.4, their tolerance to acid is limited; this is mainly due to the defect of tissue organization, blood transportation and mucosal barrier *in vivo*.

To identify whether bile acid has the similar pro-proliferation effect, we exposed the normal esophageal cells to 6 conjugated bile acids and 2 unconjugated bile acids of 250 μmol/L for 3-60 min. The concentration choice was based on median bile acid concentration found in esophageal aspiration in patients with BE[12]. We found a brief bile acid exposure (3-12 min) also increased proliferation ratios at 24 h and the cell proportion in S phase, while with prolongation of exposure time to the acid and bile acids, especially DCA, the cell number decreased, suggesting that DCA is more toxic than other bile acids. Furthermore, we found that toxic effect of acid was higher compared to bile acid with the same exposure time.

In most cases, duodenogastroesophageal reflux is the mixed reflux of acid and bile. The toxic effects of bile acids are known to vary with pH. Unconjugated bile acids (pKa>4) and glycine conjugates (pKa>6) are soluble in nonionic pattern when pH > 4, whereas taurine conjugates are freely soluble even at pH 2[12]. Bile acids in nonionic pattern are easy to enter cells because of their affinity to lipid. Esophageal perfusion studies in animal models showed that unconjugated bile acids caused mucosal damage selectively in alkaline solutions, whereas taurine conjugates were toxic in acidic conditions[13]. We investigated the influence of pH on the effect of bile acid in cells, and found that compared with bile acid exposure group, the mixed exposure group had a decreased proliferation ratio, which dropped to the lowest at pH 4, yet for GC the lowest proliferation ratio was seen at pH 6.5. So, we could conclude that acid aggravates the toxic effect of bile acid, which may be due to the influence of pH on the ionization degree of taurine conjugates and glycine conjugates. In addition, it may be also related to the synthetic toxic effects of acid and bile acid, since we found that with the same exposure time (3 min), acid or bile acid exposure enhanced cell proliferation, but the mixed exposure decreased the proliferation.

Since acid and bile reflux in esophagus have been clinically shown to be intermittent and repeated, the abnormal proliferation induced by acid and bile acid may play an important role in the development of reflux-related diseases. Though there have been various points of view about the damage mechanisms of refluxates, their pro-proliferative mechanism has been seldom reported. So, we investigated the relation between ERK signaling pathway and the proliferation effects of acid and bile acid. ERK is an important signal transduction factor, unreactive in cytoplasm in normal condition, can be activated by physicochemical stimulus to enter nucleus and is implicated in cell physiological and pathological processes, such as growth, division, proliferation, apoptosis and malignant progression[14]. We found the proliferation induced by acid and bile acid in normal esophageal epithelial cells was related to the up-regulation of ERK expression, which suggest that acid and bile acid may result in esophageal inflammation, intestinal metaplasia and malignant progression by inducing ERK-mediated proliferation.

Recently some reports have suggested the implication

of PPARγ in control of tumor cell growth and its possible role in the downstream of ERK signaling pathway[3,4]. PPARγ is over-expressed in many malignant tissues, but its expression in esophagus remains controversial. Some authors reported PPARγ mRNA level was lower in esophageal squamous cell carcinoma tissues than that of normal esophageal mucosa[3]. Others found PPARγ mRNA was expressed in biopsies of both normal esophageal mucosa and BE, but expression of this protein was detected only in BE[15]. In our study, no expression of this protein was observed either in normal esophageal epithelial cells or the cells exposed to acid or bile acid.

In conclusion, we have shown, probably for the first time, that a brief exposure to acid or bile acid induces *in vitro* proliferation in normal human esophageal epithelial cells, accompanied with the up-regulation of ERK, a potential molecular pathway whereby duodenogastroesophageal reflux may contribute to the development of reflux esophagitis, BE and esophageal adenocarcinoma. Moreover, acid aggravates the toxic effect of bile acid, which supports the view that the mixed reflux facilitates damage to the esophageal mucosa.

Abstract

AIM: To investigate the effect of angiopoietin-1 (Ang-1) on biological behaviors *in vitro* and tumorigenesis and angiogenesis *in vitro* of human gastric cancer cells.

METHODS: Human full-length Ang-1 gene was cloned from human placental tissues by RT-PCR method. Recombinant human Ang-1 antisense eukaryotic expression vector was constructed by directional cloning, and transfected by lipofectin method into human gastric cancer line SGC7901 with high Ang-1 expression level. Inhibition efficiency was confirmed by semi- quantitive PCR and Western blot method. Cell growth curve and cell cycle were observed with MTT assays and flow cytometry, respectively. Nude mice tumorigenicity test was employed to compare *in vitro* tumorigenesis of cells with Ang-1 suppression. Microvessel density (MVD) of implanted tumor tissues was analyzed by immunohistochemistry for factor VIII staining.

RESULTS: Full-length Ang-1 gene was successfully cloned and stable transfectants were established, namely 7Ang1- for antisense, and 7901P for empty vector transfected. 7Ang1- cells showed down-regulated Ang-1 expression, while its *in vitro* proliferation and cell cycle distribution were not significantly changed. In contrast, xenograft of 7Ang1- cells in nude mice had lower volume and weight than those of 7901P after 30 days' implantation ($P < 0.01$, 293.00 ± 95.54 mg *vs*. 624.00 ± 77.78 mg) accompanied with less vessel formation with MVD 6.00±1.73 compared to 7901P group 8.44±1.33 ($P < 0.01$).

CONCLUSION: Ang-1 may play an important role in tumorigenesis and angiogenesis of gastric cancer, and targeting its expression may be beneficial for the therapy of gastric cancer.

INTRODUCTION

Angiopoietin-1 (Ang-1) and angiopoietin-2 (Ang-2), two main members of angiopoietins family, are involved in both physiological and pathological angiogenesis processes. Ang-1 has been identified as a major activator of the tyrosine kinase receptor Tie2, leading to receptor autophosphorylation on binding. Ang-1 also stimulates endothelial cell migration *in vitro*[1,2]. Ang-2 is the naturally occurring antagonist to Ang-1 and inhibits Ang-1 mediated Tie2 phosphorylation; this effect leads to vessel destabilization, a necessary step in the initiation of angiogenesis[3,4].

Ang-1 and Ang-2 have been reported to be involved in several kinds of cancers, while their roles in gastric cancer progression and angiogenesis are still not fully understood. There have been several reports declaimed the effect of Ang-1 on tumorigenesis of human astrocytomas[5,6], breast cancer[7] and colorectal adenocarcinoma[8]. Previous report has identified that Ang-2 plays an important role in gastric cancer angiogenesis and progression[9,10], while little is known about the roles of Ang-1 in gastric cancer.

In the present study, we aimed to investigate the effect of Ang-1 on the biological behaviors and tumorigenesis and angiogenesis of human gastric cancer cells by modifying Ang-1 expression in SGC7901 gastric cancer cells by *in vivo* and *in vitro* examinations. Our results revealed that inhibition of Ang-1 expression would retard gastric cancer angiogenesis and progression.

MATERIALS AND METHODS

Tissue specimens and cell lines

Fresh placental tissue was obtained from the Department of Gynaecology and Obstetrics, Xijing Hospital, Xi'

an, China, with informed consent from the patients. Human gastric cancer cell line SGC7901 with high Ang-1 expression was preserved in our institute and cultured in RPMI1640 supplemented with 100 mL/L bovine serum.

Ang-1 antisense eukaryotic expression vector was conducted by RT-PCR method and directional cloning. Total RNA of fresh human placental tissue was extracted with Trizol (Life Technologies, Carlsbad, USA) according to the manufacturer's protocol. About 1 μg of total RNA was used for first strand cDNA synthesis according to the manufacturer's instructions. The full-length human Ang-1 cDNA was cloned using primer pairs: 5'-gaggggggaaagagtcaaacaaac-3' and 5'-cttgaccgtgaatctggagcc-3'. PCR parameters were 94 ℃ for 1 min, annealing at 60 ℃ for 1 min, and 72 ℃ for 2 min for 30 cycles, and the product was verified by 8 g/L gel electrophoresis. Sequence of PCR product was verified by the ABI PRISM 377 DNA Sequencer (Sangon, Shanghai, China). After PCR, the 1.9-kb fragment was cloned into the pMD18-T vector (Takara, Dalian, China) followed by *Hind*Ⅲ and *BamH* Ⅰ digestion and ligated into pcDNA3.1-V_5-His C expression vector (Invitrogen, Carlsbad, CA) named as pcDNA3.1-Ang1-. The sequence was confirmed by sequencing analysis.

Cell transfection

SGC7901 cells were plated and grown to 80% confluency without antibiotics. Stable transfections of pcDNA3.1-Ang1- and empty vector, pcDNA3.1-V_5-His C, were performed with Lipofectamine 2000 (Invitrogen, Carlsbad, CA) as directed by the manufacturer. Transfected cells were selected with 300 mg/L G418 after 48 h. Clones were picked and expanded for an additional 2 months. Efficiency of Ang-1 suppression was confirmed by RT-PCR and Western blot methods.

Semi-quantitative RT-PCR

Semi-quantitative RT-PCR was employed to compare the gene expression in different transfectants. The number of optimal replications was determined based on the linear correlations between cycle numbers and PCR products. Gene expression was presented by the relative yield of the PCR product from target sequences to that from GAPDH gene as control. PCR primers and reaction parameters were chosen according to the literature [11] and listed as follows: Ang-1, 5'-ACTGTGCAGATGTATATCAAG C-3' and 5'-GTGGAATCTGTCATACTGTGA A-3'; GAPDH, 5' -TGGGTGTGAACCATGAGAAGTA-3' and 5'-CGCTGTTGAAGTCAG AGGAGA-3'. The PCR parameters were 94℃ for 1 min, annealing at 60℃ for 1 min, and 72℃ for 1 min for 32 cycles for Ang-1 and 94℃ for 30 s, annealing at 52℃ for 30 s, and 72℃ for 45 s for 32 cycles for GAPDH.

Western blot analysis

Equal amounts of the extracted protein of cells were separated by 100 g/L SDS–PAGE; The protein bands were electro-transferred to nitrocellulose membrane. Expression of Ang-1 was analyzed using primary antibody (kindly provided by Micheal Hanner from Renegeron Pharmaceuticals, USA), followed by corresponding second antibody (Zhongshan, Beijing, China), then visualized by enhanced chemiluminescence (ECL, Amersham–Pharmacia Biotech, Beijing, China). Relative protein levels were calculated to β-actin as standard.

MTT assay

Exponentially growing cells were harvested and suspended in 96-well flat-bottomed plates (200 μL /well) (Costar). After incubation for 1, 3, 5 and 7 d, respectively, 20 μL of MTT solution (5 g/L) (Sigma, St louis, MO) was added to each well and further incubated for 4 h. One hundred and fifty μL of dimethylsulfoxide was added before absorbance at 490 nm was measured with a microplate reader BP800 (BIOHIT).

Cell cycle analysis

To evaluate whether the inhibition of Ang-1 would exert any effect on the cell cycle distribution of SGC7901 cells, we performed cytofluorimetric analysis. Briefly, cells were fixed with 70% ice-cold ethanol and stored at 4°C overnight, washed with PBS, and stained with propidium iodide (PI) (50 mg/L) for 30 min. Cell cycle histograms were generated after analysis of PI-stained cells by fluorescence activated cell sorting (FACS) with a Becton-Dickinson FACScan.

In vivo tumorigenicity

To investigate whether or not Ang-1 suppression would alter the tumorigenicity of SGC7901 cells, nude mice bred in our animal facilities were used with body weight range from 18 to 22 kilograms. Four $\times 10^6$ cells were injected subcutaneously into the right flank of nude mice. The experiment was performed on five mice in each group. The mean tumor volume was weekly measured and calculated according to the formula: $a \times (b)^2 \times 0.5$ (a = largest diameter, b = perpendicular diameter). All mice were sacrificed after 30 d and the subcutaneous tumor graft were surgically excised from the mice, fixed with formalin and paraffin-embedded 4-μm sections were prepared for immunohistochemical analysis.

Immunohistochemistry

Factor VIII staining was used to identify the microvessels in the tumor tissues by immunohistochemical method as usual. Briefly, after paraffin-embedded tissue sections were deparaffinized in xylene and rehydrated in alcohol, sections were incubated in 3 mL/L H_2O_2 to block endogeneous peroxidase activity. Each slide was incubated with normal goat serum for 20 min at room temperature, then rabbit anti-factor VIII related antigen antibody (Dako, MedBio Ltd, New Zealand) diluted at 1∶100 was applied on sections and incubated overnight at 4℃. After incubation with biotinylated goat anti-rabbit IgG (dilution 1:200) for 30 min at 37℃, each slide was rinsed in phosphate-buffered saline and was incubated in the avidin-biotin peroxidase complex for 30 min at 37℃. The peroxidase was visualized with 3-3'-diamino- benzidinetetrahydro chloride (DAB) solution and then counterstained with hematoxylin.

MVD evaluation

MVD was assessed according to the international

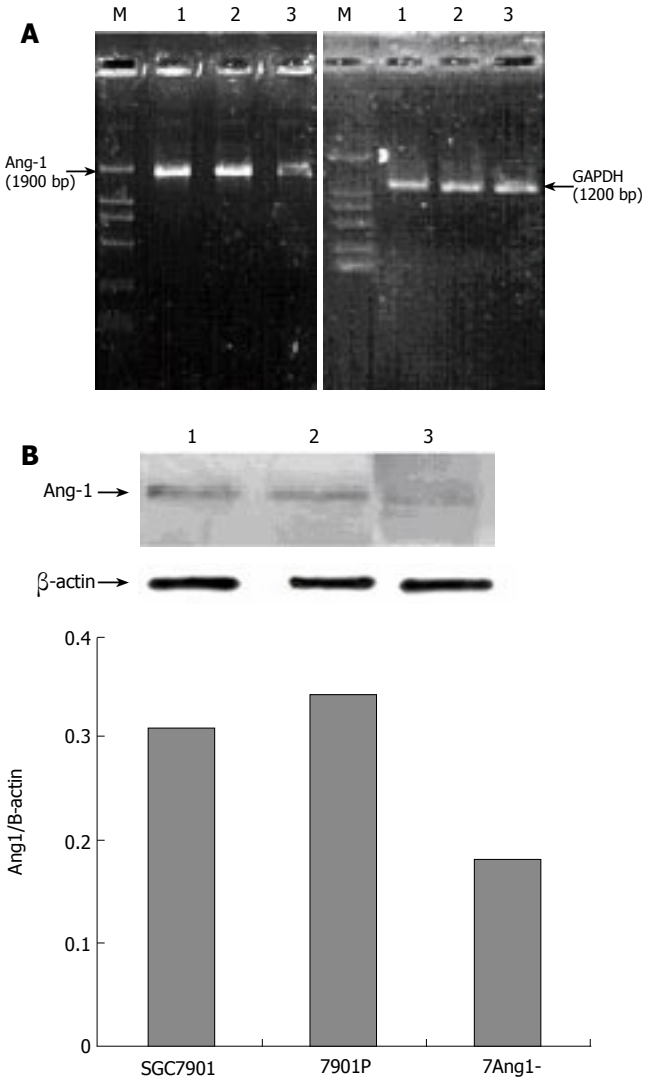

Figure 1 Verification of suppressive efficiency in parental and transfected cells. **A**: semi-quantitive RT-PCR. **B**: western blot. M: DL2000 marker; 1: SGC7901; 2: 7901P; 3: 7Ang1-.

consensus report[12]. Immuno stained slides were scanned at ×100 magnification to identify the areas with the highest number of vessels (so called "hot spot"). Counts were performed on five fields in the hot spot by two independent pathologists at ×200 magnification and the mean was taken and analyzed.

Statistical analysis

Statistical analysis was performed using SPSS software (version 10.0, SPSS Inc, Chicago). The ANOVA test was used to compare the differences between groups for MVD, tumor weight and volume. Differences were considered statistically significant at $P<0.05$.

RESULTS

Construction of Ang-1 antisense eukaryotic expression vector

Full length Ang-1 gene was amplified from placental tissues and cloned into pMD 18-T vector, then cut by by *Hind*Ⅲ and *BamH* Ⅰ digestion which would ensure inverse directional ligation into pcDNA3.1-V5-His C expression vector. The combined antisense expression vector named as pcDNA3.1-Ang1- was verified as expected by sequencing.

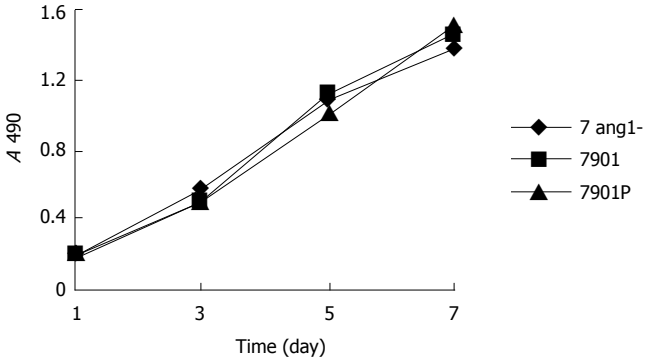

Figure 2 Proliferation of SGC7901-derived cells.

Transfectants of SGC7901-derived cells

Stable transfectants of 7901-derived cells were obtained by Lipofectamine 2000 transfection, named 7Ang1- for pcDNA3.1-Ang1- and 7901P for empty vector-transfected cells. We could clearly find that moderate targeted-inhibition effect was detected in 7Ang1- cells at both mRNA (Figure 1A) and protein (Figure 1B) levels, in contrast, control experiment with the empty vector alone showed a negligible effect on Ang-1 expression (Figure 1).

Proliferation and cell cycle of SGC7901-derived cells

To determine if interference of Ang-1 expression has an effect on the proliferation and cell cycle distribution of SGC7901 cells, MTT assay and FACS method were utilized, respectively. According to Figure 2, the proliferation of 7Ang1- cells was not significantly changed compared to that of 7901P cells. In addition, cell cycle distribution of Ang1- and 7901P were 71.9% and 59.2% for G_1 phase, 15.3% and 12.5% for G_2 phase, 25.5% and 15.6% for S phase, 0.328 and 0.281 for the proliferation index, respectively. Taken together, it suggests that interfering Ang-1 has no direct effect on *in vitro* proliferation and cell cycle of gastric cancer cells.

In vivo tumorigenicity of SGC7901-derived cells

Xenograft model was employed to compare the tumorigenicity of SGC7901 cells before and after Ang-1 inhibition. Subcutaneous tumor node of different groups became palpable almost simultaneously after 7d transplantation. Tumor from 7Ang1- cells appeared to grow slower than those from 7901P cells after 16 d (Figure 3). Finally, tumor grafts were collected and weighed after 30 d, and tumor tissues derived from 7Ang1- cells showed significantly decreased weight compared to those from 7901P cells with mean tumor graft weight (mg) being 293.0±95.5 for 7Ang1- and 624.0±77.8 for 7901P cells ($P<0.01$).

To further elucidate whether reduced angiogenesis account for the suppressed *in vivo* growth of 7Ang1- cells, MVD was assessed by immunohistochemistry. As shown in Figure 4, microvessels could easily be observed by factor

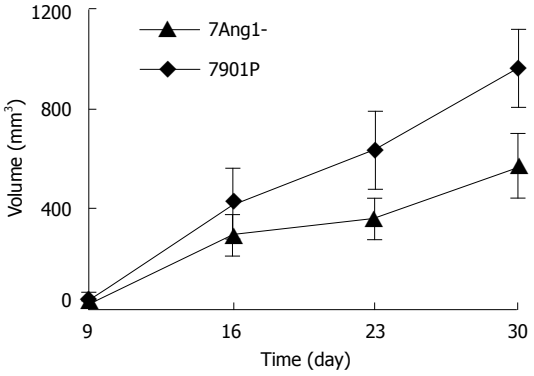

Figure 3 *In vivo* growth of tumor xenograft.

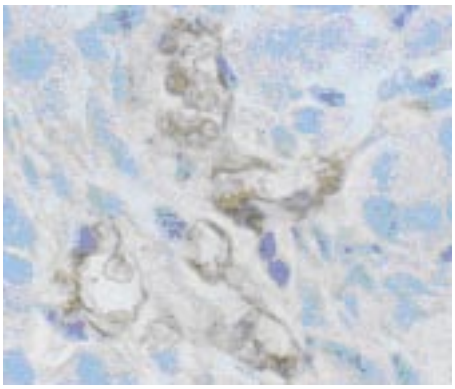

Figure 4 Factor VIII positive tumor microvessels (SABC x 200).

VIII staining. Statistics analysis showed a significantly less MVD was present in 7Ang1- group 6.0±1.7 compared to 8.4±1.3 in 7901P group ($P<0.05$). This result indicated that suppressed *in vivo* tumorigenicity of 7Ang1- cells might be mediated through reduced angiogenesis.

DISCUSSION

Gastric cancer remains a common malignancy in many countries of the world, especially in Asia, and is still among the most important causes of cancer-related death worldwide[13]. Its conventional treatment includes surgery, radiation and chemotherapy. Nowadays, increasing evidence has shown that angiogenesis is essential for the growth of solid tumor and tumor angiogenesis research has become one of the most active fields for anticancer therapies.

Several studies suggested that VEGF receptor pathway and Tie2 pathway are independent and essential mediators of angiogenesis and both play important roles in the tumor angiogenesis[14,15]. Tie2 is a novel endothelial cell-specific molecule involved in both physiological and pathological processes. Tie2 is required for normal vascular development perhaps via the regulation of vascular remodeling and endothelial cell interactions with supporting pericytes and smooth muscle cells[3]. Previous report found that inhibition of Tie2 using a kinase-deficient Tie2 construct or an adenoviral vector delivering a recombinant single-chain antibody fragment into body would inhibit the growth of human tumor xenografts[16,17].

Four ligands for the Tie2 receptor have been identified so far, named Ang-1 to -4. Among them, Ang-1 and -2 were mainly associated with tumor angiogenesis[18]. The findings from functional study of Ang-2 in several types of tumor showed that Ang-2 could stimulate tumor angiogenesis, thus promoting tumor progress[9,19,20], while those from Ang-1 showed great heterogeneity. For example, Zadeh *et al*[6] found that Ang-1 increased the vascular growth of both subcutaneous and intracranial xenografts of astrocytoma; also, Ang-1 promoted tumor angiogenesis and tumor vessel plasticity of human cervical cancer in mice[21]. In contrast, others have reported that Ang-1 could inhibit angiogenesis and growth of hepatic and colon cancer[22] and suppress breast cancer xenograft angiogenesis by blocking tumor neovasculature[7]. Taken together, it suggests that the role of Ang-1 in tumor progression may be context-dependent.

Our previous study found that Ang-1 was highly expressed in SGC7901 cells[23], while its expression in 7Ang1- cells was effectively reduced using antisense method in the present study. Further study revealed that the biological behaviors including proliferation and cell cycle of 7Ang1- cells were not significantly changed, so it seemed that interfering Ang-1 could not alter *in vitro* growth of SGC7901 cells directly; this is similar to other studies[9] in which growth of the gastric cancer cells was not affected by transfection with Ang-2.

Tumorigenicity assay showed that tumor xenograft of 7Ang1- group grew slower as their volume and weight were smaller than those from control group. MVD assessment showed significantly decreased angiogenesis in tumor from 7Ang1- group, indicating inadequate blood supply might account for suppressed *in vivo* growth. To our best knowledge, this is the first direct evidence for the role of Ang-1 in gastric cancer angiogenesis. However, in initial stage of tumor progression, two groups did not show significant difference, and until 16 d after transplantation the suppressive effect appeared dramatic when tumor grew larger. This result is consistent with our previous study in which suppressing the expression of VEGF in SGC7901 cells did not exert any significant effect on its proliferation but restricted its *in vivo* growth in nude mice[24]. Collectively, it infers that suppressing either VEGF or Ang-1 cannot prohibit the onset of tumor, but may slow *in vivo* growth of tumor cells by inhibiting angiogenesis. It was reported that Ang-2 was implicated in angiogenesis and progression of gastric carcinoma via induction of proteases such as MMP-1 and -9[9]. Combining result from our present and previous studies that significant expression of Ang-1 and Ang-2 was found in human gastric cancer tissues and cell lines[23], it infers that both Ang-1 and -2 participate in the angiogenesis and progression of gastric cancer. Previous studies indicated that Ang-1 induced the secretion of MMP-2 and small amounts of proMMP-3 and proMMP-9 in endothelial cells[25], whether or not this effect is involved in the mechanism of Ang-1 contribution to gastric cancer and progression is still unclear, however it still could be concluded from our present study that stimulating angiogenesis by Ang-1, in part at least, could promote tumor progress.

In summary, Ang-1 may contribute to the progression of gastric cancer and inhibiting its expression in gastric

cancer cells could suppress *in vivo* tumorigenicicy. It could also be a useful therapeutic target to prevent gastric cancer or inhibit its malignant progression. Tumor angiogenesis is a multi-factor associated process, and recent study showed that simultaneous phenotypic knockout of VEGF-R2 and Tie2 with an intradiabody could effectively reduce tumor growth and angiogenesis *in vivo*[26]. It suggests that combination of targeting main angiogenesis modulators including VEGF, Ang-1 and Ang-2 and their corresponding receptors can be beneficial for tumor therapeutics.

Abstract

AIM: To investigate the changes of lymphocyte subpopulations, especially $CD4^+CD25^+$ T regulatory cells in $Smad3^{-/-}$ mice.

METHODS: Hematological changes and changes of lymphocyte subpopulations were detected in $Smad3^{-/-}$ mice using cell counter and flow cytometry, respectively, and compared to their littermate controls.

RESULTS: The numbers of neutrophils and lymphocytes in peripheral blood were significantly increased in $Smad3^{-/-}$ mice compared to littermate controls. $CD19^+$ expressing cells in blood and spleen, and $CD8^+$ T cells in thymus were all markedly decreased in $Smad3^{-/-}$ mice. More important, $Smad3^{-/-}$ mice had an increased population of $CD4^+CD25^+$ T cells in peripheral lymphoid tissues, including thymus, spleen, and lymph nodes.

CONCLUSION: These observations suggest that the changes of lymphocyte subpopulations might play a role in susceptibility to inflammation of $Smad3^{-/-}$ mice.

Key words: $CD4^+CD25^+$ T cells; Lymphocyte subpopulation; SMAD3; TGF-β signaling

INTRODUCTION

TGF-β plays an important role in maintaining immune homeostasis. It signals through a set of transmembrane receptor serine/threonine kinases unique to the large superfamily of TGF-β related proteins [1]. As a downstream cytoplasm signaling element of TGF-β receptors, Smad3 mediates a positive signal pathway from the receptor serine/threonine kinases to the nuclei [2]. Previous reports revealed Smad3 plays an important role in mediating TGF-β signal in T lymphocytes and neutrophils, and demonstrated that Smad3 deficiency results in immune dysregulation and susceptibility to opportunistic infection [3].

The immune system discriminates between self and non-self, establishing and maintaining unresponsiveness to self. There is clear evidence that clonal deletion of self-reactive T and B cells is a major mechanism of self-tolerance [4]. However, the fact that potentially hazardous self-reactive lymphocytes are present in the periphery of normal adult individuals [5] reveals that the mechanisms that can prevent pathological autoimmunity exist. In recent years, a burst of papers are focused on a population of $CD4^+$ T cells that constitutively express the IL-2Rα (CD25) T cells and reveal them as key "actors" to self-tolerance[6,7]. A direct experiment to assess the regulatory role of $CD4^+CD25^+$ T cells in self-tolerance reported that the adoptive transfer of $CD4^+CD25^+$-depleted T cells could induce several organ-specific autoimmune diseases in immunodeficient animals [8]. $CD4^+CD25^+$ T cells also regulate antibody responses against self- and non-self-antigens by direct inhibitory effects on B cells or via inhibition of Th cell differentiation [9, 10]. In addition to self-tolerance and autoimmunity, there is evidence that $CD4^+CD25^+$ T cells are actively engaged in negative control of a broad spectrum of immune responses induced by microbial infection [11-13]. They can also mediate transplantation tolerance [14] and maternal tolerance to the foetus [15].

Although great progress in $CD4^+CD25^+$ T cells study has been made in recent years, many issues remain to be solved. For example, the involvement of TGF-β in $CD4^+CD25^+$ T cell immunoregulatory function is still controversial [16-19]. In the present study, we examined the changes of lymphocyte subpopulations in peripheral lymphoid tissues of $Smad3^{-/-}$ mice as well as their controls. Our results showed that $Smad3^{-/-}$ mice were associated with an increased population of $CD4^+CD25^+$ T cells, suggesting that $CD4^+CD25^+$ T cells might play a role in susceptibility to inflammation of $Smad3^{-/-}$ mice.

MATERIALS AND METHODS

Mice

$Smad3^{-/-}$ mice were generated by targeted gene disruption

in murine embryonic stem cells by homologous recombination [3]. Both Smad3$^{-/-}$ mice and their littermate controls (wild-type, Smad3$^{+/+}$) were provided by Xiao Yang (Institute of Biotechnology, Beijing, China). The mice used in these experiments were 6-8 wk of age.

Antibodies and reagents

PE-anti-CD4, FITC-anti-CD8, FITC-anti-CD3, and PE-anti-CD19 were purchased from Southern Biotechnology Associates (Birmingham, USA). FITC-anti-CD25 was purchased from Biolegend (San Diego, CA).

Analysis of leukocytes in peripheral blood

Before mice were sacrificed, approximately 20 μL blood samples were collected through tail vein, diluted, and then analyzed on Sysmex F-820 semi-automatic analyzer (Japan).

Flow cytometry of lymphocytes

Peripheral blood, thymus, spleen and lymph nodes were harvested from mice. Single-cell suspensions were subjected to hypotonic lysis of red blood cells (Becton Dickinson), washed in phosphate-buffered saline, stained with fluorescein-conjugated antibodies according to standard protocols, and then analyzed on an FACScan (Beckman Dickinson). For isolation of peripheral blood mononuclear cells (PBMC), 2 mL of heparinised peripheral blood diluted 1:1 with PBS was layered onto an equal volume of Ficoll-Hypaque density gradient solution and centrifuged at 300 r/min at room temperature. The mononuclear cells were collected, washed twice with PBS.

Statistical analysis

Difference was defined as being statistically significant when P <0.05 was obtained using Student's t test.

RESULTS

Increased numbers of neutrophils and lymphocytes in Smad3$^{-/-}$ mice

We first compared the total numbers of white blood cells and differential distributions of leukocytes in peripheral blood samples from Smad3$^{-/-}$ mice and littermate control mice. A marked increase in absolute white blood cell counts was observed in Smad3$^{-/-}$ mice (P < 0.01). Accordingly, the numbers of neutrophils and lymphocytes were also elevated in Smad3$^{-/-}$ mice compared to their controls (Figure 1). These results are consistent with a previous report that Smad3$^{-/-}$ mice exhibited invasive mucosal infection involving multiple immune organs [3].

Changes of lymphocyte subpopulations

Susceptibility of Smad3$^{-/-}$ mice to infection and tissue inflammation [3] made us wonder whether quantitative changes of lymphocytes were present in these mice. The results showed that numbers of CD19^{+}-expressing cells (most B cells) in the peripheral blood and spleen were significanty decreased in Smad3$^{-/-}$ mice compared to their controls (Figures 2A and 2C). In addition, the number of CD8^{+} T cells was also reduced in thymus in Smad3$^{-/-}$ mice (Figure 2B). Analysis of lymph nodes did not reveal any significant difference between the mutant mice and littermate controls (Figure 2D).

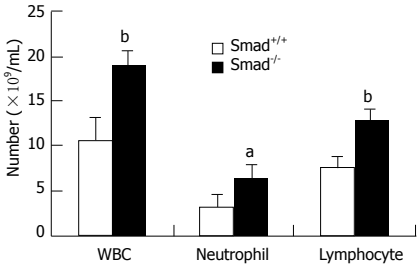

Figure 1 Total numbers and differential distributions of blood leukocytes in Smad3$^{+/+}$ and Smad3$^{-/-}$ mice. Peripheral blood samples were collected from tail veins of mice, and then analyzed on Sysmex F-820. Shown here are the means and standard deviations of total numbers and distributions of blood leukocytes from 4 wild-type and 4 mutant mice (^{a}P < 0.05, ^{b}P < 0.01).

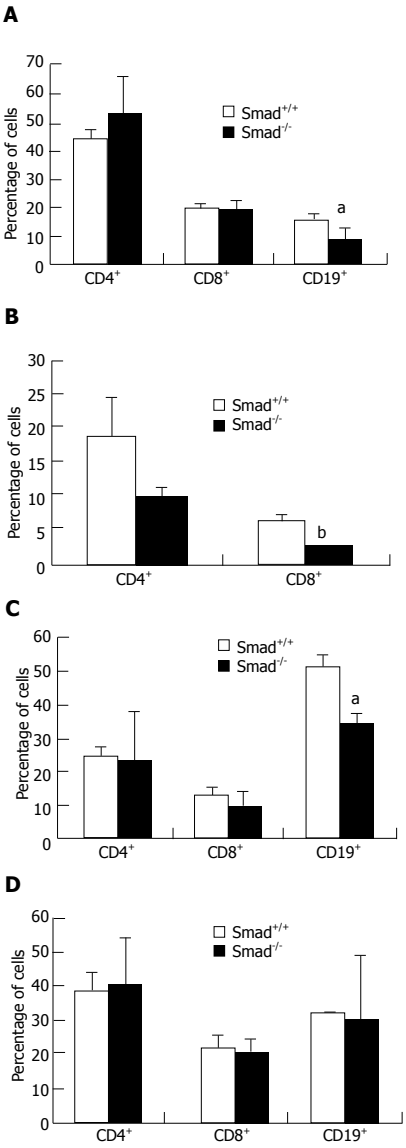

Figure 2 Percentage of lymphocyte subpopulations in peripheral blood (A), thymus (B), spleen (C) and lymph nodes (D) of wild-type and mutant mice. The cells were stained with PE-anti-CD4 and FITC-anti-CD8, or with FITC-anti-CD3 and PE-anti-CD19, and then subjected to cytometric analyses. Shown here are the means and standard deviations of percentage of lymphocyte subpopulations from 4 wild-type and 4 mutant mice (^{a}P < 0.05, ^{b}P < 0.01).

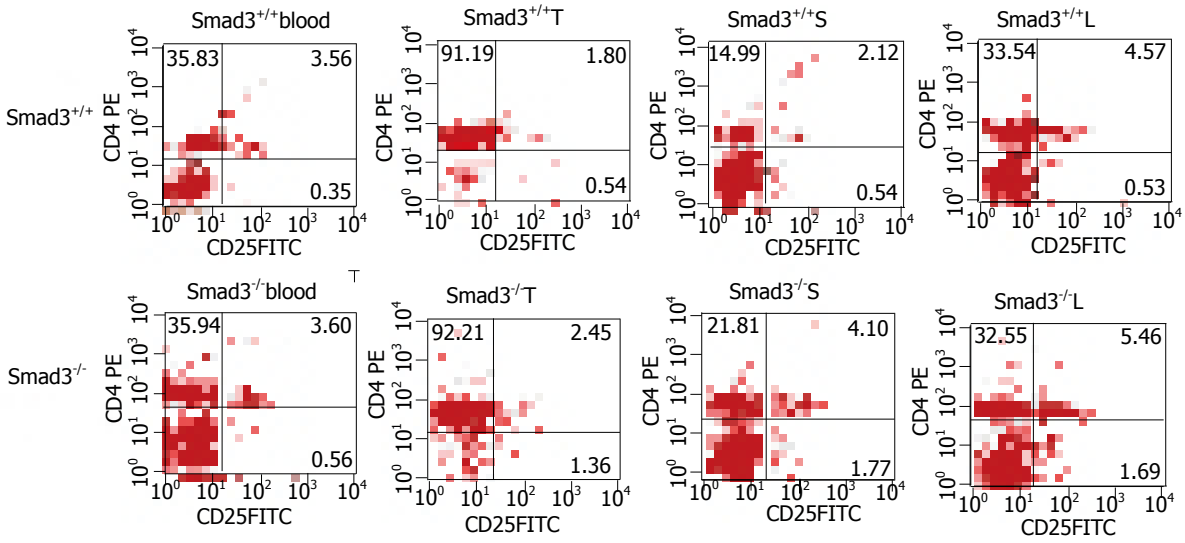

Figure 3 Percentage of CD4$^+$CD25$^+$ T cells in peripheral lymphoid tissues of Smad3$^{+/+}$ and Smad3$^{-/-}$ mice. PBMC (blood) or single-cell suspensions from thymus (T), spleen (S), and lymph nodes (L) were prepared according to "MATERIALS AND METHODS", co-labeled with PE-anti-CD4 and FITC-anti-CD25, and then analyzed by FACScan.

Increased CD4$^+$CD25$^+$ T cells in Smad3$^{-/-}$ mice

CD4$^+$CD25$^+$ T cells play an important role in maintaining the equilibrium between immunity and tolerance[20,21]. Many papers have reported that this population of cells is able to suppress proliferation and effector function of CD4$^+$ and CD8$^+$ T cells [22-24]. To explore whether the decreased lymphocytes in Smad3$^{-/-}$ mice were related to the CD4$^+$CD25$^+$ T cells, we examined this population of cells in peripheral lymphoid tissues of Smad3$^{-/-}$ mice and littermate controls. Smad3$^{-/-}$ mice exhibited a greater percentage of CD4$^+$CD25$^+$ T cells in thymus, spleen and lymph nodes, compared to controls. In peripheral blood, however, no difference was observed between mutant mice and wild type in regarding to CD4$^+$CD25$^+$ T cell proportion (Figure 3).

DISCUSSION

TGF-β is an essential endogenous regulator of T-cell function [25]. It has been recently reported that TGF-β$^{-/-}$ mice have normal numbers of CD4$^+$CD25$^+$ T cells after birth, indicating that CD4$^+$CD25$^+$ T cells are able to develop in complete absence of endogenous TGF-β expression [16, 17]. This made us think whether quantitative or functional changes of CD4$^+$CD25$^+$ T cells occurred in Smad3$^{-/-}$ mice. Our main finding in this study is that Smad3$^{-/-}$ mice had increased CD4$^+$CD25$^+$ T cells compared to their littermate controls (Figure 3). Our results showed that neutrophil and lymphocyte numbers increased (Figure 1) and that lymphocyte subpopulation decreased in the peripheral lymphoid tissues of Smad3$^{-/-}$ mice (Figure 2), which are consistent with the previous reports [3,26].

During infection, the balance between self-reactive effector T cells and regulatory T cells could determine the time of onset, the intensity and duration of autoimmune response [27]. Recent studies have focused on a population of CD4$^+$ T cells that constitutively express CD25. CD4$^+$CD25$^+$ T cells comprise 5%-10% of the peripheral CD4$^+$ T cell pool of normal mice and humans and exhibit immunosuppressive abilities both *in vitro* and *in vivo* [28, 29]. Studies of human diseases indicate that the functional CD4$^+$CD25$^+$ T cells are enriched in inflamed joints of patients with rheumatoid arthritis [30] or with the juvenile idiopathic arthritis [31]. In our study, we showed that an increased population of CD4$^+$CD25$^+$ T cells was present in Smad3$^{-/-}$ mice, which could partially account for the susceptibility to inflammation of these mutant mice. However, our results and those of a previous study [3] did not reveal any significant difference of CD4$^+$ T cells of spleen and lymph nodes between the asymptomatic mice and littermate controls. A possible explanation for the increase of CD4$^+$CD25$^+$ T cells is that they are derived from the CD4$^+$CD25$^-$ cells under the condition of Smad3 gene mutation. It is well accepted that CD4$^+$CD25$^+$ T cells can be generated by the activation of mature, peripheral CD4$^+$CD25$^-$ T cells under different stimulatory conditions [28]. Further studies should concentrate on defining the functional characteristics of the CD4$^+$CD25$^+$ T cells in Smad3$^{-/-}$ mice to gain a better insight into the mechanisms of susceptibility to inflammation.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Xiao Yang for providing Smad-3 wild-type and mutant mice. In addition, the authors thank Drs. Qi-Hong Sun, Jian-Ping Mao and Jian-En Gao for their many helpful comments and suggestions on these experiments.

Abstract

AIM: To evaluate the feasibility, safety, and tolerance of early removing gastrointestinal decompression and early oral feeding in the patients undergoing surgery for colorectal carcinoma.

METHODS: Three hundred and sixteen patients submitted to operations associated with colorectostomy from January 2004 to September 2005 were randomized to two groups: In experimental group ($n = 161$), the nasogastric tube was removed after the operation from 12 to 24 h and was promised immediately oral feeding; In control group ($n = 155$), the nasogastric tube was maintained until the passage of flatus per rectum. Variables assessed included the time to first passage of flatus, the time to first passage of stool, the time elapsed postoperative stay, and postoperative complications such as anastomotic leakage, acute dilation of stomach, wound infection and dehiscense, fever, pulmonary infection and pharyngolaryngitis.

RESULTS: The median and average days to the first passage of flatus (3.0 ± 0.9 *vs* 3.6 ± 1.2, $P < 0.001$), the first passage of stool (4.1 ± 1.1 *vs* 4.8 ± 1.4 $P < 0.001$) and the length of postoperative stay (8.4 ± 3.4 *vs* 9.6 ± 5.0, $P < 0.05$) were shorter in the experimental group than in the control group. The postoperative complications such as anastomotic leakage (1.24% *vs* 2.58%), acute dilation of stomach (1.86% *vs* 0.06%) and wound complications (2.48% *vs* 1.94%) were similar in the groups, but fever (3.73% *vs* 9.68%, $P < 0.05$), pulmonary infection (0.62% *vs* 4.52%, $P < 0.05$) and pharyngolaryngitis (3.11% *vs* 23.23%, $P < 0.001$) were much more in the control group than in the experimental group.

CONCLUSION: The present study shows that application of gastrointestinal decompression after colorectostomy can not effectively reduce postoperative complications. On the contrary, it may increase the incidence rate of fever, pharyngolaryngitis and pulmonary infection. These strategies of early removing gastrointestinal decompression and early oral feeding in the patients undergoing colorectostomy are feasible and safe and associated with reduced postoperative discomfort and can accelerate the return of bowel function and improve rehabilitation.

INTRODUCTION

At present, gastrointestinal decompression after abdominal operations is still widely practiced in clinic. Routine use of nasogastric tubes after excision and anastomosis of digestive tract is aimed to hasten the return of bowel function, prevent pulmonary complications, diminish the risk of anastomotic leakage, and increase patients' comfort and shorten hospital stay. But nasal insertion of a gastric tube for prolonged gastrointestinal decompression causes extreme discomfort, and can be easily dislodged. Several complications of nasogastric intubation have been described, including sinusitis, injury to the vocal cords, and iatrogenic gastric perforation, nasal trauma, nasal hemorrhage, laryngeal injury, esophageal ulceration, gastroesophageal reflux, fluid and electrolyte imbalances, aspiration pneumonia, feeding dysfunction, and psychological problems[1-4]. Indeed, a unique randomized study by Hoffman *et al* reaffirms that patients find nasogastric tube more inconvenient and uncomfortable than gastrostomy tubes, even though gastrostomy tubes are left *in situ* for up to 4 wk[2]. Some researches have shown that the postoperative nasogastric tube could increase postoperative complications and furthermore, affect the

nutrient intake. Recent evidence seems to indicate that immediate postoperative feeding is feasible and safe after either laparoscopic surgery or laparotomy, including gastrointestinal tract surgery[5,6].

In the light of these evidence, we conducted a randomized study to evaluate the feasibility, and safety as well as the tolerance of early removing gastrointestinal decompression and early oral feeding in the patients undergoing colorectostomy for colorectal tumor in West China Hospital of Sichuan University from January 2004 to September 2005. It is hoped that this study will help to clarify strategies to accelerate postoperative recovery and to reduce patients' complications.

MATERIALS AND METHODS

Cases selection

Between January 2004 and September 2005, three hundred and sixteen consecutive patients receiving excision and anastomosis for colorectal tumor were entered the study. All patients were randomly chosen to undergo early and or late nasogastric tube removal. Nasogastric tubes were routinely placed following anesthetic induction. Patients were divided into two groups. In the experimental group, nasogastric tubes were removed within 12-24 h after the operation. The patients were provided immediately water and gradually to a liquid fiberless diet after one day, and a semi-liquid fiber diet after three days. In the control group, nasogastric tubes were removed upon report of passage of flatus by the patient, usually within three-five days after surgery.

Methods

A nasogastric tube was placed in all patients during operation. The tube was removed in control group with gastrointestinal decompression after passage of gas by intestines with continuous vacuum aspiration. The nasogastric tubes in the experimental group without gastrointestinal decompression were removed from 12 to 24 h after operation. Then, the patients were monitored prospectively, for time to first passage of flatus, time to first passage of stool, postoperative stay, and complications. Febrile morbidity was defined as two armpit temperatures greater than 38.5℃, taken at least 4 h apart, starting 24 h after operation. For the control group patients, we also recorded the time to removal of the nasogastric tube and the postoperative complications. Postoperative stay was calculated from the first postoperative day to the day of hospital discharge. Criteria for hospital discharge included: absence of nausea, vomiting, and abdominal distention; ability to tolerate oral feeding; spontaneous micturition; adequate healing, and absence of fever. Those suffering from anastomotic leaks were subjected to treatments such as anti-infective treatment, nutritional support or colostomy. Correspondingly, acute dilatation of stomach was subjected to placement of nasogastric tubes.

Statistical analysis

The χ^2 test was used for analysis of qualitative variables and Student's *t* test for continuous variables. Results of the two groups were compared using Student's *t* test. $P<0.05$ indicated significant difference. Analyses were performed using SPSS statistical software (SPSS for Windows Ver.11.5).

Table 1 Patient characteristics

General data	Experimental group (n = 161)	Control group (n = 155)
Gender(M/F)	92/69	83/72
Mean age (yr)	55.3±16.7	57.1±19.8
Range	21-78	24-85
Type of tumor		
Colon cancer	29	28
Rectal cancer	132	127
Type of operation		
Right hemicolectomy	17	15
Left hemicolectomy	12	13
Anterior rectal resection	132	127

RESULTS

General data

It was shown that there were no significant differences between two groups in terms of sex ($P>0.05$), and age ($P>0.05$) (Table 1). No significant difference was found between two groups in case distributions ($P=1.000$).

The time to first passage of flatus, stool and the length of postoperative stay and the incidence of complications after operation are shown in Table 2. The time to first passage of flatus was seen, on average, on postoperative day 3.0 in the early removing gastrointestinal decompression and early oral feeding group and on day 3.6 in the control group ($P<0.001$). The first defecation was 0.7 d sooner in the experimental group (postoperative day 4.1) than in the control group (4.8 d; $P<0.001$). The postoperative hospital stays for the experimental and control groups were 8.4±3.4 d and 9.6±5.0 d, respectively. The postoperative complications for the experimental group and control group were seen in 23 cases and 70 cases, respectively. Compared with the control group, the total incidence of complications in the experimental group was evidently higher ($P<0.001$). But the anastomotic leakage (1.24% *vs* 2.58%), acute dilation of stomach (1.86% *vs* 0.06%) and wound complications (2.48% *vs* 1.94%) were similar in the two groups. Symptoms as fever and leakage of intestinal contents were diagnosed as anastomotic leakage. Six cases suffered from the lesion in the two groups. All the leakages occurred during excision and anastomosis of lower or ultra-lower rectal tumor and healed after clinical therapy. Those who suffered from abdominal distension, emesis and succussion splash of stomach were diagnosed as acute dilatation of stomach and then subjected to gastrointestinal decompression. Two cases suffered from the wound infection and 2 cases suffered from the wound dehiscense in the experimental groups, and 3 cases suffered from wound infection but no wound dehiscense in the control group. The fever (3.73% *vs* 9.68%, $P<0.05$), pulmonary infection (0.62% *vs* 4.52%, $P<0.05$) and pharyngolaryngitis (3.11% *vs* 23.23%, $P<0.001$) were much more in the control group

Table 2 Clinical features and complications of experimental and control groups

Parameters	Experimental group	Control group (n = 161)	P value (n = 155)
Time to first passage of flatus (d)	3.0±0.9	3.6±1.2[b]	0.000
Time to first passage of stool (d)	4.1±1.1	4.8±1.4[b]	0.000
Postoperative stay (d)	8.4±3.4	9.6±5.0[a]	0.016
Total complication			
Anastomotic leakage (n%)	2(1.24)	4(2.58)	0.441
Acute dilation of stomach (n%)	3(1.86)	1(0.06)	0.623
Wound complication (n%)	4(2.48)	3(1.94)	1.000
Fever (n%)	6(3.73)	15(9.68)[a]	0.042
Pulmonary infection (n%)	1(0.62)	7(4.52)[a]	0.034
Pharyngolaryngitis (n%)	5(3.11)	36(23.2)[b]	0.000

[a]P < 0.05 *vs* experimental group; [b]P < 0.001 *vs* experimental group.

than in the experimental group. Eight cases of pulmonary infection were found in the two groups by chest X-ray and cured with anti-inflammatory therapy. Any symptom associated with throat discomfort or pain was diagnosed as pharyngolaryngitis; 23.23% of patients suffered from pharyngolaryngitis in the control group and only 3.11% in the experimental group.

DISCUSSION

There are several traditional dicta that are transmitted from generation to generation of surgeons but lack any clear scientific foundation. These include performing gastric decompression after abdominal surgery and delaying oral feeding until the resolution of ileus, as commonly observed in daily surgical practice. In China at present, 97.5% of surgeons routinely place and keep the nasogastric tube until the passage of gas through anus after excision and anastomosis of lower digestive tract, while 2.5% of surgeons discard gastrointestinal decompression 2-3 d after operation before the passage of gas through anus[7]. Indeed, the nasogastric tube can cause moderate to severe discomfort in 88%, severe discomfort in 70% of the patients and significantly delay the return of normal gastrointestinal function[8,9].

Recently, a meta-analysis shows that routine nasogastric decompression does not accomplish any of its intended goals. The analysis included 28 studies fulfilling the eligibility criteria and 4194 patients. It was found that those not having a nasogastric tube routinely inserted experienced an earlier return of bowel function, a marginal decrease in pulmonary complications, and a marginal increase in wound infection and ventral hernia. Anastomotic leakage was similar in the two groups. For this reason, the authors suggest that the routine nasogastric decompression should be abandoned in favor of selective use of the nasogastric tube[10].

We believe that the omission of routine postoperative gastrointestinal decompression may be an important first step in improving the rate of gastrointestinal recovery and shortening hospital stay. Anastomotic disruption after surgical intervention is an infrequent complication, and may lead to severe morbidity and mortality when it occurs. Of the various gastric procedures, the Roux-en-Y gastric bypass (RYGB) has one of the highest risks for anastomotic leakage. Consequently, a nasogastric tube is frequently placed when these operations are performed. But in Italy, a prospective multicenter randomized trial showed that routine placement of a nasogastric tube after Roux-en-Y oesophagojejunostomy is unnecessary in elective total gastrectomy for gastric cancer[11]. Huerta *et al* also suggest that routine placement of a nasogastric tube after RYGB is unnecessary; on the contrary, elimination of postoperative nasogastric decompression decreased postoperative fever and pulmonary problems, and improved patient comfort by decreasing sore throat and nausea[6,12]. In colorectal surgery, the average volume of gastric juice in the group with gastrointestinal decompression was 200 mL daily after operation. Because the total volume of digestive juice is 6000-10000 mL, the gastrointestinal decompression following excision and anastomosis of lower digestive tract can not reduce the pressure of gastrointestinal tract and has no obvious preventing effects on postoperative complications[7,13].

Compared with the control group, the removal of routine gastrointestinal decompression did not increase the postoperative probability of anastomotic leakage (P = 0.441), acute dilation of stomach (P = 0.623) and wound complication (P = 1.000). The data from the present study not only confirmed that placement of a nasogastric tube can be safely omitted in colorectostomy but also demonstrated that routine gastrointestinal decompression may increase the postoperative complications, such as the fever, pulmonary infection, pharyngolaryngitis.

Surgery is a traumatic procedure. The metabolic response of the body is a physiological mechanism that, according to the magnitude and duration of the event, can impact on the patient's morbidity and survival. Early enteral feeding can help to improve energy and protein intake, decrease the negative impact of the metabolic response to injury, stimulate motor, resorption, synthetic, and barrier functions of the small intestine, improve the return of gastrointestinal function and reduce the duration of postoperative ileus, and reduce the risk of serious complications[5,14,15]. Traditionally, tolerance of oral feeding is based on the passage of flatus. However, an in-depth review of the physiology of postoperative ileus suggested that such an approach is excessively conservative. It has been shown that paralysis of the small bowel is transient; the gastric paralysis lasts 24 h, and paralysis of the colon lasts 48–72 h[16]. The gastrointestinal tract motility of the patients undergoing major abdominal surgery is transiently impaired, leading to the so-called postoperative ileus (POI). It not only causes patient discomfort, but is also related to abdominal complications and worsening of the nutritional status, as well as increases length of hospital stay and costs[15].

POI is characterized by a transient impairment of bowel function and reduced motility sufficient to disrupt effective transit of intestinal contents[17-19]. It is a transient bowel dysmotility that occurs following abdominal surgery. Multiple factors are thought to contribute to the pathogenesis of POI, including physical manipulation

of the bowel, surgical stress and inflammatory mediators (including endogenous opioids), changes in electrolyte and fluid balance, neural reflex and inflammatory changes, pharmacologic agents such as inhalation anesthetics, and use of opioids for postoperative analgesia[20-22]. In animal experiments, it shows that the pathogenesis of postoperative gastric ileus induced by intestinal manipulation involves viscero-sympathetic pathways. Intestinal manipulation causes impaired gastric motility via inhibitory sympathetic efferent pathway. Feeding may improve the postoperative gastric motility[22]. Chan *et al*[23] suggest that metoclopramide not only prevents prolonged POI at an early postoperative stage, but also can be used as a safe prokinetic drug for post-operative intestinal dysmotility.

Oral intake after intestinal anastomoses has traditionally been prescribed only after the resolution of ileus. de Aguilar-Nascimento JE *et al*[24] suggest the return of oral feeding on the first postoperative day in patients submitted to intestinal anastomoses is safe, not associated with the occurrence of anastomotic dehiscence and moreover, related to a quicker resolution of ileus. A clinical trial showed that gastrografin not only facilitates early oral feeding but also reduces hospitalization after elective colorectal surgery. It can decrease bowel-wall edema and enhance bowel peristalsis[25]. Even, gum-chewing might be beneficial for short hospital stay because it can stimulate bowel motility and should be added as an adjunct treatment in postoperative care[26]. In our study, the time to first passage of flatus ($P < 0.001$), the time to first passage of stool ($P < 0.001$) and the time of postoperative stay ($P < 0.05$) were sooner in the experimental group than in the control group. Our study showed that early oral feeding can be administered safely to patients undergoing major laparotomy for colorectal carcinoma. At the same time, oral feeding can improve the return of gastrointestinal function and shorten hospital stay.

The goal of this study was to determine whether a clinical approach including early removing gastrointestinal decompression and early oral feeding is safe and shows the potential to decrease the length of postoperative stay and reduce complications after colorectostomy. Our data provide preliminary evidence that routine gastrointestinal decompression cannot reduce the pressure of gastrointestinal tract and has no obvious preventing effects upon postoperative complications. Contrary to expectations, routine gastrointestinal decompression may increase the incidence rate of fever, pulmonary infection and pharyngolaryngitis. These strategies of early removing gastrointestinal decompression and early oral feeding in the patients after colorectostomy are feasible and highly safe and are associated with reduced postoperative discomfort and can accelerate the return of bowel function and shorten postoperative stay.

Abstract

Although foreign body ingestion is relatively common, toothbrush swallowing is rare. We report a case of a swallowed toothbrush which passed through the ileocecal valve and perforated the proximal transverse colon, then the liver. To our knowledge, this is the first case to be reported.

INTRODUCTION

Toothbrush ingestion is uncommon, but requires prompt medical attention. Although 80% of ingested foreign bodies pass spontaneously [1], there are no reports regarding swallowed toothbrushes passing through the pylorus [2]. Here we present an unusual case of a toothbrush swallowing which passed through the ileocecal valve and perforated the proximal transverse colon, then penetrated the liver. To our knowledge, this is the first case to be reported.

CASE REPORT

A 31 year-old man was admitted to the Surgical Department via the Emergency Room with one week history of right upper abdominal pain. He was diagnosed with schizophrenia 13 years earlier and treated at a local hospital. A physical examination revealed tenderness in the right upper quadrant and a temperature of 37 ℃. Laboratory tests showed a white blood cell count in the upper normal range, a slightly elevated C-reactive protein level (23 mg/L) and elevated aspartate aminotransferase/alanine aminotransferase levels (51/99 IU/L).

A plain abdominal radiograph showed a characteristic radiographic image of a toothbrush with parallel rows of short metallic radiodensities in the right upper quadrant (Figure 1). At that time, the patient stated he swallowed a toothbrush 1 year earlier. An abdominal computed tomography scan revealed a metallic density in the ascending colon (Figure 2A) and a low density lesion penetrating the lateral section of the liver (Figure 2B). The presumptive diagnosis was colohepatic penetration by a swallowed toothbrush and a laparotomy was performed. No abnormal ascites fluid was observed. Dense adhesions between the proximal transverse colon and the lateral section of the liver were found. When the proximal transverse colon was mobilized, the shaft of a toothbrush was observed penetrating the colon and liver (Figure 3). The toothbrush was removed and the perforated colonic opening was repaired. The extracted toothbrush was 20 cm long (Figure 4). The patient had an uneventful hospital course and was discharged eleven days after surgery.

DISCUSSION

Ingestion of a foreign body is commonly encountered in the clinic among children, adults with intellectual impairment, psychiatric illness or alcoholism, and dental prosthetic-wearing elderly subjects [1, 3]. However, toothbrush swallowing is rare, with only approximately 40 reported cases [2]. It was reported that a toothbrush shows a characteristic radiographic image with parallel rows of short metallic radiodensities due to the metallic plates that hold the bristles in place [4]. Unlike most other foreign bodies, there are no reports of swallowed toothbrushes passing spontaneously [2]. Thus, prompt intervention is required in order to avoid complications such as pressure necrosis causing gastritis, ulceration and perforation [5]. An initial extraction strategy to consider is endoscopy by a skilled technician, and the first successful performance of this procedure has been reported by Ertan *et al* [6]. If endoscopic removal is not possible and particular complications are not present, a laparoscopic approach may be an alternative to laparotomy [7].

To our knowledge, this is the first report of a swal-

Figure 4 Extracted 20 cm toothbrush.

lowed toothbrush passing through the ileocecal valve and penetrating the colon and liver. Similar to the present case, there are reports of toothpicks penetrating the pyloroduodenal region and migrating to the liver [8]. A Medline search indicates that other similar reports involving toothbrushes are found only in the esophagus and stomach. In the present case, it is highly remarkable that a 20 cm toothbrush could pass through the pylorus and duodenal loop.

Abstract

Prompt treatment in tumor-associated encephalopathy may prolong survival. We describe a 69-year-old male patient who was presented with fulminant hepatic failure, secondary to small-cell lung carcinoma with rapidly progressing encephalopathy. Both symptoms remitted following chemotherapy, suggesting swift diagnosis and administration of chemotherapy to be effective in treatment of fulminant hepatic failure and encephalopathy.

INTRODUCTION

Fulminant hepatic failure (FHF) is defined as a liver failure with encephalopathy, developing within eight weeks from the onset symptoms in the absence of pre-existing liver disease. The most common causes of FHF are viral or drug-induced hepatitis[1]. Small-cell lung cancer (SCLC) manifesting as acute hepatic failure resulting from diffuse parenchymal infiltration by metastatic tumor is rare. The prognosis is poor, with death usually occurring within several days[1]. We describe herein a patient with SCLC and FHF that improved after chemotherapy.

CASE REPORT

A 69-year-old male was admitted to our hospital because of a 2-wk history of nausea, anorexia, fatigue, jaundice, and pain in the right upper quadrant of the abdomen. He had no history of blood transfusion, hepatitis, intravenous drug use, or alcohol abuse, though had an average of 2 packs of cigarettes a day for 50 years. Physical examination revealed hepatomegaly and bilateral pretibial edema, but he was alert. Laboratory analyses revealed 1760 U/L alkaline phosphatase, 6695 U/L lactate dehydrogenase (LDH), 470 U/L aspartate aminotransferase (AST), 7.6 mg/dL bilirubin, 85 μg/dL ammonia, prothrombin time level of 63%, and 680 ng/mL neuron specific enolase (NSE) levels. A computed tomography (CT) of the abdomen showed multiple lesions and massive infiltration throughout the liver parenchyma (Figure 1A). A chest roentgenogram and CT scan showed a right hilar mass with pleural effusion (Figure 1B). Bronchoscopy with transbronchial lung biopsy revealed small-cell carcinoma of the lung (Figure 2). On the seventh day of hospitalization, chemotherapy was initiated with carboplatin (area under the curve 4) administered on d 1, and 80 mg/m^2 etoposide from d 1 to 3, with cycles repeated every 3 wk.

After two cycles of chemotherapy, the patient felt symptomatically better, and a CT of the chest and abdomen revealed a marked reduction of tumor size in the primary site and liver metastasis. The laboratory analyses revealed an improvement of hepatic failure. During the 2 months of initial chemotherapy, the patient's condition deteriorated due to progression of hepatic failure (total bilirubin level, 19.5 mg/dL; LDH, 4 699 U/L; AST, 424 U/L; ammonia, 145 μg/dL; glucose, 129 mg/dL; prothrombin time, 38%), the development of ascites, and stage II encephalopathy. A CT scan of the brain revealed no evidence of cerebral metastatic disease. However, the radiological examination revealed the recurrence of SCLC. Therefore, the patient was treated with 35 mg/m^2 amrubicin from d 1 to 3, with cycles repeated every 3 wk. Though grade 4 neutropenia (NCI-CTC ver 2.0) occurred after two cycles of chemotherapy, the patient had a marked improvement of encephalopathy (stage 0), general condition, and laboratory values (LDH, 180 U/L; AST, 45 U/L; ammonia, 42 μg/dL; prothrombin time 89%; and NSE, 9.6 ng/mL). Follow-up CT imaging documented a good partial response of the liver metastases, and a complete disappearance of the right hilar mass. Then,

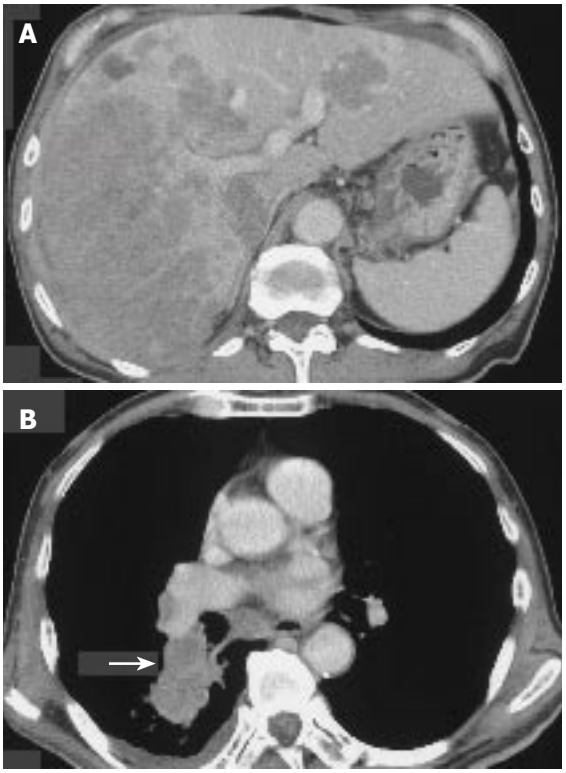

Figure 1 Computed tomography of the patient. **A**: CT of the abdomen showing multiple lesions and massively infiltrative process throughout the liver parenchyma; **B**: CT of the chest showing a right hilar mass (arrow) with pleural effusion.

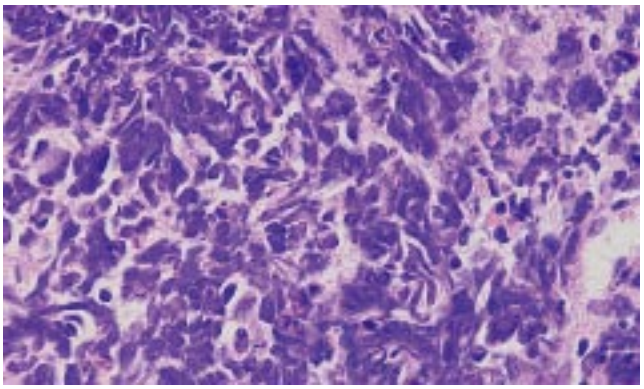

Figure 2 Histological examination of transbronchial lung biopsy specimen showing extensive infiltration small-cell carcinoma.

he was discharged from our hospital. However, the patient died of bacterial pneumonia at six months after presentation. A post-mortem was not done because of refusal of his family.

DISCUSSION

FHF secondary to metastatic SCLC is rare and results in death within days to weeks[1-3]. In literature, there are 21 previously reported cases of acute hepatic failure resulting from metastatic SCLC (Table 1). Two of the 21 reported patients presented an apparent dramatic response of severe tumor-related lactic acidosis to the initiation of chemotherapy (cyclophosphamide, doxorubicin, and vincristine)[3,4]. In most of the reported patients, however, the administration of appropriate chemotherapy was not performed, and no diagnosis was made before death. The rapid deterioration of the patient's condition may account for the difficulty of an accurate diagnosis[1]. The seven patients of acute hepatic failure with encephalopathy, even if metastatic SCLC was diagnosed before death, all died without the administration of chemotherapy because of a rapidly deteriorating course[1,5-8].

Table 1 Summary of 21 previously reported cases of acute hepatic failure due to metastatic small-cell carcinoma

[1]NR: not reported.

This case presents an apparent dramatic response of tumor-related encephalopathy to the administration of chemotherapy. There was no evidence for other, more usual causes of encephalopathy. Although the combination of carboplatin and etoposide as first-line chemotherapy was effective to acute hepatic failure, it failed to exert any effect against rapid encephalopathy. However, the encephalopathy improved dramatically after the administration of amrubicin as second-line chemotherapy.

Amrubicin (SM-5887) is a totally synthetic anthracycline and a potent topoisomerase II inhibitor[9], and is one of the most active agents for SCLC. In a phase II study of amrubicin using a schedule of 45 mg/m^2 on d 1-3 every 3 wk in 33 previously untreated extensive-stage SCLC patients, an overall response rate of 76% and median survival of 11.7 mo have been observed[10]. In this case, amrubicin, as second-line chemotherapy, was effective for the improvement of encephalopathy and liver metastases. However, the efficacy of amrubicin as a salvage chemotherapy remains unknown.

Extremely high serum LDH level represents diffuse replacement of the liver parenchyma and is associated with a higher risk of developing FHF[2]. Several reports have shown correlation between serum LDH levels with survival in SCLC patients with liver metastases, and suggested an accurate relationship between elevated LDH

levels and hepatic dysfunction[1,2,7]. These findings are in agreement with the LDH levels in our patient, who was observed with elevated LDH serum levels prior to chemotherapy, then regressing to normal LDH levels after the improvement of liver metastasis.

In the reports of malignant diseases manifesting as acute hepatic failure complicated by encephalopathy, a non-Hodgkin's lymphoma patient responded to chemotherapy and survived FHF[11]. Once FHF develops secondary to diffuse liver metastases in cancer patients, prognosis is dismal and there is no effective treatment with the exception of chemotherapy. Our case, with supporting evidence from non-Hodgkin's Lymphoma[11] and 2 cases of lactic acidosis[3,4], suggests that early diagnosis and a prompt administration of appropriate chemotherapy may result in the improvement of acute hepatic failure, and thereby improving survival.

Hence, we suggest that in addition to the efficacy of amrubicin as second-line chemotherapy, early diagnosis and prompt initiation of chemotherapy may result in the improvement of FHF, and thereby improving survival.

Abstract

Diaphragmatic hernia complicating pregnancy is rare and results in a high mortality rate, particularly if early surgical intervention is not undertaken. We report a case in which a woman presenting at 23 wk's gestation was admitted with symptoms of respiratory failure and bowel obstruction due to incarceration of viscera through a left posterolateral defect of the diaphragm (Bochdalek's hernia). Surgery (left thoracoabdominal incision) demonstrated compression atelectasis, mediastinal shift, strangulation and gangrene of the herniated viscera which led to segmental resection of the involved portion of large intestine with re-establishment of bowel continuity by end to end anastomosis. The greater omentum was partly necrotic necessitating resection. The diaphragmatic defect was closed with interrupted sutures. Postoperative period was uncomplicated. Pregnancy was allowed to continue until 39 wk's gestation at which time elective cesarean delivery was performed. It is concluded that symptomatic maternal diaphragmatic hernia during pregnancy is a surgical emergency and requires a high index of suspicion.

Key words: Pregnancy; Diaphragmatic hernia; Incarceration

INTRODUCTION

Diaphragmatic hernia complicating pregnancy is rare and is associated with a poor or complicated outcome, particularly if early surgical intervention is not undertaken[1]. Such hernias usually involve the left diaphragm through a congenital defect or a previous traumatic rupture. The main life-threatening complications described, include respiratory distress, visceral obstruction, strangulation and gangrene of the herniated viscera, visceral perforation (spontaneous or thoracentesis-induced) and maternal death[2-5].

A case of a patient with left-sided congenital diaphragmatic hernia during pregnancy is described in this report.

CASE REPORT

A 31-year-old woman in her first pregnancy (23 wk's gestation) was admitted to our hospital with a 10-day history of dyspnoea, nausea, persistent vomiting and intermittent sharp epigastric and substernal pain leading to a 3 kg weight loss. On physical examination the patient was afebrile, hypotensive with tachycardia (125 beats/min) and dyspnoea (32 breaths/min). There was distention of the neck veins fullness of the supraclavicular fossa. Chest auscultation demonstrated absence of breath sounds in the left hemithorax. Heart sounds were heard to the right of the sternum. Her abdomen was soft and moderately tender over epigastrium and left hypochondrium with audible bowel sounds. Laboratory findings were remarkable only for a white blood count of 13 800/mL (with 88% neutrophils). Electrocardiogram indicated sinus tachycardia and a T-wave flattening. A nasogastric tube was placed and returned 800 mL bilious fluid.

A chest X-ray suggested diaphragmatic hernia because of air bubbles, air-fluid level and non-homogeneous opacity in the left hemithorax (Figure 1). A right mediastinal shift and loss of the sharp left hemidiaphragm line separating the abdomen from thorax, were also noted.

A chest ultrasound examination demonstrated bowel loops in the left pleural cavity and slight pericardial and pleural effusions and confirmed definitely the diagnosis of diaphragmatic hernia. It is generally considered that the hernia could become manifest on a basis of anatomical weakness possibly evoked by a trauma or increasing abdominal pressure, however, the patient denied any previous trauma.

Due to her unstable condition and because of concerns for ischemia of the herniated viscera, the patient was rushed to surgery. On exploration through a left thoracoabdominal incision, a large segment of right and transverse colon, the greater omentum and the stomach were identified in the left hemithorax. Compression atelectasis, mediastinal shift, strangulation and gangrene of large part of the herniated colon were also noted (Figure 2). The

Figure 1 Chest radiograph: Herniation of abdominal viscera in the left hemithorax.

Figure 2 Gangrene of a large part of the herniated transverse colon.

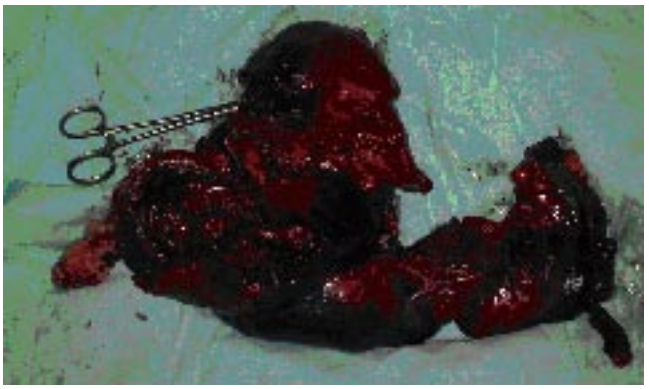

Figure 3 Large part of transverse colon resected due to strangulation and gangrene.

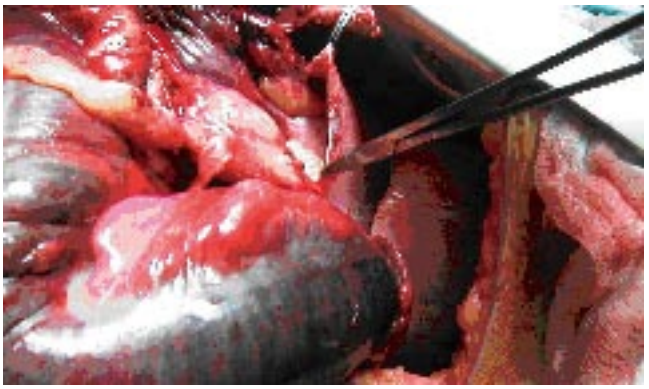

Figure 4 Bochdaleck's defect in the left hemidiaphragm.

viscera had protruded upward through a 4 cm × 7 cm posterolateral foramen of Bochdaleck diaphragmatic defect (Figure 3). The greater omentum seemed to be ischemic. A segmental resection of the involved portion of large intestine with re-establishment of bowel continuity by an end to end anastomosis was mandatory (Figure 4). Stomach was reduced in the abdominal cavity with no evidence of ischemic damage. The diaphragmatic defect was repaired with interrupted sutures. Manipulation of the uterus was avoided during surgery. Fetal well-being was confirmed throughout the procedure by continuous fetal heart rate monitoring.

After surgery, the patient recovered rapidly and her complaints ceased immediately. The postoperative course was uneventful and fetal and uterine activities were monitored daily. The patient was discharged home on postoperative day 10 after she tolerated a regular diet.

Pregnancy was allowed to continue until 39 wk's gestation at which time elective cesarean delivery was performed.

DISCUSSION

The diaphragm develops during the first 8 wk of gestation. In the eighth week this developing diaphragm leaves two channels located posterolaterally (Bochdaleck) and anteriorly (Morgagni) between the thorax and the abdomen. These two channels are closed by a two-layer membrane derived from pleura and peritoneum. When the posterolateral pleuroperitoneal channels fail to close, these are called foramina of Bochdaleck. Usually, it is rare for a defect like this to remain undetected in childhood through to adult life[6]. When the defect becomes manifest during pregnancy life-threatening events may affect both the mother and fetus. This is due to incarceration or strangulation of intraabdominal structures.

There are various symptoms in patients with congenital diaphragmatic hernia. Most of them are due to the effects of abdominal viscera within the pleural cavity and the commonest are chest pain and dyspnoea. Diminished breath sounds on the ipsilateral side are the most common physical finding. There may be signs of high or low mechanical ileus depending on which part of the gastrointestinal tract is herniated. In our patient, intraabdominal viscera herniated into the chest and caused dyspnea due to striking collapse of the left lung. Tachycardia, hypotension and distention of neck veins were the result of mediastinal shift and diminished venous return. Persistent vomitus was a sign of obstruction. However heartburn, nausea, vomiting and malaise are common symptoms during pregnancy. The failure of antacids, antispasmodics and dietary changes to relieve the symptoms especially in women with advanced pregnancy should lead the physician to suspect gastrointestinal pathology[7].

The diagnosis of a congenital diaphragmatic hernia during pregnancy requires a high index of suspicion. As in our case, the key to diagnosis is the chest radiograph. Thoracic ultrasonography, computed tomography scans and magnetic resonance imaging are possible auxilliary diagnostic methods. Pleural effusion or pneumothorax may be mimicked, leading to inappropriate thoracentesis or tube thoracostomy and inadvertent perforation of the herniated viscera[8].

The management of a pregnant patient with symptomatic diaphragmatic hernia is challenging. Traditionally, immediate repair is undertaken if symptoms arise, because further delay might be fatal both to the mother and fetus[5,6] . For asymptomatic patients Kurzel and Naunheim recommended cesarean delivery after fetal lung maturity is documented, with simultaneous hernia repair[6]. They opposed vaginal delivery under any circumstance because of the increased risk of incarceration with subsequent strangulation when the patient is bearing down. They based their recommendation on 17 cases reported in the English literature. In that case series the maternal and fetal morbidity was as high as 55% and 27% respectively, when vaginal delivery was attempted before the diaphragmatic hernia was repaired[6]. Genc *et al* suggested that gastric decompression might improve the clinical condition of the pregnant patient with a diaphragmatic hernia who presents with symptoms and signs of obstruction[9]. Such an improvement can allow surgery to be delayed until the patient is transferred to a tertiary care center or until antenatal corticosteroids are administered. Given this fact, Genc *et al* suggested observation and proposed immediate surgery whenever there is any suspicion of visceral incarceration. In our case, symptoms of cardiorespiratory failure and bowel obstruction led us to urgent repair because further delay could be fatal for both mother and fetus. Pregnancy was allowed to continue until 39 wk's gestation at which time elective cesarean delivery was performed.

The incidence of asymptomatic Bochdaleck's hernia in the adult population was reported to be at least 0.17%, with a female-to-male ratio of 17:5[10]. Despite such a high incidence, the number of pregnancies complicated by unrecognized congenital diaphragmatic hernia is extremely small - 35 cases, including this one, have been reported since 1928[5,9].

In conclusion, the diagnosis of congenital diaphragmatic hernia complicating pregnancy requires a high index of suspicion. Symptoms like abdominal pain, nausea, vomiting and dyspnoea should be investigated adequately. Signs of bowel obstruction and respiratory compromise are indications for a surgical emergency.

World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

Abstract

Understanding and characterization of pain and other sensory symptoms are among the most important issues in the diagnosis and assessment of patient with gastrointestinal disorders. Methods to evoke and assess experimental pain have recently developed into a new area with the possibility for multimodal stimulation (e.g., electrical, mechanical, thermal and chemical stimulation) of different nerves and pain pathways in the human gut. Such methods mimic to a high degree the pain experienced in the clinic. Multimodal pain methods have increased our basic understanding of different peripheral receptors in the gut in health and disease. Together with advanced muscle analysis, the methods have increased our understanding of receptors sensitive to mechanical, chemical and temperature stimuli in diseases, such as systemic sclerosis and diabetes. The methods can also be used to unravel central pain mechanisms, such as those involved in allodynia, hyperalgesia and referred pain. Abnormalities in central pain mechanisms are often seen in patients with chronic gut pain and hence methods relying on multimodal pain stimulation may help to understand the symptoms in these patients. Sex differences have been observed in several diseases of the gut, and differences in central pain processing between males and females have been hypothesized using multimodal pain stimulations. Finally, multimodal methods have recently been used to gain more insight into the effect of drugs against pain in the GI tract. Hence, the multimodal methods undoubtedly represents a major step forward in the future characterization and treatment of patients with various diseases of the gut.

INTRODUCTION

Abdominal pain is very common in the general population[1], and pain is the most prevalent symptom in the gastroenterological clinic[2]. Consequently, characterization of gut pain is one of the most important issues in the diagnosis and assessment of organ dysfunction. However, in clinical practice, the different symptoms of the underlying diseases confound the characterization of pain. These confounders may include complaints relating to psychological, cognitive and social aspects of the illness, as well as systemic reactions, such as fever and general malaise[3]. Furthermore, treatment with analgesics often causes sedation and other side effects. This will invariably bias the clinical evaluation of the pain-related symptoms. Hence, the patients tend to interpret other effects of the medication, e.g. an effect on the anxiety and depression relating to the disease, as a relief of pain[4]. Because of these confounding factors experimental pain models are often advantageous. Using these models, the investigator can control the experimentally induced pain (including the nature, localization, intensity, frequency and duration of the stimulus), and provide quantitative measures of the psychophysical, behavioral or the neurophysiological responses[3,5,6].

Experimental models have been used in different animal species. Here the investigators can study the neuronal activity in anesthetized or spinalized animals directly with invasive techniques or with assessment of behavior[7]. However, the neurobiology of the pain system differs between the animal species. This limits to a high degree the interpolation of findings from animal studies to man. Pain is the net effect of complex multidimensional mechanisms including intensity coding, affective, behavioral and cognitive components that involve most parts of the central nervous system. Furthermore, in humans, pain is closely related to linguistic terms and expressions. Thus, it is a complex sensory experience which is difficult to quantify with simple neurophysiological and/or behavioral methods. Therefore, animal experiments can only to some degree reflect the experience of clinical pain in humans and the interest in human experimental pain studies has increased rapidly during the last decade[3,8].

The primary advantages of experimental pain

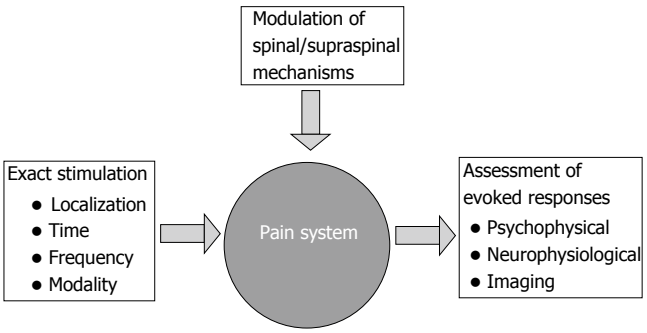

Figure 1 The concept for experimental induction, assessment and modulation of experimental gut pain in man.

approaches are that the stimulus can be controlled, delivered repeatedly and modulated, and that the responses can be assessed quantitatively with psychophysical and/or neurophysiological methods (Figure 1). Depending on the experimental model, different central mechanisms and conditions mimicking pathological pain can be studied. These are increased sensation to normal physiologic/non-painful and painful stimuli (allodynia and hyperalgesia, respectively). Experimental approaches can be applied in the laboratory for basic studies in healthy subjects and in patient groups, or used for preliminary screening of drug efficacy[9]. The methods can also be used in the clinic to characterize patients with sensory dysfunction and pain in organic and functional diseases[5,10-12]. The methods have been widely used in the skin and muscle[6]. However, due to the difficulties with access to the organs in the gastrointestinal (GI) tract, experimental pain testing is much more difficult than stimulation of the skin. The risk of perforation and other complications also limit the possibilities. Thus, most previous studies have relied on relative simple mechanical or electrical stimuli. These methods are easy to apply, but unless advanced modeling is used they have several limitations[3]. Most importantly, as pain is a multidimensional perception, it is obvious that the reaction to a single stimulus of a given modality can represent only a limited fraction of the entire pain experience. The possibility for combining different methods to stimulate the gut and evoke hyperalgesia will approximate the clinical situation, and give more comprehensive and differentiated information about the nociceptive system[3]. Multimodal models have clearly shown their value in testing of analgesics where a single stimulus has been inadequate assessing effects of specific drugs. Hence, Enggaard *et al*[13] showed that tricyclic antidepressants, which are valuable in treatment of functional pain disorders of the gut, increased the pain threshold to electrical stimuli, but did not reduce cold pressor pain. More sophisticated methods using a vide battery of tests will therefore be able to select the best test procedures to explore different basic aspects of pain as well as pharmacological modulations[9].

In this review, we outline the recent developments into test systems allowing standardized multimodal stimulations of the GI tract and their applications.

The rationale for multimodal stimulations of the gastrointestinal tract

The ideal experimental stimulus to elicit gut pain in man should be natural, minimally invasive, reliable in test-retest experiments and quantifiable[14]. The response to the stimulus should increase with increasing stimulus intensity and preferably the pain should mimic the observations in diseased organs by evoking phenomena, such as allodynia and hyperalgesia[8]. The different methods for pain stimulation of the human GI tract are electrical, mechanical, chemical, thermal and ischemic stimulation; further detailed informations regarding the advantages and shortcomings of these methods are explained elsewhere[3]. The ischemic stimuli are difficult to quantify in man and is normally not used as a direct stimulus. One of the major limitations of the different models is that they may not mimic clinical pain. Hence, they are relative short-lasting without the inflammation and subsequent activation of the many peripheral and central nervous mechanisms that are typically activated during diseases. Therefore, the basic neurobiological mechanisms in clinical pain may be different from those relating to an experimental stimulus[5,10]. For comprehensive experimental studies mimicking the clinical situation, a multimodal testing approach must therefore be used. A test battery where multimodal stimuli are used will increase the probability for activation of a range of relevant nervous mechanisms. Especially, if the stimulation is relatively long-lasting and includes modalities known to evoke peripheral as well as central sensitization, the likelihood that the model will mimic clinical pain is high despite the non-harmful nature of the stimulation.

In the GI tract, technical limitations of the currently available models have until now made a multimodal stimulation approach difficult. Some authors have combined mechanical and electrical stimuli[15,16] or used electrical stimuli combined with sensitization to acid[17]. The Center for Visceral Biomechanics and Pain in our department has recently introduced a multimodal pain model where mechanical, electrical, cold and warmth stimuli were combined. A summary of the findings in healthy subjects and patients is shown in Tables 1 and 2. Table 2 should be interpreted with caution as many data are still unpublished. In the multimodal model, mechanical stimulation is achieved with bag distension. Quantifications of the bag pressure and cross-sectional area are typically done by means of impedance planimetry or ultrasonography. Thermal stimulation is achieved by re-circulating fluid inside the bag with concomitant measurement of temperature. Chemical and electrical stimulation is done using side-holes placed proximal to the bag and by electrodes on the outside of the bag[18]. Sensitization with acid was added to the protocol to evoke allodynia and hyperalgesia together with increased referred pain areas (Figure 2)[19]. The multimodal approach gives the possibility for a differentiated stimulation of receptors in the superficial and deep layers of the gut. The possibility for induction of hyperalgesia and evoking central phenomena such as summation, allodynia and referred

Table 1 Multimodal comparison of clinical experimental data obtained in the esophagus from healthy volunteers

Group	Mechanical stimuli	Heat stimuli	Cold stimuli	Electrical stimuli	Sensitization with acid
Basic data	Differences between the sensations and referred pain areas was evoked by the stimulus modalities[18]. Reliability demonstrated[19,60] The sensation to mechanical stimulations was unaffected by relaxation of the smooth muscle[40,61]. Evidence for low and high threshold mechanoreceptors[22].	Reliability demonstrated. Stimulus-response functions obtained[18,19,60].	Reliability demonstrated. Stimulus-response functions obtained[18,19,60].	Reliability demonstrated. Stimulus-response functions obtained[18,19,60].	Allodynia and hyperalgesia evoked[19,26], although not consistent for mechanical stimuli (see text)[26,41]. Increased referred pain and amplitude of the nociceptive reflex indicating central hyperexcitability[19,26,46]. Acid perfusion sensitizes the oesophagus to heat but not cold, indicating sensitization of peripheral TRPV1 receptors[28,46]. Remote hyperalgesia was seen in the rectum after acid perfusion of the esophagus[20]. Hyperreactivity of contractions in esophagus, but tone was unaffected[26,46].
Gender differences	Males were more sensitive to stimulations, but an increased referred pain area was seen in females, reflecting sex differences in central pain processing[27,46].	No differences in sensation, but the referred area was larger in females[27,46].	As heat stimuli	Males less sensitive to single and repeated stimuli (Staahl et al., unpublished).	In females, the referred pain area increased to heat after acid sensitization, but no changes were seen to mechanical and cold stimulations[46].
Pharmacologic modulation	Oxycodone was better than morphine (and placebo) in attenuating mechanical pain[59].	Oxycodone was better than morphine (and placebo) in attenuating heat pain[59].	Not done	Both morphine and oxycodone attenuated the electrically evoked pain, but there were no differences between the opioids[59].	Not done

pain makes the models clinically relevant with respect to increasing the knowledge about peripheral and central pain mechanisms. The model have mostly been used in the esophagus, but recently also in the duodenum[20]. The pain assessment should ideally also be multimodal and, for example, include quantitative and qualitative sensations, assessment of referred pain and neurophysiological measurements[19].

Multimodal stimulation and peripheral receptors

The multimodal approach has given valuable information about the receptors in the gut wall. Theoretically, the thermal stimulation activates preferentially the receptors in the mucosa, the electrical stimulation penetrates into deeper layers of the gut and the mechanical stimulations affect predominantly receptors in the muscle layers (Figure 3).

It is generally believed that most visceral afferents are polymodal and respond to a wide range of stimuli including thermal stimuli[21]. However, sub-populations of these receptors exist and recently, we combined controlled distension with statistical modeling to demonstrate the existence of low and high threshold mechano-receptors in the human esophagus[22]. Most data on the sensation to thermal stimuli of the human viscera relate to few and relatively old studies[23-25], although some new studies have recently been published[18,19,26-29]. These studies point towards the existence of sensory pathways for thermal stimuli in the human GI tract. The thermal energy spreads from the superficial layers into the deeper layers of the gut depending on the temperature and conductance of the tissue[4]. However, as thermal stimuli are rather short-lasting in man mainly receptors in the mucosa are thought to be activated. Chemical stimulation with acid or capsaicin also activates receptors in the mucosa. Pedersen *et al*[28] used a multimodal approach to combine acid and heat stimuli of the esophagus. In this study, sensitization with acid resulted in a significant increase in the sensation to heat stimuli. The TRPV1 receptor is a polymodal detector of potential harmful stimuli, including noxious heat and protons[30]. Hence, it was suggested that TRPV1 receptors (or receptors with the same characteristics) were sensitized with acid and

Table 2 Multimodal comparison of clinical experimental data obtained in the esophagus from patient with different GI diseases

Patient group	Mechanical stimuli	Heat stimuli	Cold stimuli	Electrical stimuli	Sensitization with acid
Non-cardiac chest pain[41]	No differences to single stimuli, but increased pain to repeated stimuli and increased referred pain area, reflecting central hyperexcitability.	Not done	Not done	Not done	Increased sensation to mechanical stimulations after acid in patients only.
Esophagitis[31]	Patients were hyposensitive but with larger and more widespread referred pain. The distension induced more reactive contraction.	Patients were hypersensitive probably via increased activation of TRPV1 receptors.	No differences	Not done	Not done
Non-erosive reflux disease (Reddy *et al* unpublished data)	Patients were hyposensitive to mechanical stimuli. The distensions induced more reactive contractions in the esophagus in the patients and they had larger referred pain areas. Patients with pathological 24-h pH-measurement were more hyposensitive than the patients with normal pH profile.	The patients were hypersensitive to heat with increased referred pain areas to this modality.	No differences between patients and controls	Not done	Patients had a higher sensitivity score to acid perfusion.
Diabetes (Frøkjær *et al*, unpublished data)	Patients had hyposensitivity to distension, but increased referred pain areas, reflecting peripheral neuropathy and central hyperexcitability. Increased stiffness of the gut wall in diabetes.	As mechanical stimulations	Not done	As mechanical stimulations	Not done
Chronic pancreatitis (Dinmcevski *et al*, unpublished data)	No differences in sensation. No differentiated effect on morphine and oxycodone in attenuation of mechanical pain.	No differences in sensation Oxycodone attenuated heat pain better than morphine.	Not done	Larger referred pain area in the patients. Opioids were not better than placebo in attenuating electrical pain	Not done

subsequently resulted in increased firing of the afferents to heat stimulation. The role of this receptorsystem in the clinic was addressed in another study where selective hyperalgesia to heat but not cold stimuli was found in patients with reflux and grade B esophagitis[31]. The evidence for receptor-specific activation pattern in the experimental studies was supported in a recent study where the TRPV1 receptor was demonstrated in the human esophagus, and especially the receptor was up-regulated in esophagitis[32]. Thus, the multimodal approach gave valuable quantitative *in vivo* information about the receptor characteristics and pain mechanisms in healthy subjects as well as in patients with acid-evoked inflammation.

Multimodal stimulation and primary afferents

Electrical stimuli bypass the receptors and although all fiber populations (nociceptive as well as fibers mediating physiologic/non-nociceptive sensations) are excited by electrical stimuli, the relative proportion of activation depends on the stimulus intensity. With normal bipolar electrical stimulation, the current is believed first to activate receptors in the mucosa and submucosa, whereas the deeper layers are activated with increasing current[3]. The depth of activation also depends on the stimulation method and frequency[4]. In the gut, electrical stimulation is thought preferentially to activate thinly myelinated (Aδ) fibers[33]. Chemical and thermal stimuli, on the other hand, activate mainly non-myelinated (C) fibers and the terminals of mechanosensitive fibers are mainly localized in the muscle layers or have intraganglionic nerve endings[34,35]. Roughly speaking, the different modalities may therefore activate different fiber populations and, for example, may thermal and mechanical stimulation activate fibers in the mucosa and muscle layers, respectively. However, the difference between the stimulation paradigms may be of minor importance as Hobson *et al*[36] showed that the evoked brain potentials to mechanical and electrical stimulation of the gut were similar, reflecting that the same pathways were activated. The mechanical stimulation protocol may also be important. Hence, in the human

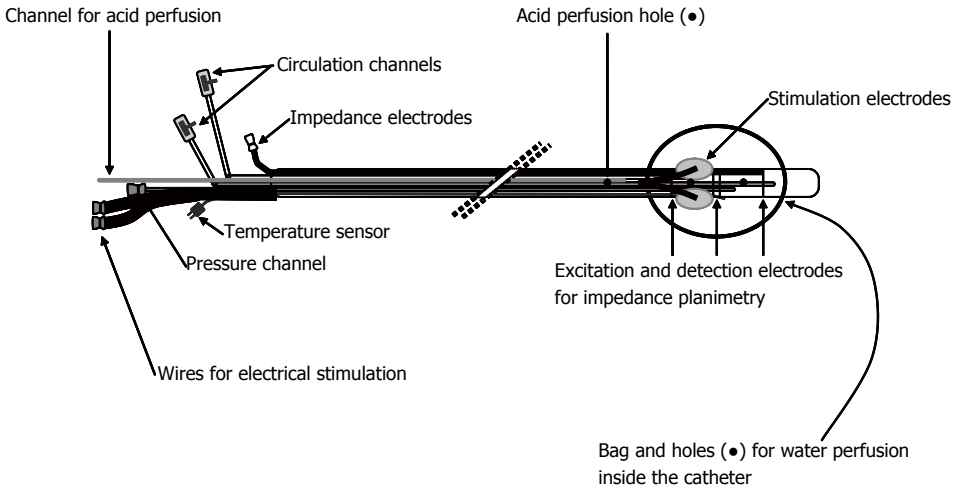

Figure 2 Schematic illustration of the probe used for multi-modal (electrical, mechanical, cold and warmth stimuli) of the esophagus.

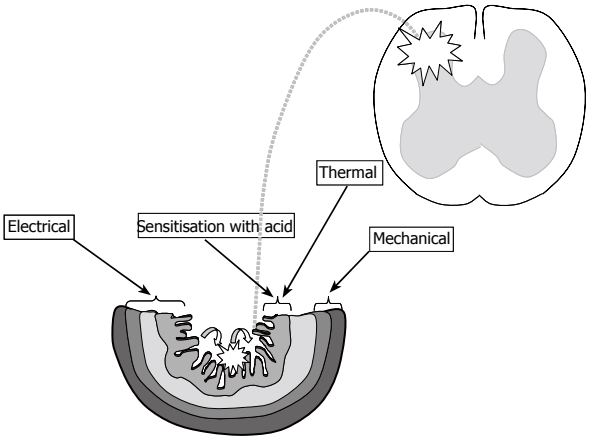

Figure 3 Schematic illustration of the proposed gut layers which are preferentially affected with: (1) Thermal stimuli (mucosa - dark grey and submucosa - light grey); (2) Mechanical stimuli (circular muscle layer - hatched grey and longitudinal muscle layer - prickled grey); (3) Electrical stimuli (all layers depending on stimulus intensity). Perfusion of the esophagus with acid (curved arrows) gives the possibility to evoke peripheral and (mainly) central sensitization (illustrated with stars).

rectum phasic distensions were shown preferentially to stimulate spinal pathways thought to mediate pain, whereas slow tonic stimuli mainly affect parasympathetic nerves[37]. We recommend a slowly ramp distension as it is more physiological and allows the subjects to assess the pain continuously. We also strongly recommend to precondition the tissue by two-three distensions until the stress-strain relationship becomes reproducible[38]. For advanced muscle analysis, we normally use butylscopolamine to relax the smooth muscle, and this does not seem to modify the sensation *per se* [20,39,40].

The multimodal approach has recently been used to compare the response to mechanical stimuli before and after chemical stimulation with acid in patients with non-cardiac chest pain[41]. In these patients, there is a normal sensory response to mechanical stimuli at baseline. However, after acid the evoked hyperalgesia resulted in a marked increase of the sensory response in the patients (Figure 4). Although peripheral sensitization may be important, the findings gave evidence for an amplification of central pain mechanisms manifested as allodynia, hyperalgesia, and increased and widespread referred pain areas to the mechanical stimulations. Mechanical stimulation together with advanced muscle analysis has also been used to explain the symptoms in patients with systemic sclerosis. In these patients, the contraction amplitude was smaller and there was an evidence for a stiffer gut wall in the small intestine[42]. The pain evoked by a controlled strain of the gut was increased and this may explain many of the symptoms reported in the clinic. In patients with diabetes, we also found evidence for increased stiffness in the duodenum using the multimodal approach (Frøkjær *et al*, unpublished data). This may reflect the increase in collagen deposition seen in these patients and may (together with autonomic neuropathy) explain the motor abnormalities seen in these patients.

Multimodal stimulations and central pain mechanisms

In diseases of the GI tract, central sensitization and neuroplastic changes are probably of major importance to understand the sensory response as manifested by pain and hyperalgesia. Central pain mechanisms may be evoked by multiple stimuli (either temporal or spatial summation), resulting in central amplification of the response. The response is comparable to early phase of the frequency-dependent "wind-up" seen in animal experiments. In practice the central integration can be evoked by repeated electrical stimulation above 0.5 Hz[43,44], resulting in increased local and referred pain. Recently, the multimodal probe was used to give repeated mechanical stimulation in patients with non-cardiac chest pain. In this study, the number of stimuli tolerated was significantly lower in the patients compared with healthy controls, reflecting central hyperexcitability as a key to understanding the symptoms in these patients[41].

Sensitization of the esophagus with acid is an another possibility to evoke central (and peripheral) sensitization. Previously, it was shown that acid perfusion of the distal esophagus resulted in an amplified response to electrical, mechanical and thermal stimuli[19,26]. The central changes were documented in an experiment where there was an amplification of the nociceptive reflex[19]. The reflex was evoked by stimulation of the sural nerve, resulting in

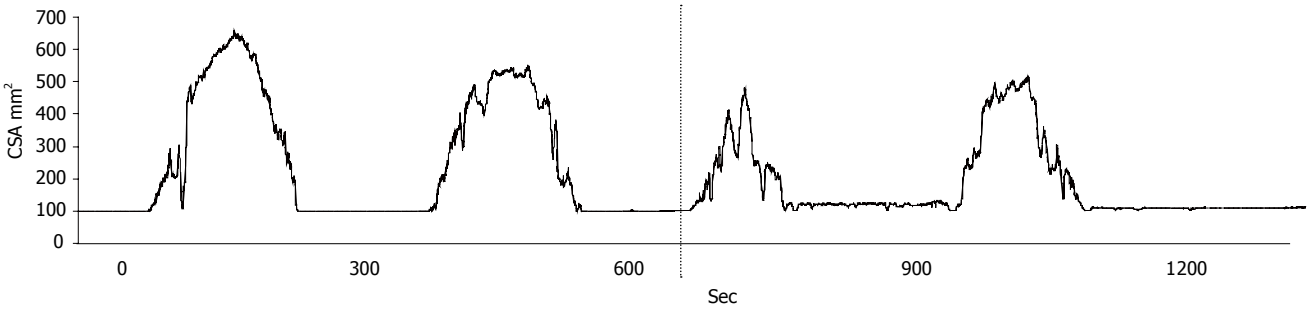

Figure 4 Cross-sectional area (CSA) at moderate pain during two distensions of the esophagus in a patient with non-cardiac chest pain. The distensions were performed before and after perfusion of the distal esophagus with acid (illustrated with the stippled line). A clear reduction in the tolerated mechanical stimulus was seen after acid perfusion.

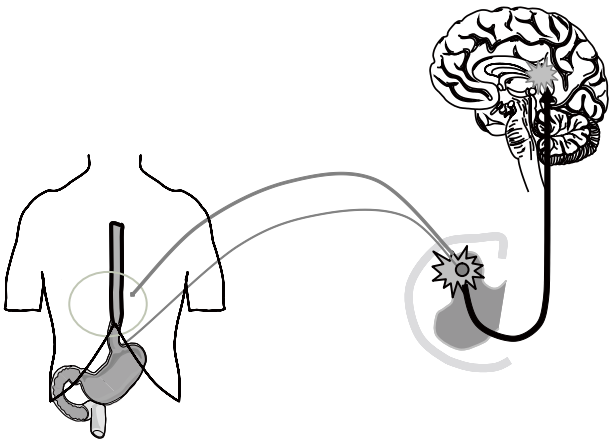

Figure 5 Referred pain in the somatic tissues is believed to be generated by central mechanisms, where visceral and somatic nerves converge on nerves in the same area of the spinal cord or at supraspinal centers. The phenomena also includes unmasking of latent connections and focal central hyperexcitability of the neurons.

activity of the biceps muscle of the thigh. The connection from the primary afferents to the motor neurons is a polysynaptic spinal pathway, which can be modulated by other afferent input, spinal neuronal excitability, and activity in descending control systems[5]. The reflex was evoked together with a painful mechanical stimulus of the esophagus. In the experiment, an amplification of the reflex was seen after sensitization of the esophagus with acid, reflecting central changes at the spinal cord level. Evidence for central changes to acid perfusion was also demonstrated by Sarker *et al*[17] who demonstrated a decreased pain threshold to electrical stimulation of the proximal esophagus after acid perfusion of the distal part. As the proximal esophagus was not affected by the acid, only central changes would explain the findings.

Referred somatic pain to visceral stimuli is regarded as a phenomenon generated by central mechanisms due to visceral nerves terminating in the same area of the spinal cord as somatic afferents[45] (Figure 5). Assessment of the referred pain area to electrical, mechanical and thermal stimulation can be used to determine the central response to these differentiated modalities[19]. The referred pain area to electrical, mechanical, cold and heat pain differs in size and localization reflecting the different peripheral (and hence central) nerves that are activated[18]. The increase in referred pain areas after acid perfusion is also an evidence for central sensitization caused by the chemical stimulation[26,46]. Recently, Pedersen *et al*[28] showed that the referred pain to heat but not cold stimulation of the esophagus increased after acid perfusion of the organ. This has also been shown in a more recent study[46]. As discussed previously, selective sensitization of the TRPV1 receptors by acid could result in an increased afferent barrage after a heat stimulus, which again was manifested as an increase in the referred pain area. The changes in local and referred pain to mechanical stimulations may, however, be difficult to determine as the acid also evokes secondary contractions that may squeeze the bag and influence the stimulus parameters[26]. On the other hand, an increase in the referred pain after acid perfusion is typically seen to mechanical stimulation of the esophagus in healthy subjects[19,26]. Increased referred pain to mechanical stimulations was also seen in patients with esophagitis and in non-erosive reflux disease, reflecting that facilitation of central pain mechanisms is important in the understanding of these diseases[31]. In patients with diabetes and chronic pancreatitis, we found hypoalgesia to peripheral stimulation, whereas there was a significant increase in the referred pain area. These data were interpreted as a descending inhibition of the afferent input counterbalancing central hyperexcitability (Frøkjær *et al*, unpublished data). Hence, the multimodal approach may be used explaining the symptoms in these patients, and may be used to evaluate the stage of disease in a more mechanism-based manner. Central changes may also result in allodynia and hyperalgesia to stimulation of other viscera[47]. Such changes are regarded important in the understanding of functional gut disorders where abnormal sensation to physiologic stimuli, such as feces or air in the gut, may contribute to the symptoms (allodynia). Recently, a multimodal approach was used to assess the sensation of the proximal esophagus, duodenum and rectum after sensitization of the distal esophagus with acid[20]. In this study, an increased sensitivity to mechanical stretch in the three gut segments was seen after acid perfusion. This was mainly due to increased sensitivity in the rectum being very remote from the experimentally inflamed esophagus.

Neuroplastic changes at the cortical level may also be shown by multimodal stimulations of the gut. Thus, Sarker *et al*[48] showed changes in the evoked brain potentials to

electrical stimulation of the proximal esophagus after acid perfusion of the distal segment. Recently, we showed that acid perfusion resulted in neuroplastic changes at the cortical level reflected. Reduction in latency and a backward shift of the electrical dipole in the anterior cingulate dipole were observed to electrically evoked pain in the esophagus after acid perfusion of the organ (Sami *et al*, unpublished data). Such changes were also found when the gut was electrically stimulated in patients with irritable bowel syndrome[49]. The backward shift in the cingulate activation after sensitization with acid in healthy subjects may, therefore, represent the central nervous system change corresponding to the allodynia and hyperalgesia to gut stimuli found in patients with functional disorders of the gut.

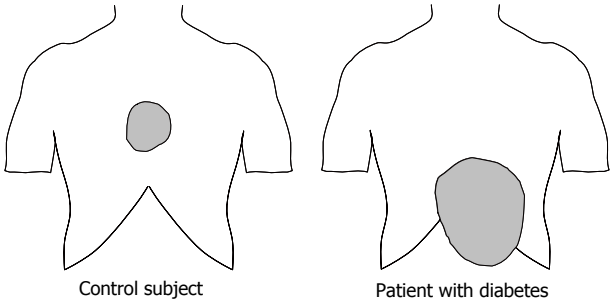

Figure 6 Referred pain area to mechanical distension of the esophagus in a typical healthy subject, and in a patient with diabetes mellitus and autonomic neuropathy. The patient complained of severe nausea and pain in the epigastrium. The referred pain area in the diabetic patient was larger and abnormally localized.

Gender differences to multimodal pain stimulations

Women are diagnosed more frequently with chronic visceral pain disorders than men[50]. Extensive evidence indicates that females and males differ in their nociceptive processing, although it seems modality- and tissue-specific. The reason for the female predominance is not known, but sex differences are found in basic GI functions, such as gallbladder emptying and colon transit[51,52]. For most studies using experimentally delivered somatic pain stimuli, females have lower thresholds, less tolerance, and higher pain ratings than males[53]. However, few studies have focused on sex-related differences in visceral pain in man, and these have been contradictory with respect to sex differences[51]. The multimodal probe was recently used to investigate any differences to mechanical and thermal stimuli of the esophagus. The results were somewhat ambiguous, but in general males seemed to be more sensitive to the stimuli[27,46]. However, a greater size of the referred pain areas to the different stimuli was seen in women. After acid perfusion, the males were also more sensitive than females to distensions, but no differences were found in response to the thermal stimuli[46]. In the females, only the referred pain area was increased to heat stimulations after sensitization with acid. The bigger referred pain areas may thus reflect that the central processing of pain to visceral stimuli differs between males and females as previously shown by our group and by Kern *et al* [54]. Thus, the multimodal stimulations revealed a differentiated response to peripheral and central pain mechanisms, which may explain the sex-related differences seen in several gastrointestinal disorders.

Multimodal stimulations outside the esophagus

Accarino *et al*[15] used multimodal stimulation (mechanical and electrical) of the jejunum. The verbal response to electrical stimuli and distension was compared, and no differences in the evoked response were found. This led the authors to conclude that the practical differences between the two modalities may probably be of minor importance. Recently, we used thermal and mechanical stimuli of the duodenum in healthy subjects[20] and in patients with diabetes and autonomic neuropathy (Frøkjær *et al*, unpublished data). The diabetes patients showed hypoalgesia to mechanical and electrical stimuli, whereas no changes were found to heat stimulation compared with controls. Furthermore, the referred pain area in the abdomen was enlarged in the patients (Figure 6). Such data may enhance our knowledge about peripheral and central pain mechanisms in these patients with implications for the treatment.

Mechanical stimulation of the rectum is one of the most used methods in experimental visceral research. Electrical and thermal stimulations have also been used in the rectum[3], but combinations of the methods were not done. However, combinations of mechanical and electrical stimulations have been used in assessment of evoked brain potentials[55] and to assess the effect of viscero-visceral hyperalgesia[20]. The stomach and other parts of the digestive system have not yet been studied with multimodal stimulations. Although the complicated anatomy, nervous innervation and function of these organs should be taken into account, multimodal models are obviously highly warranted.

Multimodal stimulations in drug research

Experimental models are widely used in research of the effect of analgesics. The differentiated information of the drug effect can be used as "proof-of concept", dose-efficacy analysis, and for designing further clinical trials. An approach to mimic the clinical situation is the use of multimodal tests, where different receptor types and mechanisms are activated. The multimodal model has clearly shown its value in somatic pain testing, where a single stimulus has been inadequate to test, for example, pathophysiological changes and effects of specific drugs[9]. Hence, differentiated effects could reflect how the drugs can modify different disease mechanisms. In the esophagus, Sarkar *et al*[56] recently used a model where the upper esophagus was stimulated following sensitization of the distal segment with acid. The secondary hyperalgesia in the proximal part was reduced with a prostaglandin inhibitor, demonstrating the preferentially central action of prostaglandins in this model. Recently, we used a multimodal (and multi-tissue) approach to test the effect of opioids. Opioids are widely used in treatment of visceral pain despite the many side effects. Opioids preferentially attenuate nociceptive responses produced by central integration (spinally amplified signals) to tonic activation

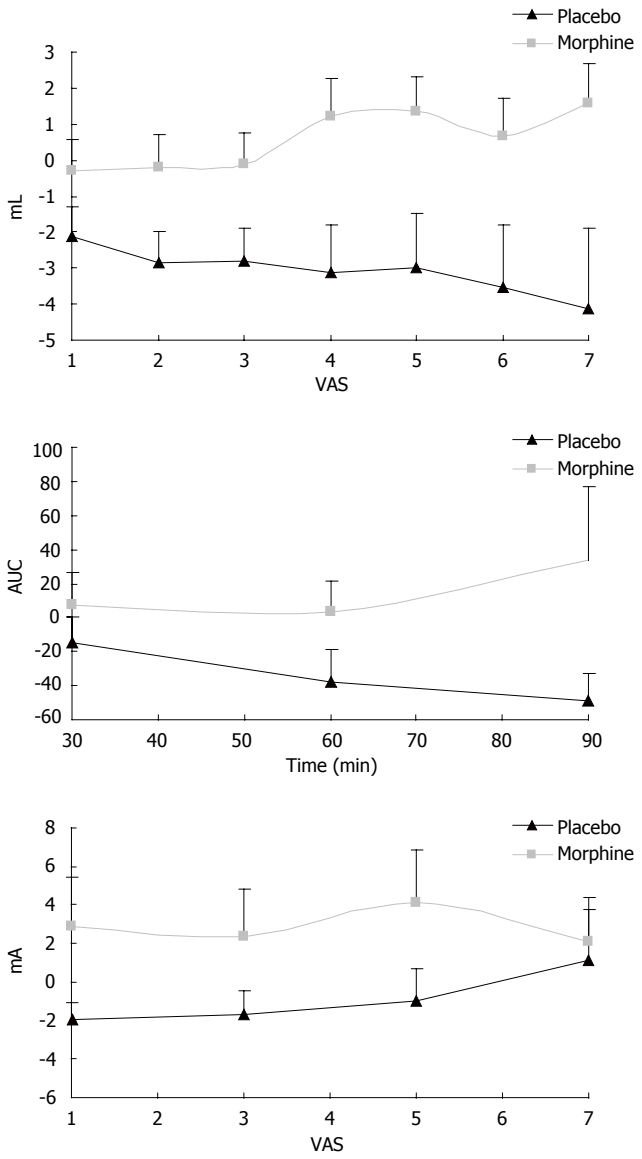

Figure 7 Change in sensory rating compared with baseline recordings for oral morphine and placebo using multimodal stimulation of the esophagus. Top picture: Morphine attenuates mechanically evoked pain better than placebo 60 min after drug intake ($P < 0.01$). VAS on the X-axis denotes the sensory rating at a visual analogue scale with 5 as the pain threshold. ML at the Y-axis denotes the bag volume. Middle picture: Morphine attenuates heat pain better than placebo ($P < 0.05$). Here the X-axis illustrates time after drug intake (min) and AUC on the Y-axis denotes the area under the temperature curve used as a proxy for the thermal energy. Bottom picture: Morphine also worked better than placebo ($P < 0.05$) on electrical stimulation 60 min after drug intake.

of unmyelinated fibers[4,5,7]. Therefore, evaluation of the anti-nociceptive effects of opioids may be clearer using slow rates of temperature or tonic pressure. In the viscera typically only one modality (pressure) has been used in the testing of analgesics[58]. However, Staahl *et al* (unpublished data) recently compared the effects of morphine and placebo on the pain thresholds to multimodal stimulation of the esophagus. A clear effect of morphine in attenuating heat, electrical and slow-ramp pressure stimulations was found (Figure 7). Morphine can definitely attenuate GI pain in the clinical situation and the model, therefore, proved its validity. The model was also used to differentiate between morphine and oxycodone, the latter was believed also to affect κ-opioid receptors thought to be predominant on visceral afferents. In equipotent doses, oxycodone was better than morphine in attenuating visceral pain, whereas there were no differences between the drugs on pain evoked in the muscle and skin[59]. The study thus demonstrated a different pharmacological profile of oxycodone compared to morphine, and therefore oxycodone may be a useful alternative to morphine in the treatment of visceral pain syndromes. We recommend that future studies evaluating analgesics in the GI tract should use a multimodal approach to get the necessary insight into visceral pain mechanisms and the effect of drugs in the gut. This will facilitate the design of subsequent clinical (phase III) studies. Hence, a substitution of the current "trial and error design" with a more mechanisms-based approach will reduce the economic and human burden in the development of new drugs targeted against pain in the GI tract.

CONCLUSION

Multimodal pain stimulation in the human GI tract is a newly developed experimental approach that mimics the clinical pain to a higher degree than previous models. The method has been used to gain more insight into basic peripheral and central pain mechanisms as well as characterizing patients with different diseases of the GI tract. Together with the possibility for pharmacological testing, the models represent a major step forward in the experimental characterization and treatment of patients with gastroenterological diseases.

Abstract

Autoimmune chronic pancreatitis (AIP) is increasingly being recognized worldwidely, as knowledge of this entity builds up. Above all, AIP is a very attractive disease to clinicians in terms of its dramatic response to the oral steroid therapy in contrast to ordinary chronic pancreatitis. Although many characteristic findings of AIP have been described, definite diagnostic criteria have not been fully established. In the year 2002, the Japan Pancreas Society published the diagnostic criteria of AIP and many clinicians around the world use these criteria for the diagnosis of AIP. The diagnostic criteria proposed by the Japan Pancreas Society, however, are not completely satisfactory and some groups use their own criteria in reporting AIP. This review discusses several potential limitations of current diagnostic criteria for this increasingly recognized condition. The manuscript is organized to emphasize the need for convening a consensus to develop improved diagnostic criteria.

Key words: Autoimmune chronic pancreatitis; Diagnostic criteria

INTRODUCTION

Autoimmune chronic pancreatitis (AIP) can be defined as a chronic inflammation of the pancreas due to an autoimmune mechanism; autoimmunity is responsible for producing the pancreatic lesion[1,2]. AIP is a distinctive type of chronic pancreatitis that shows reversible improvement of pancreatic morphology and function with oral steroid therapy, in comparison to other types of chronic pancreatitis which hardly respond to various treatments[1-5].

AIP is increasingly being recognized to be a worldwide entity[6-8]. The sudden increment in cases reported probably reflects the growing awareness of the entity, rather than a rise in the true incidence. The diagnosis of AIP is, however, still challenging. Many groups have cited the diagnostic criteria proposed by the Japan Pancreas Society (Table 1)[9], whereas some groups have used their own criteria in reporting AIP[1,2,4,5,10]. This makes it difficult to compare studies from different centers, judge the relevance of comparisons and establish evidence on AIP. Above all, the largest problem was that a substantial portion of patients revealed clinical findings compatible to AIP and even responded to the steroid, yet failed to fulfill the Japanese diagnostic criteria[11,12]. This review revisits currently used diagnostic criteria of AIP focusing on the Japanese ones, discusses the potential limitation of diagnostic criteria and raises some important issues related to the diagnosis of AIP. In view of our experiences of a relatively small cohort of 28 patients, we propose a new revision that may help physicians diagnose AIP. By revising the diagnostic criteria of AIP, more patients may benefit from this diagnosis and be spared from burdensome surgery.

OUR EXPERIENCES

We reviewed the clinical, radiologic, laboratory and histologic features of 28 patients with AIP who responded to the oral corticosteroid. The response to the steroid was defined as improvement in clinical symptoms, negative conversion of detected autoantibodies, normalization of elevated level of IgG or IgG4, and reversion of abnormal pancreatic imaging including CT and endoscopic retrograde pancreatogram.

The diagnosis of AIP in our hospital was made by the criteria as shown in Table 2. For the diagnosis of AIP, imaging criterion (CT and ERCP findings) was an essential component. If the patient fulfilled the imaging criterion (diffuse enlargement of pancreas and diffuse or segmental irregular narrowing of main pancreatic duct) together with laboratory and/or histopathologic criteria, the patient was diagnosed of AIP. Even though a patient fulfilled imaging criterion only, in other words, the laboratory criterion and histopathologic criterion were incompatible

Table 1 Diagnostic criteria for autoimmune pancreatitis by the Japan Pancreas Society

	Diagnostic criteria
I	Imaging criterion: Diffuse narrowing of the main pancreatic duct with irregular wall (more than 1/3 length of the entire pancreas) and enlargement of the pancreas
II	Laboratory criterion: Abnormally elevated levels of serum gamma-globulin and/or IgG, or the presence of autoantibodies
III	Histopathologic criterion: Marked lymphoplasmacytic infiltration and dense fibrosis
For diagnosis, criterion I must be present, together with criterion II and/or III	

Table 2 Diagnostic criteria for autoimmune pancreatitis in Asan Medical Center

Inclusion Criteria
Criterion I. Pancreatic imaging (essential)
(1) CT: Diffuse enlargement (swelling) of pancreas
and (2) ERCP: Diffuse or segmental irregular narrowing of main pancreatic duct
Criterion II. Laboratory findings
(1) elevated levels of IgG and/or IgG4
or (2) detected autoantibodies
Criterion III. Histopathologic findings
Fibrosis and lymphoplasmacytic infiltration
Criterion IV. Response to the steroid
Definite diagnosis: Criterion Ⅰ and any of criterion Ⅱ-Ⅳ

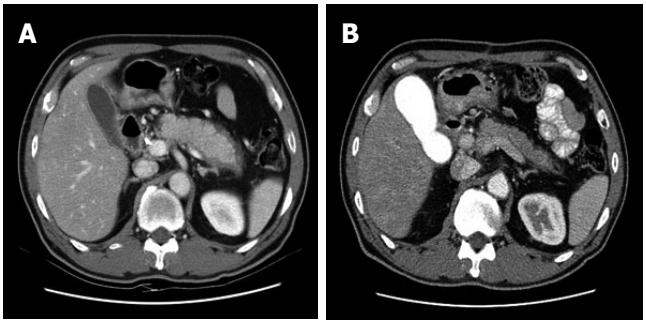

Figure 1 Abdominal CT findings. **A:** Diffusely enlarged pancreas without any calcification or stones in a 59 year-old man. A capsule-like low-density rim can also be seen around the pancreas; **B:** After steroid therapy, the pancreas returned to its normal size and the rim disappeared.

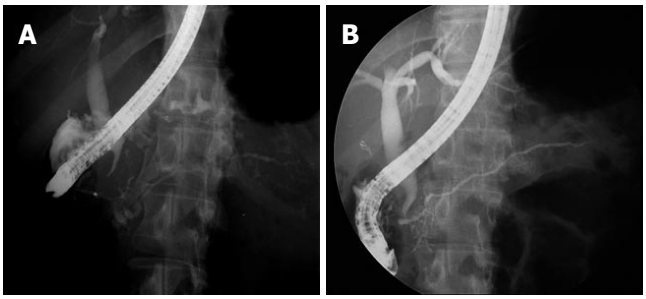

Figure 2 ERCP findings. **A:** Diffuse irregular narrowing of more than 2/3 of the entire length of main pancreatic duct noted in the 49 year-old woman; **B:** After steroid therapy, evidently widening of the main pancreatic duct.

or not available, steroid was administered and the patient was diagnosed as AIP if the response to the steroid was shown.

The patients' mean age was 55.3 years (range, 32-78 years) and they were comprised of 22 males and 6 females. None of the patients had a history of alcohol abuse or other predisposing factors for chronic pancreatitis.

On CT, all the patients revealed a diffusely enlarged pancreas with no or mild peripancreatic fat infiltration. All the patients had no any typical findings of ordinary chronic pancreatitis, such as multiple parenchymal calcifications or pancreatic ductal stones. Capsule-like low-density rim surrounding the pancreas was shown in five (18%) patients (Figure 1). On direct pancreatogram, 8 (29%) patients showed diffuse irregular narrowing of main pancreatic duct which involved entire main pancreatic duct or at least more than 2/3 of entire length of main pancreatic duct (Figure 2). In seven patients with segmental irregular narrowing, total length of ductal involvement was less than 2/3 of the entire length of main pancreatic duct and it was between 1/4 and 1/3 (Figure 3).

The IgG level was increased (>1 800 mg/dL) in 14 (50%) patients (Table 3). The IgG4 level was measured in 23 patients and it was increased in 15 (65%) patients. In 4 patients, the IgG4 level was increased without elevation of IgG level. Autoantibody was detected in 15 (68%) patients.

Pancreatic tissue specimens were obtained from 19 patients. Percutaneous ultrasound-guided core biopsy with an 18-gauge needle was performed in 17 patients and open biopsy in 2 patients. The biopsy specimen of 14 (74%) patients showed marked inflammatory infiltrates mostly of lymphocytes and plasma cells and dense fibrosis of the pancreatic tissue. However, one patient showed predominant eosinophilic granulocytes infiltrating into the pancreatic parenchyma rather than lymphoplasma cell infiltration. Overall, the biopsy findings were non-diagnostic, that is, either lymphoplasma cell infiltration or fibrosis was minimal or absent, in 5 of 19 (26%) cases.

Seven of 28 (25%) patients who responded to the steroid did not satisfy the Japanese imaging criterion because the extent of ductal narrowing was less than one third of entire length of main pancreatic duct. Another two patients showed normal IgG level, negative results of autoantibody measurements and non-diagnostic pancreatic histopathology. Taken together, 9 of 28 (32%) patients did not meet the Japanese diagnostic criteria for AIP, yet responded to the steroid.

DIAGNOSTIC CRITERIA

The diagnosis of an autoimmune disease is always an impetus to the clinician. Autoimmune conditions often lack pathognomonic findings on histopathology. The sensitivity and specificity of serologic markers also leave controversies in the diagnosis. To overcome these problems, combinations of common clinicopathologic findings are often used to guide physicians in diagnosing autoimmune diseases.

During the past decade, Japanese investigators have described many common clinicopathologic findings of AIP by reporting over three hundred cases domestically.

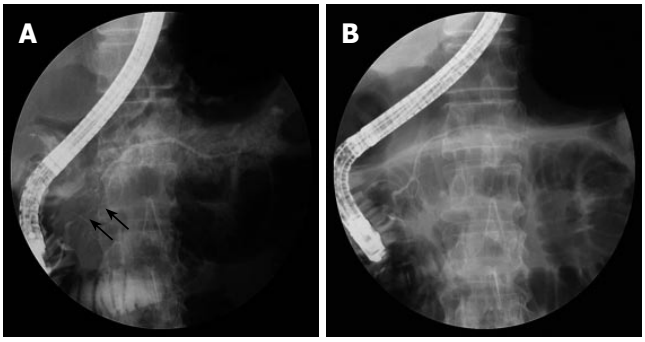

Figure 3 ERCP findings. **A:** Segmental narrowing (arrows) of the main pancreatic duct noted at the pancreatic head. The extent of irregular narrowing is less than 1/3 of the entire length of main pancreatic duct; **B:** Direct pancreatogram revealing a normal-appearing main pancreatic duct following steroid therapy.

Based on this experience, the Japan Pancreas Society published the "Diagnostic Criteria for Autoimmune Pancreatitis" in the year 2002[9]. The criteria are constituted of 3 components: (1) Pancreatic imaging: diffuse irregular narrowing of the main pancreatic duct with irregular wall (more than 1/3 length of the entire pancreas) and diffuse enlargement of the pancreas; (2) Laboratory data: elevated levels of serum gammaglobulin and/or IgG, or the presence of autoantibodies; and (3) Histopathologic findings: fibrotic changes with lymphocyte and plasma cell infiltration. For the diagnosis of AIP, criterion 1 must be present, together with criterion 2 and/or 3 (Table 1). Interestingly, the criteria does not include symptoms or common laboratory findings, as they are not specific to AIP[13,14]. The condition commonly manifests as obstructive jaundice, weight loss, and recent-onset diabetes in elderly men. None of the patients diagnosed as AIP have a history of alcohol abuse or other predisposing factors for chronic pancreatitis. In contrast to other types of pancreatitis, severe abdominal pain is infrequently encountered. These features are similar to that of pancreaticobiliary malignancies, which are the most difficult and important entities to differentiate from AIP[15].

Imaging criterion

Radiologic imaging of the pancreas is an essential component of the Japanese criteria where it is mentioned as a "must" for diagnosing AIP. The criterion is stated as diffuse narrowing of the main pancreatic duct with irregular wall (more than 1/3 length of the entire pancreas) and diffuse enlargement of the pancreas which can be identified with ERCP (endoscopic retrograde cholangiopa ncreatography) and CT, respectively[9]. Although abdominal US is most frequently performed imaging method for the screening of pancreatic disease, overlying bowel gas or obesity often hinders the sonographic visualization of the pancreatic gland, rendering the examination limited in scope and quality.

On CT, most cases of AIP reveal a diffusely enlarged pancreas with no or mild peripancreatic fat infiltration. Phlegmonous changes of the pancreas, peripancreatic fluid collection or pseudocysts formation are rare. Diffuse enlargement of the pancreas correlates with the pathology of marked stromal edema, which manifests as diffuse swelling on gross examination[16,17]. Surprisingly, CT does not reveal any typical findings of chronic pancreatitis, such as multiple parenchymal calcifications or pancreatic ductal stones. Rather, AIP resembles mild form of acute pancreatitis according to Balthazar classification[18]. Some cases of AIP reveal peculiar CT findings, such as a capsule-like low-density rim surrounding the pancreas (Figure 1)[19]. This rim is thought to correspond to the histologic findings of an inflammatory process that contains fibrous changes involving the peripancreatic adipose tissue[20]. Delayed enhancement of the pancreatic parenchyma is another distinguishing feature of AIP. On arterial enhanced phase, the pancreas appears hypodense when compared to the spleen. On the delayed phase, attenuation increases when compared to early images. This reflects fibrosis with an associating inflammatory process. These characteristic patterns observed on CT are important in differentiating AIP from pancreatic cancer[15].

The term "enlargement" of the pancreas can be subjective and vague. The size of the pancreas may be affected by many factors, including body mass, ethnic group, gender and age. There are individual variations in the size of the gland, with smaller atrophic glands seen in older individuals[21,22]. While a pancreas may seem normal for a large young man, the same size can be described as "enlarged" for an elderly patient with small body mass. Nishino *et al*[23], therefore, describe that the pancreas is considered to be enlarged when the width of the pancreatic body or tail was more than two thirds of the transverse diameter of the vertebral body or the width of the pancreatic head is more than the full transverse diameter of the vertebral body.

The Japanese imaging criterion has described the ductal pathology as diffuse narrowing of the main pancreatic duct with irregular wall (more than one third of the length of the entire pancreas), which can be observed on direct pancreatogram[9]. However, we were confronted with confusion when applying this criterion. This may be because the terms used were imprecise and vague in the meaning. First, in the previous international symposium on chronic pancreatitis[24,25], pancreatic lesion was classified as focal, segmental, or diffuse according to the extent of involvement. In this international classification, "diffuse" is used when a process involves the entire pancreatic duct or at least more than two-thirds of the entire length of the main pancreatic duct, whereas lesions that are not continuous and involve the head, body or tail are defined as "segmental" (Figures 2 and 4)[24,25]. In Japanese criteria, the terms "diffuse" and "at least one third of the entire length" in the same sentence are contradictory to each other. Thus, it may be more appropriate that the term "diffuse" irregular narrowing of main pancreatic duct in Japanese imaging criterion (Table 1) is changed to "diffuse or segmental" irregular narrowing. In AIP cases of segmental involvement, the intervening normal-appearing duct upstream to the stricture shows no or minimal dilatation in spite of the long stricture (Figure 4). These findings differentiate AIP from pancreatic cancers, which reveal stricture associated with marked upstream ductal dilatation[26,27]. Second, "narrowing" of the main pancreatic duct is a term based on subjective assessment.

S: Segmental irregular narrowing of main pancreatic duct; D: Diffuse irregular narrowing of main pancreatic duct; DE: Diffuse enlargement of pancreas; N-C: Not checked; ND: Non-diagnostic; [a]: Extent of irregular narrowing was less than 1/3 of the entire length of main pancreatic duct; [b]: Lymphoplasma cell infiltration and fibrosis; [c]: Eosinophilic infiltration.

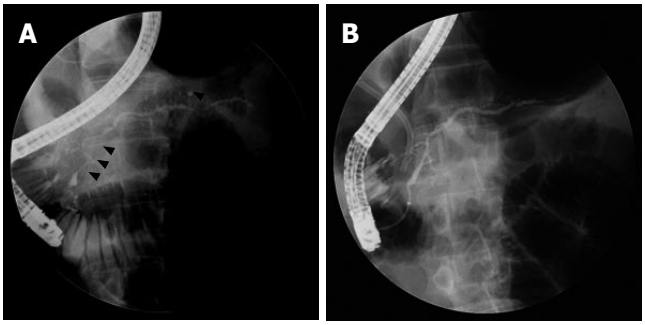

Figure 4 ERCP findings. **A:** Segmental irregular narrowing (arrow heads) of the main pancreatic duct that involves the pancreatic head and tail portion is noted in a 53-year-old man; **B:** After steroid therapy, the narrowing sites on preceding ERCP were resolved. Biliary stenting for narrowing of intrapancreatic common bile duct is noted.

At the present time, there are no references for how thin "narrowing" is. Like the size of pancreatic gland, duct diameter also varies by age, gender, and size of patient, *etc*. In the cases of AIP, most patients are elderly, which complicates matters because the diameter of the main pancreatic duct physiologically increases with age[28,29]. In patients with AIP, the ductal diameter widens to normal caliber after steroid therapy (Figures 2 and 4).

Some authors suggested that as a Japanese length criterion of direct pancreatogram, "more than 1/3" of ductal narrowing (Table 1) should be changed to "more than 1/4" because the extent of ductal narrowing was between 1/4 and 1/3 of the entire length of main pancreatic duct in some cases of AIP[30]. Actually, in our series, the extent of irregular narrowing was less than 1/3 of the entire length of main pancreatic duct in 7 of 28 (25%) patients (Figure 3, Table 3). Moreover, a variant form of AIP that is characterized by focal parenchymal swelling with a localized short stenosis of the main pancreatic duct and evident upstream dilatation has been reported[31]. Because this focal type is a rare form of AIP and mainly diagnosed after laparotomy, further discussion is beyond the scope of this review. However, studies reported that segmental narrowing progressed to diffuse narrowing on serial ERCPs without steroid treatment[32,33]. In other words, "focal" and "segmental" types can evolve into "diffuse" with time, which implies that the total length of the stricture can be less than one third at an earlier stage of the disease[32,33]. Last, "irregular wall" is another confusing term. While Japanese criteria use the term of "irregular" to portray the marginal irregularity of the narrowed ductal wall[30], we have experienced AIP patients with direct pancreatograms that reveal smooth margins not uncommonly. This may be related to the fact that pathologic specimens often reveal inflammation confined to the subepithelial space with an intact ductal epithelial lining[34,35]. Therefore, the term "irregular wall" may not always be appropriate for AIP. On the other hand, the Cambridge classification for chronic pancreatitis uses

"irregular" (*i.e.*, 'irregular dilatation' of main pancreatic duct) to describe the overall contour of the main pancreatic duct[24]. These pancreatographic findings may be explained by the heterogenous pattern of inflammatory infiltrates and fibrosis noted in pathology[34].

The intriguing point of imaging is that CT findings resembling mild acute pancreatitis are quite unusual when associating ERCP findings, which reveal diffuse or segmental irregular narrowing of the main pancreatic duct, are considered. Narrowing of the main pancreatic duct with or without intrapancreatic common bile duct stenosis on ERCP is a finding that is rarely seen in acute pancreatitis, but often in chronic pancreatitis[36]. While diffuse enlargement without calcification or stone is common in acute pancreatitis, this finding is rare in chronic pancreatitis and parenchymal atrophy is more frequently observed in ordinary chronic pancreatitis. CT findings have no evident chronic parenchymal changes in contrast to the ductal pathology detected on ERCP[37]. Coexistence of such contradicting radiologic findings (CT and ERCP) in the same patient was a rare yet peculiar association that was consistently observed in patients with AIP[38].

We believe that clinicians should vigorously obtain direct pancreatograms when patients show unusual clinical features or atypical clinical manifestation in patients suspected of pancreaticobiliary malignancies. Although direct pancreatogram holds a critical position in diagnosing AIP, hardships follow in obtaining it. Due to the possible risk related to the procedure, the visualization of pancreatic duct is not always carried out when the main pancreatic duct is not dilated on US or CT in patients with diffuse pancreatic swelling alone[39,40]. There are also pitfalls in interpreting pancreatograms. Because the main pancreatic duct is extrinsically compressed, it is technically difficult to attain whole ductal images and, sometimes, sufficient amount of contrast is not introduced into the main pancreatic duct. An "abrupt cutoff" of the main pancreatic duct may conceal a true "irregular narrowing" when ERCP is performed inadequately. Deep cannulation of catheter up to the tail portion guided by a thin guide wire can help circumvent this problem. While magnetic resonance cholangiopancreatography (MRCP) is replacing diagnostic ERCP in many pancreaticobiliary diseases, it seems to be limited in delineating the detailed pathology of main pancreatic duct associated with AIP. AIP is basically a "narrow-duct" disease and the resolution of MRCP is inferior to that of ERCP in this aspect[41,42].

Laboratory criterion

Abnormally elevated levels of serum gamma globulin and/or IgG or the presence of autoantibodies are described as the laboratory criterion of AIP by the Japan Pancreas Society[9]. In general, these features are known facets of autoimmune diseases, which provide laboratory evidence of an autoimmune pathogenesis[43]. By measuring various autoantibodies, a number of candidates have emerged for clinical usage in AIP. Detection rates for autoantibodies, however, have varied among reports[44,45]. This difference may be accounted by the number of measured autoantibodies, which can affect detection rates of autoantibodies; rates tend to increase as more autoantibodies are checked[46]. Among the conventional autoantibodies that are commonly investigated in autoimmune diseases, anti-nuclear antibody and rheumatoid factor are more frequently detected in AIP. Other markers, including anti-smooth muscle antibody and anti-mitochondrial antibody, have failed to show detection rates above 10%. On the other hand, anti-lactoferrin antibody (ALF) and anti-carbonic anhydrase II antibody (ACAII) are relatively organ-specific autoantibodies, which reveal the highest detection rates (over 50%) among autoantibodies in AIP[47]. Lactoferrin is normally present in the pancreatic acinus and carbonic anhydrase II in the ductal cells of the pancreas. ALF and ACA II, however, require a special laboratory for measurement that is unavailable to many clinicians. And, even if ALF and ACA II are measured, these markers are not 100% sensitive[48,49]. This implies that although carbonic anhydrase II and lactoferrin are considered to be the most likely target antigen for AIP, cases without ALF and ACAII, despite a good response to steroid therapy, also exist. ALF and ACAII are not specific to AIP as they may be elevated in other diseases[48,49]. Elevated levels of ACAII were also reported in patients with pancreatic cancer or ordinary chronic pancreatitis[10,50,51].

Elevated IgG and hypergammaglobulinemia are not always seen in patients with AIP. IgG4, a subtype of IgG, levels have been reported to be able to distinguish AIP from other pancreatic disorders with a high sensitivity (95%) and specificity (97%)[52]. Moreover, some cases of AIP show elevated serum levels of IgG4 in spite of normal IgG levels[53]. We, therefore, believe that both IgG and IgG4 levels should be measured in all patients suspected with AIP. In Japanese criteria, however, the increased IgG4 level was not included in the laboratory criteria and only mentioned in the appendix that there are cases with elevated levels of IgG4[9]. The Japanese criteria for laboratory data states that IgG levels should be higher than 1 800 mg/dL (normal range, 614-1295 mg/dL[54]). Although cutoff value of IgG was set at 1 800 mg/dL in Japanese criteria, another group uses different cutoff value (1 700 mg/dL) of IgG for the diagnosis of AIP[55]. If we set cutoff value of IgG at higher level, the specificity of IgG increases but the sensitivity decreases. More evidence on sensitivity and specificity according to each cutoff value should be provided for IgG before cutoff level is established.

While serologic markers have provided a base in understanding AIP, there are still controversies. As autoantibodies and IgG can rise non-specifically during the course of various injuries and diseases, the mere increment can not indicate a cause-and-effect relationship. Moreover, elevation of IgG4 level has been reported in patients suffering from pancreatic carcinoma and other types of chronic pancreatitis[50]. A number of groups have tried to find other laboratory indicators of AIP. HLA may identify patients susceptible to AIP. One report mentioned that frequencies of DRB1*0405 and DQB1*0401 were significantly higher in patients with AIP when compared with chronic calcifying pancreatitis[56]. At the present time, however, further studies are required to evaluate the value of each laboratory indicator and find a more reliable one.

Histopathologic criterion

The Japanese criteria described the histopathologic findings of AIP as marked inflammatory infiltrates mostly of lymphocytes and plasma cells and dense fibrosis of the pancreatic tissue[9]. In one report, however, lymphoplasma cell infiltration was minimal in one third of AIP cases. In general, marked infiltration of inflammatory cells is noted in early stage of an autoimmune disease, but fibrosis becomes predominant as the disease progresses. This suggests that degree of inflammatory cell infiltrates and fibrosis and predominance of either one may be dependent on the stage of AIP[57]. The characteristic lymphoplasmacytic infiltration and fibrosis may not be pathognomonic to AIP. Alcoholic chronic pancreatitis (ACP) also showed an abundant amount of lymphoplasma cell infiltration and fibrosis[58]. Although periductal inflammation and fibrosis were observed in both ACP and AIP, the detailed histologic patterns differed. While ACP mainly revealed dense interlobular fibrosis with a cirrhosis-like appearance, AIP showed loose fibrosis in both interlobular and intralobular region[58-60]. AIP showed more severe and diffuse acinar atrophy than ACP. As for extracellular matrix proteins, collagen type IV, a component of the intact basement membrane that ensures accurate regeneration of tissue, was preserved in cases associated with AIP, whereas ACP showed a significant loss of this collagen subtype[58]. Not only may this help differentiate AIP from ACP, but also aid our understanding of the regeneration of acinar structures and regression of fibrosis following steroid treatment. More specific histologic features, *i.e.*, the pattern of fibrosis and inflammation, should be supplemented for histopathologic criterion of AIP.

Periductal fibrosis and inflammatory infiltrates surrounding the duct like a cuff compress the ductal lumen into a star-like structure[61]. Intrapancreatic portion of common bile duct is often involved and the biliary involvement in AIP develops by the same mechanism as the pancreatitis[23]. Some reports of AIP show predominant neutrophilic or eosinophilic granulocytes infiltrating into the pancreatic parenchyma rather than lymphoplasma cell infiltration[62]. This acute inflammatory component of AIP is characterized by focal detachment, disruption and destruction of the duct epithelium due to invading granulocyte, which has been named "granulocytic-epithelial lesions" of the ducts. The extension and severity of chronic and acute changes in AIP vary from case to case, and even from area to area within the same pancreas.

Many clinicians come across difficulties in obtaining adequate pancreatic specimens for histologic evaluation[48]. Fine-needle aspiration biopsy often fails to gain sufficient amounts of pancreatic tissue. Large-bore needle biopsies may be used to yield adequate amounts for pathologic examinations. However, this is at the cost of increasing risks of procedure-related complications. Because of the patchy nature of inflammation seen in AIP, percutaneous biopsy may not be diagnostic due to sampling error problems[13]. Another problem is the potential risk of tumor seeding during biopsy in patients in whom cancer can not be omitted. Due to this reason, endoscopic ultrasonogram (EUS)-guided biopsy is recommended for patients in whom pancreatic cancer can not be excluded[63]. This approach is useful because the pancreatic head is the most frequently involved portion in AIP. One recent paper has reported the usage of EUS-guided trucut biopsy, which may help surmount the above problems and allow optimal histologic examination in AIP[64].

Although histologic evaluation offers a gold standard in diagnosing many disease entities, its role maybe a little different in autoimmune conditions, as seen in primary sclerosing cholangitis and autoimmune hepatitis[65,66]. In these conditions, the histopathologic findings are not disease-specific. Biopsy is often performed to exclude other entities that coexist or show resemblance rather than to make a diagnosis. Taken together, the role of histopathologic examination in patients suspected of AIP may be the exclusion of other diseases, such as malignancy, rather than the confirmation of diagnosis.

Response to the steroid

Although the dramatic response to the steroid is a well-known phenomenon in AIP, a detailed steroid schedule has not been fully established at the present time. Prednisolone is usually initiated at 30-40 mg per day and tapered after confirmation of the response to the steroid. The response to the steroid is defined as improvement in clinical symptoms, negative conversion of detected autoantibodies, normalization of elevated levels of IgG, and reversion of abnormal pancreatic imaging, including CT and endoscopic retrograde pancreatography[58]. In cases of obstructive jaundice associated with intrapancreatic common bile duct narrowing, however, biliary stenting is often needed additionally. The dose of oral corticosteroid may be tapered by 5 mg each 2-4 wk. Eventually, the steroid is completely discontinued or maintained at a dose of 2.5-10 mg/d according to the preference of the doctor[50,52,67].

The response to the oral steroid provides a circumstantial evidence of underlying autoimmune pathogenesis[68]. Among the responses to the oral steroid therapy, recovery of pancreatic ductal narrowing is top priority in the differential diagnosis of AIP. For the recovery of pancreatic ductal narrowing, histologic recovery including periductal fibrosis should be accompanied. We already reported histologic recovery, especially regression of pancreatic fibrosis in patients with AIP after steroid therapy[69]. Relief of pancreatic ductal narrowing by steroid administration is a unique and specific finding that can not be seen in any other type of chronic pancreatitis or pancreatic cancer (unpublished observation, Myung-Hwan Kim, MD). And, because marked improvement of pancreatic ductal narrowing can be observed at as early as 2 wk after steroid therapy[32,50], steroid trial may be a practical diagnostic tool that has clinical impact, especially when differentiation from cancer is an issue. This is analogous to autoimmune hepatitis where steroid treatment is justified when the entity is highly suspected, and the response to treatment is incorporated into the diagnostic scoring system[66]. If steroid therapy fails to show clinical improvement, imaging studies should be performed again to differentiate AIP from pancreatic cancer. There are opposes against

including the response to the steroid into the diagnostic criteria of AIP. They argue that steroid is not usually prescribed in any other type of chronic pancreatitis and one has to strongly suspect AIP in the first place to ever consider steroid therapy. To observe the response to the oral steroid in patients suspected of AIP, however, may be a diagnostic trial as well as therapeutic trial. Actually, in one Japanese university hospital and Italian group, they use the response to the steroid as one diagnostic criterion of AIP[50,70].

There are also concerns of the possibility of cancer progression during a trial of steroid therapy in an operable patient[6]. Despite this risk, we believe that a trial with steroids can be used to guide diagnosis when used in a proper fashion. If a patient shows typical pancreatic images of AIP, a short course (about 2 wk) of steroid may differentiate AIP from pancreatic cancer due to the fact that pancreatic ductal images of malignancy do not change[32,50]. And if the results are equivocal or do not favor AIP, the diagnosis of AIP should undergo reevaluation and the possibility of laparotomy should be considered. By including the response to the steroid into the diagnostic criteria, we can overcome the fact that there are patients who do not satisfy laboratory data and histologic findings, yet reveal typical images and an excellent response to the steroid.

Association of other postulated autoimmune diseases

Autoimmune diseases tend to cluster, and one patient may have more than one autoimmune conditions[43]. This is also the case in AIP which is frequently associated with Sjögren's syndrome, retroperitoneal fibrosis, primary sclerosing cholangitis, primary biliary cirrhosis, and inflammatory bowel disease[71]. This association may be explained by the fact that carbonic anhydrase II and lactoferrin are present in the salivary gland and biliary duct as well as the pancreas. An autoimmune response against these common antigens may result in "autoimmune exocrinopathy" which describes an autoimmune disease that involves multiple exocrine organs[72]. On the basis of the absence or presence of a systemic autoimmune diseases, Okazaki *et al*[14] divided AIP into 2 major groups: Primary or secondary forms of the disease. In contrast to the Japanese criteria, Italian group has included the association of other postulated autoimmune disease into their diagnostic criteria of AIP (Table 4)[50].

The prevalence of other postulated autoimmune diseases, however, varies among papers with some reporting rates that exceed 50%[50]. Comorbidities are manifested at various time points on the natural course of AIP; some manifest before AIP and some simultaneously and others after remission[32]. Thus, primary form of AIP may need to be changed to secondary form in cases where other autoimmune diseases are not recognized at diagnosis of AIP but develop later. For patients with AIP, the presence of an associated autoimmune disease may help the diagnosis, but if not present at the onset of the disease, we must carefully search for it.

In addition, pancreatitis in patients suffering from other autoimmune diseases does not always indicate that the cause of pancreatitis is autoimmunity. For example, when pancreatitis occurs in patients with systemic lupus erythematosus, pancreatitis can be related to various causes, such as vasculitis or medications[73]. This also adds confusion in reporting AIP in patients with underlying autoimmune conditions. In these cases, the remarkable response to steroids can help identify autoimmunity as the cause of pancreatitis[74].

REVISED DIAGNOSTIC CRITERIA FOR AIP: OUR PROPOSAL

The Japan Pancreas Society proposed diagnostic criteria in 2002 (Table 1). In our experience, a considerable number of cases of AIP is diagnosed confidently when these criteria are applied. Clinicians, however, reported cases that benefited with steroid therapy that did not satisfy the criteria[11]. In our study, 9 of 28 (32%) patients with AIP did not fulfill Japanese criteria, yet responded to the steroid (Table 3). In other words, clinicians may miss a substantial portion of patients suffering from AIP when the diagnosis is confined to those who satisfy the criteria proposed by the Japan Pancreas Society.

On the basis of a single institute experience of 28 patients, we introduce the following system for the diagnosis of AIP (Table 5). We have designed a system where patients are stratified by evidence strength for AIP into "definite", "probable" and "possible". We respect the diagnostic criteria proposed by the Japan Pancreas Society and believe that it contains the strongest findings that support the diagnosis of AIP. Some of the original descriptions create confusion and the diagnostic criteria are not completely satisfactory. Descriptions have been, therefore, rephrased and the diagnostic criteria have been expanded to include more patients who can benefit from this diagnosis. While "definite" AIP is almost same as the original Japanese criteria, those who only reveal typical pancreatic images of AIP are diagnosed as "possible" AIP. This is because the combination of pancreatic imaging (CT and ERCP) seen in AIP is quite distinctive and rarely seen in any other disease entity. When other postulated autoimmune diseases are associated with typical pancreatic images of AIP, the suspicion index becomes higher and patients are designated as "probable" AIP. The diagnosis of AIP is confirmed by the unique response to steroid that can be observed by the dramatic resolution of pancreatic ductal narrowing, and then patients are reassigned to "definite".

We believe that patients who present with typical pancreatic images of AIP deserve a short course of steroids before undergoing surgical resection, despite the lack of any serologic markers of autoimmunity or

Table 5 A proposal of revised diagnostic criteria for autoimmune pancreatitis

Diagnostic Criteria
Criterion I. Pancreatic imaging (essential)
(1) CT: Diffuse enlargement (swelling) of pancreas
and (2) ERCP: Diffuse or segmental irregular narrowing of main pancreatic duct
Criterion II. Laboratory findings
(1) elevated levels of IgG and/or IgG4
or (2) detected autoantibodies
Criterion III. Histopathologic findings
Fibrosis and lymphoplasmocytic infiltration
Criterion IV. Association of other postulated autoimmune disease
Definite
I+II+III+Ⅳ or I+II +III or I+II or I+III
Probable, I+IV; Possible, I only: Rediagnosed as "definite" if "response to the steroid" is present

Table 6 General features of autoimmune diseases

General features of autoimmune diseases

2 Lymphoplasma cell infiltration and fibrosis at lesional site
3 Association with other autoimmune diseases
4 Response to the steroid

pathognomonic histopathologic findings. The results of serologic markers and histologic examination in patients with AIP may be closely related to the disease activity (active *vs* inactive) or the stage (early *vs* late) of the disease. In our proposal, therefore, a diagnostic trial of steroid can be initiated even though serologic markers or pathologic findings do not fulfill the Japanese criteria or are not available, providing that pancreatic images are typical to AIP.

The Japan Pancreas Society emphasizes imaging (CT and ERCP) criterion and serologic abnormalities as important and relatively specific markers for this entity, while they do not use "the response to the steroid" and "association of other postulated autoimmune diseases" as diagnostic criteria (Table 1). However, Italian experience does not believe imaging findings and serologic abnormality are specific (Table 4). In our revised diagnostic criteria (Table 5), pancreatic imaging (CT and ERCP) is also essential and the findings are almost same as Japanese criteria. Instead, we abolished the condition "more than 1/3 of the entire length of main pancreatic duct" and added "segmental" irregular narrowing. In the laboratory criterion, we newly inserted elevated serum IgG4 level. Consequently, more patients may benefit from oral steroid therapy and can avoid unnecessary major operation. In addition to pancreatic imaging, we included the response to the steroid and association with other postulated autoimmune diseases in the diagnostic criteria, in order to reduce cases that might be occluded by the Japanese criteria. It is already well known that the general features of autoimmune diseases include detected serum autoantibodies or elevated IgG, lymphoplasmacytic infiltration and fibrosis at the lesional site, response to the steroid and association with other autoimmune diseases (Table 6)[68]. Among the general features of autoimmune diseases, one feature does not have more evidence of strength to be superior to the others in the diagnosis of AIP. We, therefore, used all aforementioned features of autoimmune disease for the diagnosis of AIP.

CONCLUSION

Autoimmune chronic pancreatitis (AIP) is a relatively new disease entity to many physicians, yet because of the clinical impact, they must vigilantly look for it. This review discusses several potential limitations of current diagnostic criteria for this increasingly recognized condition. The manuscript is organized to emphasize the need for convening a consensus to develop improved diagnostic criteria. These efforts will refine the diagnosis of AIP, which will lead to less inter-observer variation and provide a strong base for the research of this treatable condition.

Abstract

Anastomotic disruption is a feared and serious complication of colon surgery. Decades of research have identified factors favoring successful healing of anastomoses as well as risk factors for anastomotic disruption. However, some factors, such as the role of mechanical bowel preparation, remain controversial. Despite proper caution and excellent surgical technique, some anastomotic leaks are inevitable. The rapid identification of anastomotic leaks and the timely treatment in these cases are paramount.

Key words: Colon; Colectomy; Anastomosis; Surgical complications

INTRODUCTION

Anastomotic leakage following colorectal resection and primary anastomosis is a major clinical problem. The increased morbidity and mortality following anastomatic leakage are considerable, and lead to prolonged hospital stay. Leakage after partial colectomy with primary anastomosis may result in abscess formation, sepsis, multiple procedures and death. Despite vast improvements in surgical technique and devices, anastomotic leakage continues to be a clinical problem. The prevalence of intraperitoneal anastomotic leak varies in the literature between 0.5% and 30%, but is generally between 2% and 5%[1-3]. The double staple anastomotic technique does not appear to increase the risk for anastomotic leak, which has been reported to be 2.7%[4].

There are many factors that contribute to anastomotic leakage. Certainly, poor surgical technique can lead to an anastomotic leak. However, even when the operation is done technically well, anastomotic leaks are inevitable. Hence, a great deal of research has been done to elucidate the factors, which may decrease the rate of anastomotic leaks. Several factors have been identified that may impact on anastomotic leakage: adequacy of blood flow to the anastomoses, contamination, anastomotic technique, the presence of a pelvic drain, anastomotic tension, absence of active disease or distal obstruction, and the distance from the anal verge[5].

Numerous different techniques have been used to fashion a colorectal anastomosis. These techniques can be divided into 2 categories: hand sewn or stapled anastomosis. Hand sewn techniques include single-layer interrupted or continuous with either absorbable or nonabsorbable sutures, or various double layer techniques. The advent of stapling devices in the last century has made a significant contribution to colorectal surgery. Stapling devices have been widely accepted by surgeons performing gastrointestinal surgery. Numerous studies have been conducted comparing the various anastomotic techniques. Debates have been raised comparing single *versus* double-layered closure, absorbable *versus* nonabsorbale sutures, sutures *versus* staples, and inverting *versus* everting techniques. None of the various methods of anastomosis has been proven to be superior to the others.

HISTORY

During the early 19th century, while writing on intestinal injuries, Travers stressed the uniform contact of cut ends of intestine utilizing everting sutures. Later that century, Lembert countered this idea, instead advocating inverting sutures with serosal to serosal contact. Halsted noted that the submucosal layer was the strength-bearing layer in intestinal anastomoses. By the time that Treves published "A System of Surgery" in 1895 "Lembert Sutures" were recommended in intestinal anastomoses. The first acclaimed mechanical device to create a non-sutured anastomosis was Murphy's button introduced in 1892. It consisted of two mushroom shaped pieces, which were secured within bowel ends by purse string sutures. The pieces were then joined together. The bowel would heal as an inverted anastomosis. The excess inverted tissue would slough and the intact "button" would pass per rectum. Murphy's button gained considerable acceptance for several decades.

Circular end-to-end stapling devices were developed in the Soviet Union during the 1950s. The KT, PKS and SPTU instruments were bulky and unwieldy but served as the prototypes for today's end-to-end staplers[6]. A Soviet instrument was brought to the United States by Ravitch in 1958. Subsequently, such devices have been manufactured in the United States but did not attain widespread use until the 1970s. Thus, today's surgeon has the option of suturing or stapling intestinal anastomoses.

RISK FACTORS

Numerous risk factors have been implicated as predisposing for anastomotic leaks. Schrock *et al*[7] performed a large retrospective analysis of factors relating to leakage of colonic anastomoses. Factors that were found to correlate with an increased leakage rate were older age, anemia, prior radiation therapy, intraperitoneal infection and anatomic level of anastomosis. Conversely, steroid use, nutritional status and experience of the operating surgeon did not significantly influence the anastomotic leak rate. Rullier *et al*[8] analyzed factors associated with leakage and reported male sex and level of anastomosis as independent risk factors. In the same study, low anastomoses in obese patients were reported as associated with higher risk of leak. A higher leak rate with low pelvic anastomosis has also been reported by other investigators[9].

In a more recent study, Makela *et al*[10] compared 44 patients with anastomotic leaks to 44 control patients matched for age, gender and indications for surgery. They found that malnutrition, weight loss, alcohol intake, lengthy operative times, peritoneal contamination, and blood transfusions were independent predictors for leaks. In addition, the presence of multiple risk factors increased the risk for anastomotic leaks.

Law *et al*[11] performed a prospective study to identify risk factors for anastomotic leak in 196 patients undergoing total mesorectal excision for rectal cancer ranging from 3 cm to 12 cm from the anal verge. The overall leakage rate was 10.2%. The leakage rate was significantly higher in men (13.4%) as compared with women (5.2%) ($P=0.049$). As expected, the presence of a proximally diverting stoma significantly decreased the leakage rate especially in patients with risk factors for anastomotic dehiscence and low pelvic anastomosis. Interestingly, ages, level of anastomosis, stage of disease, or techniques of anastomosis were not significant predictors of anastomotic leak.

Mechanical forces

Investigators have used strength measurements to assess colonic healing using either breaking strength or bursting strength[12]. The breaking strength represents the uniaxial force required to break a wound *in vitro* and is a test of the entire anastomotic line. The bursting strength is a multiaxial test that measures the weakest point of an intestinal anastomosis which is the most likely location of an anastomotic leak[13].

The mechanical strength of an anastomosis is related to whether an anastomotic leak occurs. The strength of an anastomosis is dependent on the deposition of collagen. The measurement of tissue collagen content is another tool used in experimental models[14]. Martens *et al*[15] demonstrated that increased production of collagen at the anastomotic site was present 12 h after surgery. Brasken *et al*[16] showed that large amounts of type I and III collagen were present on postoperative day 4 in the anastomosis. In support of Halsted's observations, it is generally appreciated that the ultimate strength of an anastomosis depends on the collagen content in the submucosa.

Nutrition

Bowel rest (with a low-residue diet) lowered the bursting strength of non-operated colon in rats[17]. Interestingly, however, it did not impair the strength of a healing anastomosis. Dietary protein depletion impairs colonic strength in healing rat colon. Data regarding the duration of protein depletion needed to impair colonic healing in rats is conflicting. While some studies suggest that as little as one week of protein depletion has a detrimental effect, others suggest that at least 7 wk of protein restriction are needed[18,19]. In a comparison of alimentation means, Kiyama *et al*[20] showed that colonic anastomoses in rats were stronger after enteral nutrition compared to parenteral nutrition.

Bowel preparation

The role of preoperative bowel preparation has become a matter of controversy. Poth EJ[21] in 1953 proposed use of neomycin and sulfathalidine for intestinal antisepsis with reduction in the postoperative complications. Nichols RL and Condon R[22] also suggested a historic reduction in mortality and morbidity with the use of bowel preparation in a collective review of literature. In a 1973 retrospective study, Irvin TT and Goligher JC[23] reported a significant decrease in anastomotic dehiscence with the use of mechanical bowel preparation than that without mechanical bowel preparation (7% *vs* 24%). Most of the reports favoring the use of mechanical bowel preparation are based on retrospective data. However, some randomized trials have reported significant differences in outcomes with use of oral antibacterial agents and mechanical preparation. Matheson *et al*[24] reported a significant reduction in the incidence of wound sepsis and anastomotic dehiscence using both a mechanical and antibiotic preparation.

In contrast, recent literature suggests no significant advantage utilizing aggressive mechanical preparations. To assess the need for mechanical preparation to decrease the rate of anastomotic leaks in elective colorectal surgery, a number of prospective randomized trials have been completed[25-28]. Recently, Guenaga *et al*[29] conducted a meta-analysis on the existing clinical trials which studied the effect of mechanical bowel preparations on the rate of anastomotic leaks. A total of 1204 patients were enrolled in the various studies. Patients were divided into 2 groups: Group 1 ($n=595$) which received a mechanical bowel preparation; and group 2 ($n=609$) without a mechanical bowel preparation. They showed that the rate of anastomotic leaks in group 1 was obviously higher (5.5%)

compared to group 2 (2.9%) ($P=0.02$). Clearly, controversy exists on whether mechanical bowel preparations influence the rates of anastomotic leaks in elective colorectal surgery. Recent meta-analysis and prospective trials have questioned the usefulness of mechanical bowel preparations and do not support its use.

Chemo-radiation

Preoperative chemo-radiation has been used in patients with rectal carcinoma and reductions in tumor size can be achieved with its use. Chemo-radiation may predispose to anastomotic problems in patients having colon surgery, particularly in patients with anastomosis in the pelvis. Many surgeons perform a temporary diverting stoma to minimize the consequences of anastomotic disruption in patients who have had pelvic radiation therapy[30]. Anastomotic leak and radiation therapy may contribute to the formation of pelvic fibrosis, rendering the neorectum stiff and noncompliant. After reconstruction, patients may suffer from tenesmus and fecal incontinence[31].

Since many colectomies are performed for cancer, the effects of common chemotherapeutic agents and external beam irradiation on colonic healing are of interest. Immediate post-operative administration of intravenous 5-flourouracil (5-FU) in rats undergoing colectomy resulted in more conflicting data. While 4-8 mg/(kg.d) for 10 d impaired breaking strength of rat colon[32], 20 mg/(kg.d) for 5 d had no significant effect compared to controls[33]. A third study on rats showed that 600 mg/m^2 of 5-FU in the early postoperative period had no effect on colon anastomotic bursting strength[34].

In a study on rats, preoperative vitamin A supplementation protected against impaired colonic healing caused by preoperative radiation therapy[35].

Del Rio *et al*[36] showed that chronic steroids (time released via subcutaneous route) impaired colonic anastomotic strength in rats. In contrast, a large retrospective review in humans suggested no steroid effect[7].

Surgical technique

The technique used to fashion a colorectal anastomosis is largely based on surgeon preference. In order to achieve an adequate colonic anastomosis with a low rate of post-operative anastomotic leak or stricture formation, certain basic surgical principles must be met. First, the technique utilized for the anastomosis must assure an adequate lumen. Second, an adequate blood supply must be maintained for both the proximal and distal colon after resection. Finally, the anastomosis must be performed so that there is no tension to pull it apart (i.e., the surgeon must assure adequate mobilization of the proximal and distal colon). Considerable investigation has been conducted during the last century to determine the best technique for colonic anastomoses. An intestinal anastomosis may be constructed by a variety of techniques, including single layered suture, double layered suture, interrupted or continuous sutures, absorbable or nonabsorbable sutures, stapling devices or with use of a biofragmentable ring. To date, no single technique, single layer suture, double layer suture or stapling has ever been definitely demonstrated to be superior in preventing anastomotic leaks[37,38].

Table 1 Prospective randomized trials comparing the effect of mechanical bowel preparation *versus* no preparation on anastomotic leaks in elective colorectal surgery (*n*, %)

Investigators	Number of patients	Bowel preparation group (leak rate)	No bowel preparation group (leak rate)	*P*
Miettinen *et al*[25]	267	4%	2%	0.28
Zmora *et al*[26]	380	3.7%	2.1%	0.50
Santos *et al*[27]	149	10%	5%	0.52
Burke *et al*[28]	186	7.8%	11%	0.90

Surgical technique has been extensively studied in animal models. When comparing inverting *versus* everting sutured techniques, the everting technique produced less inflammation and less stricture but the inverting technique was less likely to disrupt[39,40]. (Table 1) This was also supported by the work of Irvin *et al*[41] in both animal as well as human studies. In addition, they reported no difference in the two layered *versus* single layer inverting anastomosis technique when doing intestinal anastomosis[41,42]. With disruption being the most serious problem, the inverting technique is more commonly used.

Stapled *versus* various sutured anastomoses have been compared numerous times in animal models. In a detailed study in dogs, Chung *et al*[43] showed a single layered sutured anastomosis resulted in the least reduction in anastomotic blood flow. Stapled anastomoses reduced blood flow the most. Conversely, Kozol *et al*[40] showed that early anastomotic edema was greater in two layered sewn anastomoses than in stapled. It should be noted that in some clinical circumstances, the surgeon's choice of technique is limited. For example, it is generally accepted that for low pelvic colo-rectal anastomoses stapled techniques are easier to perform.

Numerous clinical studies have been performed to define the anastomotic leak rate using sutures (Table 2). The largest of these studies was conducted by Max *et al*[44] in 1000 patients. A retrospective study was performed in 1000 consecutive patients who underwent a single layer continuous polypropylene colorectal anastomosis. The clinical anastomotic leak rate was only 1%[44-47].

Similarly multiple studies have been performed utilizing the stapled technique for colorectal anastomoses (Table 3). The leak rates from these studies ranges from 1.5% to 11%[4,48-54]. The largest of these studies was conducted by Detry *et al*[48]. A prospective study was performed in 1 000 consecutive patients undergoing stapled colorectal anastomosis by a single surgical team. The clinical leak rate was 3.5%. Also, Hansen *et al*[53] performed a large prospective study in 615 patients who underwent stapled colorectal anastomoses by a total of 18 surgeons, showing only 1.5% clinical leak rate.

Specific studies have been performed comparing stapled and sutured colorectal anastomoses (Table 4)[55-58]. Docherty *et al*[55] conducted a randomized prospective multicenter trial in 732 patients undergoing either hand-sewn ($n=321$) or stapled ($n=331$) colorectal anastomoses. The location of the anastomosis included ileocolic, colocolic, colorectal, and colostomy closures. There was no difference in the stapled or sutured group with regards to rate of anastomotic leakage. Demetriades *et al*[58] conducted

Table 2 Clinical studies utilizing sutures for fashioning colorectal anastomosis

Investigators	Number of patients	Types of suture	Continuous *vs* interrupted	Leak rate (%)

NS = not significant.

a prospective multicenter trial comparing hand-sewn to stapled colonic anastomosis in the emergent penetrating trauma setting. A total of 207 patients were enrolled in the study from 19 different centers. All patients underwent colon resection with primary anastomosis. There were 128 hand-sewn anastomoses and 79 stapled anastomoses. The demographics of both groups were similar with respect to age, gender, mechanism of injury, associated injuries, and fecal contamination. They demonstrated that there was no statistically significant difference in the 2 groups with respect to anastomotic leaks.

Surgeons have attempted several intraoperative techniques in hopes of lowering anastomotic leak rates. One is "omentoplasty" which involves wrapping the anastomosis with omentum. This was prospectively studied by the French Associations for Surgical Research[59]. In their randomized study of 705 patients, omentoplasty did not decrease the anastomotic leak rate or the clinical severity of anastomotic leaks compared to the patients without omentoplasty. Some surgeons have routinely placed a pelvic drain after low anterior resections. In a prospective, randomized study of 319 patients, the same French investigators showed that routine pelvic drainage did not lower the rate or severity of anastomotic leaks[9,60].

Many surgeons utilize intraoperative air/water testing of colon anastomoses. With this technique, after completing the anastomosis, the patient is placed in reverse Trendelenburg position. The pelvis is filled with sterile saline solution and an assistant places a sigmoidoscope (flexible or rigid) into the rectum, below the anastomosis. The colon is then insufflated with air, and the surgeon views the pelvic saline bath for bubbling (a sign of an inadequate or leaky anastomosis). If bubbling is seen, the leak is identified and repaired with sutures. There are at least two studies of the efficacy of this technique. In a study of 145 patients, Beard *et al*[61] were able to lower the "radiologic" leak rate from 29% to 11% using air/water testing in order to plan the placement of additional sutures as needed. In a study of 82 patients, Pritchard *et al*[62] found the air/water test helpful in higher anastomoses but unreliable in very low anastomoses. This may be due to the difficulty in suture repairing very low anastomoses.

In many series, the leak rates were higher for anastomoses below the peritoneal reflection[8,63,64]. One large study revealed a 12.7% leak rate in colorectal anastomoses compared to 2.9% in colo-colonic anastomoses[65]. Anastomotic leak can be a serious complication of resection for low rectal resection. Several studies have been conducted to identify risk factors that contribute to anastomotic dehiscence in patients undergoing low anterior resection (LAR) and proctectomy with coloanal anastomosis. Leaks after coloanal anastomoses are no more frequent than with colorectal anastamoses with a range of 6% to 8%[66,67]. Certain risk factors are more frequently associated with rectal resection. Meade *et al*[68] reported that a distance of less than 5 cm from anal verge, male sex, alcoholism and smoking were the risk factors for anastomotic breakdown after low rectal resections. Similar results were reported by Rudinskaite *et al*[69].

Law *et at.* investigated operative results and oncological outcomes of anterior resection for rectal and rectosigmoid cancer. They reported a significantly higher leak rate (8.1%) in patients who underwent a total mesorectal excision than those who underwent partial mesorectal excision (1.3%). Additionally, they reported that higher anastomotic leakage rate was associated with the male gender, absence of stoma, and increased blood loss[70]. Recently, Matthiessen *et al*[71] reported similar results, but they did not report any advantage of performing a temporary stoma. It should be noted that the creation of a proximally diverting stoma to protect a low pelvic or technically inadequate anastomosis does not alter the risk for dehiscence but does ameliorate the septic effects of the leak[7,71,72].

Recently, emphasis on the quality of surgical care offered has increased tremendously. There is an increasing awareness of the outcomes of surgical care as a marker of quality. Dimick *et al*[73] reported lower mortality rates in patients undergoing surgery for colorectal cancer when these procedures were performed in high volume centers. Similarly, Hannan *et al*[74] suggested an inverse relationship between in-hospital mortality rates and case volume for patients undergoing certain procedures. They reported that individual physician volume has more significant influence on the mortality rates for certain procedures. The same

authors[75] recently reported a significant reduction in mortality of patients who underwent colectomy when these procedures were performed by high-volume surgeons at high-volume centers. Conversely, the data reported by Urbach *et al*[76] did not support superior outcomes when colon operations were done at high volume centers.

CLINICAL PRESENTATION AND DIGNOSIS

Anastomotic leakage typically occurs between the 3rd and the 6th post-operative days. The clinical manifestation of anastomotic dehiscence varies in magnitude from failure to thrive to profound sepsis. The presentations in a given patient depend, in part, on the location and magnitude of the leak, and whether any adjacent tissues such as omentum or small intestine contain the leak. Indeed, a less severe leak may be walled off by adjacent organs or omentum and may present with vague abdominal pain, failure to thrive, temperature elevation, tachycardia, prolonged ileus, diarrhea or intestinal obstruction. Recognition of this situation may be delayed as the nonspecific symptoms can be attributed to delayed recovery from a major operation rather than to an anastomotic failure. However, the physician must have a high index of suspicion to make an early diagnosis. Most patients with anastomotic dehiscence will have prolonged ileus, increased postoperative abdominal pain, fever, and leucocytosis. However, the spectrum can include sepsis, peritonitis and/or hemodynamic instability. Longo *et al*[77] described the initial symptoms in 56 patients with postoperative pelvic abscess that developed after colon surgery, showing that 93% had intestinal dysfunction and 4% were in shock.

The presence of the aforementioned risk factors should raise the index of suspicion for leaks. Suspicion of a leak should lead to diagnostic imaging. A gastrografin enema is a quick and inexpensive way to evaluate the integrity of a colonic anastomosis. A gastrografin enema is less useful for right colonic anastomoses because it becomes too dilute to accurately define the anastomosis. A CT scan with intravenous, oral and rectal contrast material may also be obtained in those patients with suspected anastomotic leak and should demonstrate any abscess or extravasation of contrast from the intestine. Barium enema should not be used in this circumstance because of the increase in morbidity and mortality associated with barium-induced peritonitis. Indium-labeled leukocyte scans are occasionally helpful to identify abdominal abscesses that are suspected but not seen using conventional imaging.

MANAGEMENT

The specific method of management of an anastomotic dehiscence depends on the manifestation of the leak and the clinical condition of the patient. As many as 36% to 49% of patients with a pelvic anastomosis will have a leak demonstrated when gastrograffin enemas are routinely used during the first postoperative week[78,79]. Most of these are "subclinical" leaks. In a patient with evidence of low-grade sepsis and documentation of a contained anastomotic leak with abscess, drainage of the abscess and broad-spectrum parenteral antibiotic therapy are required and may be sufficient therapy. Drainage of an abscess can be accomplished percutaneously or operatively. A CT scan of the abdomen and pelvis with intravenous, oral, and rectal contrast medium is advocated whenever an anastomotic leak and abscess is suspected. CT scan is highly sensitive and accurate (95%) in determining the presence of abdominal or pelvic abscess[80]. CT-guided percutaneous drainage is successful in as many as 85% of appropriately selected patients[81]. For a low colorectal anastomosis, abscess drainage can be accomplished through the anastomosis if the dehiscence is readily apparent at endoscopic examination. The defect can be gently enlarged to allow better drainage, and transrectal drains can be placed in the cavity for continuous or intermittent irrigation. Transvaginal and transperineal drainage can also be performed.

Clinically ill patients with sepsis, pain and tenderness will require reoperation. Creation of a proximal colostomy or ileostomy plus peritoneal lavage and placement of drains are indicated. Some studies have advocated proximal diversion without resection if the anastomosis has been used with good results[82,83].

Gross peritonitis requires laparotomy, resection of the anastomosis with end colostomy and mucous fistula or Hartmann pouch. Diversion alone without resection of the leaking anastomosis is not ideal because of persistent sepsis from the leaking anastomosis. In such cases, wide drainage of the anastomosis should be performed. Repair of the anastomosis, either alone or in combination with a proximal stoma, is not recommended because of the high risk of recurrent anastomotic failure and/or anastomotic stricture in the presence of intra-abdominal sepsis.

Unrecognized anastomotic leaks may present as enterocutaneous fistulas. A fistulogram and/or CT scan should be obtained to determine the site of the defect in the intestine and whether any undrained collection of pus is present. Any adjacent fluid collection should be drained to facilitate closure of the fistula. After control of the source of sepsis and in the absence of distal bowel obstruction or a foreign body, the majority of colocutaneous fistulas will close without operative intervention. Other important management guidelines include correction of anemia and fluid and electrolyte abnormalities, excellent wound care, and adequate nutrition. Bowel rest and total parenteral nutrition may be necessary to facilitate closure. A late manifestation of unrecognized anastomotic leaks is anastomotic stricture. Strictures may require endoscopic dilation. Refractory strictures will require surgical revision or resection and reanastomosis.

CONCLUSION

In summary, surgeons should be aware of risk factors for colonic anastomotic leaks. The ideal is avoidance of a colonic anastomotic leak by use of proper surgical technique. In fashioning a colorectal anastomosis, some basic surgical techniques must be followed to have an acceptable result. These include the presence of adequate blood flow to the anastomosis, minimal

contamination, absence of anastomotic tension, absence of active disease, and no distal obstruction. The utility of preoperative mechanical bowel preparation in decreasing the anastomotic leak rate has been questioned by findings from several recently performed randomized prospective studies. The use of sutures or staples to create a colorectal anastomosis has never been shown to significantly alter the anastomotic leak rate.

Even when excellent surgical technique is used, a small percentage of leaks are inevitable. Characteristics, such as male gender, obesity, level of anastomosis, peritoneal contamination, age, operative time and blood transfusions, have all been implicated as potential risk factors for anastomotic leakage in various studies[84]. The clinicians must have a high index of suspicion to diagnose an anastomotic leak early. If a leak occurs, it must be identified and treated expediently. Treatment is based on the patient's conditions and the magnitude of the leak.

Abstract

AIM: To investigate the incidence of various types of postoperative pulmonary complications (POPCs) and to evaluate the significance of perioperative arterial blood gases in patients with esophageal cancer accompanied with chronic obstructive pulmonary disease (COPD) after esophagectomy.

MEHTODS: Three hundred and fifty-eight patients were divided into POPC group and COPD group. We performed a retrospective review of the 358 consecutive patients after esophagectomy for esophageal cancer with or without COPD to assess the possible influence of COPD on postoperative pulmonary complications. We classified COPD into four grades according to percent-predicted forced expiratory volume in 1 s (FEV1) and analyzed the incidence rate of complications among the four grades. Perioperative arterial blood gases were tested in patients with or without pulmonary complications in COPD group and compared with POPC group.

RESULTS: Patients with COPD (29/86, 33.7%) had more pulmonary complications than those without COPD (36/272, 13.2%) ($P < 0.001$). Pneumonia (15/29, 51.7%), atelectasis (13/29, 44.8%), prolonged O_2 supplement (10/29, 34.5%), and prolonged mechanical ventilation (8/29, 27.6%) were the major complications in COPD group. Moreover, patients with severe COPD (grade ⅡB, FEV1 < 50% of predicted) had more POPCs than those with moderate(grade ⅡA, 50%-80% of predicted) and mild (grade Ⅰ ≥ 80% of predicted) COPD ($P < 0.05$). PaO_2 was decreased and $PaCO_2$ was increased in patients with pulmonary complications in COPD group in the first postoperative week.

CONCLUSION: The criteria of COPD are the critical predictor for pulmonary complications in esophageal cancer patients undergoing esophagectomy. Severity of COPD affects the incidence rate of the pulmonary complication, and percent-predicted FEV1 is a good predictive variable for pulmonary complication in patients with COPD. Arterial blood gases are helpful in directing perioperative management.

Key words: Chronic obstructive pulmonary disease; Arterial blood gas; Esophageal cancer; Complication

INTRODUCTION

Radical esophagectomy remains the most effective method in patients with esophageal cancer, and the five-year survival rate of 40% or higher can be achieved[1-3]. However, esophagectomy may be one of the greatest surgical operations. Postoperative pulmonary complications (POPCs) are common after esophagectomy[4,5].

Chronic obstructive pulmonary disease (COPD) is a common fatal disease in China. Postoperative pulmonary complication after thoracotomy is the major complication in patients with COPD[6-8].

COPD is considered as an important risk factor for pulmonary complications due to low cardiopulmonary reserve[9-12]. However, the incidence of each type of complications and its relationship with percent-predicted FEV1 after esophagectomy in patients with COPD are unclear.

Our study was to document the effect of COPD on complication rates and the incidence of various types of pulmonary complications in esophageal cancer patients with or without COPD following esophagectomy, to elucidate the relationship between percent-predicted FEV1 and pulmonary complications and to evaluate the change and significance of arterial blood gases after operation in patients with COPD.

MATERIALS AND METHODS

A total of 358 patients who underwent esophagectomy at Beijing Friendship Hospital and Peking University First Hospital between July of 2001 and March of 2005 were included in this study. Eighty-six of the 358 patients were diagnosed having COPD.

We divided COPD into 4 grades: grade Ⅰ: percent predicted FEV1%p ≥ 80 and FEV1/FVC< 70%(45 cases); grade Ⅱ A: 50% ≤ FEV1%p < 80%, FEV1/FVC < 70% (32 cases); grade Ⅱ B: 30% ≤ FEV1%p < 50%, FEV1/FVC < 70% (9 cases); gradeⅢ: FEV1%p < 30%, FEV1/FVC < 70% (0 case).

Table 1 summarizes the patient characteristics. The two groups were similar in terms of age, sex, presence of other medical conditions, type and duration of operation, cancer stage, anastomosis site, blood loss and serum albumin. All patients underwent radical resection of tumors in the middle or lower third thoracic esophagus which were confirmed to be squamous cell cancers of esophagus after surgery. In our study, patients with tumor of the cervical and upper third thoracic esophagus were excluded because of different oncological characteristics and treatment protocols.

Basic hematological and biochemical tests, pulmonary function tests, electrocardiograph, chest CT scan, abdominal ultrasonography, barium contrast study and endoscopy were carried for all patients.

Patients were advised to stop smoking and to quit of alcohol two weeks prior to operation. Patients with hypercapnia and pulmonary hypertension were excluded. All patients in our study did not receive preoperative chemotherapy and chemoradiotherapy.

Esophagectomy via a left thoracotomy approach or cervical left thoracotomy approach was performed. Reconstruction of intestinal continuity was restored with a stomach placed in the left thoracic cavity or via orthotopic route when the anastomosis was carried out in the neck. The circular stapler was used when anastomosis was performed in the thoracic cavity and a hand-sewn anastomosis was done when it was in the neck. All patients received intravenous nutrition and continuous gastrointestinal decompression after esophagectomy.

All patients were followed up after surgery and complications occurring during the patient hospitalization were recorded. For this study, pulmonary complications were defined to include: pneumonia (manifesting fever, productive cough, increased white blood cell count, and marked infiltration on chest roentgenogram), atelectasis (manifesting segmental or lobar's atelectasis on chest roentgenogram without bronchial stenosis), pulmonary abscess (displaying intrapulmonary air containing space on chest roentgenogram and purulent exudation in the pleural cavity with fever and increased white blood cell count requiring drainage and antibiotic therapy), prolonged O_2 supplement (protracted supplemental oxygen≥14 d), acute respiratory distress syndrome(ARDS; PaO_2:FiO_2 ratio less than 250 for more than 24 h with pulmonary infiltrates, without clinical suspicion of volume overload, deterioration of respiratory status needing mechanical ventilatory support), and prolonged mechanical ventilation ≥2 d[4,6,9,13]. Postoperative pulmonary complications studied included pulmonary parenchyma but not complications of pleural cavity such as hemothorax, pneumothorax, thoracic abscess, chylothorax, pleural effusion, mediastinal emphysema.

Table 1 Baseline characteristics of study population with or without COPD undergoing transthoracic esophagectomy

Characteristics	COPD (*n* = 86, %)	Non-COPD (*n* = 272, %)	*P* value
Age, yr	61.3±5.5	63.2±7.1	0.522
Sex (male:female)	63/23	191/81	0.638

Ⅱ	48 (55.8)	145 (53.3)	0.685
Ⅲ	21 (24.4)	71 (26.1)	0.115
Ⅳ	0	0	-
Site of anastomosis			
Neck	32 (37.2)	108 (39.7)	0.679
Chest	54 (62.8)	164 (60.3)	0.679
Duration of operation (min)	162.75±51.05	185.15±66.24	0.239
Blood loss (mL)	365.50±219.36	434.00±232.48	0.344
Low serum albumin (<35g/L)	25 (29.1)	89 (32.7)	0.526
Spirometry			
FEV1 (L)	1.6±0.3	2.3±0.5	< 0.01
FEV1,% predicted	51.5±10.5	80.4±13.1	< 0.01
FEV1/FVC,%	57.6±8.9	73.3±6.8	< 0.01
DLCO,% predicted	83.7±13.4	85.0±13.9	0.774

FEV1 = forced expiratory volume in 1 s; FVC = forced vital capacity; DLCO = diffusion capacity of the lung for carbon monoxide.

Arterial blood gases were tested daily from first preoperative day to the seventh postoperative day at 4-5pm. Patients with respiratory failure or mechanical ventilation 7 d prior to operation were excluded in order to avoid intervention. Statistical analysis was performed using *t-test*, *ANOVA* and *chi-square test*. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using the SPSS statistical package (version 10.0, SPSS Inc., Chicago, IL).

RESULTS

Postoperative pulmonary complications such as pneumonia and atelectasis occurred early after operation. Pulmonary complications in the 358 patients with or without COPD are shown in Tables 2 and 3. Patients with COPD (29/86, 33.7%) had more pulmonary complications than those without COPD (36/272, 13.2%) ($P < 0.01$), Pneumonia (15/29, 51.7%), atelectasis (13/29, 44.8%), prolonged O_2 supplement (10/29, 34.5%), prolonged mechanical ventilation (8/29, 27.6%) were the major complications in COPD group.

The rate of mortality was 3.5% (3/86) in the COPD group and 66.7% (2/3) of deaths were due to respiratory failure. In patients without COPD, the rate of mortality was 1.5% (4/272) and two patients (50%) had respiratory failure as their cause of death.

Table 2 Pulmonary complications occurring in patients with or without COPD undergoing transthoracic esophagectomy

Pulmonary complications	COPD (n = 86)	Non-COPD (n = 272)	P value
Pneumonia	15	19	<0.01
Atelectasis	13	15	<0.01
Pulmonary abscess	4	5	0.227
Prolonged O_2 supplement	10	11	<0.01
Prolonged mechanical ventilation	8	10	<0.05
Acute respiratory distress syndrome	5	4	<0.05

Table 3 Degree of COPD and outcomes in patients with or without POPC in COPD group

Severity of COPD	POPCs (n = 29)	Non-POPCs (n = 57)	P value
FEV1,%predicted			
Grade Ⅰ (>80%)	10	35	<0.05
Grade Ⅱ A (50%-80%)	13	19	
Grade Ⅱ B (30%-50%)	6	3	
GradeⅢ (<30%)	0	0	

POPCs = postoperative pulmonary complications.

Table 4 Comparison of PaO_2 changes in the first postoperative week in patients with or without POPCs in COPD group (mean±SD)

Time	POPCs	Non-POPCs	P
1 preoperative day	82.17±7.37	82.75±4.45	0.758
1 postoperative day	68.38±5.24	76.00±8.28	<0.01
2 postoperative day	61.83±7.03	69.05±7.78	<0.01
3 postoperative day	61.75±6.14	67.20±7.35	<0.05
4 postoperative day	62.71±4.93	70.15±9.34	<0.01
5 postoperative day	61.13±5.62	72.75±10.30	<0.001
6 postoperative day	61.83±6.49	76.55±9.62	<0.001
7 postoperative day	61.63±6.31	80.45±7.50	<0.001

PaO_2 = partial pressure of oxygen.

Table 5 Comparison of $PaCO_2$ changes in the first postoperative week in patients with or without POPCs in COPD group (mean±SD)

Time	POPCs	Non-POPCs	P
1 preoperative day	42.85±4.10	42.37±6.03	0.766
1 postoperative day	44.42±4.61	41.24±4.93	<0.05
2 postoperative day	45.35±4.97	41.38±5.19	<0.05
3 postoperative day	46.02±4.88	42.45±5.62	<0.05
4 postoperative day	46.01±5.56	39.10±3.59	<0.001
5 postoperative day	44.63±5.31	40.62±5.44	<0.05
6 postoperative day	45.95±6.56	42.03±5.60	<0.05
7 postoperative day	45.18±5.80	40.49±6.13	<0.05

$PaCO_2$ = partial pressure of carbon dioxide.

Table 6 Comparison of SaO_2 changes in the first postoperative week in patients with or without POPCs in COPD group (mean±SD)

Time	POPCs	Non-POPCs	P
1 preoperative day	94.48±1.93	94.44±1.51	0.940
1 postoperative day	94.56±1.18	93.78±1.80	0.095
2 postoperative day	94.01±1.94	94.30±1.39	0.572
3 postoperative day	95.39±1.15	94.56±1.75	0.077
4 postoperative day	94.65±1.27	95.31±1.15	0.079
5 postoperative day	94.94±1.39	94.26±1.81	0.176
6 postoperative day	94.88±1.60	94.96±1.74	0.868
7 postoperative day	95.02±1.16	94.61±1.90	0.399

SaO_2 = arterial oxygen saturation.

Moreover, patients with severe COPD (Grade Ⅱ B, 30% ≤ FEV1%p < 50%) had more POPCs than patients with moderate (grade Ⅱ A, 50% ≤ FEV1%p < 80%) and mild (grade Ⅰ, FEV1%p ≥ 80%) COPD (P < 0.05).

The perioperative changes in arterial blood gases in patients with or without POPCs in COPD group are listed in Tables 4-6. In non-POPC group PaO_2 decreased in the first three days after operation and then gradually returned to its normal level. Values for $PaCO_2$, SaO_2 and pH were in normal range. However, in POPC group, PaO_2 dropped significantly, recovered more slowly, and failed to return to normal at the end of the first week compared with non-POPC group. $PaCO_2$ in POPC group was significantly higher than that in non-POPC group in the first 7d, reaching more than 6Kpa in first postoperative week. In addition, there was no significant difference in SaO_2 and pH between the two groups.

DISCUSSION

Transthoracic esophagectomy displays a remarkable effect on pulmonary function, including lung and chest wall compliance reduction, ventilation function reduction, increase of oxygen consumption[14]. Pulmonary complication is considered as one of the most serious and threatening complications after esophagectomy, and is associated with poor short- and long-term outcomes[9,15]. Postoperative pulmonary complications occur frequently after transthoracic esophagectomy for esophageal cancer, accounting for 7.3%-50%[9,13,16-18]. In addition to surgical techniques and perioperative management strategies, different definition criteria for pulmonary complications, patient selection and willingness of surgeons to undertake high-risk cases may influence the outcomes[4,19,20].

COPD is considered as a postoperative pneumonia risk index and is significantly associated with the occurrence of pulmonary complications[21,22]. According to our definition, a higher rate of pulmonary complication is associated with esophageal resection for esophageal cancer with COPD, particularly in patients with percent-predicted FEV1 less than 50%. Pneumonia, atelectasis' prolonged O_2 supplement and prolonged mechanical ventilation are the major complications after esophagectomy. The incidence rate of pulmonary complication in COPD group was higher than that in non-COPD group. The incidence rates of acute respiratory distress syndrome and pulmonary abscess were lower. Moreover, pulmonary complications are associated with postoperative mortality and regarded as the most common cause of operation death.

To assess the independent effect of COPD, we matched

patients with severe COPD to comparison groups of patients with moderate and mild COPD. The rate of pulmonary complication increased along with percent-predicted FEV1 reduction, suggesting that percent-predicted FEV1 is a good risk factor for anticipating postoperative pulmonary complications after esophagectomy.

Previous studies indicate that various factors predispose to pulmonary complications[4,10,23-27], including advanced age, history of smoking, cirrhosis and diabetes, abnormal chest radiograph or lung disease, blood loss and low serum albumin, preoperative chemoradiotherapy, general performance status, inadequate postoperative analgesia and stage of disease. Some cell factors have a relation with pulmonary complications after esophagectomy, such as secretary leukocyte protease inhibitor and angiotensin-converting enzyme[28,29]. Our analysis also demonstrated a correlation between percent-predicted FEV1 and pulmonary complication in patients with esophagectomy.

The changes of arterial blood gases coincided well with the timing of pulmonary complications in our patients which occurred in the first postoperative week. The pathophysiologic feature of this group was a further depression and patients had a poor prognosis. However, pH values and oxygen saturation had no remarkable change in the two groups.

Our study was not designed to determine if perioperative care could decrease the rate of pulmonary complications in patients with COPD after esophagectomy, but we believe that aggressive treatment is important in improving the outcome of pulmonary complication so that patients with COPD benefit from radical procedure. It was reported that effective treatment can reduce pulmonary complications[13]. Rehabilitation training, proper antibiotics and eliminating phlegm's drugs, atomization, stopping smoking, nutritional supplementation may have some benefits to patients with COPD before operation[30-32]. Regulation of intravenous transfusion volume can effectively prevent postoperative pulmonary edema and improve oxygenation[33].

In conclusion, chronic obstructive pulmonary disease is the critical factor for the occurrence of postoperative pulmonary complications in esophageal cancer patients undergoing esophagectomy. Pulmonary complications go up along with the severity of COPD. Percent-predicted FEV1 is a good predictor for postoperative pulmonary complications. Arterial blood gases are helpful in directing perioperative management.

Abstract

AIM: Minimal deviation carcinoma of the uterine cervix, otherwise known as extremely well-differentiated adenocarcinoma (EWDA), is characterized by its benign microscopic appearance in contrast to its aggressive behavior. In order to elucidate the clinicopathological features and biological behavior of the gastric counterpart of EWDA, we, using immunohistochemistry, analyzed nine lesions for the phenotypic expression, proliferative activity, and the expression of oncogene-associated products.

METHODS: Clinicopathological features, including preoperative biopsy diagnosis, were reviewed. Using immunohitstochemistry, Ki-67 labeling index and expression of p53 and c-erbB-2 protein in the gastric lesions were detected.

RESULT: Locations in the middle or upper third of the stomach and polypoid macroscopic features are characteristic of EWDA of the stomach. Although 4 of the 9 lesions showed only focal lymphatic or venous invasion, lymph node metastasis was not present and none of the patients died of the lesions (mean follow-up period, 56 mo). All 9 cases of EWDA could be classified into gastric phenotype (5 lesions) and intestinal phenotype (4 lesions). The former resembled gastric foveolar epithelium, mucous neck cells or pyloric glands, but their papillary structures were frequently elongated and the tumor cells and their nuclei were slightly larger and more hyperchromatic compared to normal epithelium. The latter resembled intestinal metaplasia with minimal nulcear atypia and irregular glands; two of these lesions demonstrated complete intestinal phenotype, while two demonstrated incomplete intestinal phenotype. Ki-67 labeling index was low and none of the cases revealed over-expression of p53 and c-erbB-2 protein.

CONCLUSION: Unlike minimal deviation carcinoma of the cervix, these findings suggest that EWDA of the stomach is a lesion of low-grade malignancy. This favorable biological behavior is supported by the data of a low Ki-67 labeling index and a lack of p53 or c-erbB-2 protein over-expression. Because of its resemblance to normal gastric mucosa or mucosa with intestinal metaplasia, EWDA is often misdiagnosed. To prevent the misdiagnosis of such lesions, the clinical and pathologic characteristics should be taken into consideration.

Key words: Stomach neoplasms; Extremely well-differentiated adenocarcinoma; Ki-67; p53; c-erbB-2

INTRODUCTION

Silverberg and Hurt proposed the term "minimal deviation carcinoma" for extremely well-differentiated adenocarcinoma (EWDA) of the uterine cervix[1], which has a benign microscopic appearance yet shows an aggressive behavior[1-3]. This carcinoma is characterized by mucinous glands which resemble normal endocervical glands but invade the cervical stroma. Several similar cases of adenocarcinomas which show deceptively benign appearance have been reported in the stomach[4-12]. In those reports, the difficulty with histological diagnosis based on biopsy specimens is well discussed in detail; however, the biological behavior of the lesions still remains unclear.

Based on Lauren classification[13], gastric carcinomas

have been classified into two types, intestinal-type and diffuse-type. Following recent advances in mucin histochemistry and immunohistochemistry, it has been clarified that differentiated adenocarcinoma can be classified into two subtypes, these being gastric and intestinal phenotypes[14-20]. With regard to EWDA of the stomach, Endoh *et al*[11] reported eight cases of EWDA mimicking complete-type intestinal metaplasia, confirmed by phenotypic investigation using immunohistochemical methods. Most reported cases of EWDA of the stomach seem to be intestinal-type carcinomas, resembling complete or incomplete intestinal metaplasia[4-10]. In addition, we have encountered a few reports of cases of EWDA mimicking normal gastric mucosa, where the cases were considered to be lesions of the gastric phenotype. However, in these cases, there was very little objective investigation of the phenotypic expression.

In order to elucidate the characteristics of EWDA including its biological behavior, we describe herein the clinicopathological features of nine cases, including phenotypic expression, proliferative activity and expression of some oncogene-associated products.

MATERIALS AND METHODS

Patients

EWDA is defined as neoplastic lesions composed of highly differentiated neoplastic epithelium which mimicks the normal gastric mucosa or intestinal metaplastic mucosa with mild nuclear atypia, but has the ability to invade the gastric wall. We retrospectively reviewed 3106 cases from our old consecutive files that had been diagnosed as well-differentiated adenocarcinoma of the stomach, and found three (0.1%) cases of EWDA. Other 6 collected cases of EWDA were added, making a total of 9 cases for this study. One of the reported cases[7] was included in this study. Although we encountered some similar lesions restricted to the mucosa, these were excluded because of difficulty in diagnosing them as malignant.

The clinicopathological findings were principally based on the General Rules for Gastric Cancer Study as outlined by the Japanese Research Society for Gastric Cancer[21]. Eight specimens were obtained by surgery, and one was endoscopically resected. The resected specimens were fixed in 100 mL/L buffered formalin. The early lesions were cut many times throughout the entire tumors, whereas the advanced lesions were cut only once through their center. The sections were then embedded in paraffin. Then 4-μm thick sections were routinely stained with hematoxylin and eosin stain (H&E). In addition, pre-operative biopsy specimens were also reviewed.

Immunohistochemistry

The monoclonal antibodies against human gastric mucin (45M1, Novocastra, Newcastle-upon-Tyne, UK, diluted 1:50) as a marker for gastric foveolar cells[22,23], MUC6 (Novocastra, Newcastle-upon-Tyne, UK, diluted 1:200) as a marker of gastric mucous neck cells and pyloric glands[24,25], MUC2 (Novocastra, Newcastle-upon-Tyne, UK, diluted 1:200) as a marker for intestinal goblet cells[26-28], CD10 (Novocastra, Newcastle-upon-Tyne, UK, diluted 1:200) as a marker for the small intestinal brush border[29-31], Ki-67 (MIB-1, dilution 1:100; Immunotech, Marseille, France), p53 (PAb 1801, dilution 1:100; Oncogene Research Products, Cambridge, Massachusetts, USA) and c-erbB-2 (dilution 1:200; Nichirei, Tokyo) were used. Immunohistochemical staining was carried out using streptavidin-biotin-peroxidase complex method (Histofine SAB-PO Kit, Nichirei, Tokyo, Japan) following antigen retrieval with microwave heating (citrate buffer, 30 min; phosphate-buffered saline, 10 min, respectively) utilizing an H2800 Microwave Processor (Energy Beam Sciences, Agawan, Massachusetts, USA) at 800 W. Sections were visualized with diaminobenzidine (DAB) and counterstained with methyl-green or hematoxylin. The negative controls consisted of substituting mouse normal serum for the primary antibodies.

Table 1 Phenotypic classification by immunohistochemical stains

		Human gastric mucin or MUC6	
		(-)	(+)
CD10 (+)		C - type	
CD10 (-)	MUC2 (+)	I - type	
	MUC2 (-)	U - type	G - type

C: complete intestinal, I: incomplete intestinal, G: gastric, U: unclassified.

Evaluation

The positivities of human gastric mucin (HGM), MUC6, MUC2 and CD10 were estimated as being significantly positive when more than 10% of the area was positive-stained. According to the combination of their expression, phenotypes were classified into four types: gastric type (G-type), incomplete intestinal type (Incomp. I-type), complete intestinal type (Comp. I-type), and unclassified type (Table 1)[20].

The Ki-67 (MIB-1) labeling index (LI) was defined as a percentage of MIB-1-positive nuclei, and was evaluated in the invasive areas. The MIB-1 LI was determined by counting at least 1000 nuclei in the selected fields at x400 magnification. p53 immunoreactivity was defined as positive when distinct nuclear staining was recognized in at least 10% of the cells, since most of the previously published studies employed this as the cut-off level. Cases with less than 10% positive cells were regarded as negative. c-erbB-2 was regarded as positive when there was membranous staining in more than 10% of the area of the tumor.

RESULTS

Histologic findings and phenotypic expression

All the EWDA had invaded the submucosa or even deeper; four were restricted to the submucosa, two had invaded the muscularis propria, and three had reached the subserosa beyond the muscularis propria. The EWDAs were classified into gastric phenotype (HGM+ or MUC6+/MUC2-/CD10-) containing 5 cases and

intestinal phenotype containing 4 cases. The intestinal phenotype cases were further classified into complete intestinal phenotype (HGM- / MUC6- / MUC2 + / CD10+) and incomplete intestinal phenotype (HGM- / MUC6- / MUC2 + / CD10-), each phenotype contained 2 cases. With regard to MUC6 expression which indicates differentiation to the pyloric glands, MUC6 expression was only detected in 2 of 5 cases of the gastric phenotype.

The five lesions classified as gastric phenotype were composed of well-differentiated epithelium mimicking foveolar epithelium, mucous neck cells or pyloric glands with abundant clear cytoplasm and basally situated nuclei. With careful observation, the nuclei were seen to be slightly larger than those of normal gastric mucosa, and to be markedly hyperchromatic. The superficial area

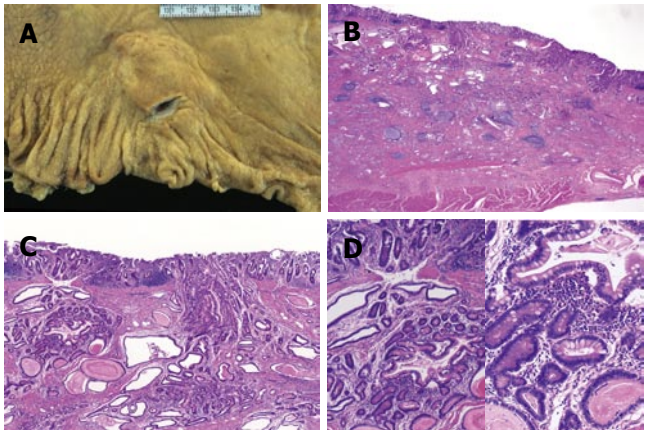

Figure 3 An advanced lesion of extremely well-differentiated adenocarcinoma of the stomach, complete intestinal-type (case 9). **A:** Macroscopic view showing a polypoid mass with an irregular surface, but unclear margin; **B:** cancer invasion of the whole thickness of the gastric wall (low-power view); **C:** carcinomatous gland infiltrating into the submucosa; **D:** carcinoma mimicking the intestinal metaplasia of complete-type with basally located small nuclei, eosinophilic cytoplasm and scattered goblet cells.

tended to resemble the foveolar epithelium while the deep area tended to resemble mucous neck cells or pyloric glands. Two lesions mainly showed remarkable papillary proliferation. The epithelium was lined with a single layer of columnar cells with abundant clear cytoplasm with basally situated nuclei. The glands in this phenotype showed intraluminal papillary projections with or without a fibrous core. In the invasive area, one of five revealed marked desmoplastic reaction, however, other four revealed only slight desmoplastic reaction. One of the cases of gastric-type EWDA is shown in Figure 1.

The four lesions classified as intestinal phenotype were composed of intestinal-type glands with various amounts of goblet cells and Paneth cells, focally showing an irregular shape. Brush border-like structures were occasionally seen, and were confirmed by CD10 staining in the two cases classified as complete intestinal phenotype. We found difficulty in diagnosing these lesions as neoplastic in the mucosa because their glands were somewhat regular in shape and their cytologic atypia was minimal. However, their glands were of varying sizes and showed irregular branching in the deep portion of the mucosa and the submucosa. The glands in the submucosa or proper muscle layer were surrounded by an acute, chronic inflammatory infiltrate with lymphoid follicles. Occasionally, cystically dilated gland was seen in the submucosa, and mucous which had partially leaked out into the stroma owing to destruction of the glands, was seen in these three lesions. In the invasive area, all the four cases revealed marked desmoplastic reaction. Two cases of intestinal-type EWDA, early and advanced, are shown in Figures 2 and 3.

Regarding the background mucosa of the tumors, the surrounding mucosa could not be examined in one gastric phenotypic lesion because the lesion had been endoscopically resected. In another gastric phenotypic lesion, no intestinal metaplasia was seen. As for the other seven cases, various degrees of intestinal metaplasia were

seen in the surrounding mucosa of both the gastric and intestinal phenotypes.

Patient characteristics

The clinicopathological findings of the nine patients with EWDA of the stomach are summarized in Table 2. The patients included eight men and one woman with ages ranged from 45 to 81 (average 62) years. There were no patients who were diagnosed as Peutz-Jeghers syndrome. None of the patients died or suffered recurrence during the follow-up periods which ranged from 5 to 136 (average, 56) mo.

Macroscopic findings

The tumors had a maximum diameter of 1.5 to 8 (average, 3.6) cm. Of the nine lesions, three tumors were located in the upper third of the stomach, the remaining six were located in the middle third. No lesions were present in the lower third. Among the four early lesions (restricted to the submucosa), two lesions were of superficial elevated (Type 0-IIa) type while the others were of superficial depressed (Type 0-IIc) type or protruding (type 0-I) type. All the advanced lesions (invading the muscularis mucosa and/or the subserosa) were of polypoid type (Type 1).

Pre-operative biopsy

Pre-operative biopsy specimens could be evaluated only in seven cases because of unavailability of specimens in two cases. Two of the seven cases were diagnosed as benign lesions, and the remaining five were initially suspected as being carcinomas, although there was difficulty in distinguishing whether they were neoplastic or regenerative lesions. Only one lesion could be finally diagnosed as a definite carcinoma through repeated biopsy (Case 9).

Ki-67, p53 and c-erbB-2 expressions

None of the cases of EWDA revealed over-expression of p53 or c-erbB-2. Regarding the proliferating activity, the mean value of Ki-67 LI of the EWDAs was 8.7% (range, 0.5%-23.9%).

DISCUSSION

Gastric carcinomas, based on Lauren classification, have been divided into two histologic types by standard hematoxylin and eosin (H&E) staining, such as

"intestinal" and "diffuse" types[13]. It has been considered that intestinal-type carcinoma is almost equivalent to differentiated type carcinoma and that diffuse-type carcinoma is almost equal to gastric or undifferentiated type carcinoma. However, gastric carcinomas are currently classified according to the expression of gastric or intestinal phenotypes, using immunohistochemical or mucin-histochemical methods[14,18]. Accordingly, we divided gastric carcinomas into three phenotypes (complete-intestinal type, incomplete-intestinal type and gastric type) according to the type of intestinal metaplasia, as suggested in previous studies[19,20], using immunohistochemical methods for CD10 (CALLA) which is considered to be expressed by the brush border of the small intestine[29,31], MUC2 which is considered to be expressed by intestinal goblet cells[26,28] and human gastric mucin (HGM) which is considered to be expressed by the gastric foveolar epithelial mucin [22,23]. Some authors have also reported that the phenotypic expression is related to the tumor growth pattern and aggressiveness[32,33], and that this classification is clearly in a good accordance with that of the background mucosa[19]. In this study, the phenotype of EWDA of the stomach was investigated using not only these three antibodies, but also MUC6 as a marker of gastric mucous neck cells and pyloric glands[24,25]. Our nine cases of EWDA could be classified into three phenotypes (complete-intestinal type, incomplete-intestinal type and gastric type).

Clinicopathologically, EWDA of the stomach had several characteristic features, in comparison with the previously reported cases of EWDA listed in Table 3[4-6,8-12]. The location and macroscopic features of the tumors are characteristic. Usually, more than 40% of the gastric carcinomas are located in the distal part of the stomach and polypoid type is rare (3.3%) among advanced gastric carcinomas, as reported by our previous study [34]. All EWDA in our study and most (13/15) ones of the previous reports were located in the middle and upper stomach. Macroscopically, the early lesions of EWDA were flatly elevated (0-IIa) or depressed (0-IIc), while all the advanced lesions were polypoid. The same tendency was also seen in the previous reports. This finding implies that the EWDA arises as a flat lesion but latter grows into a polypoid mass due to massive infiltration of carcinoma cells beneath the mucosa.

The gastric phenotype of gastric EWDA is more likely to be confused with normal gastric mucosa or hyperplastic polyps, whereas the intestinal phenotype of gastric EWDA is more likely to be confused with intestinal metaplastic epithelium. The high degree of differentiation and mild cellular atypia of these lesions result in frequent diagnostic difficulties especially with regard to biopsy specimens prior to surgery. In fact, pre-operative biopsies were negative in eight of 12 cases in previous reports and in two of our current seven cases. These highly differentiated lesions of the stomach have received relatively limited attention. Although EWDA of the stomach is very rare, it is important to take it into consideration when making a differential diagnosis of neoplastic or dysplastic lesions in the stomach.

The histological features of EWDA with regard to pre-operative biopsy specimens and surgical specimens were retrospectively reviewed. The most useful histological feature in diagnosing the intestinal phenotype of EWDA is the irregularity of the tubules in the deep portion of the mucosa and the submucosa. It is therefore important to obtain biopsy specimens from these areas. Moreover, endoscopic mucosal resection by means of which we can examine the entire thickness of the mucosal layer may be a suitable diagnostic procedure in diagnosing intestinal phenotypic lesions. In the cases of gastric phenotype of EWDA, the neoplastic epithelium resembled gastric surface mucous cells or pyloric glands. Their papillary structure was similar to that of normal foveolar epithelium and hyperplastic polyps, although some of them strikingly elongated. In addition, the individual cells and nuclei were obviously larger and their nuclei were more hyperchromatic than those in normal foveolar epithelium. Since the cellular atypism is minimal, it is important to compare their size and the amount of chromatin with that in the surrounding normal epithelium.

There have been no reports about the biological behavior of EWDA, although a low incidence of lymphovascular invasion and lymph node metastasis has been noted (Table 3). As for our cases, all the patients are currently alive. Three lesions revealed only focal venous or lymphatic invasion, but no lymph node metastasis was seen in our cases of EWDA. These findings suggest a favorable prognosis for EWDA of the stomach unlike the prognosis for minimal deviation adenocarcinoma of the uterine cervix, although it needs to be noted that our series was small with limited follow-up data. With regard to the correlation between phenotypes and clinicopathological features, there was no significant difference between the two except for tumor location. Three of the five EWDAs of gastric phenotype were located in upper third of the stomach, whereas all the EWDAs of intestinal phenotype were located in the middle third.

The proliferative compartment in normal gastric mucosa is known to be restricted to the middle layer of the mucosa. Several reports have indicated the relationship between a high Ki-67 LI and poor prognosis in cases of gastric carcinoma[35,36]. In our present study, the Ki-67 LI was lower (average, 8.7%) compared with the previously reported data(from 41.8% to 47.1%)[35-38]. A low Ki-67 LI (13%) in the submucosal invasive area has also been reported by Endoh *et al*[11], and this finding reflects the slow growth and reduced aggressiveness of EWDA of the stomach.

The reported prevalences of abnormal expression of p53 and c-erbB-2 protein have been shown to range from 47% to 60%[39-42] and from 5.7% to 33.0%[43-46], respectively. It has been reported that the over-expression of p53[37-39] and c-erbB-2 protein[43] is a marker of poor prognosis in gastric carcinoma. Fortunately, none of the lesions of EWDA showed over-expression of p53 or c-erbB-2 in our study. It seems reasonable to regard these lesions as having a low-grade malignancy, but an ability to invade downward into the gastric wall, a finding which is supported by the data of low Ki-67 LI and no over-expression of p53 or c-erbB-2. In addition, these immunoreactivities of p53 and c-erbB-2 seemed to be useless for the diagnosis of EWDA.

In the practical diagnosis of a stomach biopsy, it is important to bear in mind the existence of extremely well-differentiated adenocarcinoma (EWDA) of both intestinal and gastric types.

Abstract

AIM: To evaluate the anticancer property of the dried latex (DL) of *Calotropis procera*, a tropical medicinal plant, in the X15-*myc* transgenic mouse model of hepatocellular carcinoma and to elucidate its mechanism of action in cell culture.

METHODS: The young transgenic mice were orally fed with the aqueous suspension of DL (400 mg/kg for 5 d/wk) for 15 wk and their liver was examined for histopathological changes at 20 wk. Serum levels of vascular endothelial growth factor (VEGF) were also measured in these animals. To characterize the active fraction, DL was extracted with petroleum ether followed by methanol. The methanolic extract was sub-fractionated on a silica gel G column using a combination of non-polar and polar solvents and eleven fractions were obtained. Each fraction was analysed for cytotoxic effect on hepatoma (Huh7) and non-hepatoma (COS-1) cell lines and non-transformed hepatocytes (AML12) using tetrazolium (MTT) assay. Finally, the mechanism of cell death was investigated by measuring the levels of Bcl2, caspase 3 and DNA fragmentation.

RESULTS: DL treatment of mice showed a complete protection against hepatocarcinogenesis. No adverse effect was observed in these animals. The serum VEGF level was significantly lowered in the treated mice as compared to control animals. Cell culture studies revealed that the methanolic extract of DL as well as its fraction 8 induced extensive cell death in both Huh-7 and COS-1 cells while AML12 cells were spared. This was accompanied by extensive fragmentation of DNA in Huh-7 and COS-1 cells. No change in the levels of canonical markers of apoptosis such as Bcl2 and caspase 3 was observed.

CONCLUSION: DL of *C. procera* has the potential for anti-cancer therapy due to its differentiable targets and non-interference with regular pathway of apoptosis.

Key words: *Calotropis procera*; Transgenic mice; Hepatocellular carcinoma; Cytotoxicity; Anticancer agent; Differential killing

INTRODUCTION

The incidence of cancer is increasing worldwide and it is the single most common cause of deaths in both developed and developing countries[1,2]. Irrespective of the cause, the localized malignant tumors are best managed by surgical removal[3,4] while the treatment options for advanced and metastasized tumors include chemotherapy and radiotherapy[5-7]. However, in view of the side effects of drugs used in the chemotherapy of different cancers, traditional herbal medicine and complementary and alternative medicine (CAM) are becoming increasingly popular among cancer patients in the developed countries[8,9]. In the traditional Indian medicinal system, the Ak plant or *Calotropis procera* (Ait.) R. Br. (*Asclepiadaceae*) has been used for a variety of disease conditions that includes its use in the treatment of leprosy, ulcers, piles and tumors[10]. The root extract of *C. procera* has been found to produce a strong cytotoxic effect on COLO 320 tumor cells[11]. Recently, a hemi synthetic derivative of a cardenolide isolated from the root barks of *C. procera* shows a strong cytotoxic effect on several human cancer lines, a high *in vivo* tolerance to tumor growth and prolonged survival in the human xenograft models of nude mice[12]. The chloroform-soluble

fraction of its roots, ethanolic extract of its flowers and aqueous and organic extracts of its dried latex (DL) also exhibit a strong anti-inflammatory activity in animal models of acute and chronic inflammation[13-15]. Further, recent epidemiological studies have shown that daily intake of non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen results in a significant exponential decline in the risk of different clinical cancers[16]. In view of this, we have evaluated the cytotoxic and anti-tumor activities of the latex of *C. procera* respectively on hepatoma and non-hepatoma cell lines, and in a transgenic mouse model of hepatocellular carcinoma (HCC).

MATERIALS AND METHODS

Collection of latex and its fractionation

C. procera growing in wild was identified by the Raw Materials, Herbarium and Museum Division, National Institute of Science Communication, New Delhi, where a voucher specimen is preserved (Voucher No. PID1739). The latex was collected from the aerial parts of the plant and dried under shade (DL). DL was extracted with petroleum ether (B.P. 40-60 ℃) and methanol in a sequential order. The methanol extract (ME) was subjected to silica gel G (mesh 60-120) step column chromatography using a combination of non-polar and polar solvents and eleven fractions were collected[17]. The fractions were evaporated to dryness and tested for cytotoxic properties.

Chemicals and Reagents

Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS) and Caspase 3 assay kit were procured from Invitrogen (California, USA). Dimethylsulfoxide (DMSO) and (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl tetrazolium bromide (MTT) were purchased from Sigma (Missouri, USA). Silica gel G, petroleum ether (PE) and other chemicals were bought from Merck, India.

Treatment of oncomouse

The X15-*myc* transgenic mice expressing HBx and c-*myc* genes in the liver and thereby resulting in hepatocellular carcinoma[18], were used for this study following approval of the Institutional Animal Ethics Committee. Animals of matched age (5 wk old)) of either sex were used in this study. The overnight fasted animals were fed with bread soaked in aqueous suspension of the DL at a dose of 400 mg/kg for 15 wk (5 d/wk, $n = 6$). The control animals were given bread alone ($n = 6$). At 20 wk, the animals of both groups were sacrificed and their liver was collected in buffered formalin (100 mL/L). Paraffin blocks of samples were made and the tissue sections were stained with hematoxylin and eosin to observe histopathological changes.

Estimation of vascular endothelial growth factor (VEGF)

The serum level of VEGF was measured in the mice using a mouse specific ELISA kit (Oncogene Research Products, Germany).

Cell culture and cytotoxicity assay

The human hepatoma Huh-7 cell line[19] was a kind gift from Dr. A. Siddiqui (University of Colorado, Denver). COS-1 (African green monkey kidney cell line, CRL-1 650) and AML-12 cells (mouse hepatocyte, CRL-2 254) were purchased from the American Type Culture Collection (Virginia, USA). All cultures were grown in DMEM without phenol red ($DMEM^{-PR}$) supplemented with fetal bovine serum (100 mL/L), L-glutamine, penicillin and streptomycin and maintained at 37℃ in a CO_2 incubator. The cytotoxic effect of ME and each DL fraction was evaluated in cell cultures where the cells were seeded at a density of 4×10^5 cell/60 mm dish and allowed to settle for 12 h. Then these cells were incubated with different fractions of DL at concentrations ranging from 0.1-10 mg/L for either 24h or 48h. Cell viability was analyzed by MTT colorimetric assay[20]. Briefly, after treatment with the DL fractions, the cells were washed with culture medium and incubated with MTT solution (1 mg/mL in $DMEM^{-PR}$) for 1h at 37 ℃. The medium was decanted, the formazan product was dissolved in 1mL DMSO and the absorbance was read at 560 nm.

DNA fragmentation assay

Extract of the cells treated with DL fraction 8 was prepared in TET buffer (10 mmol/L Tris-HCl, pH 7.4, 5 mmol/L EDTA, 5 mL/L Triton X100) and incubated with proteinase K (40 mg/L) at 37 ℃ for 1h. After extraction with an equal volume of phenol, followed by phenol and chloroform, DNA was precipitated using ethanol. The DNA pellet was resuspended in H_2O and incubated with RNase A (40 mg/L) at 37 ℃ for 1h before electrophoretic separation in a 15 g/L TBE agarose gel[21].

Bcl-2 and caspase assay

The intracellular level of Bcl-2 was measured by immunoprecipitation using anti-Bcl-2 antibody (Santa Cruz Biotechnology, California, USA). The relative caspase activity was measured using the caspase 3 assay kit (Invitrogen, USA). The cell extract was prepared as per supplier's protocol and the caspase activity was measured in 50 μL aliquots by incubating with the substrate for 2 h at 37 ℃ and the absorbance was read at 405 nm.

Statistical analysis

The values are expressed as mean ± SE ($n = 6$) and the statistical analysis was performed by Student's t test. $P < 0.05$ was considered significant.

RESULTS

DL exhibits in vivo chemopreventive effect

The chemopreventive effect of orally administered DL was studied in the X15-*myc* transgenic mice. Histological examination of the liver of untreated mice at 20 wk showed a marked nuclear atypia, hyperchromatia, necrosis and loss in sinusoidal architecture (Figure 1A). Treatment of mice with DL (400 mg/kg) for a period of 15 wk protected these mice from malignant changes occurring in the liver while sinusoidal architecture and cellular integrity was slightly disrupted as compared to normal and hydropic changes were observed (Figures 1B and 1C). We further

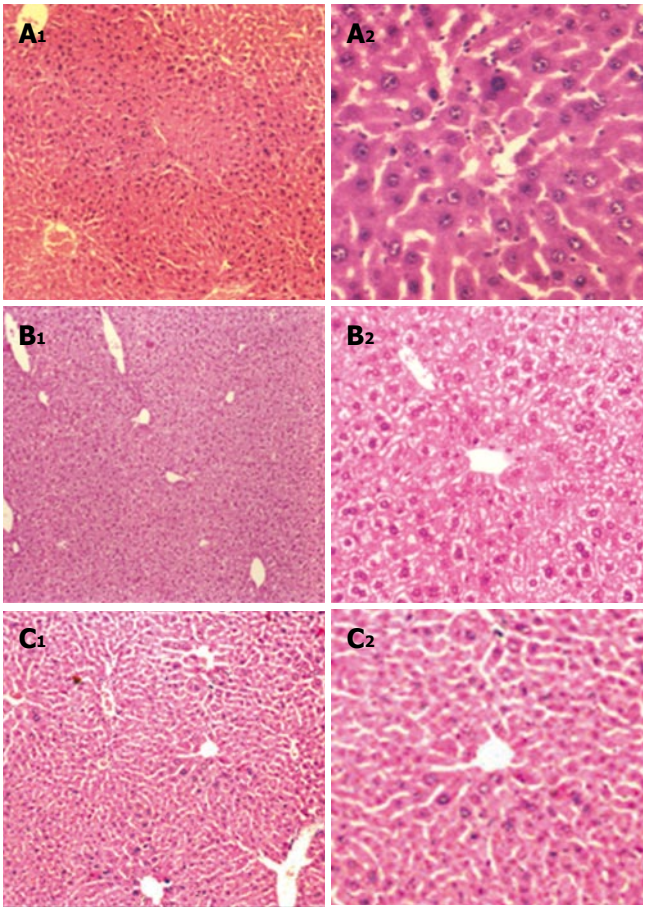

Figure 1 Histological analysis of mouse liver. **A**: X15-myc control; **B**: X15-myc mouse treated with DL suspension; **C**: Normal mouse liver. (**A**$_1$, **B**$_1$, **C**$_1$ = x100 and **A**$_2$, **B**$_2$, **C**$_2$ = x400).

measured the levels of VEGF, a marker of angiogenesis, in these mice. Treatment with DL produced a significant decrease in the serum VEGF levels of X15-*myc* mice from 12.18 ± 0.64 μg/L to 9.75 ± 0.27 μg/L (P = 0.002) while the level of VEGF in normal mice was 7.00 ± 0.55 μg/L.

DL is cytotoxic to cancer cells

Since the aqueous extract of DL showed a strong *in vivo* chemopreventive effect, the molecular basis of its action was investigated in cell culture. The ME of DL was evaluated for cytotoxicity using MTT assay on two different cell lines, viz., Huh-7 and COS-1 cells (Figure 2). ME induced cell death in both cell lines in a concentration dependent manner. Even at low concentration (0.1 mg/L), ME could induce cell death in both the cell lines. The effect was, however, more pronounced (-90% cell death) at higher doses of ME (1 and 10 mg/L).

A polar fraction of DL contributes to its cytotoxic effect

To identify the active component of DL, ME was subjected to silica gel G column chromatography and eleven fractions were collected[17]. Each fraction was evaluated for its cytotoxic activity on Huh-7 and COS-1 cells at 10 mg/L concentration and cell viability was determined by MTT assay (Figure 3). Out of 11 fractions, only fraction 8 exhibited a potent cytotoxic effect on both Huh-7 and COS-1 cells (~90% cell death) and the effect was comparable to ME (input). A marginal inhibitory effect was also seen with fraction 1 on Huh-7 cells (-24% cell death).

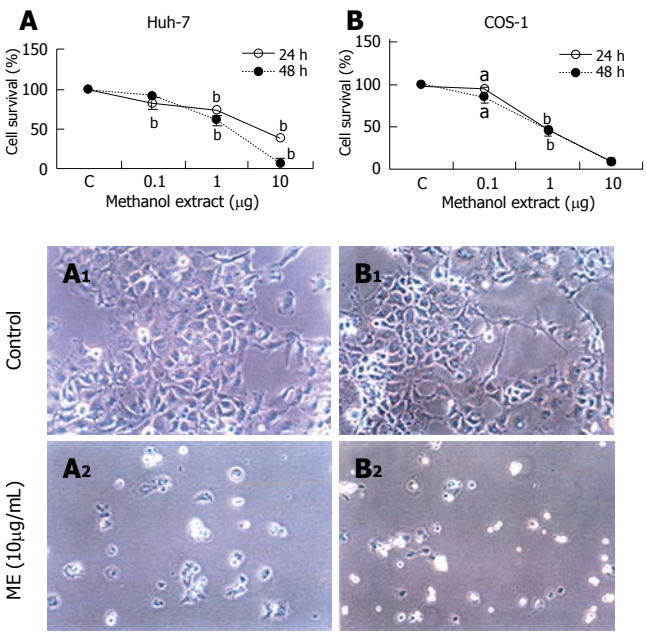

Figure 2 Cytotoxic effect of methanolic extract of DL on cancer cell lines. Huh-7 (**A**) and COS-1 cells (**B**) were incubated with different concentrations of ME and analyzed for cell viability at 24h or 48h (n = 6), mean ± SE. $^aP < 0.001$; $^bP < 0.01$; **A**$_1$ and **B**$_1$ are control Huh-7 and COS-1 cells; **A**$_2$ and **B**$_2$ are ME-treated Huh-7 and COS-1 cells (x200).

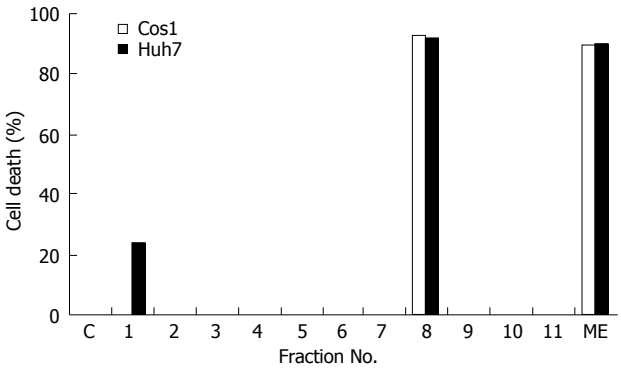

Figure 3 Cytotoxic effect of different fractions of the methanolic extract of DL on cancer cell lines. Huh-7 and COS-1 cells were incubated with either ME or its eleven fractions (all at 10 mg/L). Cell viability was measured at 48 h and results are expressed as % cell death.

We further investigated the relationship between the dose-response and cytotoxic effect of DL fraction 8 on Huh-7, COS-1 and non-transformed AML12 cells. At concentration ranging from 0.1 to 10 mg/L, it produced a dose-dependent decrease in the survival of Huh-7 and COS-1 cells leaving behind only 20%-30% living cells at 10 mg/L concentration. However, unlike the two cancer cell lines, AML12 cells showed a much better survival (-80%) in the presence of fraction 8 (Figure 4 A-C).

Fraction 8 of DL induces DNA fragmentation

To understand the mechanism of DL-induced cell death, the canonical markers of apoptosis like Bcl-2 and caspase 3 were measured in Huh-7 cells after treatment with fraction

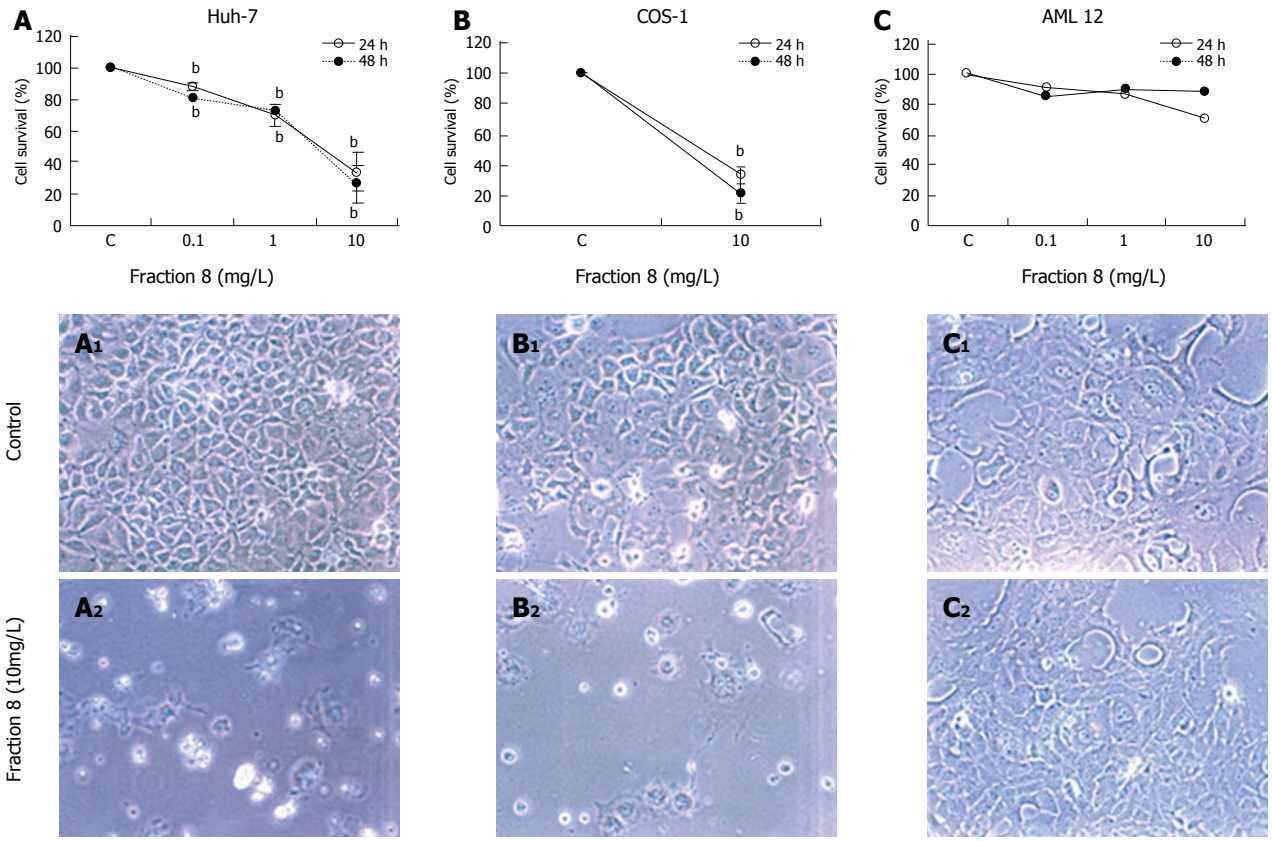

Figure 4 Cytotoxic effect of fraction 8 of the DL methanolic extract on different cell lines. Huh-7 (**A**), COS-1 (**B**) and AML12 cells (**C**) were incubated with different concentrations of fraction 8 and cell viability was measured at 24 and 48 h (mean ± SE, $^{b}P < 0.01$). **A**$_1$, **B**$_1$ and **C**$_1$ are control Huh-7, COS1 and AML12 cells; **A**$_2$, **B**$_2$ and **C**$_2$ are fraction 8 treated Huh-7, COS-1 and AML12 cells (x200).

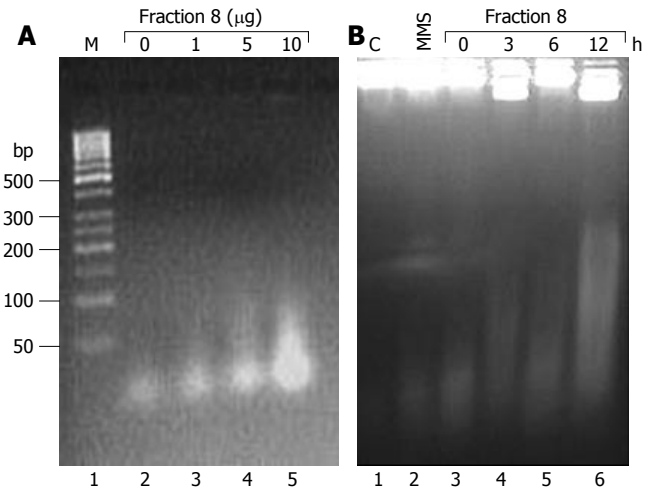

Figure 5 Effect of fraction 8 on DNA fragmentation in Huh-7 cells. Huh-7 cells were treated either with different concentrations (1, 5 and 10 mg/L) of fraction 8 for 3 h (**A**) or for 3, 6 and 12 h with 10 mg/L of fraction 8 (**B**). Total DNA was extracted after proteinase K and RNase A treatment and resolved by agarose gel electrophoresis. C: DNA from control cells; M: 100 base pair (bp) ladder; MMS, DNA from cells treated with methyl methanesulfonate (2 g/L) for 15 min.

8. Surprisingly, no change in the levels of both markers was observed (data not shown). Nonetheless, there was a marked increase in the fragmentation of cellular DNA that was both concentration as well as time dependent thereby suggesting a rise in the cellular nuclease activity (Figure 5).

DISCUSSION

The latex of *C. procera* has been shown to possess potent anti-inflammatory and antioxidant properties. In this study we have tested the latex for its chemopreventive and *in vitro* cytotoxic properties. The study was carried out in an mouse model of HCC developed by the integration of a chimeric transgene having hepatitis B virus X and murine c-*myc* genes exhibiting liver-specific neoplastic changes that are associated with inflammation and angiogenesis[18]. Five days a week oral administration of DL to the X15-myc mouse produced a marked chemopreventive effect as revealed by histological analysis. The mitotic changes produced by transgene expression were inhibited at the dose studied though some hydropic changes were observed. This was accompanied by inhibition of cellular infiltration. The DL might be producing chemopreventive effects through inhibition of different mediators of inflammation[15]. The pro-inflammatory cytokines and reactive oxygen and nitrogen species are known to activate signaling molecules involved in inflammation and carcinogenesis. These include nuclear transcription factor NF-κB, inducible nitric oxide synthetase (iNOS) and cyclooxygenase-2 (COX-2)[22]. The elevated levels of tumor COX-2 have been reported to correlate with invasiveness and elevated VEGF levels that brings about neovascularization and progression of HCC[23,24]. In fact, a recent study has revealed that COX-2 expression correlates with VEGF expression and microvessel density in HCC caused by hepatitis B virus[25]. It is interesting to note that DL not only inhibited

the inflammatory changes, but also produced a significant decrease in VEGF levels as observed with other anticancer drugs[26-28].

We further evaluated the cytotoxic effects of DL on hepatoma (Huh-7), non-hepatoma (COS-1) and non-cancerous (AML12) cell lines and observed that the cytotoxic activity was associated with one of the polar fractions of DL, i.e., fraction 8. Like total methanolic extract, fraction 8 also showed a strong cytotoxic effect on both transformed cell lines used here. However, a marginal effect on the killing of AML12 cells suggested a high degree of selectivity for transformed cells. Such differential killing of cancerous cells could relate to their altered metabolic status and/or membrane properties. In fact selective killing of cancerous cells by chemotherapeutic drugs like methotrexate and polyunsaturated fatty acids has been reported earlier as well[29,30]. Thus, it would be interesting to investigate the mechanism of such target selectivity by DL. The cytotoxic effect of DL was accompanied by intracellular fragmentation of target cell DNA. We observed a dramatic increase in the fragmentation of Huh-7 cells upon incubation with DL fraction 8. Though the action was rapid, it was not accompanied by expression of the common markers of intrinsic pathway of apoptosis such as Bcl-2 or caspase 3. Since Bcl-2 and caspases are markers of mitochondria-mediated apoptotic death, the genomic DNA can still undergo fragmentation by cellular DNase activity independent of mitochondrial pathway[31]. Hence a possible role of hypoxia and free radical-dependent activation of DNase activity or direct DNA damage and consequent degradation of cellular DNA[32] as evident here, cannot be ruled out. Thus, our study suggests that the latex of *C. procera* possesses an activity that has a chemopreventive action *in vivo* and cytotoxic action on cancer cell lines. Further study would be necessary to demonstrate its efficacy in HCC treatment.

Abstract

AIM: Although the pathogenic mechanism underlying autoimmune hepatitis (AIH) remains unclear, the immune system is thought to be critical for the progression of the disease. Cellular immune responses may be linked to the hepatocellular damage in AIH. Recently, much attention has been focused on the critical functions of costimulatory molecules expressed on mononuclear cells in the generation of effective T cell-mediated immune responses. Analysis of costimulatory molecule expressed on mononuclear cells from the patients with AIH may give us insight into the pathogenic mechanism of hepatocellular damage in AIH.

METHODS: Peripheral blood mononuclear cells (PBMC) were taken from the patients with AIH (34 cases) and healthy controls (25 cases). Liver infiltrating mononuclear cells (LIMCs) were taken from the patients with AIH (18 cases), the patient with chronic hepatitis C (CH-C) (13 cases) and the patients with fatty liver (2 cases). Using flow cytometry, the cells were analyzed for the expression of costimulatory molecules, such as CD80, CD86, and CD152 (CTLA-4). The results were compared with clinical data such as the level of gammaglobulin, histological grade, presence or absence of corticosteroids administration and the response to corticosteroids.

RESULTS: The levels of CD80+, CD86+ and CD152+ PBMC were significantly reduced in the patients with AIH as compared with healthy controls. By contrast, those cells were significantly higher in LIMC than in PBMC of the patients with AIH. Especially, the level of CD86+ LIMC showed a marked increase irrespective of the degree of disease activity in the patients with AIH, although CD86+ cells were rarely present in PBMC. The levels of CD86+ cells were present in significantly higher frequency in patients with AIH than in the patients with CH-C. Furthermore, the patients with AIH with high levels of CD86+ LIMC showed good responses to corticosteroids, whereas 2 cases of AIH with low levels of CD86+ LIMC did not respond well.

CONCLUSION: These results suggest that LIMC over-expressing costimulatory molecules such as CD80 and CD86 appears to play a role in the pathogenesis of AIH. Especially, CD86 molecule expressed on the LIMC may be useful for the diagnosis of AIH and for the prediction of the therapeutic effects of corticosteroids on AIH.

INTRODUCTION

In autoimmune liver diseases including autoimmune hepatitis (AIH) and primary biliary cirrhosis (PBC), autoimmune mechanisms are thought to affect the disease progression and manifestation. Although the mechanism of hepatocellular damage in AIH and PBC is still unclear, it is speculated that the immunological disorder is linked to host immunological targeting of hepatocytes in the liver[1-3]. It has been recently reported that polymorphism of cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) and the susceptibility to AIH and PBC were associated[4]. Among T cell-mediated immune responses, especially those mediated by CD4+ or CD8+ T cells, are likely to be associated with the hepatocellular damage in AIH[5,6]. We have previously reported that the expression of bcl-2, an anti-apoptotic molecule, in CD4+ Th1 cells was increased in peripheral blood and in the liver of the patients with

AIH[7]. Moreover, it was reported that T cells bearing certain T cell receptor clonotypes were expanded in the liver of the patients with AIH[8]. Although extensive efforts have been made to identify the target antigens expressed on the hepatocyes in AIH, the real target antigen has not been identified yet.

For the generation of effective T cell-mediated immune responses, much attention has been paid on the critical functions of a series of costimulatory molecules expressed on the cell surface of T or B cells. The T cell receives signals from antigen-presenting cells (APC) through the interaction of the T cell receptor (TCR) and major histocompatibility complex (MHC) in an antigen-dependent manner. However, these signals alone are insufficient to generate effective T cell-mediated immune responses and often lead to T cell anergy. The aberrant expression of costimulatory molecules was reported in some liver diseases other than AIH[9-14]. Although it is clear that the costimulatory molecules play a crucial role in T cell activation, few reports have addressed the role of these costimulatory molecules in AIH. In the present study, to elucidate the role of costimulatory molecules on mononuclear cells in AIH, some of the costimulatory molecules expressed on PBMC and LIMC were analyzed using flow cytometry and the results were evaluated in terms of the clinical status of the patients with AIH.

MATERIALS AND METHODS

Patients

Thirty-four patients with AIH serologically and histologically diagnosed at Kagawa University Hospital were enrolled in the present study. All patients had anti-nuclear antibody (ANA) in their sera and 19 of 34 (55.88%) patients showed hyper-gammaglobulinemia (> 2.0 g/dL). Based on the criteria proposed by International Autoimmune Hepatitis Group, all patients satisfied the score over probable AIH. PBMCs were analyzed in 34 patients with AIH. LIMCs were also analyzed in 18 of 34 patients at the liver biopsy for diagnosis. As a disease control, PBMC and LIMC of thirteen patients with chronic hepatitis C (CH-C) were analyzed. Twenty-five healthy individuals without any symptoms of liver injury were selected as normal controls for the analysis of PBMC. All of these studies were conducted with informed consent at the time of the enrollment for this study in all patients.

Flow cytometric analysis of PBMC

PBMCs from patients and healthy individuals were separated from heparinized venous blood by Ficoll-Hypaque density gradient centrifugation (Histopaque; Sigma Chemical Co., St Lois, MO). Immediately after separating PBMC, cells were washed twice in ice-cold phosphate-buffered saline (PBS), and adjusted to 4×10^5 cells per well of a 96-well U-bottom cell culture plate in flow microfluorometry medium [FMF medium: Hanks' balanced salt solution (without Ca, Mg and phenol red) containing 2 g/L bovine serum albumin, and 1 g/L sodium azide]. After centrifugation at 1200 r/min for 5 min, the supernatant was removed and cells were incubated for 30 min with FITC-conjugated or phycoerythrin (PE)-conjugated antibodies. The combinations of antibodies used were anti-CD80-FITC (Pharmingen, San Diego, USA)/anti-CD152-PE (Pharmingen), anti-CD86-FITC (Pharmingen). FITC-conjugated IgG (Dainippon Pharmaceutical Co., Ltd. Osaka, Japan) and PE-conjugated IgG (Dako A/G, Denmark) were used as the negative controls. After being washed twice, the pellets were resuspended with FMF medium, and the fluorescence detections were performed with a flow cytometer, COULTER EPICS XL. Prior to the analysis, FL1, FL2 and color compensation were adjusted so that no CD4CD8 double-positive cells were detected. The gate was set for accumulation of PBMC and ten thousand events were acquired for each analysis. Flow cytometric analysis was done immediately after isolating PBMC.

Flow cytometric analysis of LIMC

Liver specimens from the 18 patients with AIH, 10 patients with CH-C and 2 patients with fatty liver were obtained using a 16 G biopsy needle for diagnosis. Most of the patients with AIH underwent laparoscopy to obtain the liver specimen and observe the change of the liver surface for diagnosis. After incubating the liver biopsy specimen in RPMI-1640 containing 1 g/L collagenase for 2 h to destroy the connective tissue, LIMCs were separated by Ficoll-Hypaque density gradient centrifugation at 3000 r/min for 10 min. Isolated LIMCs were stained with FITC- or PE-conjugated antibodies and analyzed using flow cytometry. The cells positive for CD69, a marker for activated T cells, were also analyzed in LIMC. An anti-CD69-PE (Dako Japan A/G) was used. Three thousand events were acquired for each analysis.

Clinical markers

Levels of alanine aminotransferase (ALT) (IU/L) and gammaglobulin (g/dL) and titer of ANA were monitored. These laboratory data were compared with the level of LIMC positive for costimulatory molecules obtained in the present study. Inflammation and fibrosis in histological analysis was graded according to the classification documented by Knodell *et al*[15]. Histological staging and grading were classified based on the classification documented by Desmet *et al*[16].

Statistical analysis

Statistical analysis was performed using Macintosh software, Statview II (version 4.2) and a Mann-Whitney *U* test (non-parametric analysis). $P < 0.05$ was considered statistically significant.

RESULTS

Flow cytometric analysis of PBMC

For the analysis of costimulatory molecules, we focused on several costimulatory molecules critical for the induction of effective T and B cell-mediated immune responses. Initially, we examined the expression of those molecules on PBMC in patients with AIH. The level of positive cells for each surface molecule on PBMC was compared between the patients and healthy controls (Table 1). The results revealed that the patients with AIH had significantly

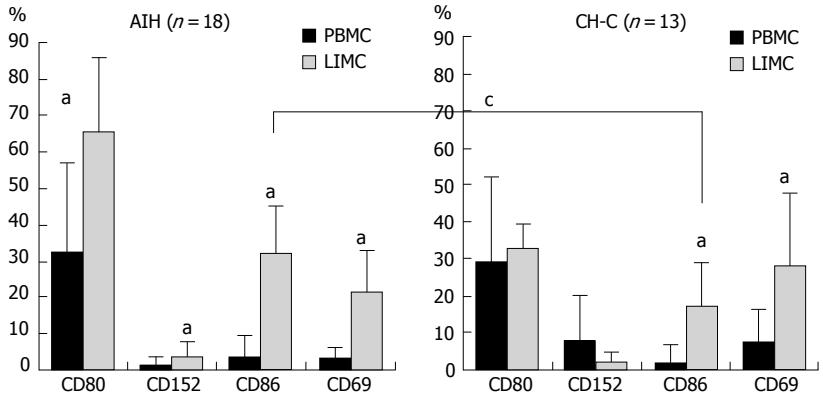

Figure 1 Isolation of PBMCs and LIMCs from peripheral blood and liver biopsy specimens in the patients with AIH and CH-C by using density gradient centrifugation. The cells were stained with anti-CD80, anti-CD86, anti-CD152 and anti-CD95 antibodies and analyzed using flow cytometry. The percentage of cells positive for those costimulatory molecules is shown. CD80+, CD86+ and CD152+ cells were significantly higher in LIMCs compared to PBMC in patients with AIH. The difference of CD86+ cells between LIMCs and PBMCs was more striking than that of CD80+ cells between LIMCs and PBMCs. (a) represents the significant difference ($P < 0.05$) from the data of PBMCs and (c) shows the significant difference ($P < 0.05$) of LIMCs between AIH and CH-C.

Table 1 Analysis of costimulatory molecules expressed on PBMCs (mean ± SD)

	Control n = 25	AIH Patients n = 34	P value
CD80	41.3 % ± 7.04 %	32.7 % ± 23.5 %	0.008
CD86	1.15 % ± 1.19 %	0.78 % ± 0.75 %	0.04
CD152 CTLA-4	13.8 % ± 10.9 %	2.32 % ± 2.80 %	0.01

The P values calculated by a Mann-Whitney's U-test are shown. Compared to the healthy controls, CD80+, CD86+ and CD152+ PBMC of the patients with AIH are shown to be significantly fewer.

fewer CD80+, CD86+ and CD152+ (CTLA-4+) cells in PBMC as compared with the healthy controls. Among the cells analyzed, CD86+ cells were present in low frequency in PBMC of both the patients and healthy controls.

Flow cytometric analysis of LIMCs

CD80 and CD86 are expressed on professional APC and activated lymphocytes, and have unique expression pattern[17]. In the patients with AIH, the predominant location of inflammation and damage is seen in the liver. Therefore, it might be reasonable to think that those decreased cells in the blood, such as CD80+, CD86+ or CD152+ cells, accumulate in the liver and are likely to be important to analyze the expression of costimulatory molecules on LIMCs as well as on PBMCs. Although it may be necessary to compare the expression of costimulatory molecules on LIMCs between the patients and healthy controls, it is ethically difficult to take mononuclear cells from the liver of healthy controls. Therefore, the frequency of LIMC positive for each costimulatory molecule was compared between PBMC and LIMC in patients with AIH and CH-C in the present study (Figure 1). In both AIH and CH-C, the ratios of CD69+ cells in LIMCs were significantly higher than that in PBMCs, suggesting infiltration of many activated T cells into the liver in both AIH and CH-C. In AIH, the ratios of CD80+ and CD86+ cells were significantly higher in LIMCs compared to PBMCs. The difference of CD86+ cells between LIMCs and PBMCs was more striking than that of CD80+ cells between LIMCs and PBMCs. Although the ratio of CD152+ cells was significantly higher in LIMCs than that in PBMCs, both the ratios were very low. In CH-C, the ratio of CD86+ cells was significantly higher in LIMCs than that in PBMC, but the ratios of CD80+ and CD152+ cells in LIMC were not significantly different from those in PBMC. Although the ratios of CD86+ cells were significantly higher both in AIH and in CH-C, the ratio of CD86+ cells in LIMCs was significantly higher in AIH than that in CH-C. Taken collectively, the most dramatic and apparent difference between PBMCs and LIMCs was the marked increase of CD86+ cells in LIMCs of AIH. By contrast, the levels of CD86+ cells in LIMCs of patients with fatty liver were low (Table 2).

Relationship between the level of CD86+ LIMCs and clinical markers

Since the most dramatic change of frequency between PBMCs and LIMCs was the increase of CD86+ cells in patients with AIH, relationship between the level of CD86+ LIMC and the clinical parameters was examined in patients with AIH (Table 2). In most of the patients with AIH tested, the levels of CD86+ LIMC were elevated by more than 20%. Three patients (No. 1-3 in Table 2) were already being treated with corticosteroids when the biopsy was performed. Even in these 3 patients, the aberrant expression of CD86 molecule on LIMCs was observed. The level of CD80+ or CD86+ LIMC did not show any significant correlation with that of ALT [correlation coefficient (r): CD80 *vs* ALT = -0.160; CD86 *vs* ALT = -0.166]. Furthermore, no significant correlation of the level of CD86+ LIMC with the level of serum gammaglobulin, ANA titer and HAI score was observed. These results suggested that LIMCs in patients with AIH are over-expressing CD80 or CD86 molecule irrespective of the degree of hepatocellular damage or disease activity. Among 18 patients analyzed for the expression of costimulatory molecule on LIMCs, clinical course after the administration of corticosteroids could be followed up in 10 patients. Administration of corticosteroids was effective in decreasing the level of transaminase in 8 of 10 patients. All of these 8 patients showed the high levels of CD86+ LIMC (> 20%). By contrast, 2 patients who did not respond satisfactorily to corticosteroids showed low levels of CD86+ LIMC (11.1% and 5.9%, respectively).

Representative AIH cases reactive and non-reactive to corticosteroids

Clinical course, laparoscopic appearance of the liver surface and liver histology of two AIH cases reactive and non-reactive to corticosteroids are shown in Figures 2 and 3. The

Comparison of the level of CD86+ LIMC and clinical data in patients with AIH (18 cases) and fatty liver (2 cases). LIMCs taken from the liver biopsy specimen of patients with AIH (18 cases) and 2 patients with fatty liver were stained with antibody against CD86 and analyzed by using flow cytometry. Three thousand events were acquired for each analysis. Patients with AIH showed high levels of CD86+ LIMC irrespective of the levels of γ-globulin, ALT, histological activity, and the presence or absence of the administration of corticosteroids (CS). Response to CS in patients with AIH was shown to be associated with the level of CD86+ LIMC. NT: not tested.

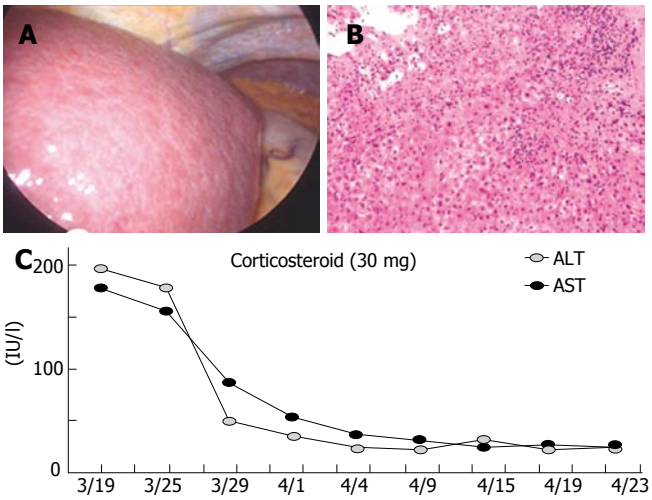

Figure 2 Laparoscopic findings, liver biopsy and clinical course after the administration of corticosteroids of a patient with AIH reactive to corticosteroids. **A:** Laparoscopic findings showing many reddish markings on the liver surface, indicating that the ongoing hepatitis was active; **B:** microscopic observation of the liver showing formation of rosette and bridging necrosis, infiltration of a large number of lymphocytes and plasma cells; and **C:** time-course of the levels of ALT and AST after the administration of corticosteroids. The levels of ALT and AST were rapidly decreased to normal ones after administration of corticosteroids.

former case was a 58-year-old female (No. 11 in Table 2) who showed a good response to the treatment of corticosteroids (Figure 2). At the time of diagnosis, she had ALT 131 IU/dL, AST 139 IU/dL, T-Bil 1.1 mg/dL, ALB 2.9 g/dL, IgG 2730 mg/dL and ANA ×5120. Laparoscopic findings of the liver showed many reddish markings on the surface of the liver, indicating that the ongoing hepatitis was active (Figure 2A). Histological findings were compatible to AIH showing the formation of rosette and bridging necrosis, infiltration of a large number of lymphocytes and many plasma cells (Figure 2B). The level of CD86+ LIMC was high, 28.9 %. The levels of ALT and AST were rapidly decreased to normal ones after the administration of corticosteroids (Figure 2C). By contrast, the latter case was a 59-year-old female (No. 10 in Table 2) who was not reactive to the treatment of corticosteroids (Figure 3). At the time of diagnosis, she had ALT 50 IU/dL, AST 29 IU/dL, T-Bil 1.9 mg/dL, ALB 2.9 g/dL, IgG 2880 mg/dL, and ANA ×1280. Laparoscopic findings of the liver showed many reddish markings and small lymph cysts on the surface of the liver (Figure 3A). Histological findings revealed the bridging necrosis, infiltration of a large number of lymphocytes and plasma cells (Figure 3B). The level of CD86+ LIMC was relatively low, 11%. Although the levels of ALT and AST were slightly improved after the administration of corticosteroids, those were elevated again despite the treatment.

As aforementioned, these 2 cases showed similar aspects of laboratory data, laparoscopic findings and histological findings. Nevertheless, one with a high level of CD86+ LIMC was responsive to corticosteroids, and the other with a low level of CD86+ LIMC was not. In these 2 cases, the differences were seen in the response to corticosteroids and in the level of CD86+ LIMC, but not in other clinical markers.

DISCUSSION

Although the mechanism of hepatocellular damage in AIH has not been well understood, many lines of evidence have demonstrated the presence of immunological disorders in AIH[5]. For example, wide ranges of circulating auto-antibodies are observed in the sera of patients with AIH[18-21]. Moreover, it has been shown that

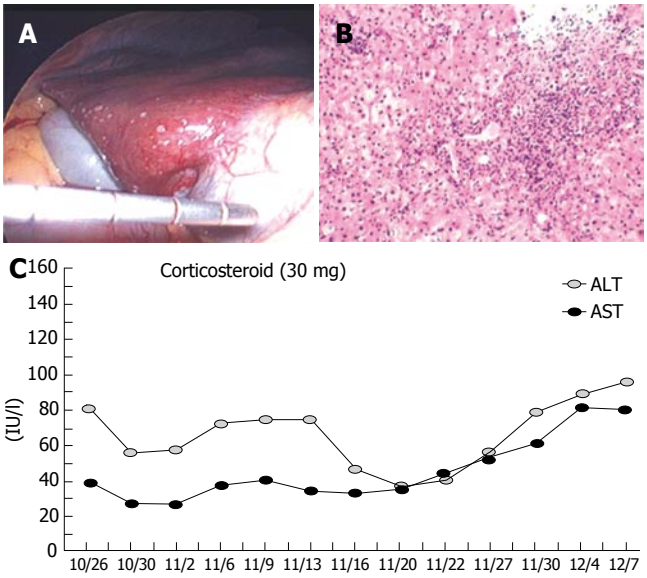

Figure 3 Laparoscopic findings, liver biopsy and clinical course after the administration of corticosteroids of a AIH patient non-reactive to corticosteroids. **A:** Laparoscopic view showing many reddish markings on the surface of the liver and small lymph cysts; **B:** microscopic findings of the liver showing bridging necrosis, infiltration of a large number of lymphocytes and plasma cells; and **C:** the time-course of the levels of ALT and AST after the administration of corticosteroids. The levels of ALT and AST were not improved to normal level after administration of corticosteroids.

the susceptibility to AIH was associated with HLA class II, DR3 and DR4 alleles[3,22,23]. Some reports have also suggested the association of cytotoxic T lymphocytes (CTL) with the hepatocellular injury in AIH using animal models[24-26].

Helper T cells (Th) receive a TCR signal from APC via HLA class II molecules. Helper T cells are divided into two subtypes, Th1 and Th2, according to their cytokine secretion profile[27]. Both Th1 and Th2 differentiate from Th0 cells. In the treatment of the patients with AIH, corticosteroids are effective in decreasing hepatocellular damage. This effect is thought to be due to the action of corticosteroids in inhibiting Th0 activation, leading to inhibition of CTL responses and antibody production[28,29]. CTL and Th receive signals from APC via the TCR-MHC complex[30]. However, this signal alone is not enough to activate T cells, and the expression of costimulatory molecules plays a crucial role in full T cell activation. Nevertheless, few reports have analyzed the expression of costimulatory molecules on mononuclear cells in AIH. In the present study, flow cytometry was used to analyze the expression of costimulatory molecules on mononuclear cells, because it is a sensitive method for detecting positive cells. PBMCs expressing CD80+, CD152+ (CTLA-4+) and CD86+ were shown to be significantly lower in the patients with AIH as compared with the healthy controls. However, in the patients with AIH, these cells existed more frequently in LIMCs than that in PBMCs. Interestingly, the most dramatic difference in frequency between PBMCs and LIMCs was detected in the ratios of cells positive for CD86 molecule, formerly designated as B7-2. Although CD86+ cells were barely detected in PBMCs obtained from the patients and healthy controls, they were considerably high in LIMCs obtained from the patients with AIH.

CD80 and CD86 molecules have unique expression patterns on professional APC and activated lymphocytes[31]. CD80 is constitutively expressed at low levels on lymphoid cells, whereas CD86 expression is rapidly increased upon activation[32]. Our results regarding the high level of CD86+ LIMC in the patients with AIH suggested that activated APC or lymphocytes might be enriched in the liver of the patients with AIH. Furthermore, the aberrant expression of CD86 was observed irrespective of the presence of hepatocellular damage and the treatment with corticosteroids, and the enhanced expression of CD86 was not observed in other liver diseases. These results suggest that the costimulatory molecules, such as CD80 and CD86, are continuously expressed on mononuclear cells in the liver even when the hepatocellular damage is not present. In addition, we often observe the relapse of liver dysfunction during the time course of tapering the dose of corticosteroids. Therefore, these lead us to speculate that excessive antigen presentation by APC to T cells, via the interaction between the CD80/86 and CD28 molecules, might contribute to the hepatocellular damage in AIH and administration of corticosteroids may block the signal transduction between APC and T cells. Indeed, it is important to identify which subtypes of PBMC or LIMC really express CD86 molecule. However, we have not identified it yet. Because the expression of CD86 on PBMCs was extremely low and the amount of LIMCs purified from a tiny liver specimen was quite a few, it was technically difficult to identity a specific subtype of the cells. The more detail analysis of this subtype and the function CD86+ cells in AIH awaits further elucidation in the next study.

Recently, extensive efforts have been made to elucidate the critical function of costimulatory molecules in various diseases. The aberrant expression of costimulatory molecules on mononuclear cells has been reported in a variety of autoimmune diseases, such as lupus, multiple sclerosis (MS), and experimental autoimmune encep halomyelitis[33-35]. The enhanced expression of CD80 and CD86 has also been reported in liver diseases, such as fulminant hepatic failure, primary biliary cirrhosis (PBC), primary sclerosing cholangitis, hepatitis C and hepatocellular carcinoma[9-14]. However, all of these reports focused on the CD80 or CD86 molecules expressed on either hepatocytes or bile ducts. There are few reports expressing the role of costimulatory molecules in AIH. The costimulatory molecules, such as CD80, CD86 and CTLA-4 (CD152), are essentially expressed on mononuclear cells. To our best of knowledge, this is the first descriptive report showing the aberrant expression of CD86 molecule on LIMCs of patients with AIH. Recently, anti-CD86 antibody or soluble CD152 (CTLA-4) was used as blocking agents for CD86 function in the treatment of autoimmune diseases[36-38]. Similarly, our data suggest that anti-CD86 antibody might be used to stabilize liver function for the treatment of AIH.

In PBC, presence of anti-mitochondria M2 antibody is a useful diagnostic marker[39,40]. In AIH, presence of ANA and the scoring system proposed by the International

Autoimmune Hepatitis Group are currently being used for the diagnosis of AIH[41]. However, some cases are still difficult to classify as definite or probable AIH. Actually, the cases with low levels of gammaglobulin (< 2.0 g/dL) were present in 8 of 18 cases whose LIMCs were examined in the present study. In contrast, all cases except No. 14 in Table 2 showed high levels of CD86+ LIMC. Furthermore, 2 patients who did not respond satisfactory to corticosteroids showed low levels of CD86+ LIMC. It is well known that non-response to the treatments of corticosteroids is uncommon in AIH. Therefore, these 2 cases might not be a real AIH although they were clarified as AIH by the scoring system. Thus, the detection of CD86+ LIMC may be useful for the diagnosis of AIH and this may lead to be helpful for the prediction of therapeutic effects of corticosteroids on AIH in the future.

In summary, our results showed lower proportions of CD80+, CD86+ and CD152+ (CTLA-4+) PBMC in the patients with AIH as compared with the healthy controls. These cells are present in greater frequency in LIMCs, suggesting that the aberrant expression of these costimulatory molecules on LIMCs might be associated with pathogenic mechanism of AIH. Especially, the level of CD86+ LIMC is likely to be helpful for the diagnosis of AIH and for the prediction of therapeutic effects of corticosteroids on AIH.

Abstract

AIM: To analyze the neutralizing activity of antibodies against E1 region of hepatitis C virus (HCV). Specific polyclonal antibody was raised via immunization of New Zealand rabbits with a synthetic peptide that had been derived from the E1 region of HCV and was shown to be highly conserved among HCV published genotypes.

METHODS: Hyper-immune HCV E1 antibodies were incubated over night at 4℃ with serum samples positive for HCV RNA, with viral loads ranging from 615 to 3.2 million IU/ mL. Treated sera were incubated with HepG2 cells for 90 min. Blocking of viral binding and entry into cells by anti E1 antibody were tested by means of RT-PCR and flow cytometry.

RESULTS: Direct immunostaining using FITC conjugated E1 antibody followed by Flow cytometric analysis showed reduced mean fluorescence intensity in samples pre-incubated with E1 antibody compared with untreated samples. Furthermore, 13 out of 18 positive sera (72%) showed complete inhibition of infectivity as detected by RT-PCR.

CONCLUSION: In house produced E1 antibody, blocks binding and entry of HCV virion infection to target cells suggesting the involvement of this epitope in virus binding and entry. Isolation of these antibodies that block virus attachment to human cells are useful as therapeutic reagents.

INTRODUCTION

Hepatitis C virus (HCV) is the major etiology of non-A, non-B hepatitis that infects 170 million people worldwide. Approximately 70% to 80% of HCV patients develop chronic hepatitis, 20% to 30% of which progress to liver cirrhosis[1]. At present, there is no vaccine available to prevent HCV infection, and current therapies are not optimal. The initial steps of HCV infection (binding and entry) that are critical for tissue tropism, and hence pathogenesis, are poorly understood. Studies to elucidate this process have been hampered by the lack of robust cell culture systems or convenient small animal models that can support HCV infection. HCV is an enveloped, positive-stranded RNA virus that belongs to the *Flaviviridae* family. Based on the sequence heterogeneity of the genome, HCV is classified into six major genotypes and 100 subtypes[1]. The viral genome (9.6 kb) is translated into a single poly-protein of 3000 amino acids (aa). A combination of host and viral proteases are involved in poly-protein processing to give at least nine different proteins[2]. Like other enveloped viruses, E1 and E2 proteins most likely play a pivotal role in the assembly of infectious particle and in the initiation of viral infection by binding to its cellular receptor(s). It has been suggested that the humoral and cellular immune responses to the E1 envelope protein are largely impaired in patients with chronic active hepatitis C, and that such responses may be important for clearance of HCV[3]. Leroux-Roels *et al*,[4] have previously reported that cellular immune responses to the E1 envelope protein are almost absent in patients with chronic active hepatitis C, while long-term responders to IFN- therapy, on average, show higher levels of E1 antibodies[5]. Depraetere *et al*,[6] suggesting that E1 antibodies contribute, at least

partially, in viral elimination. Baumert *et al*[7] confirmed the presence of such higher antibody levels directed at the HCV envelope in sustained viral responders to IFN-based therapy. Maertens *et al*[8] have been able to show that therapeutic vaccination of chronically infected chimpanzees with the HCV E1 protein induces the appearance of T-helper immune responses and antibodies which are very rarely seen in patients[6,7] or chimpanzees[9] with chronic active hepatitis C. The use of a viral envelope protein has the advantage of potentially inducing not only T-cell responses, but also neutralizing antibodies and complement activation. The E1 protein was chosen as vaccine rather than the E2 protein not only because E2 has the disadvantage of displaying a very high strain-to-strain variation in the hypervariable region I (HVRI), but also because of the higher degree of inter-genotype cross-reactivity of E1 as compared to E2. The E2 hypervariable region is immunodominant and neutralizable[10]. However, strong anti-E2 vaccine responses directed against the HVR I do not cross-neutralize with the infecting strain[11,12]. Although the E1 antigen is also variable between genotypes, it shows a relatively high degree of conservation within the subtypes, such as subtype 1b[13], the most widespread genotype worldwide. In the present study, we aimed to examine the neutralizing -related activity of an in house made antibody against the most conserved region of HCV E1 protein, for blocking the entry of HCV virion to HepG2 cells.

MATERIALS AND METHODS

Infected Serum samples

We selected 28 serum samples which tested positive for HCV RNA at different viral loads (ranging from 615 to 3.2 million IU/ mL) for infection experiments. The presence of HCV RNA was determined by nested RT-PCR and genotyped using Innolipa system (Bayer, Germany). Viral loads were determined by branched DNA method (Bayer, Germany).

Design of E1 conserved synthetic peptides

Sequence analysis of HCV quasi-species in local patients (Data not shown), revealed several conserved regions within the core and the E1 proteins. We designed 4 core and one E1-specific peptides and analyzed their ability to detect circulating antibodies in infected patients. The results of these studies showed that only one core-peptide (C1) had reasonable sensitivity and specificity. However the rest of peptides including E1 peptide had poor reactivity with circulating antibodies[14]. In the present study, we raised HCV specific polyclonal antibodies against the 4 core and an E1 peptide as follows:

(C1) DVKFPGGGQIVGGVYLLPRR, (C2) PRLGVRATRKTSERSQPRG,
(C3) IPKARRPEGRTWAQPGY, (C4) IPKDRRSTGKSWGKPGY,
(E1) GHRMAWDMM

Production of polyclonal antibodies against core and Envelope regions of HCV

New Zealand rabbits were immunized independently (two rabbits per each peptide) with purified synthetic peptides coupled with KLH protein. Equal volume of diluted core and E1 synthetic peptides and Freund's complete adjuvant were emulsified and injected subcutaneously into the rabbits in three different sites. On d 15 and 28, the rabbits were immunized again with the same protein emulsified with Incomplete Freund`s adjuvant. On d 32 the rabbits were sacrificed and sera were separated and stored at -20 ℃. For direct immuno-fluorescence, immunized polyclonal antibodies were digested with pepsin A (porcine 1:60 000 grade (sigma P-7012) ST. Louis, Mo, USA) at acidic pH and the $F(ab)_2$ portion was labeled with fluorescence isothiocyanate-FITC according to Hudson and Hay[15].

Flow cytometric analysis of E1 binding to HepG2 cells

The interaction of E1 glycoprotein with cells was quantified using a fluorescence activated cell sorting (FACS) based assay. Surface labeling was performed by direct immuno-fluorescence. Twenty eight serum samples that tested positive for HCV RNA with broad range of viral loads (617-3.2×10^6 IU / mL) were incubated with anti E1 antibody (diluted 1:250 in cultured media) overnight at 4 ℃. The pretreated sera with E1 antibody were incubated with HepG2 cells for 90 min at 37 ℃ in CO_2 incubator. Cells were centrifugated and supernatants were removed. Cell pellets were washed 4 times with PBS and incubated with FITC labeled $F(ab)_2$ portion of HCV E1 antibody (at 1:1500 dilution) for 30 min at 4 ℃. Cells were washed 3 times with PBS containing 1% normal goat serum. Cells were suspended in 500 μL PBS and analyzed with flow cytometry (FACS Calibure, BD). The mean fluorescence intensity were determined using cell Quest software (Becton Dickinson)

Isolation and extraction of RNA from serum and HepG2 cells

RNA was isolated from serum samples and HepG2 cells as reported by Lohr *et al*[16]. Briefly, cells were precipitated and washed in the same buffer to remove adherent viral particles before lysis in 4 mol/L guanidinium isothiocyanate containing 25 mmol/L sodium citrate, 0.5% sarcosyl and 0.1 mol/L β-mercaptoethanol. Cellular RNA was extracted using the single-step method described originally by Chomczynski and Sacchi[17].

PCR of genomic RNA strands of HCV

Reverse transcription-nested PCR was carried out according to Lohr *et al*.[16] with few modifications. Retro-transcription was performed in 25 μL reaction mixture containing 20 units of AMV reverse transcriptase (Clonetech, USA) with either 400 ng of total PBMCs RNA or 3 μL of purified RNA from serum samples (equivalent to 30 μL serum) as template, 40 units of RNAsin (Clontech, USA), a final concentration of 0.2 mmol/L from each dNTP (Promega, Madison, WI, USA) and 50 pmol of the reverse primer P1 (for plus strand) or 50 pmol of the forward primer P2 (for minus strand). The reaction was incubated at 42 ℃ for 60 min. and denatured at 98 ℃ for 10 min. Amplification of the highly conserved 5'-UTR sequences was done using two rounds of PCR with 2 pairs of nested primers. First round amplification was done in 50 μL reaction con-

The presence of HCV RNA was determined by nested RT-PCR and genotyped using Innolipa system (Bayer, Germany). Viral loads were determined by branched DNA method (Bayer, Germany).

PBS: phosphate buffer saline

[1]Cells not infected: HepG2 cells did not infected by positive HCV serum.

taining 50 pmol from each of P2 forward primer and P3 reverse primer, 0.2 mmol/L from each dNTP, 10 μL from RT reaction mixture as template and 2 units of Taq DNA polymerase (Promega, USA) in 1X buffer supplied with the enzyme. The thermal cycling protocol was as follows: 1 min. at 94℃, 1 min at 55℃ and 1 min at 72℃ for 30 cycles. The second round amplification was done similar to the first round, except for use of the nested reverse primer P4 and forward primer P5 at 50 pmol each. A fragment of 172 bp was identified in positive samples. Primer sequences were as follows: P1: 5' ggtgcacggtctacgagacctc 3' P2 : 5' aactactgtcttcacgcagaa 3', P3: 5' tgctcatggtgcacggtcta 3', P4: 5' actcggctagcagtctcgcg 3', P5: 5' gtgcagcctccaggaccc 3'. To control for false detection of negative-strand HCV RNA and known variations in PCR efficiency[18,19], specific control assays and rigorous standardization of the reaction were employed as previously described[20]. These specific control assays were: (1) cDNA synthesis without RNA templates to exclude product contamination, (2) cDNA synthesis without RTase to exclude Taq polymerase RTase activity, (3) cDNA synthesis and PCR step done with only the reverse or forward primer to confirm no contamination from mixed primers. These controls were consistently negative. In addition, cDNA synthesis was carried out using only one primer followed by heat inactivation of RTase activity at 95℃ for 1 h, in an attempt to diminish false detection of negative-strand prior to the addition of the second primer.

Infection of HepG2 cells with HCV

Cells were grown for 48h to semi-confluence in complete DMEM medium, washed twice with FCS -free medium then inoculated with serum samples (500 μLl plus 500 μL FCS-free DMEM/3×10^6 cells) obtained from HCV infected patients (RT-PCR and antibody positives). The viral load in the used sera was quantitated by bDNA technology and the average copy number was 615-3.2×10^6 IU/mL. After 90 min, DMEM containing FCS was added to make the overall serum contents 10% in a final volume 8 mL including the volume of human serum used for infection and cells were maintained overnight at 37℃ in 50 mL/L CO_2. Next day, adherent cells were washed three times with culture medium to get rid of the remaining infectious serum and incubation was continued in complete medium containing 10% FCS with regular medium changes. An inhibition assay of viral absorption or attachment to presumed susceptible cells has been developed for assessing the neutralizing related capacity of antibodies[21]. To analyze the neutralizing-related activity of antibodies against E1 region of HCV as compared with antibodies against core peptides, serial dilutions of serum samples were incubated with equal volumes of different amounts of the studied specific polyclonal antibodies in PBS at 4℃ overnight. One hundred microliters of pretreated serum samples were incubated with 1 mL of the cell suspension of HepG2 cells containing 0.5 million cells. Appropriate controls included HCV RNA positive sera that have neither been treated with E1 nor with core antibodies as positive controls, HepG2 cells not infected with HCV RNA positive sera as negative controls. Retrotranscription-PCR was performed on intracellular HCV RNA of HepG2 cells under the above described circumstances.

RESULTS

Selection of highly conserved peptide sequence among various HCV genotypes

The most conserved 10 amino acid stretch within the N-terminal region of E1 protein derived from several reported HCV isolates is shown in figure 1. When this 10mer peptide (GHRMAWDMM) was synthesized and used for immunization of New Zealand rabbits, the reactivity of hyper-immune E1 antibody was confirmed by enzyme-linked immunosorbent assay (ELISA) and western blot for detection of E1 protein in infected sera and infected HepG2 cells (Data not shown).

Selection of HCV positive sera and infection of HepG2 cells

Twenty eight HCV RNA positive sera with different viral loads and various subtypes of genotype 4 were used for infection experiments (Table 1). Only 18 samples were able to infect HepG2 cells, thus producing 18 different cell lines of HCV infected HepG2 cells.

Figure 1 Sequence alignment of amino acids no 311 to 370 (numbering starts from initiating methionin in the core protein of genotype 4a) of HCV E1 among representative genotypes. Eight sequences of different subtypes were aligned using ClustalW software, the output diagram is shown with the legend on the left having the accession number and the subtypes. Sequences shown in bold represent the highly conserved amino acid stretch (GHRMAWDMM) used for production of polyclonal antibody.

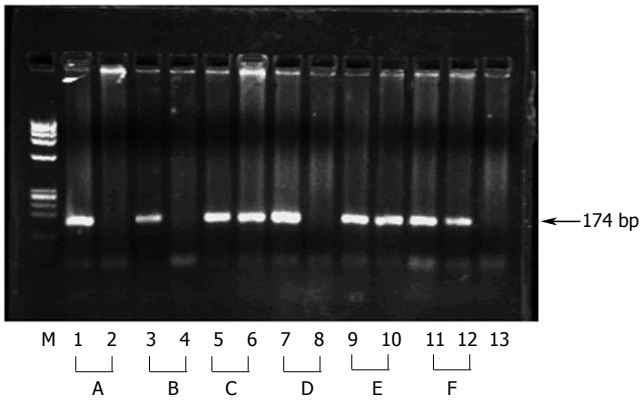

Figure 2 Inhibition of HCV entry into HepG2 cells by anti E1 Ab. Sera from 6 HCV infected patients (A to F) were used for infection of HepG2 cells before (Lanes 1,3,6,7,9 and 11) and after pre-incubation with anti E1 Ab (Lanes 2,4,6,8,10 and 12). RNA was detected in HepG2 lysates by nested HCV RT-PCR and the products were resolved on 2% agarose gel as described in materials and methods. The presence of a 174 bp band indicates presence of viral RNA while absence of the band indicates successful blocking of viral entry into cells. Lane M shows φx Hae III digest as a molecular weight marker, lane 13 shows RT-PCR of the PBS used for the last wash step of the cells.

Inhibition of HCV entry into HepG2 cells by specific E1 antibodies

Although an in vitro culture for HCV is not available, an inhibition assay of viral absorption or attachment to presumed susceptible cells has been developed by another laboratory for assessing the neutralizing related capacity of antibodies[21]. In the present study we used the HepG2 cell line to examine the biological function of E1 antibody. All 18 serum samples were positive for HCV RNA and have the ability to infect HepG2 cells as determined by PCR (Figure 2). After incubation of serum samples with E1 antibodies overnight at 4 ℃, only 5 out of 18 samples remained infectious to HepG2 cells while the remaining 13 samples did not infect HepG2 cells with an inhibition rate of 72% (Figure 2)

Inhibition of HCV binding to HepG2 cells by specific E1 antibodies

The mean fluorescence intensity of bound HCV particle was determined by flow cytometric analysis of HepG2 cells incubated with FITC labeled $F(ab)_2$ portion of HCV E1 antibody after subtraction of the nonspecific fluorescence value. Figure 3 showed a 6 fold (from 12% to 2%) reduction of mean fluorescence intensity in HepG2 cells treated with serum samples pre-incubated with specific anti E1 antibodies compared with cells incubated with untreated positive sera.

DISCUSSION

Although a detailed analysis of the viral genomic organization has led to the identification of various genetic elements[2] and the establishment of subgenomic replicons[22] in transfection experiments, the study of whole viral entry and infection is still hampered by the inability to propagate the virus efficiently in cultured cells and the limited animal tropism of the virus. The chimpanzee is the only nonhuman host serving as a model for HCV infection[23]. Binding of individually expressed recombinant glycoprotein E2 to human cell lines has been used as a surrogate model for binding of virus to host cells, allowing the study of antibody mediated neutralization of binding[24]. Using this surrogate assay, Pileri *et al*[25] have demonstrated that envelope glycoprotein E2 interacts with the large extracellular loop of cellular membrane protein CD81, a member of the tetraspanin family[26]. CD81 has been suggested as a candidate receptor for HCV[27]. Recently Brazzoli *et al*[28] suggested that productive folding of the major HCV spike protein E2 is assisted by E1. In the present study ,we developed, in house, a monospecific polyclonal antibody for an E1 peptide. The observed great homology within the N-terminal region of E1 suggests that this domain plays a major role in E1/E2 interaction and proper folding of envelop glycoproteins[29,30]. Therefore, a monospecific antibody against the amino terminal domain of E1 protein was expected to interfere with virus binding to membrane receptor. The immunogenicity of this anti E1 Ab was demonstrated by our laboratory in immunoassay techniques such as flow cytometry for detection of E1 glycoprotein in infected cells[31]. In vitro infection experiments, rather than the artificial replicon assays, was reported by others to mimic the intracellular events occurring *in vivo*[32,33]. Besides, study of the E1 Ab activity in blocking infection of cells by several infected sera is easier to accomplish via direct infection than the use of the laborious cloning to produce replicon (s) from each sample. However direct infection experiments does not facilitate 100% efficiency of HCV infection into HepG2 cells in all studied cases. In the current study, only 18 out

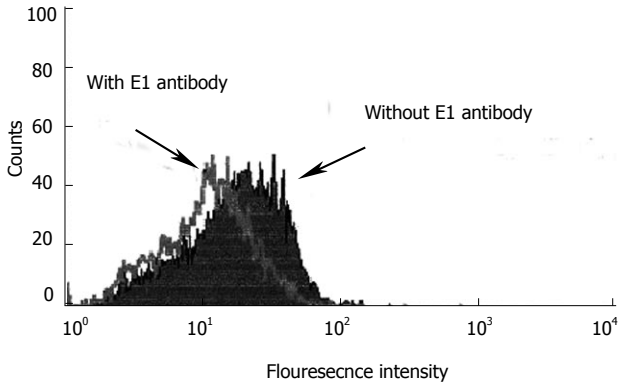

Figure 3 Neutralization of HCV infection into HepG2 cells by anti E1 antibody. The pretreated sera with anti E1 Ab or with PBS were incubated with HepG2 cells for 90 min at 37 °C in CO_2 incubator. Cell pellets were washed with PBS, incubated with FITC labeled $F(ab)_2$ portion of anti E1 Ab and analyzed with flow cytometry as described in Materials and Methods The mean fluorescence intensities decreased from 12.5% in cells incubated with PBS to 2% after treatment with anti E1 Ab using cell Quest software (Becton Dickinson).

of 28 positive samples (64%) had the ability to infect HepG2 cells as determined by intracellular detection of HCV RNA by RT-PCR. The reasons for the inability of the other ten serum samples to infect HepG2 cells is not clear. The quasispecies pool in each sample seems to play a significant role in determining viral entry in each case[34,35], Moreover, the competitive binding of viral particles and low density lipoproteins (LDL) toward the limited number of LDL receptors on cell membrane contributes in the sample to sample variation probably due to individual variations in LDL levels. Enjoji *et al*[36] reported that LDL competitively inhibit the infection of hepatocytes with HCV. On the other hand, our results showed that variations in viral counts appear not to be involved in determining the efficiency of HCV entry into HepG2 cells, a finding that agrees with earlier reports[37]**.** Anti E1 Ab could completely inhibit entry of viral particles into cells in 13 out of 18 (72%) samples. The reasons why the remaining 5 cases (28%) escaped the inhibitory effect of anti E1 Ab may be related to the relative protection of circulating viral particles by exosomes against neutralizing antibodies[38]. Alternatively, the concentration of E1 antibody may be not sufficient for complete inhibition of binding in all tested samples due to variations in the levels of circulating free E1 antigen.

The results of RT-PCR in HepG2 cells were confirmed by the results of flow cytometry. The direct immunostaining of E1 antibody conjugated with FITC and flow cytometric analysis showed reduced mean fluorescence intensity in the samples pre-incubated with E1 Ab compared with samples without E1 Ab. Shimizu *et al*[39] and Farci *et al*[11] demonstrated that a rabbit hyper-immune serum prepared against a peptide representing the 21 C-terminal amino acids of the HVR1 H77 of HCV 1a could neutralize the homologous virus *in vitro* and *in vivo*. These studies provided the first identification of a neutralization epitope on the surface of HCV. They also demonstrated that the neutralization was highly strain-specific and that minor variants of HCV bearing divergent sequences in the HVR1 were not neutralized and emerged in the cell culture and the chimpanzee as neutralization escape mutants. The development of a vaccine against HCV, based on stimulating neutralizing antibody to the HVR1, appeared to be a daunting task[40]. In the present study we provide alternative approach which may bear new hope for developing HCV vaccine based on conserved N-terminal region of E1 protein. Recently, Leroux-Roels *et al*[41] suggested that immunization of healthy individuals against HCV with the E1 protein as a prophylactic vaccine may not only raise useful (potentially neutralizing) anti-E1 antibodies but could also induce a strong T-cell response that might contribute to the prevention of chronic evolution in cases of acute hepatitis C.

In conclusion, in house produced anti E1 Ab that was raised in rabbits against the most conserved region among reported viral strains, blocks HCV infection to target cells suggesting the involvement of this epitope in virus binding and entry. Isolation of similar humanized antibodies that block virus binding and entry will be useful in providing potential therapeutic reagents and for vaccine development.

Abstract

AIM: To assess the effects of obstructive cholestasis on a wider range of gene expression using microarray technology.

METHODS: Male C57BL/6J mice underwent common bile duct ligation (BDL) and were matched with pair-fed sham-operated controls. After 7 d, the animals were sacrificed and total RNA was isolated from livers and kidneys. Equal amounts of RNA from each tissue were pooled for each group and hybridized to Affymetrix GeneChip®MG-U74Av2 containing a total of 12488 probe sets. Data analysis was performed using GeneSpring® 6.0 software. Northern analysis and immunofluorescence were used for validation.

RESULTS: In sham-operated and BDL mice, 44 and 50% of 12488 genes were expressed in livers, whereas 49 and 51% were expressed in kidneys, respectively. Seven days after BDL, 265 liver and 112 kidney genes with GeneOntology annotation were up-regulated and 113 liver and 36 kidney genes were down-regulated in comparison with sham-operated controls. Many genes were commonly regulated in both tissues and metabolism-related genes represented the largest functional group.

CONCLUSION: Following BDL, microarray analysis reveals a broad range of gene alterations in both liver and kidney.

Key words: Bile duct ligation; Cholestasis; Kidney; Liver; Microarray

INTRODUCTION

Cholestasis, defined as impairment of bile secretion, is a feature of many hepatic disorders and systemic diseases. The recent cloning and functional characterization of different transport proteins for bile acids, organic anions and cations in hepatocytes and cholangiocytes have provided new insights into the molecular biology and physiology of bile formation and have increased understanding of the pathophysiology of cholestatic disorders[1]. Thus it is now established that a number of transport proteins in the basolateral and canalicular hepatocyte membrane undergo adaptive regulation in response to cholestatic liver injury to minimize the hepatic accumulation of toxic substances, such as hydrophobic bile acids[2-4]. Previous studies have indicated that in addition to the liver, adaptive regulation of these transporters in cholestasis also occurs in extrahepatic tissues, including the kidney[5] and the intestine[6]. Other alterations in cholestasis affect hepatic signal transduction[7,8], vesicular transport[7], apoptosis[9,10], metabolism[11], and the structure of the extracellular matrix[12,13].

Given the wide range of signaling, regulatory, and metabolic pathways, structural elements, and transport proteins which may be affected in cholestasis, much

further research will be necessary to more fully understand the extent of these adaptations. High-density DNA microarrays containing thousands of DNA fragments and oligonucleotides are a potentially promising approach to identify additional genes of interest that play a role in this pathophysiologic process. Based on their ability to monitor large numbers of genes at a time, high-density DNA microarrays are a sensitive, time-saving, and efficient tool in determining gene expression and finding regulatory pathways[14].

In the present study, we, therefore, have utilized high-density oligonucleotide microarray technology to screen for gene alterations in the liver and kidney following bile duct ligation (BDL) in mice, an established model of obstructive cholestasis. This study has allowed a comprehensive gene expression profile to be obtained in cholestatic mouse liver and kidney as well as it has highlighted a number of genes whose expression is particularly altered by this process.

MATERIALS AND METHODS

Animals and animal treatment

Male C57BL/6J mice (8-12-wk-old) purchased from Jackson Lab (Bar Harbor, ME) underwent BDL or sham-surgery as previously described[15]. The common bile duct was identified, ligated twice close to the liver hilum immediately below the cystic duct, and then divided between the ligatures. Control mice underwent sham-surgery in which the common bile duct was exposed but not ligated. Since sham-operated mice tend to consume more food than BDL mice and the expression of some genes may be affected by caloric intake, food intake of BDL mice was monitored daily and sham-operated mice were pair-fed so as to receive the same amount of food as BDL mice. Animals were sacrificed 7 d after surgery and livers and kidneys were harvested. The protocol was approved by the Yale Animal Care and Use Committee, and the animals received humane care as outlined in the "Guide for the Care and Use of Laboratory Animals" (NIH publication 86-23, revised 1985).

Isolation of total RNA

Blood-free livers and kidneys were homogenized in GTC solution containing 4 mol/L guanidinium thiocyanate, 25 mmol/L Na-citrate, and 5 g/L N-lauroylsarcosine and subjected to CsCl gradient centrifugation. The recovered total RNA was further purified by phenol/chloroform extraction and ethanol precipitation. The RNA concentration was determined spectrophotometrically and the RNA quality was confirmed by formaldehyde-agarose gel electrophoresis. Equal amounts of liver and kidney, respectively, total RNA from each of four BDL and four sham-operated mice were pooled to minimize inter-animal variations and used for biotin-labeling.

DNA microarray hybridization and analysis

The biotin-labeled RNA from the different groups was hybridized with two replicates for each condition to individual high-density oligonucleotide microarray chips (GeneChip®MG-U74Av2) from Affymetrix (Santa Clara, CA) containing a total of 12488 probe sets. Microarray expression data were generated with Affymetrix Microarray Suite 5.0 software and further analysis was carried out with GeneSpring®6.0 (Silicon Genetics, Redwood City, CA). Raw intensity values from each chip were normalized to the 50th percentile of the measurements taken from that chip to reduce chip-wide variations in intensity. Each gene was normalized to the average measurement of that gene in the respective paired controls to enable comparison of relative changes in gene expression levels between different conditions. Cross-gene error model was active based on the replicates. Comparisons of gene expression data were made between BDL and sham-operated mice. Signal and detection flag from Microarray Suite 5.0 were used as quality controls. Only genes with a minimum signal intensity of 600, a detection flag present in both replicates in at least one of the comparison conditions, and a two-fold and above change in gene expression were used for further analysis. For identification of differentially expressed genes in the different groups, a one-sample *t*-test with a *P* value cutoff of 0.05 was performed to determine if the average log of the ratio of the replicates was significantly different from 1.0, which was the value of the control samples after normalization. Finally, genes were categorized into GeneOntology (GO) and annotated using NetAffx®, an analysis web interface from Affymetrix.

Northern analysis

To validate alterations in gene expression on the microarray, changes in the expression of selected genes were confirmed in aliquots of the same RNA samples used for the microarray by Northern analysis as previously described[16]. The following primers were used for the generation of specific probes: cytochrome P450 7b1 (GenBank accession number U36993): 5'-GAATCTC AGCTTAGAGAGTAAGAG-3' (sense), 5'-TTTGTA CCTAAAGGAGACGGCAG-3' (antisense); organic cation transporter 1 (Oct1) (GenBank accession number U38652): 5'-GCAGCCTGCCTCCTCATGATC-3' (sense), 5'-GGTAAATCGTGTTTTCTTTGGCC-3' (antisense); similar to putative integral membrane transport protein (GenBank accession number AI647632): 5'-TGATTACA AGAAATGTCAAGCAGG-3' (sense), 5'-CCTCTTCCTG ACTCCATCCATG-3' (antisense).

Immunofluorescence

Indirect immunofluorescence with a polyclonal antibody against Oct1[17,18] (dilution 1:100; kindly provided by Prof. Dr. H. Koepsell, Würzburg, Germany) was conducted on liver specimens from sham-operated and BDL mice as previously described[19].

RESULTS

Gene expression profile in mouse liver in obstructive cholestasis

Of the total of 12488 genes on the microarray chip, 44 and 50% were expressed in the livers of sham-operated and BDL mice, respectively. After 7 d of obstructive cholestasis 265 genes with GO annotation were up-regulated and 113 were down-regulated in livers of BDL

mice by a factor of two or more in comparison with sham-operated pair-fed controls. Metabolism-related genes represented the largest functional group among the altered genes after BDL in liver (Table 1). It should be noted that the grouping of the altered genes was primarily done to achieve a clearer arrangement for the reader. Since a considerable number of the encoded proteins have multiple, little characterized or even unknown functions, we want to point out that the classification provided is subject to the personal opinions and emphasis of the authors (Table 1). Upon request, a complete list of the altered genes including genes without GO annotation that are not mentioned here can be obtained from the authors. Alternatively, the complete list of altered genes can be accessed via http://livercenter.yale.edu/datalist.html.

Gene expression profile in mouse kidney in obstructive cholestasis

In the kidneys of sham-operated and BDL mice, 49 and 51% of the 12 488 genes on the microarray chip were expressed, respectively. Seven days after surgery, 112 genes with GO annotation were up-regulated and 36 were down-regulated in the kidneys of BDL mice at least two-fold when compared with the sham-operated pair-fed controls. Thus the number of altered genes in kidney seven days after BDL was considerably smaller than that in liver (148 *vs* 378). Of the 112 GO genes up-regulated in kidney after BDL, 53 were also up-regulated in cholestatic liver. In contrast, of the 36 genes down-regulated in kidney, 7 were also down-regulated in liver (Table 1). What was particularly striking is that many of the most highly up-regulated genes in liver were also the same genes that were most highly up-regulated in kidney, irrespective of their functional class (Table 1). This suggests that both the liver and the kidney may be responding to similar transcriptional signaling molecules in this cholestatic model. For example, the acute phase gene, *serum amyloid A3*, was up-regulated 10.0-fold in liver and 36.1-fold in kidney, the gene encoding *chemokine (C-X-C motif) ligand 1* was increased 9.6-fold in liver and 4.2-fold in kidney, and the gene encoding the transport molecule *lipocalin 2* was up-regulated 13.1-fold in liver and 66.5-fold in kidney. In addition, a number of cell adhesion and extracellular matrix genes were similarly up-regulated in both liver and kidney. However, only one membrane transporter gene was up-regulated in both tissues, the gene encoding the *β1 subunit of the voltage-gated sodium channel* (Table 1). Interestingly, several genes for nucleic acid binding proteins were also highly up-regulated in both liver and kidney including the genes encoding the transcription factors *FBJ osteosarcoma oncogene* (alias *c-Fos*), *CCAAT/enhancer binding protein (C/EBP), delta*, and *activating transcription factor 3*.

In contrast, only seven genes were commonly down-regulated in both liver and kidney. These included the *RIKEN cDNA 1700013L23 gene* and the genes encoding *similar to putative integral membrane transport protein, major urinary protein 2*, *transthyretin*, *cytochrome P450 7b1* (GenBank accession numbers AV141027 and U36993), and *thioether S-methyltransferase*.

Northern analysis of selected genes

Gene expression results from the microarray were confirmed by Northern analysis for selected genes that included *cytochrome P450 7b1*, *organic cation transporter 1 (Oct1; solute carrier family 22, member 1)* and *similar to putative integral membrane transport protein* from aliquots of the RNA samples utilized for the microarray (Figure 1).

Tissue immunofluorescence of Oct1 in liver

Indirect immunofluorescence was performed to illustrate the decreased expression of the organic cation transporter Oct1 in BDL mouse liver. Figures 2A and B demonstrate that the findings are consistent with the microarray and the Northern blot results and corroborate that obstructive cholestasis leads to a down-regulation of Oct1 in mouse liver similarly as demonstrated previously in rat liver following BDL[19,20].

DISCUSSION

Ligation of the common bile duct in rodents is a well-established model of obstructive cholestasis. While most previous studies have been limited to investigations of small numbers of genes and their encoded proteins, we have been able to simultaneously monitor the responses of large numbers of genes in this cholestatic model by using high-density oligonucleotide microarray technology. In contrast to a recent study which investigated gene expression in obstructive cholestasis only in the livers of BDL mice[21], we additionally monitored alterations of gene expression in the kidneys because the kidney is functionally closely linked to the liver and provides an alternative excretory route for cholephilic substances in cholestasis[5]. One of the interesting conclusions from this analysis is the finding that many of the most highly up-regulated genes were shared in both liver and kidney, possibly due to a common response to similar transcriptional signaling molecules in both tissues. The interpretation and discussion of our data is based on the assumption that changes in gene expression lead to changes in protein expression although it is known that changes at the mRNA level do not always result in changes in protein expression in certain time periods[22]. As others have done, we first evaluated the observed changes in gene expression in terms of what is already known about the effects of cholestasis. We then attempted to identify novel regulatory processes that have not yet been investigated[22].

For example, our microarray data largely confirm previous results obtained by conventional determination of transcription in obstructive cholestasis, such as the up-regulation of the canalicular cation transporter *multidrug resistance P-glycoprotein 1a* (*Mdr1a*, Abcb1a)[23] or the down-regulation of the basolateral *sodium-taurocholate cotransporting polypeptide* (*Ntcp*, Slc10a1)[24]. In addition, our gene expression profile obtained from cholestatic liver also closely matched the gene expression profile recently generated by Campbell *et al*[21], although there are a substantial number of additional gene alterations in our data set. This difference can be explained since Campbell

Table 1 Fold increase/decrease in liver and kidney, GenBank accession number, and classification of altered genes in mice 7 d after bile duct ligation in comparison with pair-fed sham-operated controls

Liver	Kidney	Accession number	Description

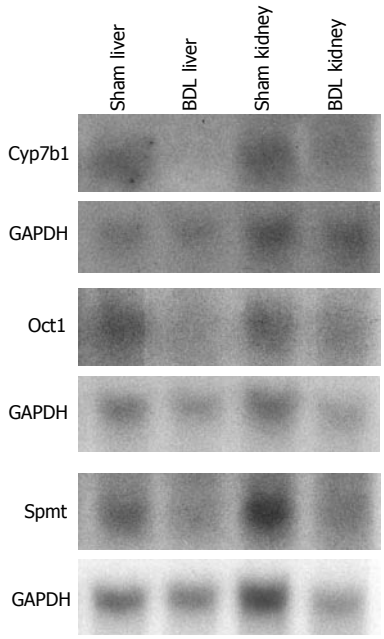

Figure 1 Confirmation of microarray data by Northern analysis of selected genes. Northern blots were performed with aliquots of pooled RNA from livers and kidneys from each 4 pair-fed sham-operated and 4 bile duct ligated mice, 7 d after surgery. Cyp7b1: Cytochrome P450 7b1; Oct1: Organic cation transporter 1; Spmt: Similar to putative integral membrane transport protein; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; Sham: Sham-surgery; BDL: Bile duct ligation.

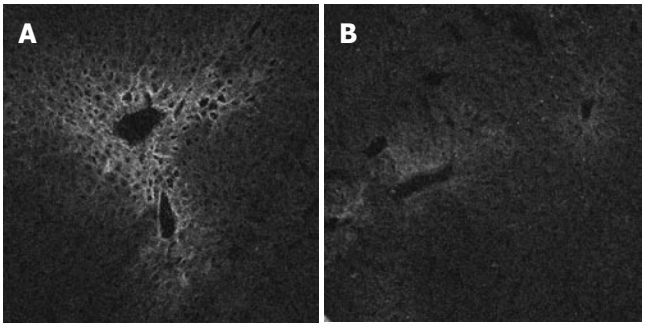

Figure 2 Indirect immunofluorescence of organic cation transporter 1 in murine liver sections. **A:** A low magnification view (x 20) shows antibody labeling at the basolateral membranes of hepatocytes of the pericentral zone of the liver lobule in the liver section of a sham-operated mouse, 7 d after surgery; **B:** In contrast, there is only a weak signal for organic cation transporter 1 after bile duct ligation.

et al[21] excluded genes with expression levels of less than 1 000, whereas we included genes with a mininum signal intensity of 600 and above. This approach led to the identification of a number of novel gene alterations of functional significance for the cholestatic phenotype. For instance, the decrease in expression of the gene encoding *Oct1* in BDL liver in the present microarray, an alteration not reported by Campbell *et al*[21] but previously reported by Ogawa *et al*[20] in the rat, led us to study this important basolateral cationic drug transporter in more detail. We were subsequently able to demonstrate that Oct1 is indeed down-regulated in rat liver, but not in kidney, in obstructive cholestasis at the mRNA as well as the protein levels and that this decrease results in reduced hepatic uptake of the Oct1 substrate tetraethylammonium[19]. Northern analysis and immunofluorescence microscopy of hepatic Oct1 performed in the present study indicated a similar pattern in mouse and confirmed the results of our microarray.

A number of other observations emerge from this analysis that deserve further study. For example, among the cell growth-related genes, the number of genes up-regulated in liver after BDL surpassed by far the number of down-regulated genes, a pattern which might reflect the extensive fibroproliferative process and tissue remodeling that takes place in this model of obstructive cholestasis. Similarly, a large number of genes related to cell adhesion, the extracellular matrix, and the cytoskeleton were found to be altered that have not been identified yet. We presume that many of these genes may play an important but as yet to be identified role in the fibrogenic response of the liver to bile duct obstruction. Alterations in the composition of the extracellular matrix are typical features of hepatic fibrosis[13], including substantial increases of collagens and non-collagenous components[25,26]. Accordingly, we observed a uniform up-regulation of genes encoding the *procollagen types* $I\alpha_1$, $I\alpha_2$, $III\alpha_1$, $IV\alpha_1$, $IV\alpha_2$, and $V\alpha_2$ in this mouse model of obstructive cholestasis. In addition, two members of the matrix metalloproteinase family, the *matrix metalloproteinases 7* and *12*, were up-regulated more than ten-fold following BDL when compared with the sham-operated controls. Matrix metalloproteinases represent a group of calcium-dependent enzymes involved in physiological and pathological degradation of extracellular matrix and tissue-remodeling[27]. *Matrix metalloproteinase 7 (matrilysin)*, an enzyme which is associated with poor prognosis in hepatocellular[28] and cholangiocellular carcinomas[29], has been closely related to the fibro-proliverative process in chronic hepatitis C[30] but not in cholestatic liver diseases. In contrast, *matrix metalloproteinase 12*, to our knowledge, has not been associated with liver fibrosis before and deserves future attention. Interestingly, the genes encoding *tissue inhibitor of metalloproteinase 1*, *vascular cell adhesion molecule 1* and *intercellular adhesion molecule* were up-regulated both in liver and kidney of BDL mice. Genes encoding the *procollagen types* $I\alpha_1$ *and* $III\alpha_1$ were also increased in the kidney of BDL mice although at lower levels than in the liver. The up-regulation of fibrosis-associated factors in kidney following BDL might be due to a paracrine action of fibrogenic mediators such as *connective tissue growth factor* whose hepatic expression is increased in cholestasis as previously described[31,32] and confirmed in our microarray. However, the functional relevance of the increased expression of these fibrotic genes in the kidney remains to be determined. Alternatively, the simultaneous up-regulation of important regulators of transcription following BDL such as *FBJ osteosarcoma oncogene*, *core promoter element binding protein*, and *activating transcription factor 3* in both liver and kidney supports the idea of coordinated gene regulation in different tissues as response to a specific stimulus. Another non-collagenous component of the extracellular matrix which was up-regulated in BDL liver is the gene for the matricellular protein *secreted acidic cysteine rich glycoprotein*. Matricellular proteins are a group of matrix-associated factors that mediate cell-matrix interactions but do not serve primarily as structural elements[13]. In particular, the expression of *secreted acidic cysteine rich glycoprotein* has been associated with cell proliferation, migration, and extracellular matrix remodeling in tissues, and *secreted acidic cysteine rich glycoprotein* has been found to be increased in different models of hepatic fibrosis[33].

The expression of a number of genes encoding

membrane proteins and transporters that were not previously known to be affected by cholestasis was also of interest. For example, the gene encoding the *β1 subunit of the voltage-gated sodium channel* which is important for the maturation and function of this channel[34] was up-regulated in liver as well as in kidney of BDL mice. In contrast, the expression of the gene encoding the ATP-binding cassette transporter *multidrug resistance-associated protein 6* (*Mrp6,* Abcc6) was reduced in cholestatic mouse liver as previously described for the rat[20]. Since mutations of human MRP6 are associated with pseudoxanthoma elasticum, a disorder characterized by calcification of the elastic fibres and abnormalities of the collagen fibrils[35], it is tempting to speculate that reduced hepatic Mrp6 expression in cholestasis might have functional implications for the development of liver fibrosis. Other genes up-regulated in cholestatic liver were the genes encoding the macrophage receptor markers *CD14 antigen* and *CD68 antigen*. Hepatic expression of both markers is increased in patients with biliary atresia[36], and expression of *CD68 antigen* may be an indicator of prognosis[37]. The functional significance of the concomitant *CD68 antigen* elevation in BDL kidney is unclear at the moment but illustrates again the close linkage between liver and kidney in this model of cholestasis and supports again a concept of coordinated gene regulation in different tissues.

In accordance with previous studies[38], obstructive cholestasis decreased the expression of a number of genes encoding *cytochrome P450* isoenzymes in liver. Since BDL results in an increase in liver concentrations of bile acids[15], the down-regulation of the *cytochrome P450 7b1 (oxysterol 7α-hydroxylase)* and *cytochrome P450 8B1 (sterol 12α-hydroxylase)* genes, that encode key enzymes in the conversion of cholesterol to bile acids[39], may represent adaptive responses to minimize the liver levels of cytotoxic bile salts. The increase of the gene encoding *cytochrome P450 27b1 (25-hydroxyvitamin D_3 1α-hydroxylase)* in BDL kidney is another interesting observation. *Cytochrome P450 27b1* catalyzes the conversion of 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D_3, the last step in vitamin D activation, which takes place in kidney[40]. Thus the increase in renal *cytochrome P450 27b1* expression may reflect an adaptive response to compensate for 25-hydroxyvitamin D deficiency in cholestasis. This may be a pathophysiologically important mechanism since patients with primary biliary cirrhosis often present with deficiencies of 25-hydroxyvitamin D but normal or even elevated levels of 1, 25-dihydroxyvitamin D[41].

In summary, the present study provides a comprehensive gene expression profile from mouse liver and kidney in obstructive cholestasis. Changes in gene expression were validated by Northern analysis, immunofluorescence, or comparison with the literature. The findings in this study provide new insights for generating novel hypotheses concerning the adaptive responses of gene expression in this mouse model of cholestasis.

ACKNOWLEDGMENTS

We thank Albert Mennone and Kathy Harry (both Liver Center, Yale University School of Medicine, New Haven, CT, USA) for excellent technical assistance and Prof. Dr. Hermann Koepsell (Institut für Anatomie und Zellbiologie, Bayerische Julius-Maximilians-Universität, Würzburg, Germany) for providing the Oct1 antibody.

Abstract

AIM: To immunohistochemically examine micrometastasis and VEGF-C expression in hilar bile duct carcinoma (HBDC) and to evaluate the clinical significance of the results.

METHODS: A total of 361 regional lymph nodes from 25 patients with node-negative HBDC were immunostained with an antibody against cytokeratins 8 and 18 (CAM 5.2), and immunohistochemical staining of VEGF-C was performed in 34 primary resected tumors.

RESULTS: Lymph node micrometastasis was detected in 6 (24%) of the 25 patients and 10 (2.8%) of the 361 lymph nodes. Patients with micrometastasis showed significantly poorer survival rates than those without ($P = 0.025$). VEGF-C expression was positive in 17 (50%) of 34 HBDC, and significantly correlated with lymph node metastasis ($P = 0.042$) and microscopic venous invasion ($P = 0.035$).

CONCLUSIONS: It is suggested that immunohistochemically detected lymph node micrometastasis has an impact on the outcome of HBDC. VEGF-C expression is highly correlated with lymph node metastasis in HBDC and might therefore be a useful predictor.

Key words: Hilar bile duct carcinoma; Lymph node metastasis; Micrometastasis; Vascular endothelial growth factor-C

INTRODUCTION

Hilar bile duct carcinomas (HBDC) are one of the most difficult to cure malignant gastroenterological tumors[1-4] and curative resection is essential for long-term survival. Because hilar bile duct tumors are in close proximity to vital structures in the hepatic hilum, such as the hepatic artery and portal vein, and since they tend to spread to the proximal biliary tract and perineural and perilymphatic spaces, hepatectomy with thorough systematic extended lymph node dissection is frequently required for curative resection. However, even with margin-negative resection, the prognosis after curative resection remains poor. One possible reason for the poor outcome is existence of occult lymph node metastasis that cannot be detected by conventional hematoxylin and eosin (HE) staining at the time of surgical resection. Immunohistochemical and molecular techniques have, however, made it possible to identify lymph node micrometastasis missed by traditional methods. Recently, immunohistochemical and/or genetic detection of lymph node micrometastases of various tumors, including carcinomas of the breast[5,6], lung[7,8], esophagus[9,10], stomach[11-14], colorectum[15,16] and gallbladder[17-19], has been reported. However, we were able to find only one report documenting this in HBDC[20].

Vascular endothelial growth factor C (VEGF-C) is a member of the highly glycosylated vascular endothelial growth factor (VEGF) family that regulates vasculogenesis, hematopoiesis, angiogenesis, lymphangiogenesis and vascular permeability, and has been implicated in many physiological and pathological processes[21,22]. Overexpression of VEGF-C cDNA in the skin of transgenic mice has been shown to selectively induce lymphatic endothelial cell proliferation and hyperplasia of the lymphatic vasculature[23]. It was also recently reported that a VEGF-C-transfected tumor cell line implanted into the stomach of nude mice gave rise to numerous lymph node metastases[24]. The most prominent VEGF-C expression has been detected in the human heart, placenta, muscle, ovary, and small intestine[25], and a positive correlation between expression and various clinicopathological factors, especially lymph node metastasis, has been reported in a number of tumors,

including carcinomas of the thyroid[26], breast[27], lung[28], esophagus[29], stomach[30,31], colorectum[32], prostate[33] and pancreas[34]. However, no investigations have been conducted with regard to VEGF-C expression in HBDC and possible clinicopathological associations. In this study, we examined lymph node micrometastasis and VEGF-C expression in patients with HBDC and evaluated the clinical significance of the results.

MATERIALS AND METHODS

Patients and specimens

From January 1981 to August 2000, 61 patients with HBDC underwent surgical resection plus systematic lymph node dissection in the First Department of Surgery, Mie University School of Medicine. Of these patients, 34 underwent macroscopic and microscopic margin-negative resection. Patients consisted of 21 males and 13 females with a mean age of 64.4±11.0 years (range: 37-89 years). The median follow-up period was 31.8 mo (minimum: 1.0 mon). No lymph node metastases were detected in 25 (73.5%) of the 34 patients by traditional pathologic examinations with HE staining.

Hepatectomy was performed in 29 (85.3%) of the 34 patients: extended right hepatectomy in 9 patients, left hepatectomy in 8, resection of segments 4a and 5 in 5, hilar resection in 4, extended left hepatectomy in 2, and caudate lobectomy only in 1. All 29 patients underwent combined resection of the caudate lobe. Two patients underwent combined resection of the portal vein, and 3 underwent pancreatoduodenectomy (PD) or pylorus-preserving pancreatoduodenectomy. Another 5 patients were treated with bile duct resection alone, including 2 patients who underwent combined PD.

A total of 361 lymph nodes dissected from 25 node-negative patients were examined immunohistochemically by staining with an antibody against cytokeratins 8 and 18, and all 34 primary tumors were immunohistochemically stained for VEGF-C. Tumor specimens and lymph nodes were collected from pathology files after obtaining informed consent from all patients in accordance with institutional guidelines.

Lymph node groups and resected margin status

Identification of the sites of lymph node metastasis were performed in accordance with the TNM Classification of Malignant Tumors proposed by the International Union Against Cancer (UICC)[35], which defines regional lymph nodes as the cystic duct, pericholedochal, hilar and peripancreatic (head only), periduodenal, periportal, celiac and superior mesenteric nodes, N0 as no regional lymph node metastasis and N1 as regional lymph node metastasis.

Evaluation of resected margin status was performed in accordance with the General Rules for Surgical and Pathological Studies on Cancer of the Biliary Tract (The 5th Edition) proposed by the Japanese Society of Biliary Surgery (JSBS)[36], which defines pEM0 as no tumor invasion within 5 mm of the resected margin, pEM1 as tumor invasion within 5 mm of the resected margin and pEM2 as distinct tumor invasion of the resected margin. pEM0 and pEM1 resections were defined as margin-negative in this study.

Immunohistochemical staining

Tissue samples were fixed in 10% formaldehyde with phosphate-buffered saline (PBS) and embedded in paraffin. Lymph node tissue was cut into six 5-μm thick sections, and primary tumor tissue was cut into a single 5-μm thick section. Briefly, the sections were deparaffinized with xylene and rehydrated through graded concentrations of ethanol. For antigen retrieval, sections were placed in 0.1*mol*/L citrate buffer (pH 6.0) and heated three times for 3 min each in a microwave oven (500 W). Lymph node sections were then incubated with a mouse monoclonal antibody (CAM 5.2; Becton Dickinson, San Jose, CA) specific for cytokeratins 8 and 18, and tumor sections were incubated with affinity-purified goat polyclonal antibodies (IBL, Fujioka, Japan) to VEGF-C at 1:30 dilution. Immunohistochemical detection of CAM 5.2 and VEGF-C was performed by a standard avidin-biotin method on an automated Ventana ES immunostainer (Ventana Medical Systems, Tucson, AZ) according to the manufacturer's instructions[37].

We examined 6 sections per lymph node and diagnosed micrometastasis when tumor cells were detected immunohistochemically, after being missed by routine histologic examinations with HE staining. VEGF-C immunoreactivity was mainly present in the cytoplasm of cancer cells and/or in the connective tissue around cancer cells. For evaluation of VEGF-C immunostaining, we examined at least 200 cancer cells per case. Cases in which at least 10% of the cancer cells were immunoreactive were defined as VEGF-C positive. All immunohistochemical evaluations were performed by an experienced histopathologist unaware of the clinicopathological features of the patients.

Statistical analysis

All statistical calculations were carried out using StatView-J 5.0 statistical software (SAS Institute, USA). Results are expressed as the means±SD. Statistical analysis for comparisons of VEGF-C expression and clinicopathological factors (age, gender, lymphatic vessel invasion, microscopic venous invasion, perineural invasion and lymph node metastasis) were performed using the chi-square test and Fisher's exact probability test. Analysis for comparisons of VEGF-C expression and other factors (pT classification and histopathological grading) was performed using the Mann-Whitney *U*-test. The Kaplan-Meier method was used to estimate postoperative survival rates, and the generalized log-rank test was used to compare differences in survival rates. All P values were two-sided and $P<0.05$ was considered statistically significant.

RESULTS

Patient outcomes

Of the 34 patients with margin-free resected HBDC, 4 died of other causes; three of multiple organ failure including 1 postoperative death (within 1 mo), and 1 of unknown causes. In addition, 15 (50.0%) of the remaining 30 patients died of disease. Recurrence sites were the

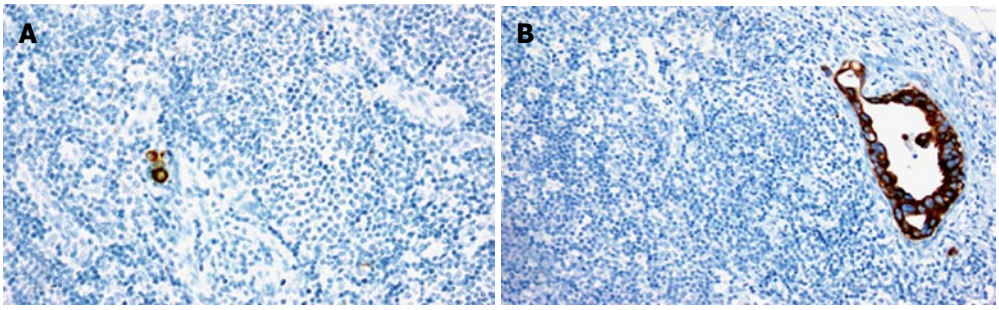

Figure 1 Immunohistochemical staining of lymph node micrometastasis with the monoclonal antibody CAM 5.2. **A:** Micrometastasis consisting of a single cell (original magnification, × 200). **B:** Micrometastasis consisting of a small cluster of tumor cells (original magnification, × 100).

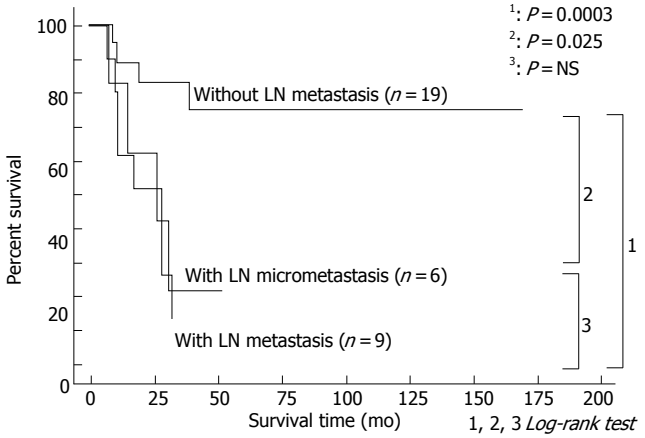

Figure 2 Survival curves after resection for hilar bile duct carcinoma according to the presence of lymph node metastasis, including micrometastasis.

liver in 2 patients including 1 patient with combined lung recurrence, the peritoneum in 1 patient, and local regions in 11 patients. Of these 11 patients, 3 showed combined recurrence in other sites; 1 showed combined liver metastasis, 1 showed combined lung metastasis, and 1 showed combined peritoneum recurrence.

Detection of lymph node micrometastasis

Micrometastasis was detected in 6 (24.0%) of the 25 node-negative patients and 10 (2.8%) of the 361 lymph nodes by immunohistochemical examination with CAM5.2. Lymph node micrometastasis was present in the form of a single-cell metastasis (Figure 1A) or a small cluster of tumor cells (Figure 1B). Of the 6 patients with lymph node micrometastasis, 5 had regional lymph node micrometastasis and 1 had regional lymph node with para-aortic lymph node micrometastases.

Impact of lymph node micrometastasis on survival

Cumulative survival rates were compared according to nodal status: the without lymph node metastasis group versus lymph node micrometastasis group versus HE diagnosed (overt) lymph node metastasis group (Figure 2). The 3- and 5-year survival rates of the 19 patients without lymph node metastasis were 81.6 and 72.5%, respectively, as opposed to 20.8 and 20.8%, respectively, in the 6 patients with micrometastasis and 29.6% and 0.0%, respectively, in the 9 patients with overt lymph node metastasis. Patients with lymph node micrometastasis showed significantly worse survival rates than those without ($P = 0.025$), and moreover, patients with overt lymph node metastasis showed worse survival rates than those without ($P = 0.0003$). There were no statistical differences between patients with lymph node micrometastasis and those with overt lymph node metastasis ($P = 0.469$). Five patients died of disease without overt lymph node or micrometastasis. Of these, 4 died of local recurrence, including 1 patient with combined liver metastasis. The remaining patient died of liver and lung metastasis. Follow-up revealed that 3 patients with lymph node micrometastasis survived with no evidence of disease for 11.7 and 36.7 and 60.3 mon after surgical resection, respectively.

To further evaluate the impact of lymph node micrometastasis on survival, survival rates were compared according to two groups: patients without lymph node metastasis versus those with overt lymph node and micrometastasis (Figure 3), and patients without lymph node metastasis and those with lymph node micrometastasis versus those with overt lymph node metastasis (Figure 4). The 3- and 5-year survival rates of the 19 patients without lymph node metastasis were 81.6 and 72.5%, respectively, as opposed to 25.5 and 8.5%, respectively, in the 15 patients with overt lymph node and micro metastasis ($P = 0.0004$). On the other hand, the 3- and 5- year survival rates of the 25 patients without lymph node metastasis and those with lymph node micrometastasis were 66.9 and 60.2%, respectively, as opposed to 14.8 and 0.0%, respectively, in the 9 patients with overt lymph node metastasis ($P = 0.0015$).

VEGF-C expression and clinicopathological factors

VEGF-C expression was observed in 17 (50.0%) of the 34 primary tumors (Figure 5). The correlations between VEGF-C expression and clinicopathological factors are shown in Table 1. Microscopic venous invasion ($P = 0.035$) and lymph node metastasis ($P = 0.042$) were significantly correlated with VEGF-C expression.

Prognostic factors for hilar bile duct carcinoma

To identify useful prognostic factors, we performed univariate analysis of the following possible independent prognostic factors: age (above 60 years versus 60 years or less), gender, operative procedure (hepatectomy versus bile duct resection), histopathological grading (well differentiated versus moderately or poorly differentiated), lymphatic vessel invasion, microscopic venous invasion, perineural invasion, microscopic resection margin (em0 versus em1), VEGF-C expression, lymph node metastasis (including micrometastasis) and lymph node metastasis (excluding micrometastasis) (Table 2). Ultimately, 4 independent variables (microscopic resection margin ($P = 0.040$), VEGF-C

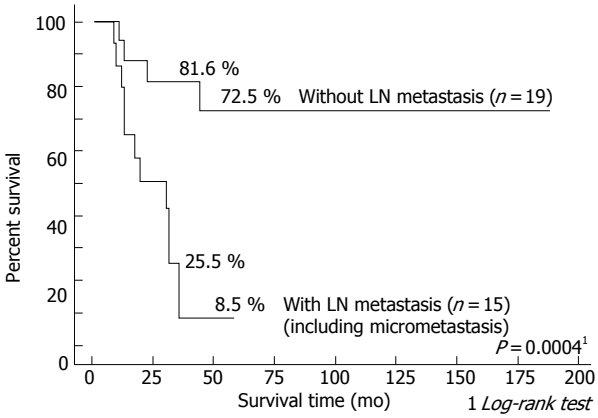

Figure 3 Survival curves after resection for hilar bile duct carcinoma according to the presence of lymph node metastasis: patients without lymph node metastasis versus those with overt lymph node and micro metastasis.

	G3	0	1	
Lymphatic vessel invasion	(presence)	14 (87.5 %)	13 (72.2 %)	0.405
Venous invasion	(presence)	10 (62.5 %)	4 (22.2 %)	0.035
Perineural invasion	(presence)	14 (87.5 %)	10 (55.6 %)	0.063
Lymph nodes metastasis	Metastasis (-)	6	13	0.042
	Metastasis (+) (including micrometastasis)	10	5	

[1]According to the TNM staging system. pT classification: pT1: Tumor confined the bile duct; pT2: Tumor invades beyond the wall of the bile duct; pT3: Tumor invades the liver, gallbladder, pancreas, and/or unilateral tributaries of the portal vein (right or left) or hepatic artery (right or left); pT4: Tumor invades any of follwing: main portalvein or its tributaries bilatellary, common hepatic artery, or other adjacent structures, e.g., colon, stomach, duodenum, abdominal wall. Histopathological Grading: G1: Well differentiated; G2: Moderately differentiated; G3: Poorly differentiated.

expression (P = 0.036), lymph node metastasis (including micrometastasis) (P = 0.0004) and lymph node metastasis (excluding micrometastasis) (P = 0.0017)) were identified as statistically significant predictors of survival.

DISCUSSION

Lymph node metastasis is a well known important predictor of prognosis with a wide variety of malignant tumors, and some studies have reported a significant relationship

Table 2 Univariate analysis of survival

Variable		5-yr survival (%)	*P* Value
Age	<60 *vs* ⩾60	40.0 *vs* 44.9	0.912
Gender	male *vs* female	42.3 *vs* 45.5	0.872

between lymph node metastasis and prognosis of HBDC patients[38-40]. However, patients with early stage carcinoma and no apparent lymph node metastasis sometimes die of metastasis after surgery despite complete resection of the primary lesion. One of the possible reason for the poor outcome in these patients is occult lymph node metastasis not identified by conventional HE staining at the time of surgical resection.

Numerous studies on the incidence and significance of lymph node micrometastasis in cancer patients have been conducted in recent years. A number of investigators have proposed the prognostic significance of lymph node micrometastasis for various tumors including lesions of the lung, esophagus, stomach and colon, while others have suggested that lymph node micrometastasis is not significant for patient outcome. Thus, there is no consensus on the clinical significance of lymph node micrometastasis. However, we were able to find only one report documenting this in HBDC. Tojima *et al*[20] investigated 954 nodes from 45 patients with pN0 hilar cholangiocarcinoma after curative resection, and found micrometastasis in 13 (1.4%) nodes from 11 (24.4%) patients. Their data yielded similar survival curves for patients with and without lymph node micrometastasis (5-year survival rates: 43.6% *vs* 42.1%, respectively).

In this study, we demonstrated significant differences between outcomes of HBDC patients with and without lymph node micrometastases. Interestingly, a stronger correlation was recognized when patients with lymph node micrometastasis were treated as lymph node metastasis positive, compared to when they were treated as lymph node metastasis negative ($P=0.0004$ versus $P=0.0017$) (Figures 3 and 4). This might suggest the need to consider lymph node micrometastasis as overt lymph node metastasis.

One possible reason for the above-mentioned differing results is the number of sections examined. The number of sections immunohistochemically stained is considered an important factor in the diagnosis of lymph node micrometastasis. Many investigators examine lymph node micrometastasis using various sections of different thickness for immunohistochemical staining; however, the total thickness examined tends to range from 3 to 30 μm[6,8,10,13-20]. Sasaki *et al* examined the correlation between the number of CAM 5.2 sections and cumulative positive rate of lymph node metastasis[41]. They found that positive metastasis detection reached a plateau when over 9 sections (total thickness 27 μm) were examined. In this study, to identify lymph node micrometastasis, we examined six 5-μm sections (total thickness 30 μm) per lymph node by immunohistochemical staining. When we examined only one to four sections per lymph node, we found fewer lymph node micrometastases (data not shown).

Another possible reason for the differing results is the criteria of lymph node micrometastasis. In many studies, including ours, micrometastasis is defined as tumor cells detected only by immunohistochemical staining. However, some authors set size criteria for micrometastasis, such as deposits less than 2[42] or 0.5 mm in diameter[20,43]. Recent progress in molecular biological techniques has led to the development of genetic methods for detecting micrometastasis, including RT-PCR. RT-PCR is capable of detecting more micrometastasis foci than immunohistochemical staining[44]. Five patients without overt lymph node or micro metastasis died of disease recurrence in this study. If we use RT-PCR to detect lymph node micrometastasis, we will be able to evaluate lymph node micrometastasis in more detail, and the significance of lymph node micrometastasis will potentially increase. Therefore, further examinations using RT-PCR appear necessary.

VEGF-C is a specific ligand of VEGFR-3 and VEGFR-2, and has been shown to stimulate lymphangiogenesis and angiogenesis both *in vitro* and *in vivo*. Nakashima *et al*[45] investigated VEGF-C expression in 52 patients with gallbladder carcinoma and found that expression was significantly stronger ($P<0.001$) in patients with lymph node metastasis than those without, and that the VEGF-C-positive group showed poorer outcomes than the negative group ($P<0.001$).

Our study revealed a significant correlation between VEGF-C expression and both the presence of lymph node metastasis (HE detected and micrometastasis) and outcome of HBDC. These results suggest that VEGF-C expression might play an important role in causing lymph node metastasis in HBDC, consistent with the findings of previous studies regarding other malignant tumors.

In conclusion, our findings suggest that immunohistochemical detection of lymph node micrometastasis provides very useful information of survival rates after surgery for HBDC. However, considering that 1 patient with lymph node micrometastasis survived for more than 5-years with no evidence of tumor recurrence, long-term survival is thus possible for some patients with lymph node micrometastasis; therefore, extended lymph node dissection is necessary in HBDC patients. Although further study is needed, VEGF-C seems to be a useful predictor of overt and micro lymph node metastasis.

Abstract

AIM: To evaluate the efficacy of water supplementation treatment in patients with functional dyspepsia or irritable bowe syndrome (IBS) accompanying predominant constipation.

METHODS: A total of 3872 patients with functional dyspepsia and 3609 patients with irritable bowel syndrome were enrolled in the study by 18 Italina thermal centres. Patients underwent a first cycle of thermal therapy for 21 d. A year later patients were re-evaluated at the same centre and received another cycle of thermal therapy. A questionnare to collect personal data on social and occupational status, family and pathological case history, life style, clinical records, utilisation of welfare and health structure and devices was administered to each patient at basal time and one year after each thermal treatment. Sixty patients with functional dyspepsia and 20 with IBS and 80 healthy controls received an evaluation of gastric output and oro-cecal transit time by breath test analysis. Breath test was performed at basal time and after water supplementaton therapies. Gastrointestinal symptoms were evaluated at the same time points. Breath samples were analyzed with a mass spectometer and a gascromatograph. Results were expressed as $T_{1/2}$ and T-lag for octanoic acid breath test and as oro-cecal transit time for lactulose breath test.

RESULTS: A significant reduction of prevalence of symptoms was observed at the end of the first and second cycles of thermal therapy in dyspeptic and IBS patients. The analysis of variance showed a real and persistant improvement of symptoms in all patients. After water supplementation for 3 wk a reduction of gastric output was observed in 49 (87.5%) of 56 dyspeptic patients. Both $T_{1/2}$ and T-lag were significantly reduced after the therapy compared to basal values [91 ± 12 ($T_{1/2}$) and 53 ± 11 (T-lag), Tables 1 and 2] with results of octanoic acid breath test similar to healthy subjects. After water supplementation for 3 wk oro-cecal transit time was shorter than that at the beginning of the study.

CONCLUSION: Mineral water supplementation treatment for functional dyspepsia or conspipation accompanying IBS can improve gastric acid output and intestinal transit time.

Key words: Mineral water; Constipation; Dispepsia; Thermal therapy

INTRODUCTION

Functional dyspepsia and irritable bowel syndrome accompanying predominant constipation (IBSc) are two of the most prevalent diseases in the industrialized world. These disturbances are among the first diseases for a gastroenterologic examination with high social and economical costs. In particular, dyspepsia is the first cause of specialized blood and invasive examination in Europe and USA[1]. Dyspepsia may be organic when associated with specific gastrointestinal or liver diseases. To diagnose functional dyspepsia gastroenterologists need specific criteria known as "Roma criteria"[2]. Prevalence of dyspepsia in general population is variable in different studies between 14% and 41%[3-5]. About 65% of dyspeptic patients result from functional dyspepsia[6]. About 35%

of patients with functional dyspepsia present a delayed gastric output which is related to clinical symptoms[7,8] or other disturbances of gastrointestinal motility[9,10]. On the contrary, the link between gastric *H pylori* infection and functional dyspepsia has not been clarified yet[6] because the data on the effect of *H pylori* eradication on dyspeptic symptoms are discordant[11,12].

Treatment of dyspepsia is based on drugs that inhibit the gastric acid secretion (such as proton pump inhibitors or H2 blocker agents) or drugs that stimulate gastrointestinal motility (prokinetics agents). However, the efficacy of such therapies is often unsatisfactory in particular for the short duration of the improvement of symptoms. It should be underlined that a prolonged treatment with these drugs is related to a high incidence of side effects. Although there is no scientific evidence, several dietetic regimens have been used in combination with drugs by dyspeptic patients.

A high enrichment of fibers in diet is the first therapeutic steps for constipation[13]. In fact, a high fiber intake is related to an increased fecal mass in healthy subjects (with high interindividual variability)[14,15]. The efficacy of this treatment seems to be time-related, probably for an intestinal adaptation to the high intake of fibers[16]. IBSc is a chronic functional disorder associated with psychological, environmental, emotional, social factors (drugs, stress, lifestyle)[17]. A reduction of water intake may play an important role in the pathogenesis of constipation and water supplementation is often suggested by a general practitioner in clinical practice to IBSc patients[18,19]. Recently, it has been described that an increased water intake up to 1.5 liters of mineral water is able to increase the effect of a diet with fiber enrichment in patients with constipation[20]. In Europe, especially in Italy, Germany and France, a large number of thermal centers stress on the real role of a treatment with thermal mineral water in functional gastrointestinal diseases. For this reason we need international studies or controlled trial to evaluate the effect of mineral water on functional dyspepsia or IBSc. These studies may allow a medical prescription by physicians and evaluate the socio-economical impact on public health systems of these treatments compared to pharmacological therapies. The efficacy of thermal treatment with mineral water on gastrointestinal diseases[21] remains to be further clarified.

This study was to evaluate the economic and health indicators for the assessment of the efficacy of thermal therapies in reducing the health costs. Moreover, the effect of water supplementation therapy on functional dyspepsia and IBSc was also evaluated.

MATERIALS AND METHODS

Patients

A total of 3872 patients with functional dysepsia and 3609 patients with IBSc were enrolled in the study from 1999 to 2000 by the medical staff of 18 thermal centres distributed throughout Italy (Bagni di Lucca, Chianciano, Comano, Franciacorta, Pejo e Rabbi, Recoaro, Sangemini, Sant'Andrea Bagni, San Carlo, S. Elena, SanPellegrino, Sarnano, DI Stabia, Vallio, Vulpacchio, Montecatini, Angolo, Boario). Patients with a history of gastrointestinal, liver, pancreatic, gall bladder, neurological, muscular, rheumatological, autoimmunitary and immunological diseses were excluded from the study. Moreover, patients with severe high blood pressure (diastolic>110, systolic>180), cancer, recent surgical resection, and pregnant women were also excluded from the study. All enrolled patients underwent abdominal ultrasonography and fecal occult blood test. Only patients negative in both tests were enrolled in the study and underwent a first cycle of thermal therapy for a standard period (2000 mL of mineral water for 21 d). Compliance was evaluated by the percentage of empty bottles returned by patients at the end of the cycle. Before the first cycle of thermal therapy was started, an informed consent was obtained from all enrolled subjects. The anamnestic and clinical data were collected by submitting a questionnaire. The questionnaire included approximately 1400 closed-answer questions (Table 1) for identifying the exposure variables and risk indicator, with special reference to the social-demographic and clinical variables including different sections (personal data, social and occupational status, family and pathological case history, life style, clinical records and social data, also including indicators of the standard living, utilisation of welfare and health structure and devices). According to the first study plan, the patients were re-examined at the same thermal centre one year after the first therapeutic cycle and received a second cycle of thermal treatment. A second follow-up was made after another year. During the follow-up the effect of the treatment was evaluated by assigning a score on side effects, personal opinion of the treatment and overall tolerability of therapy (Table 1). Moreover a retrospective assessment of the clinical follow-up, drug intake and utilisation of welfare and health service between the first and second cycles was carried out. Statistical analysis was performed using Bowker's symmetry test and ANOVA to compare uncontinuos variables.

[1]During past 12 mo; [2]Evaluation after treatment.

Methods

Sixty patients (30 females, 30 males, mean age 44±6 years) with functional dyspepsia and 60 healthy controls (30 males, 30 females, the mean age of 41±5 years) were enrolled. All patients underwent upper digestive endoscopy and abdominal ultrasonography to exclude peptic ulcer

disease, gastroesophageal reflux disease, liver, pancreatic and gall bladder diseases. Diagnosis of functional dyspepsia was made based on the Roma II criteria. All patients underwent ^{13}C octanoic acid breath test (OBT) and filled in a questionnaire for evaluation of gastrointestinal symptoms (post-prandial fullness, epigastric pain, bloating, heartburn, nausea, vomiting).

After OBT, all patients started a diet supplemented with mineral water (2000 mL of mineral water/d for 3 wk). During the mineral water treatment, patients were controlled with a standardized diet (similar caloric and fiber intake)[20]. Compliance to thermal therapy was evaluated by the number of empty bottles returned at the end of the study (20% or more of full bottles returned were considered as the indicator of in adequate compliance). After 3 wk of mineral water supplementation treatment, the OBT was repeated and a new questionnaire for evaluation of gastrointestinal symptoms was administered. Patients after an overnight fasting had 91 mg of 13-C octanoic acid dissolved in an egg with a standardized meal (50 g ham, 150 mL fruit juice, 100 g white bread and 100 mL water) in 10 min. Breath samples were collected in a test tube before and every 15 min for 4 h after ingestion of the labeled substrate.

Analysis of ^{13}C in the breath was performed using a mass spectrometer (Breath Mat; FinniganMat; Bremen, Germany). $0T_{1/2}$ and T-lag values were used to express the results after a regression analysis of exhaled air curves. Results were expressed as $T_{1/2}$ and Tlag. T-test for coupled or uncoupled data was used to compare the difference between groups. Difference in symptoms was evaluated by χ^2 test or Fisher's exact test. $P<0.05$ was considered statistically significant.

Twenty patients (10 females, 10 males, mean age 41 ± 5 years) with IBSc and 20 sex and age matched healthy controls (10 females, 10 males, mean age 40 ± 7 years) were enrolled. Diagnosis of IBSc was made based on the Roma II criteria. All patients underwent H_2-lactulose breath test (LBT) to evaluate the oro-cecal transit time. Then, all patients started a controlled diet with standard fiber and caloric intake supplemented with 2000 mL of mineral water. After 3 wk the diet was stopped and LBT was performed. All enrolled patients filled in a questionnaire for evaluation of gastrointestinal symptoms (bloating, hard stools, number of evacuations in a week, incomplete evacuation) before and after mineral water supplementation. Compliance to thermal therapy was evaluated by the number of empty bottles returned at the end of the study (20% or more of full bottles returned were considered as the indicator of in adequate compliance).

LBT was performed after 20 g of lactulose dissolved in 100 mL of water was administered. Breath samples were collected at basal time and every 15 min for 4 h in a specific test tube after the assumption of lactulose. The presence of hydrogen in the breath samples was evaluated by gascchromatography (Quintron Milwaukee, Wisconsin USA). The oro-cecal transit time was evaluated by curves of hydrogen exhaled during the test.

The Student t test for coupled or uncoupled data was used to compare the difference between groups. Difference in symptom prevalence was evaluated by χ^2 test or Fisher's exact test as appropriate. $P<0.05$ was considered statistically significant.

Table 2 Patients enrolled and re-evaluated after the first and second cycles of thermal therapy with mineral water

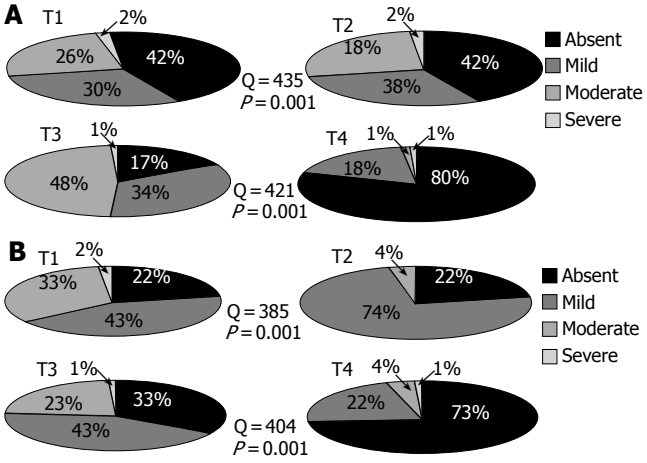

Figure 1 Prevalence of epigastric pain and heartbum (**A**) and postprandial gastric fullness (**B**) at the 4 time points of follow-up in dyspeptic patients.

RESULTS

A totae of 3872 patients with functional dyspepsia and 3069 patients with IBSc were enrolled in the first part of the study. After a year 74% and 69.5% came for follow up visit and to perform a second cycle of thermal therapy (Table 2). No difference among different mineral content of water supplemented was observed.

Figures 1A and 1B show the prevalence of dyspeptic symptoms (epigastric pain and post-prandial fullness) during the two cycles of thermal therapy. A significant reduction in the prevalence of dyspeptic symptoms was observed both at the end of the first and second cycles. In particular, 80% of the patients were symptom free after the first cycle of thermal therapy. Moreover, the score during the pretreatment period was similar between the two cycles. However, ANOVA showed reduction of symptoms when the whole follow-up period was considered. Similar results were observed for post-prandial fullness. The analysis of variance showed a real and persistant improvement of symptoms in all patients.

When the main symptoms of IBSc (bloating, hard stools, incomplete evacuation) were considered, significant improvement was observed with ANOVA (Figures

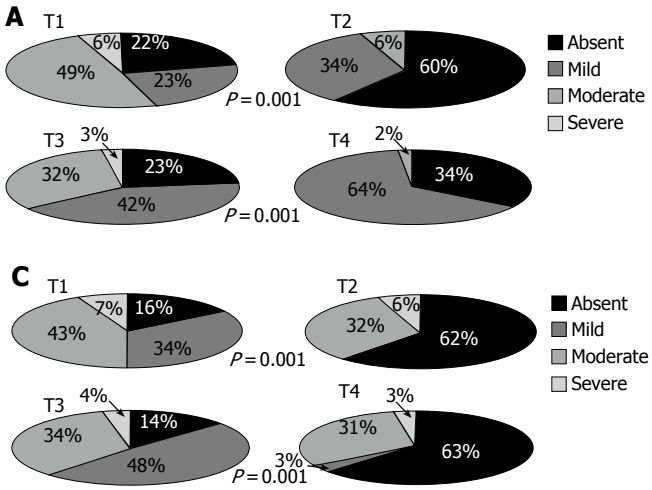

Figure 2 Prevalence of bloating (**A**), incomplete evacuation (**B**), and epigastric hard stool (**C**) at the 4 time points of follow-up in patients with IBS-c.

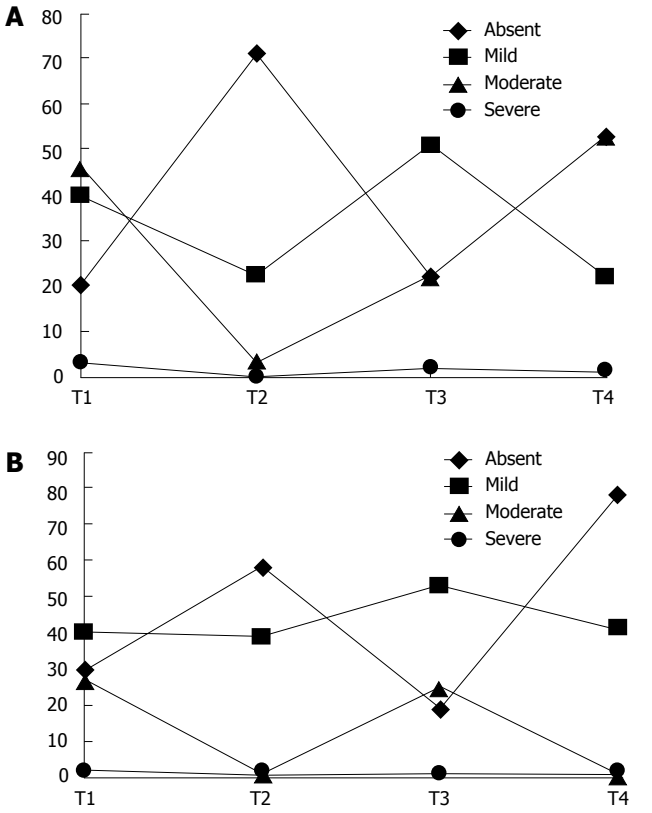

Figure 3 Mean score of symptoms in dyspeptic (**A**) and IBSc (**B**) patients at the 4 time points of follow-up.

2A-2C).

To better underline the temporal evolution of syptoms we reported the mean of scores for symptoms of dyspepsia and IBS at the 4 time points (Figures 3A and 3B).

The data on the number of hospitalization, days of absence from work and the clinical recrudescence before and after two cycles of thermal therapy were decreased by about 30% (Table 3). Moreover, data on overall tolerablity of treatment and reasons of acceptance of this treatment are shown in Table 4. About 80% of patients appreciated the treatment and about 95% gave a positive result of the treatment

Sixty patients and 60 healthy controls were enrolled in the study. Fifty-eight patients had a slow gastric output

measured by OBT (mean $T_{1/2}$: 131 ± 18; Table 2). Patients with a normal gastric output were excluded. One patient and 2 controls refusing to give their consent were excluded. One patient was excluded for low compliance with the treatment (more than 20% of full bottles returned).

Dyspeptic patients presented an alterated gastric output and a significant difference at enollment compared with healthy controls when both $T_{1/2}$ (131 ± 18 *vs* 81 ± 7; $P < 0.01$) and T-lag (92 ± 11 *vs* 51±10; $P < 0.01$) were considered.

After mineral water supplementation for 3 weeks, a reduction of gastric output was observed in 49 (87.5%) of 56 dyspeptic patients. Both $T_{1/2}$ and T-lag were significantly reduced after the therapy compared to the basal values (91 ± 12 for $T_{1/2}$ and 53 ± 11 for T-lag, Table 5) with OBT similar to that in healthy controls. In controls and 7 patients, the gastric output did not change after mineral water supplementation treatment.

The prevalence of dyspeptic symtoms was significantly lower after the therapy than at enrolment. The prevalence of bloating and gastric fullness was significantly lower after mineral water supplementation treatment (Table 6). The

T21: After mineral water supplementation therapy
NS: Not significant

overall prevalence of gastrointestinal symptoms was reduced after mineral water supplementation treatment too. At the basal point, a mean global score of symptoms was 15±4. After 30 d of mineral water supplementation treatment, the score was 7±3. A lower prevalence of abdominal pain, nausea, vomiting was also observed. No severe side effects were reported by patients. Only one control experienced mild diarrhea but treatment was not stopped. Five patients and 7 controls reported an increased number of evacuations during treatment. No effects of mineral water supplementation trealment on blood pressure, glycaemic control and heart rate were observed.

Oro-cecal transit time was longer in patients with IBSc than in controls (Table 7). All patients and 3 healthy controls had an abnormal oro-cecal transit time. After minere water supplementation treatment for 3 wk, the oro-cecal transit time was shorter than at the beginning of the study. A slight reduction in transit time was observed in healthy controls especially in those presenting a pathological transit time at the start of the treatment. The number of evacuations in a week was increased and bloating was reduced during mineral water supplementation treatment in patients with IBSc (Table 8). No side effects were reported by patients and controls.

DISCUSSION

Several diseases have been treated with thermal therapies for a long time in different countries. However, whether thermal therapy should be considered as pertinent to alternative medicines is a matter of debate and largely depends on the different cultural settings in which this practice is performed. In the Scandinavian, British and North American countries the therapeutic value and benefits of thermal (spa) treatment are seen with scepticism and looked at as an alternative and unorthodox practice. On the contrary, spa has been considered a credible medical treatment and supported by official undergraduate and postgraduate university teaching in most countries of the continent, Southern and Eastern Europe (France, Germany and Italy). It should also be mentioned that, differently from various forms of alternative medicine, spa therapy is firmly maintained in medical hands and undergoes orthodox medical control. As a consequence, thermal medicine appears as a supportive rather than alternative practice. Thus in the mentioned countries, spa therapy cannot be labelled as "alternative" medicine, but should be defined as "complementary" or "auxiliary" medicine. Nevertheless, also in these settings, an alignment to the Anglo-Saxon scepticism towards spa therapies has recently developed within the medical and academic community, although not all do so among patients and within the "civic" society.

Such scepticism is based on the scant number of studies published in medical journals of good reputation, apt to investigate with correct methodology and design the real benefits of spa therapies in various clinical conditions in term of efficacy and cost-effectiveness. Even in those countries in which "hydrology" is a recognized medical speciality with an academic background (as in Italy) most researcher work done in the past has been characterized by an approach mainly pathophysiologic and pharmacological, aimed at investigating the mechanism and biological effects of the mineral water rather than at assessing the related clinical and health economic effects with appropriate methods.

As in a number of European countries, variable kinds of financial support (public and private) have been provided for different forms of thermal treatment applied to various diseases. This issue is not a simple question of medical and academic relevance but has great implications from the socioeconomic point of view. In Italy, almost 340 thermal industries are crucial economics and social factor for many geographic areas. The yearly financial turnover related to the thermal activities amounts to 300 million dollars and 2000 million dollars as for health aspects and

linked activities, respectively, and is a key element of the national economy.

The evaluation of literature on the efficacy of spa therapies in the international bibliography can clearly show how wide the gap is in this context, if compared to traditional clinical domains and other nonconventional therapies. The limited impact of scientific research on the efficacy of spa therapies accounts the reservations of the scientific world to the actual efficacy of spa therapies, thus paving the way in Italy to discuss the public funding of these activities. On these bases in 1995, the Association of Thermal Industries and Curative Mineral Waters (Federterme", which officially represents all 340 Italian "medical" spa centres) have developed the epidemiological, health and cost-effectiveness aspects related to spa activities to assess the efficacy of thermal therapies in reducing the health costs.

The observational study has given very important results. The high number of patients who decided to come back for a second period of thermal treatment suggests a very good impact of the therapy on symptoms evaluted by ANOVA test. The data cannot be ascribed only to a placebo effect. We however, cannot conclude that thermal therapies are able to influence the natural history of studied diseases (dyspepsia and IBSc). It is possible that the beneficial effet of a single thermal treatment can influence the perception of symptoms as less severe even in a long follow-up period. This hypotesis was supported by reduction of day and number of hospitalization and day of absence by work during the follow-up period. It should be important to evaluate the economical impact of such results but it was not possible in this study. However, all cited parameters showed a reduction of about one third during the follow-up perion when compared to the former years. No reduction in drug use was observed (data not shown). It is possible to conclude that mineral water supplementation treatment for functional dyspepsia and IBSc can improve symptoms and reduce the medical cost as well as deserves further attentions. However, a best detailed analysis on cost/effectiveness should be performed.

Our data showed that mineral water supplementation therapy could reduce the gastric output of solid food and improve symptoms in patients with functional dyspepsia. The improvement of both studied parameters ($T_{1/2}$ and Tlag) suggests that mineral water can normalize both gastric output time and redistribution of alimentary bolus in the stomach. The pathophysiologic mechanism causing these effects are unknown. Our study demonstrated that mineral water supplementation therapy could improve symptoms and gastric acid output in functional dyspeptic patients evaluated by a questionnaire and OBT. The effects exerted by mineral water include stimulation of chemoreceptors and baroceptors in the gastric walls. The well known effect of water on intestinal motility (due to osmotic properties) with increased intestinal transit time induces an early duodenal transit of food with an earlier relaxation of pylorus and a faster transit of bolus from stomach to duodenum. Moreover, the presence of liquid in the stomach accelerates food disintegration and solubilization. The chemical content of particular water plays a role in the stimulation of specific gastric receptors that increases the gastric motility by secreting local hormones (gastrin, secretin, vasoactive intestinal peptide). The evidence that the effect of water is limited in patients suggests that hormones may be dysregulated in such patients. The presence of large amounts of calcium and magnesium in mineral water may directly stimulate the gastric smooth muscle to increase its motility and relax pylorus, thus producing its effect on gastric output and symptoms. The restoration of a correct gastric output reduces the time of exposition of bolus to intestinal bacteria, thus reducing the intensity of bloating due to intestinal bacteria overgrowth.

Constipation predominant irritable bowel sindrome is one of the frequent gastroenterological diseases in general population. Several pharmacological treatments have been proposed and used. Although therapies for constipation are efficacious, most of them are self-prescribed by patients with a high cost. Laxatives for example are widely used without medical control and may produce side effects. Moreover, the efficacy of laxative treatment is temporary and induces patients to increase dosage of drugs. A diet containing high fibers has been demonstrated to be a valid alternative to drugs for chronic constipation[20].

In our study, mineral water supplementation theray (2000 mL) for 3 wk accelerated oro-cecal transit time and improved symptoms in patients with IBSc. Compliance to therapy was excellent. The mechanisms of action of mineral water are not completely clear. Others iones present in mineral water may directly or indirectly (via neuroendocrine secretion of vasointestinal active peptides) stimulate smooth muscle to increase its motility. These actions reduce the transit time and increase the number of evacuations in a day with improvement of symptoms in IBSc patients. The decreased transit time improves bloating and reduces the time of contact between intestinal content and saprophytic flora with reduction in gas production.

In conclusion, mineral water supplementation theray can improve gastiric acid output, oro-cecal transit time and symptoms in patients with functional dyspepsia or IBSc. Mineral water supplementation therapy seems to be a simple, well-tolerated, cheap therapy for functional dyspepsia or IBSc and should be taken into account by physicians in the treatment of dyspepsia ad IBSc.

Abstract

AIM: To evaluate the immunohistochemical localization of interleukin-6 (IL-6) and IL-6 receptor (IL-6R) on tumor tissue specimens from patients with hepatocellular carcinoma (HCC) and the serum levels of IL-6 and sIL-6R in a group of patients with HCC as well as liver cirrhosis (LC) in a group of patients with LC alone and in a control group.

METHODS: Three groups of subjects were studied: group I ($n = 83$) suffering from HCC and LC, group II ($n = 72$) suffering from LC alone and group III ($n = 42$) as healthy controls. All patients had hepatitis C virus infection. Serum IL-6 and IL-6R levels were determined using a commercially available ELISA kit. Immunohistochemistry was performed using the streptavidin-biotin complex and rabbit polyclonal antibodies against IL-6 and IL-6R.

RESULTS: Immunohistochemistry analysis showed a medium to strong cytoplasmic and membrane reactivity for IL-6 and IL-6R respectively, in at least 40% of cases of HCC, whereas liver cirrhosis patients and controls were negative for IL-6 or showed a very mild and focal dot-like cytoplasmic reaction for IL-6R. Serum IL-6 levels in HCC group were significantly higher than those in LC and control groups ($P < 0.0001$). There was no significant difference in sIL-6R concentrations among 3 groups. When the patients with HCC were divided into groups according to Okuda's classification, a significant serum increase of IL-6 and sIL-6R level was observed from stage I to stage III ($P < 0.02$, $P < 0.0005$). When HCC and LC patients were divided into 3 classes of cirrhosis severity according to Child-Pugh, values in HCC patients were significantly higher than those in LC patients for each corresponding class ($P < 0.01$).

CONCLUSION: IL-6 serum levels in HCC patients are higher than those in LC patients and controls, suggesting an increased production of this cytokine by neoplastic cells. sIL-6R values are similar in all groups, increasing only in stage III HCC patients. These data suggest that they have a closer relationship with the neoplastic mass rather than with the residual functioning hepatic mass.

INTRODUCTION

Interleukin-6 (IL-6) is a proinflammatory cytokine which plays an important role in the host defence mechanism. Serum IL-6 levels are low in physiological conditions, but increase considerably in pathological conditions such as trauma, inflammation and neoplasia. In tumors, IL-6 may be involved in promoting the differentiation and growth of target cells. In fact, several neoplastic cell lines (such as esophageal cancer, renal cell carcinoma, multiple myeloma, prostate and ovarian cancer) have been shown to produce high *in vitro* levels of IL-6[1-5], and high concentrations of this cytokine are associated *in vivo* with a poor outcome of the disease in many types of tumours[6-12]. It has also been hypothesized that activation of the IL-6 gene is responsible for the derangement of some events which can lead to neoplastic degeneration[13].

IL-6 activity is mediated through the binding to its membrane receptor (IL-6R), which in turn promotes the

interaction with another receptor component, gp130, able to transduce IL-6 signalling at the intracellular level[14]. High concentrations of soluble IL-6R, like IL-6, are present in serum and other biological fluids in different pathological conditions, because it is released from cells expressing it on their surface[15].

Many works have reported high serum levels of IL-6 in various liver diseases, such as acute hepatitis[16], alcoholic cirrhosis[17], HBV-associated chronic hepatitis, primary biliary cirrhosis (PBC)[18], chronic hepatitis and HCV-correlated liver cirrhosis[19,20] and in hepatocellular carcinoma (HCC)[21-24].

Studies on animal models have shown that transgenic mice expressing high levels of IL-6 and sIL-6R develop hepatic nodular hyperplasia and signs of sustained hepatocyte proliferation, suggesting that IL-6 and sIL-6R could provide the primary stimulus to cell proliferation and are involved in development of HCC[25].

This study aimed to evaluate the immunohistochemical expression and localization of IL-6 and sIL-6R on tissue specimens from patients with HCC-associated liver cirrhosis and liver cirrhosis alone, and the serum levels of IL-6 and sIL-6R in patients with HCC- associated liver cirrhosis (LC) and to compare them in patients with LC alone and healthy controls.

MATERIALS AND METHODS

Patients

The study was performed in 207 subjects divided into three groups. Group I included 93 patients with HCC (61 males, 32 females, mean age 62.2 years, range 43-76 years). Diagnosis was made in 41 cases based on biopsy or cytological findings, diagnosis of the remaining cases was made on the basis of multiple, concordant imaging techniques (ultrasound, helicoidal computed tomography (CT), lipiodol-CT, selective angiography) and biochemical examination (AFP > 400 ng/mL). Some of the patients known as cirrhotics were enrolled in a prospective study for HCC screening, and others were referred to our center diagnosed as HCC. HCC was associated with the presence of serum HCV antibodies in all cases. The patients were then divided into the 3 stages of Okuda's classification[26] which as well as neoplasia size were also taken into account of serum values of bilirubin and albumin and the presence of ascites. The last three parameters were used to evaluate the hepatic functioning mass and the severity of the underlying cirrhosis. In brief, stage I was an initial stage in which the neoplasm (or the sum of the nodules) measured less than 50% of the whole liver section on CT scan. There was no ascites, albumin levels were over 3 g/dL and bilirubin levels were below 3 mg/dL. Stage II was moderately advanced, with two or more indices of advanced disease. Stage III was very advanced, with three or all indices of advanced disease. Group II included 72 patients (48 males, 24 females, mean age 56.5 years, range 36-75 years) suffering from liver cirrhosis, consecutively selected from out- or in-patients examined at our hospital. Diagnosis was made in 46 cases based on biopsy findings and diagnosis of the remaining cases was made on the basis of unequivocal clinical, biochemical and instrumental data. A post-study follow-up for at least 6 mo excluded the existence of neoplasia. The disease was associated with hepatitis C virus infection in all cases. The control group was composed of 42 healthy asymptomatic subjects (31 males, 11 females, mean age of 54.9 years, range 45-61 years recruited from donors at the blood bank of our hospital. Liver disease was excluded on the basis of anamnestic, biochemical and instrumental data. There were no cases of neoplastic disease, evaluated by a follow-up for at least six months. Daily alcohol consumption of above 30 g/d was found in none of the three groups.

Methods

Blood samples were taken after overnight fasting. After centrifugation part of the sera was used to assay the main parameters of liver function by routine methods. The remainder was frozen at - 40 ℃ for IL-6 and sIL-6R assay. Serological testing for anti-HCV was performed using the third generation of enzyme-linked immunosorbent assay (ELISA) (Orthodiagnostic System, Raritan, New Jersey, USA) in accordance with the manufacturer's instructions. Anti-HCV reacting samples were confirmed using the third generation of anti-HCV recombinant immunoblot assay (RIBA III, Chiron Corporation, Emeryville, CA, USA). Markers of HBV were tested using the Abbott RIA kit.

Liver biopsy samples were obtained for diagnostic purposes percutaneously according to the Menghini technique using 1.0-1.2 mm diameter needles (Surecut, Hospital Service, Rome, Italy). In some cases HCC was diagnosed with a thin needle (20 gauge, Surecut) guided by ultrascan using a Toshiba SSA 240 A apparatus with a 3.5 MHz probe.

Serum IL-6 and sIL-6R levels were determined using a commercially available ELISA kit (Quantikine, human IL-6 and sIL-6R, R & D Systems, Minneapolis, USA) in accordance with the manufacturer's instructions.

Immunohistochemistry analysis was performed on ten different HCC samples, five cirrhotic and two normal liver samples. Histologically normal liver tissues were obtained from patients during surgery for cholelithiasis. Written informed consent was obtained. The specimens were fixed in formalin and embedded in paraffin. Five- μm thick sections were cut and dewaxed, hydrated and incubated in 3% hydrogen peroxide for 20 min. Sections were then heated in microwave oven and non-specific binding was blocked by incubation with 3% rabbit normal serum for 20 min. Immunohistochemistry was performed using the streptavidin-biotin complex (StreptABC) with the following antibodies: rabbit polyclonal antibody against IL-6 (Santa Cruz Biotechnology, Santa Cruz, CA), rabbit polyclonal antibody against IL6R (Santa Cruz Biotechnology, Santa Cruz, CA) at a dilution of 1:100 overnight in a 4 ℃ moist chamber and mouse monoclonal antibody against proliferating cell nuclear antigen (PCNA, Dako, Santa Barbara, CA) at a dilution of 1:100 for 30 min at room temperature. Sections were then incubated for 30 min at room temperature with biotinylated anti-rabbit and anti-mouse immunoglobulin diluted in phosphate-buffered

saline (PBS), with streptavidin-biotin complex for 50 min at room temperature and colour was developed with diaminobenzidine (DAB) for 40 min at room temperature, counterstained with Mayer haematoxylin for 1 min. The expression of IL-6 and IL-6R was considered positive when >30% of cells showed cytoplasmic or membrane staining. The percentage of PCNA- stained nuclei was calculated by counting the number of stained nuclei out of 1000 cells per high-power field for 10 different tumor sections.

Statistical analysis

The data were expressed as mean ± SD. Groups were compared using the Mann-Whitney *U* test. χ^2 test was used for the frequency analyses. Simple linear regression test and Spearman's rank correlation test were used where appropriate. The cut-off values IL-6 and sIL-6R were calculated as the value of the maximized likelihood ratio (LR) obtained using the following formula: LR = probability of true positives + probability of true negatives/probability of false positives + probability of false negatives. $P < 0.05$ was considered statistically significant.

RESULTS

Table 1 shows the median, range and ratio of serum IL-6 and sIL-6R values in the 3 study groups, and also in the HCC group divided according to Okuda's classification. Analysis performed with the Mann-Withney *U* test showed that the HCC group had significantly higher IL-6 values than the LC ($z = 3.1$, $P < 0.002$) and control group ($z = 5.4$, $P < 0.0001$). However, the LC patients had significantly higher IL-6 serum levels than controls ($z = 2.3$, $P < 0.03$). A significant difference was found in sIL-6R serum levels between the HCC group and controls ($z = 2.1$, $P < 0.04$), but not between the HCC and LC groups.

Analysis of the values after division of the HCC group according to Okuda's classification showed that serum values of IL-6 were significantly higher in stage III patients than in stage II and stage I patients ($z = 2.7$, $P < 0.01$ and $z = 2.8$, $P < 0.005$, respectively). Moreover, IL-6 values in stage I HCC patients were also significantly higher than those in the LC patients ($z = 1.9$, $P < 0.05$). There was no significant difference in sIL-6R values between stage I and stage II patients and the LC patients. The only significant difference was found between the stage III HCC patients and the LC patients, stage I and stage II HCC patients ($P < 0.004$).

Spearman's rank correlation test showed a significant increase in IL-6 and sIL-6R levels from stage I to stage III ($r = 0.28$, $P < 0.02$; $r = 0.39$, $P < 0.0005$, respectively).

Table 2 shows the median and range of IL-6 and sIL-6R in the HCC and LC groups divided according to Child-Pugh classes. The median IL-6 value was higher in HCC group than in the LC group, but the difference was significant only in classes A and C ($P < 0.0005$ and < 0.04, respectively) when compared to the corresponding LC groups. The median sIL-6R value decreased from class A to C in the cirrhotic group, but increased in the HCC group. Consequently, in the LC group the median sIL-6R value was significantly higher in class A ($P < 0.04$), while in the HCC group it was higher in class C ($P < 0.03$).

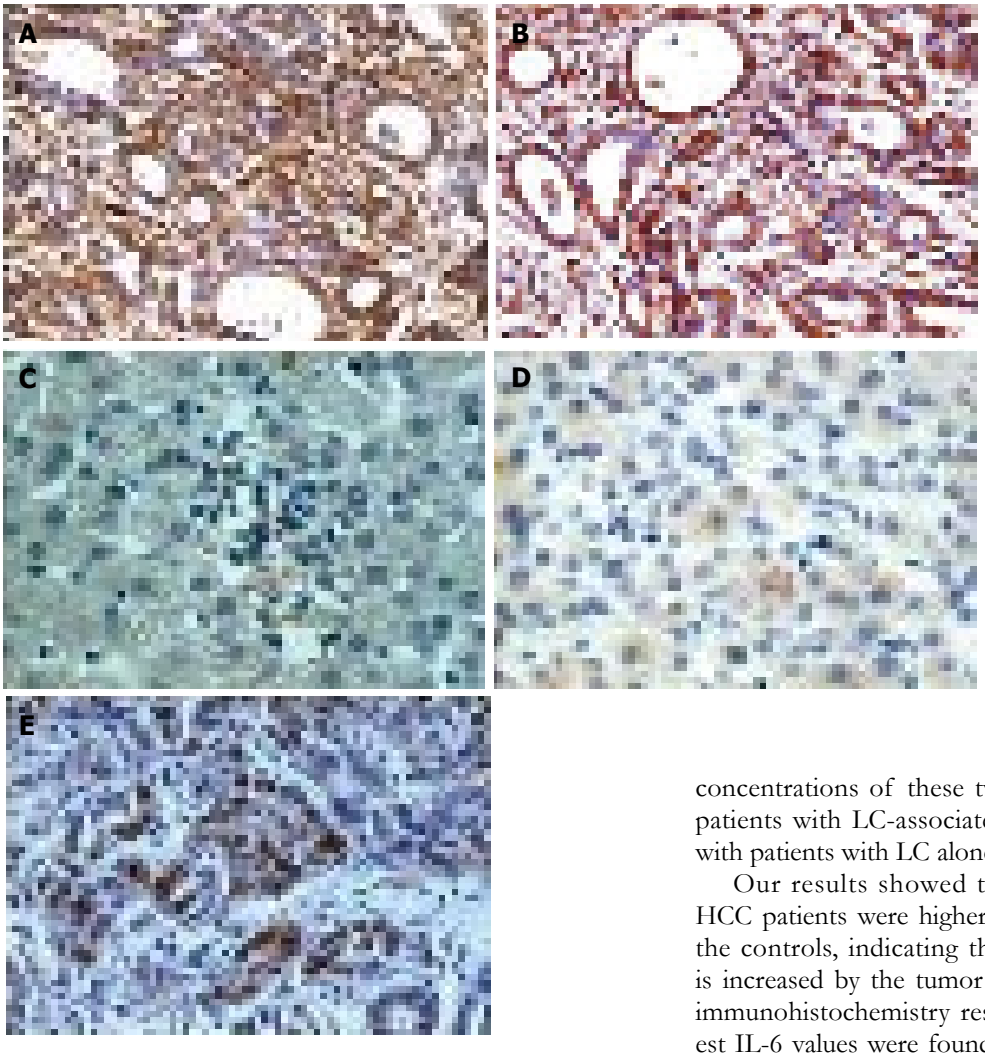

Figure 1 Results of immunohistochemical analysis of cytoplasmic and membrane reaction of IL-6 and IL-6R in HCC (**A, B**), normal liver (**C, D**), and cirrhotic (**E**) patients.

Figure 1 shows the results of the imunohistochemistry analysis. In the HCC group (ten cases), moderate to strong cytoplasmic and membrane reactivity for IL-6 and IL-6R respectively, was observed in at least 40% of cases (Figures 1A, 1B), whereas control cases of normal liver (two cases) were negative (Figure 1C) or showed a very mild and focal dot-like cytoplasmic reaction for IL-6R (Figure 1D). In liver cirrhosis group (ten cases) immunohistochemistry was negative on the whole or similar to control cases. PCNA immunoreactivity was observed in some nuclei of neoplastic cases with a mean value of 50% in the evaluated areas (Figure 1E).

DISCUSSION

Circulating IL-6 levels are elevated in patients with chronic viral[18-20] and alcoholic hepatitis[17]. Increased IL-6 is correlated with the stage of disease in liver cirrhosis [27]. Higher levels of IL-6 correlated with tumor size and cancer aggressiveness in patients with HCC[22].

At present, there are no data about the behaviour of circulating sIL-6R in patients with HCC and very few for other neoplasms. However, in multiple myeloma higher sIL-6R values correlate with a poor outcome of the disease[28]. Therefore, the aim of this study was to evaluate the expression and localization of IL-6 and sIL-6R in pathological liver tissue specimens as well as the serum concentrations of these two cytokines and their ratio in patients with LC-associated HCC and to compare them with patients with LC alone and healthy controls.

Our results showed that the median IL-6 levels in HCC patients were higher than those in LC patients and the controls, indicating that production of the cytokine is increased by the tumor cells. This is supported by the immunohistochemistry result and the fact that the highest IL-6 values were found in Okuda's stage III, in which the neoplastic mass is the most extensive. However, LC patients also had higher median IL-6 values than controls, but only for Child's classes B and C, while values in class A were close to control levels. In classes B and C, increased IL-6 serum levels compared to control values might reflect a response of the residual hepatic cells to cytolysis and to the attempt to recover the liver mass[25] associated with a clear impairment. In contrast, in HCC patients, whatever class of the disease, the median values were higher than those in LC patients, indicating that IL-6 serum levels increase when patients pass from cirrhosis to HCC. This was not true in the sIL-6R values, because the median value in HCC patients was significantly higher than that in controls ($P < 0.04$), and similar to that of LC patients. When the patients with HCC and LC were divided according to Child-Pugh's classification, the median serum values of sIL-6R tended to decrease from class A to class C in LC patients, while the opposite occurred in HCC patients, indicating that in cirrhotic patients sIL-6R production and release decrease as the disease progresses owing to the reduction of the liver parenchymal mass. On the other hand, in HCC patients, increased sIL-6R serum concentration might be due to the increasing tumor mass.

When the patients with HCC were divided according to Okuda's classification, IL-6 values significantly increased as the disease worsened. At all the stages the median IL-6 values were significantly elevated compared to the cirrhotic patients, indicating that neoplastic degeneration even in its

initial stages, causes variations in IL-6 levels, which could enable us to discriminate cirrhotic from HCC patients. Interestingly, sIL-6R levels were elevated only in patients with a more severe disease (stage III).

The high serum levels of IL-6 and sIL-6R were corroborated by the immunohistochemistry analyses, which showed the marked expression of both cytokines and their receptor in the tumor. This expression correlates to cell proliferation, as demonstrated by the concomitant presence of a high percentage of PCNA positive nuclei. The existence of such a relationship has also been reported for colorectal cancer[29]. On the whole, our results suggest that HCC cells, especially in advanced stages of the disease, may produce and secrete IL-6 and sIL-6R to stimulate their growth by an autocrine/paracrine mechanism as suggested by previous reports concerning cells derived from hepatomas or other types of cancer[30-34].

IL-6 production by tumor cells might also contribute to systemic complications such as induction of cachexia in the host[11] and local immunosuppression rather than immunopotentiation[35]. Thus, the present study might highlight the potential therapeutic benefits of approaches such as use of anti-sense nucleotides or IL-6R super antagonists, which can overcome the adverse effects of IL-6 in HCC, as in hepatoma cells, multiple myeloma, prostate cancer and other tumors[31, 34-36].

In conclusion, the IL-6 levels in patients with LC-associated HCC are higher than in patients with LC alone and controls, indicating that production of this cytokine is increased by tumor cells. This has been confirmed by the higher IL-6 values in stage III than in stages I and II of the disease. These results might be of help in differentiating cirrhosis from LC-associated HCC suggest that measures aimed at blocking adverse effects of IL-6 may be of potential clinical utility in HCC.

Abstract

AIM: To determine the diagnostic value of the rabeprazole test in patients seen by general practitioners.

METHODS: Eighty-three patients with symptoms suggestive of GERD were enrolled by general practitioners in this multi-centre, randomized and double-blind study. All patients received either rabeprazole (20 mg bid) or a placebo for one week. The diagnosis of GERD was established on the presence of mucosal breaks at endoscopy and/or an abnormal esophageal 24-h pH test. The test was considered to be positive if patients reported at least a "clear improvement" of symptoms on a 7-point Likert scale.

RESULTS: The sensitivities of the test for rabeprazole and the placebo were 83% and 40%, respectively. The corresponding specificity, positive and negative predictive values were 45% and 67%, 71% and 71%, and 62% and 35%, respectively. A receiver operating characteristics (ROC) analysis confirmed that the best discriminatory cut-off corresponded to description of "clear improvement".

CONCLUSION: The poor specificity of the proton-pump inhibitor (PPI) test does not support such an approach to establish a diagnosis of GERD in a primary care setting.

Key words: Gastro-oesophageal reflux disease; Diagnostic tool; Rabeprazole; Proton pump inhibitors; Primary care

INTRODUCTION

Gastro-esophageal reflux disease (GERD) is one of the most common disorders observed by primary care physicians. In this setting, an accurate, non-invasive and safe diagnostic test would be of great use. Proton-pump inhibitors (PPIs) are the most potent suppressors of gastric acid secretion and represent the mainstay of GERD treatment, with a therapeutic effect throughout the spectrum of the disorder. Therefore, in clinical practice, many physicians consider that rapid symptom relief after a short course of PPI therapy is a valuable marker for a diagnosis of GERD. This represents the basis for the development of so-called PPI tests, the value of which has previously been assessed by a number of different investigators, using various molecules which were tested in assorted referral populations, mainly in a secondary or tertiary care setting. The various PPIs and dosages, the duration of the PPI course and the way the results are interpreted are likely to be responsible for the conflicting results previously reported in the literature[1]. Rabeprazole is a more recently developed PPI with specific pharmacological properties such as a high pKa which may lead to both rapid accumulation in the acidic compartment of the parietal cell and more effective control of acidity during the first day of administration[2,3]. Similarly, when the target population for such PPI tests is considered, the lack of drug interference and the safety profile are both of most importance. In these respects, rabeprazole also displays some pharmacological advantages due to a partly non-hepatic metabolism and a linear response, which result in more predictable effects in terms of acid suppression[4,5].

We therefore aimed to determine the diagnostic value of the rabeprazole test in a population of patients followed up by general practitioners (GPs) for symptoms suspected to be reflux-related.

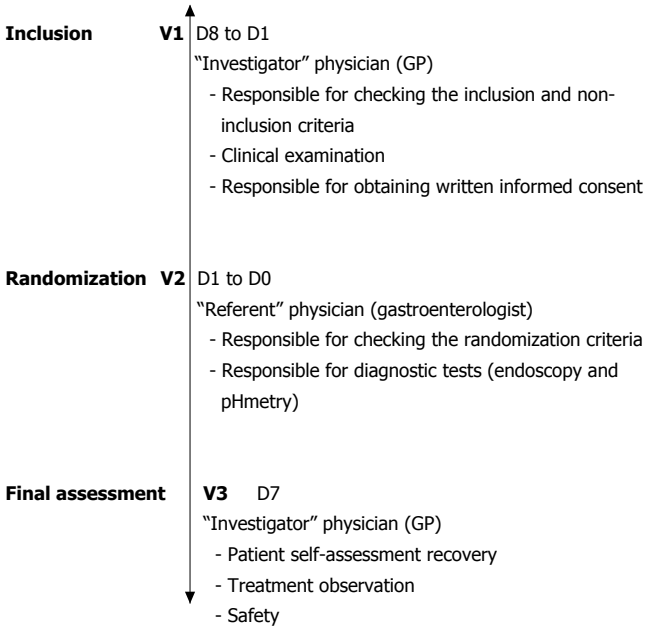

Figure 1 Diagrammatic illustration of the different phases of the study. Two visits were carried out by the investigator physician (V1: inclusion; and V3: final assessment). The second visit (V2) was carried out by the referent physician to check the inclusion criteria, to perform endoscopy (unless the patients had already undergone one endoscopy during the previous 6 months) and 24-h esophageal pH monitoring.

MATERIALS AND METHODS

Global design of the study

The study was conducted using a multi-centre, randomized and double-blind design. In order to maintain the double-blind nature of the study, each patient was examined by an "investigator" physician and a "referent" one. The investigator was a GP responsible for patient recruitment, inclusion and monitoring at the end of study assessment. The referent was a gastroenterologist with experience of endoscopy and esophageal pH monitoring, responsible for diagnostic testing, checking the randomization criteria, and prescribing treatment. The design of the study consisted three phases (Figure 1).

Phase 1 The investigator enrolled patients into the protocol according to the following inclusion criteria: (a) presence of at least 3 mo of typical (heartburn or regurgitation) or atypical (ascending burning epigastric pain, recurrent nausea, post-prandial digestive discomfort, dysphagia) gastrointestinal or extra-gastrointestinal symptoms suspected to be reflux-related; (b) occurrence of a particular symptom on at least 2 occasions during the 3 d prior to inclusion, the intensity of which being rated as "moderately uncomfortable or worse" using a 7-point Likert verbal analogue scale; (c) lack of previous investigations demonstrating esophagitis, such as esophageal pH monitoring and upper GI endoscopy; (d) absence of previous effective anti-reflux therapy, including PPIs, full-dose H_2-receptor antagonists or cisapride during the previous month. Conversely, the following patients were excluded from the trial: (a) women who were either pregnant, breast feeding or not using an effective method of contraception; (b) patients with a malignant condition or an uncompensated chronic disease, particularly uncompensated cardiac, liver or renal disease; (c) patients who had previously undergone a vagotomy or surgery that might alter gastric acid secretion; and (d) patients who were considered unable to comply with the conditions of the protocol, particularly with respect to follow-up and self-assessment questionnaires.

Written consent was obtained from all patients before inclusion. The study was approved by the Local Ethical Committee ('CCPPRB des Pays de la Loire n°2').

Patients were given a self-assessment form at the inclusion visit. On each day of the study, patients had to report their dominant symptom (i.e., the symptom which had led them to consult the investigator and that induced most discomfort for the patient). A consultation with the referral doctor was scheduled between 4 and 10 d after the inclusion visit. During this period patients were requested not to take any treatments that could be used to treat GERD, apart from the symptomatic treatment they had been given (Co-magaldrox, Maalox®).

Phase 2 The referent examined patients 4 to 10 d after their inclusion. The inclusion criteria were checked; notably the presence of at least two episodes of the dominant symptom in the 3 d prior to the consultation, rated as being at least "moderately uncomfortable" on the self-assessment form. Endoscopy was performed in all patients according to the usual practice of each centre. In patients with a normal endoscopy from the previous 3 mo, the results were considered not to contribute to a diagnosis of GERD and the investigation was not repeated. Twenty-four hour pH monitoring was performed immediately after the endoscopy. At the end of this second phase, patients who fulfilled the inclusion criteria and without any exclusion factors were randomly allocated to receive either a placebo or rabeprazole (20 mg bid) before breakfast and dinner for 1 wk. The investigators and patients were blinded to the administered treatments. Patients were not informed of the investigation results and the data was sent to a central database until the trial had been completed.

Phase 3 Patients were then received by the investigator at an end of study consultation after 7 ± 1 d of treatment. The investigator was unaware of the results of the endoscopy and pH monitoring. At this visit patients completed the response assessment form, rating any change in their symptoms. A rating according to 3 descriptions ("better", "roughly the same", or "worse") was firstly performed. Secondly, in cases where a symptom had improved, patients assessed the change using a Likert 7-point adjectival scale ("very slight improvement", "slight improvement", "clear improvement", "very great improvement", "near complete resolution", and "resolution"). The investigator recorded the number of tablets remaining, any adverse effects and any alteration in the patient's treatment over the period. According to the results of the rabeprazole test, the investigator classified the patient as a 'refluxer' or a 'non-refluxer'.

Esophageal pH monitoring

Esophageal pH monitoring was conducted using an ambulatory pH recording device (Synectics Mark II or III, Medtronics, Paris, France). The antimony electrode was positioned 5 cm above the cardia, located using the pH

step-up method[6] and an ambulatory recording was made. Patients were not given any particular lifestyle or dietary recommendations and were encouraged to behave as normally as possible. Patients were asked to record meals and sleeping periods, and the time of onset of symptoms. Patients returned to the referral centre 24 h later to stop the recording and remove the electrode. The data from the pH monitor were downloaded onto a computer, and the results were analyzed using a specific programme (EsopHogram Synectics software, Medtronics, Paris, France). For symptoms which had occurred during the recording period, analysis included symptom index determination (percentage of the total number of reported symptoms that were reflux-related) and probability of association as previously described[7,8]. Symptoms were considered to be reflux-related if they had occurred during the acid reflux event itself (pH < 4) or within 2 min after it had ended[9].

Evaluation and analysis of the results

Patients were classified as 'refluxers' or 'non-refluxers' according to the results of both upper GI endoscopy and pH monitoring. A diagnosis of reflux was established if one of the following criteria was present: (a) esophageal acid exposure (time below pH 4 during the 24-h period) greater than 4.2%; (b) statistically significant association between symptoms and reflux episodes ($P < 0.05$ or symptom index > 50%); and (c) presence of mucosal breaks at endoscopy.

The test (rabeprazole or a placebo) was considered to be positive or negative on the basis of the symptom response evaluated by the patient him/herself at the end of the one-week trial period. For this purpose, a 7-point adjectival Likert scale was used and the responses were dichotomised according to the cut-off descriptor of at least a "clear improvement". To further document the validity of that particular cut-off, a receiver operating characteristics (ROC) analysis of sensitivity was performed using different thresholds for the definition of a positive symptom response (CLINROC software - Metz Software, Chicago, IL, USA).

Sensitivity was defined as the proportion of 'refluxers' who had a positive test. Specificity was defined as the proportion of 'non-refluxers' for whom the test result was negative. The positive predictive value was defined as the proportion of 'refluxers' among patients with a positive test, whereas the negative predictive value was defined as the proportion of 'non-refluxers' among patients with a negative test.

Finally, all adverse events reported during the study period were also recorded for safety assessment.

Statistical analysis

As the study was mainly exploratory in nature, no prior forecast of subject number was made. The study period (January 2001 - May 2002) was also determined in order to reflect clinical practice in a primary care setting. We used mainly descriptive statistics and the results presented on the basis an intention-to-diagnose' (ITD) analysis. Student's *t*-test was used for quantitative variables and the Chi square test for qualitative variables. $P < 0.05$ was considered statistically significant.

Table 1 Characteristics of the intention-to-diagnose population in the placebo and rabeprazole groups (*n*, mean ± SD)

	Placebo (*n* = 39)	Rabeprazole (*n* = 33)	*P* value
Men/women (%)	46/54	33/67	0.269
Mean age (yr)(mean±SD)	47.1±11.8	49.1±11.9	0.4
BMI (kg/m^2) (mean±SD)	25.6±4.4	26.1±5.2	0.8
Smoker (%)	17.9	30.3	0.219
Previous endoscopy (%)	33.3	30.3	0.783
Time from first symptoms[1] (mo)	24.3±51.5	20.2±27.0	0.956
Post-prandial symptoms (%)	30.8	33.3	0.232
Nocturnal symptoms (%)	12.8	15.1	0.232
Hiatus hernia (%)	47.4	27.3	0.082
Esophagitis (%)	30.8	33.3	0.816
Barrett's oesophagus (%)	2.6	6.1	0.474
Diagnosis of GERD[2] (%)	67.6	62.1	0.642

[1]Suggesting the possibility of GERD; [2]Established by the presence of esophagitis and/or pathological exposure to acid during the 24-h period and/or significant association between symptoms and reflux.

RESULTS

Demographics and characteristics of population at inclusion

Ninety-one patients were selected. Of these patients, 83 were included, and 72 were randomized at the phase 2 visit. Among these 72 patients who completed the study and constituted the ITD population, 39 were in the placebo arm and 33 in the rabeprazole arm. Fourteen patients had at least one major deviation either at inclusion or during the course of the study (principally non-compliance with the intervals between visits and/or less than 6-d of treatment). The per-protocol population (PP), therefore, included 58 patients (33 in the placebo arm and 25 in the rabeprazole arm). In the two cohorts (ITD and PP), the most common predominant symptoms were epigastric pain, heartburn and regurgitation. At inclusion, the distribution of the predominant symptoms within the 2 groups was not significantly different. Approximately one third of patients in both groups had esophagitis, which was not of a severe grade in 90% of these subjects. None of the patients included had either stenosis or an ulcer at endoscopy. Compliance with treatment was good as 91% of tablets were taken; there was no significant difference between the two groups (Table 1). Since the results were very similar in the 2 cohorts, only the results from the ITD population are presented here. The characteristics of this population are shown in Table 1.

Six patients were unclassifiable due to pH monitoring technical failure. As a result, a definitive diagnosis of GERD or absence of GERD was made for 66 patients, 37 in the placebo group and 29 in the rabeprazole group. Forty-three were considered to be 'refluxers' (25 in the placebo arm and 18 in the rabeprazole arm) and 23 'non-refluxers' (12 in the placebo arm and 11 in the rabeprazole arm).

Diagnostic value of the rabeprazole test versus placebo test

In 'refluxers', the rabeprazole test was positive in 15 of 18 patients (sensitivity: 83.3%) whilst the placebo test was positive in 10 of 25 (sensitivity: 40.0%) ($P = 0.011$). In the 'non-refluxers', the rabeprazole test was negative in 5 of 11 patients (specificity: 45.5%) whilst placebo test was negative in 8 of 12 (specificity: 66.7%) ($P > 0.05$).

The positive and negative predictive values for the rabeprazole test were 71.4% and 62.5%, respectively. The corresponding predictive values for the placebo test were 71.4% and 34.8%, respectively ($P > 0.05$). The percentages of patients who were correctly classified by the rabeprazole test and the placebo test were 69.0% and 48.6%, respectively ($P > 0.05$).

The results of the ROC analysis are illustrated in Figure 2. The categories that were closest to the slope of the tangent to the 45° curve were those of "slight improvement" and "clear improvement". Nevertheless, the best compromise between sensitivity and specificity corresponded to the description "clear improvement" that was adopted for the former analysis.

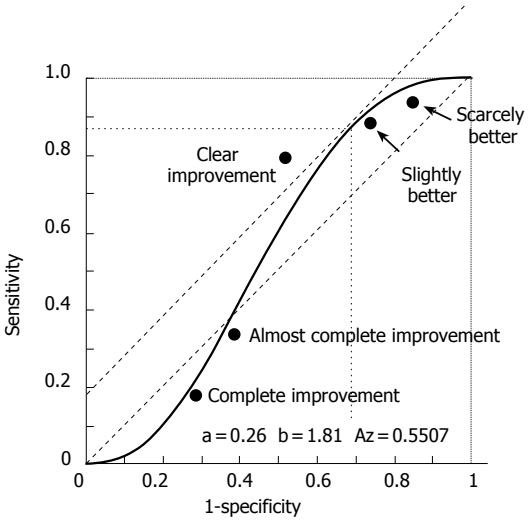

Figure 2 Receiver operating characteristics (ROC) curve. This was determined according to various satisfaction criteria (from "very slight improvement" to "resolution" of the symptoms) for patients with symptoms compatible with gastro-esophageal reflux. The symptoms were assessed after one week of treatment with a double dose of rabeprazole (20 mg bid) or a placebo.

Adverse events

Six patients (4 in the placebo arm and 2 in the rabeprazole arm) reported 7 adverse events (placebo: vomiting, diarrhoea, insomnia, dyslipidemia, urinary infection; rabeprazole: lymphadenitis, drug eruption) (non significant). No adverse event was considered to be serious.

DISCUSSION

The results of this study conducted in a primary care setting and with a placebo-controlled design showed that the rabeprazole test had high sensitivity (83.3%) but low specificity (45.5%). As compared with the placebo test, the rabeprazole test showed a superior sensitivity and negative predictive value, but non-significant differences with regard to specificity and positive predictive value.

This study is one of the first attempts to evaluate the diagnostic yield of a PPI test in primary care conditions with assessment of the results by GPs. The drug was administered for 7 d only for both practical and scientific reasons. In fact, a recent study using esomeprazole showed that although the sensitivity of the test increased each day following the start of the test, a plateau was reached after 5 d of administration, with no further improvement beyond that time point[10]. The reference tests (i.e. 24-h pH monitoring and endoscopy) were performed by independent physicians (referent) and the GP (investigator) remained blind to the results until response to PPI had been determined. In addition to acid exposure measurement, symptom analysis was also an important parameter of pH monitoring interpretation. This seems particularly relevant in a population of patients with normal endoscopy in approximately two thirds of cases. Indeed, nearly half of patients with endoscopy-negative GERD are known to have acid exposure within the normal range[11]. The use of symptom analysis permits an increase in the sensitivity of pH monitoring and therefore decreases the risk of missing genuine 'refluxers'. In addition, only patients with moderate to severe symptoms present on at least 2 occasions in the 3 d prior to inclusion were enrolled. The outcome of these rather rigorous inclusion criteria and design was a difficulty in fulfilling our initial goal of recruiting a large cohort of patients. Finally, from a number of candidate PPIs, we chose rabeprazole, since this drug has a number of potential advantages: (a) a rapid onset of action as shown by gastric pH monitoring studies[3,12,13]; (b) a good safety profile; (c) a lack of drug interactions due to its specificity in terms of hepatic and non-hepatic metabolic pathways[4,5]; and (d) its effectiveness in the treatment of some symptoms associated with GERD[14].

The results of our study are consistent with other studies of PPI tests which have without exception demonstrated the high sensitivity and poor specificity of this diagnostic approach[1]. This rather disappointing finding has recently been confirmed by the meta-analysis reported by Numans *et al*[15], which reached a similar conclusion concerning short-term trials of PPIs in GERD. The poor performance of PPI test is further reinforced by the comparison with the placebo-test which adequately 'classified' nearly half of the patients (random results). However, these results are not entirely surprising as a good placebo response has also been reported in short-term trials in GERD[10,16-18]. In addition, the above negative conclusions should be further balanced as far as negative predictive values are considered. Indeed, in the test conditions, a negative response to rabeprazole could exclude a diagnosis of GERD in 2 of 3 symptomatic patients (as compared to only one in three following the placebo). As the negative predictive value is influenced by the prevalence of the disease, our results may in fact be an underestimation and higher negative predictive values could be expected in a more representative sample of patients consulting for upper GI symptoms, supposing a 30% prevalence of GERD (i.e. approximately half of that observed in both the placebo and rabeprazole

arms of our study). Finally, our study design did not allow an appropriate evaluation of the cost-effectiveness of the PPI test as a whole and of the rabeprazole test in particular. The poor specificity of the test should, however, lead to some caution in terms of guidelines concerning long-term management strategy in GERD; there is a potential risk that 'non-refluxers' will continue to receive PPI treatment far beyond the initial test week if the symptomatic response is good. Whether such an empirical approach to acid-sensitive disorders is justified or potentially dangerous is presently unknown. Nevertheless, our data supports the conclusions of the French-Belgian consensus conference, which did not recommend the use of PPI tests for the diagnosis of GERD in clinical practice before the availability of further scientific information[19].

Abstract

AIM: To investigate the expression of gastrin-releasing peptide (GRP) and GRP-receptor mRNA in non-tumor tissues of the human esophagus, gastrointestinal tract, pancreas and gallbladder using molecular biology techniques.

METHODS: Poly A^+ mRNA was isolated from total RNA extracts using an automated nucleic acid extractor and, subsequently, converted into single-stranded cDNA (ss-cDNA). PCR amplifications were carried out using gene-specific GRP and GRP-receptor primers. The specificity of the PCR amplicons was further confirmed by Southern blot analyses using gene-specific GRP and GRP-receptor hybridization probes.

RESULTS: Expression of GRP and GRP-receptor mRNA was detected at various levels in nearly all segments of the non-tumor specimens analysed, except the gallbladder. In most of the biopsy specimens, co-expression of both GRP and GRP-receptor mRNA appeared to take place. However, expression of GRP mRNA was more prominent than was GRP-receptor mRNA.

CONCLUSION: GRP and GRP-receptor mRNAs are expressed throughout the gastrointestinal tract and provides information for the future mapping and determination of its physiological importance in normal and tumor cells.

Key words: Gastrin releasing peptide (GRP); Gastrin-releasing peptide receptor (GRPR); mRNA expression; Morphogenesis; Gastrointestinal tract

INTRODUCTION

Gastrin-releasing peptide (GRP) is a member of the bombesin family of neuropeptides. Bombesin was originally isolated from the skin of the amphibian *Bombina bombina*, whereas GRP is the homologous peptide in mammals, including humans[1]. GRP and GRP-receptor are widely expressed in the central and enteric nervous systems (ENS). GRP is known to stimulate secretion of gastrin, gastric[2] and pancreatic juice[3] and hormones[4,5] to regulate the immune system[6], and to modulate smooth muscle contractility[7,8]. The direct expression of GRP and its receptor, and thus the exact mechanism behind its actions in gastrointestinal tissues, are only sparsely examined. Immunocyochemistry revealed the expression of GRP in submucosal cells of the ileum[9]. In colon, *in vitro* autoradiography showed the GRP-receptor expression in the myenteric, but not submucosal, plexus as well as on smooth muscle cells[10]. Examination of mucosal biopsies revealed GRP-receptor mRNA in cells lining the gastric antrum, but not in any other epithelial cells of the gastrointestinal tract[11].

GRP and GRP-receptor are frequently expressed in the gastrointestinal cancer cells, such as gastric adenocarcinoma[12,13], duodenal cancer[14], and colorectal cancer[15,16,17]. Cuttitta *et al*[18] have demonstrated that human cell lines derived from small-cell lung carcinomas of the lung (SCLC) proliferate in response to autocrine release of GRP. In gastrointestinal tumors, GRP-receptor activation only modestly increased tumor cell proliferation, but regulated tumor cell appearances or differentiation and, therefore, should be considered to act as a morphogen[1,16].

Based on these findings, it appears important to establish whether or not GRP and GRP-receptor mRNAs

are expressed in non-tumor gastrointestinal tissues. In this study, we analyzed GRP and GRP-receptor mRNA expressions in the human esophagus, gastrointestinal tract, pancreas, and gallbladder by means of a reverse-transcription polymerase chain reaction (RT-PCR) technique and Southern blot analysis of the PCR amplicons.

MATERIALS AND METHODS

mRNA isolation and PCR amplification

The collection, origin and status of full thickness biopsies from the human gastrointestinal tract and surrounding tissues from surgically removed biopsies from patients undergoing surgery for gastric diseases has been described elsewhere in detail[19]. In all, 24 biopsy specimens and two control cDNAs (Table 1) were processed and analyzed for the expression of GRP and GRP-receptor mRNA. In subsequent PCR amplification experiments, mRNA and ss-cDNA preparations used were from a previous study and prepared as described recently[19].

β-actin amplification was performed in two rounds of PCR (30 and 25 cycles each time, respectively) with the same primers under cycle conditions as described above. Due to the positioning of the primers, cDNA and genomic DNA will yield β-actin fragments of different sizes (288 bp for cDNA and 400 bp for gDNA PCR amplicons, respectively). This allows monitoring for DNA contamination in ss-cDNA preparations and to assess for the integrity of the ss-cDNA used[19]. Control cDNA derived from pancreas and stomach mRNA was purchased from Clontech (BD-Biosciences, Clontech, Stockholm, Sweden).

PCR- amplification of GRP and GRP-receptor ss-cDNA

PCR was performed using a HotStarTaq Master mix kit (Qiagen, Hilden, Germany) in a final reaction volume of 25 μL. Each reaction contained 2 μL of the cDNA synthesis reaction as template. Quick-clone human pancreas and stomach cDNA (Clontech, BD Biosciences Stockholm, Sweden) were used as positive PCR amplification controls, whereas HotStar PCR amplification mix without ss-cDNA addition was used as a negative control. PCR amplification conditions, annealing temperature and primers used are shown in Table 2 and were taken from the study by Uchida *et al*[20]. For increased sensitivity, nested PCR amplifications were carried out for the detection of GRP and GRP-receptor cDNA. First round PCR amplicons were purified using a GFX PCR and Gel Band DNA Purification Kit (Amersham Biosciences, Uppsala, Sweden) and, subsequently, 1 μL was used in a nested PCR amplification. As positive PCR amplification controls, commercially available human stomach and pancreas cDNAs (Clontech, BD Biosciences Stockholm, Sweden) were included in the study. Negative PCR amplification controls (PCR mix without DNA template addition) were included to monitor possible contaminations.

Southern blot analysis of PCR amplicons

PCR amplicons were electrophoretically separated on a

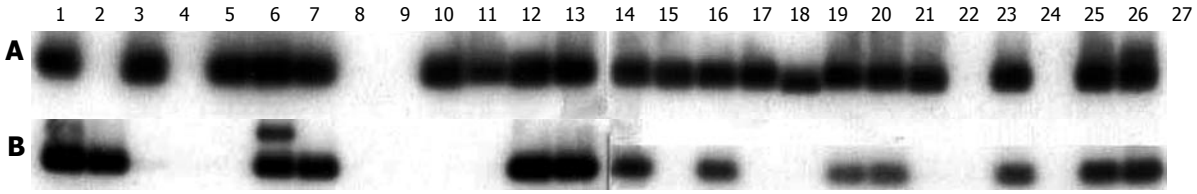

Figure 1 Southern blot hybridization analysis of nested PCR amplicons derived from ss-cDNA 1 to 26 as specified in Table 1. Lane 27 represents a negative PCR control (no ss-cDNA template added to the PCR master mix). Exposure to X-ray films was for 1 d using an intensifier screen at -70 ℃. **A:** hGRP-PCR amplicons; **B:** hGRP receptor PCR amplicons.

15 g/L agarose gel and Southern blot analysis was performed using 10 pmoles of [^{32}P]-5'-end-labelled nested primers hGRP-SE/2 and hGRP-AS/2 or hGRPR-1/SE and hGRPR-2/AS primers as hybridisation probes (Table 2) under the conditions described elsewhere[19].

RESULTS

Integrity of ss-cDNA

All analyzed ss-cDNA yielded fragments of the expected length (288 bp) after two rounds of β-actin PCR amplification and Southern blot analysis, indicating that the ss-cDNA used was essentially free of DNA contamination[19].

Differential tissue expression of GRP and GRP-receptor mRNA

Initially, first round and nested GRP and GRP–receptor PCR amplification conditions were optimized by means of annealing temperature and cycle conditions using two established, premade PCR amplification mixes (puReTaq Ready-To-Go PCR beads, Amersham Biosciences and HotStarTaq Master mix kit, Qiagen). Essentially, the HotStarTaq Master mix kit was used under the conditions described in Table 2.

Southern blot analysis (one-day exposure) of nested GRP-PCR amplicons derived from ss-cDNA revealed PCR bands of the expected size in 18 of 24 (75%) biopsy specimens and in the human stomach and pancreas control cDNA's. It appeared that GRP-PCR amplicons of two distinct sizes were present. These GRP-PCR amplicons were similar in sizes to earlier described GRP-PCR amplicons, derived from alternatively spliced GRP-mRNA[20]. However, no attempts were made to further investigate this point. Furthermore, 11 of 24 (46%) biopsy specimens and the human stomach and pancreas control cDNA yielded GRP-receptor PCR amplicons of the expected size (Figure 1, Table 1). After five-day exposure, an additional 9 of 24 (37%) biopsies yielded weak GRP-receptor PCR amplicons as judged by Southern blot analysis (Table 1), indicating a low level expression of GRP-receptor mRNA. Similarly, two tissues revealed the presence of an extra and larger GRP-receptor PCR amplicon. Its nature has not been further investigated.

No GRP and GRP-receptor PCR amplicons could be detected in the gallbladder tissue, indicating a lack of expression of these mRNAs. However, only one gallbladder biopsy was analyzed and, therefore, the result may not be conclusive since variable GRP and GRP-receptor mRNA expressions were observed in ventricle, duodenum, colon ascendens and rectum biopsies (Figure 1, Table 1). More specifically, GRP mRNA appeared to be expressed in 2 of 4 colon ascendens biopsies. In contrast, a weak band corresponding to GRP-receptor expression was detected in 4 of 4 colon ascendens biopsies after 5-d exposure, indicating a low level of GRP-receptor mRNA expression in these tissues (data not shown). Remarkably, PCR amplicons corresponding to GRP mRNA expression were detected in 4 of 4 transverse colon and 4 of 4 sigmoid colon biopsies (Figure 1). Similarly, GRP-receptor mRNA seemed to be co-expressed in 3 of 4

transverse colon and 3 of 4 sigmoid colon (Table 1).

DISCUSSION

Biopsy specimens were collected from various sites of the human gastrointestinal tract and surrounding tissues. Efforts were made to collect the biopsies from fresh, histologically normal tissues (Table 1). Our results showed that GRP and GRP-receptor mRNAs were widely expressed in the human gastrointestinal tract and surrounding tissues. It is tempting to speculate that the variation in GRP and GRP-receptor mRNA levels observed (Figure 1) may reflect a real-time mRNA expression situation. However, we can not exclude the possibility that artifacts based on sample selection (site of collecting and biopsy sizes) may contribute to the observed mRNA level variations.

Co-expression of GRP and GRP-receptor mRNA in the same tissue as observed could lend support to speculations about the existence of an autocrine and/or paracrine loop. For paracrine signaling, the communicating cells need to be in close proximity in order to establish such loops. Expressions of GRP and its receptor mRNA could be originating from different cell types in opposing parts of the tissue collected. To verify the existence of such an autocrine and/or paracrine loop, cellular co-expression of GRP and GRP-receptor mRNA and its subsequent translation into biologically active proteins must be confirmed. This could be achieved either by *in situ* hybridization or histochemistry techniques, using GRP and GRP-receptor specific hybridization probes or antibodies, respectively.

In lack of the results of such studies, the physiological importance of GRP and GRP-receptor mRNA expression in gastrointestinal tissues can only be speculated upon. However, based on earlier studies, it seems likely that GRP could act on the human colon via receptors on smooth muscle cells and gastric epithelial cells as well as on cells of the ENS[11,12]. GRP has been shown to be the primary transmitter of motor neurones to gastrin cells[2]. Pharmacological doses of GRP showed a concentration-dependent increase in the rhythmic activity of the ileocecum region[21] and evoked contractions of isolated muscle cells from jejunum[7]. Accordingly, inhibition of endogenous GRP delayed gastric emptying and gallbladder contraction[22]. In contrast, small bowel transit was prolonged by the same antagonist[22]. Thus, the effect on the small intestine may be important for mixing movements and not so much for the peristalsis. In our study, the presence of GRP and its receptor throughout the gastrointestinal tract, in addition to earlier studies that showed no expression of the peptides in the epithelial layer except gastric antrum[12] but on colonic smooth muscle cells and ENS[11], raises the hypothesis that the peptide may affect the motility along the entire GI tract. This is further underlined by the effects on smooth muscle cells[7,21]. Disturbed tissue levels of GRP have been described in patients with idiopathic intestinal pseudo-obstruction[23]. The physiology and pathophysiology behind intestinal motility and dysmotility are in many aspects unknown. It is difficult to study the physiological effect of one single peptide alone, as the ENS contains many different peptides with an important balance between them. However, GRP seems to be one of the interesting peptides in the regulation of gastrointestinal motility.

To best of our knowledge, this is the first study that describes the presence of GRP and its receptor in the human pancreas. It is in accordance with the observed effect of GRP on the secretion of pancreatic juice and pancreatic hormones[3-5]. Earlier animal studies have described that GRP is released from vagal, pancreatic nerves after stimulation[4,24]. GRP then acts by binding to a specific member of the 7 transmembrane spanning, G protein-coupled receptor superfamily where activation by GRP-receptors is coupled to phospholipase C and phospholipase D[24,25].

We were not able to detect GRP or GRP-receptor mRNA expression in the gallbladder. This may be explained by the fact that only one patient was examined. The earlier described effect of a GRP antagonist to inhibit gallbladder contraction suggests that GRP receptors are expressed in the gallbladder[22]. However, antagonists may antagonise more than one receptor, and the PCR technique in the present study was specifically examining the GRP-receptor, not similar receptors in the same family.

The effect of GRP in gastrointestinal carcinogenesis is unclear. Most of resected colon cancers aberrantly express GRP receptor mRNA[26], whereas immunohistochemically, less than three-quarters of human tumors express this protein[16]. Furthermore, not all of these receptors are functional when expressed, as only a minor amount of resected human colon cancers have been found to bind (^{125}I-Tyr^{4}) bombesin when studied pharmacologically[27]. The discrepancy between GRP-receptor mRNA and protein expression may be due to the frequency with which the coding sequence for this receptor is mutated[17]. Some authors suggest that GRP acts as a mitogen and increases tumor cell proliferation[18], while others have found that GRP/GRP-receptor co-expression in cancer promotes the development of a well-differentiated phenotype and is therefore more a morphogen than a mitogen[1]. Multiple studies suggest that the presence of these two peptides confers a survival advantage[14,16].

In conclusion, GRP and GRP-receptor mRNA appear to be expressed throughout the human gastrointestinal tract. This provides information for the future mapping of GRP and GRP-receptor expression at the cellular level, and thereby further determination of its physiological importance in normal and tumor cells.

Abstract

AIM: To evaluate the effect of ranitidine on gastric mucosal changes and on GI bleeding in long distance runners.

METHODS: Twenty-four long distance runners (M: 16, F: 8, age: 18.2 ± 1.5 years) participated in this study. A symptom questionnaire, stool hemoccult test, and upper gastrointestinal (GI) endoscopy were performed on the subjects prior to the study. The subjects took oral ranitidine (150 mg, b.i.d.) for two weeks. The upper GI endoscopy and stool Hemoccult tests were repeated after the treatment.

RESULTS: Twenty-two of the 24 runners had at least one upper GI mucosal lesion before the medication. The Endoscopic improvements were seen in eleven of the 14 cases of erosive gastritis and four of the 5 cases of esophagitis. Six subjects were Heme occult positive prior to the study, but only one was positive after the medication.

CONCLUSION: Gastric mucosal lesions and GI bleeding in long distance runners seem to be associated to acid-related factors mediated by the high level of regular running. Ranitidine seems to be and effective prophylaxis to prevent gastric mucosal lesions and GI bleeding.

Key words: Endoscopy; Exercise; Gastrointestinal bleeding; Ranitidine

INTRODUCTION

Long-distance running has become a popular exercise during the past decade, and the number of people participating in endurance racing has increased. It has been reported that troublesome gastrointestinal (GI) symptoms associated with endurance running events has been occurring more frequently[1,2]. Although the magnitudes of these symptoms are unknown, incidence rate varies from 10 to 81%, depending on factors such as the type, duration, and intensity of the exercise studied[3].

GI bleeding is not an uncommon finding after long distance races. Some of runners[3,4] who experienced macroscopic fecal blood and microscopic bleeding has been found in 8 to 87% of the runners[5,6]. Running-related GI mucosal changes such as gastric ulcer[7], hemorrhagic gastritis[8], erosive gastritis[9], ischemic colitis[10] were observed by endoscopy. These changes may contribute to runner's anemia and, if sustained, may possibly result in an iron deficiency that may potentially affect the recovery and performance of competitive runners. The mechanism by which hemorrhagic gastritis and ischemic colitis develop in runners is unknown, but it is usually attributed, in part, to ischemia. One report showed that running reduced visceral blood flow by up to 80% of pre-exercise level[11]. Another possible mechanism for the hemorrhagic gastritis is acid secretion[12]. Moderate-intensity running is not generally thought to alter gastric acidity[13] whereas heavier exertion paradoxically reduces acid secretion[14]. But some reports have suggested that acid reducing agents, i.e. cimetidine or ranitidine, might be useful in preventing running-associated

gastrointestinal bleeding and symptoms[6,15]. However, there has been only one case study regarding running related GI mucosal changes before and after treatment[15]. We, therefore, performed an observational trial to evaluate the effect of ranitidine on gastric mucosal changes and GI bleeding in long distance runners by endoscopy.

MATERIALS AND METHODS

Study subjects

Twenty-four professional long distance runners (16 male, 8 female, age range: 16-19 years) participated in this study. The Human Investigations Committee of Wonkwang University Hospital approved the protocol and each subject signed an informed consent prior to the study.

The subjects were well trained and had several years of experience in competitive running. They underwent a strict training program of 200 km of running per week and participated in three long-distance running competitions per year. All subjects were instructed to avoid nonsteroidal anti-inflammatory drugs, red meat, alcohol, iron and vitamin supplementation for at least 2 wk prior to the study

Symptom questionnaire

The questionnaire was designed with yes/no questions and a graded value scale (0: none = no symptom, 1: mild = intermittent symptoms but not interfere with the running, 2: moderate = want treatment for symptoms but rarely interfere with the running, 3: severe = want treatment for symptoms and interfere with the running) for the following symptoms: diarrhea, abdominal cramps, epigastric discomfort, epigastric pain, nausea, vomiting, and regurgitation related to running.

GI bleeding test

The presence of GI bleeding was tested before and after the study with hemeoccult test (LA Hemochaser, MIZUHO, Japan) by looking for the presence of agglutination after mixing the feces with a latex reagent within a 3 min.

Study protocols

Gastroscopy was performed on all subjects prior to the study. No pre-medication was used except for lidocaine (2 mL of viscous Xylocaine) as a local anesthetic. Two endoscopists performed the upper GI endoscopy with a flexible gastroscope (Pentax EG-2730, 9.0 mm diameter, Japan). Macroscopic observations of gastric mucosal damage were noted but not graded. *Helicobacter pylori* (*H pylori*) infection was evaluated by a rapid urease test of the one biopsy specimen obtained during endoscopy. The subjects with abnormal endoscopic findings took 150 mg of oral ranitidine (30 min postprandial, b.i.d.). The subjects commenced regular training for 2 wk while taking the medication. A second endoscopy was given to the subjects who had abnormal upper GI mucosal findings before the treatment.

Table 1 Gastrointestinal symptoms in runners (n = 24)

	None	Mild	Moderate	Severe	Percentage of symptomatic subjects (%)
Diarrhea	9	13	1	1	63
Abdominal pain	10	12	2		58
Epigstric discomfort	10	12	2		58
Epigastric pain	12	10	2		50
Nausea	14	8	2		42
Regurgitation	16	8			33
Vomiting	19	4	1		21

RESULTS

Symptom questionnaire

The results of the symptom questionnaire are summarized in Table 1. Only two subjects had no GI symptoms related to running. The most frequently experienced GI symptom was diarrhea (n = 15), followed by abdominal pain (n = 14), epigastric discomfort (n = 14), and epigastric pain (n = 12).

Gastroscopy findings

The results of the endoscopic examination before and after the treatment are listed in Table 2. Twenty-two of the 24 runners had at least one upper GI mucosal lesion, including erosive gastritis (n = 17), esophagitis (n = 8), alkaline reflux gastritis (n=8), and gastric ulcer (n = 1). Of the seventeen subjects with mucosal erosions, four subjects had stigmata of bleeding. Mucosal erosions were localized to the antrum (n = 11), gastric body (n = 8), fundus (n = 6), and gastric angle (n = 2). Sixteen out of 22 runners who had abnormal upper GI mucosal findings consented to have a second endoscopy after medication. Gastroscopic improvements were seen in eleven of the 14 cases of erosive gastritis, four of the 5 cases of esophagitis, but only one of the 5 cases of alkaline reflux gastritis.

GI bleeding

Six of the 24 participants were heme occult positive before the medication. Only one was positive after the medication (Table 2).

Helicobacter pylori status

Nine of the 24 participants were rapid urease test positive (Table 2). But there was no relation between *H pylori* status and endoscopic findings.

DISCUSSION

This study reported a high incidence of running related GI symptoms and the results confirmed the previous studies[2]. Moses reported that symptoms of the lower GI tract were more prevalent than those from the upper GI tract in most endurance events[16] and others found that frequency of GI symptoms were much higher during marathon running and/or triathlons than during other endurance sports,

Table 2 Endoscopic findings and hemoccult test before and after treatment with ranitidine

Subject/Sex	Before treatment (n = 24)			After treatment (n = 16)	
	Endoscopic findings	Hp status	OB	Endoscopic findings	OB
1/M	Alkaline reflux gastritis Erosive gastritis (upper body)	–	+	Procedure refused	–
2/M	Esophagitis, LA class A Alkaline reflux gastritis Erosive gastritis (fundus)	–	–	Erosive gastritis (antrum and body)	–

i.e. cycling, rowing, and swimming[3,17].

The duration of the exercise can be an important factor. Peters *et al*[18] showed that during a protocol of alternately cycling and running, the number of subjects with GI symptoms increased exponentially with time. They also reported that running induced more GI symptoms when compared to cycling[18]. Another factor thought to influence the exercise induced GI symptoms is the intensity of the exercise. It has been reported that as intensity increases, gastric emptying is delayed[13,19] and splanchnic blood flow decreased[11]. Other factors such as mechanical trauma of the gut[20], intestinal permeability[21], and absorption[22] may also be affected by the intensity of the exercise.

The existence of gastrointestinal bleeding associated with endurance running has previously been demonstrated[2,23]. Sullivan[2] reported bloody stools after endurance events, and another study demonstrated the high frequency of occult GI bleeding, in which 23% of runners converted from blood test negative to blood test positive using the Hemeoccult card[23]. Stewart *et al*[24] reported that 83% of runners had positive stool occult blood after competitive running and the presence of iron-deficiency anemia possibly caused by multiple etiologies including GI bleeding.

While GI blood loss can be clearly attributed to running, its etiology or pathophysiology is not readily apparent. McMahon *et al*[25] suggested an ischemic etiology for the blood loss. They studied 32 runners after a marathon, and showed that six runners, who developed hemoccult-positive stools after a marathon race, were significantly younger and had faster race times when compared to those

with hemoccult-negative stool.

Another possible mechanism for the development of GI bleedings may be mucosal damages caused by gastric acid secretion[12]. Very little data exists regarding acid secretion during exercise and immediately following exercise due to the technical difficulties in such measurements during the exercise. Several reports have suggested that cimetidine or ranitidine might be useful in preventing running associated GI bleeding[6,8,15]. Our study found that six out of 24 participants had positive heme occult positive before medication and each of these 6 subjects had abnormal endoscopic findings before medication. After 2 wk of medication, five out of these 6 subjects became heme occult negative and had improved endoscopic findings (3 normal, 2 partial improvement, 1 dropout). These findings strongly suggest that GI bleeding induced by long distance running is closely related to gastric acid secretion, and reducing acid output with ranitidine seems to be an effective treatment.

With the wide spread popularity of this kind of sport, these complications might be more frequently observed than one would expect, and physicians should be aware of them when evaluating runners with occult GI bleeding with anemia.

The actual site of GI bleeding associated with running is uncertain, but some reports have identified bleeding lesions in the stomach and colon by endoscopy[7-10]. The most frequently reported endoscopic abnormalities in runners are erosive gastritis with bleeding stigmata in the stomach[8,9] and erosion with hemorrhage in the colon[10]. GI mucosal erosions have mainly been found in the corpus region of the stomach[9,15] where stress or shock associated gastritis is normally seen[26]. In contrast, one study has shown abnormal histological features in gastric antral mucosa with decreased mucosal secretion[27]. To our knowledge, only one case report using endoscopy has demonstrated that exercise induced hemorrhagic lesions were improved after taking a therapeutic course of cimetidine[15].

Our study shown that twenty-two of the 24 runners had at least one upper GI mucosal abnormality, of which seventeen subjects had mucosal erosions, and four had stigmata of bleeding. These mucosal erosions were found mainly in the antrum, but also in the gastric body, fundus, and angle. Sixteen of 24 runners had follow-up endoscopy after 2 wk medication of ranitidine. The endoscopic improvements were seen in eleven subjects with erosive gastritis.

Gastroesophageal reflux occurs more frequently with exercise than at rest[28]. Some GI symptoms occurring with exercise can be of esophageal origin, including chest pain and heartburn. These phenomena might be caused by reduced salivary secretion, which results in poor acid clearance[30]. In addition, esophageal ischemia, due to a decrease in visceral blood flow during exercise, may play an important role in development of esophagitis[11]. Esophageal acid exposure may be reduced by a histamine H2-receptor antagonist during running[29]. However, there are no reports describing exercise-induced esophagitis assessed by endoscopy. Long-term implications of gastro-esophageal reflux in the habitual runner or exerciser are also unknown. Our study showed that eight of the 24 runners had esophagitis before treatment and four out of 5 who received a second endoscopy had improvements after medication. This suggests that gastroesophageal reflux associated with running is also closely related to acid secretion.

In conclusion, this is the first study that was evaluated by endoscopy on running associated GI symptoms before and after acid reducing medication. Our results have shown that mucosal abnormalities, such as erosive gastritis and esophagitis in long distance runners are related to gastric acid. Therefore, acid suppressive agent is an effective treatment for running related GI symptoms.

Abstract

AIM: To conduct a retrospective study to determine the risk factors for development of metaplastic gastritis in Korean population.

METHODS: The database of 113449 subjects who underwent a gastroscopy for the purpose of a regular check-up at center for health promotion, Samsung medical center during 5 years was collected and retrospectively analyzed. Among them, 5847 subjects who had endoscopically diagnosed as a metaplastic gastritis or 10076 normal as well as answered to questionnaire were included for present study. The subjects were divided into 2 groups; Group I, normal and Group II, metaplastic gastritis. Age, gender, *Helicobacter pylori* (*H pylori*) seropositivity, body mass index (BMI), family history of cancer, smoking, alcohol consumption, total daily calories, folate and salt intake and dietary habit (out-eating, overeating, irregular eating) were retrieved from questionnaire or electronic medical record and compared between group I and group II.

RESULTS: The prevalence of group II was 11% (13578/113449) increasing its prevalence with age ($P = 0.000$). But, there was no significant association between 2 groups in BMI, family history of cancer, alcohol consumption, total daily calories, folate and salt intake and dietary habit (out-eating, overeating, irregular eating). Old age ($P = 0.000$), male gender ($P = 0.000$), *H pylori* seropositivity ($P = 0.010$) and current smoker ($P = 0.000$) were significantly more common in group II at multiple logistic regression model.

CONCLUSION: Our data suggested that old age, male gender, *H pylori* seropositivity and smoking were risk factors for metaplastic gastritis, precancerous lesion of gastric cancer.

Key words: Intestinal metaplasia; Risk factors

INTRODUCTION

Gastric cancer was recognized as the first leading cause of cancer death in Korea[1] and attention turned to epidemiologic associations between risk factors and gastric cancer. In the early 1970s, Correa formulated a multi-step model of gastric cancer, which postulated a temporal sequence of pathologic changes that led from chronic gastritis to atrophic gastritis, intestinal metaplasia and dysplasia and the eventual development of gastric cancer[2]. Chronic gastric inflammation seems to be the critical common cause of gastric cancer[3].

The purpose of this paper was to determine the risk factors for development of metaplastic gastritis, precursor of gastric cancer in Korean population

MATERIALS AND METHODS

Data collection

The database of 113449 subjects who underwent a gastroscopy for the purpose of a regular check-up at center for health promotion, Samsung medical center from January 2001 through June 2004 was collected and retrospectively analyzed. Among them, 13578 subjects were endoscopically diagnosed as a metaplastic gastritis and 10521 subjects was endoscopically diagnosed as a normal. But, only 5847 subjects who had endoscopically diagnosed as a metaplastic gastritis were answered to questionnaire whereas 10076 subjects who had endoscopically diagnosed as a normal were answered to questionnaire. Both 5847 metaplastic gastritis and 10076 normal were included for present study. Subjects with peptic ulcer or erosion of stomach were excluded in this study population. The subjects were divided into 2 groups; Group I, normal and Group II, metaplastic gastritis. Demographic data [age, gender, body mass index (BMI), family history of cancer] and life style data [smoking, alcohol consumption, total daily calorie intake, folate intake, salt intake, dietary habit (out-eating, overeating, irregular eating)] were retrieved from question-

Figure 1 Endoscopic finding showed that atrophic mucosa with surface nodularity was generally diagnosed as a metaplastic gastritis.

naire or electronic medical records and compared between group I and group II. Those who have family history of any cancer were those who had a reply to yes in the question ("Do you have a blood relation who has a experience of diagnosis as cancer by a doctor?"). Data including smoking, alcohol consumption (frequency and amount of alcohol), dietary habit (out-eating, overeating, irregular eating) were collected from self administered questionnaire. Patients were asked whether they were active, past or never smoker. The subjects were divided into two groups (current smoking group and non-smoking group) by current smoking status. Nonsmoking group is composed of past or non-smoking. The subjects were divided into two groups by frequency and amounts of liquors (namely, *so-ju)* consumption in questionnaire. Over or equal 3-4 frequencies a week and $\geqslant$ 80 g once alcohol consumption is defined as the group of heavy alcohol consumption. Below 3-4 frequencies a week or $<$ 80 g once alcohol consumption is classified as the other group. Total amount of calorie, folate intake and fat intake were obtained in diet surveys. *Helicobacter pylori (H pylori)* seropositivity was retrieved from electronic medical record. *H pylori* infection was determined by measuring serum *H pylori* IgG antibodies. Specific anti- *H pylori* antibodies were measured with an enzyme-linked immunosorbent assay (ELISA) kit using an antigen (RADIM SpA, Pomezia, Italy). The sensitivity and specificity of this assay was reported to be 79% and 83%, respectively[4].

Criteria for metaplastic gastritis

Atrophic mucosa with surface nodularity on the endoscopic finding was diagnosed as metaplastic gastritis (Figure 1). 3354 individuals who showed endoscopically metaplastic gastritis had also a presence of metaplasia histologically on the updated Sydney system.

Statistical analysis

Logistic regression analysis was conducted by fixing the each group as a dependent variable and risk factors as independent variables. Continuous variables such as age, BMI, total daily calorie intake, folate intake and salt intake were analyzed by *t*-test. Gender, smoking, alcohol consumption, family history of cancer, dietary habit (out-eating, overeating, irregular eating) and *H pylori* seropositivity were analyzed by χ^2 test. The relative risk to develop metapalstic gastritis was calculated with odds ratio with 95% confidence interval. Risk factors were examined by multiple logistic regression analysis. Statistical significance was assumed at $P<0.05$. Statistical analyses were performed with SAS version 8.1 (SAS Institute Inc, Cary, NC, USA).

Table 1 Comparison of characteristics of normal and metaplastic gastritis (simple logistic regression model)

	Normal (%)	Metaplastic gastritis (%)	*P* value
Age	42.46±10.15	53.20±9.00	0.000
Sex			0.000
Men	3804 (36)	3983 (68)	
Women	6272 (64)	1864 (32)	
BMI[1]	24.52±2.36	23.97±2.86	0.208
Family history of cancer	160 (1)	125 (2)	0.065
Smoking			0.000
None or past	2933(84)	3308 (74)	
Current	550 (16)	1130 (26)	
Alcohol			0.059
Heavy alcoholics[2]	553 (15)	747 (16)	
Out-eating	2477 (23)	1535 (26)	0.110
Over eating	1743 (16)	912 (15)	0.598
Irregular eating	1824 (17)	1152 (19)	0.228
Total calories	2102.94±470.17	2226.46±486.22	0.515
Folate	246.34±91.24	289.51±108.55	0.211
Salts	22.48±7.27	23.02±4.97	0.319
H pylori seropositivity[3]	4165 (39)	3566 (60)	0.007

[1]BMI, body mass index.
[2]Over or equal 3-4 frequencies a week and $\geqslant$ 80 g once alcohol consumption is defined as the group of heavy alcoholics.
[3]*Helicobacter pylori* is abbreviated as *H pylori*.

RESULTS

Characteristics of study subjects (Table 1)

The prevalence of group II was 11% (13 578/113 449) increasing its prevalence with age ($P=0.000$). But, there was no significant association between 2 groups in BMI, alcohol consumption and family history of cancer. Male gender was a risk factor for metaplastic gastritis and current smokers were more likely to have metaplastic gastritis than none or past smokers. Neither dietary composition (folate, salts, calories) nor dietary habits (out-eating, overeating, irregular eating) was associated with metaplastic gastritis. *H pylori* seropositivity was more common in the group II.

Multiple logistic regression analysis (Table 2)

Finally, we conducted stepwise multiple logistic regression analysis in which above significant variables were used as independent variables. Number of subjects entered into the stepwise multiple logistic regression model were 4438 in group II and 3483 in group I. Entered variables were age, gender, BMI, family history of cancer, smoking, alcohol consumption, total daily calorie intake, folate intake, salt intake, dietary habit (out-eating, overeating, irregular eating), and *H pylori* seropositivity.

Old age ($P=0.000$), male gender ($P=0.000$), *H pylori* seropositivity ($P=0.010$) and current smoker ($P=0.000$) were significantly more common in the group II at multiple logistic regression model.

DISCUSSION

Gastric cancer was recognized as the first leading cause of

cancer death in Korea[1] and many epidemiologic studies about risk factors for gastric cancer were reported[5,6]. So far, we had no a large-scale epidemiologic studies about metaplastic gastritis, precursors of gastric cancer in the Korean population.

In the early 1970s, Correa formulated a multi-step model of gastric cancer, which postulated a sequence from chronic atrophic gastritis, intestinal metaplasia, dysplasia and gastric cancer[2]. Chronic gastric inflammation leads to repetitive injury and repair resulting in hyperplasia[3]. Whereas acute injury and inflammation associated with healing are usually self-limited, chronic injury or inflammation leads to a sustained expansion of tissue proliferation[7-10]. Sustained tissue proliferation is generally accepted as a risk factor for cancer[3]. As is well known, metaplastic gastritis is precursors of gastric cancer.

Our understanding of gastritis and cancer underwent a marked shift with rediscovery of *H pylori*[7-13]. *H pylori* is now thought to account for most of gastritis[13] whereas *H pylori* infection is not an only important factor for development for gastric cancer[5]. But, it is not clear whether *H pylori* infection is also important for development for metaplastic gastritis. Our study demonstrated that *H pylori* seropositivity is an independent risk factor for the metaplastic gastritis.

In the intestinal type of gastric cancer, environmental factors other than *H pylori* infection seem to play a part in the carcinogenesis[12]. Environmental factors may facilitate the development of atrophic gastritis and intestinal metaplasia[12,14]. Based on epidemiologic studies of dietary histories, the first step in the Correa pathway was believed to be initiated by a diet rich in salt and nitrates/nitrites as well as deficiencies in fresh fruits and vegetables[5]. Dietary factors and continued effects of chronic inflammation were felt to be responsible for the progression from gastritis to atrophy, metaplasia, dysplasia and carcinoma[12]. Ingestion of sodium chloride is thought to promote gastric carcinogenesis[14]. Exposure to N-nitroso compounds probably facilitates advancement of chronic atrophic gastritis and intestinal metaplasia in adulthood[5]. Our study showed that neither dietary habits, salts nor folate intakes is a risk factor for the metaplastic gastritis. The major limitation of our study is that diet survey used in our study is carried out by not-validated questionnaire.

Both superficial and chronic atrophic gastritis are common in alcoholics[6]. Alcohol consumption can also cause acute gastritis[15]. Our study demonstrated that alcohol is not a risk factor for the metaplastic gastritis. Male dominance of the metaplastic gastritis can be explained, in which male gender tends to have more dangerous environmental factors such as smoking. But, our study demonstrated that male gender and smoking are independent risk factors for the metaplastic gastritis, respectively.

First, the limitation of present study is selection-bias. The substantial numbers of subjects did not have information about all items of the questionnaire. Numbers of subjects entered into the multiple logistic regression model were 4438 (4438/13578, 32%) in group II and 3483 (3483/10521, 33%) in group I. The other limitation of our study is inter-examiner or intra-examiner bias of endoscopic diagnosis about metaplastic gastritis and normal. To ascertain the precision in endoscopic diagnosis of gastritis, we undertook a pilot study on 10 individuals. Endoscopic finding was obtained 2 times on 10 individuals by 2 examiners. We examined the inter-examiner bias between 2 examiners and intra-examiner bias between 2 examinations by same examiner. Kappa value of intra-examiner was 1.0 ($P=0.002$), 0.737 ($P=0.016$), respectively. Kappa value of inter-examiner was 0.875 ($P<0.001$).

Our data suggested that old age, male gender, *H pylori* seropositivity and smoking were risk factors for metaplastic gastritis, precancerous lesion of gastric cancer.

Table 2 Multiple logistic regression analysis about risk factors for development of metaplastic gastritis

Variable[1]	Odds ratio (95% CI[2])	*P* value
Age	8.945 (7.204-11.105)	0.000
Male gender	1.144 (1.133-1.155)	0.000
Current smoking	2.137 (1.693-2.697)	0.000
H pylori[3] seropositivity	1.223 (1.049-1.426)	0.010

[1]All variables in the model are as follows: age, sex, body mass index, family history of cancer, smoking, alcohol consumption, total daily calorie intake, folate intake, salt intake, dietary habit (out-eating, overeating, irregular eating), and *H pylori* seropositivity.
[2]CI, confidence interval.
[3]*Helicobacter pylori* is abbreviated as *H pylori*.

Abstract

AIM: To identify patients with a high-risk of having a synchronous cancer among gastric cancer patients.

METHODS: We retrospectively analyzed the prospective gastric cancer database at the National Cancer Center, Korea from December 2000 to December 2004. The clinicopathological characteristics of patients with synchronous cancers and those of patients without synchronous cancers were compared. Multivariate analysis was performed to identify the risk factors for the presence of a synchronous cancer in gastric cancer patients.

RESULTS: 111 of 3291 gastric cancer patients (3.4%) registered in the database had a synchronous cancer. Among these 111 patients, 109 had a single synchronous cancer and 2 patients had two synchronous cancers. The most common form of synchronous cancer was colorectal cancer (42 patients, 37.2%) followed by lung cancer (21 patients, 18.6%). Multivariate analyses revealed that elderly patients with differentiated early gastric cancer have a higher probability of a synchronous cancer.

CONCLUSION: Synchronous cancers in gastric cancer patients are not infrequent. The physicians should try to find synchronous cancers in gastric cancer patients, especially in the elderly with a differentiated early gastric cancer.

Key words: Synchronous cancer; Gastric cancer; Colorectal cancer

INTRODUCTION

Gastric cancer is the most common form of cancer in Korea[1]. The overall age-standardized incidence rates of gastric cancer in 2002 were 69.6 per 100 000 among males and 26.8 per 100 000 among females. Despite the improved prognosis of gastric cancer resulting from early diagnosis, radical operations, and the development of adjuvant therapy, gastric cancer remains the second most common cause of cancer death worldwide[2,3]. In 1995, early gastric cancer (EGC) accounted over 30% of patients who underwent gastric cancer surgery in Korea and this percentage continues to increase[4]. As the prognosis of patients with EGC is excellent and age at diagnosis for gastric cancer is increasing, there is a greater risk that patients will also have a second primary cancer[5,6].

Second primary cancer influences the prognosis of gastric cancer patients, and because primary or secondary prevention is the best way to cure cancer, some investigators have focused on the characteristics of second primary cancers in gastric cancer patients[7-10]. However, few studies have been performed in this regard, and most of these studies are limited to metachronous cancers or the treatment-related second primary malignancies of gastric cancer patients[11,12]. The detection of synchronous cancers gives us the opportunity to treat both cancers simultaneously using less invasive techniques and thus to beneficially influence the prognosis and quality of life of these patients.

The aim of this study was to find a means of identifying gastric cancer patients at risk of having a synchronous cancer.

MATERIALS AND METHODS

Subjects

We retrospectively analyzed the prospective gastric cancer database at the National Cancer Center (NCC), Korea from December 2000 to December 2004. A total of 3291 gastric

cancer patients were registered (the registered patients were consecutive patients who had ever visited out patient clinic in the Center for Gastric Cancer with a diagnosis of gastric cancer or who were diagnosed as having gastric cancer at our center) during the study period. Gastric and synchronous cancers were all pathologically confirmed.

Methods

Synchronous cancers were defined as cancers detected in organs other than the stomach, which were diagnosed at the time of or within 6 mo of the first cancer diagnosis[13]. For each synchronous cancer we ruled out of the possibility that synchronous cancer represented metastasis of gastric cancer by histologic examination. Clinicopathological characteristics including age, sex, histological classification, a preoperative diagnosis of early or advanced gastric cancer, and multiplicity of gastric cancer were compared for patients with and without synchronous cancers. As for histological classifications, tubular carcinoma and papillary adenocarcinoma were classified as differentiated types, whereas poorly differentiated adenocarcinoma, mucinous adenocarcinoma, and signet ring cell carcinoma were classified as undifferentiated types[14]. The characteristics of synchronous cancers including operability and when they were diagnosed were separately analyzed.

Statistical analysis

All statistical analyses were performed using the statistical software 'Statistical Package for Social Sciences' (SPSS) version 10.0 for Windows (SPSS, Inc, Chicago, IL). Inter-group (for patients with and without synchronous cancer) comparisons of clinicopathological variables were made using the Student t-test for continuous variables and using the two-tailed Chi-square test for discrete variables.

Risk factors influencing synchronous cancers were determined by logistic regression analysis. Hazard ratio as determined by multivariate analysis, was defined as the ratio of the probability that an event (with synchronous cancer or not) would occur to the probability that it would not occur. The predicting powers of covariates were expressed by calculating hazard ratios with a 95% confidence interval. The accepted level of significance was $P < 0.05$.

RESULTS

Clinicopathological characteristics of the patients

Among the 3291 gastric cancer patients, 111 patients (3.4 %) had a synchronous cancer other than in the stomach; 2 patients (2/111 patients, 1.7%) had three cancers and the others had a single synchronous cancer. The mean age of patients with a synchronous cancer was higher than that of patients without (64.6 ± 9.5 *vs* 59.4 ± 12.5, t = -0.453, $P < 0.001$) and male patients were more common among those with synchronous cancers (χ^2=9.81, P=0.002). Differentiated type and early gastric cancer were more common among patients with synchronous cancers (χ^2=73.97, $P < 0.001$, χ^2=19.65, $P < 0.001$ respectively, Table 1).

Characteristics of synchronous cancers

The most common synchronous cancer was colorectal cancer (42 cases, 37.2%), followed by the lung (21 cases, 18.6%), esophagus (19 cases, 16.8%), and liver cancer (11cases, 9.7%) (Figure 1, Table 2). Gastric cancer was the most common form of cancer among colorectal cancer patients with a synchronous cancer. Of the 2 triple cancer patients, one patient had esophageal cancer and prostate cancer and the other patient had lung cancer and colorectal cancer. Forty-three patients (38.1%) were diagnosed with gastric cancer and synchronous cancer simultaneously and 45 patients (39.8%) were diagnosed with synchronous cancers before gastric cancer, and 25 cases (21.1%) were diagnosed after receiving a diagnosis of gastric cancer.

Operation of gastric cancer

Of the 111 patients with synchronous gastric cancers, 73 (64.6%) underwent gastric cancer surgery. Despite having a potentially resectable gastric cancer, 38 patients (34.2%) were treated non-surgically because of advanced

Table 2 Distribution of synchronous cancer according to gastric cancer location and diagnosis

Location	Time interval between the diagnoses of synchronous and gastric cancers			
	6 mo ~ (n=45)	Simultaneous (n=43)	~ 6 mo (n=25)	Total (n=113[1], %)
Colorectal	28	6	8	42 (37.2)

Others	2	1	3	6 (5.3)

[1]Two patients have double synchronous cancers.

synchronous cancer (19 patients, 50.0%), an advanced gastric cancer (6 patients, 15.8%), or patient refusal (11 patients, 28.9%), and other causes (2 patients).

Logistic regression analysis of risk factors

Logistic regression analysis identified age at gastric cancer diagnosis, differentiation, and early or advanced gastric cancer as independent risk factors of synchronous gastric cancer. The incidence of synchronous cancer in elderly patients (≥60 years) with differentiated early gastric cancer was 9.3% (43/418 patients), while that in other patients was 2.4% (68/2 830 patients). Moreover, the incidence of colon cancer in elderly patients (≥60 years) with differentiated early gastric cancer was 3.5% (15/418 patients, Table 3).

DISCUSSION

The main findings of this study are; 1) That synchronous cancer has an incidence of 3.4% (111/3 291 patients) in gastric cancer patients; 2) That the most common type of synchronous cancer in gastric cancer patients is colorectal cancer (42 patients, 37.2%), followed by lung cancer (21 patients, 18.6%); and 3) That age at diagnosis, a differentiated gastric cancer, and early gastric cancer are risk factors of synchronous cancer in gastric cancer patients. The incidence of synchronous cancer has been reported to vary from 0.7% to 3.5%[7-12]. Reasons for these wide ranges of incidence are attributed to different study populations and methods. The lowest incidence of synchronous cancers in gastric cancer patients reported was 0.7%, and this study was a population-based study, whereas, the other studies were institution-based, like the present study. The relatively high incidence of synchronous cancer in our study (3.4%), despite the inclusion of patients with EGC and AGC, may be due to time. Most studies were performed before 2000, whereas the patients included in this study were diagnosed as having gastric and synchronous cancer from 2001. Thus, radiologic diagnostic tools, such as, computed tomography (CT) and positron emission tomography (PET) were considerably developed and diagnostic accuracy improved over the intervening period[15,16]. Another possible explanation might be that this study was conducted as a retrospective analysis of a prospective database, and that our institution is a cancer center and as such diagnostic efforts are more focused on the detection of cancers.

In the present study, colorectal cancer was the most common cancer among gastric cancer patients with a synchronous cancer. On the contrary, gastric cancer was the most common form of cancer among colorectal cancer patients with a synchronous cancer. This association between colorectal cancer and gastric cancer may be incidental; however, there is some basis to support the existence of such a relation. It is well known that gastric cancer is the second most common extra-colonic malignancy associated with hereditary non-polyposis colorectal cancer (HNPCC) syndrome[17]. Moreover, a defect in the mismatch repair system has been suggested to play a role in the development of multiple cancers, but mechanistic basis for the development of synchronous cancers is unclear[18]. Preoperative endoscopy is a routine procedure in the Center for Colorectal Cancer in NCC for the patients with a colorectal cancer.

Most patients with synchronous colorectal cancers in this study were diagnosed within one month prior to receiving a diagnosis of gastric cancer, or were diagnosed while gastric cancer diagnosis. Patients with colorectal cancer frequently have symptoms of obstruction or bleeding, whereas the symptoms of gastric cancer patients are rare and vague[19,20]. In addition, esophagogastrodu odenoscopy (EGD) in colorectal cancer patients is one of our institutional policies. Thus, it is frequently the cases that the stages of gastric cancer and associated colorectal cancer are early and advanced, respectively. The incidences of most cancers are higher in men than in women and tend to increase with age, and patients with synchronous cancer in this study were more commonly elderly males. These findings are consistent with those of previous studies and might be associated with recent trends in gastric cancer epidemiology in Korea and characteristics of gastric cancer[1,2,4]. The high incidence of synchronous cancers found among early gastric cancer patients in the present study might be associated with the increasing incidence of early gastric cancer in Korea, and the fact that patient diagnosed as having colorectal cancer undergo routine gastroscopy. However, the reason for the higher incidence of differentiated

type in gastric cancer patients with synchronous cancer is unclear, and requires further investigation.

The incidence of synchronous cancer in those with multiple gastric cancers tended to be higher than for those with a single gastric cancer. Thus, genetic instability such as microsatellite instability might be involved in the development of synchronous cancer and multiple gastric cancers. However, the multiplicity of gastric cancer proved not to be a risk factor of synchronous cancer by multivariate analysis.

Regardless of the fact that they had potentially curable gastric cancer, 38 (35.4%) patients did not undergo an operation, and the presence of an advanced synchronous cancer was a principal reason. The major factor influencing treatment plans was cancer stage. Therefore, urgent efforts should be made to identify those at high-risk of having a synchronous cancer.

Multivariate analysis showed that age at gastric cancer diagnosis of, tumor differentiation, and preoperative stage are risk factors for the presence of synchronous cancer in gastric cancer patients. Elderly patients ($\geqslant$ 60 years) with differentiated type of early gastric cancer had a synchronous cancer incidence of 9.3% and a synchronous colon cancer incidence of 3.5%. This result suggests that elderly patients with differentiated type of early gastric cancer should be assessed for the presence of a synchronous cancer. Most synchronous cancers, such as, colorectal, lung, esophageal, and liver cancers can be discovered during routine preoperative staging work up using EGD and radiologic examinations, such as, chest X-ray or abdomino-pelvic CT. However, the early detection of colorectal cancer, which proved to be the most common synchronous cancer type, requires colonoscopy.

Despite the fact that this study was conducted based on an analysis of a prospective database, not all patient information was recorded, because almost one third of the patients were not treated at our institution. Therefore, the preoperative stage was not always the same as the pathological stage. However, considering that the accuracy of preoperative staging for EGC or AGC is $>80\%$, we believe that our results would have been comparatively unchanged had we adopted pathological stage[21].

Colonoscopy is not routinely performed at our center in gastric cancer patients scheduled to undergo an operation or endoscopic mucosal resection. Because the indications for endoscopic mucosal resection are a differentiated cancer of <2cm in diameter, those patients that undergo EMR present a group at high-risk of having a synchronous cancer[22]. Moreover, it is likely that the incidence of synchronous colon cancer may have been higher if we had performed routine colonoscopy in these patients. We now plan to perform a routine colonoscopic examination on those determined by this study to be at high-risk.

In conclusion, synchronous cancers in gastric cancer patients are not infrequent. Considering the trend that the peak age of gastric cancer patients and the incidence of early gastric cancer are increasing, the present study cautions that physicians should try to find synchronous cancers in gastric cancer patients at risk, such as, in elderly patients with differentiated early gastric cancer.

Abstract

AIM: To study an inherent effect of insulin on small intestinal transit and to explore involvement of various systems/mechanisms in normal mice.

METHODS: Insulin at the doses of 2 μU/kg, 2 mU/kg, 2 U/kg or vehicle was subcutaneously administered to four groups of overnight fasted normal male mice. Blood glucose (BG) levels were measured 2 min before insulin administration and 2 min before sacrificing the animals for the measurement of small intestinal transit (SIT). Charcoal meal was administered (0.3 mL) intragastrically 20 min after insulin administration and animals were sacrificed after 20 min and SIT was determined. For exploration of the various mechanisms involved in insulin-induced effect on SIT, the dose of insulin which can produce a significant acceleration of SIT without altering BG levels was determined. The following drugs, atropine (1 mg/kg), clonidine (0.1 mg/kg), ondansetron (1 mg/kg), naloxone (5 mg/kg), verapamil (8 mg/kg) and glibenclamide (10 mg/kg), were administered intravenously 10 min prior to the administration of insulin (2 μU/kg).

RESULTS: The lower doses of insulin (2 μU/kg and 2 mU/kg) produced a significant acceleration of SIT from 52.0% to 70.7% and 73.5% without lowering blood glucose levels ($P < 0.01$), while the highest dose of insulin (2 U/kg) produced a fall in blood glucose levels which was also associated with significant acceleration of SIT ($P < 0.01$). After pretreatment of insulin (2 μU/kg) group with atropine, insulin could reverse 50% of the inhibition produced by atropine. In clonidine-pretreated group, insulin administration could reverse only 37% of the inhibition produced by clonidine and inhibition of SIT was significant compared with vehicle + insulin-treated group, i.e. from 74.7% to 27.7% ($P < 0.01$). In ondansetron-pretreated group, insulin administration could produce only mild acceleration of SIT (23.5%). In naloxone-pretreated group, insulin administration could significantly reverse the inhibition of SIT produced by naloxone when compared with naloxone *per se* group, i.e. from 32.3% to 53.9% ($P < 0.01$). In verapamil-pretreated group, insulin administration could only partially reverse the inhibition (65%). In glibenclamide-pretreated group, insulin administration produced further acceleration of SIT (12.2%).

CONCLUSION: Insulin inherently possesses an acceleratory effect on SIT in normal mice. Adrenergic and cholinergic systems can play a significant role. Calcium channels and opioidergic system can play a supportive role; in addition, enhancement of endogenous insulin release can augment the effect of exogenously administered insulin on SIT.

INTRODUCTION

Insulin is the drug of choice in the management of elevated blood glucose level in type 1 and sometimes in type 2 diabetes mellitus[1]. In addition to its effect on glucose metabolism, insulin is reported to act as a neuromodulator in the central nervous system[2] and as a

mild analgesic[3]. Takeshita and Yamaguchi[4] characterized an inherent antinociceptive response for insulin when administered subcutaneously in mice. Their study has also shown that the antinociceptive response is independent of hypoglycemic action of insulin.

Gastrointestinal (GI) disorders are common in diabetic patients[5]. About 75% of these patients suffer from GI disorders due to GI neuropathy leading to considerable morbidity[6,7]. These GI disorders include nausea, gastric stasis, constipation, fecal incontinence and diarrhea[8,9]. Clinical studies are available that report insulin therapy increases the gastric emptying through hypoglycemic effect[10,11], but no detailed report is available in normal experimental animals on its effect on small intestinal transit and mechanism involved. In this study, we, therefore, investigated an inherent effect of insulin on small intestinal transit in normal mice and explored the involvement of possible mechanisms. The outcome of this experiment may provide valuable insights into the effect of insulin on normal intestinal transit.

MATERIALS AND METHODS

Animals

Adequate number of randomly bred normal/healthy adult Swiss albino male mice, weighing between 20-25 g, were obtained from Central Animal House, JIPMER, Pondicherry. One week before the study, the animals were housed at Departmental Animal House in polypropylene cages under standard laboratory conditions. Animals were fasted overnight prior to the experiment in cages with mesh bottom and had free access to water. Experiments were performed during the day time (09:00 to 18:00). The experimental protocol was approved by JIPMER Institutional Animal Ethics committee.

Drugs and chemicals

Atropine injection IP (S K Parenterals Pvt. Ltd., Tetali), clonidine HCl (C.H. Boehringer Sohn Ingelhein, Germany), glibenclamide (Hoechst India Ltd., Bombay), gum acacia IP (Hikasu Chemicals, Mumbai), insulin injection IP (purified bovine insulin, 40 U per milliliter; Knoll Pharmaceuticals Ltd., Aslai, India), naloxone HCl (Endo Labs, USA), ondansetron (Cipla Ltd., Mumbai), verapamil (Torrent Laboratories Pvt. Ltd., Ahmedabad), wood charcoal (SD Fine Chemicals, Boisar) were used in this study. All the drugs were dissolved in sodium chloride injection IP except glibenclamide which was dispersed in 50 g/L Tween 80 in water for injection before administration.

Administration of insulin

Mice were randomly divided into four groups, each group consisted of 6 mice. Each group was subcutaneously (sc) administered insulin 2 μU/kg, 2 mU/kg, 2 U/kg or vehicle. Blood glucose level was recorded before insulin administration. Charcoal meal was administered 20 min after insulin administration and SIT was determined after 40 min.

Measurement of small intestinal transit

The small intestinal transit (SIT) was determined by identifying leading front of intragastrically (ig) administered marker in small intestine of an animal[12,13]. Charcoal meal marker was freshly prepared by dispersing 10 g of wood charcoal in 50 g/L gum Acacia mucilage. After 20 min of insulin administration, each mouse received 0.3 mL of this suspension intragastrically using metallic oral cannula. After 20 min, animals were sacrificed by intravenous administration of sodium pentobarbital (100 mg/kg), abdomen opened, the leading front of marker was identified in the small intestine and tied immediately to avoid movement of marker. The entire length of small intestine was isolated by cutting at pyloric and ileocaecal ends. The distance travelled by the charcoal meal and the total length of the intestine were measured in cm. The SIT was expressed as percentage (%) of the distance travelled by the charcoal meal to length of the intestine. This was carried out in the animals 40 min after insulin administration.

Measurement of blood glucose

Blood glucose (BG)[14] was measured by placing a drop of blood obtained by tail venipuncture, over an appropriate glucostix, read by Advantage Glucometer (Boerhinger Mannheim Corporation, Indianapolis, USA) and expressed as %, change in the glucose level considering the initial value of that animal as 100. This estimation was done 2 min before insulin/vehicle administration and 2 min before sacrificing the animal for measuring small intestinal transit.

Mechanisms of insulin-induced acceleration of small intestinal transit

Insulin at 2 μU/kg dose significantly accelerated (35.7%) small intestinal transit without affecting the blood glucose level; hence this dose was selected to evaluate the mechanism of insulin-induced intestinal hypermotility (Table 1). For exploring the various systems/mechanisms involved in insulin-induced effect on SIT, the antagonists or agonists (agents) of the following systems were attempted (Figure 1).

Cholinergic system

Involvement of cholinergic system was evaluated by using a well studied non-specific cholinergic antagonist atropine. The dose selection was based on a study reported by Chaudhuri *et al*[15]. Atropine (1 mg/kg) was injected intravenously (iv) 10 min before insulin administration (2 μU/kg sc) to one group of animals. After 40 min of insulin administration, the animals were sacrificed to measure SIT. Another group was treated similarly but with vehicle + insulin (Figure 1).

Adrenergic system

Involvement of adrenergic system was evaluated by using clonidine (0.1 mg/kg iv). The dose selection was based on studies reported by Donoso *et al*[16] and DiTullio

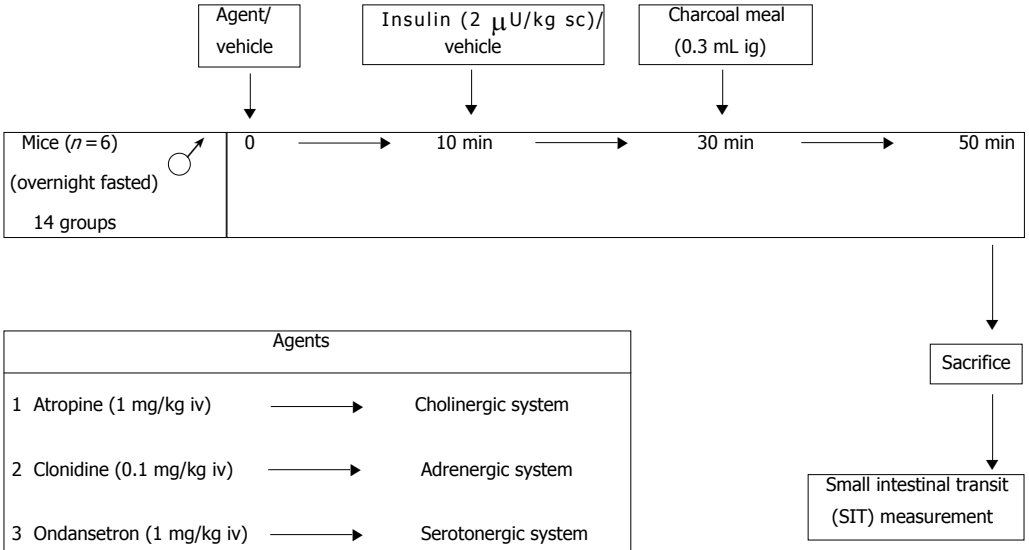

Figure 1 Experimental design carried out to explore various systems/mechanisms involved in insulin-induced acceleration of small intestinal transit in normal mice.

Table 1 Effect of insulin administration on small intestinal transit and blood glucose levels in normal mice

Treatment Insulin (U/kg sc)	% SIT[1]	Blood glucose (%)[2]
Vehicle	52.06 ± 1.48	103.73 ± 4.19
2 μ	70.77 ± 0.62[a]	99.47 ± 1.59
2 m	73.53 ± 0.63[a]	94.54 ± 4.62
2	80.10 ± 1.93[a]	42.09 ± 1.78[a]

Each value represents the mean ± SE (n = 6) sc: subcutaneous; SIT: small intestinal transit; [a]P < 0.01 *vs* vehicle treated group; [1]Values are % SIT considering the total length of the intestine as 100, SIT was determined 40 min after insulin administration; [2]Blood glucose was estimated 2 min before insulin/vehicle administration and 2 min before sacrificing the animals for the measurement of small intestinal transit (SIT), final blood glucose expressed as % considering the initial blood glucose of each animal as 100.

et al[17]. Clonidine (0.1 mg/kg iv) was injected 10 min before insulin administration (2 μU/kg sc) to one group of animals. After 40 min of insulin administration, the animals were sacrificed to measure SIT (Figure 1).

Serotonergic system

Involvement of serotonergic system was evaluated by using ondansetron (1 mg/kg iv). The dose selection was based on a study reported by Nagakura *et al*[18]. Ondansetron (1 mg/kg iv) was injected 10 min before insulin administration (2 μU/kg sc) to one group of animals. After 40 min of insulin administration, the animals were sacrificed to measure SIT (Figure 1).

Opioidergic system

Involvement of opioidergic system was evaluated by using naloxone (5 mg/kg iv). The dose selection was based on studies reported by Stein *et al*[19] and Peana *et al*[20]. Naloxone (5 mg/kg iv) was injected 10 min before insulin administration (2 μU/kg sc). After 40 min of insulin injection, the animals were sacrificed to measure SIT (Figure 1).

Calcium channels

Involvement of calcium channels was evaluated by using verapamil (8 mg/kg iv). The dose selection was based on studies reported by Ramaswamy *et al*[21] and Amos *et al*[22]. Verapamil (8 mg/kg iv) was injected 10 min before insulin administration (2 μU/kg sc). After 40 min of insulin administration, the animals were sacrificed to measure SIT (Figure 1).

Insulin secretogogue

Influence of elevated endogenous insulin levels on SIT was evaluated by using glibenclamide (10 mg/kg iv). The dose selection was based on studies reported by Ramaswamy *et al*[23] and Ojewole *et al*[24]. Glibenclamide (10 mg/kg iv) was injected 10 min before insulin administration (2 μU/kg sc) to one group of animals. After 40 min of insulin administration, the animals were sacrificed to measure SIT (Figure 1).

Statistical analysis

Results are expressed as mean ± SE and analyzed statistically using ANOVA, followed by Dunnett's multiple comparisons test. A P < 0.05 was considered statistically significant.

RESULTS

Effect of insulin on small intestinal transit

Insulin administration at lower doses (2 μU/kg and 2 mU/kg) produced a significant acceleration of SIT without altering the blood glucose levels (P < 0.01 Table 1), while the higher dose of insulin (2 U/kg) produced a profound fall in blood glucose levels (P < 0.01) which was associated with an acceleration of SIT.

Cholinergic system

Atropine (1 mg/kg) *per se* produced an attenuation of SIT by 47.0% when compared with vehicle treated group. In

atropine-pretreated group, insulin administration (2 μU/kg) could not completely reverse the inhibition produced by atropine. Insulin could overcome only 50% of the inhibition produced by atropine (Table 2 and Figure 2).

Adrenergic system

Clonidine (0.1 mg/kg) *per se* produced an inhibition of SIT by 72.0%. Conversely, in clonidine-pretreated group, insulin administration (2 μU /kg) could partially reverse (37%) the inhibition produced by clonidine but the inhibition of SIT was still significant (P <0.01) when compared with vehicle + insulin-pretreated group (Table 2 and Figure 2).

Serotonergic system

Ondansetron (1 mg/kg) *per se* could not alter the SIT when compared with vehicle-treated group. Conversely, in ondansetron-pretreated group, insulin administration (2 μU/kg) could produce only mild acceleration of SIT (23.5%) (Table 2 and Figure 2).

Opioidergic system

Naloxone (5 mg/kg) *per se* produced a significant inhibition of SIT by 41.2% when compared with vehicle-treated group. In naloxone-pretreated group, insulin administration (2 μU/kg) could significantly reverse the inhibition produced by naloxone (P < 0.01) when compared with naloxone *per se* group (66.4%). However, the reversal of inhibition was still significantly lower than insulin *per se* group (P <0.01) (Table 2 and Figure 2).

Calcium channels

Verapamil (8 mg/kg) *per se* produced a significant deceleration of SIT by 26.0% when compared with vehicle-treated group. In verapamil-pretreated group, insulin administration (2 μU/kg) could only partially reverse the deceleration produced by verapamil (65%) (Table 2 and Figure 2).

Insulin secretogogue

Glibenclamide (10 mg/kg) *per se* produced a significant acceleration of SIT by 43.8% when compared with vehicle-treated group. In glibenclamide-pretreated group, insulin administration (2 μU/kg) produced a further acceleration of SIT by 12.2% (Table 2 and Figure 2).

DISCUSSION

Recent experiments in streptozotocin (STZ)-induced diabetes in rats have demonstrated deleterious effects on the neuromuscular junction as well as on muscle itself. Actions at both sites may contribute to neuropathy and functional alterations in muscle contractile properties[25,26]. Abnormalities in gastric emptying and small intestinal motor function were also reported in STZ-treated rats[27,28]. This may be ascribed to the ability of STZ, which not only destroys β-cells of pancreas leading to diabetic state, but also affect the nervous system function which maintains the tone and motility of GI smooth muscles. Hence, STZ-induced experimental diabetic model became untenable to explore the effect of any agent on SIT, instead normal or healthy animals are appropriate for exploring inherent effect of any substance on SIT. Therefore, the data obtained can reflect the true changes and are devoid of the influence of degenerative changes induced by STZ in laboratory animals.

Our study with insulin administration demonstrated an interesting finding that after 40 min of its administration in normal mice, lower doses of insulin (2 μU/kg and 2 mU/kg) significantly accelerated the small intestinal transit (P< 0.01) without lowering blood glucose levels. On the other hand, the highest dose of insulin (2 U/kg) produced a significant fall in blood glucose levels which was also associated with an acceleration of SIT (P<0.01). The available literature indicated that insulin-induced hypoglycemia accelerates gastric emptying of solids and liquids in long-standing type 1 diabetes[29] or stimulates gastric vagal activity causing an increase in gastric emptying in healthy volunteers[30]. These effects on gastric emptying were dependent on blood glucose levels[29,30]. Moreover, these findings were observed with normal or higher doses of insulin. In our experiment, the blood glucose levels were not affected by the lower doses of insulin (2 μU/kg or 2 mU/kg) but produced a significant acceleration of SIT. The sub-hypoglycemic doses of insulin were used to avoid the hypoglycemic effect on intestinal motility. We suggest that the blood glucose levels may not play a significant role in accelerating SIT at least in the lower doses of insulin, indicating an inherent acceleratory effect of insulin on SIT. Our findings are partly in agreement with Takeshita and Yamaguchi[4] who reported antinociceptive effect of insulin was independent of blood glucose level in normal mice. It seems that insulin therapy may bring about an additional benefit in diabetic patients by normalizing the derangement of the gastrointestinal motility.

The gastrointestinal tract is in a continuous state of contraction, relaxation and secretion. These functions are controlled by neurohumoral systems, which in turn are regulated by various receptor systems, such as cholinergic, adrenergic, serotonergic, opioidergic and cell surface channels[31]. Many drugs affect GI transit by acting as agonists or antagonists at specific cellular receptors[32,33]. Acceleration of GI motility can be achieved by direct stimulation of gastrointestinal muscle, by activation of excitatory neural pathways or by inhibition of inhibitory pathways. Deceleration can be produced by direct relaxant effect on smooth muscle, by inhibiting the excitatory neural pathways or by activation of inhibitory pathways. Insulin's inherent acceleration of SIT can be evaluated by exploring the following systems.

Cholinergic system

Atropine is frequently used as a tool for identifying mechanisms involving cholinergic pathways[34]. It is a non-specific competitive antagonist of acetylcholine for muscarinic receptors and abolishes the effects of acetylcholine completely on the GI tract. Both in normal subjects and in patients with GI diseases, full therapeutic doses of atropine (0.5-1 mg) produce definite and prolonged inhibitory effect on the motor activity of the

Table 2 Influence of various systems / mechanisms on insulin-induced acceleration of small intestinal transit in normal mice

[4]compared with vehicle + insulin group.

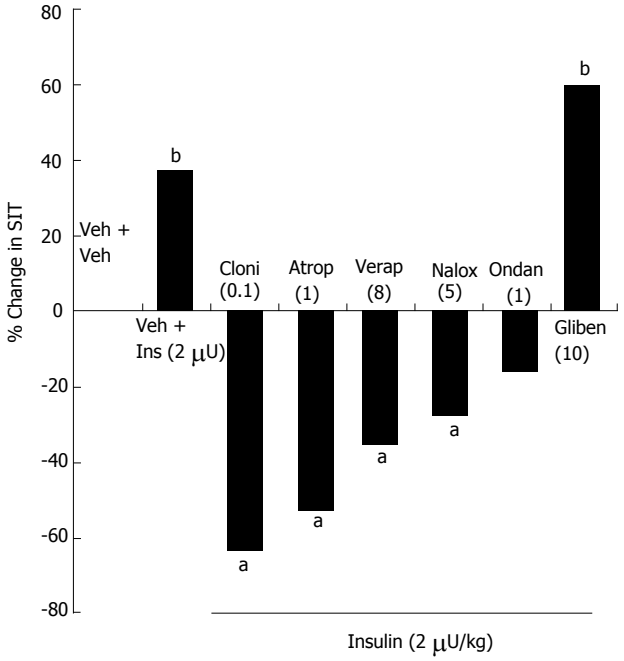

Figure 2 Involvement of various mechanisms in insulin-induced acceleration of SIT in normal mice. Each value represents % acceleration of SIT. [b]P < 0.01 *vs* vehicle + vehicle-treated group [insulin (2 μU/kg); glibenclamide (10 mg/kg)] or % inhibition of SIT. [b]P < 0.01 *vs* vehicle + insulin-treated group (2 μU/kg) (data was derived from Table 2). Cloni (0.1): clonidine (0.1 mg/kg); Atrop (1): atropine (1 mg/kg); Verap (8): verapamil (8 mg/kg); Nalox (5): naloxone (5 mg/kg); Ondan (1): ondansetron (1 mg/kg).

stomach, duodenum, jejunum and ileum[35]. Our study also confirmed inhibitory effect of atropine on SIT in normal mice. When atropine-injected group (1 mg/kg) was treated with insulin (2 μU/kg), insulin failed significantly to reverse the inhibition of SIT induced by atropine when compared with insulin *per se* treated group (Table 2). This finding indicates that insulin acts directly through muscarinic receptors to accelerate the SIT. Since atropine at the given dose could produce 50% inhibition of the insulin effect on SIT, this indicates a possibility that insulin could partly produce acceleratory effect by some other pathways in addition to cholinergic pathways as atropine could not completely prevent the acceleratory effect of insulin (Figure 2).

Adrenergic system

Clonidine has presynaptic α_2 receptor agonistic activity. Stimulation of α_2 receptors which are present on excitatory cholinergic intramural neurons in the intestine[36,37] attenuates the release of acetylcholine presynaptically, thereby producing depression of intestinal motility. In our study, we observed a significant attenuation of SIT in clonidine (0.1 mg/kg) *per se* treated group when compared with vehicle-treated group (P < 0.01), thus confirming the inhibitory effect of clonidine on SIT in mice.

When clonidine-injected group (0.1 mg/kg) was treated with insulin (2 μU/kg), the SIT was inhibited by 63% as compared with vehicle + insulin-treated group (Figure 2), thereby indicating that even though insulin could partially reverse the SIT (37%), the inhibitory effect of clonidine was still significant when compared with insulin *per se* treated group (P < 0.01) (Table 2). This finding indicates α-adrenergic pathways may be dominant in producing acceleratory effect of insulin on SIT. Insulin might have interfered with presynaptic α_2 receptors and facilitated the release of acetylcholine from excitatory neurons in the intestine. Since clonidine could not completely inhibit the SIT, we suggest that in addition to α-adrenergic pathways, insulin action may be associated with any other pathways but playing a minor role.

Serotonergic system

5-Hydroxy tryptamine (5-HT) receptors are broadly classified into five subtypes: 5-HT_1, 5-HT_2, 5-HT_3, 5-HT_4 and 5-HT_7[38]. Of these principal receptors, 5-HT_3 receptor has been suggested to play a role in the regulation of gastrointestinal motor function in many animal species and humans[39]. In the mouse ileum, 5-HT_3 receptors modulate neuronal activity within the enteric nerves leading to the contraction of the smooth muscle. The selective antagonists of 5-HT_3 receptors block the depolarizing actions of 5-HT on vagal afferents in gastrointestinal tract and have been proved to be a major breakthrough in the control of chemotherapy and radiotherapy-induced emesis[40,41]. In our study, a selective 5-HT_3 receptor antagonist, ondansetron (1 mg/kg), *per se* could not alter the normal SIT. Indeed, we selected the dose of ondansetron (1 mg/kg) which had significantly increased whole gut transit time in mice[18]. On the other hand, in ondansetron-pretreated group, insulin administration (2 μU/kg) slightly accelerated SIT (23.5%) (Table 2). This finding indicates that at this dose, ondansetron might rather partially inhibit the insulin-induced acceleration on SIT (14.6%) (Figure 2). Ondansetron (1 mg/kg) might have a prominent effect on the large intestine of mice. Hence, we propose that dose-

dependent studies are required to show the involvement of serotonergic systems with ondansetron in small intestinal motility and to evaluate insulin's acceleratory effect on SIT in this animal model.

Opioidergic system

Opioid neurons constitute the largest population of peptide-containing neurons in the myenteric plexus of the gut[42]. Opioid receptors are present on enteric nerves, epithelial cells and muscle cells[43,44]. It is known that opioid agonists slow intestinal transit particularly at the proximal portion and also reduce luminal secretions[45]. The administration of naloxone will antagonize or reverse the actions of opioids and of similar agents[44]. Therefore, the use of naloxone is expected to produce normal SIT, followed by administration of any opioids. In contrast, we observed that naloxone (5 mg/kg) *per se* produced significant attenuation of SIT ($P < 0.01$) in this animal species. This finding indicates that naloxone acts similar to opioids (Table 2).

In support of this finding, we came across similar contrasting reports but on gastric emptying. Champion *et al*[46] reported that naloxone (2 mg) delayed gastric emptying of radio-opaque material in healthy volunteers. They suggested that naloxone inhibited endogenous opiate system which normally stimulates gastric emptying and they had used the dose of naloxone two to three times greater than those usually given to reverse narcotic-induced respiratory depression and in large doses, naloxone itself may inhibit gastric emptying. Similarly, Asai and Power[47] also reported naloxone (0.01-10 mg/kg) *per se* significantly inhibited gastric emptying in rats. These studies revealed effect of naloxone on gastric emptying, but our study reveals a similar finding in the small intestine. Our study with naloxone *per se* may also suggest that naloxone may inhibit a subset of endogenous opiate system which normally stimulates movement of the contents of the intestine in this animal species. We used higher dose of naloxone to block all the receptors, thereby masking the effects of endogenous opioids, and to explore whether any subset of opioid receptors were involved in insulin-induced acceleration of SIT.

When naloxone-injected group (5 mg/kg) was treated with insulin, the SIT was significantly reversed as compared with naloxone *per se* treated group ($P < 0.01$) (Table 2). However, the naloxone-induced inhibition of SIT (28%) in insulin-treated group was still significant when compared with insulin *per se* treated group (Figure 2). This finding suggests that insulin may act through a subset of opioid receptors in the intestine to accelerate the SIT and that might be inhibited by naloxone treatment.

Calcium channels

Calcium is involved in the initiation of contraction of smooth muscle[48]. The visceral smooth muscle has a poorly developed sarcoplasmic reticulum and the increase in intracellular calcium concentration is primarily due to Ca^{2+} influx from the extracellular fluid via voltage-gated Ca^{2+} channels[49]. The L-type calcium channel is present in many cells and it is the main source of Ca^{2+} for contraction of smooth muscle[50]. This channel is blocked by dihydropyridines such as nifedipine, and other drugs such as verapamil and diltiazem[50]. Verapamil, a phenylalkylamine derivative, blocks the calcium channels on the surface of smooth muscle cells and relaxes the smooth muscle, thereby attenuating the intestinal motility[45,51]. The objective of this experiment was to evaluate the involvement of Ca^{2+} in insulin-induced acceleration of SIT. Verapamil at the given dose (8 mg/kg) *per se* significantly inhibited SIT, indicating the involvement of Ca^{2+} channels in normal physiology of small intestinal motility (Table 2). In verapamil-pretreated group, insulin administration could reverse the inhibition produced by verapamil by 65%. This finding may indicate that as insulin could not completely reverse inhibition of calcium channels, some other systems are also involved in acceleratory effect of insulin action on SIT.

Insulin secretogogue

Glibenclamide, an oral hypoglycemic drug, acts by stimulating insulin release from β-cells of pancreas[1]. The objective of this experiment was to find whether endogenously released insulin can potentiate the action of exogenously administered insulin effect on SIT. Glibenclamide (10 mg/kg) *per se* produced a significant acceleration of SIT by 43.8% (Table 2). This finding may indicate that endogenous release of insulin by glibenclamide increases the SIT.

When insulin-injected group was pretreated with glibenclamide, the SIT was further accelerated by 12% (Figure 2). This observation indicated that insulin from endogenous sources might have contributed to the additional acceleration of SIT by exogenously administered insulin.

Figure 2 indicates the significant involvement of following systems in decreasing order of acceleratory effect of insulin on SIT: adrenergic system > cholinergic system > calcium channels > opioidergic system ($P < 0.01$). In addition, release of endogenous insulin augments the effect of exogenously administered insulin on SIT.

In conclusion, the sub-hypoglycemic doses (2 μU/kg or 2 mU/kg) of insulin accelerate the small intestinal transit in normal mice without markedly changing blood glucose levels. It can be assumed that therapy of type 1 diabetes with insulin can simultaneously relieve at least one of the diabetic GI complications, such as constipation or sometimes may aggravate the diabetic neuropathy-associated diarrhoea. Furthermore, we explored influence of various systems, channels and endogenous insulin in acceleratory effect of exogenously administered insulin. Based on these observations, we report that adrenergic and cholinergic pathways play a significant role in hypermotility of small intestine induced by insulin administration in mice. Calcium channels and opioidergic pathways play supportive role; in addition, enhancement of endogenous insulin release can augment the effect of exogenously administered insulin on SIT.

Abstract

AIM: To determine whether the number of non-rejoining G2-chromatid breaks can predict the radiosensitivity of human cell lines.

METHODS: Cell lines of human ovary carcinoma cells (HO8910), human hepatoma cells (HepG2) and liver cells (L02) were irradiated with a range of doses and assessed both of cell survival and non-rejoining G2-chromatid breaks at 24 h after irradiation. Cell survival was documented by a colony assay. Non-rejoining G2-chromatid breaks were measured by counting the number of non-rejoining G2 chromatid breaks at 24 h after irradiation, detected by the prematurely chromosome condensed (PCC) technique.

RESULTS: A linear-quadratic survival curve was observed in three cell lines, and HepG2 was the most sensitive to γ-radiation. A dose-dependent linear increase was observed in radiation-induced non-rejoining G2-PCC breaks measured at 24 h after irradiation in all cell lines, and HepG2 was the most susceptible to induction of non-rejoining G2-PCC breaks. A close correlation was found between the clonogenic radiosensitivity and the radiation-induced non-rejoining G2-PCC breaks ($r = 0.923$). Furthermore, survival-aberration correlations for two or more than two doses lever were also significant.

CONCLUSION: The number of non-rejoining G2 PCC breaks holds considerable promise for predicting the radiosensitivity of normal and tumor cells when two or more than two doses lever is tested.

INTRODUCTION

An important goal of current research in radiation oncology is the development of an assay or a combination of assays to predict the radiation response of individual human tumors and normal tissues. Accurate prediction of response to conventional therapy could lead to treatment modification when necessary. The important radiobiological factor that has a significant effect on a tumor's response to radiotherapy is intrinsic radiosensitivity, which, determined with a colony assay, is significantly associated with treatment outcome after radiotherapy[1,2]. However, it is unlikely to use colony formation as a routine predictive assay, as it takes several weeks to complete. This is usually too long for patients to wait for appropriate treatment. Other assays should therefore be developed which can be used routinely in a clinical setting. Such assays should give a direct or indirect measure of cell killing, and chromosomal radiosensitivity is one of the potential endpoints for assessing cellular intrinsic radiosensitivity.

Researchers have studied the metaphase chromosome aberrations using conventional techniques, and found a close relationship between radiation-induced chromosome aberrations and cell kill[3,4]. However, it is difficult to obtain enough metaphase for cytogenetic analysis because of the cell cycle delay or interphase cell death after irradiation. These problems might be solved by studying the interphase cell aberration directly. Thus, PCC technique using phosphatase inhibitors is optimal. Because the method involves non complex procedures and generates results in the non-cycling state, it is an advantage for measuring chromatin damage by qualitatively different types of radiation because one can observe chromatin

damage in the situation in which the effects on an LET-dependent cell-cycle delay and interphase cell death are removed, and PCC technique is very useful for measuring the radiation-induced chromatid breaks in all of the cell cycles, especially in G2 phase[5-8].

It has been shown a linear dose response in the same dose range used for cell-survival experiments in different *in vitro* cell systems using PCC assay to measure chromosomal damage[9-12]; and the repair kinetics of radiation-induced chromatid breaks has been studied[9,13,14]. Furthermore it was demonstrated that there is a good correlation between the induction of non-rejoining PCC breaks in interphase cells and cellular radiosensitivity[15-17]. However, it is well established that the radio-sensitivity is dependent of cell cycle progression, and among each stage of interphase, G2 phase is the most radiosensitive, G1 phase the second radiosensitive, and S phase the least radiosensitive; while G0 phase is radio-resistant for lack of oxygen and enough repairing time[18-20]. Previous studies led to the conclusion that G2 phase is a very important stage. However, there were only a few reports on the chromosome aberrations in G2 phase and little is known of the relationship between G2 chromosomal aberration and cellular clonogenic radiosensitivity.

The purpose of this study was to explore the chromosome aberrations in G2 phase. The non-rejoining G2-PCC breaks after 24 h of post-irradiation incubation by γ-rays of two human tumor cell lines were measured using PCC technique. In order to evaluate the potential of the PCC assay as a predictor of cellular radiosensitivity, the correlation between radiation-induced non-rejoining G2-PCC breaks and the cellular clonogenic radiosensitivity was studied. Furthermore, the results were analyzed together with the author's previous results of human normal liver cells L02[21].

MATERIALS AND METHODS

Cell culture and irradiation

Human ovary carcinoma cells (HO8910) and human hepatoma cells (HepG2) were grown in RPMI-1640 medium supplemented with 100 mL/L foetal calf serum, 100 kU/L penicillin and 100 g/L streptomycin at 37 ℃ in a 50 mL/L CO_2 atmosphere with 950 mL/L humidification.

Irradiation was generated from ^{60}Co source (Radiology Department, Affiliated No.1 Hospital, Lanzhou University, Lanzhou). HO8910 cells and HepG2 cells were irradiated at doses of 0, 0.5, 1.0, 2.0, 4.0, 6.0 or 8 Gy, with a dose rate of 0.2 Gy/min.

Survival assay and PCC induction

After irradiation, cells were plated at a density of about 100 surviving cells per 6 cm culture dish and incubated for about 14 d, and then fixed and stained with a solution of Giemsa.

Calyculin A, a specific inhibitor of protein phosphatase types 1 and 2A, which can induce PCC in various types of cells with high efficiency[5,22], was purchased from Wako Chemicals (Osaka, Japan), dissolved in 100% ethanol as a 1 mmol/L stock solution and stored at -20 ℃. After irradiation, cells were incubated at 37 ℃ in a 50 mL/L CO_2 atmosphere. Twenty-four hours later calyculin A was added (to give a final concentration of 50 nmol/L) to the cell cultures and cells were further incubated for 30 min. Chromosome spreads were then harvested by cell swelling in 75 mmol/L KCl for 20 min at 37 ℃ and fixed with Carnoy's fixation. A final wash and fixation in the same fixative was completed before dropping cells onto a glass slide and hot humidity drying.

Table 1 Parameters of cell survival and non-rejoining G2-chromatid breaks of the three cell lines after exposure to γ-rays irradiation

Cell line	$\alpha(Gy^{-1})^1$	$\beta(Gy^{-2})^1$	$SF2^2$ (mean ± SE)	$Slope^3$ (mean ± SE)
HepG2	0.2	0.075	0.455±0.06	2.17±0.225 (r=0.974)
HO8910	0.08	0.065	0.652±0.07	1.83±0.013 (r=0.987)
L02	0.04	0.05	0.863±0.09	1.134±0.06 (r=0.992)

[1]α and β values were determined from the linear quadratic equation.
[2]Survival fraction at 2 Gy was measured from the raw data.
[3]Slope from the fitted linear regression represents non-rejoining G2-chromatid breaks per cell per unit dose.

Observation and data evaluation

Colonies of more than 50 cells were counted as survivors. The number of colonies per dish was counted and the surviving fractions were calculated as the ratio of plating efficiencies for irradiated and non-irradiated cells. Plating efficiency was defined as the colony number divided by the number of cells plated. The survival data were fitted to the linear-quadratic model: $LnS = -\alpha D - \beta D^2$, where S is the survival fraction and D is the radiation dose.

Chromosome was stained with 50 g/L Giemsa for 20 min. Fifty well-spread G2 phase cells were scored under oil immersion with a light microscope for each dose point according to the standard criteria[23]. Briefly, chromatid discontinuing, misalignment of the distal to the lesion, or a non-stained region longer than the chromatid width were classified as a break. Iso-chromatid breaks were scored two breaks. The total chromatid breaks were calculated by summing the production of chromatid-type breaks and iso-chromatid breaks. The mean aberration values for the three separate experiments were obtained. These mean values and the standard error of the means were plotted and fitted by linear regression, and the slopes of the dose-response curves were calculated.

RESULTS

Cell survival

Cell survival parameter from the linear quadratic model fitted to the survival data is shown in Table 1. SF2 was measured from the raw data also shown in Table 1. For radiosensitivity, three cell lines displayed the different potency, in the order of, HepG2 > HO8910 > L02.

Non-rejoining G2-chromatid breaks

All cell lines showed a dose-related increase in the induction of non-rejoining G2-chromatid breaks (Figure 1). The dose-response curves were fitted by linear regression and the slopes of the dose-response curves were evaluated.

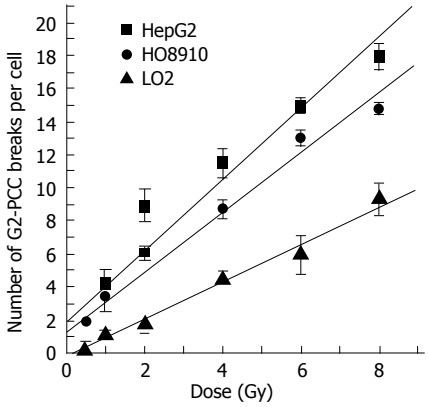

Figure 1 Dose-response curves for the induction of non-rejoining G2-PCC breaks 24 h after irradiation.

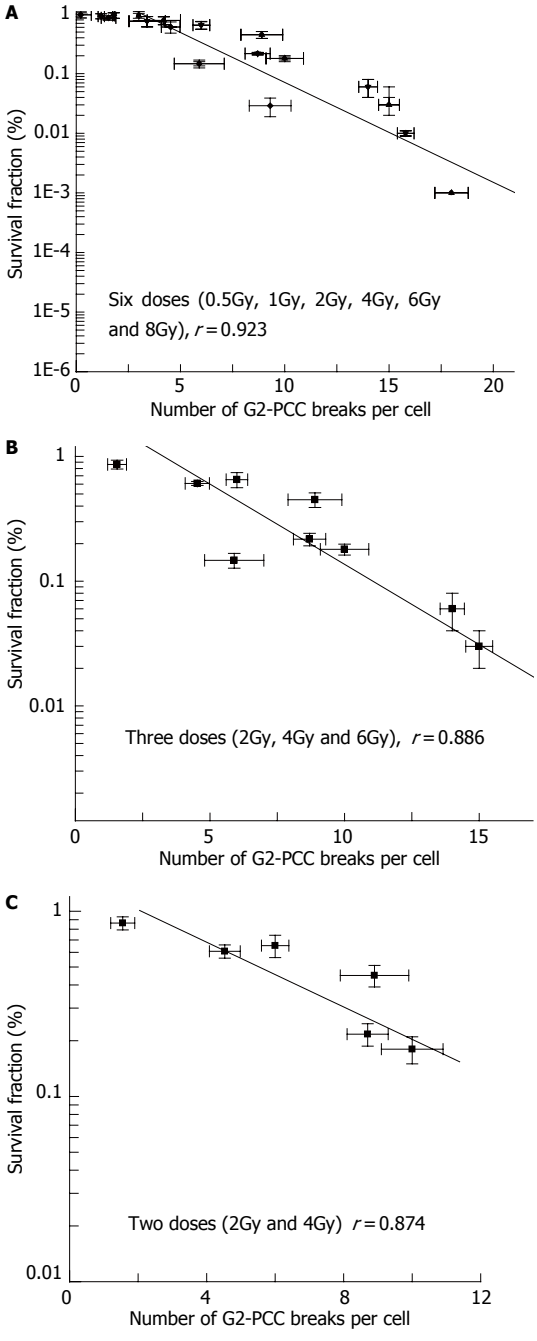

Figure 2 The relationship between survival fraction and non-rejoining G2-PCC breaks 24 h after irradiation.

Table 2 Correlation between non-rejoining G2 chromatid breaks and cell survival

	Dose (Gy)	*r*	*P*
Multiple	2+4	0.874	0.023
	2+4+6	0.886	<0.01
	0.5+1+2+4+6+8	0.923	<0.001

The slope of HepG2 was the steepest, and that of HO8910 the second and L02 the least. Namely, the order of the slopes was HepG2 > HO8910 > L02. The values for the slopes of the curves are given in Table 1.

Correlation between cell survival fraction and non-rejoining G2 chromatid breaks

To examine the correlation between clonogenic radiosensitivity and the non-rejoining G2-chromatid breaks, the non-rejoining G2 chromatid breaks were plotted against the surviving fractions (Figure 2A). Correlation coefficient was 0.923 for three cell lines. The relationships for non-rejoining G2 chromatid breaks at different multiple doses (Figure 2) were investigated. Correlation coefficients are shown in Table 2. It is clear that increasing combining doses improves the correlation coefficients. This is true for any combination of two doses or more than two doses (data not shown).

DISCUSSION

Consistent with previous studies[21], fitted cell survival curve of three cell lines were linear quadratic in the present study. Among the three cell lines, survival fraction of L02 cells was the highest after absorbing same dose of radiation. These suggested that human normal liver cells were of much lower sensitivity to γ-rays than both human ovary carcinoma cells and human hepatoma cells. These may be because reductive glycogens synthesized in normal liver cells which interact with free radicals reduce the radiation injury[21]. In addition, the theoretic basis of radiotherapy is that the normal cells are of low radiosensitivity, and our results further confirmed this.

It has been shown that the rejoining of radiation-induced DNA double strand breaks (dsbs) was saturated within 2-4 h in mammalian cell lines[24,25] and that the number of residual dsbs did not change between 4 and 20 h using the neutral filter elution[26]. So it is considered that the most important parameter related to clonogenic radiosensitivity is the residual dsbs for 4 h or more after irradiation[27]. The PCC technique measures the chromatid breaks caused by the dsbs[28,29], and the processes of chromosomal breaks rejoining contain a fast component and a slow component[5]. The G2-PCC breaks were rejoined with a half-time of 5 min for the fast component and about 3 h for the slow component after irradiation[5], implying that the rejoining of chromosome breaks occurred mainly during the early hours after irradiation. Furthermore, Borgmann[29] reported that the number of PCC fragments induced by radiation plateaued at 4-6 h after irradiation, and did not change for about 10 h. In

addition, Suzuki[13] reported that the repairing process of radiation-induced chromosome aberration occurred during the early 10 h after irradiation. Based on previous studies, most kinds of cells end their spontaneous repair process within 24 h if they are injured, and after 24 h, injured and normal cells without any artificial factors will be stable and continue synthesizing, mitosis processes. Therefore, it is reasonable that the non-rejoined excess fragments examined after incubation for 24 h after irradiation may be the most important parameter related to clonogenic radiosensitivity. Based on these, the non-rejoining G2-PCC breaks were examined after incubation for 24 h post-irradiation in this study, and a good linear relationship was found between dose and the non-rejoining G2 chromatid breaks after the cells were exposed to ^{60}Co γ-rays (Figure 1). In addition, we found that cells which were more sensitive to the cell killing were similarly more susceptible to induction of non-rejoining G2 chromatin breaks (Table 1 and Figure 1). Suzuki[15-17] and Borgmann[29] found similar results. Additionally, a good linear relationship was also found between dose and the initial chromatid breaks[7,21,30]. It is easy to study the radiation-induced chromatid damage with the PCC technique[11,31,32], and the data obtained thereby may accurately reflect the radiation damage for the chromatin level without the competition as a result of cell cycle and/or interphase cell death. Therefore the PCC technique is very useful for detecting chromatin damages by qualitatively different types of radiation. Furthermore, it is faster in obtaining the result by the PCC technique than by most of other techniques.

In the present study we have attempted to validate the use of radiation-induced non-rejoining G2 chromatid breaks as a measure of cellular radiosensitivity. One of the prerequisites for the potential use of such a rapid assay would be that the relationship with clonogenic survival, the Gold Standard and most relevant assay for tumor control, should be high. In this research, a good correlation (r=0.923) was found between cell survival and the number of non-rejoining G2-chromatid breaks in the three cell lines (Figure 2A). It implies that radiosensitivity can be determined by the induction of non-rejoining G2-PCC breaks.

To our knowledge, few researches have looked at the relationship between non-rejoining G2 chromatid breaks and cell killing, and only a few studies have investigated the relationship between the induction of non-rejoining chromatid breaks in interphase detected by PCC technique and cell killing. Ofuchi[17] showed a strong correlation between non-rejoining chromatid breaks and cell survival in human hepatoma cells. Suzuki[11] showed a good correlation between induction of non-rejoining PCC breaks and cell death in normal human cells, in human tumor cell lines[12], and in 6 primary cultured cells[15]. All these suggest one possibility that radiosensitivity can be determined by the induction of non-rejoining PCC breaks.

Dependent on the amount of primary tumor material (biopsy), it might not be feasible to obtain a complete dose-response curve consisting, for example, of four or more different doses. It is therefore more likely that only one or two doses could be studied with any statistical significance. Because of the limited number of cell lines in this study, it was not reliable to analyze the correlation between cell survival and the induction of non-rejoining G2-chromatid breaks for individual doses. For multiple doses, highly significant and good correlation were observed if two or more doses were used (Figure 2 and Table 2). Coco Martin[3] found similar correlation coefficients as reported here for 13 human tumor cell lines at two or more radiation doses using metaphase cytogenetic techniques. It indicates that two doses can be applied on fresh tumor tissue to obtain a relative high correlation. As for the individual doses, it is necessary to expand the number of cell lines to confirm the correlation between cell survival and the induction of non-rejoining G2-chromatid breaks.

In conclusion, it is suggested that the PCC technique is useful for determining chromosome aberration in G2 cells, and the amount of non-rejoining G2-PCC breaks induced by radiation can evaluate the cellular clonogenic radiosensitivity. To assess the general applicability of this approach, further studies are needed to expand the number of human cell lines.

Abstract

AIM: To summarize the performing essentials and analyze the characteristics of remote Zeus robot-assisted laparoscopic cholecystectomy.

METHODS: Robot-assisted laparoscopic cholecystectomy was performed in 40 patients between May 2004 and July 2005. The operating procedures and a variety of clinical parameters were recorded and analyzed.

RESULTS: Forty laparoscopic cholecystectomy procedures were successfully completed with Zeus robotic system. And there were no post-operative complications. Total operating time, system setup time and performing time were 100.3 ± 18.5 min, 27.7 ± 8.8 min and 65.6 ± 18.3 min, respectively. The blood loss and post-operative hospital stay were 30.6 ± 10.2 mL and 2.8 ± 0.8 d, respectively. Camera clearing times and time used for operative field adjustment were 1.1 ± 1.0 min and 2.0 ± 0.8 min, respectively. The operative error was 7.5%.

CONCLUSION: Robot-assisted laparoscopic cholecystectomy following the principles of laparoscopic operation has specific performing essentials. It preserves the benefits of minimally invasive surgery and offers enhanced ability of controlling operation field, precise and stable operative manipulations.

Key words: Zeus; Robotic surgical system; Laparoscopic cholecystectomy

INTRODUCTION

During the past two decades, the benefits of laparoscopic surgery for the patients are less trauma and pain, a shorter post-operative hospitalization, a better cosmetic result and a faster return to normal activity[1]. However, although there are clear benefits to the patients, surgeons face distinct disadvantages. Working through fixed entry points limits maneuverability of the instruments inside the body cavity to five degrees of freedom (DOF). Looking at a two-dimensional screen, surgeons are handicapped by the loss of the visual perception of depth, and the need for a human assistant to hold and move the camera makes surgeons loss the independent ability of controlling operation field [2]. Reduced dexterity and impaired visual control are considered the major burdens of laparoscopic surgery and the attempts in developing robotic telemanipulation systems aim at overcoming these problems. Nowadays both Zeus and da Vinci robotic telemanipulation systems are available to patients. After the success of the first laparoscopic cholecystectomy with Zeus robotic surgical system of our hospital on 26 April 2004, we performed the same operation in the other 40 patients between May 2004 and July 2005, and acquired some experience.

MATERIALS AND METHODS

Patients

Between May 2004 and July 2005, forty patients (24 females and 16 males), with average age 36 years (range 14-50 years) underwent the robot-assisted laparoscopic cholecystectomy in our hospital. Six cases were cholecystopolyp and the others were cholecystolithiasis combined with chronic cholecystitis. Informed consents were obtained from all patients before operation.

Operation

Zeus robotic surgical system (Computer Motion Com-

pany, IEC 60601, Class III, Type CF) consists of Aesop (automatic endoscopic system optimal position), Hermes (acoustic center), Zeus surgical system (three separate robotic arms, operator console, optic console), and Socrates (remote co-operating system).

All the patients in supine position were under the total intravenous combined inhalation anesthesia. The left and right robotic arms were placed at each side of the patient's head. Aesop arm was placed beside the left hip. All robotic arms were attached to the sidebars of the operating table. The movable lower limits of the three arms were set at an optimal distance that a palm was able to insert between the robotic arm and the patient's abdominal wall, and then the instrument adapter was installed onto its robotic arms. Pneumoperitoneum was established after the puncturation with Verres needle at the umbilicus and the cavity pressure was maintained at 12 mmHg. The first 10-mm trocar was introduced at the umbilicus and the 10-mm 30º laparoscope was inserted to explore the abdominal cavity. Under laparoscopic vision, another 10-mm trocar and a 5-mm trocar were respectively introduced at 5-cm below the xiphoid process and 5-cm below the right costal margin in anterior axillary line. A dissection clamp and a grasper were inserted through the trocars. The laparoscope, a grasper and a dissection clamp were engaged with the instrument adapters of Aesop arm, left robotic arm and right robotic arm. Then the three robotic arms were adjusted in a double 90º position, i.e., the angle between the forearm and the upper arm of a robotic arm was 90º, and the angle between the laparoscopic instruments in the adapters and the forearm was also 90º. The condition of double 90º offered the largest range of motion. The surgeon wearing a microphone sat before the operator consol which was placed about 5 m far from the operating table, and steered two egg-shaped manipulators to control the left or right robotic arm. In the mean time, Aesop was acoustically controlled to move up and down, left and right, forward and backward, so as to offer the optimal operative field. An assistant standing by the operating table prepared to adjust the tiny regulator of Aesop or another two robotic arms. An instrument nurse also stood by the table to replace the instruments at any moment. The surgeon steered the grasper of the left robotic arm to retract the neck of gallbladder to expose the Calot's triangle and manipulated the dissection clamp of the right robotic arm to dissect the cystic duct and cystic artery. The cystic artery and duct were sheared after double ligation with clips separately, and then gallbladder was cut down from the liver with the diathermy hook. The gallbladder was pulled out by the assistant from the port below xiphoid process[3].

All the operation procedures were recorded on videotape for later analysis. Time parameters included total operative time, system setup time and performing time. The total operative time was defined as the time from disinfection of the operative field to skin closure. The system setup time was defined as the time from disinfection to the start of grasping the neck of gallbladder. The performing time was defined as the time from the start of grasping the neck of gallbladder to the moment the gallbladder was completely freed from the liver. Minimally invasive parameters included the blood loss, post-operative complications and post-operative hospital stay. Parameters of operative field included camera clearing time and time used for operative field adjustment. Camera clearing time was defined as the time that the laparoscope was taken out to clear the contaminant on the camera during operation. Time used for operative field adjustment mean the time which was taken for the surgeon to stop perform to adjust the operative field or clear the camera. The rate of operative error mean the percent that the cases in which operative errors, such as hepatic laceration or gallbladder perforation happened, occupied among the 40 cases. Conversion cases mean the number of procedures converted to other procedures, such as open procedure or conventional laparoscopic procedure.

RESULTS

Forty laparoscopic cholecystectomy procedures were successfully completed with Zeus robotic system and there were no conversion cases. Total operating time, system setup time and performing time were 100.3 ± 18.5 min, 27.7 ± 8.8 min and 65.6 ± 18.3 min, respectively. The blood loss and postoperative hospital stay were 30.6 ± 10.2 mL and 2.8 ± 0.8 d, respectively. Camera clearing time and time used for operative field adjustment were 1.1 ± 1.0 and 2.0 ± 0.8 min, respectively. The operative error was 7.5%. All the patients began to intake diet at 6-9 h after operation. Their wound healed well without oozing blood and infection, and there were no post-operative complications in any of the patients.

DISCUSSION

At the beginning of 1999, two US companies, Computer Motion and Intuitive Surgical, received European CE accreditation for the clinical application of Zeus and da Vinci robotic surgical systems that were independently invented. In 2000, the two companies received FDA accreditation too, which indicated that robotic surgical systems began to be formally available to patients in the world[4]. In 2001 September 7, a medical team led by French doctor Marescaux accomplished the famous Zeus robot-assisted cholecystectomy, cross over Atlantic Ocean, named as "Lindbergh operation", which created a precedent of remote operation[5]. Up to now, the safety and feasibility of robotic surgical systems applied in general surgery, thoracic/vascular surgery and gynaecology/urology have been demonstrated. Until 2000, more than 6000 robot-assisted procedures were performed, thirty-seven percent among them were in general surgery, mainly cholecystectomy[6]. In the late two years, the technique of robot-assisted operation became more and more mature and wide, and the number of procedures increased quickly. After the success in the first Zeus robot-assisted laparoscopic cholecystectomy in Chinese mainland by our hospital, the other 40 cases were accomplished between May 2004 and July 2005. Based on these, the robot-assisted operative characteristics and performing essentials were analyzed.

Robotic surgical system is a new achievement which is resulted from the medical application of highly developed automatic technique, computer image technique and con-

trol technique. The advanced system possesses the enormous superiority over conventional laparoscopic surgery and forms its characteristics. During Zeus robot-assisted procedures, there was no need for a human assistant to hold the camera, who often provides error and unstable operative field or contaminates camera by touching tissue. The surgeon directly control the camera engaged with Aesop arm by voice, which restores his capability to master operative field as open operation. Moreover, the arm cannot shake and has the ability to memory the previous position. Therefore, the adjustment of operative field is quick and convenient and the operative field is direct-viewing and stable[7]. In our study, camera clearing time and time used for operative field adjustment were merely 1.1 ± 1.0 and 2.0 ± 0.8 min, respectively. There was no vibration of laparoscopic instruments in all the 40 procedures, which benefits from the mechanism and working principle of Zeus robot. First, with the surgeon sitting at a remote and ergonomically designed workstation, Zeus robotic system eliminates the need to twist and turn in awkward positions, which is in favour of the long and precise operation[8]. Second, it is the 12- to 15-fold magnification of image by the camera of Zeus system that conduces to accurate operation[9]. Third, it provides adjustable motion scaling and tremor reduction. Motion scaling reduces the surgeon' s motion at the console to finer movements within the patient. When the system is set to 5:1, a 5-cm sweep by surgeon's hand is a 1-cm sweep within the abdomen. This promotes the accuracy of operation. Tremor reduction can completely eliminate any tremor from the surgeon's hand, which increases the stability of operation, thereby decreasing operative errors[10]. The operative error was lower than that of early conventional laparoscopic surgery. The endowrist at the tip of instrument provides the surgeon with six degrees of freedom inside the patient's body. The additional degrees of freedom increase the dexterity and create the sense of actually having the surgeon's hand within the abdominal cavity during laparoscopic surgery. This vastly simplifies tasks such as suturing, tying and complex dissection, all of which are extremely challenging for most surgeons with standard laparoscopic equipment[11]. Nio *et al*.[12] selected 20 medical students without any surgical experience to perform at random a set of laparoscopic tasks either manually or robot-assisted (Zeus). This task consisted of dropping beads into receptacles, running a 25-cm rope, capping a hypodermic needle, suturing, and performing a laparoscopic cholecystectomy on a cadaver liver of a pig. The dropping beads exercise and the laparoscopic cholecystectomy required more time when performed with robotic assistance, as compared with manual performance. Grasping the beads, the rope, and either the needle or the cap were tasks that required fewer actions to complete when performed with robotic assistance. As compared with the robot-assisted rope-passing exercise, more failures were made in the manually performed procedure, mainly caused by unintentional dropping of the rope. Therefore, robot-assisted laparoscopic surgery by participants without any surgical experience might require more time, but actions can be performed more precisely as compared with manual laparoscopic surgery. Zeus robot-assisted laparoscopic cholecystectomy preserves the benefits of minimally invasive surgery. Robotic surgical system overcomes the technical limit of conventional laparoscopic surgery and expends the field of minimally invasive surgery into cardiac surgery. Kappert *et al*.[13] performed 29 off-pump totally endoscopic coronary bypass (TECAB) on a beating heart with the Da Vinci system and an endoscopic stabilizer (Intuitive Surgical Company). Patients were operated upon via four 1-cm chest incisions using the da Vinci robot for the internal thoracic artery (ITA) harvesting and for performance of anastomoses on the beating heart. In this series, they had a 100% survival rate. Conversion rate to a median sternotomy was 3.4%; time of harvesting was 26 min; time of anastomosis was 29 min; and operating time was 130 min. Post-operative time in ICU was 17 h; and post-operative hospital stay was 7 d. In robotic surgery, extra time is needed to setup and position the robotic arms and instruments before starting of the actual dissection[14]. However, the setup time decreased from 40-50 min to 20-30 min with increasing experience. If the robotic systems are placed at independent operating room and arms are fixed on the operating table the total operative time will reduce.

Zeus robot-assisted cholecystectomy is performed by the surgeon who controls the robotic arms via manipulators to accomplish the operation. It is not a job fulfilled 'automatically' by the robot according to a certain input program. The surgeon should follow the operative principle of conventional laparoscopic cholecystectomy, be familiar with the working rational of robotic systems, and continue to summarize the performing essentials as the accumulation of experience: (1) Installation of the robotic arms. Installation should depend on the body height and body type of the individual patient. Generally, the left and right robotic arms were placed at each side of the patient's head. Aesop arm was placed beside the left hip. The movable lower limits of the three arms were set to insert a palm between the robotic arm and the patient' s abdominal wall. The three robotic arms are adjusted in a double 90º position; (2) Place of trocar ports. The left trocar port should be placed in anterior axillary line 5 cm below the right costal margin, lower than that of conventional laparoscopic cholecystectomy, so as to favor the left robotic arm to retract gallbladder from various angles; (3) Tactile feedback is compensated by visual feedback. During robot-assisted procedures the surgeon cannot touch both the tissue and the instruments and lose the tactile feedback, which makes performing and judging more difficult. But, high-resolution and vivid three-dimensional operative field provided by robotic surgical system make it possible for the surgeon to observe the tiny morphological change of tissue. Thus the surgeon should utilize the high-quality visual feedback to compensate the lost tactile feedback, such as observing the deformation of tissue under pressure to judge strength[15]; (4) Conversion of the performing habits. During robot-assisted procedures, basic surgical manipulations, such as incision, separation, hemostasis, suture and so on, are converted to squeeze, relax, or rotate the egg-shaped manipulators. Due to these entirely changes of operative maneuvers, the surgeon is forced to form new habits through special training and practice.

Though the experience through the 40 Zeus robot-as-

sisted laparoscopic cholecystectomies was preliminary, we understood the advanced technical advantages of robotic surgical system, such as independent fine visualization, restored dexterity, *etc*. With the experience accumulated and performing craft enhanced, these advantages will convert to superior therapeutic efficacy, and the system will become a new therapeutic technical platform for the surgeons.

Abstract

AIM: To investigate the effect of three-dimensional conformal radiotherapy (3-DCRT) in combination with FOLFOX4 chemotherapy for unresectable recurrent rectal cancer.

METHODS: Forty-eight patients with unresectable recurrent rectal cancer were randomized and treated by 3-DCRT or 3-DCRT combined with FOLFOX4 chemotherapy between September 2001 and October 2003. For the patients without prior radiation history, the initial radiation was given to the whole pelvis by traditional methods with tumor dose of 40 Gy, followed by 3-DCRT for the recurrent lesions to the median total cumulative tumor dose of 60 Gy (range 56-66 Gy); for the post-radiation recurrent patients, 3-DCRT was directly given for the recurrent lesions to the median tumor dose of 40 Gy (36-46 Gy). For patients in the study group, two cycles chemotherapy with FOLFOX4 regimen were given concurrently with radiotherapy, with the first cycle given simultaneously with the initiation of radiation and the second cycle given in the fifth week for patients receiving conventional pelvis radiation or given in the last week of 3-DCRT for patients receiving 3-DCRT directly. Another 2-4 cycles (average 3.6 cycles) sequential FOLFOX4 regimen chemotherapy were given to the patients in the study group, beginning at 2-3 wk after chemoradiation. The outcomes of symptoms relieve, tumor response, survival and toxicity were recorded and compared between the study group and the control group.

RESULTS: For the study group and the control group, the pain-alleviation rates were 95.2% and 91.3% ($P > 0.05$); the overall response rates were 56.5% and 40.0% ($P > 0.05$); the 1-year and 2-year survival rates were 86.9%, 50.2% and 80.0%, 23.9%, with median survival time of 25 mo and 16 mo ($P < 0.05$); the 2-year distant metastasis rates were 39.1% and 56.0% ($P = 0.054$), respectively. The side effects, except peripheral neuropathy which was relatively severer in the study group, were similar in the the two groups and well tolerated.

CONCLUSION: Three-dimensional conformal radiotherapy combined with FOLFOX4 chemotherapy for unresectable recurrent rectal cancer is a feasible and effective therapeutic approach, and can reduce distant metastasis rate and improve the survival rate.

Key words: Rectal neoplasms; Radiotherapy; Chemotherapy

INTRODUCTION

Despite all previous efforts at radical curative resection and multidisciplinary treatment, locally recurrent rectal cancer (LRRC) occurs in up to one third of patients[1-3]. A curative treatment is possible only when local recurrences represent limited disease that may be amenable to surgical re-excision[4,5]. Unfortunately, most patients with LRRC will be excluded from curative surgery on the basis of medical fitness, the presence of distant metastasis, locally unresectable disease or an unwilling to accept the considerable associated morbidity and mortality. In these patients, palliative intervention still may be required[6].

Patients with unresectable LRRC are often treated with nonsurgical palliation, including radiation therapy, chemotherapy and chemoradiation. Radiation has been confirmed as an effective method to palliate the symptoms and dose-response relationship between radiation doses and subjective response of LRRC has been revealed by some studies[7-10]. The strategy to elevate the radiation dose by adopting

new techniques, such as three-dimensional conformal radiotherapy (3-DCRT) or intensity-modified radiotherapy (IMRT), is needed to improve the local control of LRRC. It is also reasonable to combine chemotherapy into the multi-modality treatment for LRRC patients because systemic metastasis is a common problem. We designed herein a randomized, controlled study to compare the efficacy and the toxicities of exclusive 3-DCRT and 3-DCRT combined with FOLFOX4 chemotherapy for patients with unresectable LRRC.

MATERIALS AND METHODS

Patients and characteristics

Between September 2001 and October 2003, 48 patients with unresectable LRRC were randomized and treated by 3-DCRT at the Radiation Oncology Department, Sir Run Run Shaw Hospital. Twenty-five cases among them were treated by exclusive 3-DCRT and defined as the control group, while the other 23 cases received 3-DCRT combined with FOLFOX4 regimen and were defined as the study group. Table 1 shows the clinical data and pathologic characteristics with the initial operation. The diagnosis of local recurrence of rectal cancer mainly depended on imaging exam. Of 44 patients, presacral masses were detected by pelvis B-ultrasound, computerized tomography (CT) or magnetic resonance imaging, 10 cases were confirmed by biopsy pathological result. Thirty-five cases among them had solitary presacral mass, 9 cases (5 cases in the study group and 4 cases in the control group) had multiple masses or accompanied with adjacent lymph nodes metastases, but all the lesions can be dealt as a whole target. Of the other 4 cases, solitary masses in the pelvic sidewall were found by imaging exam. All the cases were consulted by radiologists and surgeons and evaluated as unresectable. Systemic examination was carried out to exclude distant metastasis. The median interval between local recurrence and initial operation was 15 (range 7-42) mo. Eighteen cases among the study group and 20 cases among the control group had received peri-operative radiotherapy with dose of 40-50 Gy. Twenty cases among the both groups had received 5-flurouracil (5-Fu)-based peri-operative chemotherapy.

Table 1 Clinical and pathologic characteristics of the patients

Variables	Control group (n = 25)	Study group (n = 23)
Age (yr): Median (range)	62 (36-70)	62 (40-72)
Sex		
Male	17	14
Female	8	9
Dukes' stage of initial lesion		
A	1	1
B	7	5
C	17	17
Tumor pathologic type		
Well and moderately differentiated adenocarcinoma	19	17
Mucinous adenocarcinoma	4	3
Signet ring cell carcinoma	2	3
Recurrent sites		
Presacral	23	21
Pelvic sidewall	2	2

No significant differences in clinical or pathologic variables between the two groups were observed.

Treatment

For the patients without prior radiation history, the initial radiation was given to the whole pelvis by traditional methods with tumor dose of 40 Gy, followed by 3-DCRT for the recurrent lesions to the median total cumulative tumor dose of 60 Gy (range 56-66 Gy); for the post-radiation recurrent patients, 3-DCRT was directly given for the recurrent lesions to the median tumor dose of 40 Gy (36-46 Gy). The entire pelvis was irradiated with 10 MV photons using AP/PA portals or PA portal and two lateral wedged portals. The schedule was once daily, 5 times a week, using 200 cGy fractions, to a final dose of 40 Gy. Belly board was used to reduce the volume of small bowel irradiated. For 3-DCRT, all patients had a CT scan in the treatment position immobilized by thermoplastic molds for treatment planning purposes. Using the CT data set, the clinical target volume defined as the gross tumor volume with 5-mm margin was delineated and confirmed by radiologists, radiation oncologists and radiotherapy physicians. An additional 5-10 mm was added for planning target volume. Radiotherapy treatment planning was performed using Pinnacle3 3-D conformal radiation treatment planning system. Three to seven fields with individualized blocks derived from beam's-eye-view were used to implement the 3-DCRT. PTV was surrounded by 90% isodose curvature. Three-dimensional CRT was delivered with 10 MV photon and conventional fractionization: once daily, 5 times a week, 200 cGy per fraction. For patients in the study group, two cycles chemotherapy with FOLFOX4 regimen were given concurrently with radiotherapy, with the first cycle given simultaneously with the initiation of radiation and the second cycle given in the fifth week for patients receiving conventional pelvis radiation or given in the last week of 3-DCRT for patients receiving 3-DCRT directly. Another 2-4 (average 3.6) cycles sequential FOLFOX4 regimen chemotherapy were given to the patients in the study group beginning at 2-3 wk after chemoradiation. FOLFOX4 regimen comprised of intravenous injection of oxaliplatin at a dose of 85 mg/m^2 on d 1, intravenous injection of leucovorin at a dose of 300 mg/m^2 and intravenous injection of 5-Fu at a dose of 400 mg/m^2 and continuous intravenous injection of 5-Fu at a dose of 600 mg/m^2 on d 1 and d 2.

Evaluation of patients

Patients were observed at 3-mo intervals for 18 mo after the completion of therapy and every 6 mo for 3 years. All patients were followed up till December 2004, with follow-up duration of 6-39 (median 23) mo, except two who were lost to follow-up and presumed dead. Assessment of pain was scored from 0 (no pain) to 10 (as bad as you can imagine) by numeric rating scale. If the pain score decreased more than a half, good pain palliation was considered. Assessments of tumor dimensions by CT scan were performed before the start of treatment and repeated

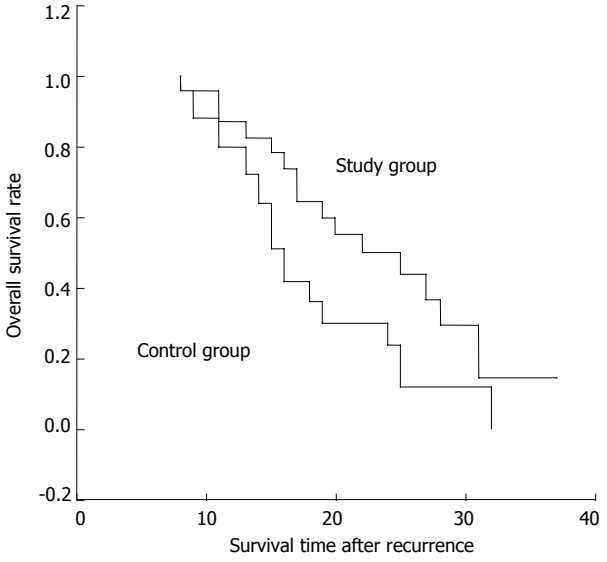

Figure 1 Overall survival curves of patients in the two groups. Five patients survived in the control group, and 8 patients survived in the study group.

1 mo after the end of 3-DCRT. Tumor objective responses were classified as complete response, partial response, stable disease and progression disease based on standard World Health Organization (WHO) criteria. The data of toxicity were ranked according to the WHO evaluation.

Statistical analysis

Survival estimates were calculated using Kaplan-Meier curves and a two-sided log-rank test was used to compare survival curves. χ^2 test was used to determine the difference of pain palliation rates, objective response rates and distant metastasis rate. P value < 0.05 was considered statistically significant.

RESULTS

Good pain palliation rate was 95.2% (20/21) in the study group and 91.3% (21/23) in the control group, with median palliation time of 13 d (range 6-58 d) and 15 d (range 8-65 d), respectively ($\chi^2=0.261$, $P=0.609$).

The overall objective response rate in the study group was 56.5% (1 complete response, 12 partial responses), while that in the control group was 40.0% (0 complete response, 10 partial responses) ($\chi^2=1.283$, $P=0.257$).

Figure 1 shows overall survival of the two groups. In the study group, 1-year and 2-year overall survival rates were 86.9% and 50.2%, while those of the control group were 80.0% and 23.9% with median survival time of 25 mo and 16 mo, respectively (Log-rank = 4.01, $P = 0.045$).

Interestingly, 2-year distant metastasis rates of the two groups were 39.1% and 56.0% with median distant metastatic time of 16 (range 7-26) mo and 10 (range 3-23) mo, respectively ($\chi^2=3.715$, $P=0.054$).

Toxicities of patients were scored according to WHO scale. A detailed description of acute toxicities was given in Table 2. The main toxic reactions of the control group patients included diarrhea, rectal tenesmus, perianal area skin reaction and bone marrow suppression. The main toxicities of the study group patients were similar but relatively severer peripheral neuropathy. No toxicity-related death was observed in both the groups. In the study group, radiotherapy of 3 patients was interrupted and delayed for 2-4 d due to severe diarrhea and rectal tenesmus, and the 2nd cycle chemotherapy of 1 patient was canceled due to severe bone marrow suppression. In the control group, radiotherapy of 2 patients was interrupted and delayed for 2 and 3 d, respectively, due to severe diarrhea and rectal tenesmus. No severe late toxicity was observed in both groups in the follow-up duration.

Table 2 WHO scale for acute toxicities

$P>0.05$. P value was calculated by subgroups for toxicity grade $\geqslant 3$.

DISCUSSION

The optimal treatment for locoregionally recurrent rectal cancer after curative surgery has not yet been defined[5,11,12]. Most of the recurrent rectal cancers are not resectable and require nonsurgical approaches. Multimodality treatment would probably offer the best result[13]. In the past, patients with locally unresectable recurrent rectal cancer were assumed incurable and received mostly palliative therapy. Traditional radiotherapy and chemotherapy given with palliative goal have been confirmed good palliation result of symptoms, such as local pain and bleeding with unknown effect on survival. Noticeably, several series have found a dose-response relationship of radiotherapy for symptoms control[9,14,15]. Some of them revealed the relationship also for local control and survival rate[9]. Sanfilippo *et al*[16] reported that despite aggressive multimodality therapy, a high rate of pelvic recurrence occurred in patients with clinically staged T_4 disease, and regional disease recurred almost exclusively in the radiation field. Under such circumstances, there is a significant need to adopt new techniques, such as intraoperative radiation therapy, brachytherapy and 3-DCRT, to safely deliver tumoricidal dose of radiation in an attempt to improve the local control[17-20].

Moreover, 3-DCRT allows more accurate definition of target volume and anatomy of critical normal structures. This technique focuses radiation to specific sites of disease, thereby minimizing injury to normal tissues. Higher doses of irradiation can be delivered by this technique to produce better tumor control without increasing the probabilities of particular sequela. It is controversial that whether previously irradiated LRRC patients could receive reirradiation and whether the reirradiation is of any value. Several investigators reported that high doses of reirradiation could be delivered with acceptable risks without prohibitive long-term side effects in patients with LRRC and could result in surgical salvage and long-term survival in selected patients[10,21,22]. This may be related to the location of local recurrence. A multicenter analysis of 123 patients with recurrent rectal cancer within the pelvis revealed that recurrent tumors were mainly situated in the posterior part of the bony pelvis and patients received abdominoperineal resection had a significantly more extension of recurrent tumors in the inferior parts of the pelvis comparing to those patients received low anterior resection[23]. There are fewer organs at risk in the lower and posterior pelvis. The usual local recurrent location of rectal cancer and 3-DCRT technique make it feasible to deliver higher radiation dose comparing with conventional radiation or to reirradiate with high dose for patients suffered from LRRC. In this study, we treated all patients with 3-DCRT or 3-DCRT boost to relatively higher dose, resulting in good palliation of pain in 93.2% (41/44) patients, the objective response rate in 47.9% (23/48) patients, and well tolerated toxicities. Thus we can roughly draw a conclusion that 3-DCRT for LRRC patients is feasible and effective.

It is now generally accepted that exclusive radiotherapy plays a minor role in improvement in survival unlike its major role in palliation of symptoms and improvement of local control for rectal cancer. Combined modality treatment is the recommended standard adjuvant therapy for patients with locally advanced rectal cancer. Currently, most adjuvant therapy includes chemotherapy[24]. Traditional chemotherapy or chemoradiation focuses on 5-Fu-based regimens, which have been confirmed to be effective. In our previous study, we have reported that preoperative radiotherapy combined with full course chemotherapy (LV + 5-Fu + 5'DfuR) is effective and safe[25]. Because of the clinical appliances of oxaliplatin during the recent years, substantial progress has been made in chemotherapy of rectal cancer. Chemotherapy with oxaliplatin combined with 5-Fu, such as FOLFOX4 regimen, is more effective and has become the standard treatment for advanced stage colorectal cancer[26]. In the United States, using similar chemotherapy regimens as adjuvant therapy has been approved. The advantages of oxaliplatin, such as its mild toxicities in gastrointestinal tract and bone marrow suppression, make it feasible to combine it with radiotherapy, especially when new radiation techniques, such as 3-DCRT, are applied. Local recurrence of rectal cancer is more common in the locally advanced patients, who have received 5-Fu-based chemotherapy in primary treatment, as exhibited in this study. For these patients, chemotherapy using more effective new drugs without cross-resistance is mandatory. In this study, we attempted to adopt 3-DCRT combined with FOLFOX4 chemotherapy for unresectable LRRC. The tumor response rates were similar in the both groups, but the 1- and 2-year overall survival rates and median survival time of the study group were better than those of the control group. Further analysis of the data revealed that the distant metastatic rate and median distant metastatic time of the study group marginally surpassed those of the control group ($P = 0.054$). We postulate that for LRRC patients receiving radiation and the combination of chemotherapy with FOLFOX4 regimen can reduce distant metastatic rate, delay the occurrence of distant metastasis and then influence the overall survival rate, even majority of the patients have received full course 5-Fu-based chemotherapy. In summary, 3-DCRT combined with FOLFOX4 chemotherapy appears to be a feasible and effective treatment for unresectable LRRC. Larger-scale studies are needed to evaluate the potency of this kind of therapeutic strategy.

Abstract

AIM: To elucidate the role of Wnt/β-catenin signaling pathway in pancreatic development of rat embryo.

METHODS: The mRNAs of β-catenin, APC, cyclin D1 genes were amplified by means of semiquantitative reverse transcription polymerase chain reaction (RT-PCR) from embryonic pancreas in different periods and normal pancreas of rat, respectively. Protein expression of these genes in embryonic pancreas of E14.5-E18.5 was examined by immunohistochemical method.

RESULTS: In embryonic pancreas of E14.5, the transcript amplification of β-catenin and cyclinD1 genes was detected. In embryonic pancreas of E18.5, the transcription levels of β-catenin and cyclinD1 genes became much higher than in other periods. But in adult rat pancreas the transcription of cyclinD1 gene could not be observed. Only until E18.5, the transcript amplification of mRNA of APC gene could be detected. Surprisingly, the transcription level of APC gene became much higher in adult rat pancreas than in embryonic pancreas. By means of immunohistochemical staining, identical results were obtained to the above by RP-PCR, except for β-catenin protein in adult rat pancreas.

CONCLUSION: Active Wnt/β-catenin signaling occurs in rat embryonic pancreas and is probably important for pancreatic development and organ formation.

Key words: Wnt/β-catenin signaling; Pancreas; Development; Embryo

INTRODUCTION

The fetal pancreatic development begins at the end of fourth week of gestational period in human being. The pancreatic bud comes from entodermal epithelium in the foregut. In rat embryo the pancreatic bud occurs at 9.5 d after mating (E9.5)[1]. With pancreatic islet arising, the rat embryonic pancreas began to become a special organ including external secretory portion and internal secretory portion. E14.5 - E18.5 is a crucial period for rat pancreatic cell proliferation, differentiation and structure formation[2-3]. Wnt/β-catenin signaling is involved in many developmental processes such as proliferation, differentiation, cell fate decisions, and morphogenesis[4]. However, little is known about Wnt/β-catenin signaling during pancreas development. β-catenin serves not only as a structural component of the E-cadherin-mediated cell-cell adhesion system, but also a signaling molecule of the Wnt/β-catenin pathway. In present study, we tried to investigate the role of Wnt/β-catenin signaling pathway in rat pancreatic development by means of RT-PCR and immunohistochemical method for collecting more data on diagnosis and therapy of pancreatic diseases.

MATERIALS AND METHODS

Experimental animals and specimen preparation

Healthy SD rats (male 10 and female 20), weighing 200-250 g, were purchased from the experimental animal center in Huaxi University of Medical Sciences, Chendu, China. Every two female rats and one male rat was put into one cage after these animals were fed for a week. Assessment of the embryonic age of the fetuses was based on the plug date, defined as embryonic d 0 (E0). The embryos were harvested from female rats with E14.5, E15.5, E16.5, E17.5 and E18.5, respectively. A part of pancreases was rapidly frozen in liquid nitrogen as soon as they were dissected from embryos under microscope.

Reagents and antibodies

Kits used in this study were as follows: Total RNA extraction kit (W6701, Watson, Shanghai), reverse transcription kit (RevertAid HMinus First Strand cDNA Synthesis Kit, Fermentas), and PCR reaction kit (DRR01AM, TaKaRa, Japan).

Table 1 Primers for RT-PCR

Genes	Sequence of primer (5′→3′)	Length of production (bp)	Annealing temperature (Tm)
	F: ACAGCACCTTCAGCACTCT		
β-catenin	R: AAGTTCTTGGCTATTACGACA	168	58.2
	F: CGGAACATGCATGACTGAGAC		
APC	R: GTCACGAGGTACGACCTCAGAT	310	60
	F: CAGAAGTGCGAAGCTTAGGTCT		
cyclin D1	R: GTAGCAGGAGAAGTTGTTGG	470	58
	F: CATGTGCAAGGCCGGCTTCG		
β-actin	R: GTAGCAGGAGAAGTTGTTGG	665	60

The following antibodies were used in this study: Rabbit polyclonal antibody against β-catenin, mouse monoclonal antibody against cyclin D1, rabbit polyclonal antibody against APC (Santa Cruz, USA).

Semiquantitative RT-PCR

Semiquantitative PCR was performed to determine the levels of the mRNA transcripts encoding β-catenin, APC and cyclinD1 genes in embryonic pancreas on E14.5-E18.5. The published sequences of the primers for amplification of β-catenin, APC, cyclinD1 and the housekeeping gene β-actin are showed in Table 1. To determine the optimum number of cycles required for the amplification of these genes or β-actin, an aliquot of first strand cDNA generated from normal rat pancreas was amplified with the respective primers using an increasing number of PCR cycles (20-36). To avoid primer-dependent artifacts, the reaction mixtures were denatured at 95 ℃ for 5 min prior to the addition of the Taq polymerase. The subsequent cycling programs consisted of denaturation at 95 ℃ for 30s, annealing at 60 ℃ (Table 1) (β-actin for 30 seconds) and extension at 72 ℃ for 1 min, followed by a final extension at 72 ℃ for 8 min. A linear relationship between the band intensity of the PCR products and the number of amplification cycles performed was observed. Based upon these observations, the optimum numbers of cycles for the amplification of these genes were 28-30 cycles and of β-actin was 28 cycles. PCR reactions in which the first strand cDNA were omitted served as negative controls and cDNA generated from endometrial samples were used as positive controls for these studies. To avoid technical error, each PCR experiment has been repeated twice. The PCR products were separated on 1.5% agarose gels, stained with ethidium bromide, and photographed using Gel Imaging System (BioRad, USA). The intensity of the bands specific for each target gene or β-actin was quantified using the Phoretix Gel Analysis Software Version 3.01 (NonLinear Dynamics, UK). The relative mRNA levels of these genes for each sample obtained from embryonic pancreas of E14.5-E18.5 were normalized to the corresponding β-actin levels.

Immunohistochemical detection of β-catenin, APC and cyclin D1 proteins

The avidin-biotin peroxidase complex (ABC) technique was used for immunohistochemical staining. Sections were cut at 5μm thickness, deparaffinized in xylene, rehydrated and washed with water. They were treated with 3% hydrogen peroxidase for 20 min to quench endogenous peroxidase and heated in a citrate buffer solution (0.1 mol/L sodium citrate, pH 6.0) at 95℃ for 10 min. After pre-incubation with 10% normal goat serum to block non-specific binding, sections were incubated with the primary antibodies against β-catenin, APC and cyclin D1 at 4℃ overnight. Alternatively, the sections were incubated with biotinylated anti-rabbit or mouse IgG (dilution of 1 : 200) for 40 min at room temperature and with ABC (dilution of 1 : 200) for 30 min at room temperature. Between incubations, sections were washed with 0.1 mol/L PBS (pH7.4). Color was developed with diaminobenzidine tetrahydrochloride supplemented with 0.04% hydrogen peroxidase and counterstained with Mayer's hematoxylin.

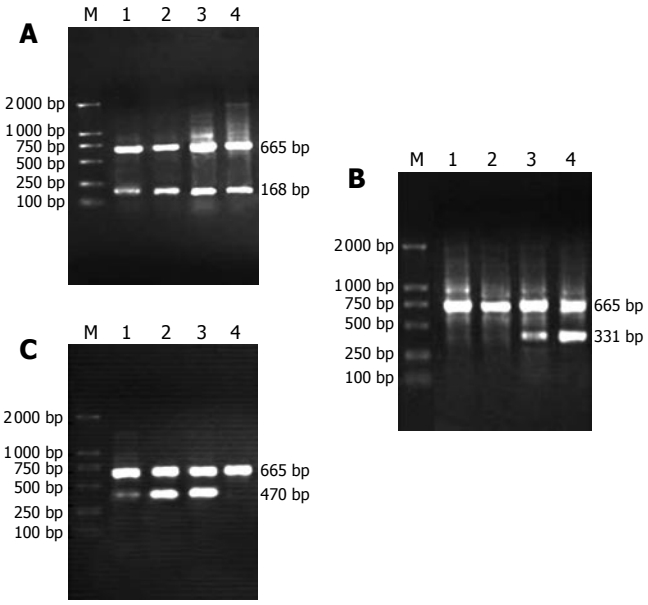

Figure 1 (**A**-**C**): Representative RT-PCR results of β-catenin, APC and cyclin D1 genes in embryonic pancreas of E14.5-E18.5 and adult rat. **A**: RT-PCR results of β-catenin gene (low) and β-actin gene (top, same in other lanes); **B**: RT-PCR results of APC gene (low); **C**: RT-PCR results of cyclinD1 gene (low). M: Molecular -weight marker, lane 1-4: amplification result of RT -PCR for β-catenin, APC and cyclin D1 genes from embryonic pancreas of E14.5, 16.5, 18.5 d and adult rat, respectively.

Statistical analysis

The results of semiquantitative RT-PCR are presented as the ratio of the mean relative absorbance of β-catenin, APC and cyclin D1 to corresponding β-actin respectively for at least three independent experiments of each sample. Statistical differences among different periods of embryo were assessed by *t* test. A $P < 0.05$ was considered significant.

RESULTS

Expression of β-catenin, APC and cyclinD1 mRNA in different pancreas

As shown in Figure 1(A-C), the amplification bands of mRNA of β-catenin and cyclinD1 genes could still be detected in rat embryonic pancreas from E14.5-E18.5. In

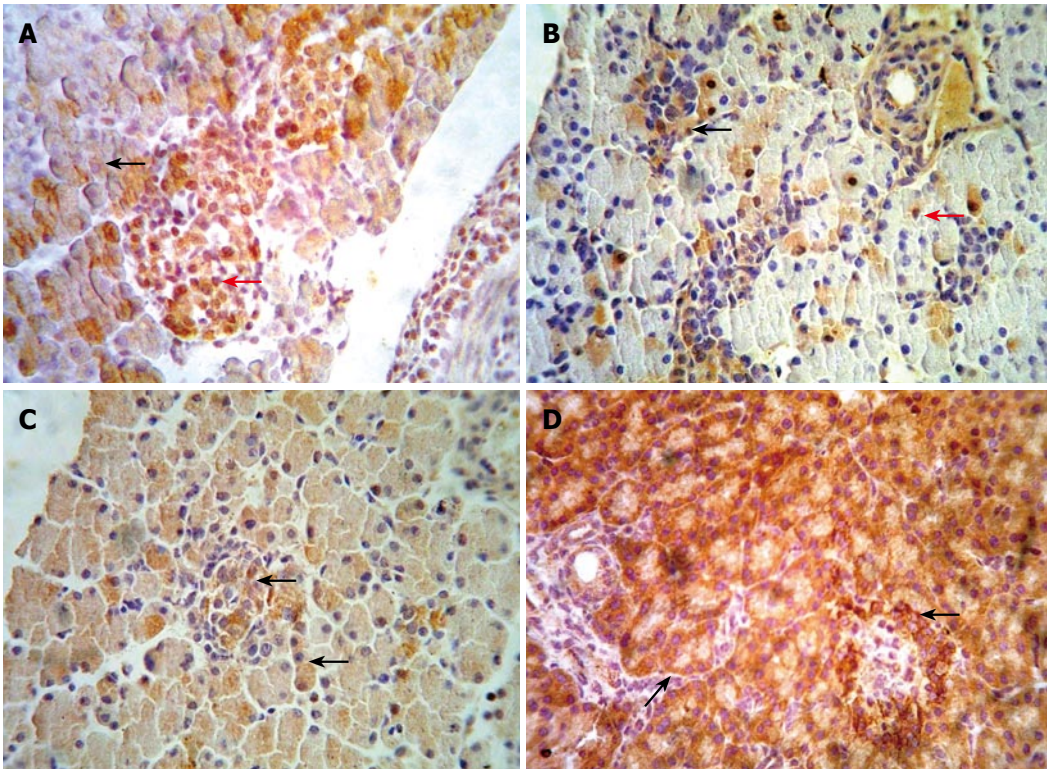

Figure 2 (**A-D**) Representative immunohistochemical results of β-catenin, APC and cyclin D1 proteins in embryonic pancreas of E14.5-E18.5 and adult rat. Immunohistochemical staining was performed using an anti-β-catenin APC and cyclin D1antibodies respectively. Slides were detected at ×400 magnification under a light microscope. **A:** showed staining of β-catenin at cytoplasm (black arrow) and nucleus (red row) in embryonic pancreas of E18.5. **B:** showed staining of cyclin D1 within cytoplasm (black arrow) and/or nucleus (red row) in embryonic pancreas of E16.5. **C:** showed staining of APC within cytoplasm (black arrow) in embryonic pancreas of E18.5. **D:** showed staining of APC within cytoplasm (black arrow) in adult rat pancreas.

adult rat pancreas the transcription of cyclinD1 gene could not be observed while the transcription of β-catenin gene could be found. Only in pancreas of E18.5, the transcript amplification of mRNA of APC gene could be detected. Surprisingly, the transcription level of APC gene was higher in adult rat pancreas than in embryonic pancreas.

Immunohistochemical staining of β-catenin, cyclinD1 and APC

We examined the β-catenin, cyclinD1 and APC protein in embryo from E14.5-E18.5 by immunohistochemical staining. Representative results are shown in Figure 2 (A-D). In the embryo of E14.5, β-catenin staining appeared at the cytoplasm of pancreatic cells. The cells with positive staining showed a diffuse distribution in embryonic pancreas. In the embryo of E18.5, we could observe full pancreas including external and internal secretion portions in morphology. At the same time, our results showed that β-catenin could be detected frequently both in external and internal secretion portions. The positive cells of cyclinD1 with diffuse distribution were observed in the pancreas of E14.5. The positive staining located in the cytoplasm and/or nuclei of pancreatic cells. In pancreas of E18.5, the expression of cyclinD1 protein was significantly higher than that in other period. However, none of positive cells expressing cyclinD1 protein was observed in adult pancreas. Expression of APC has not been observed in the early embryonic pancreas until E18.5. In contrast, the positive cells of APC staining scattered throughout the pancreas in adult rat.

DISCUSSION

At present, morbidity rate of diabetes has an ascending tendency in the world while high morbidity and mortality of pancreatic carcinoma is becoming one formidable topic for surgeon[5]. In order to treat these diseases effectively, fully understanding of the development and differentiation of embryonic pancreas, as well as the underlying molecular mechanism of pancreatic diseases is needed.

Wnt/β-catenin signaling pathway is highly conservative during embryonic development and tumorigenesis of human being and animal[6]. Recent studies have suggested that activation of Wnt/β-catenin signaling pathway may play an important role in hematonosis[7], gastroenteric tumor such as colon cancer[8], and development of embryo[9]. In this study, we have investigated the transcription of gene and expression of protein of β-catenin, APC and cyclin D1 which are three important components in Wnt/β-catenin signaling pathway.

β-catenin serves not only as a structural component of the E-cadherin-mediated cell-cell adhesion system, but also as a signaling molecule of the Wnt/β-catenin signaling pathway. The β-catenin protein is at the core of the canonical Wnt/β-catenin signaling pathway. Wnt stimulation leads to β-catenin accumulation, nuclear translocation and interaction with T-cell factor/lymphoid enhancer factor (TCF/LEF) transcription factors to regulate genes important for embryonic development and proliferation. In a word, accumulation of ββ-catenin protein in the cytoplasm and/or nuclei of cell are popularly considered a hallmark of activation of the canonical Wnt/β-catenin signaling pathway[7,10]. At this study, we have observed the transcription of β-catenin gene by the RT-PCR and positive stain of β-catenin protein with immunohistochemical techniques in pancreas of E14.5-E18.5. Moreover the positive cells of β-catenin existed in not only the external secretion portion but also internal secretion portion. Therefore we presumed that Wnt/β-catenin signaling pathway may be very important for morphogenesis of pancreas. In pancre-

as of E18.5, the positive stain of β-catenin protein could be found in nucleus especially in pancreatic islet. We have known that pancreatic islet began to mature during late period of embryo[11]. So β-catenin may be essential for proliferation and differentiation of pancreas islet in embryo. Dessimoz *et al*[12] examined the role of β-catenin gene in development of pancreas using an animal model with the conditional gene knockout.They found a reduction in endocrine islet numbers after deleting the β-catenin gene in the epithelium of the pancreas. This result in some degree coincided with our conclusion. On contrast, Murtaugh *et al*[13] confirmed β-catenin is essential only for pancreatic acinar not for islet development. Obviously the development process of pancreas is too complicated to be understood only by Wnt/β-catenin signaling.

In the study, we investigated simultaneously cyclin D1 gene which is one of target genes of Wnt/catenin signaling pathway[14]. The changed tendency of cyclin D1 on the transcription level of mRNA and protein expression is almost in step with β-catenin in pancreas of E14.5-E18.5. It is known that cyclin D1 is a key regulator of the G1 phase of cell cycle[15]. Expressing of cyclin D1 protein in the cytoplasm and/or nuclei indicated that pancreatic cells should be in the condition of proliferation and differentiation. We therefore had come to another conclusion that cyclin D1 exactly is one of activated target genes of Wnt signaling pathway in development of embryonic pancreas.

It has been reported that APC is a negative regulatory factor as well as Axin in Wnt signaling pathway[16]. Experiments in Drosophila ultimately revealed that genetic ablation of APC indeed resulted in upregulation of β-catenin signaling[17]. In pancreas of E14.5-17.5, we could not observe the amplification band of mRNA and protein expressing of APC gene. Only in pancreas of E18.5, could we first find positive stain of APC protein as well as transcription of mRNA of APC gene. In adult rat the positive cells of APC protein spread throughout external secretion portion and internal secretion portion of pancreas. We have known that the proliferation level of pancreas is very low in adult rat particularly in diabetes[18]. This is coincident with the negative role of APC in Wnt/β-catenin signaling pathway.

In this study the cell with positive stain of β-catenin couldn't be found in adult rat pancreas although the transcription of β-catenin gene could be detected by RT-PCR. The reasons are discussed below. First the destruction complex including GSK3、Axin and APC can degradate the free β-catenin in the cytoplasm in time in adult rat pancreas[19]. Secondly the quantity of β-catenin protein which are attached to membrane with E-cadherin may be too little to be detected by immunohistochemical techniques used in present experiments[20].

Although this signaling pathway was active, we had known little about the role of Wnt /β-catenin signaling pathway in development of embryonic pancreas indeed. Which are the upperstream signals[21-22]? Which target genes beside of cyclin D1 are activated? How to crosstalk with other signaling pathway[23]? All these topics need us to investigate further.

Meanwhile, some workers have investigated the Wnt/β-catenin signaling in tumor of pancreas. They suggested the notion that Wnt/β-catenin signaling pathway had been activated in adenocarcinoma, cystocarcinoma and solid tumor of pancreas[24-26]. We will believe that the more we know the Wnt/β-catenin signaling in embryonic pancreas and tumor of pancreas, the better the therapeutic measures for patient with diabetes and tumor of pancreas clinically.

Abstract

This is a case report of an 85-year old patient who presented with abdominal pain, nausea and vomiting associated with altered liver function test. The plain X-rays and CT scan showed pneumobilia with an ectopic gallstone. The patient was diagnosed with Bouveret syndrome and managed surgically. The report is followed by a discussion about Bouveret syndrome.

Key words: Bouveret syndrome; Gall bladder; Stone; Fistula; Gastric outlet obstruction

INTRODUCTION

Gallstone ileus is a rare complication of gallstones but it accounts for almost 25% of non strangulated intestinal obstruction in patients above 65 years of age. Mortality has improved but remains at 15%-18% due to the age and co-morbidity of patients[1]. Bouveret syndrome, first described in 1896, is a subgroup of gallstone ileus in which a cholecystoduodenal fistula allows the passage of a stone which impacts in the duodenum and causes gastric outlet obstruction. It is rare with 175 cases reported in the literature up to the year 2000[2]. We present a case of Bouveret syndrome, with typical radiological findings, that was successfully managed surgically.

CASE REPORT

An 85-year old lady presented with a five-day history of right upper quadrant (RUQ) abdominal pain radiating to her back, associated with nausea and vomiting. On examination she had tenderness, guarding and rebound in the RUQ and epigastrium. The leukocyte count was 20.6 (predominantly neutrophils), the amylase 1039 and urea and creatinine were elevated. Plain abdominal X-ray showed a radio-opaque shadow in the right side of the abdomen, air in the gall bladder and biliary tree but no evidence of small bowel obstruction (Figure 1). She was assumed to have pancreatitis and a suspected cholecystoenteric fistula.

CT scan with oral contrast revealed a large amount of air in the biliary tree, a fistula between the second part of duodenum and the gall bladder and a large stone in the third part of duodenum. A small amount of contrast outlined the stone and reached the small bowel (Figure 2). This impacted stone (7.5 cm × 4 cm × 4 cm) was removed surgically from the junction of the second and third part of duodenum through a small jejunostomy after mobilization of the duodenum and the DJ flexure. Her post operative recovery was uneventful.

DISCUSSION

Cholecystoenteric fistulae occur in less than 1% of patients with gallstones. Most (60%) are cholecystoduodenal fistulae, but cholecystocolic, cholecystogastric and choledochoduodenal fistulae have been described. Large stones passing through the fistula may cause intestinal obstruction, especially in the terminal ileum[1,3]. A plain abdominal X-ray is diagnostic in about 50% of cases[3] and may demonstrate intestinal obstruction, pneumobilia, an ectopic gallstone, alteration in the position of the previously observed stone or two air fluid levels in the right upper quadrant secondary to air in the gall bladder.

Patients with Bouveret syndrome usually present with symptoms of gastric outlet obstruction, though presenting with other complications of gall stone disease or upper gastrointestinal bleeding has been reported[4]. A plain abdominal X-ray may show a dilated stomach, and CT may demonstrate pneumobilia, intestinal obstruction and an ectopic gallstone[5]. Open surgery, endoscopic removal[6] and laparoscopic or laparoscopic assisted enterolithotomy[7] have all been used successfully for stone removal. A stone in the duodenum can be difficult to access laparoscopically but may be reached endoscopically[6].

Whether the gallbladder should be disturbed is controversial but the recurrence of gallstone ileus following enterolithotomy is rare, and complications related to the persistence of a cholecystoenteric fistula are unusual[3,8].

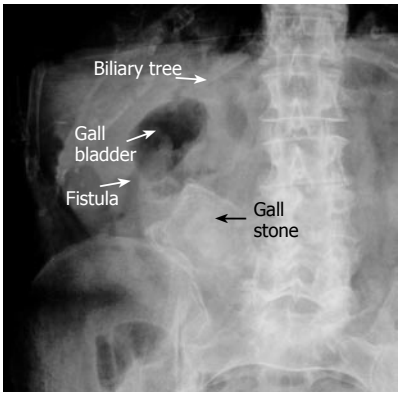

Figure 1 Plain X-ray showing air in the biliary tree and an ectopic bizarre-shaped gall stone suggesting the diagnosis of cholecystoenteric fistula.

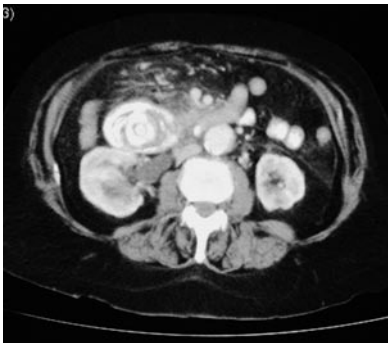

Figure 2 CT abdomen with contrast showing the gall stone in the duodenum with some contrast passing distal to the stone.

Bouveret syndrome is a rare complication of cholelithiasis with a relatively high mortality. In the patient has a pre-operative diagnosis of Bouveret syndrome, endoscopic disimpaction should be attempted. Failing this laparotomy is likely to be required but laparoscopy may allow identification of the stone's position minimizing subsequent skin incision.

Abstract

Intestinal Behcet's disease in a 38-year-old woman was diagnosed because of the history of recurrent oral aphthous ulcers, erythema nodosum-like eruptions, genital ulcer, and endoscopic findings of esophageal and ileocolonic punched-out ulcers with colonic longitudinal ulcers. Esophageal lesions and colonic longitudinal ulcers are rarely seen in intestinal Behcet's disease. The ulcers of esophagus and ileocolon healed with 3 wk of treatment with prednisolone and mesalazine without any adverse effect. Mesalazine may decrease the total dose of prednisolone required to treat the disease.

Key words: Colonic longitudinal ulcer; Esophageal ulcer; Intestinal Behcet's disease; Mmesalazine

INTRODUCTION

In Japan, Behcet's disease, when accompanied by intestinal involvement, is called intestinal Behcet's disease, which primarily affects the terminal ileum, caecum, or ascending colon[1]. However, esophageal aphthous ulcerations and colonic longitudinal ulcers are rare in intestinal Behcet's disease. Intestinal lesions in Crohn's disease tend to be longitudinal ulcers with a cobblestone appearance, while those in Behcet's disease are round and oval "punched-out" ulcers. Moreover, epithelioid granuloma is one of the pathological characteristics of Crohn's disease, whereas it is uncommon in intestinal Behcet's disease. Another feature of Behcet's colitis is lymphocyte venulitis, which is a disorder of vasculitis. Despite these differences, it can be difficult on occasions to make a differential diagnosis between these two diseases. We present a case of intestinal Behcet's disease with esophageal and colonic longitudinal ulcers.

CASE REPORT

The patient was a 38-year-old woman who was admitted to our department in December 2003 for epigastralgia and melena that occurred after transient fever. For the previous two days, she was in good health, except for numerous recurrences of aphthous stomatitis. Physical examinations on admission revealed the presence of multiple oral aphthous ulcers, in addition to slight tenderness in the epigastrium. Ophthalmologic and neurologic examinations showed no remarkable findings despite the presence of erythema nodosum-like eruptions in the bilateral inferior limbs and genital ulcers. Negative results were obtained by a prick test of the skin. Clinical laboratory tests showed the following: white blood cells, 7 830/μL; red blood cells, 360×10^4/μL; hemoglobin, 9.6 g/dL; hematocrit, 29.7%; platelets, 61×10^4/μL; C-reactive protein, 10.9 mg/dL; total protein, 8.6 g/dL; AST, 36 IU/L; ALT, 64 IU/L; LDH, 171 IU/L; and total bilirubin, 0.2 mg/dL. Human lymphocyte antigens were negative for B51, but positive for B52. All bacteriologic examinations of blood, urine, and cultured stool showed negative results. Upper gastrointestinal endoscopy demonstrated small oval and discrete ulcers with reddish margin scattered between the middle and lower parts of the esophagus (Figure 1A). Colonoscopy revealed multiple aphthas and erosions scattered in the terminal ileum (Figure 1B) as well as small aphthas on the ileocecal valve (data not shown). However, punched-out ulcers were not observed on ileocecal lesions. Multiple erosions and ulcers including longitudinal irregular-outlined ulcers were extant in the ascending and transverse colon (Figure 1C). Pathological examination of the endoscopic biopsy specimen showed nonspecific ulceration and no evidence of Crohn's disease could be found.

Figure 1 Endoscopic view of discrete ulcers with reddish margin in the middle part of the esophagus (**A**), multiple aphthas and erosions scattered in the terminal ileum (**B**), and multiple erosions and ulcers including longitudinal irregular-outlined ulcers extant in the transverse colon (**C**).

4[1]	39	Female	+		+	+	Incomplete	Ascending Transverse	Nonspecific colitis	Ileum	Healing Mesalazine	Healing

[1]Case reported here.

In this patient, ulcers were detected in the esophagus, terminal ileum, and ascending and transverse colon, in addition to erythema nodosum-like eruptions in the bilateral inferior limbs and genital ulcers. Based on these findings and the history of recurrent oral aphthous ulcers, the patient was diagnosed as having incomplete type intestinal Behcet's disease.[1] The treatment for this patient was initiated by oral administration of prednisolone (50 g) and mesalazine (1 500 mg daily). Consequently, her symptoms disappeared rapidly, and the results of all clinical laboratory tests were normalized. Upper gastrointestinal endoscopy and colonoscopy performed 3 wk after admission revealed the disappearance of ulcers. Mesalazine was maintained at the same dose, but the dose of prednisolone was gradually decreased to 2.5 mg daily, which was maintained thereafter. However, remission was not obtained until 8 mo.

DISCUSSION

Behcet's disease is characterized by repeated eye, skin and visible mucosal lesions. The prevalence of this disease differs widely among races; the rate is 0.3/100 000 in the United States, but 1/10 000 in Japan[2]. Abdominal complaints also differ among races. Shimizu *et al* reported abdominal pain in 75% of patients with Behcet's disease[3], as noted in the present patient showing epigastralgia.

In Japan, diagnostic criteria for Behcet's disease have been established by the Behcet's Disease Research Committee[1]. Based on these criteria, a diagnosis was made in the present case of incomplete type intestinal Behcet' s disease manifests mainly in the terminal ileum, cecum, and ascending colon, although esophageal lesions are rare and colonic longitudinal ulcers are very rare rather than esophageal lesions. To the best of our knowledge, there are only three existing reports describing intestinal Behcet's disease with longitudinal ulcers (Table 1)[4-6]. Although Lee presumed the cause of the longitudinal ulcers to be multifocal vasculitis, in our case vasculitis was not significant. However, we cannot conclude that the patient had Crohn's disease, because microscopic characteristics of Crohn's disease - that is, chronic inflammation involving all layers of intestinal wall or granulomas - were absent.

In addition, only nine cases including our case of intestinal Behcet's disease with both esophageal and ileocolonic ulcers were reported in English literature[7-13]. One case was of the complete type; 6, the incomplete type; and 2, the suspected type. Three patients had strictures; and 2 had perforation. The treatment of intestinal Behcet's disease is controversial. Surgical treatment was not effective in 1 of the 9 patients (Table 2). However, the esophageal ulcers healed in 6 of 7 patients with medical treatment, including corticosteroids or acid suppressive drugs. Corticosteroids, the major therapeutic agent in this disease, were effective in 3 of the 4 patients. However, they can have serious adverse effects, and their use may be

[1]Case reported here.

associated with colonic perforation.

Sonta *et al* have suggested that mesalazine is effective for treatment of intestinal Behcet's disease[13]. It may decrease the total dose of a corticosteroid required to treat the disease. The esophageal and ileocolonic ulcers in the present case healed 3 wk of treatment with prednisolone and mesalazine without any adverse effect. However, it was reported that the recurrence rate even with medical treatment was 90% in patients with Behcet's disease[14]. The present case has not relapsed for 8 mo with treatment of 2.5 mg prednisolone and 1 500 mg mesalazine. Thus, the post-treatment course of this patient should be followed up carefully.

Abstract

We report the remission of primary gastric lymphoma of the mucosa-associated lymphoid tissue (MALT) type in two immunocompromised pediatric patients. Patient 1, a 14-year-old boy in an immunocompromised state of unknown cause, complained of repeated abdominal pain. Examinations revealed gastric MALT with local invasion and lymph node involvement. Serum anti-*Helicobacter pylori* (*H pylori*) antibody was positive. *H pylori* eradication was abandoned due to its adverse effects. The MALT lesion spontaneously regressed over the next 24 months without any treatment for lymphoma. Patient 2, a 6-year-old boy, underwent cord blood transplantation for the treatment of adrenoleukodystrophy. He was administered immunosuppressants for graft-versus-host disease after transplantation. Nausea and hematochezia appeared and further examinations revealed gastric MALT with *H pylori* gastritis. Treatment consisting of medication for the *H pylori* infection alone eradicated the *H pylori* and completely resolved the patient's MALT lesion, as well. Patients 1 and 2 were followed up over periods of 10 years and 3 years, respectively, without any signs of relapse. In conclusion, gastric lymphoma of the MALT type can be cured by conservative treatment even in immunocompromised pediatric patients.

INTRODUCTION

The stomach is one of the most common sites of extranodal malignant lymphomas. Since the first report by Isaacson and Wright in 1983, the concept of low-grade gastric B-cell lymphomas of the mucosa-associated lymphoid tissue (MALT) type has become widely accepted[1]. Studies from the 1990s have established that the development of low-grade gastric lymphoma of the MALT type is strongly associated with chronic gastritis caused by Helicobacter pylori[2-4]. Low-grade gastric lymphoma of the MALT type occurs commonly in middle and old age but rarely in children[5,6]. The first long-term follow-up of a pediatric patient with *H pylori*-associated gastric lymphoma of the MALT type was reported in 1995[7]. The present report describes the development of primary gastric lymphomas of the MALT type in two pediatric patients in immunocompromised states followed by tumor regression with conservative treatment.

CASE REPORT

Patient 1

A 14-year-old boy complained of repeated abdominal pain. Upper gastrointestinal endoscopy revealed a tumor-like lesion in the stomach and the patient was referred to our hospital. The patient had a history of autoimmune hemolytic anemia at the age of 1 year and measles infection at 2 years. Thereafter, he developed systemic lymphadenopathy and hyper-gamma-globulinemia. He had been administered oral prednine from the age of 5 years onward based on a putative diagnosis of immunoblastic lymphadenopathy.

A tender mass, hen-egg in size, was discovered in the epigastrium upon admission. Endoscopy revealed a polypoid lesion in the posterior wall of the lower corpus of the stomach. The mass was diagnosed as a low-grade gastric lymphoma of the MALT type based on examination of a biopsy specimen (Figure 1). The

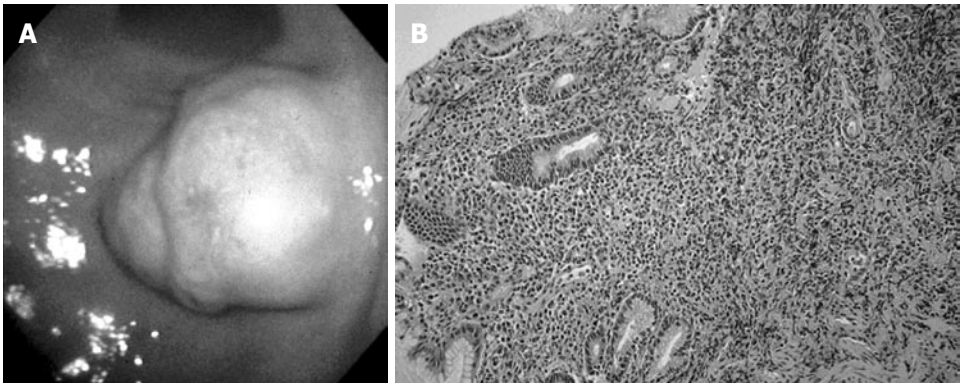

Figure 1 Mucosa-associated lymphoid tissue lymphoma in Patient 1. **A:** A polypoid lesion on the posterior wall of the lower corpus of the stomach, suggesting the existence of lymphoproliferative disease; **B:** The histological features show characteristic appearance of low-grade gastric lymphomas of the mucosa-associated lymphoid tissue type with a diffuse infiltrate of centrocyte-like cells and the formation of lymphoepithelial lesions (H & E, original magnification x10).

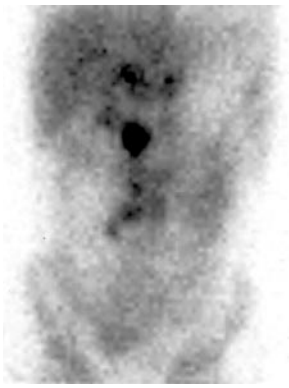

Figure 2 Gallium scintigraphy in Patient 1 shows an abnormal accumulation of the nuclide in the para-aortic lymph nodes.

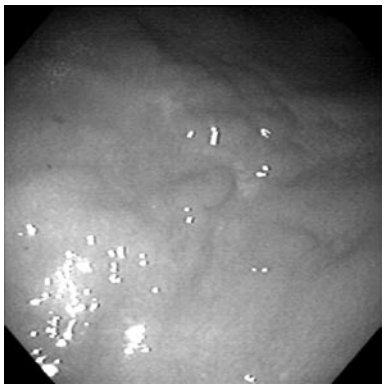

Figure 3 Twenty-four months later, an area of partly whitish rugged mucosa appeared at the site previously occupied by the mucosa-associated lymphoid tissue lymphoma in Patient 1.

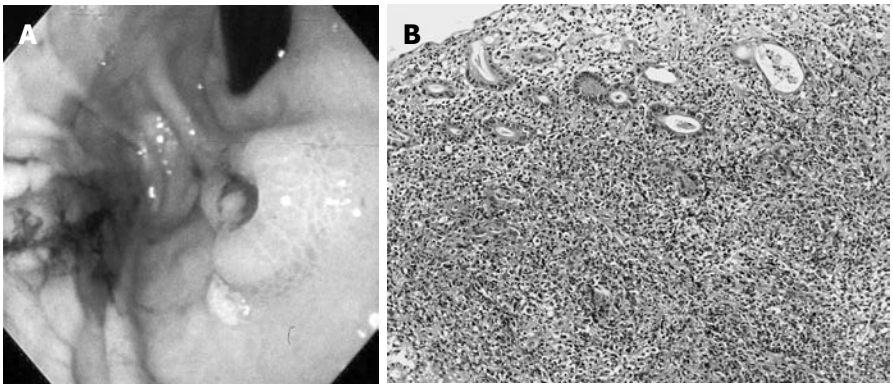

Figure 4 Mucosa-associated lymphoid tissue lymphoma in Patient 2. **A:** An ulcerated lesion on the anterior wall of the upper corpus before eradication; **B:** The histological features show the appearance of low-grade gastric lymphomas of the mucosa-associated lymphoid tissue type similar to that found in Patient 1 (H & E, original magnification x10).

biopsy also confirmed an invasion to the duodenum. Both computed tomography and Gallium scintigraphy strongly suggested metastases to the para-aortic lymph nodes (Figure 2).

Fearing that a complete, en bloc removal of such an advanced tumor would be too invasive in an immunocompromised patient, the authors opted for a watch-and-wait strategy. The patient's serum was positive for anti-*H pylori* antibody, but *H pylori* eradication had to be abandoned due to its adverse effects. Thankfully, the MALT lesion spontaneously regressed over the next 24 mo without any treatment for lymphoma (Figure 3). As the MALT lesion grew less serious, an abdominal pain gradually disappeared. The patient has been followed up for 10 years and continues to do well with no signs of relapse as of this writing.

Patient 2

A 6-year-old boy was referred to our department with a complaint of nausea with hematochezia. He had been diagnosed with adrenoleukodystrophy at the age of 5 years and underwent cord blood transplantation for the treatment of the condition at that time. After the transplantation he was administered oral immunosuppressants, including methylprednisolone and FK506, for graft-versus-host disease.

Upper gastrointestinal endoscopy revealed an ulcerated lesion in the anterior wall of the upper corpus of the stomach. The mass was diagnosed as a low-grade gastric lymphoma of the MALT type associated with *H pylori* gastritis, based on an examination of a biopsy specimen (Figure 4). Neither local invasion nor lymph node involvement was present on diagnostic modalities. When the dosages of the immunosuppressants were tapered he was additionally treated for the *H pylori* infection using a proton pump inhibitor combined with clarithromycin and amoxicillin according to international guidelines[8]. The treatment not only eradicated the *H pylori*, but brought

about a complete remission of the MALT lesion as well (Figure 5). The patient has been followed up for 3 years and continues to do well without any signs of relapse as of this writing.

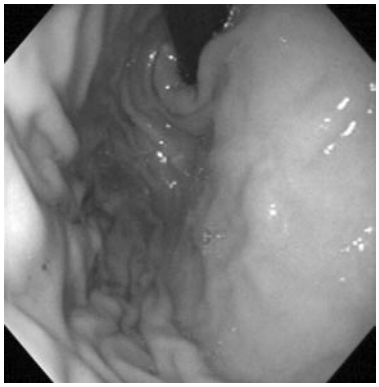

Figure 5 Two months after eradication therapy in Patient 2, an area of glossy whitish mucosa appeared at the site previously occupied by the low-grade gastric lymphoma of the mucosa-associated lymphoid tissue type.

DISCUSSION

Primary low-grade gastric B-cell lymphoma of the MALT type is generally defined as an extranodal lymphoma characterized by an infiltration of the mucosa by centrocyte-like B-cells with formation of lymphoepithelial lesions[9]. Gastric lymphoma of the MALT type is thought to be derived from chronic gastritis caused by *H pylori*[2-4]. *H pylori* infection has been documented in up to 90% of patients with low-grade gastric lymphoma of the MALT type. At first, it has been believed that the MALT acquired in response to *H pylori* infection provides the background on which unidentified factors act and then lead to the development of lymphoma. However, the immune response of B-cell lymphomas of MALT type to *H pylori* antigen is proved to occur only with the presence of T cells on the culture[10,11]. Furthermore, the cellular proliferation of low-grade gastric B-cell lymphomas of MALT type to *H pylori* seems to be dependent on *H pylori*-specific T cells and their products, rather than the bacteria themselves[11]. The inhibitive action against such a mechanism would break down in immunocompromized state so that B-cell lymphomas of MALT type may develop even in *H pylori* infected children.

H pylori eradication is now established to be effective in reducing primary gastric lymphomas of the MALT type and is well accepted as an initial therapy for patients with localized low-grade gastric lymphomas. Remission rates in the recent literature range from 60% to 80%, though recurrence can be expected in some 5% of cases[12-15]. As described above, authors addressed the contributions of the persistent exposure to *H pylori* antigen and the presence of *H pylori*-specific T cells in the pathogenesis of lymphomas of MALT type. With the eradication of *H pylori*, chronic inflammation decreases and the density of submucosal lymphocytes dramatically declines[7]. Thus, the cessation of exposure to *H pylori* antigen due to either the spontaneous cure of *H pylori* or the result of the eradication might progress the tumor regression through the immunologic response.

The major negative predictive factor of tumor response to anti-*H pylori* treatment in patients with primary low-grade gastric lymphoma of the MALT type is involvement of the regional lymph nodes. The depth of the tumor infiltration in the gastric wall correlates with the involvement of the regional lymph nodes and with the degree of tumor malignancy[16-18].

Primary gastric lymphoma of the MALT type has been documented in liver, heart, and kidney transplant recipients[19-22]. The development of these post-transplantation lymphomas of the MALT type appears to be closely related to the abnormal response of the dysregulated host immune system. Post-transplantation lymphoma of the MALT type is also associated with *H pylori* infection and is usually of an Epstein-Barr Virus-negative, B-cell origin. A combination of treatments to minimize immunosuppression and eradicate *H pylori* frees most patients from disease[21-23].

Primary gastric malignant tumors are very rare in children, as are most lymphomas. The majority of primary gastric lymphomas are high-grade non-Hodgkin's lymphomas of B-cell origin. To our knowledge, the literature has not reported significant numbers of primary gastric lymphomas of the MALT type in children[7,24-26]. The clinicopathological features in pediatric cases are considered to be similar to those observed in adults.

In this report we have described the complete remission of primary gastric lymphomas of the MALT type in two pediatric patients under an immunocompromised state. In patient 1, an advanced gastric lymphoma of the MALT type with duodenal invasion and lymph node involvement regressed spontaneously without any treatment. This experience prompts us to question whether regional lymph node involvement is a negative predictive factor of the tumor response, as described above. Anti-*H pylori* treatment with minimization of immunosuppression was satisfactory in our second patient. To the best of our knowledge, patient 2 is the first reported case of primary gastric lymphoma of the MALT type occurring in a post-cord blood transplantation setting.

In conclusion, the authors propose that low-grade gastric lymphoma of the MALT type can be cured by conservative treatment even in immunocompromised pediatric patients. A watch-and-wait strategy combined with *H pylori* eradication and close follow-up should be an option before attempting more aggressive treatments, even in cases with advanced disease.

Abstract

Colonic varices are a very rare cause of lower gastrointestinal bleeding. Fewer than 100 cases of colonic varices, and 30 cases of idiopathic colonic varices (ICV) have been reported in the English literature. Among these 30 cases of ICV, 19 cases were diagnosed by angiography, and 7 operated cases were diagnosed later as ileocecal vein deficit, hemangioma, and idiopathic in 1, 1, 5 cases, respectively. We report the case of a 24-year-old man who suffered from multiple episodes of hematochezia of varying degree at the age of 11 years. He had severe anemia with hemoglobin of 21 g/L. On colonoscopy, tortuously dilated submucosal vein and friable ulceration covered with dark necrotic tissues especially at the rectosigmoid region were seen from the rectum up to the distal descending colon. It initially appeared to be carcinoma with varices. Mesenteric angiographic study suggested a colonic hemangioma. Low anterior resection was done due to medically intractable and recurrent hematochezia. Other bowel and mesenteric vascular structures appeared normal. Microscopic examination revealed normal colonic mucosa with dilated veins throughout the submucosa and serosa without representing new vessel growth. Taken all of these findings together, the patient was diagnosed as ICV. His postoperative course was uneventful.

Key words: Idiopathic colonic varices; Hematochezia; Colon cancer; Hemangioma

INTRODUCTION

Colonic varices, a very rare cause of lower gastrointestinal bleeding, are usually secondary to portal hypertension. It was reported that the incidence of colonic varices is 0.07% (2 of 2912 cases)[1]. One case had liver failure, and the other case had chronic pancreatitis. There are no autopsy data about idiopathic colonic varices. Fewer than 100 cases of colonic varices have been reported[1], and 23 reports containing 30 patients with idiopathic colonic varices (ICV) have been reported in the English literature[2-23]. Diagnosis of idiopathic colonic varices is most accurately achieved by mesenteric angiography[3-19]. But in some cases, operation could reveal secondary causes or changed pathologic diagnosis[18,19,24]. We report a patient whose diagnosis of idiopathic colonic varices was confirmed by the segmental colonic resection.

CASE REPORT

A 24-year-old man was admitted to hospital with exertional dyspnea and weakness. He had a 13-year history of multiple episodes of hematochezia of varying degree. At age 22, he visited our hospital due to dizziness. He denied alcohol consumption, or any family history of gastrointestinal bleeding. He had severe anemia with hemoglobin of 27 g/L. After 2-unit blood transfusion, he refused further investigations or management.

On admission, he was pale with mild tachycardia but had no abnormality on physical examination. Laboratory studies showed 4.93×10^9/WBC, 21 g/L hemoglobin, 0.09% hematocrit, 256×10^9/L platelets, and 22.2 μmol/L iron. Coagulation studies, liver function tests, and viral hepatitis serology were normal. Colonoscopy revealed considerable bluish and tortuously dilated submucosal veins which were seen from the rectum up to the distal descending colon, and friable ulceration covered with dark necrotic tissues

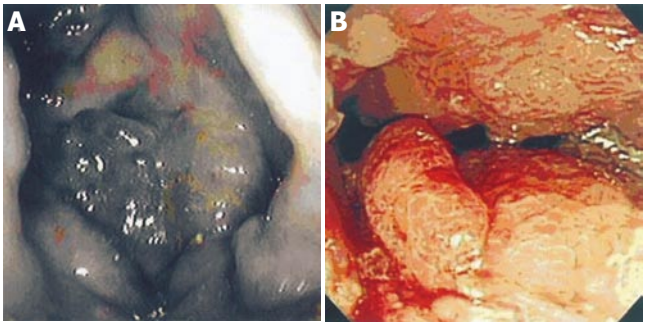

Figure 1 Colonoscopy view of colonic varices at the rectosigmoid region.

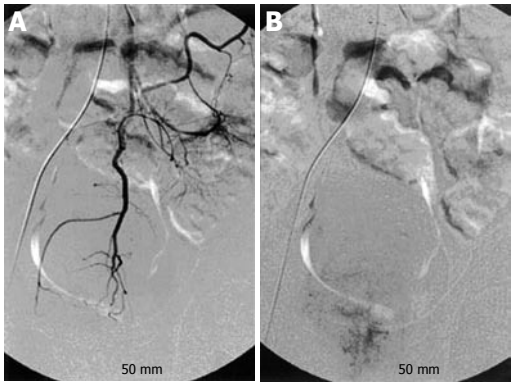

Figure 4 Selective angiography of superior and inferior mesenteric artery showing normal arterial phase (**A**) and venous pooling in rectum in the delayed phase (**B**).

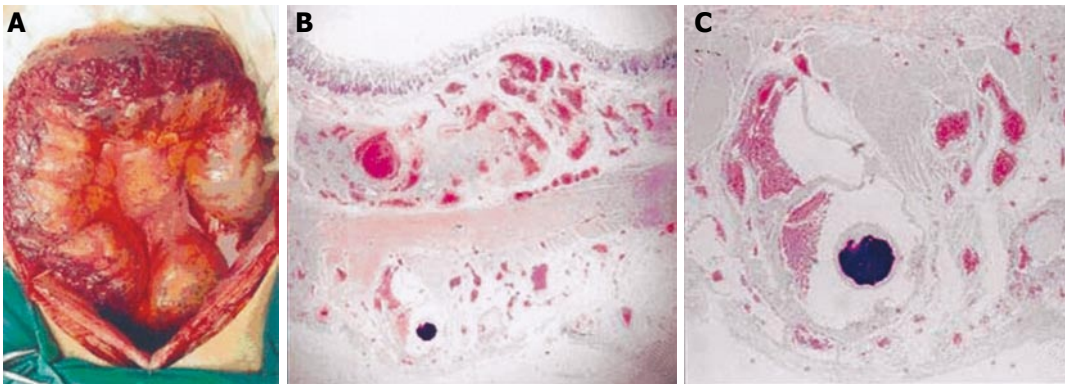

Figure 5 Dilated subserosal veins seen in operation (**A**), great enlarged vessels observed in submucosal and serosal layer at low power, HE×10 (**B**), and distortion of vascular wall found in enlarged vessels at high power, HE×40 (**C**).

especially at the rectosigmoid region (Figure 1). It seemed to be carcinoma with varices. Gastroduodenoscopic examination showed unremarkable finding, without evidence of varices or arteriovenous malformations. Abdominal ultrasonography also revealed no abnormal finding. An abdomen-pelvis triphasic computed tomography showed thickened bowel wall, intramural calcification and delayed enhancement from the rectum up to the descending colon (Figure 2). Transrectal Doppler sonography also demonstrated diffuse wall thickening with internal hypervascular structure (Figure 3). Selective angiography of the superior and inferior mesenteric artery showed delayed venous pooling in rectum but no other abnormal vascular structure (Figure 4). The angiographic diagnosis was a colonic hemangioma.

Low anterior resection was done due to medically intractable and recurrent hematochezia. During surgery, tortuously dilated subserosal and mesenteric vessels were seen at the rectum, sigmoid colon and distal descending colon (Figure 5A). Other bowel and mesenteric vascular structures appeared to be normal. Microscopic examination revealed normal colonic mucosa with dilated veins throughout the submucosa and serosa without new vessel formation (Figures 5B and 5C). In addition, thrombi were frequently observed in the endovascular lumen, and dystrophic calcification was also often found in the wall of vessels. He remained well showing no further signs of gastrointestinal hemorrhage at the time when he was reported in this paper.

DISCUSSION

Colonic varices are a very rare cause of lower gastrointestinal bleeding. Portal hypertension is the most common cause of colonic varices, which are usually located in the rectosigmoid region and the cecum[16]. Other less common causes of colonic varices are congestive heart failure, mesenteric vein thrombosis, pancreatitis with splenic vein thrombosis and adhesions, and mesenteric vein compression[1, 2].

The varix is a descriptive term of enlarged and convoluted vein, artery or lymphatic vessel, which does not indicate the etiology of them. Establishing the diagnosis of ICV amid various factors remains difficult. It needs to exclude secondary causes by laboratory and imaging studies, such as liver function test, hepatitis serology, and liver sonography or computed tomography. Diagnosis of ICV usually requires angiography with visualization of the enlarged vessels showing prolonged observation of the venous phase but no portal/mesenteric vein obstruction[3, 5]. Gross examination and biopsy under laparoscope or exploration can definitely confirm ICV.

We fully reviewed 30 cases reported as ICV. Hemangioma and vascular malformation are described as ICV in some of these reports[2,3,18,19]. But hemangioma has obviously different pathologic findings, and vascular malformation has plainable etiology. So, in our opinion, hemangioma and vascular malformation can be ruled out from ICV. According to these, 21 reports containing 25 patients remain to be idiopathic[4-17,20-23]. In more than half of the cases, the total colon is affected[6-9,14-16,20-22], and in segment-involved cases, the lesions are distributed equally between right and left colon. About 30% of these have familial tendency[8-11,14-16,20,21] and more than half of these manifest the onset of hematochezia before the third decade[9-13,15-17,22], suggesting that ICV may be congenital in origin. But the number of the cases is too small to conjecture the inheritance pattern of ICV. Angiography has been performed in only 19 cases[3-19]. Before angiography, two of these cases, suspected to be ICV, were diagnosed as congenital anomaly of the portocaval system[2] and hemangioma[3]. 7 cases which were surgically confirmed, were diagnosed as congenital failure of ileocecal vein[18], hemangioma[19], and ICV[15-17,19,20] in 1, 1, 5 cases, respectively.

ICV is usually accompanied with recurrent and massive rectal bleeding. It is presumed that bleeding from colonic varices is the result either of abrasion from hard stool in the distal colon, or of pressure ischemia and sloughing of the overlying mucosa in the cecum[16].

The barium contrast enema may be helpful, but is often misinterpreted as air bubble, fecal material, polyposis, carcinoma, or as normal[12]. Therefore, it is unreliable. Colonoscopy is more sensitive, but collapse of varices by excessive air inflation can make the physician to mistake ICV as normal condition. ICV can mimic polyp, cancer, and ulcerative colitis. Biopsy may induce massive hemorrhage[15].

Scintigraphic studies have not been found to be adequate in localizing the segment of colon associated with bleeding varices but can detect hemorrhage with greater sensitivity than angiography[25].

Mesenteric angiography is a most accurate radiologic diagnostic tool, but secondary colonic varices could be misinterpreted as an ICV on angiography. Defreyne *et al*[24] have explained that angiographical diagnosis is in disagreement with the histopathological diagnosis of an arteriovenous malformation probably because the blood passage through the small fistulas is too slow. The same principle can be applied to our case. In about 30% cases, operation revealed secondary causes or changed histopathologic diagnosis as previously described[15-21], suggesting that angiography is an incomplete tool to confirm ICV. Laparoscopy may be a more accurate and definitive diagnostic tool than histology, because histological tissue sampling is very dangerous if not in operation.

The prognosis of ICV seems to be good at all ages compared with cirrhotic varices, which may be related to low pressure in the varices as well as the absence of significant hepatocellular disease[5]. Conservative therapy is sufficient for most ICV patients. Patients with intractable and persistent bleeding may require partial colectomy for involved area.

In conclusion, it is very difficult to diagnose ICV as in our case. The most important thing is to role out secondary causes of varices. In the suspected case, the physician should consider the clinical, radiologic, and surgical information collectively for the proper diagnosis. This case report describes a life-threatening bleeding episode of ICV, mimicking carcinoma in colonoscopy and hemangioma in angiography. ICV can be confirmed by surgical histopathogy, and successfully treated with partial colectomy on involved area.

Abstract

Hydatid disease is caused by the larval stage of the genus *Echinococcus*. Live hydatid cysts can rupture into physiologic channels, free body cavities or adjacent organs. Although hydatid disease can develop anywhere in the human body, the liver is the most frequently involved organ, followed by the lungs. Cysts of the spleen are unusual. There are only five case reports of spontaneous cutaneous fistulization of liver hydatid cysts in the literature. But there isn't any report about cutaneous fistula caused by splenic hydatid cyst. We report a first case of spontaneous cutaneous fistula of infected splenic hydatid cyst.

A 43-year-old man was admitted to our Emergency Service with abdominal pain and fluid drainage from the abdominal wall. He has been suffering from a reddish swelling on the abdominal wall skin for four months. After a white membrane had been protruded out from his abdominal wall, he was admitted to our Emergency Service. On physical examination, a white membrane was seen to protrude out from the 2 cm x 1 cm skin defect on the left superolateral site of the umblicus. Large, complex, cystic and solid mass of 9.5 cm-diameter was located in the spleen on ultrasonographic examination. At operation, partial cystectomy and drainage was performed. After the operation, he was given a dosage of 10 mg/kg per day of albendazole, divided into three doses. He was discharged on the postoperative 10th d. It should be kept in mind that splenic hydatid cysts can cause such a rare complication.

Key words: Hydatid cyst; Cutaneous fistula; Spleen

INTRODUCTION

Hydatid disease is caused by the larval stage of the genus *Echinococcus*. Echinococcosis has a worldwide distribution because of increasing migration and a growing incidence of world travel. It is endemic in many Mediterranean countries, the middle and Far East, South America, Australia, New Zealand and East Africa[1].

The most common form, cystic hydatid disease, is caused by *Echinococcus granulosus*, whereas the alveolar type is caused by *E. multiocularis*. Approximately 70 percent of hydatid cysts are located in the liver and there are multiple cysts in one-quarter to one-third of these cases[2].

Live hydatid cysts can rupture into physiologic channels, free body cavities or adjacent organs[1]. There are only five case reports of spontaneous cutaneous fistulization of liver hydatid cysts in the literature[3-7]. But there isn't any report about cutaneous fistula caused by splenic hydatid cyst.

We report a first case of spontaneous cutaneous fistula of infected splenic hydatid cyst.

CASE REPORT

A 43-year-old man was admitted to our Emergency Service with abdominal pain and fluid drainage from the abdominal wall. He has been suffering from a reddish swelling on the abdominal wall skin for four months. He stated that some hemopurulent drainage was occured from this swelling two months before. He didn't go to any doctor during this period. The drainage was stopped spontaneously in two days. He was no other complaints after that. Two days before, hemopurulent drainage and pain were started again. After a white membrane had been protruded out from his abdominal wall, he was admitted to our Emergency Service. On physical examination, there was a 2 cm x 1 cm skin defect on the left superolateral site of the umblicus (Figure 1). This defect was at a distance of 3 cm to the umblicus. A white membrane was protruded out from this defect. This membrane looked like the germinative memb-

Figure 1 Germinative membrane protruded out from the 2 cm x 1 cm skin defect on the left superolateral site of the umblicus.

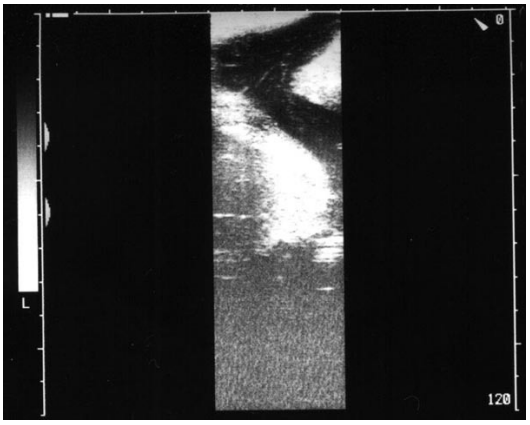

Figure 2 Fistula tract on the anterior abdominal wall.

rane of hydatid cyst. Laboratory findings were as follows; hemoglobin: 11.7 g/dL, white blood count: 18 800/mm^3, platelet: 632 000/mm^3, alkaline phosphatase: 270 U/L, gamma glutamyl trans-peptidase: 51 U/L. Other laboratory findings were normal. Ultrasonography (USG) was the modality of choice for this patient. Large, complex, cystic and solid mass of 9.5 cm-diameter was located in the spleen. Mass showed a complex internal character with multiple floating membranes, echogenic foci due to hydatid sand and heterogenous-echogenic matrix which are characteristic imaging findings for hydatid disease. Mass passed through the anterior abdominal wall from 5 cm-diameter peritoneal defect. Fistula tract on the anterior abdominal wall and cutaneous orifice were also seen (Figures 2 and 3).

At operation, 300 mL purulent material was drained from the subcutaneous tissue after skin incision. The germinative membrane in the fascial defect was taken in the abdomen. Approximately 1.5 liters of infected hydatid cyst material was aspirated from the cyst cavity. On exploration, the cyst was found to be localized in the splenic parenchyma. There were multiple adhesions between the cyst and spleen, liver, stomach and abdominal wall. There was a 5 cm-diameter fascial defect on the lateral side of the left rectus muscle. This was the defect from where the germinative membrane was protruded out of the abdomen. Adhesions were dissected and partial cystectomy was performed. There were splenic fragments in the cyst cavity. The cyst cavity was cleaned and 10% povidone iodine was applied to the cyst wall. Two drains were left in the abdomen; one in the cyst cavity and the other in the left paracolic region. The perforated skin area was debridated but not sutured. After the operation, he was given a dosage of 10 mg/kg/d of albendazole, divided into three doses. He was discharged on the postoperative 10th d. He came to first control three mo after the operation. USG and computerized tomography (CT) examinations together with serologic tests were normal.

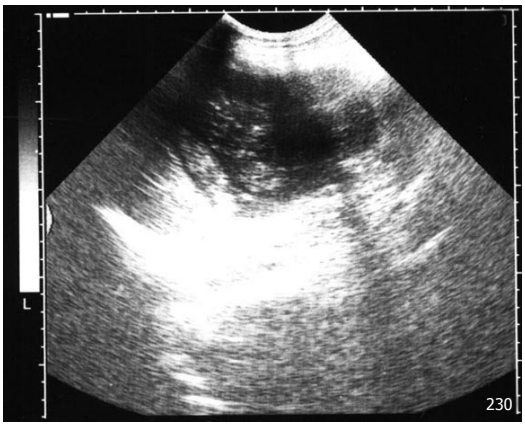

Figure 3 Large, complex, cystic and solid mass located in the spleen.

DISCUSSION

We present the first case of spontaneous cutaneous fistula of infected splenic hydatid disease. The clinical features of hydatid disease depend on the site, size, stage of development, whether the cyst is dead or alive and whether there is a complication or not[1]. Patients with simple or uncomplicated multivesicular cysts are usually asymptomatic. The clinical symptoms are related to pressure on adjacent organs or the presence of complications. Abdominal pain and tenderness are the most common complaints[2].

The hydatid disease can remain symptom-free for years or cause serious complications resulting in death. The main complications are rupture into the peritoneal cavity, infection, compression of the biliary tree, intrabiliary rupture, anaphylaxis, and secondary hydatosis[8].

Intrabiliary rupture represents the most common complication and occurs in 5 to 10 % of cases[2]. T-tube drainage, choledochoduodenostomy and transduodenal sphincteroplasty are effective procedures in the management of intrabiliary ruptured hydatid disease[9-11]. Suppuration, the second most common complication, is caused by bacteria from the biliary tract. Intraperitoneal rupture results in the showering of hydatid fluid, brood capsules, and scolices into the peritoneum; leading to systemic anaphylactic reactions or the development of new hydatid cyst[2,12,13].

Spontaneous cutaneous fistulization is a very rare complication of liver hydatid cysts. There are only five case reports in the literature[3-7]. Two of them are cysto-hepato-bronchial fistula[3,5]. In these cases, liver hydatid cysts were

fistulized simultaneously and spontaneously to the skin and in the bronchia. The other cases were cutaneous fistula of liver hydatid cysts[4,6,7].

A viable hydatid cyst is a space-occupying lesion with a tendency to grow. In confined areas, such as the central nervous system, small cysts cause serious symptoms. In less restricted areas the symptoms depend on the site and size of the cyst. Symptoms may result from direct pressure or distortion of neighboring structures or viscera. The cyst grows in the direction of the least resistance. Another consequence of cyst enlargement is that it can rupture. Live hydatid cysts can rupture into physiologic channels, free body cavites or adjacent organs. The other factor responsible for fistulization of hydatid disease is inflammation. Infection and continued expansion of the cyst causes pressure erosion and adhesion to the adjacent structures. In time, with increasing intracystic pressure, the cyst ruptures. Inflammation leads to necrosis and causes fistulization[1]. In our case, inflammation is probably the main factor of cutaneous fistulization.

Although hydatid disease can develop anywhere in the human body, the liver is the most frequently involved organ (52%-77%), followed by the lungs (10%-40%)[8]. Cysts of the spleen are unusual. Parasitic cysts are usually due to echinococcal involvement, while non-parasitic cysts can be categorized as dermoid, epidermoid, epithelial, and pseudocysts[2]. The spleen is infrequently involved in hydatid disease. Ozdogan *et al*[14] reported that the spleen was involved in 2.5% of all abdominal hydatidosis cases. They suggested that although splenectomy was the conventional treatment, partial cystectomy and omentopexy could be another choice for the treatment of splenic hydatosis.

Splenic abscess is an uncommon cause of splenic abdominal sepsis. Splenectomy is the operation of choice, but some patients have been treated with splenectomy and drainage when there were gross adhesions or the condition of the patient did not permit splenectomy[2]. In our case, we performed partial cystectomy and drainage. Because of dense adhesions and abscess formation, we didn't perform splenectomy. There was no recurrence in abdominal cavity, including spleen, at USG and CT imaging performed 3 mo after the operation. If recurrence occur, we will perform total splenectomy as a second operation.

Benzimidazole carbamates (mebendazole and albendazole) are antihelmintic drugs that kill the parasite by impairing its glucose uptake. Albendazole is the drug of choice because of its better absorption and better clinical results in comparison with mebendazole. Continuous daily treatment for a 3-mo period has better results[13]. We proposed our patient a dosage of 10 mg/kg per day albendazole for 3 mo and a 3-mo period controls.

We reported a first case of spontaneous cutaneous fistula of infected splenic hydatid cyst. It should be kept in mind that splenic hydatid cysts can cause such a rare complication.

ACKNOWLEDGMENTS

Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those were published and those were rejected in this issue) during the last editing period of time.

Minoti Vivek Apte, Associate Professor
Pancreatic Research Group, South Western Sydney Clinical School, The University of New South Wales. Liverpool, NSW 2170, Australia

World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

World J Gastroenterol 2006 April 28; 12(16):2640
World Journal of Gastroenterology ISSN 1007-9327

World Journal of Gastroenterology standard of quantities and units

Number	Nonstandard	Standard	Notice
1	4 days	4 d	In figures, tables and numerical narration
2	4 days	four days	In text narration
3	day	d	After Arabic numerals
4	Four d	Four days	At the beginning of a sentence
5	2 hours	2 h	After Arabic numerals
6	2 hs	2 h	After Arabic numerals
7	hr, hrs,	h	After Arabic numerals
8	10 seconds	10 s	After Arabic numerals
9	10 year	10 years	In text narration
10	Ten yr	Ten years	At the beginning of a sentence
11	0,1,2 years	0,1,2 yr	In figures and tables
12	0,1,2 year	0,1,2 yr	In figures and tables
13	4 weeks	4 wk	
14	Four wk	Four weeks	At the beginning of a sentence
15	2 months	2 mo	In figures and tables
16	Two mo	Two months	At the beginning of a sentence
17	10 minutes	10 min	
18	Ten min	Ten minutes	At the beginning of a sentence
19	50% (*V/V*)	500 mL/L	
20	50% (m/*V*)	500 g/L	
21	1 M	1 mol/L	
22	10 μM	10 μmol/L	
23	1N HCl	1 mol/L HCl	
24	1N H_2SO_4	0.5 mol/L H_2SO_4	
25	4rd edition	4^{th} edition	
26	15 year experience	15- year experience	
27	18.5 kDa	18.5 ku,18 500u or M_r18 500	
28	25 $g.kg^{-1}/d^{-1}$	25 g/(kg·d) or 25 g/kg per day	
29	6900	6 900	
30	1000 rpm	1 000 r/min	
31	sec	s	After Arabic numerals
32	1 pg $\cdot L^{-1}$	1 pg/L	
33	10 kilograms	10 kg	
34	13 000 rpm	13 000 *g*	High speed; *g* should be in italic and suitable conversion.
35	1000 *g*	1 000 r/min	Low speed. *g* cannot be used.
36	Gene bank	GenBank	International classified genetic materials collection bank
37	Ten L	Ten liters	At the beginning of a sentence
38	Ten mL	Ten milliliters	At the beginning of a sentence
39	umol	μmol	
40	30 sec	30 s	
41	1 g/dl	10 g/L	10-fold conversion
42	OD_{260}	A_{260}	"OD" has been abandoned.
43	One g/L	One microgram per liter	At the beginning of a sentence
44	*A*260 nm	A_{260} nm	*A* should be in italic.
	$^bP<0.05$	$^aP<0.05$	In Table, no note is needed if there is no significance instatistics: $^aP<0.05$, $^bP<0.01$ (no note if $P>0.05$). If there is a second set of *P* value in the same table, $^cP<0.05$ and $^dP<0.01$ are used for a third set: $^eP<0.05$, $^fP<0.01$.
45	**F*=9.87, $^§F$=25.9, $^\#F$=67.4	^1F=9.87,^2F=25.9, ^3F=67.4	Notices in or under a table
46	KM	km	kilometer
47	CM	cm	centimeter
48	MM	mm	millimeter
49	Kg, KG	kg	kilogram
50	Gm, gr	g	gram
51	nt	N	newton
52	l	L	liter
53	db	dB	decibel
54	rpm	r/min	rotation per minute
55	bq	Bq	becquerel, a unit symbol
56	amp	A	ampere
57	coul	C	coulomb
58	HZ	Hz	
59	w	W	watt
60	KPa	kPa	kilo-pascal
61	p	Pa	pascal
62	ev	EV	volt (electronic unit)
63	Jonle	J	joule
64	J/mmol	kJ/mol	kilojoule per mole
65	$10\times10\times10cm^3$	10 cm×10 cm×10 cm	
66	N·km	KN·m	moment
67	$x\pm s$	mean±SD	In figures, tables or text narration
68	Mean±SEM	mean±SE	In figures, tables or text narration
69	*im*	im	intramuscular injection
70	*iv*	iv	intravenous injection
71	Wang et al	Wang *et al.*	
72	EcoRI	*Eco*RI	*Eco* in italic and RI in positive. Restriction endonuclease has its prescript form of writing.
73	Ecoli	*E.coli*	Bacteria and other biologic terms have their specific expression.
74	Hp	*H pylori*	
75	Iga	*Iga*	writing form of genes
76	*igA*	IgA	writing form of proteins
77	-70 kDa	~70 ku
