Contrast-enhanced ultrasound (CEUS) versus follow-up examination Of the 62 patients with a negative diagnosis (metastatic disease) on contrast-enhanced sonography, 53 had a follow-up examination 3-6 months after the initial examination. In 47 patients (88.7%) no additional lesions could be found at the follow-up examination. In 3 patients (5.7%) new lesions were found, which turned out not to be metastatic. Only 3 patients (5.7%) showed new metastatic lesions at the follow-up examination which were not diagnosed at the initial CEUS examination. One of these patients also showed no lesion on initial CT and MRI, so that this metastasis initially could not be detected by any of the 3 imaging modalities. In the other 2 patients, CEUS initially detected 5 lesions and 1 lesion respectively, but these lesions were not classified as metastatic and so, based on CEUS alone, the initial diagnosis was false negative. In the first patient (with 5 lesions), CT identified 1 of these lesions as metastasis

with peripheral portal-venous enhancement and MRI with SPIO particles identified 2 lesions as metastases. At follow-up, 3 lesions proved to be metastatic lesions. In the other patient (with 1 lesion), all methods (CT, MRI and CEUS) initially classified the lesion as nonmetastatic, and only at follow-up were 3 metastatic lesions identified. However, even versus the 3-6 mo follow-up, CEUS showed 94.4% correct assessment for nonexistence of metastatic liver disease, demonstrating the suitability of contrast-enhanced ultrasound for follow-up examinations of patients with primary extrahepatic tumors.

Safety and tolerability of the ultrasound contrast agent

The patients received 1-3 bolus injections of 2.4 or 4.8 mL SonoVue®, with a total dose of 2.4 mL (11.2%), 4.8 mL (12.8%), 7.2 mL (41.6%), 9.6 mL (5.6%) or 12.0 mL (28.8%) per patient. Only one adverse event - dry mouth of mild intensity - was reported. Thus the overall adverse event rate per patient in this study was 0.8%.

DISCUSSION

Brightness(B)-mode ultrasonography is highly sensitive and specific in characterizing cysts and calcifications, leading to a definitive diagnosis, but shows several limitations in patients with primary and secondary liver tumors. In addition, some focal lesions have the same echogenicity of normal liver parenchyma leading to false negative findings. To improve the detection of focal liver lesions, ultrasound imaging must also provide information on vascularity, exploiting the differences in blood flow between normal and pathological tissue.

It was recently shown that CEUS using contrast-specific nonlinear high-mechanical-index imaging techniques improves the detection rate of liver metastases in comparison with B-mode ultrasound, achieving a detection rate similar to that reported for computed tomography and magnetic resonance imaging techniques[1,2,4,5,8-9] In these recently published detection studies mainly using Levovist® in the portal venous and liver-specific late phase in patients with known malignancies, additional lesions could be found in 30-55% of patients. Additionally, it was shown that examination techniques employing Levovist® allow differentiation of histologically proven benign and malignant liver lesions. In 79 patients with histologically proven malignant liver lesions and in 95 patients with benign liver lesions it was shown that hypoechoic contrast enhancement in the portal venous or late phase as a predictive sign of malignancy had 100% sensitivity in patients mostly without underlying liver disease. Homogeneous Levovist® enhancement in the portal venous and late phase had 93% specificity as an indicator of benign disease[7]. It should be noted that there were no false negative findings in patients without underlying parenchymal liver disease. Furthermore, a lower interobserver variability was found in contrast-enhanced sonography than in baseline ultrasonography[10]. But there are still some important limitations since contrast-enhanced high-mechanical-index techniques must be performed intermittently and the examination technique is therefore difficult.

The present study employed a new-generation contrast medium (SonoVue®) allowing real-time imaging, providing similar information to the more difficult intermittent imaging technique using Levovist®. This method proved useful in routine application and is easy to learn. Contrast-enhanced sonography using low-mechanical-index techniques with SonoVue® has also proved useful intraoperatively[11] and in conjunction with 3D techniques[12] and additionally may differentiate between adenoma and focal nodular hyperplasia[13]. It was shown that these techniques gave a statistically significant improvement in the accuracy of detection of metastatic disease versus unenhanced sonography. In comparison with baseline ultrasound the number of metastatic lesions increased with a sensitivity comparable to contrast-enhanced triple-phase CT. In two thirds of patients the same numbers of metastatic lesions were found with contrast-enhanced sonography and CT. In the remaining patients, sometimes CT and sometimes sonography found more lesions, with no significant superiority of one method. Since contrast-enhanced sonography was not part of the gold standard this may introduce a possible bias in the calculation of accuracy. There were two patients in whom CEUS found a lesion but CT and MRI did not. One patient (female, 54 years, with breast cancer) had a 29 mm lesion and the other (female, 67 years, with pancreatic cancer) had an 11 mm lesion, which were both non-enhancing in the portal-venous phase. However, owing to the definition of the gold standard both were rated as false positive for CEUS, since no biopsy was obtained for clarification. This illustrates the limitation of such studies comparing imaging methods, since there is no absolute non-invasive gold standard. Additionally, contrast-enhanced sonography has the best specificity and accuracy for detection or exclusion of metastatic disease when compared with unenhanced sonography and triple-phase spiral CT. In 11% of the patients the existence of lesions could be ruled out, indicating the high specificity of contrast-enhanced sonography.

Monitoring of adverse events was mandatory and performed in all patients and demonstrated no relevant reaction, leading to an excellent tolerability of the ultrasound contrast agent.

In conclusion, contrast-enhanced ultrasound in the portal venous and late phase following injection of SonoVue® considerably improves the detection of liver tumors compared with conventional B-mode sonography and is therefore a suitable method for the follow-up of patients with primary extrahepatic cancer.

Abstract

AIM: To evaluate the long-term histological outcome of patients transplanted for HBV-related liver disease and given HBIg prophylaxis indefinitely after LT.

METHODS: Forty-two consecutive patients transplanted for hepatitis B were prospectively studied. HBsAg, HBV-DNA and liver function tests were evaluated in the serum 3, 6 and 12 mo after LT and then yearly. LB was obtained 6 and 12 mo after LT and yearly thereafter. Chronic hepatitis (CH) B after LT was classified as minimal, mild, moderate or severe.

RESULTS: HBV recurred in 7/42 (16.6%) patients after 6-96 mo of follow-up. A hundred and eighty-seven LB were evaluated. Four of 7 patients with graft reinfection, all with unknown HBV DNA status before LT, developed cirrhosis at 12-36 mo of follow-up. Of the 122 LB obtained from 28 HBsAg+/HCV- recipients with no HBV recurrence after LT, all biopsies were completely normal in only 2 patients (7.1%), minimal/non-specific changes were observed in 18 (64.2%), and at least 1 biopsy showed CH in the remaining 8 (28.5%). Twenty-nine LB obtained from 7 patients transplanted for HBV-HCV cirrhosis and remaining HBsAg- after LT revealed recurrent CH-C. Actuarial survival was similar in patients with HBsAg+ or HBsAg- liver diseases.

CONCLUSION: Though protocol biopsies may enable the detection of graft dysfunction at an early stage, the risk of progression and the clinical significance of these findings remains to be determined.

Key words: Liver transplantation; Hepatitis B virus; Liver biopsy; Anti-HBs Immunoglobulins

INTRODUCTION

Hepatitis B virus (HBV)-related liver disease is a common indication for liver transplantation (LT)[1,2]. Before the advent of effective prophylaxis, the rate of HBV recurrence after LT was reportedly more than 90% at one year in viremic patients and around 30% in those who were negative for serum HBV-DNA at the time of LT[3]. The majority of patients with recurrent infection develop progressive liver damage resulting in graft and patient survival rates being reduced to around 50% at 2 years after LT[4,5]. The prevention of HBV recurrence is based on long-term treatment with hepatitis B immunoglobulin (HBIg), with or without lamivudine[1,6-9,10-15]. The major drawback of using HBIg is its high cost, while the efficacy of lamivudine is limited by the onset of drug resistance[13,14,16-18].

The most reliable way to diagnose and establish the severity of any liver disease recurrence is by histological evaluation of the graft. Serial liver biopsies (LB) may identify subclinical histological changes in LT recipients with normal biochemical data and are useful in assessing disease progression during long-term follow-up[19]. At most centers, liver biopsies are performed in patients with graft dysfunction due to HBV reinfection. There is limited experience of protocol biopsies in patients after LT for HBV. The aim of the present study was to evaluate the usefulness of protocol liver biopsies in assessing long-term histological outcome in patients on indefinite HBIg

Table 1 Pre-transplant HBV-DNA in the study population and outcome after liver transplantation

Indication	*n*	HBV DNA		Total recurrence
		Negative	Unknown

Fulminant hepatitis	4		4	

Subgroups of HBV patients (with HDV/HCV coinfection and fulminant hepatitis) showing pre-transplant HBV-DNA status and disease recurrence.

prophylaxis following LT for hepatitis B.

MATERIALS AND METHODS

Study population

From November 1990 to December 2000, 246 adults underwent 268 LT at our center, and 55 (22.3%) of them were hepatitis B surface antigen (HBsAg)-positive. Among the patients with HBV infection, 45 (81.8%) had cirrhosis and 10 (18.2%) had fulminant hepatic failure (FHF). Eight patients with cirrhosis also had hepatocellular carcinoma (HCC), 6 were diagnosed pre-LT and 2 were incidental findings. HBV DNA detection methods became available at our center in August 1991. Since then, patients with HBV-related cirrhosis have only been listed for LT if their serum HBV DNA was negative. HBV DNA was unavailable for 5 cirrhotic patients transplanted before August 1991 and for all patients with FHF. Hepatitis delta virus (HDV) antibodies (anti-HDV IgG) were positive in 14 patients (25.4%), hepatitis C virus (HCV) antibodies in 7 (12.7%). Three patients (5.4%) had a history of alcohol abuse but had all abstained for at least 6 mo before LT. Eleven patients who died within 6 mo of LT (5 with cirrhosis and 6 with FHF) and 2 patients with a follow-up of <6 mo (both with cirrhosis) were excluded from the analysis.

Liver tests and serological/virological tests for HBV, HCV and HDV were obtained for all patients 6 and 12 mo after LT and yearly thereafter. Enzyme immunoassays were used to detect HBsAg (ELISA II Abbott Diagnostics, North Chicago, IL), anti-HDV (ELISA II Abbott Diagnostics) and anti-HCV (ELISA II-III, Ortho Diagnostics Raritan, NJ). Samples positive for anti-HCV were confirmed by recombinant immunoblotting assays (RIBA II, Ortho Diagnostics Raritan, NJ). Serum HCV RNA was investigated by RT-PCR and HBV DNA by chemiluminescence (Digene Hybrid Capture System) in serum samples and by PCR in liver tissue using primers from the conserved region of the surface gene of HBV[20].

Histological analysis

Liver biopsies were performed using a modified Menghini needle (16-17 gauge). Informed consent for liver biopsy was obtained from all patients. Hematoxylin and eosin, periodic acid-Schiff (PAS), van Gieson, reticulin and iron stains were available for all biopsy samples. Immunohistological staining was done for HBsAg and HBcAg.

Chronic viral hepatitis was defined as minimal, mild, moderate or severe according to Scheuer and Desmet[21-23]. Recurrent hepatitis C was graded according to Ishak's classification[24]. Acute and chronic rejection was classified according to Snover's classification[25]. Minimal and not-otherwise-specified changes were defined according to Pappo's classification[26].

HBIg prophylaxis

Patients received 10 000 IU of iv HBIg (VENBIG, Hardis) during the anhepatic phase of LT, daily from days 1 to 7 and weekly for 4 wk following LT. Long-term immunoprophylaxis consisted of weekly doses of 1600 IU of im HBIg (IMMUNOHBS, Hardis) indefinitely. Serum anti-HBs concentrations were investigated weekly before hospital discharge, at 3, 6 and 12 mo after LT and yearly thereafter. Target anti-HBs titers were >400 IU/L throughout the follow-up. HBIg therapy was discontinued in patients who became HBsAg-positive following LT.

Immunosuppression

Immunosuppressive therapy was a combination of cyclosporine or tacrolimus with corticosteroids. Azathioprine or mycophenolate mofetil were added in patients with serum creatinine >200 mol/L. No anti-lymphocyte antibody induction therapy was used. Hist-ologically-proven acute cellular rejection was treated with one or two courses of 1 g/d of iv methylprednisolone for 3 consecutive days.

Antiviral therapy

Lamivudine therapy (100 mg/d) was indicated in patients with detectable serum HBV DNA following LT, with or without reappearance of HBsAg.

Recurrent HBV infection and related liver disease

Recurrent HBV infection was defined as the detection of HBsAg in the serum at any time after LT.

Statistical analysis

The Kaplan-Meier method was used to calculate actuarial survivals and the log-rank test for comparisons between groups.

RESULTS

The study population included 42 patients transplanted for hepatitis B with a mean follow-up of 96 mo.

The overall rate of HBV recurrence was 16.6% (7/42 patients): 18.4% in patients with cirrhosis (7/38) and 0% in cases of FHF (0/4) (Table 1). Among the 38 patients with cirrhosis, the HBV recurrence rates varied according to etiology, pre-LT HBV DNA status and presence of HCC. Graft reinfection occurred in 5/19 patients with pure HBV-cirrhosis (26%), 2/12 patients with HBV/HDV cirrhosis (16.6%) and none of 7 with HBV/HCV-cirrhosis (Table 1). HBV DNA before LT was unavailable in 4 patients, who all developed recurrent infection - as opposed

to only 3/34 (8.8%) with negative HBV DNA ($P=0.013$). Finally, HBV recurred in 2/7 patients (28.5%) with HCC (1 with unknown pre-LT HBV DNA) and 5/31 (16.1%) without HCC: among the 4 patients with unknown pre-LT HBV DNA status, 2 died of recurrent HBV 17 and 44 mo after LT, 1 developed graft cirrhosis after 2 years and 1 had moderate chronic hepatitis with a stable clinical course; the remaining 3 patients with HBV recurrence had undetectable HBV DNA prior to LT and became HBsAg-positive 12, 12 and 14 mo after LT. In the first of these 3 patients, HBV recurrence at 12 mo coincided with de novo HCV infection. Although histology revealed mild chronic hepatitis, it was difficult to differentiate the role of HBV and HCV infection in allograft injury. Protocol liver biopsies showed cirrhosis 3, 4 and 5 years after LT. Now, 9 years after LT, without lamivudine treat-ment (which was not indicated because transaminases always remained within the normal range), the patient has compensated cirrhosis.

The second patient, though non-replicating at the time of LT, had intermittently positive HBV-DNA while on the waiting list. At the time of HBV recurrence, 12 mo after LT, liver biopsy showed mild chronic hepatitis. Lamivudine led to serum HBV DNA clearance after 2 mo of treatment. Repeated liver biopsies 2 and 3 years after LT showed stable, mild chronic hepatitis with focal cytoplasmic HBsAg on immunohistochemistry.

The third patient, who had HDV coinfection, developed mild chronic hepatitis 14 mo after LT and was treated with lamivudine.

Six of 7 patients with HBV-HCV coinfection developed histologically-proven recurrent HCV 12 to 48 mo after LT.

Liver HBV DNA, obtained from the first 11 transplanted patients, was positive in 1 patient who had recurrent positive serum HBsAg.

HBIg administration was well tolerated in all patients and no episodes of immunocomplex syndrome were observed. Mean anti-HBs titers 5 years after LT were 713±314 mIU/mL.

Only 2 of the 7 patients with recurrent HBV received lamivudine treatment because it was unavailable in 1991 and 1992 when the other 5 developed graft reinfection. Both patients were cleared of serum HBV-DNA after 6 mo of lamivudine therapy; they are both still taking the treatment with no evidence of any development of the escape mutants.

Actuarial survival was similar among patients with HBsAg-positive or HBsAg-negative liver disease (Figure 1), while it was significantly lower ($P=0.009$) in patients who had LT for fulminant HBV hepatitis than in those transplanted for HBV cirrhosis, HBV/HDV cirrhosis or HBV/HCV cirrhosis. Moreover, it was not significantly different in patients transplanted for HBV cirrhosis with vs without HCC, despite a decreasing trend in survival 100 mo after LT in patients with HCC (70% *vs* 88%).

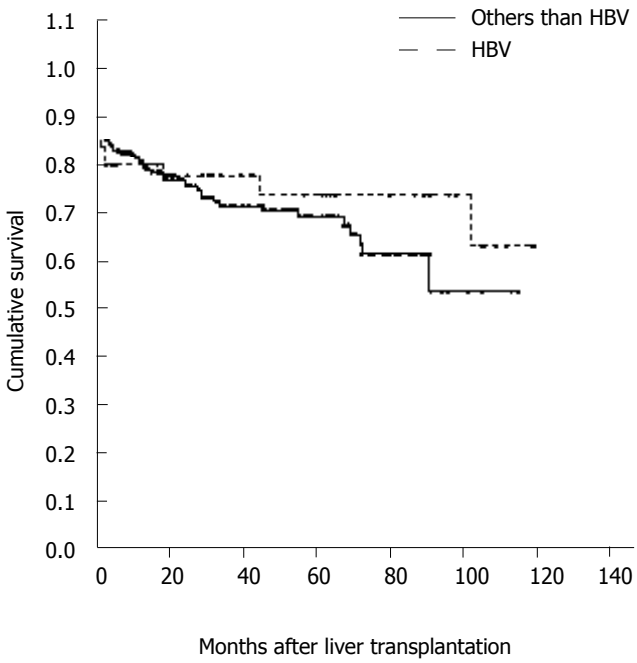

Figure 1 The figure shows the rate of cumulative survival in patients transplanted for HBV-related liver disease (cirrhosis plus fulminant hepatic failure) compared to the survival of patients transplanted for liver diseases of different etiologies. Outlined bar: survival in patients after liver transplantation fot HBV-related liver disease. Plain bar: survival in patients after liver transplantation for non-HBV-related liver disease. The difference is not statistically significant (Kaplan Meier Survival Analysis).

Histopathological features

The results of the 187 protocol biopsies performed were analyzed depending on the patients' HBV and HCV status after LT. A hundred and fifty-eight biopsies were obtained from the 35 HCV-negative recipients (mean 4.5 biopsies per patient; range 1-10) during the 6-96 months of follow-up: 36 from 7 patients with recurrent HBV (5.1 per patient; range 2-10) and 122 from 28 patients with no HBV recurrence (4.3 per patient; range 1-11).

Among the 6 HBsAg+/anti-HCV- patients (there were originally 7, but 1 became anti-HCV+ a year after LT and was consequently included in the HBsAg+/anti-HCV+ group), two had signs of mild chronic hepatitis in all biopsies (follow-up 6-24 mo), and one had at least 1 biopsy showing moderate chronic hepatitis (follow-up 6-96 mo). The other 3 patients, all with HBV-DNA unavailable before LT, developed cirrhosis (two at 12 mo and one at 24) (Figure 2).

As for the 28 HBsAg-/anti-HCV- patients (follow-up for 6-96 mo), biopsies were normal in 2 (7.1%), intermittent, mild inflammatory changes (follow-up for 6-96 mo) were observed in 18 (64.2%), at least 1 biopsy showed mild chronic hepatitis (follow-up for 6-84 mo) in 6 (21.4%) and at least 1 biopsy revealed moderate chronic hepatitis (follow-up for 6-84 mo) in 2 (7.1%). None of the patients in this group had severe chronic hepatitis or cirrhosis. Only 3 patients were HBeAg+ and due to this small number, no biochemical or histological correlations between HBeAg+ and anti-HBeAg+ patients were performed.

The histological features of the 28 patients without HBV recurrence are shown in Table 2. Twenty-nine biopsies in all were obtained from the 7 HCV+/HBsAg- patients during 6-60 mo of follow-up (4.1 biopsies per patient; range 2-6). All 7 patients developed chronic hepatitis with

Table 2 Histological features in anti-HCV negative patients, transplanted for HBV-related liver cirrhosis with no HBV recurrence

Cirrhosis	-	-	-	-	-	-	-	-	

Histological features in 122 liver biopsies performed in 28 anti-HCV negative patients transplanted for HBV-related liver disease with no HBV recurrence. The number of patients considered declined year by year and the total number of liver biopsies performed each year is less than the number of patients per year.

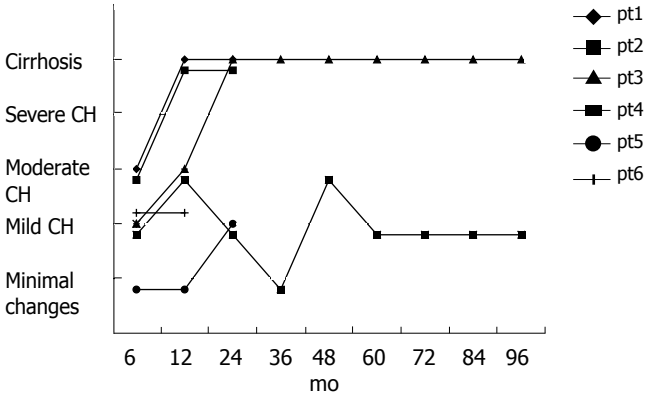

Figure 2 The figure shows the histological damage progression in the 6 anti-HCV negative patients with HBV recurrence.

Table 3 Staging and grading of liver damage in patients transplanted for HBV- and HCV-related liver cirrhosis

Pts	Stage	Grade	Months after transplantation
1	1	4	36
2	2	4	48
3	1	4	24
4	2	10	12
5	0	2	36
6	2	5	12
7	1	2	12

The worst grades and stages were in the 7 HBV/HCV coinfected patients. Staging and grading are based on Ishak's classification [24].

fibrosis 12 to 48 mo after LT (Table 3). The patient with recurrent HBsAg+, who also became anti-HCV positive 1 year after LT, developed mild chronic hepatitis a year after transplantation and cirrhosis 3 years after LT.

Immunohistochemistry was performed on 106/187 (56.7%) liver biopsies. Focal HBcAg positivity was seen in 4/106 (3.7%) biopsies, obtained from 4 HBsAg negative patients, all of them HBV-DNA negative at the time of the biopsy and offering no clue as to the clinical relevance of this finding. Focal HBsAg positivity was seen in only 1 patient with recurrent HBV.

Acute cellular rejection was histologically confirmed in 11/42 patients (26.1%), with a total of 14 episodes (0.33 episodes/patient), 1 to 6 mo after LT; 8 patients had one episode of rejection and 3 patients had two. None of the patients developed steroid-resistant or chronic rejection.

DISCUSSION

HBV-related liver disease is now a common indication for liver transplantation[1,27,28], since graft and patient survival rates are comparable with those of patients transplanted for other conditions[29]. Although perioperative mortality was high in this study, it was unrelated to recurrent HBV infection. Previous studies have shown that the outcome of LT is worse in patients with fulminant HBV hepatitis[30,31] and fulminant non-HBV liver failure[32], as confirmed by our findings. The survival rate was similar, however, between HBsAg positive and negative patients transplanted at our center.

The overall HBV recurrence rate in this series (16.6%) was low and similar to the rate reported in other studies using long-term HBIg monotherapy[14,33-36]. When the analysis was restricted to the cirrhotic cases with negative pre-transplant HBV-DNA, the recurrence rate was even lower (8.8%). These good results confirm that patients without HBV replication before LT and given long-term immunoglobulin prophylaxis are at low risk of recurrent infection, as amply reported elsewhere[5,37-41]. Our study also shows that iv infusions of HBIg are not required beyond the perioperative period; putatively protective levels of anti-HBs (>400 IU) can be obtained using the im route, as reported elsewhere[42-45].

In our series, the rate of HBV recurrence was similar in HBsAg-positive patients with and without HDV coinfection, unlike the situation observed in previous publications[28,46-49], where HDV coinfection was associated with

a lower rate of HBV recurrence and improved survival. Only 2 of our patients with HBV/HDV-cirrhosis developed recurrence, however, and one of them had unknown (but probably positive) pretransplant HBV-DNA.

Similarly, although HBV recurred more frequently in cirrhotic patients with HCC, as in previous publications [50-52], the difference was not statistically significant. In addition, one of the 2 HCC patients with HBV recurrence was intermittently positive for HBV-DNA, while the other had unknown (but probably positive) HBV-DNA pre-LT.

The strength of this study lies mainly in the performance of long-term per-protocol serial liver biopsies, the clinical utility of which is still not clear (though the value of protocol biopsies has recently been confirmed[19,53-55]). The International Liver Transplantation Society Expert Panel Consensus Conference on liver transplantation for hepatitis C considered per protocol biopsies essential: all anti-HCV+ liver transplant recipients should undergo annual liver biopsy to determine histological progression and provide additional data on the natural history of the disease[56].

Among the 28 patients treated with HBIg who remained HBsAg and anti-HCV-negative after LT, only 7% had a completely normal histology up to 3 years after LT. Although the majority of abnormal biopsies showed only minimal inflammatory changes, almost 30% fulfilled the criteria for the diagnosis of chronic hepatitis, as reported elsewhere[26,55]. The features of mild or moderate chronic hepatitis were seen in nearly 1/3 of our cases.

Protocol biopsies obtained from the 7 HBsAg-negative recipients with post-LT HCV re-infection showed recurrent hepatitis C with variable degrees of inflammation and fibrosis. It is worth noting, however, that none of the patients progressed beyond stage 2 fibrosis after a mean follow-up of 36 mo, suggesting that the HBIg preparation used may contain HCV neutralizing antibodies that may attenuate the severity of recurrence, as reported by Feray *et al*[57], but this is a controversial issue because no other papers have confirmed these data since 1990. HBcAg expression was found in the liver tissue of a minority of biopsies from HBsAg-negative recipients, but it was focal and transient. In addition, the finding of HBV-DNA in liver tissue correlated with serum HBV-DNA positivity. Despite the limited number of cases studied, we feel confident in saying that serum assay is clinically useful, whereas tissue HBV DNA should not be investigated because it is expensive and time-consuming. We did not assess HBV genotypes, but it has been recently reported that genotype C seems to be associated with a higher risk of reactivation of hepatitis B and progression to cirrhosis than genotype B[58]. As previously reported, we observed a low rate of acute rejection among patients transplanted for hepatitis B[59-60]. This may be an indirect consequence, at least in part, of the long-term administration of human polyclonal immunoglobulins, which have immunosuppressive properties[59].

In short, this study shows that 25% of patients transplanted for hepatitis B and remaining HBsAg-negative with HBIg prophylaxis develop histological features of mild or moderate chronic hepatitis despite having normal liver test results and negative virological markers[26,55]. These cases will require additional follow-up to estimate the risk of disease progression and further clarify the cause of liver damage. Our findings confirm that normal liver function test results cannot guarantee a healthy graft. The performance of protocol liver biopsies may enable the identification of early histological anomalies potentially capable of progressing to significant liver damage[19,53], but this needs further confirmation.

Abstract

AIM: To our knowledge, the inter-observer variability of the liver biopsy findings in HBV-infected children have not been studied as yet. Hence, we aimed to compare different pathologist's assessment of grading and staging in liver biopsies obtained from children prior to interferon treatment.

METHODS: We collected 920 biopsies from 11 medical centers. The biopsies were independently reviewed by 6 pathologists from academic centers who assessed Batts-Ludwig score for grading and staging. Satisfactory agreement among observers was defined as at least 60% of observers having the same opinion. Satisfactory dispersion between maximal and minimal score for the same biopsy specimen was defined as a maximum 1 point.

RESULTS: Satisfactory inter-observer agreement for grading was obtained in 51.6% and for staging in 75.7% of biopsies. Satisfactory dispersion for grading scores was observed in 44.5% and for staging in 72.7% of cases.

CONCLUSION: Our study demonstrates that: (1) pathologists differ in their assessment of grading and staging of liver biopsies; (2) inter-observer variability for staging is lower than that for grading; and (3) regardless of the inter-observer variability of assessments, the majority of children with chronic HBV infection have mild to moderate inflammation and mild to moderate fibrosis.

Key words: Grading; Staging; Type B Hepatitis; Children

INTRODUCTION

Many authors believe that a liver biopsy is a gold standard in hepatology[1]. However, there is considerable confusion in terminology and the methods of liver biopsy evaluation are still under discussion. These are the reasons why many different scoring systems for liver histological evaluation were proposed. The first scoring system developed by Knodell *et al*[2] has been used in clinical trials since 1981. This classification differentiated necroinflammatory changes and fibrotic liver damage. However, both features were combined in one histological activity index. This was the reason why the Knodell classification was replaced by other systems with clear differentiation between grading of inflammation and staging of fibrosis[3-6]. Nowadays, the scoring systems are widely used by pathologists and clinicians. It often happens that the grading and staging scores replace the descriptive evaluation of biopsy slides. In this situation, one can raise the question: which grading/staging classification is a true gold standard for a liver biopsy assessment? The other issues that can be discussed are results reproducibility and inter-observer variability of the grading and staging scores for the same biopsy. These problems are vital for the clinicians who receive the biopsy reports. However, they are not frequently addressed in the literature.

Table1 The inter-observers agreement definitions

Agreement rate Number of equal assessment/number of observations	Description	Percentage of agreement (%)
6/6, 5/5, 4/4	All observers gave the same score	100
3/4, 5/6, 4/5,	One observer scored differently than others	75-85
4/6, 3/5	Two observers scored differently than others	60-66
3/6. 2/4	Agreement of half of observers	50
2/6, 2/5, 1/4	Agreement of less than half of observers	25-40

We met the problem of liver biopsy interpretation when we analyzed the results of a nationwide program for interferon treatment of chronic HBV infection in children, conducted in Poland between 1993 and 1999. Twenty-six centers from all over the country participated in this program and 3700 children received treatment there. All centers used their local laboratory facilities, but the entry criteria and treatment regime (interferon 3 MU TIW for 20 wk) were the same. The data collected in the local centers was entered into CRF and sent for central analysis. The results published for 1688 children showed 51.5% of HBe clearance at one year after interferon discontinuation. The response was better in younger children and there was a positive correlation with ALT activity[7]. This observation clearly illustrates the problems with liver biopsy result interpretation that are often met by physicians who review the biopsy reports provided by different pathologists.

The liver biopsy specimens could be easily stored in paraffin blocks and as microscopical slides and used for microscopic evaluation many times. These gave us the opportunity to return to the biopsy slides taken from children with chronic HBV infection, treated with interferon in a Polish therapeutic program, and to re-evaluate them according to selected grading and staging classification. Therefore, we asked all participating centers to provide liver biopsy slides for central review. We wanted to see whether the liver biopsies obtained as part of the routine procedure were representative and whether the quality of slides used for diagnosis was satisfactory. We selected scoring system[6] which was used to evaluate the grading and staging of liver damage, and also performed inter-observer variability analysis. The biopsy results were compared with a patient's clinical and serological data to evaluate the role of liver biopsy in the decision-making process regarding children with chronic HBV infection.

The aim of this study was to present the inter-observer variability of liver biopsy assessment performed according to the Batts and Ludwig grading/staging system[6]. The other questions raised in our project will be discussed in further publications.

MATERIALS AND METHODS

The liver biopsy slides taken from 920 children were provided by 11 centers. The number of slides per one biopsy ranged from 1 to 6 (mean 2.36). Hematoxylin-eosin staining were available for all biopsies and for most of them Azan or PAS stains were available as well.

Six independent pathologists, from academic centers, participated in the study. All of them have been collaborating with hepatology units. Before the study was started, the consensus meeting had been organized and Bats-Ludwig liver biopsy assessment scale was chosen for the study as it is widely used in Poland and has a recommendation of Polish Association of the Study of the Liver. Small sample of biopsy slides was reviewed by every pathologist at this consensus meeting and methods of biopsy assessment and results recording were discussed.

The biopsies were divided into sets, which were circulated among observers. The original identification of the biopsies was withheld and pathologists had no additional clinical data on any particular biopsy. Each observer was asked to assess representativity (size of the sample and number of portal zones) and the technical accuracy (fixation and staining) of the slides and to score grading and staging. The assessments were recorded in standard CRF and stored in a central database. For each biopsy, at least four observers' assessments were obtained.

We analyzed the score distribution for every observer and the agreement rate between different observers for the same biopsy (Table 1). Agreement of 60-66% of observers was selected as the desired minimal level of inter-observer agreement.

For each biopsy, the dispersion between maximal and minimal score for grading and staging was calculated. Satisfactory dispersion between maximal and minimal score was defined as being not greater than 1 point.

All biopsies were taken as part of a routine diagnostic procedure and the parents were asked to sign the consent for liver biopsy. This project of biopsy retrospective assessment received the approval from the Ethics Committee of Children's Health Memorial Institute in Warsaw (decision No 185/KE/2000).

RESULTS

Biopsy representativity and technical accuracy assessment

A total of 5 295 opinions on biopsy specimen representativity were available. In 83.9% of the reports, the observers stated that the specimen was representative of the tissue and could be used for grading and staging evaluation. However, the rate of representative specimens varied among different observers from 65.9% to 93.3% (Figure 1). The agreement of at least 60% of observers was reached in 97% of cases (Figure 2).

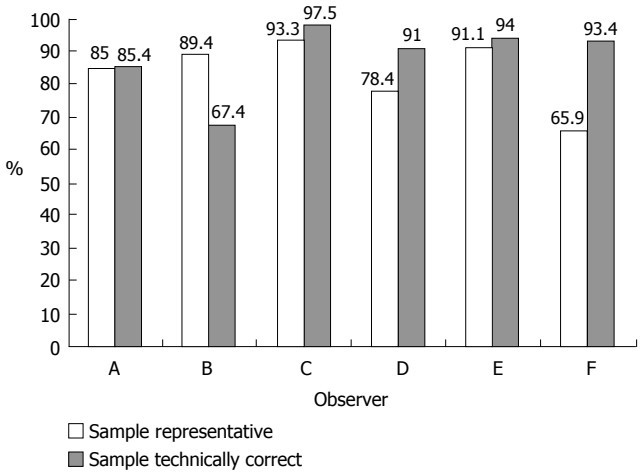

Figure 1 Observers' opinions on representativity and technical accuracy of liver biopsy specimens.

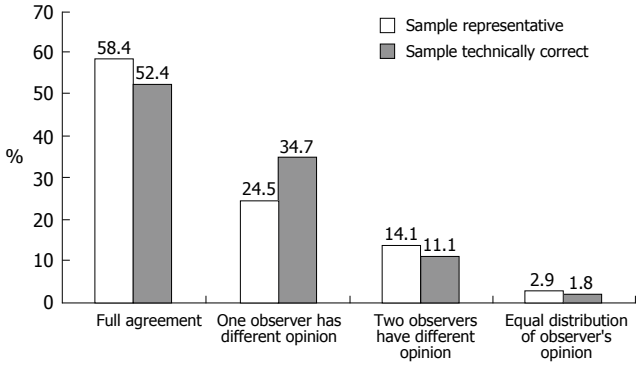

Figure 2 Inter-observer agreement in the assessment of liver biopsy specimen representativity and technical accuracy of the slides.

The opinions on technical accuracy of the biopsy slides were available in 5 296 reports and 88.1% of them showed that the slides were technically correct. The individual observers differed in their opinion on technical accuracy of the biopsy by between 67.4% and 97.5% (Figure 1). The desired level of agreement was reached in over 98% of cases (Figure 2).

Grading assessment

Four or more observers' assessments of biopsy grading were available for 844 biopsies and a total of 4 900 reports were analyzed. The frequency of different scoring varied among observers (Figure 3). The smallest differences in grading score frequencies among observers were noted for a score of 0 (0.3-17.2%, mean frequency for all observers: 8.1%) and 4 (0-7.8%, mean: 4.1%). The largest differences were noted for a score of 1 (13-50%, mean for all observers: 31%) and 3 (4-35.9%, mean: 22%).

The grading assessment agreement of more than 60% of the observers was obtained in 51.6% of cases, but full agreement of all observers reached in only 3.1% of cases. For 13.4% of biopsies, a large difference in observers' opinions was noted (Figure 4)

Different observers' grading score dispersion for the same biopsy equal or lower than 1 point was noted in 44.5% of cases and a dispersion of 2 points was noted in 47.3%. Substantial score dispersion among observers was noted in 8.2% of the cases (Figure 5).

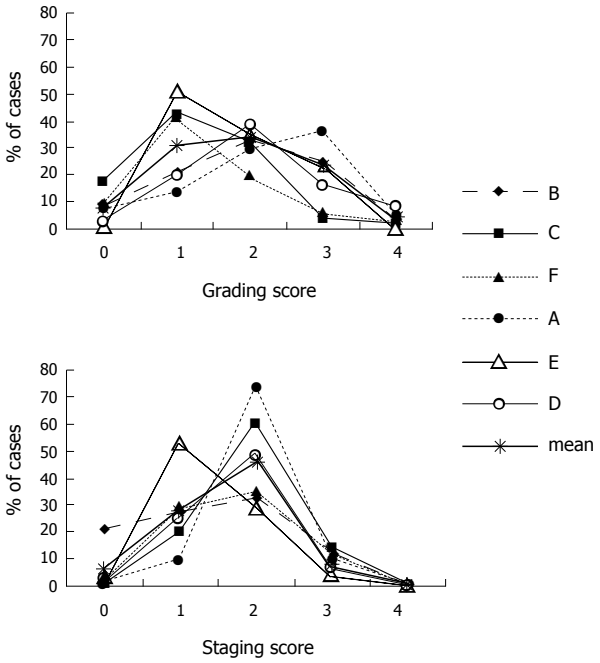

Figure 3 The frequency of different grading and staging scores for individual observer and the mean score frequency for all observers.

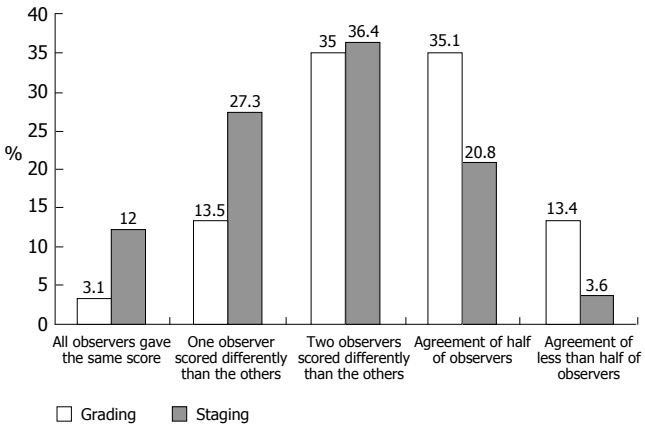

Figure 4 The agreement between different observers' grading and staging score for the same liver biopsy.

Staging assessment

Four or more observers' staging assessments were available for 843 biopsies and a total of 4 895 reports were analyzed. The frequency of different scoring varied among observers (Figure 3). The smallest differences in staging score frequency among observers were noted for a score of 4 (0-0.76%, mean frequency for all observers: 0.4%). The largest differences in score frequency among individual observers were noted for a score of 1 (9.6-52.7%, mean for all observers: 27.1%) and a score of 2 (28.4-72%, mean for all observers: 46.4%).

The staging assessment agreement of more than 60% of the observers was obtained in 75.7% of cases and

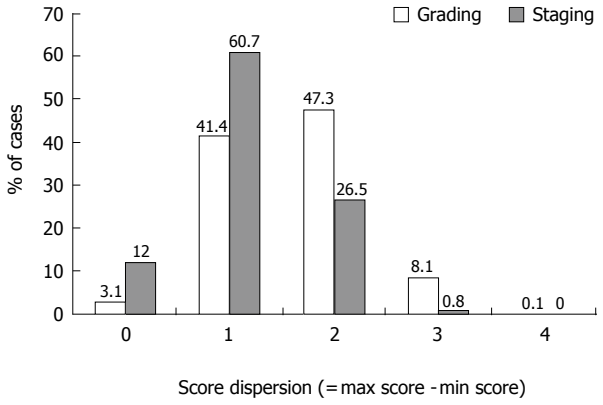

Figure 5 Grading and staging dispersion of assessments among different observers (maximal score - minimal score for the same biopsy).

full agreement of all observers reached in 12% of cases. Substantial differences in observers' opinion were noted in only 3.6% of biopsies (Figure 4).

Different observers' staging score dispersion for the same biopsy equal or lower than 1 point was noted in 72.7% of cases and dispersion of 2 points was noted in 26.5%. Substantial score dispersion among observers was noted very rarely, in only 0.8% of the cases (Figure 5).

DISCUSSION

Liver biopsy is a complex diagnostic procedure performed in many medical centers and evaluated in many laboratories. The aim of the biopsy is to obtain objective information about the condition of the liver tissue. However, there are many factors that influence the objectivity of this examination. Rousselet *et al*[8] have shown that the pathologists' experience is one of the most important factor influencing the inter-observer agreement on viral hepatitis liver biopsy assessment. The other factors that can be taken into account are: the place of liver biopsy sampling; the size of liver biopsy; fixation and staining of the liver tissue specimen; patient's age and reason for liver damage[9].

To our best of knowledge, there are no comprehensive studies addressing the inter-observer variability in liver biopsies taken from children with HBV infection. We, therefore, aimed to investigate the inter-observer error among pathologists who receive a series of biopsies taken in every day practice.

When analyzing the inter-observer variability, one must take into account the definition of agreement. Peutz *et al*[10] showed that the tolerance ±1 point markedly increases the reproducibility of staging results on the Ishak scale. The complexity of assessment scale and number of observers can also influence the variability of diagnoses. Gronback *et al*[11], in their report on a series of 46 liver biopsies analyzed independently by 5 observers, showed that the more complex the scale, the bigger the variability of results. The variability in different pathologists' assessment of the liver biopsy may lead to variability of therapeutic decisions based on liver biopsy reports. Thus, in our study, we compared the results obtained from different pathologists for the same biopsies. To provide a practical value of the results for every day life, we have resigned from sophisticated statistics. The questions that we asked were very simple but vital for the clinician who collaborates with different independent pathologists.

In our biopsy series, we demonstrated that inter-observer variability depended on the scale complexity and agreement cut-off. When the same opinion of at least 60% of observers (≥4 out of 6, or ≥3 out of 5 observers) was used as a cut-off point, the inter-observer agreement for representativity reached 97% and for technical accuracy of the biopsy reached 98%. Even with the higher cut-off, the inter-observer agreements for these two parameters were satisfactory. These positive results could be obtained in a simple scale with a two-option (yes/no) selection[12].

The Batts-Ludwig grading and staging scale is more complex. With the same cut-off as specified above (agreement of at least 60% of observers), the inter-observer agreement for grading reached in 51.6% of cases and for staging 75.7% of cases. A large number of observers was probably the reason why the agreement with the higher cut-off level was very low.

Moreover, a large number of observers was also the reason why the dispersion between the maximal and minimal score for single biopsies was high. In a four-step scale, a maximal difference of 1 point should probably be used as acceptable tolerance. This level of dispersion was achieved for grading in 44.5% of cases and for staging in 72.7%. We found a higher inter-observer agreement and a lower score dispersion for staging than for grading, showing that staging assessment is more reliable and probably more reproducible than grading assessment. This has also been confirmed by other studies[1,8].

The analysis of inter-observer grading and staging agreements and score dispersion showed that despite the same assessment scale being used by pathologists, their reports differed. This is because grading and staging assessments are essentially subjective[13] and this is not a unique situation for liver biopsy only. Similar discrepancies have been reported for other diagnostic techniques in hepatology as well[14]. However, despite the inter-observers variability, the numbers of children with extremely low and extremely high grading or staging were small. Our data showed that the vast majority of children with chronic HBV infection had mild to moderate inflammatory changes and mild to moderate fibrosis. The risk of biopsy-proven HBV-related cirrhosis in this age group is minimal. This observation confirms the clinical observations of Bortolotti *et al*[15] who could not find a progression to liver cirrhosis in children with HBV infection. On the other hand, our data indicated that the chance of completely normal liver tissue in children with chronic HBV infection is small. These observations suggest that the approach to liver biopsy should be changed. Liver biopsy should not be a mandatory examination in all children with active HBV infection, but it should be performed only in selected patients: those with persistently abnormal ALT despite HBeAg clearance, or those with initial signs of liver destruction. In everyday practice, the grading and staging scores should not replace the descriptive biopsy report, as scoring systems are not reliable and they reduce the amount of information on liver tissue. Grading and staging scores become important information in a liver biopsy

report when the series of liver biopsies for the same patient are analyzed for research or follow-up reasons, providing, however, that all the patients' biopsies are reviewed by the same pathologist on the same occasion. It seems important that both clinician and pathologist are aware of the liver biopsy limitations and they closely collaborate with each other.

In conclusion, our study shows that pathologists differ in their assessment of grading and staging of liver biopsy, but the inter-observer variability for staging is lower than that for grading. The majority of children with chronic HBV infection have mild to moderate inflammation and mild to moderate fibrosis. Thus, the value of liver biopsy as a guide for current therapeutic decision in children with chronic HBV infection is limited. The liver biopsies should rather be used as a tool for research or long-term disease dynamics assessment.

Abstract

AIM: To evaluate the effects of betaine on the ethanol-induced secretion of IGF-I and IGFBP-1 using radioimmunoassay and Western blotting, respectively, in primary cultured rat hepatocytes.

METHODS: Hepatocytes isolated from male Sprague-Dawley rats were incubated with various concentrations of ethanol and PD98059 procedures. The hepatocytes were also treated with different doses of betaine (10^{-5}, 10^{-4}, and 10^{-3} mol/L). We measured IGF-I and IGFBP-1 using radioimmunoassay and Western blotting, respectively.

RESULTS: The ethanol-induced inhibition of IGF-I secretion was attenuated by betaine in a concentration-dependent manner in primary cultured rat hepatocytes. At 10^{-3} mol/L, betaine significantly increased IGF-I secretion but decreased IGFBP-1 secretion. In addition, p42/44 mitogen-activated protein kinase (MAPK) activity was accelerated significantly from 10 min to 5 h after treatment with 10^{-3} mol/L betaine. Furthermore, the changes in IGF-1 and IGFBP-1 secretion resulting from the increased betaine-induced p42/44 MAPK activity in primary cultured rat hepatocytes was blocked by treatment with the MAPK inhibitor PD98059. Betaine treatment blocked the ethanol-induced inhibition of IGF-I secretion and p42/44 MAPK activity, and the ethanol-induced increase in IGFBP-1 secretion.

CONCLUSION: Betaine modulates the secretion of IGF-I and IGFBP-1 via the activation of p42/44 MAPK in primary cultured rat hepatocytes. Betaine also alters the MAPK activations induced by ethanol.

INTRODUCTION

Betaine, an organic osmolyte, is a precursor of S-adenosylmethionine (SAMe) in the liver. It has been shown that betaine administration has the capacity to elevate hepatic levels of SAMe and to prevent ethanol-induced fatty liver[1]. Kanbak *et al*[2] reported that betaine protects the liver from ethanol-mediated hepatotoxicity in rats, and it was reported recently that it also protects the liver from ischemia/reperfusion injury, niacin toxicity, CCl_4-, hyperosmolarity-, and ethanol-induced apoptosis.

Alcohol consumption is associated with the nutritional metabolism system, which reduces hepatic glucose production and insulin secretion, and increases protein catabolism and triacylglycerol levels. The liver is predominantly responsible for ethanol metabolism and it appears to be the primary source of blood-borne insulin-like growth factor (IGF)-I. Impairment of hepatic synthesis could be responsible for at least a portion of the alcohol-induced decrease in serum levels of IGF-I. Alcohol can affect various organ conditions, thus alcohol consumption may regulate IGF, IGF binding protein (IGFBP) and the IGF-I receptor, which may be involved in growth disorders. It has been shown that IGFBPs are associated with alcohol metabolism[3,4], and we found recently that alcohol administration not only reduces the level of IGF-I, but also increases the level of IGFBP-1 in rat liver, kidney, and serum[5]. It may also contribute to the metabolic dysfunction that occurs following chronic

alcohol consumption. Acute alcohol ingestion also reduces the level of IGF-I in serum, but promptly increases serum IGFBP-1 levels in human subjects[3]. In a pilot study, we observed a reduction in the level of IGF-I in alcohol-treated primary rat hepatocytes.

Based on these previous results, we can speculate that betaine will affect IGF systems in the liver. However, the effects of betaine on the ethanol-mediated secretions of IGF-I and IGFBP-1 in primary cultured rat hepatocytes remain poorly understood. In the present study, therefore, we investigated the effects of betaine on the ethanol-mediated secretions of IGF-I and IGFBP-1 in primary rat hepatocytes.

MATERIALS AND METHODS

Materials

IGF-I antigen, and IGF-I and IGFBP-1 antibodies were purchased form Gropep (Thebarton, Australia). The mitogen-activated protein kinase (MAPK) inhibitor PD98059 was purchased from New England Biolabs (Beverly, MA, USA), and antibodies against phosphor-p42/44 MAPK, p42/44 MAPK were obtained from Cell Signaling (Beverly, MA, USA). All routine culture media were obtained from Gibco-BRL (Grand Island, NY, USA). Aqualsol, reflection X-ray film, and I^{125} (isotope) were purchased from Dupont-NEN. Immobilon-P polyvinylidene difluoride (PVDF) membranes were purchased from Millipore. Bovine serum albumin (fraction V), glycine, sodium dodecylsulfate (SDS), acrylamide, glycerol, and Tween 20 were obtained from Sigma Co. (St. Louis, MO, USA).

Isolation and culture of rat hepatocytes

Hepatocytes were isolated from male Sprague-Dawley rats weighing 200-300g by a two-step perfusion procedure with 0.5g/L collagenase that has been described previously (Seglen, 1976: Weng and Shukla, 2000). Cell viability, as assessed by exclusion of trypan blue, was 90% ± 5%. Isolated hepatocytes were plated onto collagen-coated plastic culture dishes (60 mm in diameter) at a density of 5×10^4 cells/cm^2 in William's medium E containing 100ml/L fetal bovine serum (FBS) in an incubator with an atmosphere of 50ml/L CO_2. After 3 h, the medium was replaced with FBS-free-Williams medium E and various concentrations of ethanol and PD98059 were carefully added to the cells. The dishes immediately were sealed tightly with parafilm and the cells were incubated in this way for 10-180 min at 37℃.

Cells were rinsed twice with ice-cold phosphate-buffered saline and lysis buffer was added (20 mmol/L HEPES, pH 8.8, 136 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 10 g/L Triton X-100, 10 mmol/L KCl, 2 mmol/L MgCl, 1 mmol/L phenylmethylsulfonyl fluoride, 1 mmol/L sodium orthovanadate, 1 mmol/L dithiothreitol, 1 mmol/L benzamidine, 10-B-glycerophosphate, 10 mg/L aprotinin, 10 mg/L leupeptin, and 1 mg/L pepstatin A). Cell lysates were collected and sonicated for 5 min in a VibraCell ultrasonic processor. After centrifugation of the sonicated samples at 12000 × *g* for 10 min at 4℃, the supernatant was collected and protein concentrations were estimated using a bicinchoninic acid assay kit.

IGF-I radioimmunoassay

Recombinant human IGF-I was iodinated to a specific radioactivity of 5.55 - 11.10 MBq/g with the isotope I^{125} using a modified version of the chloramin-T method (Kodak, NY, USA). The specific activity of the iodinated IGF-I was approximately 2.22 - 4.07 MBq/g protein. The iodination mixture was purified on a Sephadex G-50 column (150 cm) and pre-equilibrated with phosphate-buffered saline (0.1 mol/L, pH 7.4). Serum and tissue IGFBPs were separated using the method of Lee *et al*[6], and IGF-I immunoreactivity was determined using the method of Lee *et al*[7]. IGF-I data are expressed in terms of nanograms of pure human IGF-I per milliliter assuming equal cross-reactivity of rat and human IGF-I in the RIA. Fifty microliters of rat polyclonal IGF-I antibody diluted to 1:1,500 was added to 100 μL of each sample/standard and then incubated for 1 h at room temperature. [^{125}I]-IGF-I (20000 cpm) was then added, and the sample/standard was incubated for an additional 18 h at 4℃. Fifty microliters of horse serum (Sigma) was added to the incubated sample, which was then centrifuged at 3000*g* for 30 min. The supernatant was discarded, and the radioactivity of the precipitate containing bound [^{125}I]-IGF-I was counted in a gamma scintillation counter (Wallac, Finland). All assays were performed in duplicate. Intra- and interassay coefficients of variation for IGFs were 8% and 10%, respectively.

Western blotting

Supernatants were concentrated for 5 h using a Centricon processor (Millipore) at 4℃. Equal amounts of concentrated protein and cell lysates (20-30 μg) were separated on 100 g/L SDS-polyacrylamide gel electrophoresis (PAGE) gels. After electrophoresis, proteins were transferred to a PVDF membrane. The membrane was washed with Tris-buffered saline containing Tween 20 (TBS-T; 25 mmol/L Tris, pH 7.4, containing 137 mmol/L NaCl and 10 g/L Tween-20) and then blocked with TBS-T containing 50g/L nonfat dry milk for 2 h at room temperature. Blots were incubated with antibodies against IGFBP-1 overnight at 4℃ and then incubated with anti-rabbit horseradish peroxidase. After washing, the specific protein band was visualized using an enhanced chemiluminescence detection system (Pierce Chemical, IL, USA). For MAPK blotting, cell lysates were separated on 100 g/L SDS-PAGE and blotted with p-p42/44 MAPK antibody.

Statistical analysis

All experiments were repeated at least three times. The data obtained from this investigation were analyzed using ANOVA and Student's *t* test and are expressed as mean ± SD values.

RESULTS

Regulatory effects of betaine on ethanol-mediated IGF-I and IGFBP-1 secretion

Chronic alcohol treatment is associated with liver and kidney damage. IGF is the major growth factor that is affected by alcohol consumption. Recently, we found that

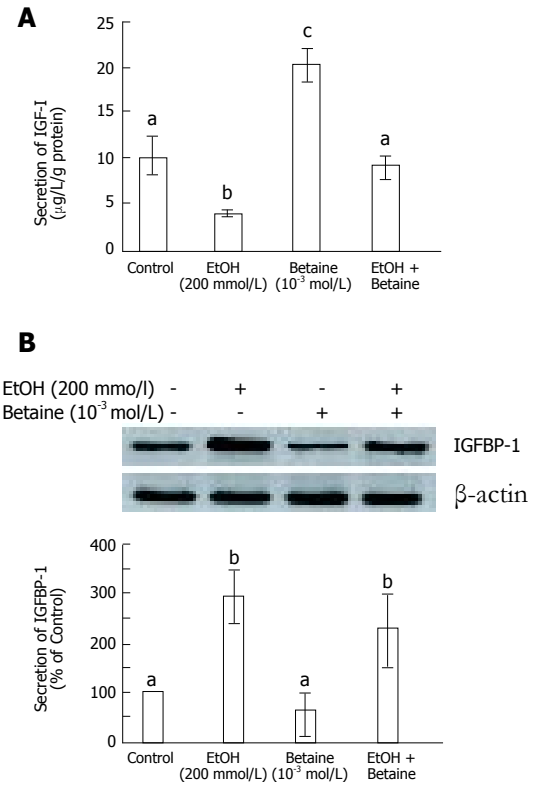

Figure 1 Betaine inhibits the ethanol-stimulated reduction in IGF-I and increases in IGFBP-1 secretion in primary rat hepatocytes (mean ± SD). **A**: IGF-I, **B**: IGFBP-1.

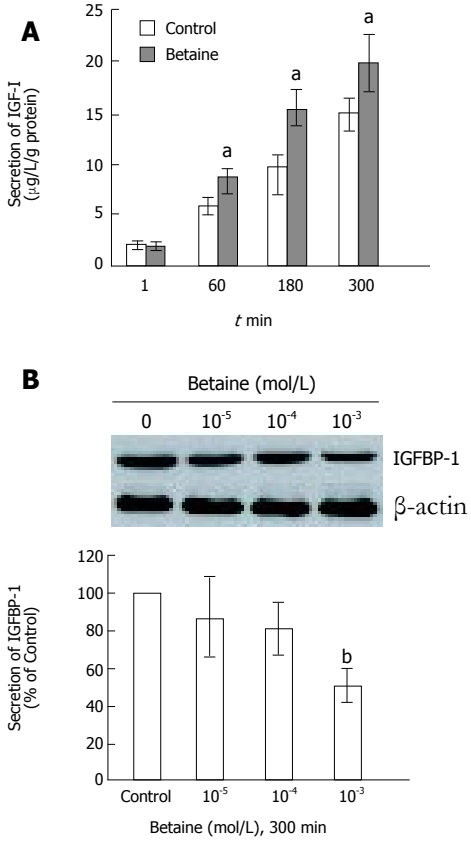

Figure 2 Betaine stimulates IGF-I secretion and decreases IGFBP-1 secretion in primary rat hepatocytes (mean ± SD). **A**: IGF-I, **B**: IGFBP-1. $^{a}P<0.05$; $^{b}P<0.01$ *vs* control.

alcohol reduces the level of IGF-I and increased that of IGFBP-1 in the serum, liver, and kidney of Sprague-Dawley rats[5]. To examine the possible effect of betaine, an osmolyte, on the regulation of alcohol-stimulated IGF-I and IGFBP-1 secretion, we measured the secretion of IGF-1 and IGFBP-I after cotreatment with betaine (for 300 min) and alcohol (for 180 min) in primary cultured rat hepatocytes. Whereas the secretion of IGF-I was significantly reduced by alcohol treatment alone, co-treatment with betaine resulted in IGF-I secretion being maintained at control levels (Figure 1A, $P<0.05$). In addition, betaine reduced alcohol-stimulated IGFBP-1 secretion (Figure 1B). Taken together, these results suggest that betaine ameliorates the alcohol-mediated secretion of IGF-I and IGFBP-1 in primary cultured rat hepatocytes.

Effects of betaine on IGF-I and IGFBP-1 secretion in primary rat hepatocytes

To evaluate the modulatory effects of betaine, we examined its effect on IGF-I and IGFBP-1 secretion in primary rat hepatocytes. Confluent cells were treated with 10^{-3} mol/L betaine for the times indicated in Figure 2. Supernatant was removed and the levels of IGF-I were measured by RIA (Figure 2A). The secretion of IGF-I increased significantly with increasing time after betaine treatment (Figure 2A, $P<0.05$ *vs* Control). To examine the effect of betaine on IGFBP-1 secretion, rat hepatocytes were treated with the concentrations of betaine indicated in Figure 2B for 300 min, and secretion of IGFBP-1 was monitored. Betaine decreased IGFBP-1 secretion in primary rat hepatocytes in a dose-dependent manner (Figure 2B). In summary, IGF-I secretion was significantly increased by betaine treatment, whereas IGFBP-1 secretion was decreased.

Involvement of MAPK in the betaine-induced stimulation of IGF-I and reduction of IGFBP-1 secretion.

To determine the molecular mechanism by which betaine stimulates IGF-I and reduces IGFBP-1 secretion in rat hepatocytes, we examined the involvement of MAPK. The effects of phosphorylation of p42/44 MAPK on the secretions of IGF-I and IGFBP-1 were monitored for 300 min after treatment with betaine alone (10^{-3} mol/L) and with betaine (10^{-3} mol/L) after pretreatment with PD98059 (10 μmol/L). Pretreatment with PD98059 not only significantly decreased betaine-stimulated IGF-I secretion (Figure 3A), but also attenuated the betaine-induced reduction in IGFBP-1 secretion (Figure 3B).

Given the effects of PD98059 on IGF-I and IGFBP-1 secretion, we performed an immunoblot analysis with antibody binding to phosphorylated MAPK 1/2 molecules. Whole lysates of cells treated with betaine were subjected to 100 g/L SDS-PAGE and blotted with phospho-p44/42 MAPK. The phosphorylation of MAPK 1/2 was increased at 60, 180, and 300 min after betaine stimulation, reaching a maximum after 300 min (Figure 4A). Betaine stimulated the phosphorylation of p42/p44 MAPK in a dose-dependent manner (Figure 4B). A significant ($P<0.05$) phosphorylation of p42/p44 MAPK was observed at a betaine concentration of 10^{-3} mol/L compared with the

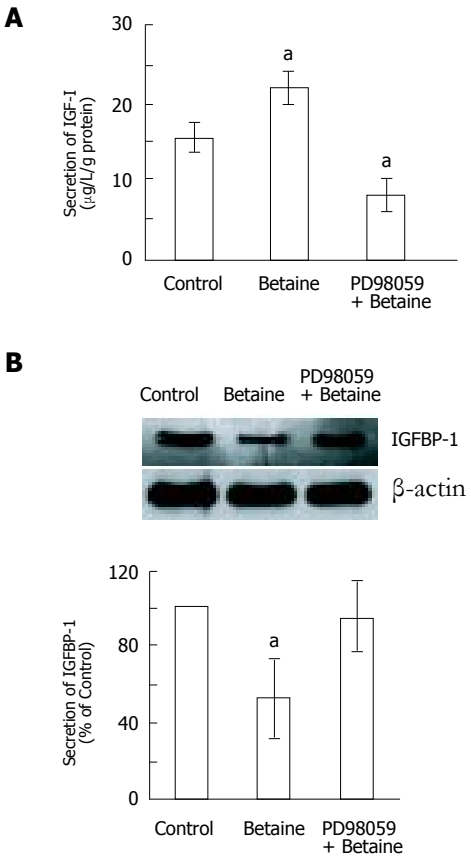

Figure 3 PD98059 attenuates the stimulation of IGF-I and attenuation of IGFBP-1 secretion effected by betaine (mean ± SD). **A**: IGF-I, **B**: IGFBP-1. $^{a}P<0.05$, *vs* control.

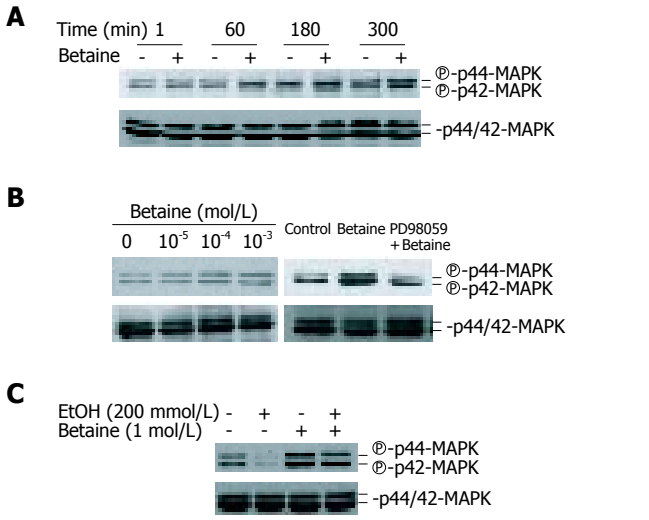

Figure 4 Betaine stimulates the phosphorylation of p42/44 MAPK in primary rat hepatocytes. **A**: Time-dependent activation of p42/44 MAPK by 10^{-3} mol/L betaine, **B**: Dose-dependent activation of p42/44 MAPK by betaine for 300 min (left panel). Treatment with betaine following pretreatment with PD98059 for 10 min (right panel), **C**: Betaine-stimulated recovery of p42/44 MAPK activation in ethanol-treated cells.

control (Figure 4B). Western blot of anti-phospho-MAPK was then reprobed with a specific antibody for MAPK 1/2. The resulting bands coincided with the immunoreactive bands of MAPK 1/2 (Figure 4B). Betaine ameliorated the activation of MAPK, although alcohol treatment inhibited the basal phosphorylation of p42/44 MAPK (Figure 4C). The effect of betaine on MAPK activation was also monitored at 300 min after treatment of the hepatocytes with betaine (10^{-3} mol/L); betaine induced the activation of p42/44 MAPK.

DISCUSSION

Alcohol abuse is associated with deleterious effects on several organs of the body, particularly the liver and brain[8]. Alcohol-induced liver damage is one of the major causes of morbidity and mortality among alcoholics, exposure to ethanol leading to both short- and long-term changes in liver function. Ethanol alters hepatic carbohydrate and lipid metabolism, as well as the synthesis of protein and DNA, which leads to liver dysfunction and cirrhosis[9]. The mechanisms and mediators underlying this liver injury, however, are not clearly understood. Kanbak *et al*[2] reported that betaine protects the liver from ethanol-mediated hepatotoxicity in rats, and it was reported recently that betaine also protects the liver from ischemia/reperfusion injury, niacin toxicity, and CCl_4-, hyperosmolarity-, and ethanol-induced apoptosis.

In the present study we found that the secretion of IGF-I, which is inhibited by ethanol, is increased by treatment with betaine, whereas that of IGFBP-1, which is increased by ethanol is reduced by betaine. It has been reported recently that lipid peroxidase activity is involved in the effects of ethanol on the secretions of IGF-I and IGFBP-1, but the underlying mechanism remains to be elucidated[10]. It has also been reported that acute ingestion of ethanol raises the plasma levels of IGFBP-1 in normal subjects[3,11]. Intake of ethanol influences the bioavailability of IGF-I in normal individuals. Barak *et al*[1] has shown that betaine, which is a naturally occurring substance, may be used as a protective agent against hepatotoxic substances such as ethanol and CCl_4. It may prevent the generation of reactive oxygen species in hepatocytes that results from treatment with ethanol, which is thought to be responsible for attenuation of IGF-I and increase in IGFBP-1 secretion.

This study also aimed to determine whether changes in IGF-I and IGFBP-1 secretion induced by betaine involve signal transduction in hepatocytes. Dose-dependent influences of betaine on the secretion of IGF-I and IGFBP-1, and on MAPK activity were observed. A significant increase in the secretion of IGF-I, a decrease in the secretion of IGFBP-1, and a significant increase in the phosphorylation of p42/p44 MAPK were observed 300 min after treatment with 200 mmol/L ethanol. The activation of p42/44 MAPK was blocked by the MAPK inhibitor PD98059 (10 μmol/L), and this greatly influenced the secretion of IGF-I and IGFBP-1.

In conclusion, the modulation of hepatocyte secretion of IGF-I and IGFBP-1 by betaine involves alteration of p42/44 MAPK activity; betaine may prevent ethanol-induced changes in IGF-I and IGFBP-1 secretion in hepatocytes.

Abstract

AIM: To determine by brain functional magnetic resonance imaging (fMRI) whether cerebral processing of non-visceral stimuli is altered in irritable bowel syndrome (IBS) patients compared with healthy subjects. To circumvent spinal viscerosomatic convergence mechanisms, we used auditory stimulation, and to identify a possible influence of psychological factors the stimuli differed in their emotional quality.

METHODS: In 8 IBS patients and 8 controls, fMRI measurements were performed using a block design of 4 auditory stimuli of different emotional quality (pleasant sounds of chimes, unpleasant peep (2000 Hz), neutral words, and emotional words). A gradient echo T2*-weighted sequence was used for the functional scans. Statistical maps were constructed using the general linear model.

RESULTS: To emotional auditory stimuli, IBS patients relative to controls responded with stronger deactivations in a greater variety of emotional processing regions, while the response patterns, unlike in controls, did not differentiate between distressing or pleasant sounds. To neutral auditory stimuli, by contrast, only IBS patients responded with large significant activations.

CONCLUSION: Altered cerebral response patterns to auditory stimuli in emotional stimulus-processing regions suggest that altered sensory processing in IBS may not be specific for visceral sensation, but might reflect generalized changes in emotional sensitivity and affective reactivity, possibly associated with the psychological comorbidity often found in IBS patients.

Key words: Visceral hypersensitivity; Irritable bowel syndrome; Brain processing; fMRI; Auditory stimulation; Emotion

INTRODUCTION

Visceral hypersensitivity has been shown to play a pathogenic role in the irritable bowel syndrome (IBS)[1,2]. At least in a subgroup of patients, this might be caused by altered brain processing of visceral sensation as has been suggested on the basis of brain imaging studies. Another important characteristic of IBS is the extraintestinal comorbidity. There is a high prevalence of non-gastrointestinal functional diseases, such as fibromyalgia or chronic fatigue syndrome, and also psychological disorders, such as depression and anxiety[3,4]. The frequent co-occurrence of these different disorders on the one hand, and the impact of psychological factors on all of them on the other hand[5], leads to the question whether these disorders might share a common pathogenesis such as a generalized increase in emotional and sensory sensitivity that could be involved in the alterations of sensory brain processing observed in these disorders[6-9].

Indeed, there is some evidence that altered cerebral

response patterns in IBS may not be specific for gastr-ointestinal stimuli. In patients with IBS and concomitant fibromyalgia, alterations in the central processing of painful somatic stimuli have been observed[7]. Moreover, even IBS patients without a manifest fibromyalgia may exhibit a somatic hypersensitivity with altered cerebral processing of somatic sensation[10]. These forms of somatic hypersensitivity, which are in contrast to earlier descriptions of somatic hyposensitivity states in IBS, are caused by viscerosomatic convergence mechanisms. The latter are thought to occur, because visceral and somatic sensations are both passed through the dorsal root ganglia and the dorsal columns of the spinal cord, where neural interactions have been described[11]. Therefore,any peripherally generated visceral hypersensitivity could subsequently induce a somatic hypersensitivity in the corresponding somatic dermatoma, and altered cerebral response pattern to somatic stimuli would actually reflect increased sensory input from the periphery. However, further support for cerebrally located processing alterations in IBS is provided by two studies demonstrating an increased reactivity of event-related potentials to auditory stimuli in IBS patients[12,13]. Since auditory stimuli are transmitted directly to the brain via the eighth cranial nerve, there is no peripheral connection to visceral sensory input and changes in the central reactivity could be allocated directly to the sensory processing circuits of the brain.

With this study, we aimed to test the hypothesis that IBS patients differ from healthy controls in the cerebral processing of non-visceral stimuli, detected by functional magnetic resonance imaging (fMRI). To be able to focus on the cerebral processing level, we chose auditory cues as non-visceral stimuli. The specific aims were 1) to analyze by fMRI the cerebral response patterns to non-visceral, auditory stimuli in IBS patients compared with healthy controls, and 2) to evaluate whether different brain responses are influenced by the emotional impact of the stimulus.

MATERIALS AND METHODS

Subjects

Eight right-handed patients with IBS [five females, three males; mean age, 41.3 (27-64) years; diarrhea-predominant, $n=5$, alternating stools, $n=3$] established by Rome II criteria [14] were recruited at our institution's outpatient clinic for gastrointestinal functional disorders. To exclude other causes for bowel symptoms, all patients had undergone a thorough work-up including laboratory tests, stool analysis for bacterial, fungal, or parasite infection, abdominal ultrasound, colonoscopy, lactose- and fructose hydrogen breath test. Moreover, a rectal sensitivity testing by computerized barostat was performed. The mean individual perception threshold of first sensation of the rectal barostat distension was 16.4 mmHg (SD 6.2). None of the patients had previous abdominal surgery and all patients had symptoms for more than 1 year. None of the patients used centrally acting agents to treat bowel symptoms, and peripherally acting IBS treatments were stopped 7 d prior to the study. As controls, 8 right-handed healthy volunteers [5 males, 3 females; mean age, 39.4 (24-54) years] were selected after exclusion of individuals with concomitant or previous GI-disorders by history and the IBS symptom score-questionnaire [15]. In all subjects, written informed consent as approved by the institutional ethical committee was obtained, and concomitant psychiatric disorders were excluded by using the standardized German Diagnostic Interview for Psychiatric Disorders (DIPS[16]), a structured clinical interview based on the Anxiety Disorders Interview Schedule[17].

Personality-questionnaires

For the assessment of personality characteristics, all study participants were asked to fill in the following questionnaires: The German form of the State-Trait-Anxiety-Inventory (STAI)[18] for the assessment of depression, neuroticism and complaints, the German form of the Beck's Depression Index (BDI)[19] for the assessment of depression, and the German form of the NEO-Five-Factor-Inventory (NEO-FFI)[20] for the assessment of neuroticism, openness to experience, extroversion, agreeableness, and conscientiousness.

Stimulation protocol for MRI-scanning

We used a block design of four auditory stimuli of different emotional impact: an unpleasant peep (a sound of 2000 Hz), pleasant sounds of chimes, words with emotional impact and neutral words. The part of the protocol using neutral words had served as a neutral, non-visceral control stimulus, in a previous study investigating visceral stimulation[21]. All words were chosen from a list of words that had been evaluated as neutral or emotional by a group of 20 healthy volunteers. The stimulation paradigm had been evaluated in event-related potential studies for patients with psychosomatic disorders. The stimulation phases of 48 s each were separated by resting phases and applied in the following order: peep, chimes, neutral words, chimes, emotional words, neutral words, peep.

MRI acquisition

Magnetic resonance images were collected on a 1.5 T whole body scanner (Siemens Magnetom Vision, Erlangen, Germany) with a standard head coil. A vacuum pad was used to minimize head movements. First, a T1-weighted localizer scan was recorded. Next, T2-weighted oblique scans were obtained (TR/TE 4500/128 ms, field of view 230 mm), primarily to aid Talairach transformation for data analysis. For the functional scans, an echo-planar sequence (TR/TE 4000/66 ms; flip angle 90 degrees; field of view 230 mm; matrix 128 × 128; slice thickness 6 mm, interslice gap 0.6 mm; in-plane resolution 1.8 mm × 1.8 mm) was used. One hundred and twenty images per slice were acquired. Sixteen slices adjusted at a transverse-to-coronal angle of approximately 20° covering the whole brain with the exception of the most superior frontal and superior parietal lobe, inferior temporal pole, and cerebellum (most superior z about 60 and most inferior z about -25 according to Talairach and Tournoux[22]) were obtained for all studies. Structural 3D data sets were acquired using a T1-weighted sagittal sequence with isotropic voxels (TR/TE 11.4/4.4 ms; flip angle 15 degrees; number of slices

Table 1 Personality characteristics (mean ± SD)

Personality test	Control	IBS	IBS *vs* control	Reference-population [18-20]
STAI X2	34.8 ± 6.1	41.3 ± 11.0	$P = 0.17$	35.7 ± 9.4

STAI=State-Trait-Anxiety-Inventory, with X2=Trait-Anxiety Subtest, BDI= Beck's Depression Index, NEO= NEO-Five-Factor-Inventory

160, matrix 256 × 256, field of view 256 mm, voxel size 1 mm3).

Data analysis

For data analysis we used the Brainvoyager® software (Brain Innovation B.V, Postbus, Maastricht, Netherlands). The 2D functional data were reconstructed within the 3D structural data set. The 3D-data were then transformed into the standardized Talairach spaced brain[22]. Finally, the reconstructed data set underwent subsequent procedures of motion correction, intensity scaling and detrending.

Statistical maps were constructed using the general linear model module of the Brainvoyager software. The stimulation conditions were used as predictors, and the contrasts of each stimulation condition versus rest were analyzed. For the between group comparison, predictors were defined for each stimulus type as the interaction of the group with this stimulus type. Therefore, each predictor represented a larger signal increase of one group at the referred stimulus type.

Activated clusters were only accepted if they showed highly significant ($P < 0.001$) activation increase. In order to correct for multiple comparisons, a minimal cluster size of 6 voxels was defined.

Definition of regions of interest (RoI)

As regions of interest (RoI) for the data analysis (Table 2), we selected brain areas known to be involved in emotional processing[23]. All regions were neuroanatomically predefined by an expert neuroradiologist according to the coordinates of Talairach *et al*[22], and according to neuroanatomical visualization.

RESULTS

Subject characteristics

The personality traits were not significantly different between IBS patients and healthy controls. Results are summarized in Table 1. Descriptively, IBS patients had higher values for anxiety ($P = 0.17$), depression ($P = 0.19$) and neuroticism ($P = 0.11$) relative to healthy controls (Table 1).

Group analysis-auditory stimulation

Both groups responded to all stimuli with a significant activation ($P < 0.001$) in the auditory cortex, with a higher signal response to the word processing stimulus conditions and in the speech processing areas for the word stimulations (data not shown). With regard to the emotional processing regions we observed the following:

Response to unpleasant peep

To unpleasant peep, both groups responded with significant deactivations ($P < 0.001$) in the anterior cingulate cortex (ACC) and prefrontal cortex (PFC) with a relatively stronger ACC deactivation in controls, as indicated by the number of deactivated voxels. By contrast, only IBS patients responded with significant deactivations ($P < 0.001$) in the amygdala and the hippocampus (HC) (Table 2).

Response to pleasant sounds of chimes

To pleasant sounds of chimes, both groups responded with significant deactivations ($P < 0.001$) in the PFC and the posterior cingulated cortex (PCC) with a relatively stronger PCC deactivation in controls, as indicated by the number of deactivated voxels. Only controls responded with deactivations ($P < 0.001$) in the Insula and HC, and with significant activations ($P < 0.001$) in the ACC and a different region of the PFC. In IBS patients, on the contrary, the ACC was significantly deactivated ($P < 0.001$) (Table 2).

Response to emotional words

To emotional words, both groups responded with significant deactivations ($P < 0.001$) in the parietal sensory association cortex (PSAC), the ACC, the PFC, and the HC. However, the overall deactivation response in the ACC, PFC and HC, as indicated by number and size of deactivated clusters, was much stronger in IBS patients relative to controls (Table 2, Figure 1). By contrast, only controls responded with a significant deactivation ($P < 0.001$) in the PCC, while only in IBS patients, emotional words induced deactivations ($P < 0.001$) in the insula and moreover a significant activation ($P < 0.001$) in a different region of the PFC (Table 2).

Response to neutral words

To neutral words, both groups responded with significant activations ($P < 0.001$) in the PFC and PSAC. However, the overall activation response, as indicated by number and size of activated clusters, was much stronger in IBS patients relative to controls. Only in controls, neutral words induced a deactivation ($P < 0.001$) in the ACC. By contrast, only IBS patients responded with significant activations ($P < 0.001$) in the ACC, PCC, HC, and insula (Table 2, Figure 2).

DISCUSSION

Altered cerebral processing of visceral sensation has been proposed to play a pathogenic role in IBS. Whether these alterations are specific for visceral stimuli is currently not

Table 2 Significant activations (signal increase) and deactivations (signal decrease) induced by different acoustic stimuli

clear. In this study, we analyzed cerebral processing of non-visceral, auditory stimuli using fMRI. In a separate protocol, all IBS patients included in this study also underwent rectal stimulation by balloon distension adapted to the individual rectal perception thresholds, which were lower in IBS patients than in controls[21]. In IBS patients, decreased ACC and PFC activation with subliminal and supraliminal rectal stimuli and increased HC activation with supraliminal stimuli suggested disturbances of the associative and emotional processing of visceral sensation[21]. Our current findings demonstrate that IBS patients exhibit differences in the central processing of auditory stimuli of different emotional impact in brain regions involved in emotional sensory processing. Our main observations were: 1) To distressing auditory stimuli (peep and emotional words) both controls and IBS patients responded with significant deactivations in emotional processing regions demonstrating stronger responses in a greater variety of brain areas in IBS patients. 2) To pleasant auditory stimuli (chimes) IBS patients also responded with significant deactivations only, while in controls significant activations in the ACC and PFC were observed. 3) To neutral auditory stimuli (neutral words) IBS patients, unlike controls, responded with large significant activations in a variety of emotional processing regions. Taken together, IBS patients reacted more intensively with deactivations following emotional auditory stimuli, not differentiating, unlike controls, between distressing or pleasant sounds, and more intensively reacted with activations to neutral auditory stimuli.

Thus, this fMRI study indicates alterations of auditory sensory processing in IBS patients in brain regions participating in emotional stimulus processing. The cerebral processing differences involve both activation and deactivation responses. However, the specific cerebral function of deactivations observed in fMRI is still not completely understood and has been widely discussed[24]. Within the context of BOLD (Blood Oxygen Level Dependent) responses, on which the fMRI technique is based on, an activation reflects an increase in regional oxyhemoglobin that is believed to result from an increased blood flow coupled to neural activation ("neurovasular coupling"). In contrast, a "deactivation" reflects a stimulation-induced regional decrease of oxyhemoglobin of which the functional meaning is unclear. Vascular steal mechanisms or "neurovascular decoupling" resulting in reduced oxyhemoglobin have been suggested as possible cause of signal decrease[24]. In this case, the signal decrease would also reflect a neural *activation*. On the other hand, there is some evidence that the signal decrease could actually reflect a reduction of neural activity[25-27]. In fact, it has been proposed, that deactivations might contribute to cortical protection from incoming stimuli, for example in the context of chronic repetitive subconscious somatic stimuli[28] or in the context of sleep preservation[26,27]. A study demonstrating that the same auditory stimulus can induce either activation or deactivation responses of the amygdala just depending on the psychosocial background of the subjects[29],also supports a distinct neuro-functional meaning of deactivations. However, the uncertain functional meaning of deactivations to date makes the detailed interpretation of our findings difficult and we therefore restrict the following discussion to a rather descriptive evaluation of the dem-

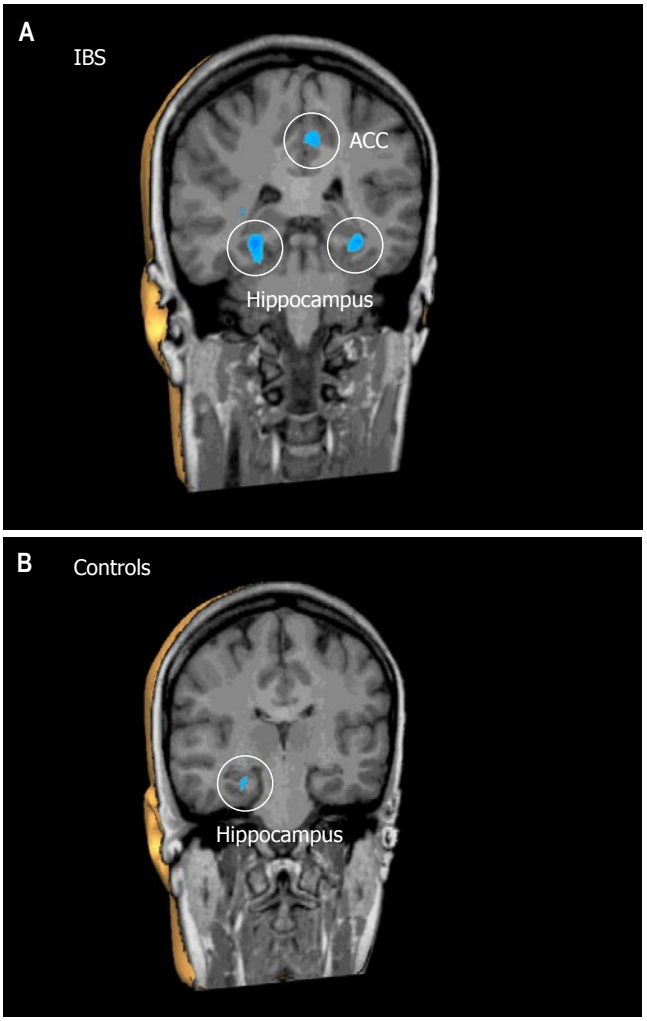

Figure 1 Auditory stimulation with emotional words induced significant deactivations of the hippocampus bilateral, and of the anterior cingulated cortex (ACC) in IBS patients, but only a very small deactivation of the right hippocampus in controls ($P < 0.001$).

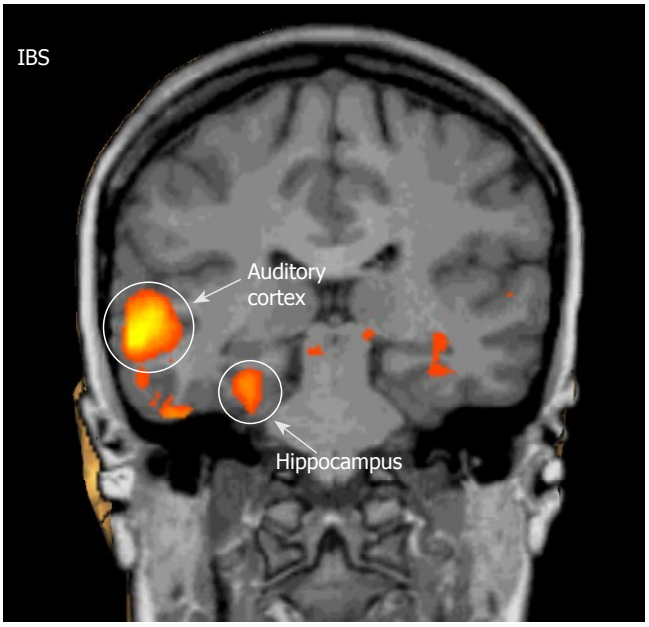

Figure 2 In IBS patients, auditory stimulation with neutral words induced significant activation of the hippocampus ($P < 0.001$).

onstrated brain processing differences.

Though both IBS patients and controls responded to distressing emotional stimuli mainly with deactivations, the deactivated regions in IBS patients were larger and involved a greater variety of emotional processing regions, among them parts of the limbic system like the amygdala or the hippocampus. In general, these observations could suggest a greater emotional reactivity to distressing stimuli in IBS patients as compared with healthy controls. This is in line with previous literature that demonstrate a central hyperreactivity of IBS patients to rectal stimuli in the presence of distressing auditory or visual stimuli[30-32].

Interestingly, IBS patients responded to pleasant sounds with similar deactivation patterns as to distressing stimuli whereas controls also reacted with activations. It is conceivable that an underlying alexithymia, a disorder characterized by the difficulty to recognize or express emotions and found to be significantly increased in IBS patients[33], could possibly accord for this finding. However, this has to remain speculative, because alexithymia was not specifically assessed in this study.

Neutral words, as expected, did hardly induce any reaction in emotional processing centers in healthy controls. By contrast, IBS patients responded with significant activations in these brain regions. These findings could indicate that IBS patients have a generalized increase in the sensitivity and reactivity of emotional processing brain regions even in response to neutral stimuli. Interestingly, the reaction to neutral stimuli is limited to activation-responses, while the emotional stimuli induced deactivation patterns in the same brain regions. This provides further evidence that activations and deactivations represent different processing functions depending on the emotional impact of the stimulus[29].

Overall, our findings indicate that IBS patients relative to controls show a greater cerebral reactivity to auditory stimuli with a larger involvement of limbic structures suggesting a higher sensitivity of emotional processing brain regions. Thereby, our results underline earlier observations by Blomhoff *et al* and Berman *et al*[12,13,34] who demonstrated a cerebral hyperreactivity to both emotional and neutral auditory stimuli in IBS patients. While altered cerebral processing in IBS has previously been demonstrated in the context of visceral stimulation[6,35,36], the current findings suggest that differences in cerebral stimulus processing in IBS might not be restricted to visceral sensation. Rather it is conceivable that differences in the emotional state might be an underlying factor. In fact, Blomhoff could demonstrate that the hyperreactivity to auditory stimuli is especially found in IBS patients with concomitant phobic anxiety disorders[34]. Accordingly, in our study, higher levels of anxiety, depression, and neuroticism in the IBS patient group (though differences were not reaching the level if significance possibly due to small sample sizes) could account for some of the observed differences in brain activation responses.

We acknowledge that this study has several limitations: The sample size of $n = 8$ for each group is rather small, and the bowel dysfunctions are heterogeneous in the IBS group. There is some evidence that diarrhea- versus

constipation-predominant IBS patients have different cerebral response patterns to rectal stimulation[37]. Whether this could also affect the cerebral processing of auditory stimuli is unknown. Furthermore, it is conceivable that the increased scores for anxiety, neuroticism and depression can alone account for the different stimulus processing of patients versus controls independent of IBS status. Future studies should include more patients, compare also to other psychologically distressed patients free of IBS, assess further psychometric variables such as alexithymia and allow for different subgroup analyses to further elucidate the nature of altered sensory processing in IBS.

Overall, the current observations of altered cerebral response patterns to neutral and emotional auditory stimuli in IBS patients indicate that altered emotional stimulus processing in IBS may not be specific for visceral sensation, but might reflect a generalized increase in emotional sensitivity and affective reactivity. This could account for the frequent association of IBS with psychological or extra-intestinal functional disorders[3].

Abstract

AIM: To study the expression of endothelial and inducible nitric oxide synthases (eNOS and iNOS) and their role in inflammatory bowel disease (IBD).

METHODS: We examined the effect of sera obtained from patients with active Crohn's disease (CD) and ulcerative colitis (UC) on the function and viability of human umbilical vein endothelial cells (HUVEC). HUVECs were cultured for 0-48 h in the presence of a medium containing pooled serum of healthy controls, or serum from patients with active CD or UC. Expression of eNOS and iNOS was visualized by immunofluorescence, and quantified by the densitometry of Western blots. Proliferation activity was assessed by computerized image analyses of Ki-67 immunoreactive cells, and also tested in the presence of the NOS inhibitor, 10^{-4} mol/L L-NAME. Apoptosis and necrosis was examined by the annexin-V-biotin method and by propidium iodide staining, respectively.

RESULTS: In HUVEC immediately after exposure to UC, serum eNOS was markedly induced, reaching a peak at 12 h. In contrast, a decrease in eNOS was observed after incubation with CD sera and the eNOS level was minimal at 20 h compared to control (18% ± 16% *vs* 23% ± 15% $P<0.01$). UC or CD serum caused a significant increase in iNOS compared to control (UC: 300% ± 21%; CD: 275% ± 27% *vs* 108% ± 14%, $P<0.01$). Apoptosis/necrosis characteristics did not differ significantly in either experiment. Increased proliferation activity was detected in the presence of CD serum or after treatment with L-NAME. Cultures showed tube-like formations after 24 h treatment with CD serum.

CONCLUSION: IBD sera evoked changes in the ratio of eNOS/iNOS, whereas did not influence the viability of HUVEC. These involved down-regulation of eNOS and up-regulation of iNOS simultaneously, leading to increased proliferation activity and possibly a reduced anti-inflammatory protection of endothelial cells.

INTRODUCTION

The two major forms of inflammatory bowel disease (IBD), ulcerative colitis (UC) and Crohn's disease (CD) are characterized by chronic inflammatory ulceration of the intestine. In an early[1], and in some recent studies[2, 3], the contribution of mucosal microvascular dysfunction is implicated in the development of CD. Histological analy-

Table 1 Data of patients with ulcerative colitis and Crohn's disease

Group	*n*	Age (yr)(range)	M/F	Endoscopic activity score	Clinical activity score	CRP (mg/L)	Treatment
UC	21	27 (18-33)	3/8	G_1: 4 G_2: 9 G_3: 8	4≤UC-DAI	>10	5-ASA
CD	18	31 (23-45)	13/5	8≤CDEIS≤14	150≤CDAI≤450	>10	5-ASA
Control	16	29 (25-39)	8/8				

G_{0-3}: Endoscopic grading of UC (Br Med J 1964; 1:89); CDEIS: Crohn's disease endoscopic index of severity (Gut 1989; 30:983-89); UC-DAI: Ulcerative colitis disease activity index (Br Med J 1955; 2:1041); CDAI: Crohn's disease activity index (*Gastroenterology* 1979; 77:843)

sis of IBD colonic mucosa indicated structural changes of the vascular system. In CD, arterial thickening and the appearance of an increasing number of capillaries were observed[1, 3]. Dysfunction in the vasodilatory capacity of microvessels from areas of chronic inflammatory damage was also shown in IBD[2]. Inflammatory cytokines modify and regulate the level of NO, and they are also involved in vascular endothelial response to inflammatory injury[3, 4]. Apoptosis of endothelial cells induced by proinflammatory cytokines and reactive oxygen species is counteracted by the endothelial nitric oxide (NO). The suppression of apoptosis may contribute to the anti-inflammatory and pro-angiogenic effect of endothelial NO[5].

The endothelial form of nitric oxide synthase (eNOS) plays a significant protective role against experimental colitis[6]. Decrease of eNOS immunoreactivity in the endothelium is suggested as a putative cause of arterial thickening and the appearance of an increasing number of capillaries in the mucosa of Crohn's colitis[3]. Moreover, weak eNOS immunoreactivity in the endothelium together with structural alteration of the vascular wall, both found in biopsies of Crohn's patients suggest that malfunction of local blood supply may also contribute to the development of the disease[3]. Human umbilical vein endothelial cells (HUVEC) are frequently used as a specific model for studying endothelial function. HUVECs are also sensitive to pro-inflammatory stimuli induced by interleukins. NO is produced in HUVEC constitutively by eNOS and by inducible nitric oxide synthase (iNOS) in the case of different stimuli[7, 8]. NO also contributes to the regulation of apoptosis, cell differentiation and proliferation (angiogenesis) in this cell type[9-11].

The changes in the activity of eNOS and iNOS as well as their role in the endothelium of IBD patients have not been examined in detail. In the present study, we examined the effect of sera from patients diagnosed with UC and CD on cultured HUVEC. The expression and localization of eNOS and iNOS were determined in highly confluent and in semi-confluent HUVEC cultures, and the apoptotic/necrotic characteristics and proliferation activity upon distinct treatments were also assessed.

MATERIALS AND METHODS

Collection of blood sera

Blood was sampled for examination from patients who had relapsing UC or CD. Among 21 UC patients, 16 were on their 1st relapse (mean time from diagnosis [*mtd*] was 1 yr), and 5 on 2nd relapse (*mtd* = 3 yr), whereas all the 18 CD patients were on their 1st relapse (*mtd* = 4 yr). Control sera were obtained from 16 healthy volunteers. They received no systemic or locally applied corticosteroids, and their medication was stable for the last four weeks before sampling. All the patients were on 5ASA oral therapy. Patients diagnosed as having UC had left side colitis (Table 1). Crohn's patients had colonic localization and a non-stricturating, non-penetrating form of the disease (Table 1) according to the Vienna classification (1998), and an elevated C-reactive protein level (CRP>10 mg/L), without abscess or sign of infection (all of the patients had negative abdominal ultrasound). In cases which raised the suspicion of abdominal or pelvic abscess, CT or MRI (to exclude the presence of perianal / perirectal abscesses) was performed. Five milliliters of blood were taken from patients of UC, CD and control subjects respectively, placed into collecting tubes, and centrifuged at 2000 r/min for 10 min. The sera were removed and mixed, and kept frozen at -80℃ until use.

Preparation and culturing of HUVEC

Freshly isolated umbilical cords were obtained from the Department of Obstetrics and Gynecology (University of Debrecen, Medical and Health Science Center). Umbilical cords were immersed into a sterile flask containing culture medium (components are described below) and carried to the cell culture room. Both ends of the cords were bound and the ends of the umbilical vein were cannulated. The vein vessel was washed through the cannulas by sterile PBS, followed by Hanks' Balanced Salt Solution (HBSS), and M199 media (all purchased from Sigma, Budapest, Hungary). Then, the vein vessel was filled with 1 g/L collagenase in M199, and placed in a CO_2 incubator for 12 min at 37 ℃. Endothelial cells were isolated in a sterile centrifuge tube from the vessel by washing twice with 20 mL M199 medium. Cell suspension was centrifuged at 1000 r/min for 15 min, and the supernatant was discarded and the cells were resuspended in the culture medium.

The cells (2×10^9 cells/L) were inoculated into a plastic culture dish. The culture medium contained the following components: 500 mL/L normal human serum, 20 g/L HEPES, 10 g/L L-glutamine, 10 g/L amphotericin, 10 g/L penicillin, 450 mL/L sterile filtered M199. One day after inoculation, dishes were washed with 37 ℃ HBSS, and put into the culture media again. After 4-5 d of culturing, dur-

ing which time cells grew extensively over the entire space of the dish, cells were washed with HBSS, then digested with 1 mL tripsin-EDTA (tripsin : EDTA = 1 : 25). The cells were suspended in 1 mL culture medium and collected into a sterile flask, then mixed well. The cells were inoculated into the culture dish and the cell propagation and collection procedure were repeated again as described above. Then, cells were passed onto culturing plates at about 2 $\times 10^9$ cell/L concentration. Cell monolayers that reached 20%-30% or 70%-80% confluency were used for the experiments. The cells were kept in 50% normal, 50% UC or 50% CD sera dissolved in culturing medium for 2, 4, 8, 12, 20, 24, 36, and 48 h, then processed for visualization of eNOS or iNOS.

Western blot

After removal of the culture media, cells were washed with ice-cold PBS, then harvested by a cell scraper into 50 μL RIPA lysis buffer (0.01 mol/L NaH_2PO_4, 10 g/L Nonident P-40, 10 g/L Na-deoxycholate, 1 g/L Na-dodecyl sulfate (SDS), 0.15 mol/L NaCl, 2 mmol/L EDTA), containing 100 kU/L protease inhibitor mix (Sigma-Aldrich, Budapest, Hungary). Cell lysis was accelerated by continuous shaking. Five microliters of this mixture were added to 45 μL RIPA buffer for protein measurement. All protein solutions were frozen and kept at -80 ℃ until use.

The protein concentration of the lysates was determined by the BCA method using BSA as standard in an ELISA reader at 540 nm. Data were analyzed by GraphPad Prism software using linear regression to determine the protein concentration (g/L). Proteins were resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) using the conditions of Laemmli (1970) on 100 g/L acrylamide gels in a Bio-Rad MiniProtean apparatus[3]. Samples for immunoblot analysis were diluted in the RIPA buffer, dissolved in an equal volume of 2 ×SDS sample buffer (100 mmol/L Tris pH 6.8, 2 g/L bromophenol blue, 200 mL/L glycerol, 200 mL/L β-mercaptoethanol) and boiled for 5 min. From each solution, aliquots (30 μg protein) were applied to SDS-PAGE and electrophoresed at 120 V for 1 h. Separated proteins were blotted onto a nitrocellulose membrane (Pharmacia, Vienna, Austria) at 100 V for 90 min during the continuous mixing and cooling of the transfer buffer (192 mmol/L glycine, 25 mmol/L Tris-base, 200 mL/L methanol). Membranes were rinsed twice in 0.1 mol/L PBS (pH 7.6) containing 1 g/L Tween 20 (PBS-Tween), then blocked for 1 h with 50 mL/L non-fat dried milk in PBS-Tween. After 3 × 5 min of washing with PBS-Tween, the membranes were incubated overnight at 4 ℃ with the anti-eNOS (diluted into 1 : 5000, Cat. No.: 482726, Merck-Calbiochem, Darmstadt, Germany) or anti-iNOS (1 : 2000, Cat. No.: AB5384, Chemicon, Temecula, CA) polyclonal antibodies raised in rabbits. After washing with PBS-Tween for 3 × 5 min, membranes were incubated with horseradish peroxidase conjugate of anti-rabbit IgG (diluted into 1 : 5000 in PBS-Tween, Vector, Bulingame, CA) for 30 min. After washing the membranes subsequently with PBS-Tween for 2 ×5 min, and once with PBS for 5 min. The blots were developed with the enhanced chemiluminescent (ECL) reagent kit (Pierce, Rockford, IL) and the immunoreactions were visualized on X-ray films.

Densitometry of the blots was performed and the scans were analyzed by the Volume Analyse feature of the Molecular Analyst Software (Bio-Rad, Hercules, CA). The densities for the NOS bands were normalized in each blot to the NOS-IR band obtained from the sample of 2 h treatment with normal serum and expressed as percentage of this control. Means of the percentages obtained from three independent experiments were presented in figures as mean ± SEM. The significance of the data between groups (normal, UC, CD) was tested by analysis of variance (ANOVA). Differences were considered significant for values of $P < 0.01$.

Immunofluorescence

Cells were cultured on coverglasses coated with sterile filtered 100 g/L gelatine in PBS. Cultures showing 20%-30% confluence were used for detection of proliferation, cell distribution and apoptosis/necrosis characteristics, whereas those with 70%-80% confluency were used for visualization of NOS isoforms. After treatments, cells were fixed in an ascendant ethanol gradient (500 ml/L, 700 mL/L, 960 mL/L), then rehydrated with PBS. For specific detection of eNOS and iNOS proteins, non-specific binding sites of primary antibodies were blocked by incubation of the fixed cells for 1 h with 50 mL/L normal goat serum in PBS also containing 1 g/L bovine serum albumin (BSA), 1 g/L Triton-X 100 and 0.1 g/L Na-azide (referred to as solution-A below). NOS primary antibodies used for immunocytochemistry were the same as those used for immunoblotting. Both eNOS and iNOS antibodies were applied at 1 : 200 dilution in solution-A overnight at 4 ℃. After extensive washing with PBS (3×5 min), cells were incubated with FITC conjugated anti-rabbit IgG diluted to 1 : 40 in solution-A for 30 min at room temperature. Cells were washed for 3 ×5 min with PBS and cover glasses were mounted on microscope slides (with one drop of PBS-glycerol (1 : 1) solution on them).

For evaluation of the proliferation activity, HUVECs were incubated in a medium containing 500 mL/L normal, 500 mL/L UC or 500 mL/L CD sera, or in a medium containing 500 mL/L normal sera plus 10^{-4} mol/L nitro-L-arginine methyl-ester (L-NAME, Sigma-Aldrich), an NOS inhibitor. Cells were exposed to a monoclonal antibody (at 1 : 100 dilution) specific for the proliferation marker Ki-67 antigen (clone No. MIB-1, Dako, Denmark) for 2 h at room temperature. In this case, FITC-conjugated anti-mouse IgG (1 : 40 in solution-A, Dako) was used as a secondary antibody. For testing of the effect of normal and IBD sera on the viability of HUVEC, apoptotic/necrotic cells were assessed by the annexin-V-biotin kit (Cat. No. 1828690, Boehringer-Mannheim, Germany). Briefly, after removal of the incubation media and washing with PBS, cells were labeled with the annexin-V-biotin/propidium iodide solution (1 : 50 annexin-V-biotin stock solution diluted in a 0.01 mol/L HEPES buffer, pH 7.4, containing 0.14 mol/L NaCl, 0.005 mol/L $CaCl_2$, and 1 mg/L propidium iodide) for 15 min. After subsequent washing with HEPES, cells were fixed with methanol-ethanol (1 : 1) solution for 1 min, and labeled with 5 mg/L avidin-fluorescein for 15 min. After consecutive washing with

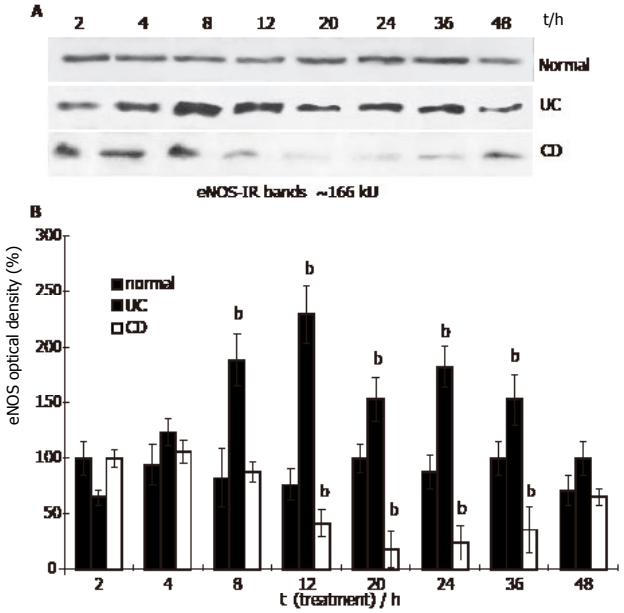

Figure 1 eNOS content in HUVEC treated with IBD sera (Western blot. Mean ± SE, $n = 3$; $^bP<0.01$ *vs* normal).

HEPES and PBS, cells were put on microscope slides as described above. Preparations used for the assay of proliferation activity and assessment of apoptosis/necrosis were stained prior to covering with 10 g/L toluidin blue in PBS. The latter labeled the cell nuclei and helped to determine total cell numbers for calculation of apoptotic/necrotic indices. The integrity of the cytoskeleton was examined by visualization of actin filaments by incubation with 0.2 mg/L phalloidin-FITC (Sigma-Aldrich) for 1 h.

Examination was carried out and digital images were captured with an Olympus AX-70 fluorescence microscope. In each case, the brightness-contrast of the images was set in the same manner by the Jasc software Paintshop Pro 7.0. Images were taken from Ki-67 immunoreactive (IR), annexin-labeled, and propidium iodide reactive cell nuclei, respectively. The same sites of the preparations were also captured in bright visual illumination to count the toluidin blue stained nuclei (total cell number). The images were quantitatively analyzed by the computer image analysis software Olympus analysis 2.11 (SiSoft), developed and validated by Olympus (Tokyo, Japan). At least 10^3 cells were counted for each data point and the ratios of proliferative, apoptotic and necrotic cells were given as the percentage of total cell numbers.

Statistical analyses

Statistical analyses were performed to compare the data obtained from the different treatments groups of IBD and normal sera using the ANOVA test. $P<0.05$ was considered as significant.

RESULTS

eNOS

Western blots from HUVEC lysates detected eNOS immunoreactive bands at approximately 160 kU, corresponding to the molecular mass of human eNOS (Figure 1A).

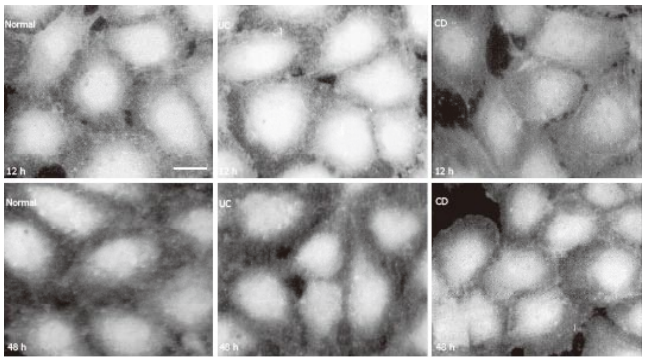

Figure 2 eNOS in HUVEC (immunoreaction was visualized by FITC. bar: 10 μm).

HUVEC was cultured in a medium containing 500 mL/L normal human serum. The amount of eNOS did not change significantly during the experimental period (0-48 h). However, in the presence of 500 mL/L UC serum, eNOS level increased after 8 h, and peaked at 12 h (relative optical density value was 188% ± 23% and 229 %± 26%, $P < 0.01$, respectively). At 12 h, eNOS level appeared to have doubled compared to the normal level at 2 h (100% ± 15%). Over the 12 h period in the presence of 500 mL/L UC serum, eNOS level began to decline (36 h, 153% ± 23%, $P < 0.01$), and reached control level at 48 h (100%± 8%). In the presence of 500 ml/L CD serum, the level of eNOS was close to normal until 8 h, and decreased after 12 h (41% ± 12%, $P < 0.01$), reaching the lowest level at 20-24 h (18% ± 16% and 23% ± 15%, $P < 0.01$, respectively), and then slowly increased rising close to normal at 48 h (65% ± 8%, Figure 1A, B).

Localization of eNOS in HUVEC by immunofluorescence revealed that the enzyme mostly accumulated in the nuclear area of the cytoplasm and was also detected at the periphery of the cells (Figure 2). Normal human serum had no effect on the distribution and intensity of eNOS immunoreactivity in HUVEC. Prolonged treatment (12 h) with UC serum extended eNOS immunoreactive area and simultaneously enhanced slightly the intensity of eNOS immunofluorescence in HUVEC. In contrast, in the presence of CD serum (after more than 4 h), eNOS immunoreactivity seemed to contract toward the centre of the cells and its immunofluorescence intensity decreased (Figure 2). At the end of the experimental period (48 h treatment), no visible difference could be detected in eNOS immunofluorescence of HUVEC in the presence of normal, UC or CD sera.

iNOS

Western blots in HUVEC lysates detected faint iNOS immunoreactive bands at around 130 kU, corresponding to the molecular mass of human iNOS (Figure 3A). HUVEC was cultured in the presence of 500 mL/L normal human serum, the relatively low level of iNOS expression did not change significantly during the 48 h incubation period. In the presence of 500 mL/L UC serum, iNOS level increased at 4 h (relative optical density value was 225% ± 20%, $P < 0.01$), peaked at 8 h (300% ± 21%, $P < 0.01$), and then declined to about normal level at 48 h (117% ± 15%). In the presence of 500 mL/L CD serum

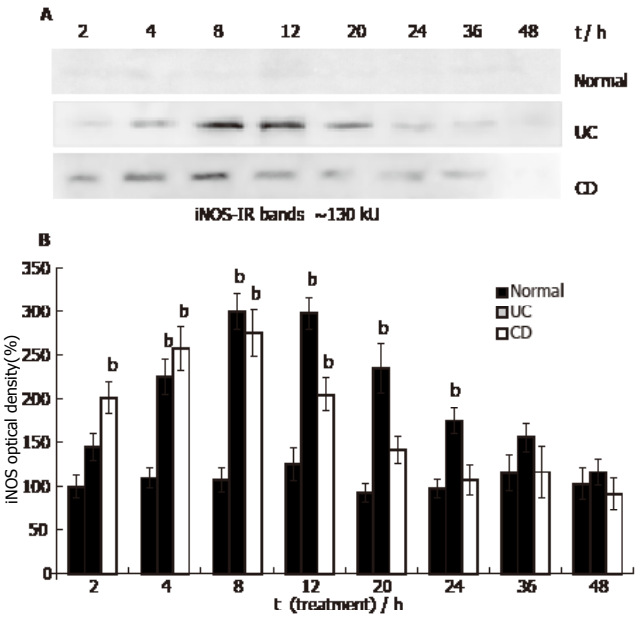

Figure 3 iNOS content in HUVEC (Western blot. Mean ± SE, n=3; ^bP<0.01 *vs* normal).

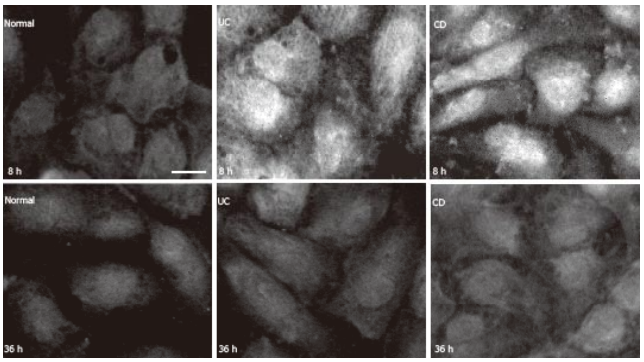

Figure 4 iNOS in HUVEC (immunoreaction was visualized by FITC. bar: 10 μm).

the iNOS level in HUVEC increased after 2 h (201% ± 19%, $P < 0.01$) and peaked at 8 h (275% ± 27%, $P < 0.01$). From 12 h iNOS level declined and was not distinguishable from the control during the 24-48 h period (at 48 h: 92% ± 18%, Figure 3A, B).

In the presence of 500 mL/L normal serum, HUVEC exhibited faint iNOS immunofluorescence (Figure 4). Expression of iNOS in HUVEC by immunofluorescence could obviously be detected in the presence of IBD sera during the 4-12 h period. Figure 4 shows that iNOS was dispersed in the cytoplasm, accumulated in certain areas showing a high intensity of fluorescent signal. Both UC and CD sera significantly increased iNOS immunofluorescence at the 4-12 h period. Before and after this time interval, iNOS could not be detected unequivocally in HUVEC by immunofluorescence (Figure 4).

HUVEC proliferation activity

Ten to fifteen percent of HUVEC was observed to be in the state of proliferation in the cultures with 20%-30% confluency at the beginning of the experiments as revealed by Ki-67 immunostaining (Figure 5). During the 2 to 48 h period no difference was detected in the ratio of Ki-67-IR/toluidin blue stained cell nuclei in cultures in

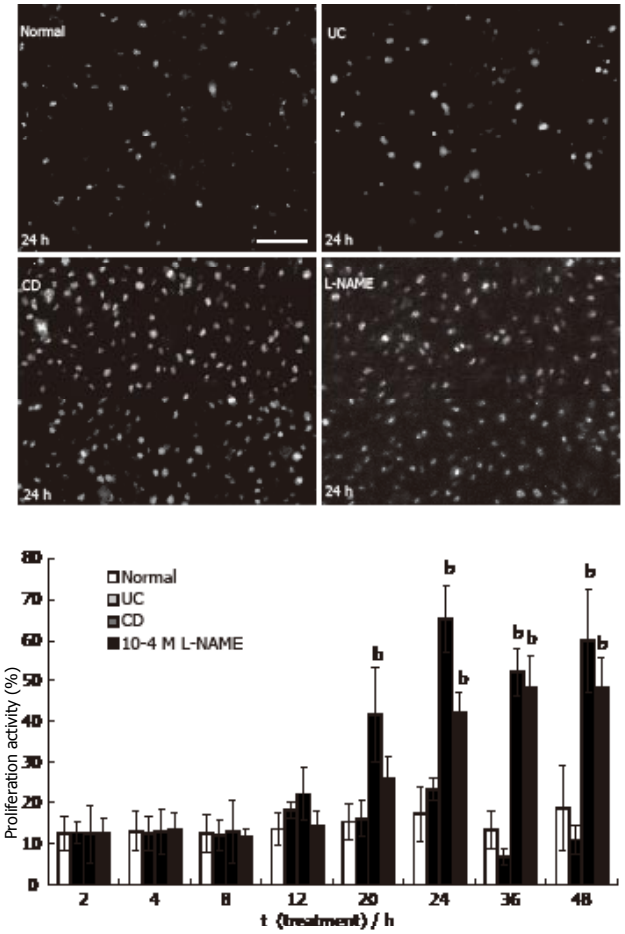

Figure 5 Proliferation activity of HUVEC (Ki-67 immunoreactivity was visualized by FITC. bar: 50 μm. mean ± SE, n = 3; ^bP<0.01 *vs* normal).

the presence of 500 mL/L normal (at 48 h: 19% ± 10%) or 500 mL/L UC sera (at 48 h: 10% ± 3%). In the presence of 500 mL/L CD serum a significant increase in the number of proliferating cells was apparent at 20 h (41% ± 12%, $P < 0.01$). About 50%-65% of HUVEC nuclei exhibited Ki-67 immunofluorescence in the presence of CD serum for 24-48 h (Figure 5). The presence of 10^{-4} mol/L L-NAME in the medium containing 500 ml/L normal serum, increased the proliferation activity significantly from 24 h (42% ± 5%, $P < 0.01$) to 48 h (48% ± 7%, $P < 0.01$).

HUVEC viability

By the annexin-V-biotin method, early apoptotic cells revealed fluorescent signals only on the cell membrane (Figure 6A), whereas necrotic cells showed propidium iodide binding to DNA (nuclear fluorescent signal, Figure 6B). Both signals could be detected in late apoptotic cells (Figure 6C). During the experimental period (2-48 h), the number of apoptotic cells was low (1%-3%) in the presence of 500 mL/L normal serum, but a continuous increase of apoptotic cell numbers was observed in the presence of 500 mL/L CD serum (2%-5%, with a maximum level at 36 h), which proved not to be significant (Figure 7A). In the presence of UC serum the apoptotic index did not differ from that of the control. Incubation of HUVEC with normal or CD sera slightly increased the number of necrotic cells during the examination period (2-48

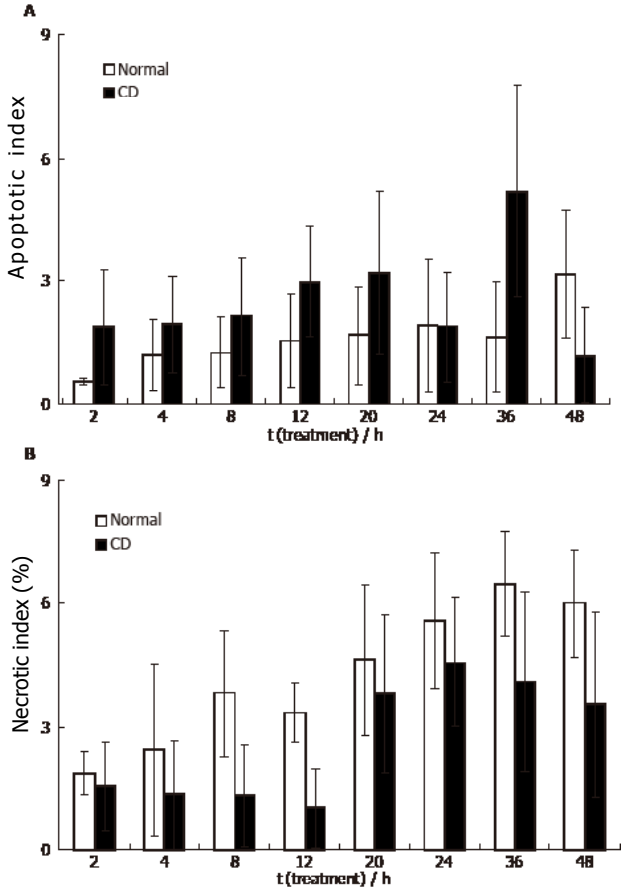

Figure 7 HUVEC 48 h incubation with CD sera (mean ± SE, *n* = 3).

h), but no significant changes were observed between the necrotic indices (Figure 7B). Actin filaments visualized by phalloidin-FITC seemed to be intact in cells independent of the media used and the time of incubation (Figure 6D).

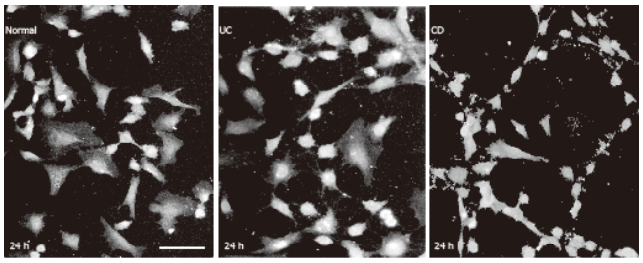

Figure 8 HUVEC visualized by eNOS immunofluorescence in culture. bar: 50 μm.

Shape and structure of HUVEC

HUVEC cultures of 20%-30% confluency were used also to investigate the effect of IBD sera on the distribution and shape of the cells. Cells visualized by eNOS immunofluorescence were partly found to be accumulated in islands exhibiting polygonal shape and attached to each other. In addition, single cells exhibiting long processes were also present. In the presence of 500 ml/L normal or 500 ml/L UC sera cells did not change in distribution and shape over the 48 h experimental period. However, in the presence of 500 mL/L CD serum, after 20 h cells were distributed in a two dimensional reticular network, which changed the shape of the culture reminiscent of the appearance of early vascular vessels in tissues (Figure 8).

DISCUSSION

In this study, we investigated the effect of sera from patients with active UC or CD on the expression and localization of eNOS and iNOS in HUVEC cultures. Induction of both iNOS and eNOS was observed in the presence of UC serum. In contrast, upon addition of CD serum to HUVEC media a transient increase in the expression of iNOS was observed in parallel with a marked decrease in the expression of eNOS. The number of apoptotic and necrotic cells was not altered significantly, and the structural integrity of the cytoskeleton (revealed by staining of the actin filaments) remained intact during the exposure of the cells to either CD or UC serum.

It has been shown previously that NO might enhance or reduce the cascade reaction of chronic inflammation in humans and animal models[12-14]. We found opposite changes in the expression of eNOS in HUVEC exposed to UC and to CD sera. The generation of eNOS is modified by elevated levels of cytokines (Th1 in CD) and the cytokine-induced expression and presentation of endothelial cell adhesion molecules[15]. UC and CD sera are known to contain a distinct cytokine and pro-inflammatory molecule profile. It was reported that TNF-α reduced eNOS protein expression in a time dependent manner in human endothelial cells[16, 17]. Moreover, TNF-α downregulated eNOS mRNA by decreasing its stability[18]. In our experiment, the low eNOS level in the presence of CD serum, could be due to TNF-α, which is a key cytokine in Th1 mediated inflammation in CD. Inflammation could result in functional and antigenic changes of the endothelium, including eNOS down-regulation and consequently increased expression of leukocyte adhesion molecules (ICAM, VCAM, E-selectin)[19-23]. At the same time, a lag in the fall of enzyme

activity was observed which may reflect a greater stability of eNOS protein compared to its mRNA, or may involve posttranslational modification(s) in the increase and stabilization of the enzyme activity[9]. Leukocyte-endothelial binding is exacerbated in an eNOS deficient state and injury during ischemia-reperfusion is more severe[24, 25].

A high amount of iNOS is generated during inflammation which can be harmful, worsening the course of disease in the animal colitis model[26]. In Crohn's colitis, human intestinal microvascular endothelial cells may lack the capacity to express iNOS, which makes them susceptible to leukocyte mediated injury[27, 28]. In UC, it has been shown that there is an elevation in iNOS level which is well correlated with disease severity[29]. Elevated iNOS activity was demonstrated in the mesenteric microvascular endothelial cells in active UC, indicating a close relationship between vascular activation and the pathogenesis of UC[30]. Stimulation of HUVEC with pro-inflammatory cytokines (Il-1β, TNF-α) or hormones (eg. relaxin, estrogen) induces the expression of iNOS and the NO produced increases the biosynthesis of prostaglandins and other mediators[31-33]. The maximal level of iNOS detected in primary cell cultures was not related to lipopolysaccharide contamination. It did not affect cell proliferation and was decreased when cells became confluent[34]. Dual modulation of NOS expression was detected upon estradiol treatment in a concentration dependent manner; estradiol in nanomolar range could induce eNOS, whereas in micromolar range it could evoke iNOS expression[35]. In previous studies, INF-γ in conjunction with TNF-α, or together with IL-1β, increased NOS activity, whereas these cytokines alone had different effects on NOS expression[9, 36, 37]. Up-regulation of iNOS by IBD sera may be an adaptive response of HUVEC to this culture environment.

The effect of UC and CD sera on eNOS expression could be of special interest and may be implicated in the distinct pathophysiological and morphological features of the two diseases. Inhibition of NO production *in vivo* results in reduced VEGF induced angiogenesis and vascular permeability[38]. Recent studies have provided evidence that basic fibroblast growth factor (bFGF), which is an important component of CD serum, induced angiogenesis by different mechanisms[39]. An impaired VEGF response was suggested in CD with down-regulation of the VEGF receptor (VEGF-Ets-1) and the angiogenic cascade supporting the vascular hypothesis of the disease[40-43]. The deficiency in eNOS expression and concomitant alteration of VEGF-induced angiogenesis and vascular permeability could be an important step in the pathomechanism of CD. However, bFGF, the most potent angiogenic molecule in CD has an NO independent activity[39, 44]. In addition, the pathomechanism of UC appears to be VEGF independent[39, 44]. The reciprocal reaction of cytokines and angiogenic molecules results in changes in the expression of eNOS and iNOS and causes an imbalance between the two isoforms which may play a role in the dysfunction of angiogenesis in IBD.

Angiogenesis is an important pathophysiological process in chronic inflammation and it includes proliferation, migration, and tube formation of endothelial cells. This process is tightly regulated by different angiogenic factors, and one of them is NO which has a pro-angiogenic effect[45, 46]. HUVEC, in the presence of CD serum, but not in the presence of UC serum, showed morphological changes reminiscent of vascular like structures, forming loop like rearrangement of the cells. It was shown recently that reactive oxygen species (ROS) have a putative pro-angiogenic activity *in vivo* possibly via iNOS up-regulation[47]. ROS also play a significant role in proliferation through regulation of eNOS activity, whereas antioxidants stimulate NO production and proliferation of HUVEC[48]. However, it was suggested also that antioxidants may enhance the activity of NOS[49, 50]. This dual effect could have a role in the pro-angiogenic and proliferation activity of HUVEC.

Recent data revealed that NO, by regulating mitochondrial respiration and cytochrome c release, triggers a defensive mechanism against cell death induced by pro-apoptotic stimuli[51-53]. In the present study, HUVEC incubated in the presence of CD serum exhibited a low expression level of eNOS, which could explain the slightly elevated apoptotic index. It also suggests a defective anti-apoptotic mechanism. The TNF-α level is known to be high also in CD serum and this could alter cell viability by inducing apoptosis in an NO independent pathway[54]. In contrast, in control and UC sera treated cells, the higher eNOS level may result in protection against apoptosis.

Our present results correlate well with our previous immunohistochemical findings through biopsy studies, and suggest the presence of a cytokine composition, which is able to evoke changes in the eNOS/iNOS ratio in endothelial cells in the blood of IBD patients. Simultaneous down-regulation of eNOS and up-regulation of iNOS, together with the increase of cell proliferation activity may reduce the anti-inflammatory capacity of endothelial cells. The latter may contribute to the initiation of pro-inflammatory cascade reactions leading to endothelial barrier dysfunction and causing structural changes in the microvessels in Crohn's mucosa.

Abstract

AIM: To develop a new experimental model of esophagitis that serves a complementary tool to clinical investigation in an insight into the mechanism of the damage to the esophagus mucosa by aggressive factors, and role of COX inhibitors in this process.

METHODS: The study was conducted in 56 male mice. Animals were divided into seven groups: (1) perfused with HCl, (2) perfused with HCl and physiologic concentration of pepsin (HCl/P), (3) perfused with similar HCl/P solution enriched with conjugated bile acids (glycho- and tauro-sodium salts) designated esophageal infusion catheter under the general anesthesia, (4) perfused as in group 2 treated with indometacin, (5) perfused as in group 2 treated with NS-398, (6) perfused as in group 3 treated with indometacin, and (7) perfused as in group 3 treated with NS-398. The esophagus was divided into 3 parts: upper, middle and lower. The PGE2 concentration was measured in all parts of esophagus using RIA method. Esophagus of sacrificed animals was macroscopically evaluated using a low power dissecting microscope (20×). Specimens, representing the most frequently seen changes were fixed, stained with H&E and assessed microscopically using the damage score, and inflammatory score.

RESULTS: The macroscopic changes were significantly severer in HCl/P than those in HCl animals (77%) and in HCl/P/BA group (43%). In HCl/P NS-398 group we noticed significantly less changes than those in not treated group (42%) and in analogical group treated with indomethacine (45%). In HCl/P/BA INDO group we observed significantly severer changes than that in not treated group (52%). We noticed less changes in HCl/P NS-398 than that in group with indomethacine (46%). In HCl/P/BA NS-398 group we had less changes than that in indometacin group (34%). The microscopic changes observed in HCl/P/BA INDO group were severer than that in not treated group (48%). Esophagitis index in HCl group was significantly lower than in HCl/P and also HCl/P/BA group (32% and 33 %). In HCl/P/BA/INDO group the esophagitis surface was larger than that in not treated group (33%). In HCL/P group the surface of esophagus with ulceration was significantly larger (10-fold) than that in HCl/P/BA group. The PGE2 concentration was significantly higher in HCl/P group than in HCl/P/BA group. The PGE2 concentration in lower part of esophagus was also significantly higher in middle than those in HCl and HCl/P/BA groups. In upper part of esophagus the PGE2 concentration was significantly higher in HCl/P/BA group than that in group treated with indomethacine (46%). We also observed higher PGE2 concentration in middle part of esophagus in HCl/P/BA group than those in group treated with indomethacine and in group treated with indometacin and NS-398 (by 52% and 43% respectively).

CONCLUSION: Pepsin is the pivotal factor in the development of chronic esophageal injury. Bile acids diminish chronic esophageal injury induced by HCl/P, indicating its potential negative impact on pepsin proteolytic potential, pivotal for mucosal injury in low pH. The role of selective COX inhibitors is still unclear, and needs more investigations. This novel chronic experimental esophagitis is an excellent model for further study on the role of cytokines in genetically modified animals.

Key words: Bile acids; ProstaglIndins; Oesophagitis mouse model

INTRODUCTION

Primary gastroesophageal reflux disease (GERD) is an ac-

id-related disease in majority of patients. However, there is evidence that in some patients with GERD reflux of duodenal contents into the stomach and esophagus may be involved in the disease[1, 2].

Chronic GERD may induced Barrett`s metaplasia[3]. This clinical situation has increased risk for the development of esophageal adenocarcinoma and is considerate to be a premalignant condition[4]. The complications in Barrett's esophagus was accompanied with presents of duodenal juice in gastroesophageal refluxate (GER)[3]. In the patients with esophagitis, Barrett`s esophagus strictures compared to patients with minimal injury the concentration of bile acids in refluxate was significantly higher [5]. The concentration of bile was significantly higher in patients with early adenocarcinoma arising in Barrett`s esophagus, compared to GERD patients, esophagitis group and asymptomatic volunteers[6]. Clinical trials have begun in order to assess the efficacy of selective COX-2 inhibitors to prevent the progression of Barrett's esophagus to adenocarcinoma. Bile salts and acid are likely to early induce COX-2 in this sequence, although other factors, such as proinflammatory cytokines, inducible nitric oxide synthase and growth factors such as TGF-beta, are potential COX-2 inducers in the esophagus[7]. In animal studies it has been shown that reflux of gastric contents with addition of duodenal juice into the esophagus may lead to esophageal adenocarcinoma[2]. The carcinogenetic effect of duodenal contents on gastric mucosa was clearly demonstrated[8].

Bile acid may induce mucosal injury by two mechanisms. The detergent properties of bile salts may destabilize membranes and increase permeability, disrupt cellular homeostasis and potentially result in cell death[9]. Bile acids may also create cytotoxic effect through cellular absorption of bile salts, witch is dependent upon the salt`s ionization[10].

COX-1 activity is constitutive in the rabbit esophageal mucosa, but both COX-2 and COX-1 activity are increased under the impact of acidified pepsin. Treatment with the COX-2 inhibitor DFU is associated with improvement of mucosal damage, which may have therapeutic implications[11].

PGE2 plays the important role in development of Barrett`s esophagus and adenocarcinoma of the esophagus. The concentration of PGE2 was significantlly higher in high grade displasia cells and also in adenocarcinoma cels of esophagus [12].

Our new experimental model of chronic esophagitis seems to be very useful tool to determinate the role of HCl/P/BA, major components of duodenogastroesophageal reflux, and the role of COX inhibitors on pathological changes in mucosa of the esophagus during refluxate episodes.

MATERIALS AND METHODS

The study was conducted in 56 male mice (CD1 strain from Charles River) according to study protocol approved by Animal Research Committee at KUMC. Animals were divided into seven groups: (1) Animal perfused with HCl (100 mmol/l, pH1.1), (2) Animals perfused with HCl (100 mmol/l, pH1.1) and physiologic concentration of pepsin (0.5 mg/l of HCl) (HCl/P), (3) Animals perfused with similar HCl/P solution enriched with conjugated bile acids (glycho- and tauro-sodium salts) designated esophageal infusion catheter under the general anesthesia, (4) Animals perfused as in group 2 treated with indometacin (5 mg/kg b.w. s.c.), (5) Animals perfused as in group 2 treated with NS-398 (10 mg/kg b.w. p.o), (6) Animals perfused as in group 3 treated with indometacin (5 mg/kg b.w. s.c.), and (7) Animals perfused as in group 3 treated with NS-398 (10 mg/kg b.w. p.o). The total perfusion time per day for each mouse was 1.5 h. At the end of experimental procedure the animals were sacrificed under prolonged metoxyflurane anesthesia, esophagus was removed, opened and evaluated microscopically after stained with Alcian blue (0.1%, pH 5.8), using a low power dissecting microscope (20×) with stage micrometer for measurement of the area of macroscopic damage. The macroscopic changes was evaluated based on macroscopic score: 0 - no changes; 1 - erosion - max 3, size - 3-6 mm; 2 - erosion - 6 and up, size - 6-9 mm; 3 - ulcer without perforation with small hemorrhagic areas; 4 - ulcer with perforation and large hemorrhagic areas.

Specimens, representing the most frequently seen changes were fixed, stained with hematoxylin and eosin, and assessed microscopically using the damage score [15]: 1-normal esophagus, 2-submucosal edema or separation of epithelial layer, 3-focal areas of intramural hemorrhage or partial epithelial loss, 4 - large areas of hemorrhage or complete epithelial desquamation; and inflammatory score[16]: 0 - no infiltration, 1-very mild infiltration, 2-mild infiltration, 3 - moderate infiltration, 4 - marked infiltration.

The concentration of PGE2 was measured in 1/3 upper, 1/3 middle and 1/3 lower parts of esophagus using RIA kit (*Amersham, Arlington Heights, Illinois*).

Statistical analysis was performed with S-Stat (Jandel Sci. Co).

RESULTS

The macroscopic score was significantly higher in animals perfused with HCl/P than those in groups with HCl/P/BA and with HCl (3.69 ± 0.23 *vs* 2.58 ± 0.25 and 3.69 ±0.23 *vs* 2.08 ± 0.11, $P < 0.05$). The macroscopic score was significantly lower in group HCl/P/NS-398 than that in not treated group (2.13 ± 0.21 *vs* 3.69 ± 0.23, $P < 0.05$) and also lower than that in analogical group treated with indometacin. In HCl groups, the microscopic changes were less evident in groups with HCl and HCl/P/BA than that in HCl/P (2.63 ± 0.38 *vs* 3.90 ± 0.10 and 2.64 ± 0.27 *vs* 3.90 ± 0.10, $P < 0.05$, respectively). The microscopic score was the same in HCl group and in HCl/P/BA group. The microscopic changes were significantly severer in group HCl/P/BA/INDO than that in not treated group (3.90 ± 0.10 *vs* 2.64 ± 0.27, $P < 0.05$) and also than that in analogical group treated with NS-398 (3.90 ± 0.10 *vs* 2.58 ± 0.14, $P < 0.05$). We noticed significantly higher score of microscopic changes in group HCl/P/INDO than that in group treated with NS-398 (3.92 ± 0.07 *vs* 2.12 ± 0.13, $P < 0.05$). Inflammation of esophagus in HCl group was significantly lower than that in HCL/P group (2.63 ± 0.24 *vs* 3.90 ± 0.10, $P < 0.05$). The inflammation score in HCl/P/BA group was also lower than that in HCl/P (2.23 ± 0.26 *vs* 3.90 ± 0.10, $P < 0.05$). Inflammation was less evident in HCl/P/NS-398 than those in not treated group and in group treated with indometacin (2.21 ± 0.11 *vs* 3.90 ± 0.10 and

Table 1 Macroscopic and microscopic changes in mice esophageal mucosa (mean ± SE)

Model	Grades of acroscopic changes	Grades of microscopic changes	Grades of inflammation	Surface of esophagitis (% of all esophagus)	Ulcers of esophagus (mm^2)
HCl	2.08 ± 0.11	2.63 ± 0.38	2.63 ± 0.24	15.50 ± 2.02	0 ± 0.0
HCl/P	3.69 ± 0.23[a]	3.90 ± 0.10[a]	3.90 ± 0.10[a]	23.00 ± 2.31[a]	7.09 ± 2.17[a]
HCl/P/BA	2.58 ± 0.25[c]	2.64 ± 0.27[c]	2.23 ± 0.26[c]	23.46 ± 3.85[a]	0.71 ± 0.49[ac]
HCl/P/INDO	3.90 ± 0.08	3.92 ± 0.07	3.86 ± 0.11	25.12 ± 2.14	8.11 ± 2.31
HCl/P/NS-398	2.13 ± 0.21[cg]	2.12 ± 0.13[g]	2.21 ± 0.11[cg]	19.12 ± 1.34	5.12 ± 2.13
HCl/P/BA/INDO	3.92 ± 0.06[e]	3.90 ± 0.10[e]	3.93 ± 0.03[e]	31.17 ± 2.45[e]	1.35 ± 0.11[e]
HCl/P/BA/NS-398	2.32 ± 0.11[g]	2.58 ± 0.14[g]	2.42 ± 0.13[g]	21.23 ± 1.21[g]	0.98 ± 0.27

[a]P<0.05 *vs* HCl; [e]P<0.05 *vs* HCl/P/BA; [g]P<0.05 INDO; [c]P<0.05 *vs* HCl/P.

2.21 ± 0.11 *vs* 3.86 ± 0.11 respectively, $P < 0.05$). Inflammation score was higher in HCl/P/BA/INDO than those in not treated group and in group treated with NS-398 (3.93 ± 0.03 *vs* 2.23 ± 0.26 and 3.93 ± 0.03 *vs* 2.42 ± 0.13 respectively, $P < 0.05$). Esophagitis index in HCl group was significantly lower than those in HCl/P and HCl/P/BA groups (15.50 ± 2.02 *vs* 23.00 ± 2.31 and 15.50 ± 2.02 *vs* 23.46 ± 3.85 % of all esophagus surface, $P < 0.05$). Surface area of esophagitis was significantly larger in HCl/P/BA/INDO group than that in not treated one (31.17 ± 2.45 *vs* 23.46 ± 3.85, $P < 0.05$) and also larger than that in group treated with NS-398 (31.17 ± 2.45 *vs* 21.23 ± 1.21, $P < 0.05$). In the HCl group of animals we did not observed any ulceration of the esophagus. In HCL/P group the surface of esophagus with ulceration was significantly larger than that in HCl/P/BA group (7.09 ± 2.17 *vs* 0.71 ± 0.49 mm^2, $P < 0.05$). The surface of ulceration in esophagus was significantly larger in HCl/P/BA/INDO group than that in not treated group (1.35 ± 0.11 *vs* 0.71 ± 0.49, $P < 0.05$). All data are showed in Table 1.

In the HCl group the concentration of PGE2 in middle part of esophagus was significantly higher than in lower part (1 027 ± 166 pg/mg of protein *vs* 378 ±69 pg/mg of protein, $P < 0.05$). We also observed the higher concentration of PGE2 in the middle part of esophagus than that in lower one in animals from HCL/P/BA groups (1 264 ± 134 pg/mg of protein *vs* 332 ± 59 pg/mg of protein, $P < 0.05$). In the HCL/P/BA group the concentration of PGE2 was significantly higher in the middle part of esophagus than that observed in the HCl/P (1 264 ± 134 pg/mg of protein *vs* 766 ± 95 pg/mg of protein, $P < 0.05$). The concentration of PGE2 in upper part of esophagus in HCl/P/BA/INDO group was significantly lower than that in not treated group (553 ± 50 *vs* 807 ± 111 pg/mg of protein, $P < 0.05$). We noticed lower PGE2 concentration in middle part of esophagus in HCl/P/BA treated with indometacin and NS-398 than that in not treated analogical group (614 ± 64 *vs* 1264 ± 134 and 733 ± 67 *vs* 1 264 ± 134 pg/mg of protein respectively, $P < 0.05$). All data are shown in Table 2.

DISCUSSION

In our current study we demonstrated the significantly increase of macroscopic damage score in esophageal mucosa in animals perfused with HCl/P when compared with HCl and HCl/P/BA group. In addition in group perfused with HCl/P the microscopic changes were significantly remarkable compared to that in HCl and HCl/P/BA perfused animals. Inflammation of esophagus in HCl/P group was evidently severer than that in HCl only perfused animals. Inflammation of the esophageal mucosa in group with perfusion mimicking duodenogastroesophageal reflux was significantly higher than in HCl and HCl/P/BA perfused groups. The total surface of esophagitis in HCl/P perfused animals was significantly larger than that in HCl perfused group of animals. We observed wider surface of esophagitis in group perfused with HCl/P/BA – mimicking duodenogastroesophageal reflux, than in HCl/P perfused animals but the differences was not significant. However, the surface of esophagus with esophagitis in group mimicking the duodenogastroesophageal reflux was significantly larger than that observed in HCl perfused group. In group of mice with perfusion of esophagus with HCl we did not find any ulceration. We demonstrated in group with HCl/P significantly larger surface of esophagus with ulcer (10-fold) than in HCl/P/BA group. In our study we also found the significant decrease of macroscopic damage in esophageal mucosa in group of animals perfused with HCl/P and treated with NS-398. Macroscopic score in this group was lower than that in analogical group treated

with indomethacine. We also observed this phenomenon in microscopic and inflammatory scores. We noticed that animals perfused with HCl/P/BA and treated indomethacine had higher values of all macro- and microscopical scores than in not treated group. In addition, HCl/P/BA group of mice treated with NS-398 showed lower values of all macro-and microscopical scores than that observed in animals treated with indomethacine.

It was recently documented that in patients with reflux esophagitis the concentration of bile acids in refluxate is significantly higher than that in asymptomatic volunteers[15,16].

Chronic GERD may induced Barrett`s metaplasia[3]. This clinical situation has increased risk for the development of esophageal adenocarcinoma and is considered to be a premalignant condition[4]. The concentration of bile was significantly higher in patients with early adenocarcinoma arising in Barrett`s esophagus, compared to GERD patients, esophagitis group and asymptomatic volunteers[6].

In our previous clinical study we demonstrated that perfusion with acid, pepsin and bile acids, mimicking the duodenogastroesophageal reflux episodes increased the esophageal protective components secretion in asymptomatic volunteers, and less evidently in GERD patients.

There are some surgical experimental model of esophagitis, Barrett`s esophagus and also adenocarcinoma of esophagus[17,18]. In animal studies it has been shown that reflux of gastric contents with addition of duodenal juice into the esophagus may lead to esophageal adenocarcinoma[19]. The carcinogenetic effect of duodenal contents on gastric mucosa was clearly demonstrated [8]. The higher concentration of PGE2 in esophagus may be connected with deeper impact of bile acids on the esophagus wall, and induction of COX-2 in the esophagus muscle cells [5]. The role of COX-2 inhibitors in that phenomenon is still unclear and need more experiments.

Our new experimental model of esophagitis in mice mimicking the clinical scenario of gastroesophageal or duodenogastroesophageal reflux seems to be a useful tool to investigate some pathological problems in esophageal pathophysiology.

In conclusion, pepsin is the pivotal factor in the development of chronic esophageal injury. Bile acids diminish chronic esophageal injury induced by HCl/P, indicating its potential negative impact on pepsin proteolytic potential, pivotal for mucosal injury in low pH. The COX-2 inhibitors are much more active than not selective inhibitors in patients with esophageal mucosa injury, especially during duodenogastroesophageal reflux scenario. This novel chronic experimental esophagitis is an excellent model for further study on the role of cytokines in health and disease of the esophageal mucosa in genetically modified animals.

Abstract

AIM: Gastrointestinal stromal tumors (GISTs) are rare. GISTs differ from other mesenchymal tumors of the gastrointestinal tract (e.g. leiomyomas and schwannomas). The purpose of this study was to investigate the role of Ets-1 in the growth and differentiation of GISTs.

METHODS: Twenty-eight GISTs, nine leiomyomas and six schwannomas were examined by immunohistochemical staining method for Ets-1 in this study. Specimens were selected from surgical pathology archival tissues at Nagasaki University Hospital.

RESULTS: Ets-1 protein was expressed in the cytoplasm of cells in all of these tumors. Immunohistochemical staining revealed that 27 GISTs (96.4%), six leiomyomas (66.7%), and five schwannomas (83.3%) were positive for Ets-1. Ets-1 expression was statistically different between GISTs and leiomyomas ($P < 0.005$). However, there was no correlation between Ets-1 expression and clinical risk categories.

CONCLUSION: Ets-1 plays an important role in the growth and differentiation of GISTs, leiomyomas and schwannomas.

Key words: Ets-1; GISTs; Leiomyoma; Schwannoma; Immunohistochemistry; Risk category

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare mesenchymal tumors of the gastrointestinal tract that may occur from the oesophagus to the anus, including the omentum. These tumors have a wide clinical spectrum from benign, incidentally detected nodules to frankly malignant tumors[1]. Small GISTs are often detected incidentally during surgery for other conditions, during gastroscopy, or on routine X-ray[1,2]. GISTs may present with bleeding, perforation, pain, obstruction or a combination of these symptoms[3-6]. The mechanisms of tumorigenesis, progression and differentiation of GISTs are unknown. Traditionally, all primary mesnchymal spindle cell tumors of the gastrointestinal (GI) tract were uniformly classified as smooth muscle tumors (e.g., leiomyomas, cellular leiomyomas or leiomyosarcomas). Tumors with epithelioid cytologic features were designated leiomyoblastomas or epithelioid leiomyosarcomas[7]. Recently, Sircar *et al* postulated that GISTs origin-ate from Cajal cells in the gastrointestinal tract and differ from leiomyomas and schwannomas, which are of mesenchymal cell origin[8]. Cajal cells are thought to be gastrointestinal pacemaker cells that regulate intestinal motility[9]. GISTs are characterized by frequent expression of the bone marrow leukocytic progenitor cell antigen CD34[10] and the c-kit proto-oncogene[8,11,12]. Ets-1 was characterized originally as the v-ets retroviral gene, one of two oncogenes (v-myb and v-ets) of the avian leukemia retrovirus, E26[13]. The ets family of genes encodes transcription factors for mesodermal cell development during embryogenesis[14, 15].

Ets-1 plays a role in the regulation of physiological processes such as cell proliferation and differentiation[16]. Ets-1 also is expressed in astrocytes and vascular smooth muscle cells[17,18] but its expression has not been reported in Cajal cells. Increased Ets-1 expression was observed in several tumors in our previous studies[19-22]. We reported

Table 1 Ets-1 immunohistochemistry in intestinal stromal tumors. *n* (%)

	n	-	+	++
GISTs	28	1 (3.6)	4 (14.3)	23 (82.1)[a]

[a]$P<0.005$ *vs* leiomyomas.

that Ets-1 is correlated with the progression of carcinoma cells of the stomach, pancreas, and thyroid and cells of astrocytic tumors[19-22]. These studies suggest that Ets-1 is involved in tumor growth and differentiation. However, there are no data concerning Ets-1 expression in GISTs, leiomyomas or schwannomas or the role of Ets-1 in the etiology of these tumors. The purpose of this study was to investigate the expression of Ets-1 in GISTs.

MATERIALS AND METHODS

Samples

A total of twenty-eight GISTs included 24 cases from the stomach and four from the small intestine. Nine leiomyomas included four from the oesophagus, two from the stomach and three from the large intestine, and five schwannomas included four from the stomach and one from the large intestine. Specimens were selected from surgical pathology archival tissues at Nagasaki University Hospital between 1999 and 2004. The GISTs were 0.8 - 12.0 cm in diameter, the leiomyomas were 0.1 - 4.5 cm, and the schwannomas were 0.6 - 5.0 cm. In this study, GISTs were defined as expressing both c-kit and CD34 surface antigens. GISTs were classified by risk categories, mitosis counts and tumor size[23]. The number of mitoses was determined by counting 50 high-power fields (HPF, x400) in Nikon (Tokyo, Japan) E400 microscope. Leiomyomas were defined as expressing α-smooth muscle actin (SMA) but not c-kit, CD34 and S100-protein. Schwannomas were defined as expressing S100-protein but not c-kit, CD34 and SMA. Tumor identification/classification was determined by two independent pathologists (T. Nakayama and I. Sekine).

Immunohistochemical staining

The subcellular localization of Ets-1 was determined in GISTs using a monoclonal antibody directed against the unique middle sequence of Ets-1 and this antibody was devoid of any cross-reaction with other proteins in the Ets family. Formalin-fixed and paraffin-embedded specimens were cut into 4 μm thick sections, deparaffinized and preincubated with normal bovine serum to prevent non-specific binding. The sections were incubated overnight at 4°C with the primary monoclonal antibody to human Ets-1 (1 g/L; Santa Cruz Biotechnology, Inc., Santa Cruz, CA) and then with a horseraddish peroxidase conjugated goat anti-mouse IgG antibody (0.4 g/L; Santa Cruz Biotechnology, Santa Cruz, CA). The reaction products were resolved using diaminobenzidine (DAB; DAKO Ltd., Glostrap, Denmark). Negative controls involved replacing the primary antibody with non-immunized mouse serum and human gastric cancer tissue served as the positive control[19]. Ets-1 expression was classified into three categories depending upon the percentage of cells stained and/or the intensity of staining: -, 0% to 10% tumor cells positive; +, 10% to 50% tumor cells positive; and ++, >50% tumor cells positive.

Statistical analysis

The Stat View II program (Abacus Concepts, Inc., Berkeley, CA) was used for statistical analyses. Analyses comparing the degree of Ets-1 expression in GISTs, leiomyomas and schwannomas were performed using the Mann-Whitney's test.

RESULTS

The results of immunohistochemical staining for Ets-1 are summarized in the Table 1. Ets-1 expression was heterogeneous in GISTs and localized to the cytoplasm (Figure 1). Twenty-three of the GISTs (82.1%) were strongly positive, four (14.3%) were positive and one (3.6%) was negative for Ets-1. Similarly, four of the schwannomas (66.7%) were strongly positive, one (16.7%) was positive and one (16.7%) was negative. However, only three of the leiomyomas (33.3%) were strongly positive, three (33.3%) were positive and three (33.3%) were negative. There is a statistical difference in Ets-1 expression between the GISTs and the leiomyomas ($P<0.005$). Positively stained cells, i.e. those classified as ++ or +, were found in 96.4% of the GISTs, 66.7% of the leiomyomas and 83.3% of the schwannomas. Ets-1 was expressed in the cytoplasm of cells in all three tumors. However, normal stromal cells and smooth muscle cells showed faint or focal positivity of expression. GISTs were classified by risk categories, mitosis counts and tumor size in Table 2. In risk categories, all nine cases of high and intermediate groups were strongly expressed Ets-1 protein. In mitosis counts, all eight cases with over 6 mitoses per 50 HPF strongly expressed Ets-1. In tumor size, all five cases with over 5 cm strongly expressed Ets-1. However, there was no correlation between

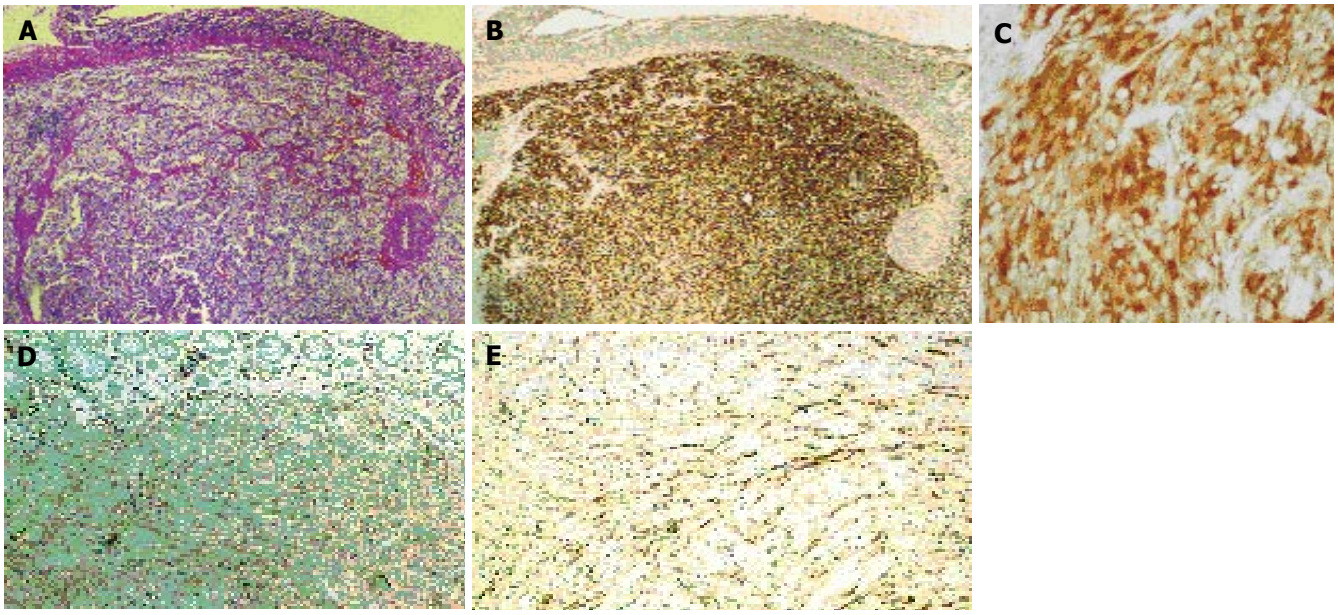

Figure 1 Ets-1 expression in GISTs (**A**-**C**), Leiomyomas (**D**) and Schwannomas (**E**). (magnification; **A**, **B**:x20, **C**: x 200, **D**, **E**: x100).

Ets-1 expression and each classification.

DISCUSSION

GISTs are known to originate from the Cajal cells of the neural crest[8] and schwannomas are thought to originate from the peripheral nerve sheath cell[24]. In this study, Ets-1 expression was higher in GISTs and schwannomas than in leiomyomas. Ets-1 expression has been reported in neural cells and astrocytes[22], but not yet in Cajal cells, cells that are all of neurons origin. Vascular smooth muscle cells also express Ets-1[18]. These findings suggest that Ets-1 may play a role in neural differentiation of intestinal stromal tumors. Previous studies have demonstrated Ets-1 expression in several tumors and normal stromal cells[19-22,25]. Furthermore, Ets-1 has been shown to play a role in the proliferation and/or differentiation of stromal cells[25]. We have shown already that Ets-1 may function as a growth factor in several tumors[19-22]. However, there have been no studies of Ets-1 expression in GISTs, leiomyomas and schwannomas, or of the potential role of Ets-1 in the growth of these tumors. Our results demonstrate substantial levels of Ets-1 expression in the cytoplasm of GIST, leiomyoma and schwannoma cells. These results suggest that Ets-1 may play a role in the growth and/or differentiation of intestinal tumors.

Ets-1 regulates the expression of many proteins, such as matrix metalloproteinases, urokinase type-plasminogen activator and parathyroid hormone-related peptide (PTHrP), which promote tumor growth and/or progression[26,27]. In our previous study, PTHrP and its receptor were found to be highly expressed in GISTs, leiomyomas and schwannomas[28]. Ets-1 may promote tumor growth and/or progression through regulating the expression of these proteins.

In recent studies, mutations affecting c-kit that cause constitutive tyrosine kinase activation have been shown to be important for the pathogenesis of GIST[29,30]. Joensuu *et al* reported a patient in whom STI-571 (imatinib, Gleevec), a tyrosine kinase inhibitor, was effective against a GIST[31]. And STI-571 has proven to be remarkably efficacious in heavily pretreated GISTs patients with advanced disease in phase II clinical trials[32]. The expression of the Ets family protein is upregulated by the activation of tyrosine kinase through the mitogen-activated protein kinase pathway[33]. Ets-1 expression may be upregulated by the c-kit/tyrosine kinase pathway.

ACKNOWLEDGEMENTS

We are grateful to Mr. Toshiyuki Kawada (Nagasaki University Graduate School of Biomedical Sciences) for his excellent immunohistochemical assistance.

Abstract

AIM: To detect plasma levels of new adipocyte derived hormone adiponectin and resistin in type 2 diabetes patients and to explore their potential roles in insulin resistance in type 2 diabetes.

METHODS: According to the body mass index (BMI), 60 type 2 diabetes patients were divided into two groups, one group was non-obese diabetes patients with BMI < 25Kg/M^2 (30 cases) and the other group was obese diabetes patients with BMI > 25Kg/M^2 (30 cases). There were 28 healthy persons in the control group. ELISA technique was employed to determine the plasma adiponectin and resistin concentrations. The fasting blood glucose, insulin and blood lipid were detected respectively by electrocheminescence immunoassay and immunoturbidimetric assay. Insulin resistance index and insulin sensitive index were calculated by the homeostasis model assessment (HOMO).

RESULTS: The levels of plasma adiponectin were decreased significantly in diabetes group compared to that in control group (non-obese: 8.58 ± 0.86, obese: 6.22 ± 1.34 *vs* 10.53 ± 1.47 $P < 0.05$); moreover, adiponectin concentration in obese diabetes group was significantly decreased compared to that in non-obese diabetes group (6.22 ± 1.34 *vs* 8.58 ± 0.86, $P < 0.05$). The levels of plasma resistin were increased significantly in diabetes group compared to that in control group (obese: 18.64 ± 4.65, non-obese: 24.05 ± 9.07 *vs* 14.16 ± 5.25, $P < 0.05$, $P < 0.05$); furthermore, the levels of resistin in obese diabetes group were increased significantly compared to that in non-obese diabetes group ($P < 0.05$). Plasma adiponectin was correlated negatively with BMI, blood glucose, insulin resistance index and triglyceride (respectively, $r = -0.55$, $P < 0.01$; $r = -0.51$, $P < 0.05$; $r = -0.52$, $P < 0.05$; $r = -0.39$, $P < 0.05$), while it was positively correlated with insulin sensitive index (r=0.45, $P < 0.05$). Conversely, plasma resistin correlated positively with BMI, blood glucose, triglyceride and insulin resistance index (respectively, $r = 0.40$, $P < 0.05$; $r = 0.52$, $P < 0.05$; $r = 0.46$, $P < 0.01$; $r = 0.27$, $P < 0.05$), and negatively correlated with insulin sensitive index ($r = -0.32$, $P < 0.05$).

CONCLUSION: Plasma adiponectin and resistin are associated with the disorder of metabolism of glucose and lipid in diabetes. The relationship between these hormone and insulin sensitivity suggests that they may take part in the development of insulin resistance of type 2 diabetes.

Key words: Adiponectin; Resistin; Adipocyte; Type 2 diabetes

INTRODUCTION

The prevalence of obesity is rapidly increasing with the changes of life style and structure of meals. The high prevalence of obesity has led to an increase in medical conditions that accompany obesity, especially type 2 diabetes (also known as non-insulin dependent diabetes mellitus, NIDDM), hypertension, cardiovascular disease (CVD), and certain cancers. Perhaps most importantly, obesity generally confers a significantly increased rate of mortality when compared with individuals of normal body weight[1].

Adipose tissue was once considered to be an inert storing depot for energy, in the form of triglyceride. However, in recent years, a line of evidence has

Table 1 Subject characteristics and plasma glucose, insulin, and lipid levels

Parameter	Control group	Non-obese diabetes group	Obese diabetes group
n	28	30	30
Age (yr)	47±11	48 ± 8	52 ± 9
Gender (M/F)	14/14	14/16	16/14
BMI (kg/m^2)	24.03±4.05	23.13±1.62	27.25±1.71^{ac}
FPG (mmol/L)	4.97±0.56	9.9±2.03^a	10.03±2.08^a
FINS (mU/L)	6.25±4.22	9.52±7.81	8.72±4.64
IR	0.50±0.35	0.98±0.59^a	1.22±0.53^a
ISI	-3.61±0.35	-4.09±0.59^a	-4.33±0.54^a

TG (mmol/L)	1.48±1.74	2.45±1.46^a	3.05±1.92^a
NEFA (mmol/L)	0.71±0.18	0.95±0.21^a	1.13±0.24^a

BMI: body mass index; FPG: fasting plasma glucose; FINS: fasting insulin; IR: insulin resistance; ISI: insulin sensitive index; TCH: total cholesterol; TG: plasma triglyceride; NEFA: non-esterified fatty acids. $^aP<0.05$ *vs* control group; $^cP<0.05$ *vs* non-obese diabetes group.

demonstrated a much more complex function of adipose tissue, as an endocrine organ that releases hormones into the blood stream to take part in their potential implication in insulin resistance, obesity and diabetes[2]. The recent boom of interest in adipocyte derived factors has resulted in identification of a large group of adipocyte specific proteins, such as adiponectin, acylation stimulating protein, resistin, leptin, etc[3]. These adipocyte derived hormones are presently subject to intensive research concerning their involvement in the regulation of adipose tissue physiology, and in particular, their potential implication in insulin resistance, obesity and diabetes[4].

Both adiponectin and resistin are new hormones secreted exclusively from adipose tissue. They have important biological activity on glucose and lipid metabolism; moreover, they can affect insulin resistance. The present study was carried out based on the hypothesis that plasma adiponectin and resistin would play some roles in type 2 diabetes.

MATERIALS AND METHODS

Subjects and fasting blood samples

A total of 88 subjects were recruited from outpatient clinics at the Tongji Medical Centre, TongJi Hospital, Wuhan, Hubei province, China. All participants gave informed consent and the study was approved by Tongji Hospital Ethics Committee. Type 2 diabetic patients ($n=60$) were recruited at the time of their initial screening at the Endocrinology Clinic. Non-diabetic control subjects ($n=28$) were normal healthy adults recruited at their yearly checkups. Diabetes was defined in conformity with 1999 World Health Organization. According to the obesity criteria established in 2000 of Asia area, the diabetes patients were divided into two groups: (1) Non-obese diabetes group: BMI <25 ($n=30$); (2)Obese diabetes group: BMI $\geqslant 25$ ($n=30$). The type 2 diabetic participants had not taken any medication (including antidiabetic medication or herbal preparations) before we collected the blood samples. Subjects in diabetic and control groups were confirmed to have no known disease (including cardiovascular disease, thyroid disease, hypertension or any other acute and chronic disease condition) or any current infectious condition.

Table 2 Plasma adiponectin and resistin levels in diabetes patients divided by body weight

	Control group	Non-obese diabetes group	Obese diabetes group
Adiponectin (mg/L)	10.53±1.47	8.58±0.86^a	6.22±1.34^{ac}
Resistin (mg/L)	14.16±5.25	18.64±4.65^a	24.05±9.07^{ac}

$^aP<0.05$ *vs* control group; $^cP<0.05$ *vs* non-obese diabetes group.

Blood samples were drawn after an overnight fast from an antecubital vein. Fasting plasma samples were used for measurement of all parameters. The samples were centrifuged, aliquoted and immediately frozen at -80℃ for analyses of lipoproteins and proteins

Analytical procedures

Plasma samples were analyzed for concentrations of adiponectin, resistin, insulin, glucose, non-esterified fatty acids (NEFA), triglycerides (TG), total cholesterol (TCH). Plasma triglycerides (TG) were measured by GPO-PAP method and total cholesterol was measured by COD-PAP method. The plasma NEFA concentration was determined by colorimetric enzymatic assay (WAKO Chemicals, Tokyo, Japan).

Plasma glucose was determined by glucose-oxidase method (AVE-852 half-auto biochemical analyzer). Plasma insulin was measured by electrocheminescence immunoassay (Elecsys 1010, Roche Instrument Center AG).

Plasma adiponectin was measured by ELISA (B-Bridge International, Phoenix, AZ, USA) and plasma resistin also measured by ELISA (BioVendor Laboraory Medicine, USA).

Calculation

Body mass index (BMI) was calculated as weight (kg) per height (m^2). Insulin resistance index (IRI) was calculated by homeostasis model assessment, HOMA-IR as (fasting insulin IU/L) × (fasting glucose mmol/L) / 22.5 as previously reported by Matthews[5]. Insulin sensitivity index (ISI) was calculated as 1/[(fasting insulin IU/L) × (fasting glucose mmol/L)].

Statistical analysis

All results are displayed as mean ± SE (standard error of mean) unless stated otherwise. ANOVA analyses were used to compare means among the groups and correlations were calculated using Pearson correlation coefficient or multiple regression analysis. $P<0.05$ was considered statistically significant for all analyses.

RESULTS

The age and gender had no significant differences between diabetes group and control group. Subject characteristics are presented in Table 1.

The results of adiponectin and resistin are shown in

Table 3 Correlation analysis of fasting plasma adiponectin and resistin with the other parameters

	Adiponectin		Resistin	
Parameter	*r*	*P* value	*r*	*P* value
BMI	-0.55	0	0.4	0
FPG	-0.51	0	0.52	0
FINS	0.15	0.16	0.1	0.39
IR	-0.52	0	0.46	0
ISI	0.45	0	-0.32	0
TCH	-0.15	0	0.07	0.53
TG	-0.39	0.02	0.27	0.01
NEFA	-0.45	0	0.29	0

BMI: body mass index; FPG: fasting plasma glucose; FINS: fasting insulin; IR: insulin resistance; ISI: insulin sensitive index; TCH: total cholesterol; TG: plasma triglyceride; NEFA: non-esterified fatty acids. $^{a}P<0.05$ *vs* control group; $^{c}P<0.05$ *vs* non-obese diabetes group.

Table 2. There was a significant decrease in adiponectin in diabetes group as compared to that in control group ($P<0.05$). Furthermore, adiponectin in obese diabetes group was lower than that in non-obese diabetes group ($P<0.05$), while plasma resistin levels of non-obese diabetes group and obese diabetes group were apparently increased as compared to that in control group ($P<0.05$). Moreover, resistin level of obese diabetes group was also apparently higher than that of non-obese diabetes group ($P<0.05$).

There were significant differences in blood lipid parameters, including TG, TCH and NEFA, as given in Table 1. Cholesterol and triglyceride in non-obese diabetes group and obese diabetes group were apparently higher than that in control group ($P<0.05$), but there was no significant difference between non-obese diabetes group and obese diabetes group. The level of fasting insulin was not significantly different among the three groups ($P>0.05$). Fasting plasma glucose in diabetes group was apparently higher than that in control group ($P<0.05$), and there was no significant difference between non-obese and obese diabetes groups.

Pearson correlation analysis was used to identify the factors that most closely related to the hormones adiponectin and resistin, as shown in Table 3. Plasma adiponectin correlated negatively with BMI, blood glucose, insulin resistance index and triglyceride (respectively, $r=-0.55$, $P<0.05$; $r=-0.51$, $P<0.05$; $r=-0.52$, $P<0.05$; $r=-0.39$, $P<0.05$); whereas it was positively correlated with insulin sensitive index ($r=0.45$, $P<0.05$). Plasma resistin was correlated positively with BMI ($r=0.39$, $P<0.05$), fasting plasma glucose ($r=0.37$, $P<0.05$) and triglyceride ($r=0.41$, $P<0.05$); and it was correlated positively with insulin resistance index ($r=0.49$, $P<0.05$), but negatively with insulin sensitive index ($r=-0.34$, $P<0.05$). There was no significant correlation between plasma resistin and insulin and cholesterol, but there was significant correlation between plasma adiponectin and cholesterol ($r=-0.15$, $P<0.05$).

DISCUSSION

Recent clinical and experimental data have radically modified the concept of adipose tissue as one solely devoted to energy storage and release. Adipose tissue is also an important endocrine organ. It can release hormones into the blood stream in response to specific extra cellular stimuli or changes in metabolic status. The factors secreted by adipose tissue are actively involved in energy homeostasis in that they signal to the brain, the pancreatic β-cells, the liver and skeletal muscle in order to adapt to changes in energy stores by modulating feeding, insulin secretion and insulin sensitivity [6]. Secreted factors may include leptin; steroids and glucocorticoids; peptide hormone precursors, e.g. angiotensinogen; complement factors, e.g. adipsin, acylation-stimulating protein (ASP) adiponectin; pro-inflammatory cytokines, e.g. tumor necrosis factor α (TNF-α), interleukin 6 (IL-6); resistin; etc. Most of these products probably act through paracrine or autocrine mechanisms[7].

Adiponectin, also known as adipose most abundant gene transcript 1 (apM1), adipoQ and adipocyte complement related protein of 30 Kdaltons (ACRP30) was originally identified as the product of a highly induced gene after 3T3-L1 differentiation. It is a relatively abundant plasma protein (around 0.01% of total plasma proteins) that is exclusively synthesized and secreted by white adipose tissue (WAT)[8]. Adiponectin has many metabolic actions involving peripheral tissue and the regulation of energy homeostasis, particularly energy expenditure. The new adipocykin can decrease plasma glucose, increase clearance of a glucose load and ameliorate insulin resistance in mouse models with normal (C57Bl/6J), reduced (ob/ob, db/db) or absent (lipoatrophic mice) adiponectin pathways[9]. Acute administration in mice reduces elevated postprandial NEFA resulting from ingestion of a high-fat test meal or lipid intravenous injection[10]. Daily administration of adiponectin in mice on a high-fat/ high-sucrose diet induces marked and sustainable weight loss without affecting food intake[11]. Adiponectin decreases muscle and liver TG content, increases gene expression related to muscle NEFA uptake and utilization, increases muscle NEFA oxidation, and enhances hepatic insulin-mediated suppression of glucose production[12]. Adiponectin knockout mice demonstrate insulin resistance after a glucose load or after a high-fat/ high-sucrose diet (2 wk), delayed NEFA clearance and decreased expression of NEFA transporters in muscle[13]. It is apparent that adiponectin is very important for the metabolism of lipid and glucose, as well as insulin sensitivity.

Adiponectin is the only WAT derived hormone whose levels are downregulated in obesity. Human, primate and mouse models of obesity and/or insulin resistance (Type II DM and ob/ob mice) have reduced circulating adiponectin concentrations and expression in WAT[14]. In a recent study in adolescents, plasma adiponectin was shown to correlate with insulin sensitivity but was inversely proportional to plasma triglyceride and intra-myocellular lipid, suggesting its functional link to insulin resistance[15]. During weight-reduction or prolonged negative energy balance, circulating adiponectin is elevated in human[16]. We found that plasma adiponectin was decreased significantly in diabetes group, especially in obese diabetes group. Moreover, plasma adiponectin correlated negatively with insulin resistance

index, triglyceride and correlated positively with insulin sensitive index. It is well known that adiponectin improves insulin sensitivity of the whole body, so we speculated the decreased adiponectin in type 2 diabetes may be one of the reasons to cause insulin resistance. The change of plasma adiponectin was correlated with the development of insulin resistance in diabetes. It is unclear why adiponectin levels were decreased in obese diabetes with more fat tissue which can produce adiponectin. Some researchers speculated that the suppression of adiponectin production in obesity and diabetes may be mediated by an autocrine negative feedback inhibition in WAT, for instance, lower expression of adiponectin mRNA was found in cultured human visceral WAT and microarray study demonstrated that adiponectin expression is suppressed with the development of obesity and diabetes in mice[17].

Resistin is another protein identified recently as a hormone secreted by adipocytes which leads to insulin resistance *in vivo* and *in vitro* and might therefore be an important link between obesity and diabetes[18]. 3T3-L1 cells can secrete abundant resistin into the medium and its mRNA is induced (reduced?) markedly during adipocyte differentiation of 3T3-L1 cells[19]. When these adipocytes were exposed to specific resistin antibody, the insulin-stimulated glucose uptake was increased significantly. Consistent with the results, treatment of 3T3-L1 adipocytes with purified resistin reduced insulin-stimulated glucose uptake[20]. These studies suggest that resistin functions as a signal to decrease insulin-stimulated glucose uptake. Administration of anti-resistin antibody also can improve blood glucose and insulin action in mice with diet-induced obesity[21]. Resistin gene and protein expression were increased in human abdominal adipose tissue. In this study we found that plasma resistin levels of non-obese diabetes group and obese diabetes group were apparently higher than that in control group. Furthermore, resistin levels in obese diabetes group were increased as compared to non-obese diabetes group. Meantime plasma resistin was correlated positively with insulin resistance index. Al-Harithy *et al*[22] had similar result in their study on type 2 diabetes. It was well known that resistin levels were increased in differentiation of adipocytes, obesity and people on high fat diet?, and it is increased in abdominal vs. thigh adipose tissue. There is a potential link between central obesity and type 2 diabetes and/or cardiovascular disease[23]. Functionally, resistin impairs glucose tolerance, insulin action, and increases hepatic glucose production, while a neutralizing antibody normalizes glucose levels and tissue glucose uptake[24]. It suggests that increased plasma resistin may be correlated with the development of insulin resistance in type 2 diabetes.

Type 2 diabetes mellitus is characterized by target-tissue resistance to insulin. It is strongly linked to obesity as over 80% of sufferers are obese[25]. While the molecular basis for this link has remained a mystery. Insulin resistance is the core pathogenic factor for diabetes. In addition, it is also strongly associated with obesity, hypertension and cardiovascular disease, etc. The new adipocytes derived hormones adiponectin and resistin may be an important link between increased fat mass and insulin resistance and disorder of metabolism of lipid and glucose in diabetes. Adipocytes have become the center for the study of the association of insulin resistance and type 2 diabetes[26]. Studies of the roles of adiponectin and resistin will shed new light on prevention and treatment of type 2 diabetes, and open a new field for the development of new drugs to improve insulin resistance.

ACKNOWLEDGMENTS

Abstract

AIM: To investigate the effect of the serum of patients with chronic hepatitis B (CHB) on apoptosis of renal tubular epithelial cells in vitro and to study the role of hepatitis B virus (HBV) and transforming growth factor-β1 (TGF-β1) in the pathogenesis of hepatitis B virus associated glomerulonephritis (HBV-GN).

METHODS: The levels of serum TGF-β_1 were measured by specific enzyme linked immunosorbent assay (ELISA) and HBV DNA was tested by polymerase chain reaction (PCR) in 44 patients with CHB ,and 20 healthy persons as the control. The normal human kidney proximal tubular cell (HK-2) was cultured together with the sera of healthy persons, CHB patients with HBV-DNA negative(20 cases) and HBV-DNA positive (24 cases) for up to 72 h. Apoptosis and Fas expression of the HK-2 were detected by flow cytometer.

RESULTS: The apoptosis rate and Fas expression of HK-2 cells were significantly higher in HBV DNA positive serum group 19.01±5.85% and 17.58±8.35%, HBV DNA negative serum group 8.12±2.80% and 6.96 ± 2.76% than those in control group 4.25±0.65% and 2.33 ± 1.09%, respectively ($P < 0.01$). The apoptosis rate and Fas expression of HK-2 in HBV DNA positive serum group was significantly higher than those in HBV DNA negative serum ($P < 0.01$). Apoptosis rate of HK-2 cells in HBV DNA positive serum group was positively correlated with the level of HBV-DNA ($r = 0.657$). The level of serum TGF-β_1 in CHB group was 163.05 ± 91.35 μg/L, significantly higher as compared with 81.40 ± 40.75 μg/L in the control group ($P < 0.01$).

CONCLUSION: The serum of patients with chronic hepatitis B promotes apoptotic damage in human renal tubular cells by triggering a pathway of Fas up-regulation. HBV and TGF-β_1 may play important roles in the mechanism of hepatitis B virus associated glomerulonephritis.

Key Words: Renal tubular epithelial cells; HBV; TGF-β_1; Apoptosis

INTRODUCTION

Hepatitis B (HBV) viruses are well-recognized causes for chronic hepatitis, cirrhosis, and even for hepatocellular carcinoma. Apart from liver disease, these viral infections are known to be associated with a spectrum of extrahepatic manifestations [1]. Hepatitis B is prevalent in China and hepatitis B virus associated glomerulonephritis has been one of the common renal damages secondary to HBV infection in Chinese children [2]. The cause of HBV-GN is generally believed to be immune mediated [3]. Recent studies showing expression of HBV viral antigens in kidney tissue and HBV DNA distributed generally in the nucleus and cytoplasm of epithelial cells of renal tubules suggest direct viral-induced pathological alterations and chronic immunologic injury [4,5]. Apoptosis is an active mode of cell death that promotes cell loss during both acute and chronic renal damage [6,7,8]. Here we investigated cell apoptosis in human renal tubular epithelial cells induced by sera of patients with chronic HBV infection and explored its mechanism.

MATERLALS AND METHODS

Patients and serum samples

Forty-four patients with chronic HBV infection (mild degree) came from Department of Infectious Diseases of the Affiliated Hospital of Luzhou Medical College, China

during 2003-2004. All the patients conformed to the revised standard of the Sixth National Meeting of Infectious Disease and Parasitosis in 2000. There were 38 men and 6 women. The median age was 34 years (range: 17-62 years). According to the HBV DNA levels in serum assayed by polymerase chain reaction (Positive criteria: $>1\times10^6$ copies/L), the patients were divided into HBV DNA positive patients group (24 cases) and HBV DNA negative patients group (20 cases). Twenty healthy persons whose serum markers of HBV were negative were used as the control. The blood collected from these persons was centrifuged at 4℃ and the serum samples were stored at -80 ℃ until examination. The serum samples were in the water bath at 56 ℃ for 30 min to inactivate complement. The level of HBV DNA in the serum samples was estimated by polymerase chain reaction (Shanghai Fortune Medical Science Co. Ltd, China) and TGF-β1 protein concentration was determined by specific-ELISA (Jingmei Biotech Co. Ltd, China).

Cell culture

All experiments were performed using the human kidney proximal tubular epithelial cell line (HK-2)[9] (American Type Culture Collection, USA). Cells were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum, at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2. Fresh growth medium was added to cells every three to four days until confluent.

Flow cytometry analysis

HK-2 was cultured in the presence of the serum (50 μL) of healthy persons, CHB patients with HBV-DNA negative and HBV-DNA positive for up to 72 h, respectively. The survival rate and apoptotic rate of HK-2 cells were determined by Annexin V and propidium iodide (PI)(Bio Vision, USA) staining. HK-2 cells were digested by 0.25% trypsin. Cells (5×10^5) were suspended in Binding Buffer. Annexin V (5 μL) and PI (5 μL) were then added and incubated with cells at room temperature for 5 min in the dark until detected by flow cytometry. HK-2 cells (5×10^5) suspended in binding buffer were stained at room temperature with CD95-FITC (20 μL) (Bio Vision, USA) for 20 min in the dark and evaluated by flow cytometry to determine Fas expression.

Statistical analysis

The data are expressed as means ± SD. Statistical analysis of data was performed using *t* test or *F* test, with a value of $P < 0.05$ considered to represent a significant difference.

RESULTS

Detection of HBV DNA

Serum samples of forty-four patients with chronic HBV infection were assayed by polymerase chain reaction. There are 24 cases with HBV DNA positive (9.36×10^6-1.57×10^{12} copies/L) and 20 cases with HBV DNA negative.

Detection of TGF-β1

The level of serum TGF-β1 in CHB group was 163.05 ± 91.35 μg/L, significantly higher as compared with 81.40 ± 40.75 μg/L in the control group (Table 1, $P<0.01$).

Table 1 Comparison between levels of TGF-β 1 in two groups

Group	Cases	TGF-β1 (μg/L)
Control	20	81.40 ± 40.75
CHB serum	44	163.05 ± 91.35[b]

[b]$P<0.01$ *vs* control.

Table 2 Apoptosis of HK-2 in all groups

Group	Cases	Apoptosis (%)
Control	20	4.25 ± 0.65
HBV DNA negative serum	20	8.12 ± 2.80[b]
HBV DNA positive serum	24	19.01 ± 5.85[bd]

[b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* HBV DNA negative serum.

Table 3 Expression of Fas of HK-2 cells in all groups

Group	Cases	Fas (%)
Control	20	2.33 ± 1.09
HBV DNA negative serum	20	6.96 ± 2.76[b]
HBV DNA positive serum	24	17.58 ± 8.35[bd]

[b]$P<0.01$ *vs* control; [d]$P<0.01$ *vs* HBV DNA negative serum.

Detection of apoptosis by flow cytometry

The apoptosis rate of HK-2 cells was significantly higher in HBV DNA positive serum group 19.01 ± 5.85% and HBV DNA negative serum group 8.12±2.80% than that in control group 4.25 ± 0.65%, respectively ($P < 0.01$) (Table 2, Figure 1). The apoptosis rate of HK-2 in HBV DNA positive serum group was significantly higher than that in HBV DNA negative serum group($P < 0.01$) (Table 2). Apoptosis rate of HK-2 cells in HBV DNA positive serum group was positively correlated with the level of HBV-DNA ($r = 0.657$) (Figure 2).

Detection of expression of Fas by flow cytometry

The expression of Fas of HK-2 cells was significantly higher in HBV DNA positive serum group 17.58 ± 8.35% and HBV DNA negative serum group 6.96 ± 2.76% than that in control group 2.33 ± 1.09%, respectively ($P<0.01$) (Table 3, Figure 3). The expression of Fas of HK-2 cells in HBV DNA positive serum group was significantly higher than that in HBV DNA negative serum ($P < 0.01$) (Table 3).

DISCUSSION

Apoptosis plays an essential role in the regulation of renal cell number in both healthy and diseased kidneys [10]. Efficient deletion by apoptosis of excessively damaged, or nonfunctioning renal cells and infiltrating inflammatory cells may be beneficial. However, the loss of resident renal cells by uncontrolled apoptosis is detrimental as it may in-

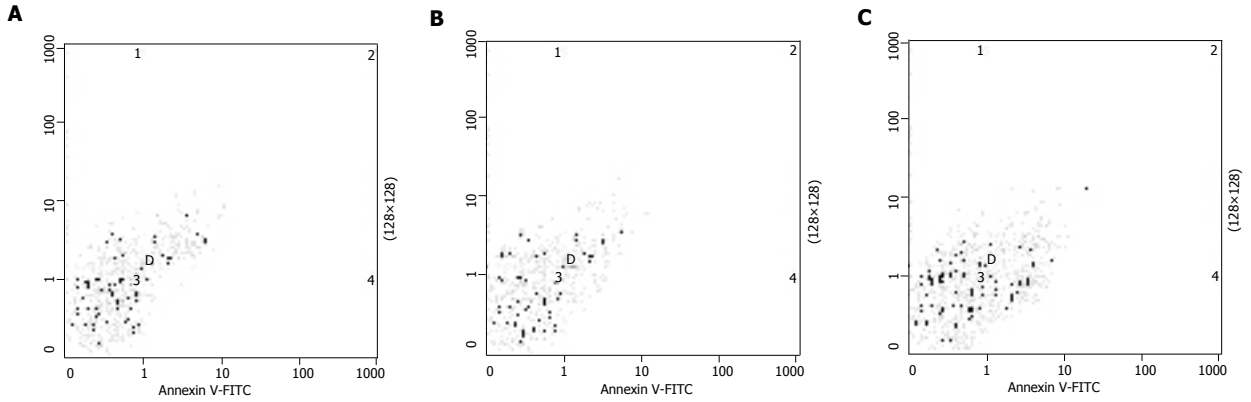

Figure 1 Flow cytometric analysis of HK-2 cells stained with Annexin V and PI. **A**: Treated with serum of healthy persons. **B**: Treated with HBV DNA negative serum. **C**: Treated with HBV DNA positive serum.

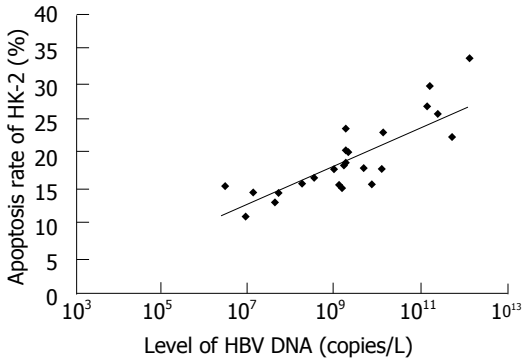

Figure 2 Relationship between apoptosis of HK-2 and levels of HBV DNA in HBV DNA positive serum.

duce a reduction of functional renal mass and lead to renal insufficiency [11-13]. Several external and internal signals can induce apoptosis, which is then effected via a number of pathways. These pathways are either the Fas/FasL pathway and downstream MAPK (mitogen-activated protein kinases) and JNK (c-Jun N-terminal kinase) signal transduction, or the RANK/RANK-L (receptor activator of NFkB) pathway via activation of the caspase cascade [14,15]. Finally, irreversible branch of these pathways is the release of cytochrome c from the mitochondria, leading to nuclear fragmentation [16,17]. Previous studies indicated that pathological factors had a toxic effect on HK-2 cells by triggering an apoptotic pathway involving caspase activation, Fas up-regulation, Fas ligand (FasL) expression, the increase of Bax, the decrease of Bcl-2 protein expression and JNK signaling transduction[18,19], thus potentially interacting with mechanisms of cell loss which have been already shown to be activated in chronic renal diseases. In this study, we showed that CHB serum induced a significant increase in apoptosis in HK-2 cells detected by flow cytometry. It suggested that CHB serum might play a crucial role in the apoptosis of HK-2 cells. Excessive apoptosis of renal proximal tubular cells might be associated with renal injury in patients with chronic HBV infection.

Hepatitis B virus associated glomerulonephritis is occurring at a high prevalence in most Asian endemic areas [20]. The detailed mechanism of renal tubular epithelial cells (RTC) injury in HBV-GN remained unclear. The cause of HBV-GN is generally believed to be immune mediated [3]. Recent studies suggest hepatitis B viral direct infection in RTC may be correlated with renal pathological alterations. HBV DNA and HBV antigen were distributed generally in epithelial cells of renal tubules and the positive results from HBV DNA in situ hybridization correlated well with HBV antigen assays[4,5,20]. The analyses implied that the more extensive the existence of HBV DNA in the nephron unit, the more severe the clinical manifestation. The duration of proteinuria in cases with HBV DNA in renal tubules was much longer than in those with no HBV DNA in renal tubules [5]. Our previous study has observed that the rate of early impairment of renal cells in HBV DNA positive patients with HBV chronic infection was higher than that in HBV DNA negative patients with HBV chronic infection[21]. In this study, we demonstrated that apoptosis of HK-2 cells stimulated by HBV DNA positive serum was significantly higher than that of HBV DNA negative serum, and the apoptosis rate of HK-2 cells was correlated with serum level of HBV-DNA positively. These data suggested that the level of HBV DNA in CHB serum may have a significant effect on the apoptosis of HK-2 cells, and supported the viewpoint that hepatitis B viral direct infection in RTC could lead to cellular apoptosis and might cause renal pathological alterations.

Epithelial cell loss characterized as tubular atrophy is considered to be a hallmark in the development of chronic renal interstitial fibrosis[22]. Large amounts of research demonstrated that the proximal tubular cell may contribute to the pathogenesis of renal interstitial fibrosis[23,24]. Although the mechanism of epithelial cell loss remains uncertain, it is conceivable to assume that tubular atrophy primarily results from apoptotic cell death under pathologic conditions[25,26]. Previous studies demonstrated that TGF-β1 markedly potentiated cell apoptosis initiated by accelerating the activation of pro-caspase-9 and -3[27]. We observed that the level of TGF-β1 significantly increased in CHB serum compared with healthy person serum. Apoptosis of HK-2 cells stimulated by HBV DNA negative serum was notablely higher than that of healthy person serum. We speculate that TGF-β1 may contribute to progressive renal dysfunction after severe tubular injury.

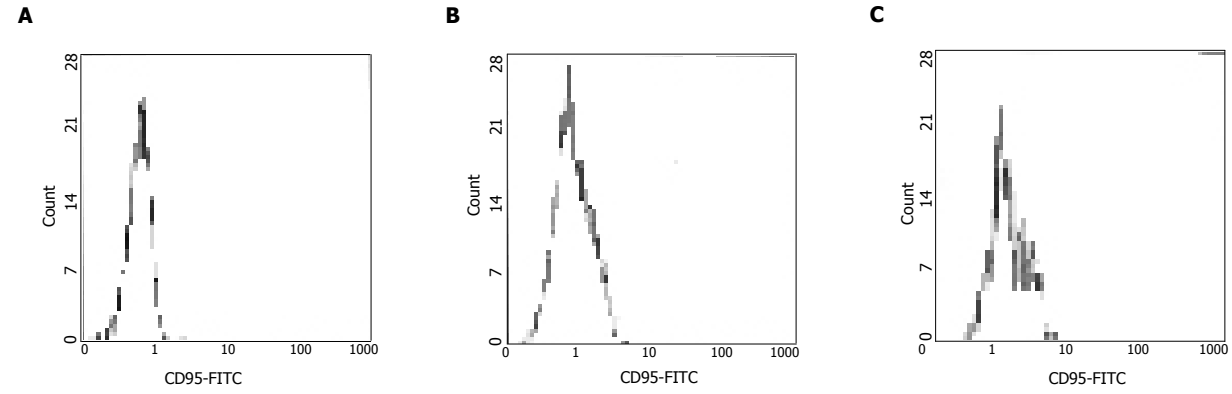

Figure 3 Flow cytometric analysis of HK-2 cells stained with CD95-FITC. **A**: Treated with serum of healthy person. **B**: Treated with HBV DNA negative serum. **C**: Treated with HBV DNA positive serum.

Fas (CD95, APO-1) is a ubiquitously expressed member of the tumor necrosis factor receptor superfamily, which mediates diverse cellular responses, including proliferation, inflammation, angiogenesis, and apoptosis[28]. Fas and FasL are exclusively expressed in RTC undergoing apoptosis. Fas and FasL expression were related to the apoptosis of RTC[29,30]. The Fas-mediated cell death of a tubular cell may be true cell suicide or fratricide in which the FasL is derived from the same or neighboring tubular cell [31]. Binding of FasL to Fas leads to receptor oligomerization and recruitment of the cytoplasmic adapter protein FADD (i.e., Fas-associated death domain protein)[8]. FADD binds caspase 8, which subsequently becomes autoactivated. The catalytically active caspase 8 then initiates the caspase cascade, which leads to the rapid demise of the cell [32]. Our study showed that Fas was clearly up-regulated in HK-2 cells stimulated by CHB serum. These results indicate that apoptosis of proximal tubule kidney cells effects by triggering a pathway of Fas up-regulation. The extracellular microenvironment of injured kidneys may sensitize parenchymal renal cells to Fas induced death, leading to cell loss in the course of acute or chronic renal damage.

Abstract

AIM: To investigate the morphological characterization of tumor infiltrating dendritic cells (TIDCs) and tumor infiltrating lymphocytes (TILs) in human rectal cancer.

METHODS: Light and electron microscopy as well as immunohistochemistry were used to observe the distributive and morphological changes of TIDCs and TILs.

RESULTS: TIDCs were mainly located in tumor-surrounding tissue. The number of TIDCs in the earlier stage was higher than that in the later stage ($P < 0.01$). TILs were mainly seen in adjacent tissue of cancers and tumor-surrounding tissue. There were more TILs in the earlier stage than that in the later stage ($P < 0.01$). Under electron microscope, TIDCs were irregular in shape and exhibited many dendritic protrusions. It isn't obvious that cancer cells perforated the basement membrane and TILs were arranged along the basement membrane in the earlier stage. In the later stage, it is explicit that cancer cells perforated the basement membrane and surrounded by TILs. There were contacts among TIDCs, TILs and tumor cell. One TIDCs contacted one or several TILs which clustered around TIDCs. Glycogen granules were seen between TIDCs and TILs.

CONCLUSION: The number of TIDCs and TILs is related with tumor progression There exist close relationships among TIDCs, TILs and tumor cell.

Key words: Rectal cancer; Tumor infiltrating dendritic cells; Tumor infiltrating lymphocytes

INTRODUCTION

Antitumor effects of human body are mainly achieved by tumor infiltrating immunocytes, including TIDCs, TILs, natural killer(NK) cells and lymphokine-activated killer(LAK) cells. Because of their prominent role in antitumor effects, TIDCs and TILs have drawn more and more attention. DCs are the most powerful professional antigen-presenting cells (APCs) so far. Immunophenotype and function of DCs in biological therapy of tumor are the focus of immunological study [1,2]. Although studies on tumor immunotherapy involving injection of DCs cultured *in vitro* are reported [3-5], infiltrating DCs in tumor microenvironment have not been fully investigated and studies usually concentrate on the correlation between infiltrating DCs and tumor progression[6,7]. Morphological studies on the relation among TIDCs, TILs and tumor cells, are few. TILs are heterogenous lymphocytes, most of them are T lymphocytes. TILs are a new kind of antitumor effectors after LAK cells. In this study, the morphology of TIDCs and TILs in earlier and later stage of human rectal cancer was investigated, which may provide morphological evidence for antitumor effect of tumor infiltrating immunocytes.

MATERIALS AND METHODS

Patients

Eighteen rectal cancer patients surgically treated in earlier or later stage in the Second and Third Hospitals of Harbin Medical University were studied. According to their clinical manifestations and pathological features, the patients were divided into earlier stage group ($n = 8$) and later stage group ($n = 10$).

Methods

Fresh rectal cancer samples were obtained during surgery. Immediately after surgical resection, tissues were rinsed in redistilled water and then in 0.2 mol/L phosphate-buffered saline (PBS). Tumor-surrounding tissues were obtained and fixed in 3% glutaraldehyde for transmission electron microscopy or in 10% neutrally buffered formalin solution. The cut into slices, embedded in paraffin and sectioned at 4 μm for HE and immunohistochemical staining. The

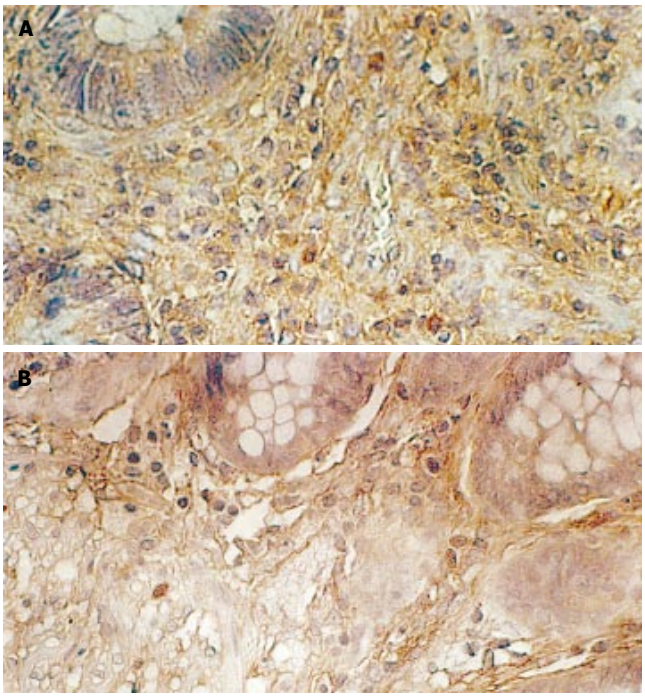

Figure 1 TIDCs in earlier (**A**) and later (**B**) stages of rectal cancer. (magnification: A, B x 400)

Table 1 Number of immunocytes between earlier and later stages (mean±SD)

	Earlier stage	Later stage	*P*-value
Number of cases	8	10	
Number of TIDCs	49.32 ± 5.48	17.02 ± 3.14	<0.01
Number of TILs	107.38 ± 13.61	48.21 ± 5.13	<0.01

deparaffinized sections were washed with PBS. Primary antibodies used were rabbit-anti human S-100 protein and CD3 (Boster Biological Technology Ltd). Secondary antibody used was mouse-anti rabbit IgG. The procedure was performed with SABC kit following the manufacturer's instructions.

Statistical analysis

Student *t* test was used for statistical analysis. $P < 0.05$ was considered statistically significant.

Cell counting

Under the light microscope, the number of infiltrating S-100 (+) and CD3 (+) cells in each section was calculated under 5 high power fields (×400) and statistically analyzed.

RESULTS

Observation of HE and immunohistochemical staining under light microscope

TIDCs were mainly seen in tumor-surrounding area, only a small number of TIDCs were located in cancer tissue scat-

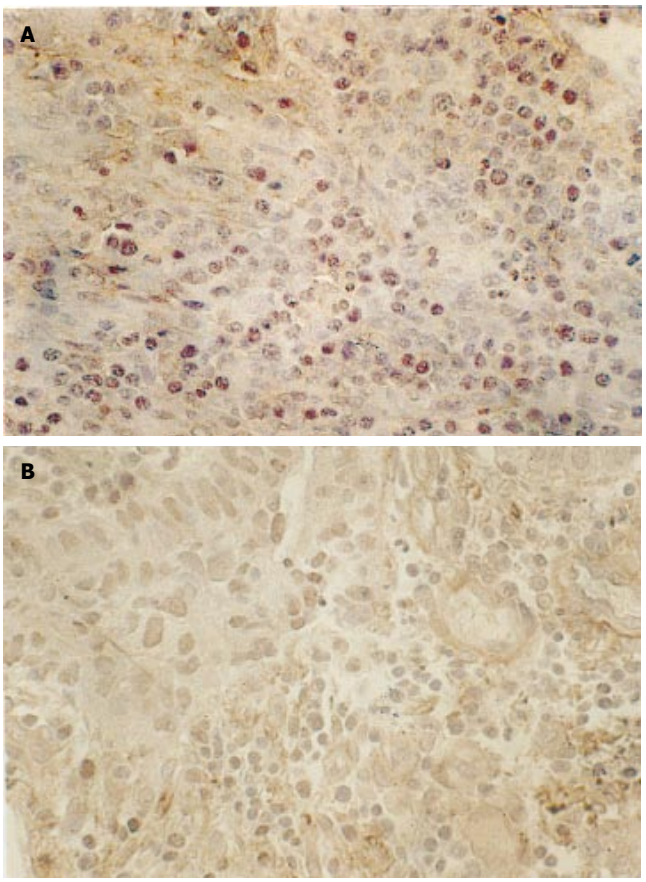

Figure 2 TILs in earlier (**A**) and later (**B**) stages of rectal cancer. (magnification: A, B x 400)

teredly by HE staining. Using anti-S-100 antibody with the SABC method, Brown S-100 (+) DCs could be observed in each section. Comparatively large DCs exhibited many dendritic protrusions, mainly located in tumor-surrounding tissue. The number of TIDCs was large in the earlier stage (Figure 1A) and comparatively small in the later stage (Figure 1B). The number of TIDCs in earlier stage was significantly higher than that in later stage and the difference was statistically significant ($P < 0.01$, Table 1).

Brown CD3 (+) TILs could be seen in each section. Circular CD3 (+) lymphocytes, little cytoplasm and large nuclei were distributed uniformly and densely. In the earlier stage, the number of TILs was large and TILs were primarily located centrally (Figure 2A). In the later stage, the number of TILs was small and TILs were scattered, only a small number of TILs were distributed centrally (Figure 2B). The number of TILs in earlier stage was significantly higher than that in later stage and the difference was statistically significant ($P < 0.01$, Table 1).

Transmission electron microscopy

Under electron microscope, TIDCs were seen in tumor-surrounding tissue. TIDCs were irregular in shape and displayed many dendritic cytoplasmic protrusions with varying width. The nuclei were irregular in shape and the nucleoli were small. Heterochromatin was highly marginated along the nuclear membrane. Mitochondria and endoplasmic reticulum were prominent in these cells. A fraction

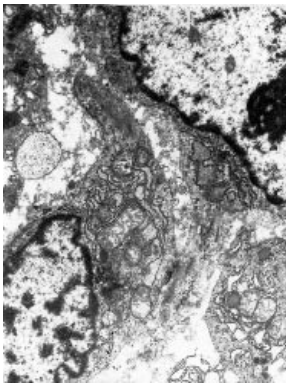

Figure 3 Morphology of TIDCs . D represents TIDCs, T represents tumor cells. (magnification x 10000)

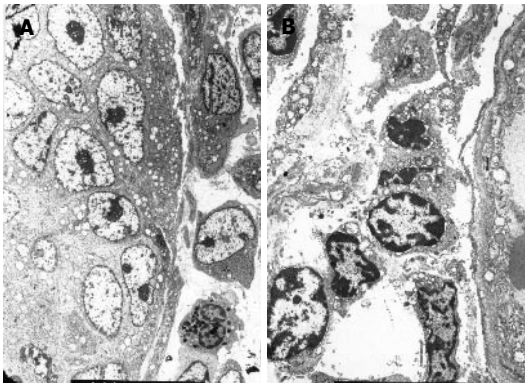

Figure 4 Lymphocytes in earlier (**A**) and later (**B**) stages of rectal cancer. (magnification: A x4000, B x2000)

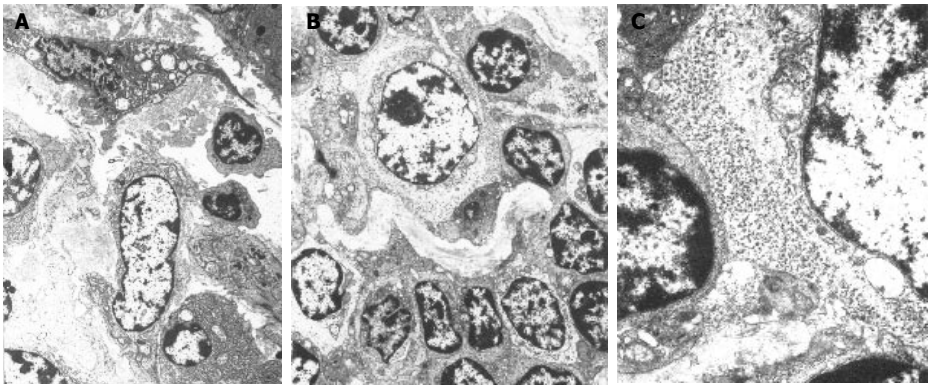

Figure 5 Relations between TILs and tumors cells (**A**), TIDCs and TILs (B) and glycogen granules (**C**). (magnification: A, x 4000, B x3500, C x15000)

of endoplasmic reticulum and some mitochondria were expanded (Figure 3).

It isn't obvious that cancer cells perforated the basement membrane. Lymphocytes were arranged serially along the basement membrane in earlier stage (Figure 4A). However, in the later stage, it is explicit that cancer cells perforated the basement membrane and were surrounded by TILs (Figure 4B). Mitochondria in cancer cells perforating the basement membrane degenerated and the cancer cells were surrounded by DCs, lymphocytes and plasma cells (Figure 5).

TIDCs were contacted with TILs in tumor-surrounding tissue, forming DC-lymphocyte clusters (Figure 5A). Clusters of glycogen granules were seen between TIDCs and TILs (Figure 5B). In addition to contacting TILs, TIDCs also contacted cancer cells at the same time. TILs could be seen surrounding the cancer nests, basement membrane of cancer was fragmentary, and TIDCs contacted cancer cells directly (Figure 5C).

DISCUSSION

DCs are the most powerful professional antigen-presenting cells (APCs)[1]. Studies on immunophenotype and function of DCs are now available[2-5]. Morphological studies on DCs and TIDCs are few. In this study, the morphology of TIDCs and correlation between TIDCs, TILs and cancer cells in human rectal cancer were investigated.

Antitumor immune responses of human body are mainly centralized in local cell-mediated immunity. The infiltrating degree of lymphocytes surrounding tumor tissue reflects the status of antitumor immune responses of human body. Activation of T lymphocytes needs the assistance of APCs. DCs are the most important APCs in human body and are closely related with the function of T lymphocytes. TILs are heterogenous lymphocytes, most of which are T lymphocytes. TILs play an important role in immunity and anti-tumor effects[8,9]. In our study, TILs were closely related with tumor immunity and mainly distributed in adjacent tissue of cancer, suggesting that localization of TILs in tumor-surrounding tissue limits the growth of cancer and confines cancer to a local site, which is the first barrier of anti-tumor effects of human body and contributes to immune response and prevents tumor spreading, which is the second barrier of anti-tumor effects of human body. Infiltration of TILs represents anti-tumor immune responses of human body. The infiltrating degree of TILs plays a decisive role in invasion and metastasis of tumor as well as prognosis of patients. In our study, the number of TILs in earlier stage of rectal cancer was significantly higher than that in later stage ($P < 0.01$), demonstrating that the number of TILs is related with the progression of rectal cancer.

It was reported that metastasis and prognosis of tumor are related with the infiltrating degree of DCs in tumor tissue [6]. Wright-Browne *et al* [7] showed that the number of TIDCs in human gastric cancer, colon cancer and carcinoma of esophagus is negatively correlated with lymph node metastasis, size of tumor and survival time, that is, the more the number of TIDCs, the better the patient's prognosis. In this study, the number of TIDCs in earlier stage was significantly higher than that in later stage ($P < 0.01$), suggesting that the number of TIDC is related with the progression of rectal cancer.

DCs play an important role in tumor immunity. The powerful antigen-presenting function of DCs can induce

efficient and specific anti-tumor immunity activated CTLs can kill tumor cells[10-12]. In this study, TIDCs were closely contacted with TILs. TILs were clustered around TIDCs and cluster of DCs-lymphocytes cluster was formed. Glycogen granules could be seen between TIDCs and TILs. All these suggest that there exists some relation between TIDCs and TILs. It has been reported that DCs mainly present antigen to lymphocytes, stimulate naïve T lymphocyte proliferation and activation to kill tumor cells [13]. The contact of TIDCs and TILs observed in our study may provide morphological evidence and suggests that TIDC can present antigen to TILs and activate TILs. Moreover, fraction of endoplasmic reticulum and some mitochondria in DCs were expanded. These data suggest that these active cells can capture and identify antigens by their cytoplasm protrusions, and subsequently transmit antigens to lymphocytes and prime anti-tumor immunity to kill tumor cells through cytotoxicity.

DCs participate in local anti-tumor immune response and have corresponding changes during oncogenesis and tumor progression, suggesting that DCs are closely related with anti-tumor immunity. DCs are not only professional APCs, but also immunological adjuvant. DCs play an important role in immunoregulation. It has been shown that antigen-sensitized DCs can induce specific CTL *in vivo* and directly inhibit or kill tumor cells [13-16]. But whether DCs can directly inhibit the growth of tumor *in vivo* or directly kill tumor cells remains unclear and should be further studied.

Abstract

AIM: To discuss the protective effect of electroacupuncture at the Foot-Yangming Meridian on gastric mucosal lesion, somatostatin (SS) and the expression of SS receptor genes (SSR$_1$mRNA) in rabbits with gastric ulcer and to further explore the relative specificity of meridians and viscera at gene expression level.

METHODS: Forty rabbits were randomly divided into control group (A), gastric ulcer model group (B), Foot-Yangming Meridian group (C), Foot-Shaoyang Meridian group (D) and Foot-Taiyang Meridian group (E). The gastric ulcer model was prepared by infusing alcohol into stomach. Groups C－E were treated with electro-acupuncture at points along the above meridians using meridian stimulating instruments for 7 days respectively. By the end of treatment, the index of gastric ulcer was determined, the amount of epidermal growth factor(EGF) and somatostatin was measured by radioimmunoassay (RIA). SS-R$_1$mRNA expression in gastric mucosa was determined by RT-PCR.

RESULTS: The value of EGF in model group was obviously lower(73.6 ± 14.8 *vs* 91.3 ± 14.9 pg/mL, $P < 0.01$) than that in control group**.** The index of gastric ulcer, content of SS and expression of SSR$_1$mRNA in gastric mucosa were significantly higher than those in control group (24.88 ± 6.29 *vs* 8.50 ± 2.98 scores, $P < 0.01$; 2978.6 ± 587.6 *vs* 1852.4 ± 361.7 mIU/mL, $P < 0.01$; 2.56 ± 0.25 *vs* 1.04 ± 0.36, $P < 0.01$) . The value of EGF in Foot-Yangming Meridian group was higher than that in model group(92.2 ± 6.7 *vs* 73.6 ± 14.8 pg/mL, $P < 0.01$). The index of gastric ulcer, content of SS and expression of SS-R$_1$mRNA in gastric mucosa were significantly lower than those in control group(10.88 ± 3.23 *vs* 24.88 ± 6.29 scores, $P < 0.01$; 1800.2 ± 488 *vs* 2978.6 ± 587.6 mIU/mL, $P < 0.01$; 1.07 ± 0.08 *vs* 2.56 ± 0.25mIU/mL, $P < 0.01$). Compared to the model group, the content of SS and expression of SSR$_1$mRNA in gastric mucosa in Foot-Shaoyang Meridian group decreased (2441.0 ± 488. *vs* 2978.6 ± 587.6 mIU/mL, $P < 0.05$;1.73 ± 0.16 *vs* 2.56 ± 0.25 mIU/mL, $P < 0.01$). But the above parameters in Foot-Taiyang Meridian group did not improve and were significantly different from those in Foot-Yangming Meridian group ($P < 0.05$).

CONCLUSION: Electro-acupuncture at Foot-Yangming Meridian can protect gastric mocusa against injury. The mechanism may be releted to the regulation of brain-gut peptides and the expression of SSR$_1$mRNA.

INTRODUCTION

Studies have shown that needling the Foot-Yangming (stomach) Meridian can protect gastric mucosa against injury in rabbits[1-3]. This study was to further explore its mechanism and specificity in the experimental gastric ulcer model of rabbits and to compare its effect on the index of gastric mucosal lesion, brain-gut peptides and expression of SSR$_1$mRNA by investigating the correlation between Foot-Yangming Meridian and stomach.

MATERIALS AND METHODS

Main reagents and instruments

TRIZOL reagent and RT reagent kit as well as TagDNA polymerase were obtained from GZBOD BRL and Pro-

gmego Company respectively. RIA kits of EGF and SS were provided by Beijing SINO-UK Institute of Biological Technology. Hypothermia Eppedorflow-temperature centrifuge, Strategene Eagle Eye II figure recognition analytical system(made in USA), Xuanshou Meridian Unblocking Instrument (China Peace Economic Technic Counseling Corporation) were used in the study.

Preparation of experimental gastric ulcer

Gastric ulcer model was induced by ethanol[4]. In brief, the animals were perfused with 100% ethanol (2.35 mL/kg) into the stomach after fasted for 48 h. Twenty-four hours after the perfusion, the animals were allowed to have normal foods. The model group received normal saline (2.35 mL/kg) through an esophageal cannula.

Grouping and disposing

Forty New Zealand white rabbits of either sex, weighing 1 500-2 500 g were supplied by the Medical Animal Center of Hunan College of Traditional Chinese Medicine. The animals were randomly divided into 5 groups: control group (A), gastric ulcer model group (B), Foot-Yangming (stomach) Meridian group (C), Foot-Shaoyang (gallbladder) Meridian group (D) and Foot-Taiyang (bladder) Meridian group (E). NS was perfused into stomach of the control group. Dehydrated alcohol was administered intragastrically (i.g.) using a metal tube in B-E groups. C-E groups were treated with electro-acupuncture at points along the meridians of stomach, gallbladder and bladder for 7 d respectively. All the animals were killed at the end of the treatment. Gastric mucous membrane was removed for the detection of the indexes.

Location of acupoints and method of electro-acupuncture

Acupoints were selected on the basis of *Experiment Acupuncture Science*[5] and the method was chosen according to the human body[6]. For Foot Yangming (stomach) Meridian, the acupoints of "Neiting", "Jiexi", "Zusanli", "Liangqiu", "Tianshu" and "Liangmen" were chosen as stimulating points. According to the above stimulating points, acupoints in other meridians were selected at the same level of Foot Yangming Meridian in corresponding regions. For example , the acupoints of "Jiaxi","qiuxu", "Yanglingquan","Qiyangguan","Daimo","Jingmen" were selected for Shaoyang Meridian while the acupoints of "Zutonggu","Shenmo","Chengjin","Fuxi","Beishangdian","Beixiadian" were selected for Taiyang Meridian.

The method of stepwise stimulation along the meridians was used as previously described[7]. Then the instrument entered the state of making program and the single way of running was turned at the running speed of 0.5 second. The stimulation parameters included two-direction narrow pulse and continuous wave with a frequency of 50Hz and a width wave of 0.5ms. The output claps of stimulating instrument were clapped with 6 inserted needles at acupoints. Stimulating excitation was turned from low limber to body. The output intensity of instrument was controlled between "2-3" sections. Acupuncture was performed for 30 min a day for 7 d.

Index of gastric ulcer measurement

The abdomen was opened with the stomach removed 7 d after acupuncture. The stomach was then cut from pylorus to cardia. The index of gastric ulcer was calculated as previously described[8].

Determination of EGF and SS

Samples of gastric mucosa were homogenized and disposed with the test kit according to the manufacturer's instructions. EGF and SS were determined by radioimmunoassay.

Determination of SS-R$_1$mRNA

The expression of SS-R$_1$mRNA was analyzed RT-PCR. A small piece of gastric mucosa tissue was cut with a sterilized operating knife and mounted on a mortar stuffed with liquid nitrogen. After the tissue was ground into powders, the total RNA of was extracted by one step method with Trizol reagent kit. The rRNA bands of 28S, 18S and 5S were observed by electrophoresis. The proportion of A260/A280 of the total RNA in all samples was between 1.7 and 1.95. mRNA from 2 μg total RNA in samples was reversed to cDNA at 65℃ using oligo (dT)$_{18}$ as primer for 5 min. Then, 20 μL RT reaction system comprised of 20 uRNA enzyme inhibitor (offered by Promega corporation), 0.5 mmol/L dNTP, 10u AMV RT enzyme as well as 5xRT buffer. PCR was performed with the follow primers. The sense primer of SS-R$_1$ was 5' -CAAGACGACGCCACCGTGAGCCA-3', antisense primer was 5' -GGGGTTGGCACAGCTGTTG-3'. The sense primer of cyclophilin(cyc) was 5'-CCATCGTGTCATCATCAAGGACTTCAT-3' and antisense primer was 5'-TTGCCATCCAGCCAGGAGGTCT-3'. The 50 μL PCR reaction system comprised of 5 μL 10×PCR reaction buffer, 1.5 mmol/L $MgCL_2$, 200 umol/L dNTP, 5 μL cDNA template, 0.1 mmol/L specific primers, and 3u Taq DNA polymerase covered by paraffin oil. The PCR conditions for SS-R$_1$ and cyc cDNA were as follows: predenaturation at 94℃ for 2 min; denaturation at 94℃ for 30s, annealing at 60℃ for 30s, and an extention at 72℃ for 30s for 26 cycles; then a final extention at 72℃ for 5 min. Ten μL product of PCR was put in 1.5% sepharose to go on electrophoresis in ranks in different groups. The products of SS-R$_1$ and cyc were 66 bp and 216 bp, respectively. The products of electrophoresis were stained with ethidium bromide and photographed under ultraviolet lamp. The electrophoresis band was scanned by figure recognition analytical system. The proportion of SS-R$_1$/cyc was calculated as the relative expression level of SS-R$_1$mRNA.

Statistical analysis

All data were presented as mean ± SD and analyzed by the software of SPSS10.0. Statistically significant differences were calculated by analysis of variance (ANOVA). If the mean square deviation was regular, it was analyzed by LSD test. Otherwise it was analyzed by Dunnett T3 test.

RESULTS

Effect of electro-acupuncture on index of gastric ulcer

The highest gastric ulcer index was observed in the model group (24.88 ± 6.29, $P < 0.01$). After electro-acupuncture, the gastric ulcer index in stomach Meridian group was significantly lower than that in the other groups ($P < 0.01$),

Table 1 Index of gastric ulcer in different groups (mean ± SD)

Group	*n*	Index of gastric ulcer
Group A	8	8.50±2.98[b]
Group B	8	24.88±6.29[d]
Group C	8	10.88±3.23[b]
Group D	8	19.38±3.66[d]
Group E	8	24.13±1.64[d]

[b]$P<0.01$ *vs* group B; [d]$P<0.01$ *vs* group C.

Table 2 EGF and SS in gastric mucosa in different groups (mean ± SD)

Group	*n*	EGF(pg/mL)	SS(mIU/mL)
Group A	8	91.3±14.9[b]	1852.4±361.7[b]
Group B1	8	73.6±14.8[d]	2978.6±587.6[d]
Group C	8	92.2±6.7[b]	1800.2±488.1[b]
Group D	8	74.9±9.0[d]	2441.0±488.1[a c]
Group E	8	65.4±12.8[d]	2592.7±426.8[d]

Group	*n*	SSR1/cyc
Group A	8	1.04±0.36[b]
Group B	8	2.56±0.25[d]
Group C	8	1.07±0.08[b]
Group D	8	1.73±0.16[b c]
Group E	8	2.39±0.39[d]

[a]$P<0.05$, [b]$P<0.01$ *vs* group B; [c]$P<0.05$, [d]$P<0.01$ *vs* group C.

indicating that electro-acupuncture at Stomach Meridian could significantly decrease the gastric ulcer index in rabbits with experimental gastric ulcer (Table 1).

Effect of electro-acupuncture on content of EGF and SS

The content of EGF in the control group was significantly higher than that in the other groups ($P<0.01$) except for the control group. However, the content of SS in the Stomach Meridian group was significantly lower than that in the other groups except for the control group ($P<0.05$), indicating that electro-acupuncture at Foot-Yangming Meridian could increase the content of EGF in ulcer rabbits and decrease the content of SS (Table 2).

Effect of electro-acupuncture on SS-R$_1$mRNA expression in gastric mucosa

The expression of SS-R$_1$mRNA in model group was obviously lower than that in control group and there was a significant difference ($P<0.01$). The expression of SS-R1mRNA in gastric mucosa after acupuncture treatment was Foot-Yangming Meridian group> Foot-Shaoyang Meridian group> Foot-Taiyang Meridian group. There was a significance difference ($P<0.05$), suggesting that acupuncture at Stomach Meridian had a distinct effect on inhibiting expression of SS-R1mRNA of experimental gastric ulcer (Table 3).

DISCUSSION

Cytoprotection is referred to the fact that some substances can protect epithelial cells of the digestive tract against injury. Studies showed that acupuncture confers quite good protective effect on gastric mucosal lesion[1,2]. The protective mechanism may be as follows. Acupuncture can increase the level of PGE_2 in gastric mucusa[3], inhibit release of GAS, influence metabolism of oxygen free radicles[9], increase gastric mucosal NO and NOS[10], regulate expression of Bcl-2 and Fas and depress gastric mucosal epithelial cell apoptosis[11]. Acupuncture at Stomach Meridian can decrease gastric mucosal ulcer index, thus protecting gastric mucosa against injury.

Epidermal growth factor is secreted by salivary gland, duodenum Brunner gland and pancreas[12], which can resist the destructive effect of gastric and pancreatic protease and chymotrypsin, inhibit secretion of gastric acid and gastric protease, promote proliferation of gastric epithelial cells and synthesis of DNA in gastric mucosa, prevent formation of ulcer[13-15]. Studies showed that epidermal growth factor can accelerate healing process[16-18]. Zhao *et al*[19] showed that electro-acupuncture at "Zusanli" can increase EGF in upper alimentary cannel and depress gastric acid secretion. Jin *et al*[20] reported that EGF remains normal in stress rats and electro-acupuncture can relieve the gastric ulcer index, suggesting that EGF plays an important role in protecting gastric mucusa from injury during acupuncture. In our study, acupuncture at Stomach Meridian could increase EGF in gastric mucosa of experimental gastric ulcer rabbits, suggesting that acupuncture at Stomach Meridian can promote the healing of gastric mucosal lesion by regulating EGF.

SS is the main inhibitory hormone in digestive tract and can inhibit release and activity of the gastrointestinal hormones as well as gastric acid secretion and participates in protecting gastric mocusa[21-23]. Somatostatin receptors exist in gastrointestinal tract and central nervous system. Among the 5 subtypes of SS-R, SS-R_1 is highly expressed in gastric mucosa and can inhibit secretion of gastrin, histamine and gastric acid and plays an important role in adjusting gastric acid secrection. SS can also inhibit upper gastrointestinal hemorrhage and epithelial hyperplasia[24-26]. There are reports on the change of SS in digestive ulcer[27-29]. Lin *et al*[30] found that stomach perfusion with alcohol can result in gastric mucosal lesion and increase SS, but after electro-acupuncture at Foot-Yangming Meridian, SS in gastric antrum and medulla is decreased. Wang *et al*[31] showed that under psychological stress, gastric mocusal lesion of rats is associated with level of SS, but after electro-acupuncture at Zusanli, the degree of gastric mucosal lesion is reduced and SS in blood plasma tends to decrease. Chen *et al*[32] showed that Codonapsis pilosula, one of the Chinese herbs, can increase SS in stomach and duodenum mucosa, thus promoting healing of alimentary tract ulcer, suggesting that the level of SS and expression

of SS-R_1mRNA are increased in rabbits with experimental gastric ulcer due to the process of compensation feedback.

Konturek *et al*[33] found that SS may play a role in inhibiting epithelial proliferation and mocusal healing in stomach. However, Pfeiffer *et al*[34] found that epithelial growth factor receptors and SS receptors can increase the healing process of experimental gastric ulcer. Our study showed that the level of SS and expression of SS-R_1mRNA in Foot-Yangming Meridian group were significantly lower than those in model group, suggesting that the effect of SS on cell proliferation is weakened during the process of ulcer healing[35].

The protecting effect of acupunture at Foot-Sanyang Meridian on gastric mocusal lesion indicates that the action of acupuncture at Foot-Yangming Meridian is the strongest, suggesting that Foot-Yangming Meridian is closely related with stomach. This result accords with traditional meridian theory and clinical practice of acupuncture and has confirmed once again the relative specificity between Foot -Yangming Meridian and stomach.

Abstract

AIM: To examine the effects of cyclin D1 antisense oligodexoyneucleotides (ASODN) on growth and chemosensitivity of gastric carcinoma cell lines SGC7901 and its mechanism.

METHODS: Phosphorothioate modified cyclin D1 ASODN was encapsulated by LipofectAMINE2000 (LF2000) and transfected into cells, the dose-effect curves and growth curves were observed. 5-FU, MTX, CDDP of different concentrations were given after transfecting cells with cyclin D1 ASODN for 24 h，the dose-effect responses were observed and IC50s were calculated. The mRNA expression of cyclin D1, thymidylate synthase (TS), thymidine phosphorylase (TP) and dihydrofolate reductase (DHFR) was detected by reverse transcription-PCR (RT-PCR) at 24 h and 48 h after transfection.

RESULTS: Dose-dependent inhibitory effect was caused by cyclin D1 ASODN in SGC7901 cells. Transfecting gastric carcinoma cells with 0.2 μmol/L cyclin D1 ASODN for 24 h could inhibit growth significantly and reduce expression of cyclin D1 mRNA. Cyclin D1 ASODN could increase the chemosensitivity to 5-FU, MTX, CDDP in cells, The IC50s of different chemotherapeutic agents in ASODN plus chemotherapy groups were significantly lower than those in controls. Transfection with cyclin D1 ASODN leaded to an increase in TS and DHFR mRNA and a decrease in TP mRNA as determined by RT-PCR at 24 h, the alterations were more significant at 48 h.

CONCLUSIONS: Cyclin D1 ASODN can decrease mRNA expression of cyclin D1，inhibit growth and enhance the chemosensitivity by changing the expression of enzymes related to metabolism of chemotherapeutic agents in SGC7901 gastric carcinoma cells.

INTRODUCTION

Cyclin D1 involves in the regulation of G1 phrase in cell cycle, with three subtypes (D1, D2, D3), cyclin D1 located in 11q13, cDNA is 4.3 Kb, is identified as the proto-oncogene and overexpressed in breast, esophageal, and hepatic carcinoma. Cyclin D1 is an important cell cycle regulatory protein that is expressed in the early G1 phase. This protein, in association with the cyclin-dependent kinases CDK4 and CDK6, mediates the phosphorylation of pRb [1]. In this study, we transfected gastric carcinoma cells with cyclin D1 antisense oliogodeoxyneucletides，to observe the effects of it on growth and chemosensitivity to 5-fluorouracil (5-FU)，methotrexate (MTX) and cisplatin (CDDP), furthermore, we examined the expression of enzymes related to metabolism of chemotherapeutic agents, including TS, TP and DHFR, to find out the underlying mechanism.

MATERIALS AND METHODS

Cell culture and reagents

Human moderately differentiated gastric adenocarcinoma cell line SGC7901 was kindly gifted by the Prof. Daiming Fan (the Fourth Military Medical University, Xi'an, China). Cells were cultured in DMEM medium (GIBCO) with 10% newborn calf serum (GIBCO) at 37 ℃ in 50mL/L CO_2. Cyclin D1 antisense oliogodeoxyneucletide 5'-GGA GCT GGT GTT CCA TGG-3' (ASODN) was complementary to the translation start site of the cyclin D1 cDNA and sense oligomers 5'-CCA TGG AAC ACC AGC TCC-3' (SODN) was used as control[2], the two sequences were synthesized and phosphorothioate modified by Shanghai Shengong Biotechnology Corp. The lyophilized ODNs was diluted by sterile water and filtered, storaged in -20 ℃. Lipofectamine2000 (LF2000, Invitrogen)-ODN complexes were prepared as described in the instruction. 5-FU, MTX and CDDP were purchased from SIGMA.

Dose-effect curves

Cells were plated in 96-well plates, SODN and ASODN were mixed with LF2000 respectively, diluted to a increasing concentration (from 0.05 to 0.5 μmol/L) and added to plates, after transfection for 24 h, the media were replaced with DMEM contain serum and cells were continue cultured for 72 h. The viability was determined by MTT assay and survival rates were calculated. The optimal concentration, able to inhibit cell growth of at least 50% *vs* control, was selected for further experiments.

Growth Curves

Cells were plated in 12-well plates, treated with LF2000-SODN or ASODN complexes at concentration of 0.2 μmol/L, after transfection for 24 h, replaced with media with serum and cultured for 6 d, cell numbers were counted everyday and the growth curves were drawn.

Chemotherapy-induced cytotoxicity

Cells were plated in 96-well plates and divided into three groups: (1) chemotherapy group, (2) SODN + chemotherapy group, (3) ASODN + chemotherapy group. After transfection with 0.2 μmol/L LF2000-ASODN or LF2000-SODN complexes for 24 h, cells were incubated with medium contain chemotherapeutic agents (5-FU, MTX or CDDP) for 72 h. Cell variability was examined by MTT assay, and dose-effect curves were drawn. The IC50s were calculated by software Prism3 (Graphpad, USA).

Reverse transcriptase polymerrase chain reaction (RT-PCR) analysis

Cells were plated in 6-well plates, transfected and cultured as described, the cells were harvested at 24h and 48h after transfection. Total RNA was isolated by TRIZOL Reagent (GIBCO). Reverse transcription was carried out on 1 μg of total RNA, 20 μL reaction system contained oligo(dT) 0.1μg, 2 mmol/L dNTPs 4 μL, Rnasin 0.1μg, MMLV 200U, incubated at 42 ℃ for 1h and enzymes were inactivated at 95 ℃ for 5min. 2.5μL RT products were used for PCR reaction, the dNTPs, sense and antisense primers (100 pmol), Taq DNA polymerase were added into reaction system of 40 μL. G3PDH was used as the control, primers and PCR condition as follow(Table1)

PCR conditions After denaturation for 4 min at 94 ℃, thirty-five cycles were accomplished as follow: Cyclin D1, 94 ℃, 60 s → 65 ℃, 1.5 min→ 72 ℃, 1.5 min; TS, 94 ℃, 30 s → 55 ℃, 30 s → 72 ℃, 30 s; TP, 94 ℃, 3 0s→ 60 ℃, 30 s → 72 ℃, 30 s; DHFR, 94 ℃, 30 s → 60 ℃, 30 s → 72 ℃, 30 s; G3PDH, 94 ℃, 30 s → 54 ℃, 30 s → 72 ℃, 30 s.

RT-PCR products (cyclin D1:514 bp; TS：208 bp; TP:353 bp; DHFR:231 bp; GAPDH: 309 bp) were analyzed by 2% agarose gel electrophroesis and visualized by EB staining, densitometric scanning of the bands was carried on and relative amount of each gene mRNA expression was estimated by normalized to the G3PDH mRNA detected in the same sample.

Statistical analysis

Results were expressed as mean±SD and the Student's *t* test was used for statistical analysis (two sides). $P < 0.05$ was taken as level of significance.

RESULTS

Cyclin D1 ASODN inhibits the growth of SGC7901 cells

Dose-dependent inhibitory effects were caused by cyclin D1 ASODN in SGC7901 cells， as shown in Figure 1. At concentration of 0.2 μmol/L, the inhibitory rate was 54.7% and 0.2 μmol/L was taken as optimal concentration for further experiments. Transfection with 0.2 μmol/L cyclin D1 ASODN significantly inhibited the growth of cells. IC50 in ASODN group was lower than that in the control from the third day as shown by growth curves, and there was no difference between SODN group and the control (Figure 2).

Cyclin D1 ASODN enhances the chemsensitivity of SGC7901 cells

After transfecting with cyclin D1 SODN or ASODN, cells were treated with 5-FU, MTX or CDDP in different concentrations. We found that transfection with cyclin D1 ASODN enhances the cytotoxicity of 5-FU, MTX and CDDP significantly, the IC50s in ASODN + chemotherapy groups to different chemotherapeutic agents were significantly lower than the those in chemotherapy group and SODN+ chemotherapy group. The dose-effect curves and IC50s to different treatment are shown in Figure 3 and Table 2.

Table 2 IC50 of *5-FU*, *MTX* and *CDDP* in each group ($\times 10^6$ mol/L)

	5-FU	MTX	CDDP
Chemotherapy Group	3.95 ± 0.92	1.27 ± 0.32	2.12 ± 0.22
SODN+Chemotherapy Group	4.43 ± 0.41	1.25 ± 0.10	1.88 ± 0.07
ASODN+Chemotherapy Group	0.98 ± 0.15 [ac]	0.38 ± 0.04 [ac]	0.52 ± 0.07 [ac]

[a]P<0.05 *vs* Chemotherapy Group; [c]P<0.05 *vs* SODN+ Chemotherapy Group.

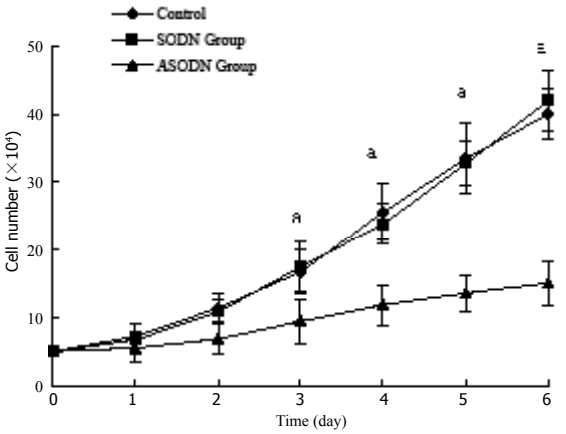

Figure 2 Growth curves of SGC7901 cell lines. [a]$P<0.05$ *vs* control.

Effect of cyclin D1 ASODN on mRNA expression of cyclin D1 and enzymes related to chemotherapy

Relative cyclin D1, TS, TP and DHFR mRNA expression is quantified by densitometric analysis, and illustrated in Figure 4. Comparing with the control, the cyclin D1 mRNA expression reduced to 26.3% and 50.0% at 24 h and 48 h, respectively. In comparison with the control, TS mRNA levels were reduced to 83.5% and 48.4% at 24 h and 48 h, respectively. TP mRNA levels were significantly increased to 124.6% and 148.3% at 24 h and 48 h, respectively. DHFR mRNA levels were reduced to 52.3% and 37.5% at 24 h and 48 h, respectively.

DISCUSSION

The use of antisense oligonucleotides as selective inhibitor of gene expression has become an important tool in current laboratory research and clinical trails. In our study ASODN were phosphorothioate modified and encapsulated by LipofectAMINE2000, to enhance the efficiency of transfection and prolong the time of action. We found dose-dependent inhibitory effects were caused by cyclin D1 ASODN in SGC7901 cells, the percentage of inhibition were 54.7% in cells treated with 0.2 μmol/L cyclin D1 ASODN for 24 h, and the growth of cells in ASODN group were also inhibited as shown by growth curves. Furthermore, cyclin D1 ASODN markedly reduced mRNA expression of cyclin D1. It suggested that cyclin D1 ASODN could inhibit the growth of gastric carcinoma cells through decreasing the cyclin D1 expression. The expression of cyclin D1 mRNA at 48h elevated a little, the lost of inhibitory effect of ASODN may be due to digestion by nucleases existed in cells.

5-fluoro-2'-deoxyuridine 5'-monophosphate (FdUMP), metabolic product of 5-FU, forms a tight-binding complex with TS and thereby blocks DNA synthesis process. Inhibition of TS by FdUMP is one of main mechanism underlying 5-FU action, the degree of inhibition of TS and the persistence of inhibition are essential factors for maximal in vivo growth inhibition by 5-FU[3]. TP is an enzyme that involved in pyrimidine nucleoside metabolism, and able to catalyze the conversion of 5-FU to 5-fluoro-2'-deoxyuridine (5-FdUR), which is the first step in one pathway for the metabolic activation of 5-FU. The 5-FdUR can

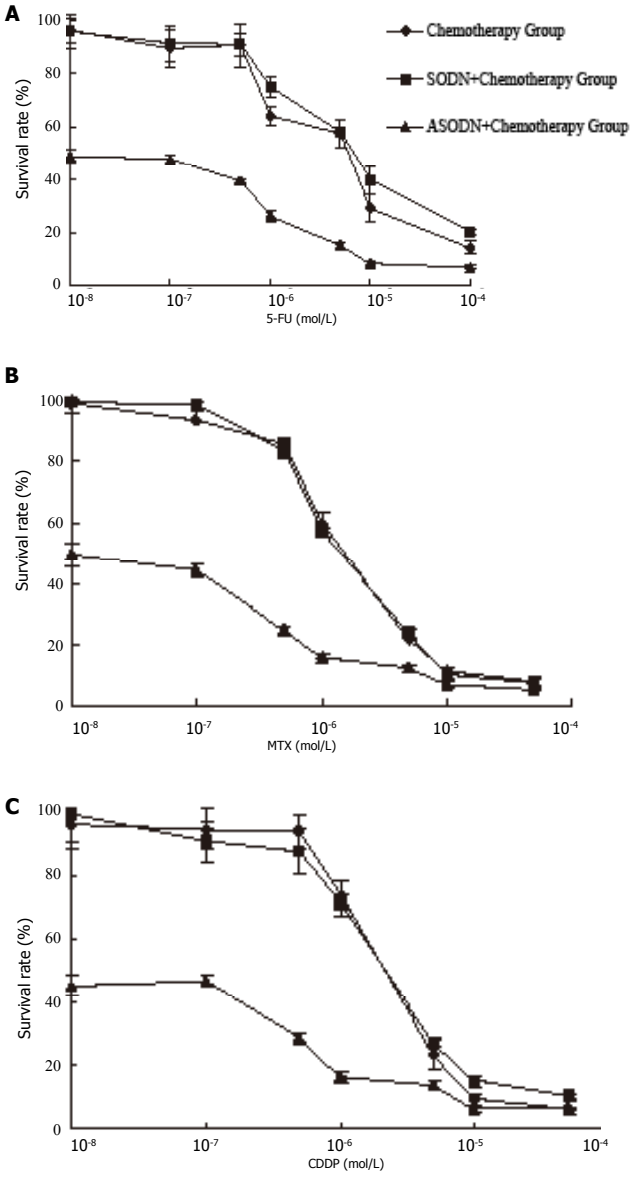

Figure 3 Effect of Cyclin D1 ASODN on chemosensitivity in SGC7901 cells. **A**: 5-FU; **B**: MTX; **C**: CDDP.

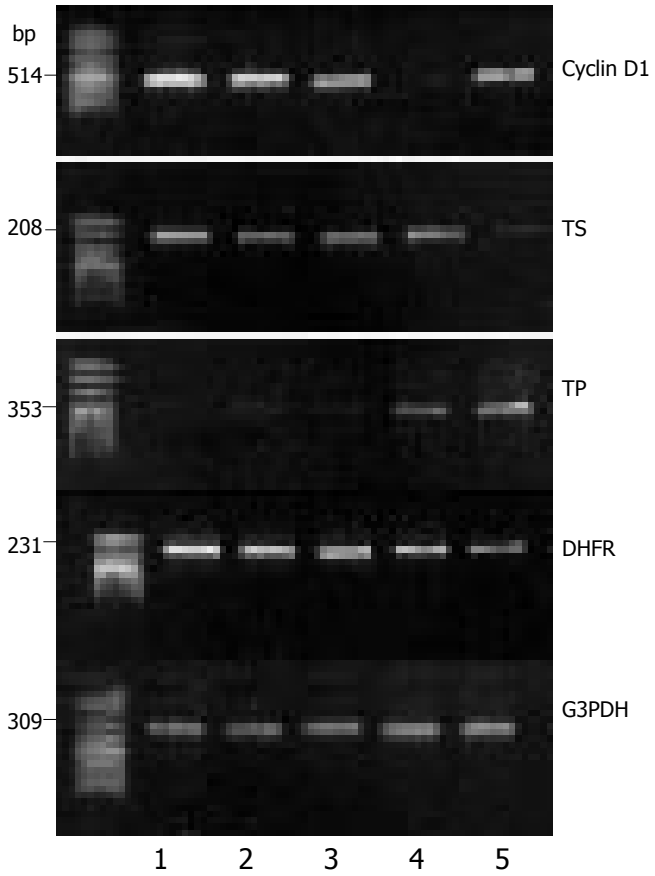

Figure 4 Effect of Cyclin D1 ASODN on mRNA expression of Cyclin D1, TS, TP and DHFR. 1, the Control; 2, SODN group at 24 h; 3, SODN group at 48 h; 4, ASODN group at 24 h; 5, ASODN group at 48 h.

be activated to 5-FdUMP, which blocks TS activity, and exerts antiproliferative effect.[4] The major target for MTX is the enzyme DHFR, which is important in biosynthesis of RNA and DNA. MTX has a chemical structure similar to folic acid, and can competitively inhibit DHFR activity. At 48 h after cyclin D1 ASODN transfection, the mRNA expression of TS, TP, DHFR in SGC7901 cells changed significantly in accompany with enhancement of chemosensitivity as shown in our study.

E2F may play an important role in this alteration. E2F is a cellular transcription factor, which can induce a number of genes important in the passage of cell cycle through the G1/S phase transition as well as in the initiation of DNA synthesis. When E2F binds the promoter and pRb simultaneously, the pRb-E2F complex acts as a transcriptional suppressor and completely silences the transcription of target genes. Interaction with E2F is the means through which pRb exerts its antiproliferative effect[5]. It would be expected that decreased expression of cyclin D1 by ASODN might affect pRb phosphorylation and might lead to change of level of E2F protein as a consequence of alteration in their interactions with pRb, thus change the expression of TS, TP and DHFR and enhance the chemosensitivity to 5-FU and MTX.

Warenius *et al* [6] firstly found that high cyclin D1 expression is related to CDDP resistance in the 16 human cell lines. Furthermore, CDDP resulted in significantly higher rates of cell killing in the antisense cyclin D1 transfected laryngeal squamous cell carcinoma cell lines CCL23 than parental cells, and ID50 decreased, which suggest the decreased expression of cyclin D1 may enhance the DNA-damaging effects of CDDP [7]. It is possible that the blockade of autocrine mitogenic signals by inhibiting cyclin D1 expression might also be a mechanism for increase in CDDP chemosensitivity[8]. As shown in our study, cyclin D1 ASODN can increase the cheosensitivity to CDDP in SGC7901 cells, but the exact mechanism needs further research.

Cyclin D1 ASOND could inhibit the growth of gastric carcinoma cells and change the expression of enzymes related to metabolism of chemotherapeutic agents through the influence on expression of cell cycle regulators, and enhance the chemosensitivity to 5-FU, MTX and CDDP, indicating that ASODN technology is a feasible way to enhance the efficiency of chemotherapeutic agents and provide a new strategy for combination therapy of gastric cancer.

Abstract

AIM: To study the effects of drug treatment on hyperplastic gastric polyps infected with *Helicobacter pylori* (*H pylori*).

METHODS: Forty-eight patients with hyperplastic gastric polyps (3-10 mm in diameter) infected with *H pylori* were randomly assigned to a treatment group (n = 24) which received proton-pump inhibitor (omeprazole or lansoprazole), clarithromycin, bismuth citrate and tinidazole, and a control group (n = 24) which received protective agent of gastric mucosa（tepretone）. Patients underwent endoscopy and *H pylori* examination regularly before enrollment and 1-12 mo after treatment.

RESULTS: Twenty-two patients in the treatment group and 21 in the control group completed the entire test protocol. In the treatment group, polyps disappeared 1-12 mo (average, 6.5 ± 1.1 mo) after the treatment in 15 of 22 patients (68.2%) and *H pylori* infection was eradicated in 19 of the 22 patients (86.4%). However, 12 months after the study, no change in polyps or *H pylori* status was seen in any controls ($^bP < 0.01$).

CONCLUSION: Most hyperplastic gastric polyps disappear after eradication of *H pylori*.

INTRODUCTION

The risk of conversion of hyperplastic gastric polyps is very low, only accounting for 1.5%-3% [1]. Patients with gastric polyps may present with bleeding of the upper gastrointestinal tract, abdominal pain, or gastric outlet obstruction. Large gastric polyps or polyps associated with complications can be removed endoscopically or surgically. *Helicobacter pylori* (*H pylori*) infection is closely associated with hyperplastic gastric polyps and *H pylori* is present in 100% of hyperplastic gastric polyps[2-4]. Hyperplastic gastric polyps may disappear in 40-71% patients after eradication of *H pylori*[5, 6]. Since the pathogenicity of *H pylori* is different in various regions, we conducted this randomized, controlled trial to see whether hyperplastic gastric polyps disappear after eradication of *H pylori*.

MATERIALS AND METHODS

Selecting and grouping of patients

Forty-eight patients were from the Gastroenterology Department, First Affiliated Hospital of Zhejiang University and Red Cross Hospital of Hangzhou (26 men, 22 women, age range from 21 to 73 years, average 47 years). All patients did not receive antibiotics, bismuth, steroid and non-steroid drugs before their enrollment in the study. Hyperplastic gastric polyps (3-10 mm in diameter) were diagnosed on the basis of the examination results at least three histological samples. Patients were considered to have multiple gastric polyps (at least 5) when they were easily cut. Our criteria for hyperplastic gastric polyps included hyperplasia of the foveolar epithelium on histologic examination and infiltration of inflammatory cells into the stroma in biopsy specimens [7, 8]. Hyperplastic gastric polyps were diagnosed by two blinded pathologists. Patients with adenomatous gastric polyps, Peutz-Jegher syndrome and juvenile polyps were excluded. The diagnosis of *H pylori* infection was based the positive results of staining with Giemsa and ^{14}C-urea breath test. The patients were randomly assigned to two groups and sequentially numbered. In the treatment group (n = 24), patients received proton-pump inhibitor (omeprazole 20mg/d or lansoprazole 30 mg/d), clarithromycin (1g/d), bismuth citrate (440 mg/d) and tinidazole (1g/d), 2 weeks a course. In the control group (n = 24), patients had endoscopic examination and received protective agent of gastric mucosa (tepretone 150 mg/d). Two patients of the treatment group did not take the drugs for one course. In the control group, 2 patients lost follow-up and 1 patient took both proton-pump in-

hibitor and amoxicillin. These 5 patients exited from our study. If polyps progressed and were accompanied with malignant transformation, the study was stopped and the polyps were removed endoscopically. After completion of our study, endoscopic removal of polyps or eradication of *H pylori* was proposed for those who failed in *H pylori* eradication.

Endoscopy, histologic examination and assessment of H pylori eradication

Patients in the treatment group underwent endoscopy every 3 months after the treatment. On each occasion, biopsy specimens were taken from the same areas (three from the antrum and three from the body) for histologic examination. If patients without eradication of *H pylori* were not adapted to endoscopic examination very well, controls underwent endoscopy every 3 months after enrollment. Biopsy specimens for histologic examination were stained with Giemsa and evaluated for the presence of *H pylori*. Histologic diagnosis of the biopsied mucosa of the antrum and body was made by two blinded pathologists. The severity of activity, inflammation, atrophy, and metaplasia was graded on a scale from 1 to 4 and expressed as the histologic index according to the updated Sydney System: 1: normal, 2: mild, 3: moderate, and 4: marked [9]. Eradication of *H pylori* was confirmed by the negative results of these two tests 1-3 months after the treatment and endoscopic examination. The size and number of polyps were measured at each endoscopic examination using biopsy forceps (GIF XQ240 or GIF140, Olympus) placed near the polyp (open size: 6 mm in diameter; closed size: 2 mm in diameter). The endoscopic data on the disappearance and regression of polyps were reviewed independently by two blinded endoscopists.

Statistical analysis

All data were analyzed by unpaired *t* test (for age), Wilcoxon rank-sum test and Fisher's exact test. $P < 0.05$ was considered statistically significant. All data were coordinated by SPSS RDS and statistical analyses were done by SPSS software.

RESULTS

Comparison of baseline clinico-pathological characteristics between treatment and control groups

Twenty-two patients in the treatment group and 21 patients in the control group completed the entire study. The two groups were similar with respect to the number, age, sex, coexisting disease, as well as the number, size and distribution of polyps, histologic findings (Table 1). The two groups were comparable.

Analysis of curative effects between treatment and control groups

In the treatment group, *H pylori* was eradicated without serious side effects in 19 of 22 patients (86.3% [95% CI, 63%-99%]), and polyps disappeared in 15 of 22 patients (68.2% [95% CI, 54%-91%]) 1-12 months after treatment (Figure 1). Hyperplastic gastric polyps in the other 4 patients with successful *H pylori* eradication regressed to a certain extent, decreasing in size or number. However, in the remaining 3 patients without *H pylori* eradication, no polyps showed regression and no diminution of inflammation in the gastric mucosa 12 months after the treatment. In the control group, all patients showed no change of *H pylori* infection (0% [95% CI, 0%-21%]), no hyperplastic gastric polyp regression or disappearance (0% [95% CI, 0%-21%]) and no significant diminution of inflammation (Table 2). Polyps were enlarged or increased in number in 5 of the 21 patients. The rates of eradication of *H pylori* and disappearance of polyps in the treatment group were significantly higher than those in the control group ($P < 0.01$).

Table 1 Clinico-pathological characteristics of treatment and control groups

Characteristics	Treatment groups (n = 22)	Control groups (n = 21)
Mean age(mean±SD，yr)	49 ± 9	47 ± 8
Men, n(%)	13(59.1)	11(52.4)
Coexisting disease, n(%)		
Chronic atrophic gastritis	10(45.4)	12(57.1)
Duodenal ulcer	2(9.1)	2(9.5)
Gastric ulcer	0(0)	1(4.8)
Mean number of polyps	5.6	4.2

Atrophy	2.4, 2.6	2.5, 2.4
Metaplasia	0.9, 0.6	1.0, 0.6

DISCUSSION

In our study, *H pylori* was successfully eradicated in 19 of the 22 patients. The regression or disappearance of hyperplastic gastric polyps was seen in the 19 patients. The polyps disappeared in 15 of the 19 patients 1-12 months (average, 6.5 ± 1.1 mo) after the treatment. However, none of the polyps in any of the controls or in patients without *H pylori* eradication showed regression. These results strongly suggest that eradication of *H pylori* leads to regression and disappearance of hyperplastic gastric polyps. *H pylori* is the main cause of chronic active gastritis and can produce multi-virulence agents, damage the gastric mucosa, stimulate gastric body to release inflammation medium, activate various cytokines and promote inflammation reaction. *H pylori* infection damages the gastric mucosa and glandular cells, stimulates crypt epithelia and muscularis mucosa hyperplasia with eminent mucus. If the damage factors continue their existence, the pathological changes can progress to intestinal metaplasia or atypical hyperplasia and even

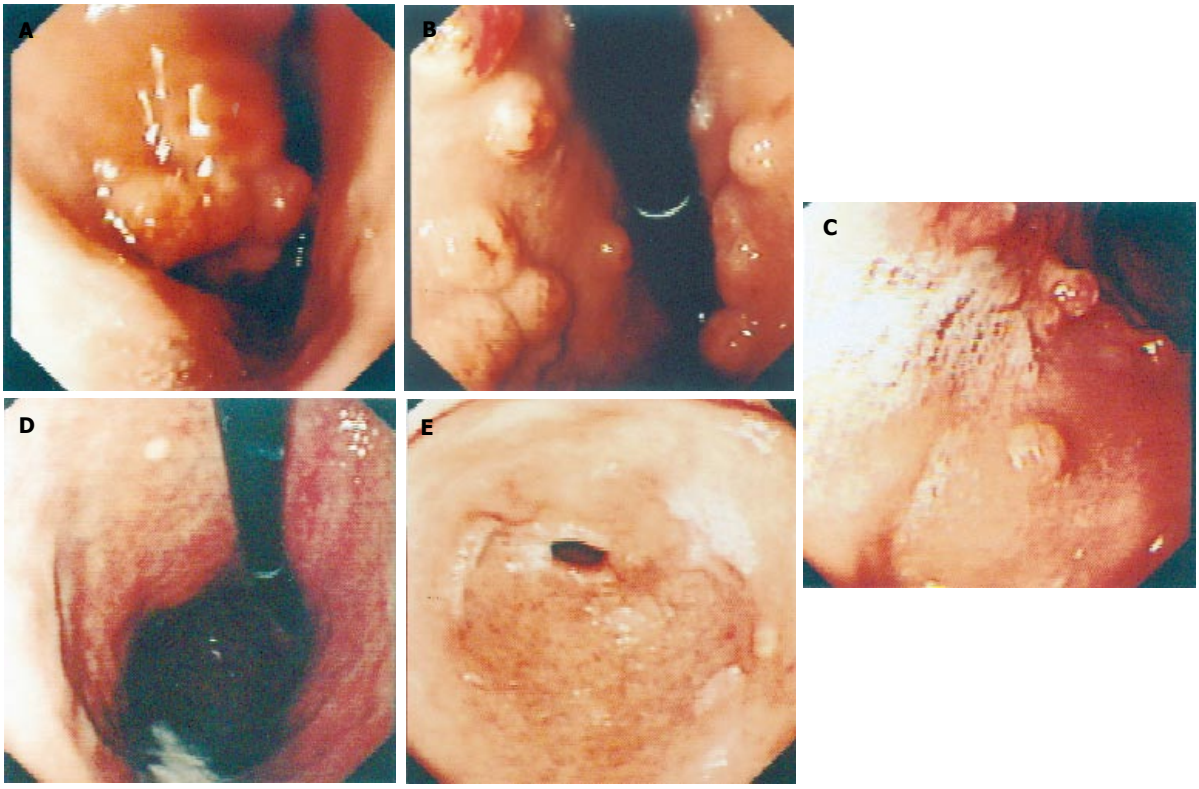

Figure 1 Effect of drug treatment on hyperplastic gastric polyps infected with *H pyori*. **A** and **B**: Multiple gastric polyps of the antrum and body; **C**: Decreased size of gastric polyps 7 mo after treatment; **D** and **E**: Disappearance of gastric polyps 11 mo after treatment.

Table 2 Inflammation status in treatment and control groups

Variable	Treatment groups (n = 22)	Control groups (n = 21)	P
Histologic findings			
Inflammation	1.6, 1.5	2.4, 2.3	<0.01
Activity	1.1, 1.3	2.4, 2.5	<0.01
Atrophy	2.2, 2.1	2.4, 2.4	>0.05
Metaplasia	0.8, 0.6	0.9, 0.7	>0.05

carcinoma. Yasunaga *et al* [10] reported that increased production of interleukin-1 beta and hepatocyte growth factor due to *H pylori* infection may contribute to thickening of the stomach by stimulating epithelial cell proliferation and foveolar hyperplasia in patients with enlarged fold gastritis, leading to formation of hyperplastic polyps.

Although hyperplastic gastric polyps did not accompany malignant transformation during the 9-12 month follow-up period in our study, *H pylori* infection is closely associated with gastric carcinoma. We therefore recommend that when hyperplastic gastric polyps are detected during endoscopy, serologic and pathologic tests should be done to detect and eradicatw *H pylori*.

Though the risk of hyperplastic gastric polyps conversing into cancer is very low, large hyperplastic gastric polyps should be snared and removed completely. Because of the malignant potential, all gastric polyps (0.5 cm or larger in diameter) should be removed. In addition, about 1 year after eradication of *H pylori* (4 patients in this study), any remaining hyperplastic polyps should be removed endoscopically because of the potential for development of cancer.

In conclusion, *H pylori* infection is related with hyperplastic gastric polyps and inflammatory cell infiltration, eradication of *H pylori* can prevent formation of hyperplastic gastric polyps.

Abstract

AIM: To investigate the effect of replication-incompetent adenovirus vector expressing MDA-7/IL-24 on tumor growth and apoptosis in human hepatocellular carcinoma (HCC) cell line HepG2 and normal liver cell line L02.

METHODS: We constructed the recombinant replication-incompetent Ad.mda-7 virus vector and infected it into the human HCC cell line HepG2 and normal liver cell line L02. RT-PCR was performed to detect the mRNA expressing in cells. by ELISA was used to detect MDA-7/IL-24 protein expression in the culture supernatant. The effect of apoptosis induced by Ad.mda-7 was confirmed by Hoechst staining and flow cytometry assay with Annexin-V and PI staining. MTT assay was used to determine growth inhibition of HepG2 cells, and cell-cycle and hypodiploidy analyses were performed by flow cytometry.

RESULTS: Recombinant replication-defective virus expressing MDA-7/IL-24 was constructed successfully. RT-PCR showed that the Ad.mda-7 could mediate the expression of the exogenous gene MDA-7/IL-24 into HepG2 and L02. The concentration of MDA-7/IL-24 protein in supernatant was 130 pg/mL and 110 pg/mL in Ad.mda-7-infected L02 and HepG2 cells, respectively. Ad.mda-7 infection obviously induced apoptosis (from 2.60±0.72% to 33.6±13.2%, $P = 0.00012$) and growth suppression in HepG2 (inhibition ratio IR = 68%) and an increase in the percentage of specific cancer cell types at the G2/M phase of the cell cycle (from 6.44% to 32.29%, $P < 0.01$), but not in L02 cells.

CONCLUSION: These results confirm selectively induction of apoptosis and growth suppression by the mda-7/IL-24 gene with replication-incompetent adenovirus vector in human hepatocellular carcinoma cell line HepG2.

http://www.wjgnet.com/1007-9327/12/1774.asp

INTRODUCTION

Primary hepatocellular carcinoma (HCC) is one of the most common lethal malignant tumors in the world[1], causing an estimated 1 250 000 deaths every year worldwide. Unfortunately, about 50% new cases are from China. The clinical therapies for HCC include surgical resection and liver transplantation, but only few HCC patients can receive these treatments. Moreover, the recurrent rate is very high even the patients received surgical treatments. Besides clinical therapies, the gene therapies for HCC are running, including transgenic therapy by antioncogenes such as p53 and Rb, anti-sense nucleotide technique, drug gene therapy such as suicide gene-like HSV-TK, tumor vaccine, and so on. However, the clinical effect of gene therapies was limited because these genes were not specific to tumor cells, which means they kill the normal cells and the tumor cells simultaneously. The research on the treatment protocol selectively killing tumor cells but not influencing normal cells has become a hot topic of research on tumor treatment[2]. Melanoma differentiation-associated gene-7 (MDA-7)/IL-24 was identified by a combination of recombinant fibroblast interferon (IFN-b) and the protein kinase C activator mezerein (MEZ) subtraction hybridization by Fisher in 1995[3], according

to the chromosomal location on 1q32, the presence of a secretory signal, its association with specific cells of the immune system, and the ability of MDA-7 protein to act as an immune modulator. Now mda-7 has been renamed IL-24[4-7].

Some studies indicated that over-expression of mda-7/IL-24 by a replication-defective adenovirus vector results in growth suppression and apoptosis in a broad range of different carcinoma cell lines, including mesotheliomas[8], osteosarcoma[8], melanoma[2,3,9,10], and carcinomas of the lung[11,12], breast[13], pancreas[14], glioblastoma[15,16] and prostate[17]. The anti-tumor effects were independent of the genomic status of p53, RB, p16[2]. Although MDA-7/IL-24 has the properties potentiality kill many different types of cancer cells, it has not any harmful effects in many kinds of normal cells. These unique potentiality of mda-7/IL-24 suggested that this gene could prove beneficial for cancer gene therapy[2]. In the present study, we investigated the impact of Ad.mda-7 on growth, cell cycle and survival of human HCC cell line HepG2 and normal liver cell line L02, resulting in selectively induction of apoptosis and growth suppression by the mda-7/IL-24 gene with replication-incompetent adenovirus vector. In these contexts, the study provides important support to the use of Ad.mda-7 for selective cancer gene therapy for HCC.

MATERIALS AND METHODS

Cell lines, transfection and culture conditions

Human HCC cell line HepG2 and normal human liver cells line L02 (gift from Dr Guanjian) were cultured in high glucose DMEM supplemented with 100 mL/L fetal bovine serum (FBS) at 37℃ in a humidified incubator containing 50 mL/L CO_2 95% in air.

Virus construction, identification and purification

The recombinant replication-defective Ad.mda-7 virus was created in our laboratory. Briefly, human MDA-7/IL-24 cDNA was directionally cloned into pSGCV to produce pSGCMV-MDA7. By using plasmid transfection method, the pSGCMV-MDA7 and adenovirus skeletal plasmid were co-transfected to HEK293 cells to construct the recombinant adenovirus vector Ad.mda-7, carrying MDA-7/IL-24 gene, by intracellular homologous recombinant. The genomes were analyzed to confirm the recombinant structure and then the virus was plaque purified and amplificated in 293 cells.

RNA isolation and RT-PCR

After cells infected with 1 000 VP/cell (virus particle/cell) of Ad.vec and Ad.mda-7, respectively, were harvested at 48 h, total RNA was extracted from cells using the Qiagen RNeasy mini kit (USA) according to the manufacturer's protocol. Primers used in PCR were designed according to the reported IL-24 cDNA sequence. The primer sequences were 5'-GGGCTGTGAAAGACACTAT-3' (forward) and 5'-GCATCCAGGTCAGAAGAA-3' (reverse). The primer sequences of β-actin were 5'-CCTTCCTGGGCAATGGAGTCCT-3' (forward) and 5'-GGAACAATGATCTTGATCTT-3' (reverse). The reaction mixture with corresponding primers was amplified through 30 cycles, each cycle consisting of denaturation at 94℃ for 30 s, primer annealing at 55℃ for 30 s, and extension at 72℃ for 30 s. Cycles were preceded by incubation at 95℃ for 3 min to ensure the full denaturation of the target gene and also an extra incubation at 72℃ for 5 min to ensure full extension of the product. The products of PCR were analyzed on 10 g/L agarose gel electrophoresis.

ELISA assay

The cell culture supernatant was collected and stored at -20℃ until use. A total of 100 μL of the supernatant was added to Microplate wells, and 200 μL of anti IL-24 (Biotin USA) was added 10 s later. After incubation at 37℃ for 30 min, the sample was washed 5 times with wash buffer, followed by addition of 200 μL of HRP to each well following an incubation at 37℃ for 30 min. Then the wells were washed 5 times, followed by addition of 100 μL of TMB and incubation in room temperature with protection from light. Twenty minutes later, 100 μL of stop solution was added, and the absorbance was read on a microplate reader at 450 nm. All experiments were performed in duplicate. Finally, we calculated the value of results with standard curve.

MTT assay to determine cell growth

Cells were seeded in 96-well tissue culture plates ($1x10^3$ cells/well) and treated with PBS, 1 000 VP/cell of Ad.mda-7 and Ad.vec (1 000 VP/cell), respectively, at the next day. At the indicated time points, the medium was removed, and fresh medium containing 0.5 mg/mL MTT (Roche Diagnostics GmbH Co., Germany) was added to each well. The cells were incubated at 37℃ for 4 h, followed by addition of about 150 μL of solubilization solution (0.01 mol/L HCl in 100 g/L SDS) to each well, and incubation of cells for a further 10 min at 37℃ with gentle shaking. The optical density of the plates was read on a microplate reader at 540 nm.

Hoechst staining test (fluorescent microscopy evaluation of cell apoptosis)

After 48 h of infection, cells were washed once with PBS and fixed in 40 g/L paraformaldehyde for 30 min at room temperature. After two washes with PBS, cells were stained for 30 min in the dark at room temperature with 0.05 mg/mL Hoechst 33258 (Sigma USA) in PBS. Nuclear fragmentation was visualized using a fluorescence microscope equipped with a UV-2A filter and Olympus BX60 photographic camera. Apoptotic cells were identified by condensation of nuclear chromatin and its fragmentation.

Apoptosis and necrosis assay (Annexin-V-PI assay)

Cells were trypsinized and washed once with complete media. Aliquots of cells (5×10^5) were resuspended in complete media (0.5 mL) and stained with FITC-labeled Annexin-V (Jinmei Co., China) according to the manufacturer's instructions. Propidium iodide (PI) was added to the samples after staining with Annexin-V

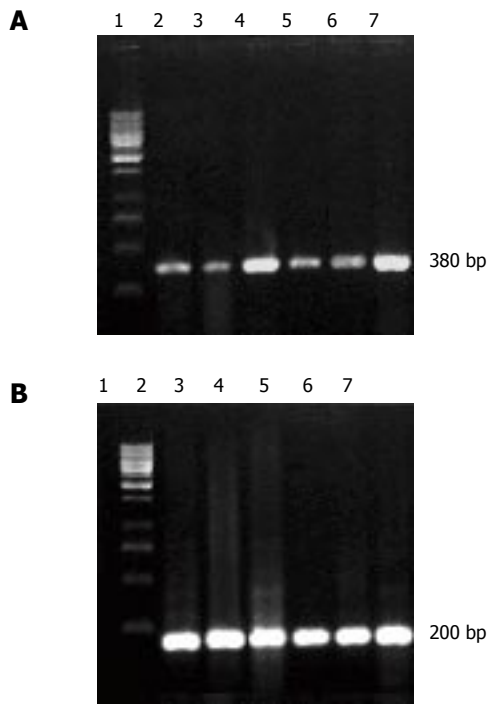

Figure 1 Expression of mda-7/IL-24 mRNA. Infection of normal human liver cells and HCC with Ad.mda-7 resulted in an expression of mda-7/IL-24 mRNA. Cells infected with 1 000 VP/cell of Ad.vec or Ad.mda-7 were harvested at 48 h, treated as described in "Materials and Methods". The total RNA was extracted and the RT-PCR was performed. (**A**) Lane 1: marker; lane 2: control L02 cells; lane 3: Ad.vec-infected L02 cells; lane 4: Ad.mda-7-infected L02 cells; lane 5: control HepG2 cells; lane 6: Ad.vec-infected HepG2 cells; lane 7: Ad.mda-7-infected HepG2 cells. (**B**) Expression of β-actin.

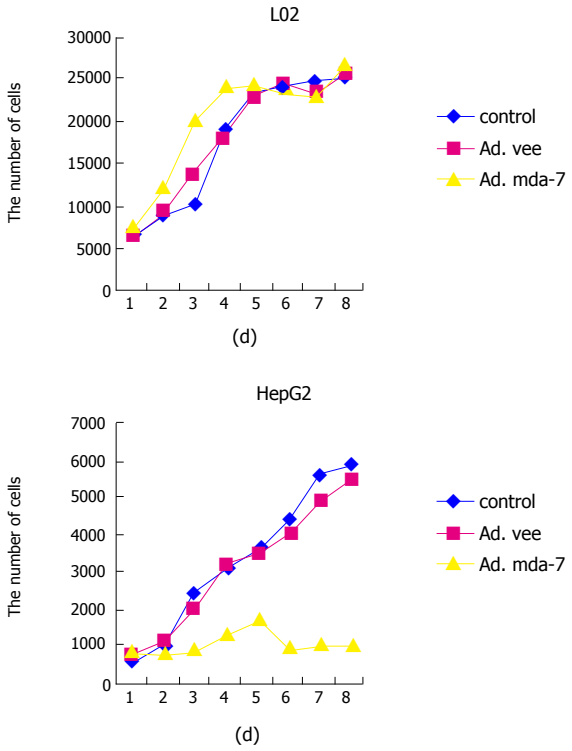

Figure 2 Ad.mda-7 expression causing in vitro inhibition of growth of HCC cells, but not normal liver cells. The various cell types were uninfected (control) or infected with 1 000 VP/cell of Ad.vec or Ad.mda-7. Cell numbers were determined over an 8-d period. Cells were seeded in 96-well plates and treated the next day as described in 'Materials and Methods'. After 24 h, the medium was removed, and cells were stained with MTT. Experiments were repeated three times in quadruplicates, and the results were presented as mean±SE.

to distinguish late apoptotic and necrotic cells. Flow cytometry (Becton Dickinson, San Jose, CA, USA) was performed immediately after staining.

Cell-cycle and hypodiploidy analyses

Cells were cultured as aforementioned. After reaching 30% confluence, the cells were treated with DMEM without FCS for 24 h for synchronization. At the next day, cells were treated with PBS, Ad.vec and Ad.mda-7, respectively. Forty-eight hours later, cells were trypsinized, washed with PBS and fixed in 700 mL/L ethanol overnight at -20℃. Cells were then washed with PBS, and aliquots of $1x10^6$ cells were resuspended in 1 mL of PBS containing 1 mg/mL of RNase A and 0.5 mg/mL of PI. After 30 min of incubation, cells were analyzed by flow cytometry using a FACScan flow cytometer (Becton Dickinson, San Jose, CA, USA).

Statistical analysis

All the experiments were performed at least three times. The results were expressed as mean ± SE. Statistical comparisons were made using an unpaired two-tailed Student's t test. A $P<0.05$ was considered statistically significant.

RESULTS

mRNA expression of MDA-7/IL-24 gene

To determine the efficiency of transgenic expression, HepG2 and L02 cells were infected with Ad.vec and Ad.mda-7, and mRNA expression was detected using RT-PCR (Figure 1). The results suggested that the expression of MDA-7/IL-24 mRNA could be detected in both HepG2 and L02 cell lines infected by Ad.mda-7 but not by Ad.vec or control team. MDA-7/IL-24 gene could be expressed in cells with infected with Ad.mda-7.

Protein expression of MDA-7/IL-24

Secreting MDA-7/IL-24 protein was confirmed by ELISA assay after Ad.mda-7 infection. After 48 h of L02 and HepG2 cells infection with Ad.mda-7, the concentration of MDA-7/IL-24 protein in the supernatant was detected 130 pg/mL and 110 pg/mL, respectively, whereas no MDA-7/IL-24 protein expression was detected in L02 and HepG2 cells treated with PBS and Ad.vec.

Growth suppression and viability assays

HCC cell line HepG2 and normal liver cell line L02 were infected with Ad.mda-7 and proliferation and cell viability were determined by MTT. As shown in Figure 2, no proliferation arrest effect was observed on normal liver cell line L02 of Ad.vec, Ad.mda-7 or control groups. However, the anti-proliferative activity of Ad.mda-7 was readily apparent in HCC cell line HepG2, and the inhibition ratio was 68%.

Apoptotic effect determined by Hoechst staining

We observed that Ad.mda-7 infection induced apoptosis of human HCC cell line HepG2. As shown in Figure 3, a

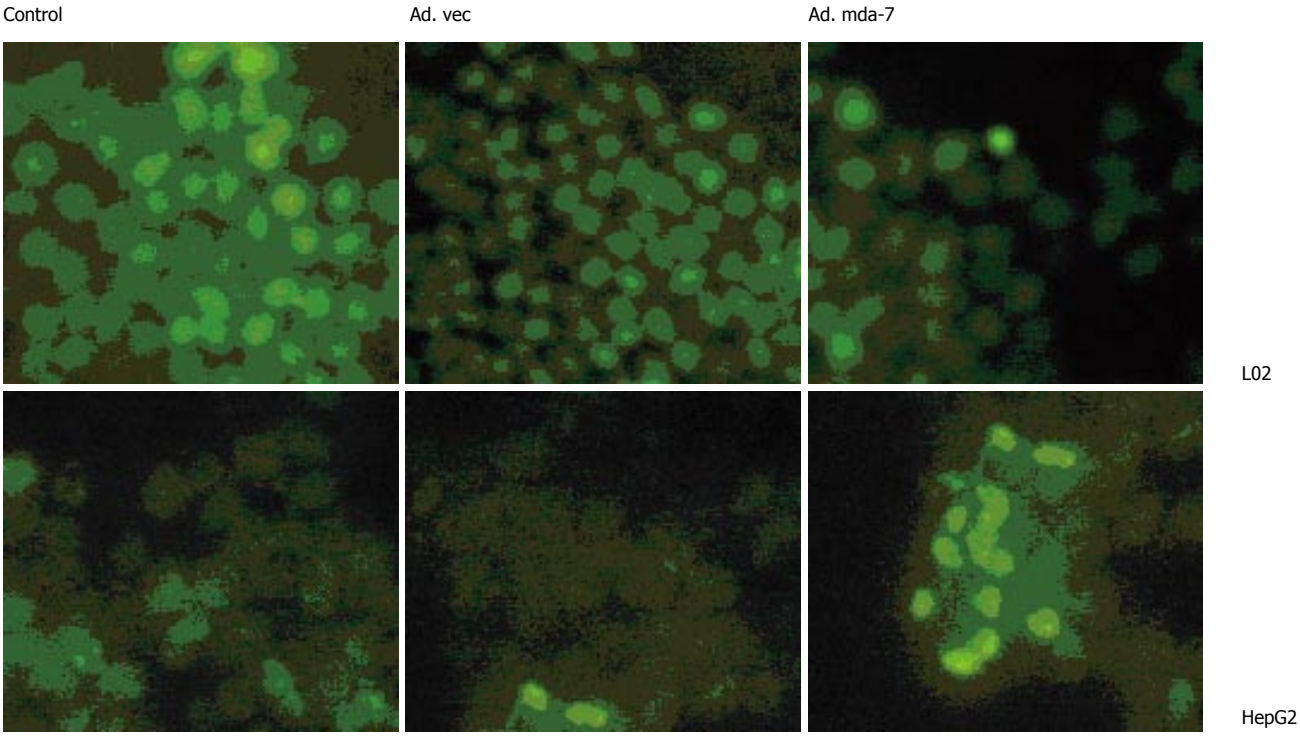

Figure 3 Over-expression of mda-7 causes apoptosis selectively in HCC cells (400×). Cells were infected with 1 000 VP/cell of Ad.mda-7 and all assays were performed 48 h after infection as described in 'Materials and Methods'. To evaluate characteristic apoptotic morphology with fluorescence microscopy, the cells were seeded on glass slides and fixed with 40 g/L paraformaldehyde in PBS for 1 h at room temperature. After washing twice with PBS, cells were stained for 30 min in the dark at room temperature with 0.05 mg/mL Hoechst 33258 in PBS. The nuclear fragmentations were visualized by using a fluorescence microscope equipped with a UV-2A filter and Olympus BX60 photographic camera. Apoptotic cells were recognized by condensation of nuclear chromatin and its fragmentation.

Table 1 Over-expression of mda-7 induces apoptosis selectively in HCC cells

	L02			HepG2		
	Control	Ad.vec	Ad.mda-7	Control	Ad.vec	Ad.mda-7
Early apoptotic cells	110±23	120±36	100±11	50±37[b]	300±85[d]	1 990±430
Late apoptotic cells	60±14	100±21	130±15	10±40[b]	200±63[d]	1 370±902
Total cells	170±28	220±45	230±16	60±72[b]	500±150[d]	3 360±132

The table shows the apoptotic cells in 10 000 cells. The percentage of early apoptotic cells (stained with Annexin-V only) and late apoptotic and necrotic cells (stained with PI) was calculated using the CellQuest software (Becton Dickinson, San Jose, CA, USA). [b]$P<0.01$ *vs* Ad.mda-7 group; [d]$P<0.01$ *vs* Ad.mda-7 group.

significantly higher apoptotic rate was observed in HepG2 cells infected with Ad.mda-7 (48%) compared to those infected with Ad.vec (1.6%) and the control group (1.1%) (counted 1 000 cells consecutively) ($P<0.005$), whereas no apparent changes were observed in normal liver cell L02, the rate of apoptosis being 1.7%, 1.9% and 2.1%, respectively ($P>0.05$). These data indicated that MDA-7/IL-24 could induce apoptosis in HepG2.

Evaluation of apoptosis effect by flow cytometry

Annexin-V and PI staining assays with flow cytometry quantified the effect of Ad.mda-7 on apoptosis induction in human HCC cell HepG2 and normal liver cell L02 (Table 1). We observed a significantly increased percentage of apoptotic HCC cells HepG2 infected with Ad.mda-7 as compared to HepG2 infected with Ad.vec and the control cells. In contrast, L02 cells did not show significantly increased apoptotic rate after being infected with Ad.mda-7. Thus, these results suggested that Ad.mda-7 infection could kill HCC cells but not normal liver cells.

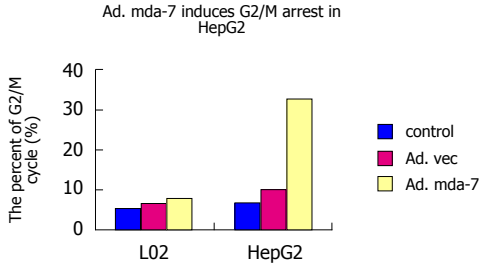

Figure 4 Induction of G2/M arrest in HCC cells HepG2, but not in normal liver cells L02 by Ad.mda-7 infection.

Cell cycle analysis by flow cytometry

Cell cycle phase assayed by flow cytometry after the fixed cells were stained with PI. As shown in Figure 4, Ad.mda-7 markedly induced a G_2/M accumulation in HepG2 cell lines, showing that the rates of G_2/M phase cells were 32.29% in Ad.mda-7 group, 10.30% in Ad.vec and 6.44% in control groups ($P<0.01$). However, the

rates of G_2/M phase cells were 7.95%, 6.65% and 5.54% in L02 cells of Ad.mda-7, Ad.vec and control groups, respectively ($P > 0.05$), demonstrating only minimal G_2/M accumulation in normal liver cells L02. Thus, these results suggested that Ad.mda-7 infection could significantly induce an increase in the percentage of HCC cell line HepG2 in the G2/M phase of the cell cycle, but not in normal liver cell line L02.

DISCUSSION

A study by Jiang *et al*[3] demonstrated that melanoma differentiation-associated gene-7 (MDA-7/IL-24) was highly expressed in melanocytes, but low expressed in melanoma cells, and because of the inducing capacity of growth arrest and differentiation in human melanoma cell line, named MDA-7. After the MDA-7/IL-24 was transfected into malignant melanoma cells, it could obviously block the growth, and promote apoptosis and differentiation, even reverse the malignancy of the melanoma[3]. Now it is clear that the MDA-7/IL-24 gene has been localized to chromosome 1q32 and its exon/intron structure has been established. Mda-7 is composed of seven exons with the first exon being noncoding. The chromosomal assignment and gene structure have been independently confirmed[4-6]. The region includes IL-10, IL-19, IL-20 and mda-7[4]. Moreover, based on structure of protein and the receptor, the gene has been reclassified and grouped into a newly recognized family of IL-10-related interleukins, IL-24[7]. Several independent studies have demonstrated that over-expression of the MDA-7/IL-24 gene, using vectors either plasmid or a replication-defective adenovirus, resulted in growth arrest and induction of apoptosis in a broad range of cancer cells, including lung cancer[11,12], breast cancer[13], pancreatic cancer[14], glioma[15,16], and prostate cancer[17]. Some signal transduction pathway and molecules have been reported as being regulated during mda-7-induced tumor suppression, including activation of the caspase cascade, PKR, p38, STAT3, PI3K, GSK-3, ILK-1, BAX, BAK, Fas, DR4, TRAIL, inducible nitric oxide synthase (iNOS), IRF-1, IRF-2 and p53[8]. Treatment of tumor cells with Ad-mda7 resulted in an increase in cells in the G2/M cell cycle phase[2]. In comparison to the antioncogenes, such as p53, the inhibitory effect of MDA-7/IL-24 on the growth of cancer cells was not related with the state of antioncogenes in these cancer cells (p53, Rb, or p16ink4)[2,11,14], so it could be used in cancer treatment more effectively without the influence in the expression of these anticancer genes in various kinds of cell lines. Surprisingly, the previous studies revealed that MDA-7/IL-24 gene had no any toxic and side effects on the normal cells, such as epidermal cells, lung fibroblasts, breast cells, prostate and lung epithelia, astrocytes, endothelia, melanocytes and so on[2,3], suggesting its selective property to malignant tumors. Therefore, MDA-7/IL-24 is considered a unique cytokine –tumor suppressor in the IL-10 family and there is no any toxic effect in normal cells, suggesting it as a perfect gene for use as a human cancer gene therapy.

In this study, the replication-incompetent adenovirus vector carrying MDA-7/IL-24 was successfully constructed and transfected into human normal liver cell line L02 and HCC cell line HepG2. Its effects on the two kinds of cells were observed, which provided the theoretical foundation for its application in the gene therapy for HCC in clinical practice. RT-PCR indicated MDA-7/IL-24 was successfully transfected into L02 and HepG2 cells with Ad.mda-7, but the control and Ad.vec groups could not show the mRNA expression. The protein expression was confirmed by ELISA assay and the effect was very different, although protein expression was seen both in L02 and HepG2. MTT assay revealed the capability of Ad.mda-7 in tumor growth arrest of HCC cell line HepG2, but not of normal liver cell line L02, indicating that MDA-7/IL-24 induces growth arrest only in HCC cells. Like the pervious studies, Ad.mda-7 induced a G_2/M accumulation in HCC cell line HepG2, but not in normal liver cell line L02. Moreover, infection with Ad.mda-7 could increase the percentage of apoptotic cells apparently in HCC cells. On contrary, no increased percentage of apoptotic cells appeared in L02 cells.

In conclusion, Ad.mda-7 can induce the gene MDA-7/IL-24 expression in normal liver cells and hepatocellular carcinoma cells. Over-expression of MDA-7/IL-24 obviously induces the apoptosis and growth suppression in hepatocellular carcinoma cell line HepG2, without any toxic effect on normal liver cell line L02. These findings provide support for future clinical applications of MDA-7/IL-24 in the gene therapy of hepatocellular carcinoma.

Abstract

Tumors arising from the anal canal are usually of epithelial origin and are mostly squamous cell carcinoma or basal cell carcinoma. We present a case of benign anal adenomas arising from the anus, an extremely rare diagnosis. A 78-year-old white man presented with rectal bleeding of several months duration. Examination revealed a 4 cm friable mass attached to the anus by a stalk. At surgery, the mass was grasped with a Babcock forceps and was resected using electrocautery. Microscopic examination revealed a tubulovillus adenoma with no areas of high grade dysplasia or malignant transformation. The squamocolumnar junction was visible at the edges of the lesion confirming the anal origin of the tumor. We believe the tubulovillus adenoma arose from either an anal gland or its duct that opens into the anus. Although seen rarely, it is important to recognize and treat these tumors at an early stage because of their potential to transform into adenocarcinoma.

INTRODUCTION

The anal canal is lined by transitional mucosa in its proximal one-half and by stratified squamous epithelium in the distal portion. Anal glands and ducts arise from this area and are lined by stratified columnar epithelium. The anal glands have secretary functions and help lubricate the anal canal[1]. Tumors of the anal canal are uncommon and are classified according to their tissue of origin. These consist of tumors of epithelial origin (squamous cell carcinoma, basal cell carcinoma, adenosquamous carcinoma), lymphoid tissue (lymphoid polyp, malignant lymphoma), mesenchymal tissue (fibroma, fibrosarcoma, leiomyoma, leiomyosarcoma), neural tissues (neurofibroma, ganglioneuroma), and vascular tissue (hemangioma, angiosarcoma)[2].

The most common tumor of the anal canal is squamous cell carcinoma, which arises from the squamous epithelium of the anal canal. Rarely, adenocarcinoma of the anus has been recognized and is believed to arise from the anal glands or ducts. There is a single report of multiple adenomatous polyps arising in the transitional zone of the anus in a patient with familial adenomatous polyposis (FAP), seven years after colon resection and ileo-anal anastomosis[3].

We describe a patient with a tubulovillus adenoma arising from the anal canal. These tumors are rarely encountered in patients without predisposing risk factors, such as FAP, ulcerative colitis or Crohn's disease.

CASE REPORT

The patient was a 78 years old white man who presented with history of rectal bleeding for several months. Bleeding occurred with almost every bowel movement and consisted of passage of fresh blood. The patient was otherwise healthy with no recent change in bowel habit, weight loss or reduced appetite. The patient was referred to the gastrointestinal service for work-up of rectal bleeding. His past history was positive only for hypertension. General physical examination was unremarkable. At the time of colonoscopy, rectal examination revealed a 4 cm friable mass attached to the anus by a definite stalk. The mass was located entirely outside the anal canal, with no extension into the rectum. Colonoscopy showed polyps in transverse (tubular adenoma), descending (tubulovillus adenoma with high grade dysplasia) and sigmoid colon (villous adenoma), which were removed endoscopically by the snare technique. At surgery, the anal polyp was found to be attached to the anus by a stalk. The mass was grasped with a Babcock forceps and was resected using electrocautery.

Gross examination of the specimen showed a tan-red, soft tissue mass, measuring 4.0 cm x 1.4 cm x 1.2 cm (Figure 1A). Microscopic examination revealed a tubulovillus adenoma (TVA), with nearly 30% of the surface of the polyp showing villous architecture (Figure 1B). There were no areas of high grade dysplasia or malignant transformation. The squamocolumnar junction was visible

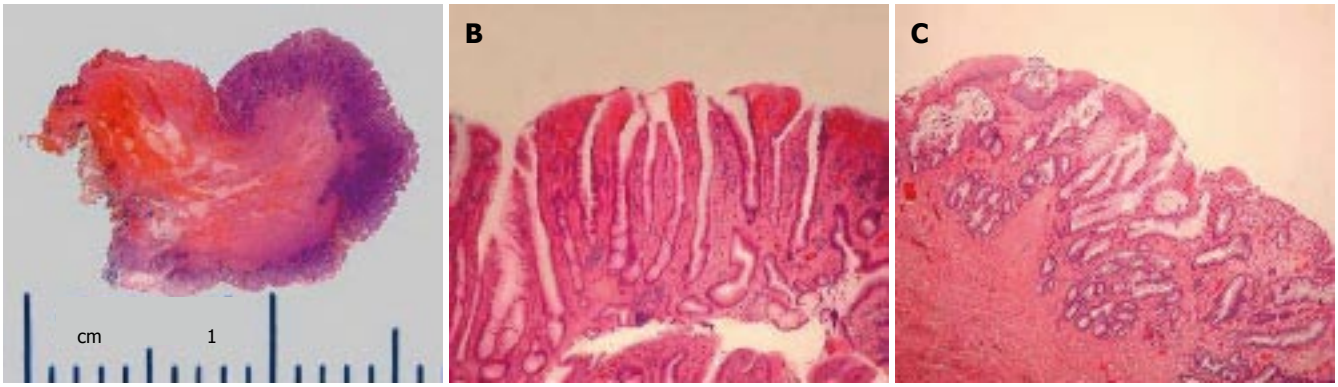

Figure 1 A: Gross appearance of the tubulovillus adenoma mounted on a glass slide. **B:** Areas with villous architecture were apparent (Hematoxylin and Eosin, original magnification x 400). **C:** The squamocolumnar junction is seen at the upper left (arrow). No atypical features were noted in the squamous component. (Hematoxylin and Eosin, original magnification x 400).

at the edges of the lesion and did not show any atypical changes (Figure 1C).

DISCUSSION

The anal canal is lined by stratified squamous epithelium and the most common tumor arising from this site is squamous cell carcinoma. Rarely, adenocarcinomas have been reported and these are believed to arise form the anal glands or their ducts which open into the anus. The current concept of the etiology of colorectal adenocarcinoma is based on the multistep genetic sequence of events which lead to the transformation of normal mucosa to adenoma and finally carcinoma[4]. That a similar sequence may occur in the development of adenocarcinoma of the anus was shown in a recent study which described the development of an invasive apocrine adenocarcinoma arising from a benign adenoma in the perianal region of a 45 year old women[5]. In our patient, the polyp was attached to the anus by a narrow stalk. Moreover, at histopathology, squamocolumnar junction was visible at the edges of the histological specimen confirming that the polyp arose from the anus and not from the rectum. We believe the site of origin of the tubulovillus adenoma in our patient was from one of the anal glands which are the only adenomatous elements in the anus. It is unclear why such tumors are not diagnosed more frequently. It is possible that because of the submucosal location of the anal glands, such adenomas are not easily visible and only become apparent when malignant transformation takes place. Clinically, it is important to recognize and treat these tumors at an early stage because of their potential to transform into adenocarcinoma.

Abstract

Acute biliary pancreatitis (ABP) is rare in childhood and endoscopic sphincterotomy should be avoided in the child due to the risk of both early and late complications but, when necessary, the optimal timing between endoscopic procedure and cholecystectomy is still uncertain. A nine years old child with acute biliary pancreatitis underwent successfull laparo-endoscopic "Rendez-Vous" procedure in which endoscopic drainage of the common bile duct and laparoscopic cholecystectomy were performed simultaneously. This is the first case reported of laparo-endoscopic Rendez-Vous in a child. The excellent outcome of this patient and the review of the literature concerning other available options for the treatment of such cases suggest that this procedure offers great advantages, especially in children, of reducing the required number of treatments, the risk of ineffectiveness, the number of anaesthesia, the length of hospital stay and the risk of iatrogenic morbidity.

http://www.wjgnet.com/1007-9327/12/1782.asp

INTRODUCTION

Acute biliary pancreatitis (ABP) is rare in childhood and endoscopic sphincterotomy should be avoided in the child due to the risk of both early and late complications but, when necessary, the optimal timing between endoscopic procedure and cholecystectomy is still uncertain. In the child the literature concerning therapeutic ERCP with ES for ABP is scarce, and ERCP, combined with ES or not, carries also the well known risk of iatrogenic acute pancreatitis. The optimal diagnostic and therapeutic approach and the timing of the procedures in children with cholecystolithiasis will often depend on the level of expertise of both the biliary endoscopist and laparoscopist. A nine years old child with acute biliary pancreatitis underwent the first successfull laparo-endoscopic "Rendez-Vous" procedure in which endoscopic drainage of the common bile duct and laparoscopic cholecystectomy were performed simultaneously. The favourable outcome of the reported case led us to deepen this issue.

CASE REPORT

A nine-year-old girl, weighing 52 kilograms, BMI of 27, was urgently admitted to our department because of pain in the right upper abdomen associated with vomiting. The only abnormal laboratory tests were the serum ALT 163 u/L (normal value 10-55), amylase 131 U/L (normal value < 110), lipase 482 U/L (normal value < 300), and ALP 168 U/L (normal value 38-126). Abdominal ultrasonography revealed multiple gallstones (3-5 millimeter) and sludge in the gallbladder and a normal common bile duct (CBD). The patient was kept NPO with intravenous fluids and analgesics and was discharged from the hospital after being asymptomatic for 24 h against medical advice, because her parents refused laparoscopic cholecystectomy (LC). The patient was followed in the paediatric outpatient clinic where metabolic or haematologic causes of cholecystolithiasis were excluded.

Three weeks later the patient was again urgently admitted because of a recurrence of abdominal pain, vomiting and a fever (38.6℃). Ultrasonography showed gallstones, a dilated CBD (8 mm) and pancreatic edema. Laboratory test showed a nine fold increased serum amylase of 998 U/L and of serum lipase 2430 U/L. Total and direct bilirubin were both increased to 2.81 mg/dl and 1.58 (normal

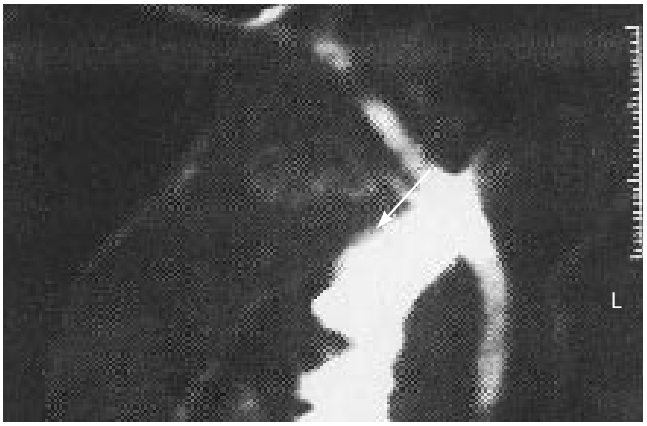

Figure 1 Cholangio-MRI showing a persistent filling defect (arrow) in the extrahepatic bile duct suspected to be biliary sludge or a stone.

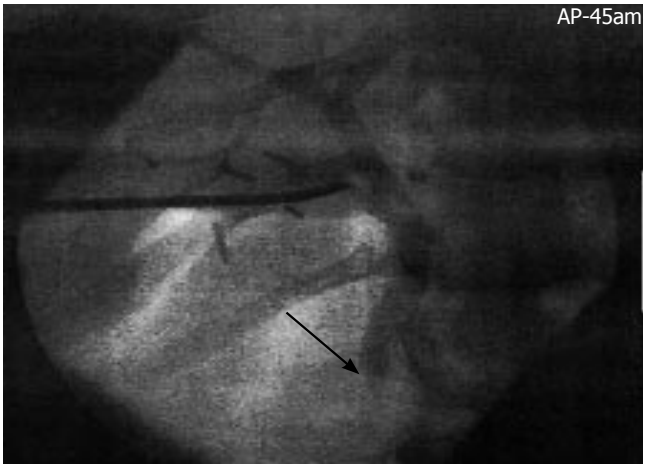

Figure 2 Intra-operative transcystic cholangiography 30 min after contrast medium injection showing the stop of contrast medium passage into the duodenum and a vanished image of the papilla of Vater (arrow) due to occluding biliary sludge.

value 1.3 and 0.5) respectively and other pathologic parameters were: gamma GT 479 U/L (normal value 78), ALT 1032 u/L, AST 584 U/L (normal value 10-45), LDH 1855 U/L (normal value 313-618), ALP 283 U/L and C reactive protein (CRP) 6.8 mg/d (normal value <1). White blood cell count (WBC) was 13 200 (normal value 6000-9000) with 91% polymorphonucleates, and blood glucose was 132 mg/dL. According to the Atlanta classification and Ranson's criteria[1] the diagnosis of mild acute biliary pancreatitis was given and a conservative treatment was started with fluids, analgesics and imipenem. The main symptoms disappeared after 12 h so that the conservative treatment was continued. After 48 h a CT scan showed a pancreatic and peripancreatic oedema that was classified as Balthasar stage B[2]. The bilirubin remained slightly abnormal (1.62 total and 0.74 direct) but serum amylase and lipase were increased to 1300 and 30560 U/L respectively, whereas CRP reduced to 4.4 mg/dL. A cholangio-MRI was performed (Figure 1) showing a filling defect in the upper portion of the CBD that was highly suspicious for a gallstone, sludge or mucinous aggregate.

Based on increased experience in adults with cholecystocholedocolithiasis, we decided to perform a laparoendoscopic "Rendez-vous" for both the endoscopic drainage of the CBD and treatment of gallstones despite the fact that there was no evidence in the literature of this procedure being performed on a child that was considered suitable, without contraindication and useful. Laparo-endoscopic "Rendez-Vous" procedure was as follows: The whole laparo-endoscopic procedure was carried out to maintain the patient in the same supine "french" position used for the laparoscopic cholecystectomy. Three trocars (10-10-5 mm) were introduced with open technique. The first manoeuvre was the preparation, encircling and clipping of the cystic duct to avoid migration of stones in the CBD. An intra-operative cholangiography was performed to introduce a Pedinelli catheter (8 fr) in the cystic duct. This showed a dilated CBD and a delayed passage of the contrast medium in the duodenum (Figure 2), but could not confirm the filling defect. The X-ray picture of the whole biliary tree remained unmodified without any flow of the contrast medium in the duodenum, up to 30 minutes after the injection and despite intravenous administration of a dose of antispastic drug (cymetropio bromide). This led us to suspect an underlying sphincter of Oddi dysfunction but a manometry was considered unnecessary because the indication for retrograde exploration of the papilla was given. During the time waiting to control the passage of the contrast medium in the duodenum, the cholecystectomy was carried out. The endoscopist performed the procedure using an adult lateral view duodenoscope. The papilla appeared normal but without any flow of bile. A guide wire could be introduced through the papilla and its correct position inside the still contrasted CBD could be confirmed. In this way the standard and more dangerous unpreventable retrograde injection of the Wirsung duct could be avoided. A paediatric endoscopic balloon catheter Olympus Swift ® (4 mm diameter) was then introduced in the CBD, inflated, and retrieved trough the papilla. Some biliary sludge could be retrieved and immediately bile flowed. This procedure was repeated twice and a gentle dilatation of the papilla was also performed for 2 minutes. The endoscope was then extracted and the laparoscopic procedure ended after clipping of the cystic duct. The post-operative laboratory controls showed the normalization of amylase, lipase and bilirubin the day after. On day two after the procedure a control US showed a normal CBD. The patient was discharged three days after the procedure. Neither recurrence of symptoms, nor abnormality in laboratory tests or US controls occurred up to the last 24 mo follow-up.

DISCUSSION

Acute biliary pancreatitis in the child is rare and the main causes are congenital disorders or malformations of the pancreatic-biliary ductal system. In children, the main indication of diagnostic ERCP with or without endoscopic sphincterotomy (ES) are biliary atresia, intrahepatic cholestasis, anomalous arrangement of the pancreatic-biliary ductal system including the dilatation of the CBD.[3,4,5] In the adult, ES is a part of the treatment of ABP when this is caused by stones or sludge impacted in the papilla.[6,7] Concerning the timing of ERCP +/- ES, early ap-

proach is not more beneficial than conservative treatment in patients without jaundice.[8] In the child the literature concerning therapeutic ERCP with ES for ABP is scarce, especially because the pancreatitis, according to Hsu and Nowak[9,10] is often not "biliary" in the "adult" meaning of the term. In the reported case the pancreatitis was truly "biliary", because related to micro-lithiasis and sludge and also combined with an underlying sphyncter of Oddi dysfunction which can often be related to recurrent pancreatitis also in children.[11] The treatment of ABP in childhood needs a multidisciplinary approach[12] to optimize laparoscopic treatment,[13,14] and intraoperative cholangiography is considered mandatory to minimize unnecessary ERCP.[15] In fact ERCP, combined with ES or not, carries the well known risk of iatrogenic acute pancreatitis because of papilla manipulation, pancreatic intraductal hyperpression and/or chemical damage all factors related to unpreventable retrograde injection of the pancreatic duct.[16,17] When ABP in children is related to gallstones there is a relevant risk of recurrence and therefore the standard treatment is endoscopic treatment sequentially combined days or weeks before or after cholecystectomy.[18,19] The sole case of urgent ERCP-ES in a 9-year-old patient with ABP due to a stone impacted in the papilla was reported recently[10] and was performed under anaesthesiological control of sedation. This patient was discharged after ES, with a planned laparoscopic cholecystectomy and was therefore still at risk of recurrent pancreatitis in the possible event of an incomplete sphincterotomy. There is the well known problem of the optimal timing between ERCP and LC, also considered " The bilateral interface…" between the two procedures[20] but the optimal diagnostic and therapeutic approach in children will often depend on the level of expertise of both the biliary endoscopist and laparoscopist.[19,21,22] All these considerations and the favourable outcome of the case convinced us that simultaneous laparoendoscopic treatment carries great advantages especially in children. The literature shows that comparable good success rate of ERCP between adults and children (98% *vs* 97.5%) with a comparable low incidence of complications (2.5% *vs* 3.4%) are obtainable only by very experienced teams[22] but unfortunately complications can reach up to 33%.[18,21,23] Therefore ERCP in the paediatric population should be minimized because stones often pass spontaneously[19] and also because the only sure way to avoid post-ERCP complications is to avoid ERCP itself.[24] This is certainly possible with the combined laparo-endoscopic approach because ERCP is avoided and ES is limited only to those patients with stones or abnormal cholangiography that cannot be resolved laparoscopically via the cystic duct or when a sphyncter of Oddi dysfunction can not be resolved through a simple dilatation. The balloon papilla dilatation carries comparable effectiveness but with a discordant incidence of relevant complications like pancreatitis that can be related to unnecessary retrograde injection of the pancreatic duct or manipulation, but anyway in children dilatation should be preferred to preserve the papilla.[25,26] The dilatation is also effective in early stone retrieval during the attack of ABP.[27]

Other favourable considerations concerning effectiveness of this combined approach can be found in the literature concerning the standard sequential approach. In a large prospective randomized study[28] the effectiveness of ERCP/ ES to clear CBD stones was only 84%, when performed prior to laparoscopic cholecystectomy and therefore 16% can be ineffective. Unfortunately, these patients often also have to undergo urgent surgery, with exposure to a second X-Ray for the mandatory cholangiography and often the need for a surgical opening of the CBD. This carries the need of relevant surgical skill but carries also an increased risk of complications, often need of T tube or other biliary drain, and prolonged hospitalization[29,30]. In the child both open and laparoscopic surgery and especially suturing of the small duct requires a high degree of surgical expertise to avoid the risk of late stenosis of the CBD. On the other hand, laparoscopic clearance of CBD stones in a large prospective study[28] of adults was impossible in 15% of the cases, despite all being operated on by experienced surgeons, and conversion to open surgery or post-operative ERCP carried a relevant incidence of biliary complications, but the post-operative ERCP can itself be related to risk of ineffectiveness.

A recent analysis of management of suspected common bile duct stones in children[31] shows clearly the poor results and pitfalls of the two common pathways of the sequential treatment with ERCP-ES and laparoscopic cholecystectomy. If performed prior to cholecystectomy a total of 71% of ERCP were unnecessary and 7% failed, if performed after cholecystectomy 50% of ERCP were unnecessary because stones were not found. Despite a reported incidence of 0% complication rate, 9 of 12 ES (75%) were unnecessary based on findings of an intraoperative cholangiography, some days prior. Therefore, a large number of unnecessary invasive procedures, all potentially related to morbidity and mortality, are often ineffective especially because they are out of synch with the evolving pathophysiology of gallstone disease.[19] On the other hand, the simultaneous approach of RV is tailored to a "real time" picture of the CBD and the compliance of the papilla, eliminating all previous and subsequent unnecessary procedures, and also minimizing the factors of ineffectiveness. Concerning ABP, endoscopy and laparoscopy, a recent review[32] pointed out that the sequential approach of ERCP-ES first followed by LC is the least efficient, and despite simultaneous treatment is theoretically the best option, the laparoscopic CBD clearance is considered difficult and time consuming.[32] The main experiences with the simultaneous laparoendoscopic approach[33,34] were always extremely positive, showing a high effectiveness in stone clearance of 97%-100%, a low morbidity and hospital stay comparable to simple laparoscopic cholecystectomy.[35] It is also important to consider that for a child younger than 10 years of age the ERCP usually requires general anaesthesia[5,22] and an additional administration is certainly needed for the successive cholecystectomy. On the other hand, to perform the laparoendoscopic RV only one administration of anaesthesia and related psychological trauma is necessary for the child. The outcome of the case and the analysis of the literature, with a comparison of combined laparoendoscopic Rendez-Vous to the other available options convinced us that considering the technical aspects, the related risk of iatrogenic complications, optimization

of the timing and the effectiveness of the procedure, the laparo-endoscopic Rendez-Vous in these cases is the best option for the child, perhaps also for the adult, the surgeon, the endoscopist and the hospital itself.

Abstract

The gallbladder is an unusual location of pancreatic heterotopia, defined as the presence of pancreatic tissue lacking anatomical and vascular continuity with the main body of the gland. A 28-year-old man presented with anorexia, nausea and pain in the right upper abdomen. On physical examination, the abdomen was tender to palpation and Murphy sign was positive. The patient underwent a cholecystecomy. This case, in our opinion, is very interesting since it permits to consider a controversial issue in the pathology of the gallbladder. The histological appearance of ductal structure in pancreatic heterotopia resembles the histological picture of both Aschoff-Rokitansky (AR) sinuses and adenomyomas. This finding suggests that these lesions are linked by a common histogenetic origin. We suggest that the finding of an adenomyoma in the gallbladder should prompt an extensive sampling of the organ in order to verify the coexistence of pancreatic rests.

Key words: Pancreatic heterotopia; Gallbladder; Hypertrophic duct; Adenomyoma; Aschoff-Rokitansky sinuses

INTRODUCTION

The gallbladder is an unusual location of pancreatic heterotopia, defined as the presence of pancreatic tissue lacking anatomical and vascular continuity with the main body of the gland[1]. About 75% of all pancreatic rests are located in the stomach, duodenum and jejunum, the appendix, diverticulum of Meckel and the ampulla of Vater[2] tract, ectopic pancreas has been found in the umbilicus, fallopian tube, mediastinum[2], spleen[3] and omentum[4]. Here, we describe a case of gallbladder pancreatic heterotopia associated with a hypertrophic duct simulating a small intrapancreatic adenomyoma.

CASE REPORT

A 28-year-old man presented with anorexia, nausea and pain in the right upper abdomen. On physical examination, the abdomen was tender to palpation and Murphy sign was positive. The patient underwent surgery, and a cholecystectomy was performed. The gallbladder was 10.5 cm in length and 3.5 cm in width, with a mural thickness of 0.3 cm. No stones were present. An intramural, firm, yellow nodule measuring 0.6 × 0.5 cm was seen in the gallbladder body: it was well circumscribed and showed a central umbilication on the mucosal surface. Light microscopy revealed diffuse proliferation of the surface epithelium, resulting in numerous invaginations into a thickened wall and numerous Aschoff-Rokitansky (AR) sinuses. The muscular layers appeared hypertrophied and possibly hyperplastic, with frequent foci of adenomyomatosis. No inflammatory infiltrate was seen. The epithelial component had typical features of pancreatic tissue. Acini were composed of polygonal cells with basal nuclei and apical granular cytoplasm surrounding a minute lumen. Endocrine islands were occasionally detected. The ductal system consisted of intercalated, intralobular and interlobular ducts: the major duct, surrounded by bundles of smooth muscle, appeared to drain into the gallbladder lumen. Ductal epithelium was surrounded by a smooth muscle component and displayed a typical pancreatic duct-like immunophenotype, characterized by immunoreactivity for cytokeratins 7, 8, 18, 19 and CA19-9. No reactivity against CEA and cytokeratin 20 was found. Acinar cells arranged in a single layer with typical exocrine differentiation were focally positive for α1-antitrypsin, chimotrypsin and cytokeratins 8 and 18. They were negative for CEA, CA19-9 and cytokeratins 7, 19 and 20. The patient, after cholecystectomy, had an uneventful recovery and normal development at follow-up.

DISCUSSION

This case, in our opinion, is very interesting since it

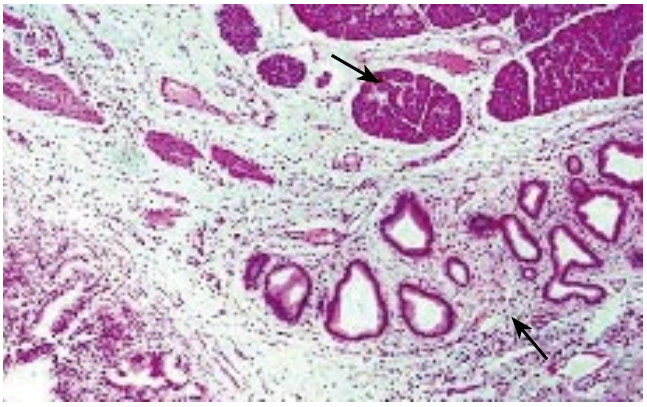

Figure 1 Complete pancreatic ectopia of gallbladder: red arrow indicates acinar components, green arrow indicates ductal structures surrounded by smooth muscle bundles (HE, original magnification, x100).

permits to consider a controversial issue in the pathology of the gallbladder. The histological appearance of ductal structures in pancreatic heterotopia resembles the histological picture of both AR sinuses and adenomyomas. This finding suggests that these lesions are linked by a common histogenetic origin.

In fact, AR sinuses are structures consisting of down growth of the gallbladder mucosa into the wall[5]. They are thought to be the consequence of increased intraluminal pressure, analogous to colonic diverticula[5]. Sometimes, mucosal proliferation is so exuberant as to result in formation of branching sinuses and cystic structures. In many cases, the muscular layer is hypertrophic and hyperplastic, thus resembling focal adenomyomatosis[5]. The latter feature is seen in our case (Figure 1), where the major duct, surrounded by a thickened muscular layer, shows morphological features overlapping those of adenomyomas. Analogously, it is not precisely defined when florid AR sinuses become adenomyomatosis[5].

Likewise, adenomyomas consist of glandular formations lined with cuboidal-to-columnar epithelium and surrounded by bundles of smooth muscle[6,7], similar to the prominent duct seen in our case.

Also heterotopic pancreas, when it includes only ducts, without acinar cells (canalicular or abortive form), shows the same morphological appearance[5].

On the basis of such morphological observations, we believe that AR sinuses, adenomyomas (when focal), adenomyomatosis (when diffuse), and abortive forms of pancreatic heterotopia can be considered variable manifestations of the same pathological process and be grouped into the same nosological category.

Consistent with this hypothesis, several authors have suggested that adenomyomas associated with pancreatic heterotopia found in other organs (stomach and duodenum) should be considered as an abortive variant of pancreatic heterotopia missing an acinar component[7,8]. This hypothesis emphazises the concept of a common pathogenetic origin of these lesions[7,8].

In contrast, Ryan *et al* believed that the adenomyomas of the gallbladder, in spite of histology, arise from diverticular disease of the gallbladder and are not pathogenetically related to heterotopic pancreas[9].

To our knowledge, only 30 cases of ectopic pancreas in the gallbladder have been reported; if the association between adenomyosis and pancreatic rests is true, as we propose, this finding should be more frequently observed. Therefore, we suggest that the finding of an adenomyoma in the gallbladder should prompt an extensive sampling of the organ in order to verify the coexistence of pancreatic rests. Unfortunately, it is not possible to provide immunohistochemical support to our hypothesis, since the gallbladder and the pancreas have the same embryologic origin, and thus there are no specific markers allowing unequivocal differentiation between pancreatic tissue and gallbladder epithelium. Recently, Ko *et al*[10] reported that proliferating duct cells of the pancreas express vimentin. Accordingly, we used immunohistochemistry to detect the expression of vimentin in order to verify their observations, but in our hands duct cells of both normal pancreas and pancreatic adenocarcinoma were negative for this marker. Further studies are thus required, apart from morphology, to support an unequivocal link between adenomyomas and pancreatic heterotopia in the gallbladder.

Abstract

To study the clinical correlates of the H63D mu-tation we have analysed the phenotype of H63D homozygotes identified through mutation analysis in a referral laboratory. A total of 366 blood samples referred for *HFE* analysis were screened for C282Y and H63D mutations. Four H63D homozygotes were identified. All had raised serum ferritin but normal transferrin saturation. They were negative for hepatitis B and C and only one patient consumed excess alcohol. In all 4 cases ultrasonography revealed fatty liver. In two patients a liver biopsy was done and showed mild siderosis with an unusual distribution and macrovesicular steatosis. These data confirm the association between fatty liver, hyperferritinemia and increased hepatic iron, but do not clarify whether siderosis was related to steatosis rather than homozygosity for the H63D mutation. Patients with fatty liver may complicate the interpretation of data in population studies of the expression of H63D homozygosity.

INTRODUCTION

Hereditary haemochromatosis (HH) is a common autosomal recessive disorder of iron metabolism with an incidence of up to 1 in 200 and an estimated frequency of carriers of 1 in 10 among people of Northern European descent[1-3]. The disease is characterized by enhanced gastrointestinal absorption of iron to excessive accumulation in tissue, which may result in damage to liver and other target organs[4]. C282Y missense mutation in the *HFE* gene was found to be strongly related to the occurrence of HH[2]. In a UK study, homozygosity for the C282Y mutation was found to account for 91% of HH[5]. A second missense mutation in the *HFE* gene, H63D, is found in around 4% of patients with HH, but its role in iron overload is still debated[2,6-8]. The H63D mutation is variably distributed worldwide. It is more prevalent than the C282Y mutation so that approximately one in five of the European population are H63D heterozygotes[3,9]. Individuals who are compound heterozygous for C282Y and H63D can have iron overload in the range diagnostic of haemochromatosis, although the penetrance of the genotype is low[2,10,11]. Similarly, homozygosity for H63D has been associated with iron overload, ranging from asymptomatic subjects to patients with typical haemochromatosis. As with compound heterozygosity for C282Y/H63D, the penetrance is low and the phenotypic presentation of this genotype varied considerably[11,12]. The aim of this study was to analyse the phenotypic expression of H63D homozygotes identified through the genetic screening of patients referred to our Centre for *HFE* mutation analysis.

366 consecutive blood samples, referred to the Centre for Hepatology at the Royal Free and University College Medical School (UCL), were analysed for *HFE* mutations. Mutation analysis was requested on the basis of biochemical or clinical suspicion of HH, family screening or known diagnosis of haemochromatosis. Samples were obtained after informed written consent, where appropriate. C282Y and H63D mutations were detected by polymerase chain reaction (PCR) amplification of total genomic DNA followed by restriction digestion with RsaI and MboI enzymes respectively, as previously described[5].

Table 1 Clinical, biochemical and serological features of the four H63D homozygous patients

	Case 1	Case 2	Case 3	Case 4
Age (yr)	36	35	44	66
BMI (kg/m^2)	30	24	32.5	31
Blood pressure (mmHg)	140/100	130/80	160/100	150/95
Alcohol intake (g/wk)	8	0	60	0
Blood sugar (mmol/L)	4.2	4.6	5.6	9.5
Total cholesterol (mmol/L)	4.1	4.3	5.5	6
Triglicerides (mmol/L)	1.6	1.5	3.6	2.9
AST (U/L)	46	69	44	15
ALT (U/L)	117	175	112	18
γGT (U/L)	50	45	70	30
Ferritin (μg/L)	454	350	568	423
HCV/HBV serology	neg	neg	neg	neg

Legend: BMI=body mass index; wk=week; neg=negative. Normal ranges: BMI 18-25 kg/m^2; blood pressure max<120mmHg, min<80mmHg (see the seventh report of the Joint National Committee on high blood pressure, NIH publication no 03-5233, December 2003); blood sugar<6mmol/L.

CASE REPORTS

Four males were found to be homozygous for the H63D mutation. Their main features are summarised in Table 1.

Case 1

English male patient aged 36 years with suspected iron overload indicated by a serum ferritin concentration of 454 μg/L (reference range: 39-340). Serum iron, transferrin saturation and total iron binding capacity (TIBC) were normal. He was referred because of abnormal levels of liver enzymes and elevated serum ferritin found during investigation for dyspepsia. He consumed 8 g of alcohol per week. He had a positive family history for obesity and maturity onset diabetes mellitus. There was no family history of haemochromatosis. On examination he was well, overweight and mildly hypertensive (140/100). Abdominal examination was normal. Liver function tests showed: ALT 117 U/L, AST 46 U/L and γGT 50 U/L. Viral markers for hepatitis B and C were negative. Ultrasonography revealed a large liver, with diffuse hyperechogenicity, characteristic of fatty change. Since the liver enzymes and the ferritin remained persistently elevated, a liver biopsy was performed. It showed moderate macrovesicular steatosis (grade 2 on a scale of 0 to 3) with grade 1 siderosis (on a scale of 0 to 4)[13] in periportal hepatocytes and Kupffer cells, with evidence of pericellular fibrosis of zone 3 (stage 1 of steatohepatitis according to Brunt *et al*[14]). The sinusoidal cells had unusual granular siderosis (Figures 1A, 1B, 1C). The hepatic iron concentration was increased being 185 μg/100g dry weight (reference range: 35-136). The patient was seen every three months for 2 years to monitor transaminases and ferritin. On the basis of the result of the liver biopsy, venesection therapy was started, together with dietary restrictions. Over a period of two years, he was treated with seven phlebotomies and approximately 1.3 g of iron were removed. The serum ferritin concentration returned to normal at 95 μg/L as did liver function tests except for minimal elevation of ALT at 45 U/L.

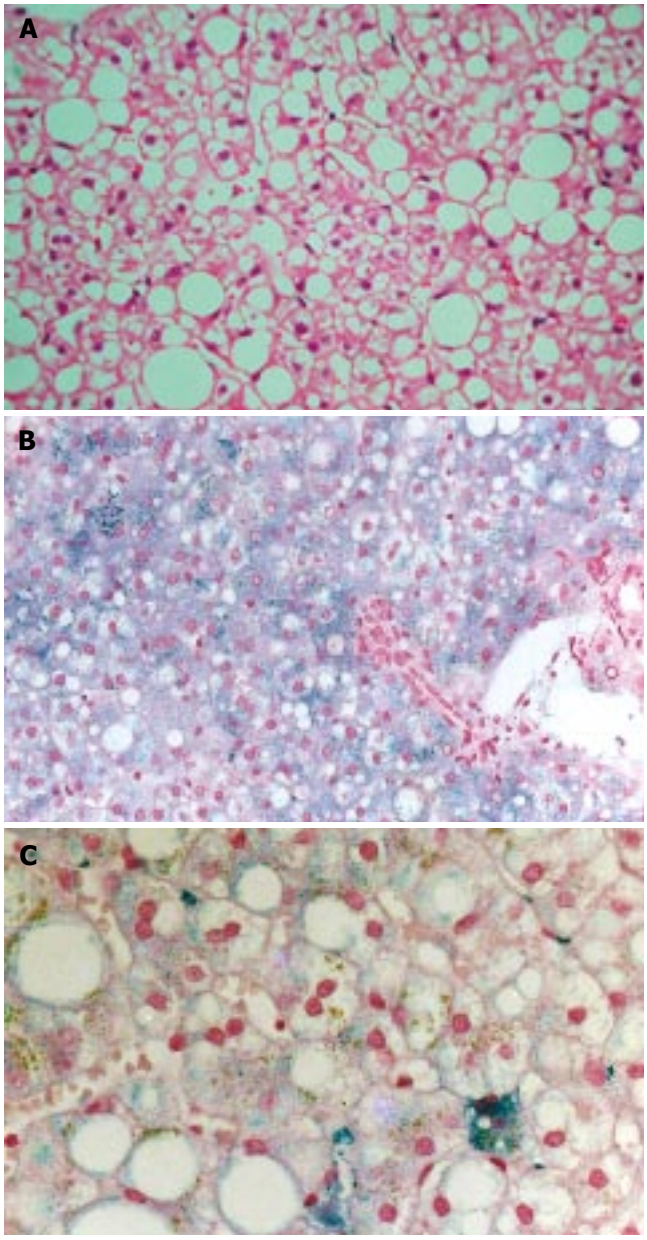

Figure 1 Case 1 liver histology. **A**: Hematoxylin and eosin staining shows grade 2 hepatic steatosis; **B**: Perls' staining shows grade 1 hepatocyte siderosis with predominant periportal distribution; **C**: Higher power of Perls' staining shows clustered Kupffer cell siderosis (right lower field) and also irregular large granular deposits in sinusoidal cells.

Case 2

Male patient aged 35 years from Lebanon with mild abnormality of iron indices. In 1996 he had a routine check-up and was found to have abnormal ALT (175 U/L) and AST (69 U/L), together with a minimally elevated serum ferritin (350 μg/L). Serum iron, TIBC and transferrin saturation were normal, as were the other liver function tests. The family history was negative for haemochromatosis. The patient did not drink alcohol. Viral markers for hepatitis B and C were negative. Between 1989 and 1995 he had been a blood donor giving approximately 2 units (approximately 450 mL each) of blood every year. On examination he had a normal build with gynaecomastia. Blood pressure was normal. Abdominal examination showed a palpable liver

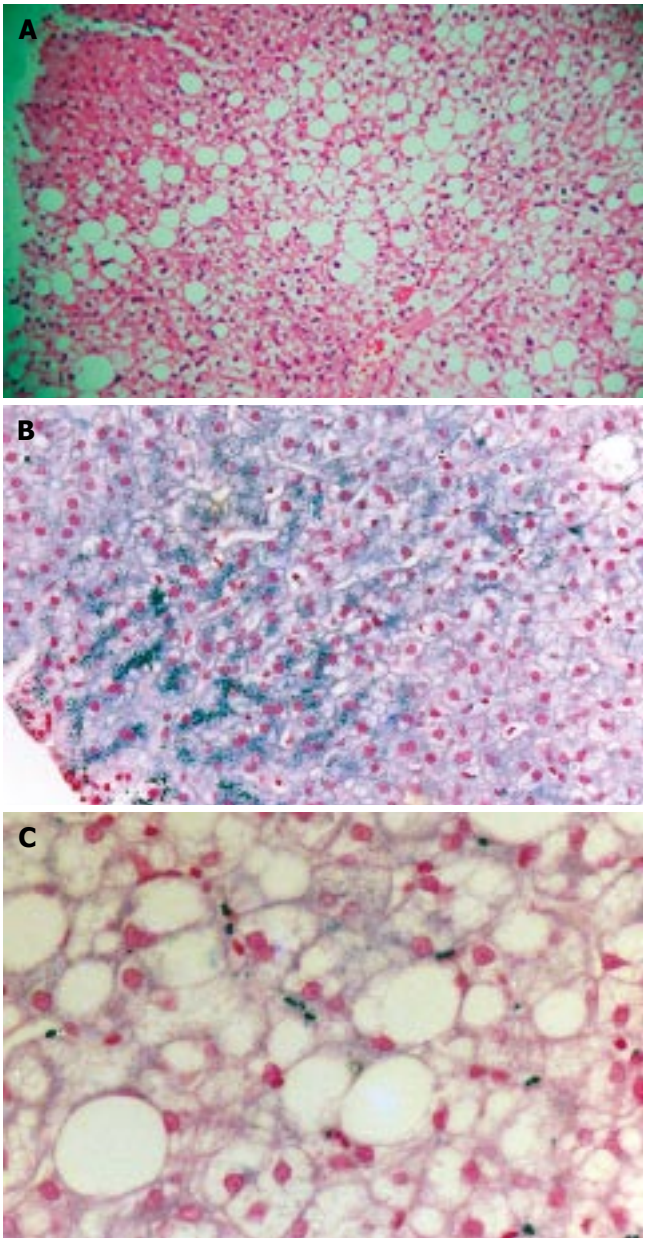

Figure 2 Case 2 liver histology. **A**: Hematoxylin and eosin staining shows grade 2 hepatic steatosis; **B**: Perls' staining shows grade 2 hepatocyte siderosis with predominant periportal distribution; **C**: Higher power shows focal Kupffer cell siderosis and more granular irregular sinusoidal siderosis.

on deep inspiration (2 cm) but no other abnormalities. The alpha-1-antitrypsin level was 1.0 g/L (normal range 1.2-2.6 g/L). Analysis showed him to have phenotype MZ. Ultrasound examination revealed a hyperechogenic liver compatible with hepatic steatosis. A liver biopsy was performed and showed moderate macrovesicular steatosis (grade 2) without fibrosis (stage 0 of steatohepatitis[14]). There was grade 2 siderosis in periportal hepatocytes, and focal Kupffer cell iron. The sinusoidal cell iron had a granular pattern similar to that seen for case 1 (Figures 2A, 2B, 2C). No cholestasis or alpha-1-antitrypsin staining was detected.

The patient was seen every three months for 4 years to monitor transaminases and ferritin, which remained persistently elevated.

Case 3

Irish male patient aged 44 years referred with possible iron overload indicated by a ferritin concentration of 568 μg/L. Serum iron, transferrin saturation and TIBC were normal. He was referred to our clinic in November 1998 to investigate raised levels of liver transaminases: ALT was 112 U/L, AST 44 U/L and γGT 70 U/L. The family history was positive for obesity and maturity onset diabetes mellitus and was negative for haemochromatosis. Physical examination showed a middle aged obese man (103 kg/178 cm; Body Mass Index (BMI) =32.5 kg/m^2). Blood pressure was elevated in the supine position (160/100) and the hypertension was treated with Tenif one per day (atenolol 50 mg, nifedipine 20 mg) and Valsartan (80 mg/day). The patient had also a history of moderate alcohol abuse (alcohol intake: 60 g/week) and elevated triglyceride levels (3.61 mmol/L). Viral markers for hepatitis B and C were negative. Ultrasonography of the abdomen revealed a liver of normal size, but with echoreflectivity consistent with fatty liver. No liver biopsy was done. The patient was seen every three months for 2 years to monitor weight, transaminases and ferritin. He abstained from alcohol. Dietary therapy was started and the patient lost 6 kg in weight. No venesection was performed. During follow-up, liver function tests remained mildly abnormal with an ALT of 84 U/L. The other enzymes fell to normal levels and triglycerides fell to 1.73 mmol/L. Despite abstinence and losing weight, his ferritin remained elevated (482 μg/L). The possibility of iron overload was raised and the patient was genotyped for mutations in the *HFE* gene and found to be homozygous for H63D.

Case 4

English male patient aged 66 years with an elevated serum ferritin concentration (423 μg/L) on a background of type 2 diabetes and peripheral neuropathy. Serum iron, transferrin saturation and TIBC were normal. He was diagnosed as hypertensive in February 1988 and he is currently treated with Enalapril. He also had atrial fibrillation for which he has been treated with warfarin. He was treated for diabetes mellitus with gliclazide, metformin and acarbose. Physical examination showed no features of chronic liver disease and no hepatomegaly. Liver function tests were normal. Viral markers for hepatitis B and C were negative. Abdominal ultrasonography revealed an enlarged and fatty liver. Since his ferritin levels remained in the region of 400 μg/L, the patient was tested for mutations in the *HFE* gene and found to be homozygous for H63D mutation.

DISCUSSION

Four H63D homozygotes were identified by screening 366 blood samples referred for genetic analysis in the *HFE* gene. All the four patients had high serum ferritin. It is noteworthy that in all the cases an abdominal ultrasonography showed fatty liver. In the two cases where liver biopsy was done and histology showed not only mild siderosis of hepatocytes, typical of iron overload of HFE-related haemochromatosis, but also siderosis of sinusoidal cells, with a granular pattern that could be related to nonalco-

holic steatohepatitis (NASH). Both patients had significant macrovesicular steatosis. One patient was treated with dietary restriction and venesection, after which liver function tests and serum ferritin concentration returned to normal. These findings suggest that hepatic steatosis, together with a biological effect of the H63D mutation, could be responsible for the hepatic siderosis in these patients. Recent evidence suggests that H63D homozygosity could lead to iron overload with variable penetrance and phenotype[12]. However, an association with fatty liver has not been previously reported. Another study of more than 10,000 blood donors suggested an effect of H63D homozygosity on iron metabolism[15], although the mean serum iron indices for this genotype were within the normal range, possibly reflecting the fact that blood donors are in general healthy and young (mean age was 38 years for men and 36 years for women). These findings have been reinforced experimentally by the demonstration that transgenic mice homozygous for the H63D mutation have elevated transferrin saturation and hepatic iron concentration compared to wild type mice[16].

H63D homozygosity could thus contribute to iron overload but the phenotypic expression may be influenced by cofactors. Sex, age, diet and modifier genes are likely to influence penetrance of the genotype. In this series all 4 cases were male and this reflects the relative protection of women from iron overload by menstruation and pregnancy. Furthermore, three of the cases had one or more metabolic disorders which are part of the insulin resistance syndrome (IRS)[17]. Case 1 was overweight (BMI>25 kg/m^2) and mildly hypertensive, Case 3 was obese (BMI>30 kg/m^2) and had hypertriglyceridemia and hypertension requiring antihypertensive treatment. Case 4 was obese, he had type 2 diabetes mellitus requiring therapy, hypertrigliceridemia and hypertension under therapy.

Although hyperferritinemia may be associated with hepatic steatosis per se[18,19], in two patients presented here hepatic siderosis with an unusual histological pattern was present. Homozygosity for H63D may have played a role, but the unusual cellular pattern raises the possibility that in some cases of hepatic steatosis there are other changes in cellular iron handling which result in iron accumulation. Alterations in cytokines and hence hepcidin may result in accumulation of iron in sinusoidal cells[20,21]. A role for the mutations in the *HFE* gene in other diseases, however, has been suggested by their over-representation in subjects with NASH and with the dysmetabolic iron overload syndrome (DIOS) characterized by an association between iron overload and insulin resistance[22-24]. The molecular mechanism explaining these associations is not clear. Hepatic steatosis has been recognised as the first of two "hits" in the pathogenesis of NASH, since the presence of oxidisable fat within the liver is enough to trigger lipid peroxidation[25]. However, many patients with fatty liver do not progress to necroinflammation[26]. It has been suggested that the second hit for the development of NASH may be oxidative stress, leading to necroinflammation[27]. Several potential second hits have been suggested. Iron even in relatively low concentrations could synergize with lipid overload and induction of ethanol-inducible cytochrome P450 2E1 (CYP2E1) to increase oxidative stress in hepatocytes[28].

If iron leads to oxidative stress and to progression of non-alcoholic fatty liver to NASH, venesection therapy is theoretically beneficial, and this may have contributed to the normalisation of serum ferritin concentration and improvement of liver function tests in Case 1. In conclusion, our findings confirm a link between fatty liver and mild iron accumulation. Whether homozygosity for H63D contributed to the association is uncertain. Further studies of iron regulatory proteins are needed in hepatic steatosis.

Abstract

A 62-year-old male with decompensated liver cirrhosis due to hepatitis C virus developed severe hepatic encephalopathy with status epileptic us. The blood ammonia level on admission was more than twice the normal level. Brain computed tomography and magnetic resonance imaging were normal. In addition, electroencephalogram showed diffuse sharp waves, consistent with hepatic encephalopathy. The status epilepticus was resolved after antiepileptic therapy (phenytoin sodium) and treatment for hepatic encephalopathy (Branched chain amino acids). The blood ammonia level normalized with the clinical improvement and the patient did not have a recurrence of status epilepticus after the end of the antiepileptic treatment. Additionally, the electroencephalogram showed normal findings. Thus, we diagnosed the patient as hepatic encephalopathy with status epilepticus. We consider the status epilepticus of this patient to a rare and interesting finding in hepatic encephalopathy.

INTRODUCTION

Hepatic encephalopathy typically presents with alterations in behavior, impairment of consciousness, and alterations in motor tone[1]. Although, according to some reports, the incidence of seizures in patients with hepatic encephalopathy is unknown, reports of epileptic seizures in patients with hepatic encephalopathy during the clinical course are very rare, but not in the terminal stage of liver cirrhosis[2-4]. We present a rare and interesting case of a 62-year-old male with hepatic encephalopathy with status epilepticus accompanying decompensated liver cirrhosis.

CASE REPORT

A 62-year-old patient was diagnosed as having decompensated liver cirrhosis due to hepatitis C virus one year earlier. At that time he reported a ten-year history of mild psychosis but no history of diabetes mellitus, epilepsy, stroke, or brain trauma. He was admitted to our hospital because of generalized tonic-clonic seizures for several hours and loss of consciousness (status epilepticus) in October 2004. He had a history of recurrent episodes of hepatic encephalopathy. The results of further clinical examination, except for signs of decompensated liver cirrhosis, were normal. Laboratory data showed anemia, thrombopenia, increased transaminase, alkaline phosphatase and total bilirubin, and decreased albumin, total cholesterol and BTR (branched chain amino acid/tyrosine ratio). Furthermore, the plasma ammonia (NH_3) level on admission was twice the normal level (186 μmol/L; normal value is 23-76 μmol/L). Chest and abdominal roentgenograms, brain computed tomography (CT) and magnetic resonance imaging (MRI) were also normal, although abdominal echosonography and CT revealed atrophic cirrhotic liver and splenomegaly. Electroencephlogram (EEG) on day 2 after admission showed diffuse sharp waves, consistent with hepatic encephalopathy (Figure 1). According to the history and the results of EEG, in combination with laboratory and radiological data, hepatic encephalopathy with status epilepticus was suspected. Status epilepticus and loss of consciousness were resolved after antiepileptic therapy (phenytoin sodium) and treatment for hepatic encephalopathy (branched chain amino acids; BCAA). The plasma NH_3 level returned to a normal level concurrently with his clinical improvement. He did not have a recurrence of status epilepticus after the end of antiepileptic treatment and his conscious level returned to normal with continuous therapy for hepatic encephalopathy with BCAA. Another EEG on day 33 after admission showed a normal level (Figure 1). Thus, we diagnosed our patient as having hepatic encephalopathy with status epilepticus. In the follow-up, 7 mo later, he was in good condition, in spite of

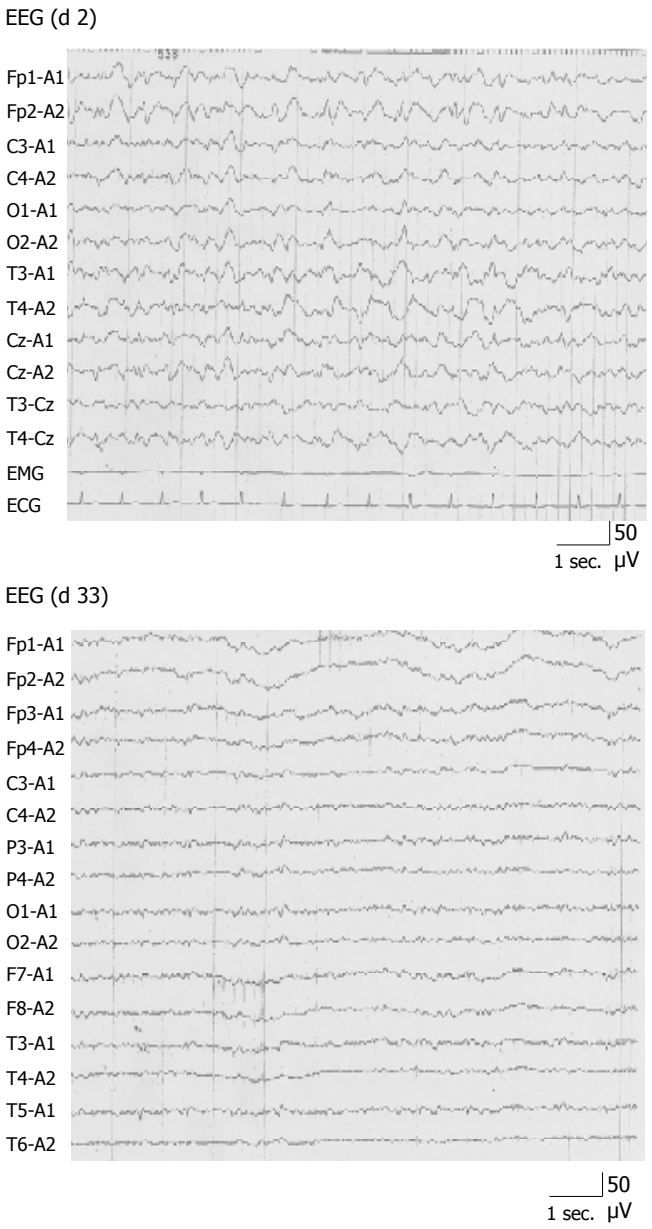

Figure 1 Diffuse EEG activity on day 2 after admission characterized by delta waves mixed with theta waves. Signs compatible with hepatic encephalopathy. The EEG activity on day 33 after admission returned to normal.

the recurrence of hepatic encephalopathy.

DISCUSSION

The present case was diagnosed as hepatic encephalopathy with status epilepticus. Although the patient had a history of mild psychosis, there were no psychological findings except for the loss of consciousness at the time the seizures occurred. In addition, he had a history of recurrent episodes of hepatic encephalopathy. Second, no focal brain lesion could be detected by brain CT and MRI, and the EEG was suggestive of metabolic dysfunction, especially hepatic encephalopathy. Third, the elevated plasma NH_3 level and EEG findings (diffuse sharp waves) on admission and its subsequent normalization with the clinical improvement after the end of antiepileptic treatment strongly suggested hepatic encephalopathy with status epilepticus.

Epileptiform abnormalities in EEG, seizures and status epilepticus may be seen in patients with hepatic encephalopathy, although their incidence is unknown. Ficker DM et al. reported in a retrospective study that the majority of cirrhotic patients with epileptiform changes in EEG either died or deteriorated[3]. However, reports of epileptic seizures in hepatic encephalopathy during the clinical course are very rare[5, 6].

The pathophysiology of seizures in hepatic encephalopathy remains unknown. Various metabolic factors may be suggested. The plasma NH_3 levels are consistently elevated, while other factors, such as short chain free fatty acids, phenols, mercaptanes and false neurotransmitters, have also been implicated. These factors may be responsible for the generation of epileptiform discharges as well as epileptic seizures in patients with hepatic encephalopathy[7, 8].

On the other hand, it has been reported that the focal hyperemia/hypermetabolism may be related either to the seizures or to the encephalopathy itself, based on intracranial ultrasonography and single-photon-emission computed tomography (SPECT)[6].

Abstract

Paraduodenal hernia is the most common internal hernia. The clinical symptoms of paraduodenal hernia may be intermittent and nonspecific. Therefore, it is difficult to diagnose preoperatively. Abdominal computed tomography (CT) scan currently plays an important role in the evaluation and management of paraduodenal hernia before surgical operation. We report one unique case of preoperatively diagnosed left paraduodenal hernia complicated by advanced ascending colon cancer and reviews of Japanese literature.

INTRODUCTION

Paraduonenal hernia is an uncommon cause of small bowel obstruction. It has been reported that the most common type of internal hernia, reported in more than 50% of internal hernia cases. We report a case of left paraduodenal hernia complicated by ascending colon cancer, which was diagnosed correctly with abdominal CT. This case was confirmed at surgical operation and the clinical and imaging findings of these hernias were reviewed in Japanese literature.

CASE REPORT

A 47-year-old woman was admitted with right lower quadrant pain and nausea. An elastic hard mass was palpable in the right lower quadrant abdomen. The body temperature was 36.8℃. Arterial blood pressure and cardiac rate were 96/80 mmHg and 70/min respectively. Laboratory tests detected only an anemia. Plain abdominal X-ray showed air-fluid levels of the small intestine loop in the upper abdomen (Figure 1). Abdominal CT scans with intravenous administration of contrast medium showed ascending colon with enhanced mass and ileum dilatation (Figure 2). Abdominal CT scan also showed an encapsulated small bowel loop with no dilatation in the left upper abdomen and the inferior mesenteric vein (IMV) was located in the anterior of the encapsulated small bowel loop formation (Figure 3). Colonoscopy revealed advanced ascending colon cancer with obstruction. We preoperatively diagnosed as ascending colon cancer with left paraduonenal hernia.

Laparotomy revealed the hernia orifice and hernia sac was located in left mesocolon (Figure 4). IMV was located in the upward of the anterior portion of the hernia sac. Approximately 40 cm of jejunum was within a hernial sac. There were no volvulus or ischemic changes of the jejunum. The patient underwent right hemicolectomy with an end-to-end ileocolonic anastomosis. Anterior hernial sac incision was also performed. The postoperative course was uneventful.

DISCUSSION

Paraduonenal hernia has been reported that the most common type of internal hernia, reported in more than 50% of internal hernia cases[1,2]. The clinical symptoms of paraduodenal hernia may be intermittent and nonspecific. It is difficult to diagnose preoperatively. Therefore, paraduodenal hernia was found incidentally at laparotomy, autopsy or during radiological investigation for unrelated disease[2-5].

Based on the published cases of paraduodenal hernia in Japan, approximately 68% (82/120 cases) were left sided, and 32% (38/120 cases) were right sided. 70% of these cases were man, and 30% cases were woman[6,7]. The mean age of the onset was 39.5 years. These frequencies of

Figure 1 Plain abdominal X-ray showed air-fluid levels of the small intestine loop in the upper abdomen.

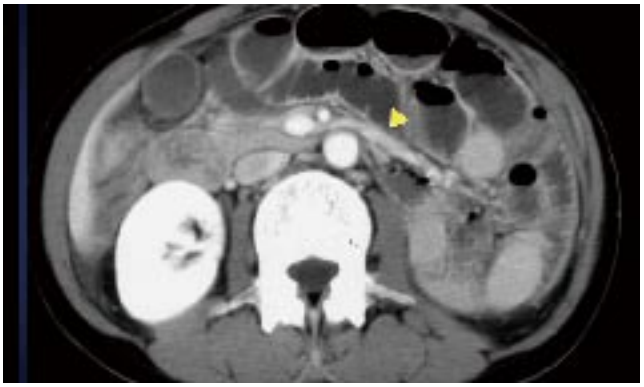

Figure 3 Inferior mesenteric vein (IMV) was located in the anterior of the encapsulated small bowel loop formation (yellow arrow head).

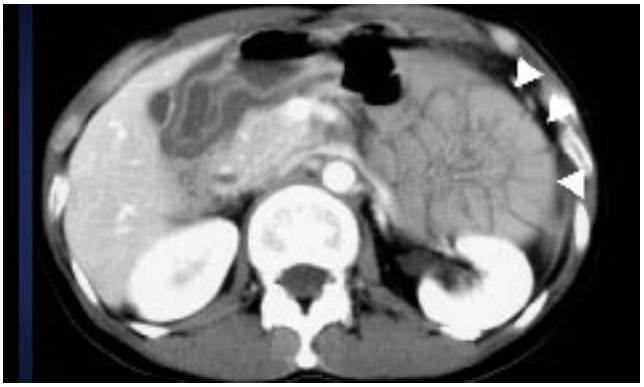

Figure 2 Abdominal CT scan also showed an encapsulated small bowel loop with no dilatation in the left upper abdomen (white arrow head).

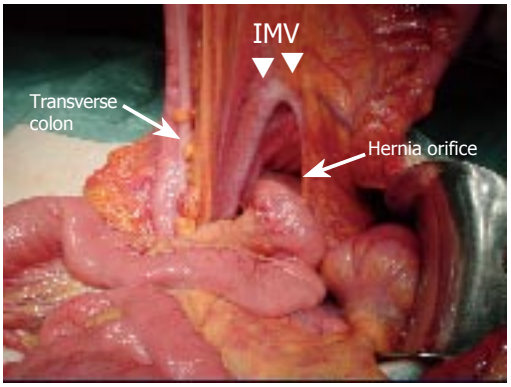

Figure 4 Large orifice of the hernia sac (white arrow) in the transverse mesentery and IMV formation. The small intestine had herniated through hernia orifice.

paraduonenal hernia were almost similar to the incidence in English literature.

Internal hernia complicated by colorectal cancer was reported only 3 cases. In our patient case, the origin of the bowel obstruction was not caused by left paraduonenal hernia but obstructed by advanced ascending colon cancer. Clinical findings of paraduodenal hernias are variable, ranging from mild digestive complaints to acute or chronic symptoms of obstruction, sometime asymptomatic.

Many of the paraduodenal hernia can be diagnosed incidentally at laparotomy, autopsy or during radiological investigation for an unrelated disease. Therefore, diagnosis of asymptomatic paraduodenal hernia has been difficult. On the other hand, recently reported cases of symptomatic paraduodenal hernia, 80% (8/10 cases) were diagnosed before operation[6,7]. Especially, abdominal CT currently plays an important role in the evaluation and management of internal hernias[2,3,8,9].

Enhanced CT is helpful in establishing a preoperative diagnosis of the presence of paraduonenal hernia. The specific findings of paraduonenal hernia by CT scan show clustering of small bowel loops, well-circumscribed edge that corresponds to the hernia sac, stretched and engorged mesenteric vessels. In the case of left paraduodenal hernia, IMV were usually located in the upward and anterior displacement of the hernia sac. Abnormalities in the mesenteric vessels including engorgement, crowding and stretching, and displacement of the main mesenteric trunks to the left are important clues to this diagnosis[1,10].

Paraduodenal hernias are believed to occur due to a congenital defect in the descending mesocolon. The small bowel may occur to invaginate into this space, the fossa of Landzert, which lies to the left of the fourth portion of the duodenum. The herniated small-bowel loops may become trapped within this mesenteric sac.

Treatment for the duodenal hernia is based on reduction of the hernia sac and closure of the defect or incision of the hernia sac[11,12]. Paraduodenal hernia induces an over 50% lifetime threat of incarceration, leading to bowel obstruction and strangulations. Therefore, surgical operation should be performed to avoid these complications. Indeed, 20% cases of internal herinas needed for small intestinal resection caused by bowel necrosis[6,7]. In general, postoperative course was uneventful, recurrence case was rare. Recently, laparoscopic surgery for left paraduodenal hernia without bowel necrosis may be useful surgical method because of its minimal invasiveness and aesthetic advantage[13,14]. In our case, we performed anterior hernia sac incision following the right hemicolectomy. Surgeons should pay attention to the mesenteric vessels located near the hernia sac orifice. The displacement of the main mesenteric trunks may

cause vessel injury during surgical treatment.

Abstract

We herein report the case of an idiopathic liver cystic mass which aggressively infiltrated the thoraco-abdominal wall. A 74-year-old woman who had a huge cystic lesion in her right hepatic lobe was transferred to our hospital for further examinations. Imaging studies revealed a simple liver cyst, and the cytological findings of intracystic fluid were negative. She was followed up periodically by computed tomography (CT) scans. Seven years later, she complained of a prominence and dull pain in her right thoraco-abdominal region. CT revealed an enlargement of the cystic lesion and infiltration into the intercostal subcutaneous tissue. We suspected the development of a malignancy inside the liver cyst such as cystadenocarcinoma, and she therefore underwent surgery. A tumor extirpation was performed, including the chest wall, from the 7th to the 10th rib, as well as a right hepatic lobectomy. Pathologically, the lesion consisted of severe inflammatory change with epithelioid cell granuloma and bone destruction without any malignant neoplasm. No specific pathogens were evident based on further histological and molecular examinations. Therefore the lesion was diagnosed to be a destructive granuloma associated with a long-standing hepatic cyst. Since undergoing surgery, the patient has been doing well without any signs of recurrence.

INTRODUCTION

A liver cyst is a common lesion that tends to be mostly asymptomatic, however, once it is associated with other events such as bleeding, infection and rupture, it often becomes symptomatic and treatment is thus usually needed. Granulomas can be seen in any part of the body and they reflect a host inflammatory responses elicited by a wide variety of stimuli[1, 2], however, it is uncommon that a granulomatous reaction develops in a liver cyst[3].

We experienced the case of highly destructive, non-malignant, granulomatous lesion that originated from a long-standing hepatic cyst that infiltrated the thoraco-abdominal wall mimicking hepatic cystadenocarcinoma. To the best of our knowledge, this is the first known occurrence of a case of a hepatic granuloma that developed secondary to a liver cyst with a highly invasive capacity.

CASE REPORT

A 73-year-old Japanese woman presented at our hospital with right. hypochondralgia on September 1997. Computed tomography (CT) showed a huge liver cyst measuring 10cm in the right lobe of the liver without any solid component (Figure 1A). Subsequently, 2.4L of serous fluid were percutaneously drained, without any sclerosing agent administered into the cyst. A cytological examination of the aspirated fluid was negative for neoplastic cells. Since her symptom had subsided after the fluid drainage, she was carefully followed-up without any further treatment. On May 2003, she was again referred to us with abdominal distention and pain in the right thoraco-abdominal region. The results of laboratory tests showed slight elevations in the C-reactive protein (CRP) level (0.5mg/dL, normal range < 0.17). Serological tests for hepatitis B and C virus were negative. The serum levels of carcinoembryonic antigen, carbohydrate antigen 19-9 and α-fetoprotein were all within the normal ranges. Other tests including her liver function were within the normal limits. A CT scan showed a cyst in the right. lobe of the liver similar to the one observed 6 years previously. In addition, a calcified lesion was also found around the cyst (Figure 1B). An axial and coronal view of an MRI showed a multilocular cyst with a thick wall and solid component extending into the subcutaneous tissue (Figure 2A and B). MR cholangiopancreatography demonstrated no dilatation in the biliary system, thus indicating that there was most likely no communication with the liver cyst (Figure 2C). These findings closely resembled hepatic cystadenocarcinoma.

After admission, the cystic tumor gradually increased

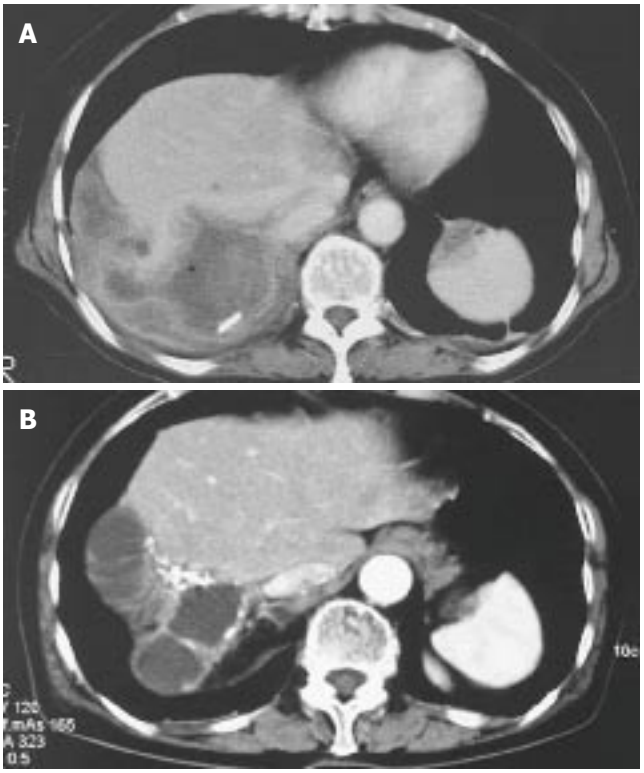

Figure 1 Computed tomography revealed a huge multilocular cyst measuring 10 cm in the right lobe of the liver on September 11th, 1997 (**A**). A similar cyst with a calcified lesion was found in the right lobe of the liver on May 15th, 2003 (**B**).

in size and finally her skin above the invasion site became reddish and swollen (Figure 2D), thus suggesting malignant tumor invasion. After obtaining the patient's informed consent, we performed an *en bloc* resection of the hepatic right lobe including the whole cyst, along with the diaphragm, rib bone, and skin. After completing the resection, the defect of the diaphragm was covered with the great omentum, and the thoraco-abdominal wall defect was reconstructed using a musculo-cutaneous flap including the anterior sheath and the left rectus abdominis muscle which both receive the blood supply from the superior abdominal artery (Figure 3A and B). Macroscopically, the cystic tumor directly invaded the intercostal space through the diaphragm (Figures 4A and 4B). No microorganism was found in the cyst fluid or the resected materials according to the results of microbilological culture examinations. A pathological examination revealed that the bone had been destroyed by the invasion of the granuloma, which was composed of epithelioid cells with necrotic areas (Figure 4C). No malignancy or microorganism was detected in any tissue samples. Because the histology was similar to tuberculosis, Ziehl-Neelsen staining and DNA-PCR using three different primers for a tubercle bacillus were performed with negative results. Hepatic hydatid disease was excluded by the fact that she had no history of living or traveling to the epidemic area such as Hokkaido prefecture in Japan and her blood samples did not show the presence of the antibodies against ehinococcus. From these findings, the cystic tumor was therefore histologically diagnosed to be a hepatic epithelioid granuloma. (Figure 4D)

The patient had an uneventful postoperative course and was discharged on postoperative day 27. She remains asymptomatic until 24 mo postoperatively, without any signs of recurrence.

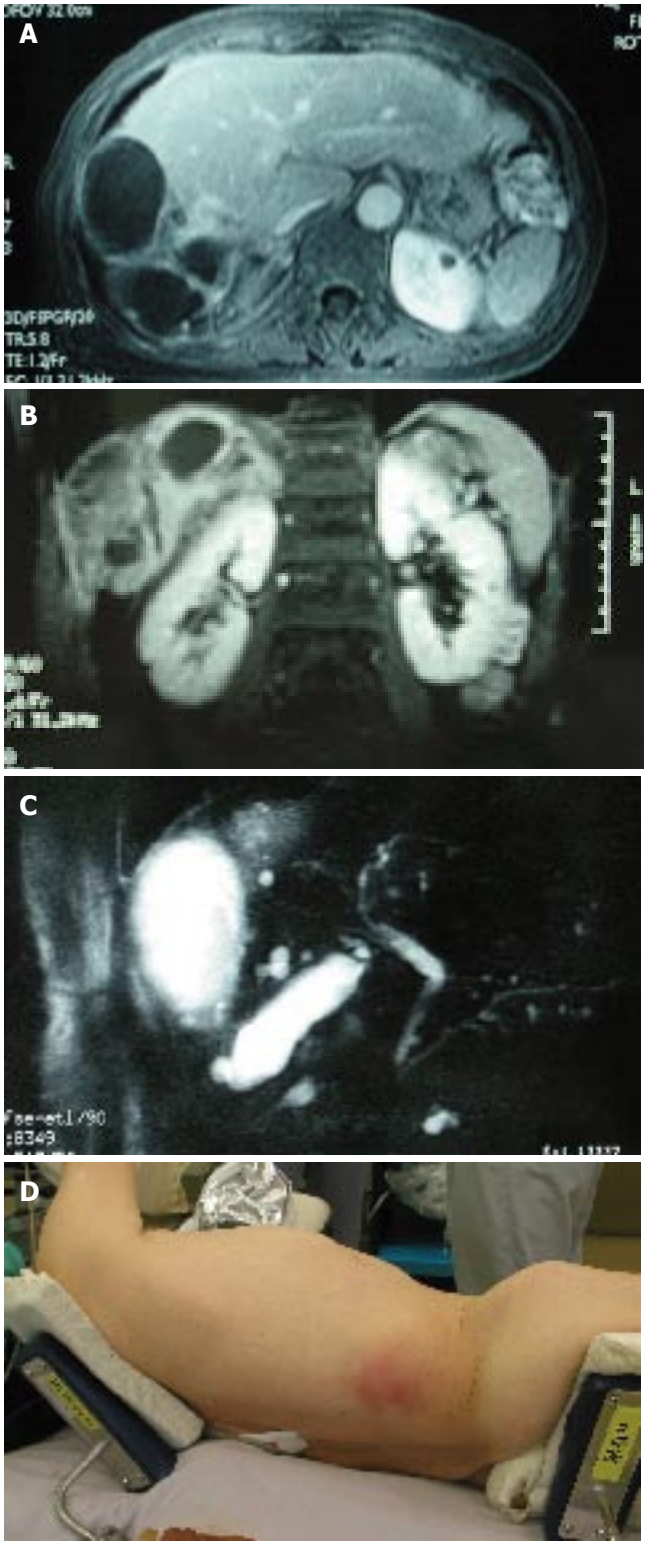

Figure 2 An axial (**A**) and coronal (**B**) view of magnetic resonance imaging (MRI) showed a multilocular cyst with a thick wall with a solid component extending into the subcutaneous tissue. MR cholangio-pancreatography showed no dilatation in the biliary system, and most likely no communication with the liver cyst (**C**). The skin showed red swelling by the subcutaneous extension of the hepatic cyst (**D**).

DISCUSSION

There has been a great progress in the diagnostic modali-

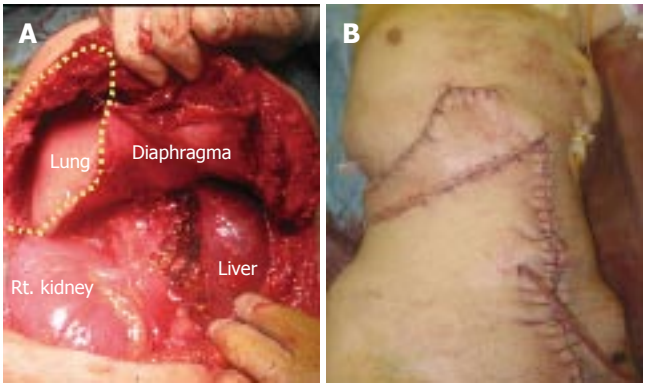

Figure 3 An en bloc resection resulted in a huge defect (**A**, yellow dotted circle). The defect of the diaphragm was covered with the great omentum, and the thoraco abdominal wall defect was reconstructed by a musculo-cutaneous flap including the anterior sheath and the left rectus abdominis muscle which both receive the blood supply comes from the superior abdominal artery (**B**).

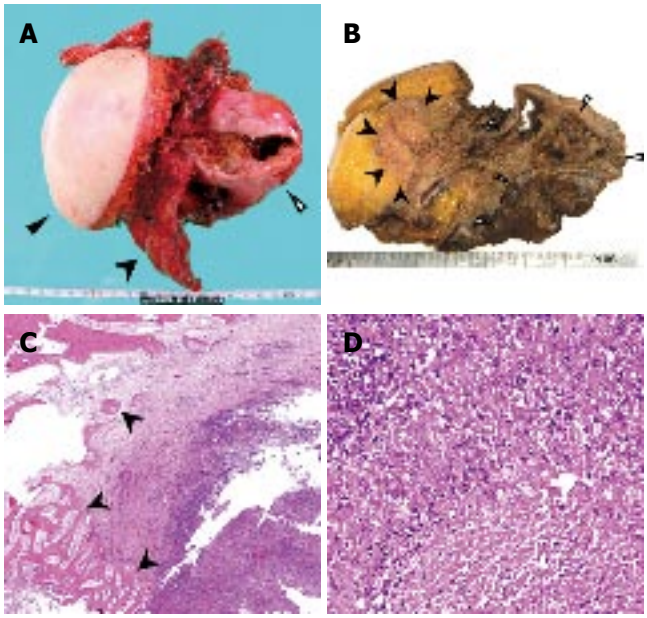

Figure 4 Macroscopically, the cystic mass directly invaded the intercostal space through the diaphragm (**A**. Resected crude specimen, black triangle; skin, black arrow head; ribs, white triangle; cystic tumor; **B**. Cut surface of the specimen, black arrow head; subcutaneous invasion, white triangle; cystic tumor). Microscopically, the bone was destroyed by an invasion of granuloma tissue (**C**). The granuloma was composed of epithelioid cells with necrotic areas (**D**).

ties for hepatic lesions including ultrasonography, CT, magnetic resonance imaging (MRI) and angiography[4]. Cystic lesions of the liver, which occupy a large part of hepatic lesions and are seen in up to 5% of the population, can be classified as developmental, neoplastic, inflammatory, or miscellaneous lesions. If a solid component develops inside the cyst, the possibility of a malignant transformation should be considered[5]. However, even routine imaging procedures such as CT or MRI generally fail to differentiate hepatic granulomas from other neoplasms[2].

Aspiration cytology can help in making a preoperative diagnosis, however, it is sometimes difficult to accurately hit the target tumor under US guidance, and this procedure also carries a risk of potentially causing needle-track and peritoneal seeding if the lesion is a malignant tumor[6, 7].

A wide variety of underlying conditions such as sarcoidosis[8], malignant lymphoma[9], tuberculosis[2], and HCV infection[10,11] can cause hepatic granulomas, with resulting prognostic and therapeutic implications. However, the histological features of such granulomas are not distinctive, while a specific etiological agent often cannot be identified despite serological, immunological microbiological, and radiological investigations, thus often resulting in a diagnosis of "idiopathic" hepatic granulomas. Although the exact etiology and pathogenesis of this aggressively infiltrating granuloma seen in the present case remains unclear, we speculated that an unidentified organism infection possibly occurred via two different routes: (1) the endogenous route, via the blood stream; (2) the exogenous route: a reverse infection through a drainage catheter when aspiration had previously been performed.

A spontaneous regression occurs in some cases of hepatic granulomas, therefore, patients can be treated by simple observation or conservative therapy with anti-inflammatory drugs including antibiotics or steroids in most cases. In the present case, the fact that destroyed and necrotic tissue caused inflammatory reactions suggested that empirical antibiotic therapy would be ineffective, to make matters worse, such conservative treatment could have possibly induced the development of such antibiotic-resistant bacteria as Methicillin-Resistant Staphylococcus Aureus (MRSA). In addition, steroid treatment is generally effective for sarcoidosis, however, it risks exacerbating tuberculosis and an earlier paper described a patient who died from miliary TB after the administration of empirical steroids [12].

Great improvements in operative techniques, perioperative patient management, and patient selection criteria have not made a hepatic resection one of the standards and effective methods for liver cysts[13]. As a result, a hepatectomy is recommended for cystic lesions when a tumor of the liver with a potential malignancy cannot be ruled out[14,15].

In the present case, the clinical course in which a solid component developed during the follow-up of a liver cyst, while infiltrating into the subcutaneous tissue with the destruction of the ribs was highly suggestive of the development of a malignancy, such as cystadenocarcinoma. The pathological diagnosis turned out to be a cancer-free lesion, namely, benign granuloma. Despite the highly invasive capacity of this lesion, the good clinical outcome in this case supports the suitability of a hepatic resection with the total removal of the affected areas as the treatment of choice.

Abstract

A 58-year-old Japanese man had tarry stool and severe anemia. Neither upper nor lower gastrointestinal (GI) endoscopy showed any localized lesions. Thus, the source of his GI bleeding was suspected to be in the small intestine, and he underwent peroral double-balloon enteroscopy (DBE) using EN-450T5 (Fujinon-Toshiba ES System Co., Tokyo, Japan). There were no lesions considered to be the source of GI bleeding. After the procedure, the patient began to experience abdominal pain. Laboratory tests revealed hyperamylasemia and abdominal computed tomography revealed an inflammation of the pancreas and the peripancreas. He was thus diagnosed to have acute pancreatitis. Conservative treatments resulted in both clinical and laboratory amelioration. He had no history of alcohol ingestion, gallstone disease or pancreatitis. Magnetic resonance cholangiopancreatography demonstrated no structural alterations and no stones in the pancreatobiliary ductal system. As his abdominal pain started after the procedure, his acute pancreatitis was thus thought to have been related to the peroral DBE. This is the first reported case of acute pancreatitis probably associated with peroral DBE.

INTRODUCTION

The small intestine is located quite far from both the mouth and the anus, and thus it has been difficult to be examined by endoscopy until recently. However, capsule endoscopy and double-balloon enteroscopy (DBE), new methods of enteroscopy, have been introduced in recent years which have now made the observation of the entire small intestine possible.

DBE is a novel technique which was developed by Yamamoto *et al*, in Japan[1-3], and is spreading also in other countries. Both a 200-cm enteroscope and a 145-cm overtube which have a soft latex balloon at their tips are included in the system. Both balloons can be inflated or deflated by a balloon-pump controller which thus allows for a shortening of the proximal intestine, thus allowing the enteroscope to be inserted into the deep small intestine. Currently, two different diameter enteroscopes, EN-450P5/20 (Fujinon-Toshiba ES System Co., Tokyo, Japan) with an outer diameter of 8.5 mm (an overtube with an outer diameter of 12.2 mm) and EN-450T5 with an outer diameter of 9.4 mm (an overtube with an outer diameter of 13.2 mm) are available. With a larger accessory channel, EN-450T5 allows the performance of a variety of enteroscopic treatments including argon plasma coagulation/ablation, coagulation/biopsy (hot biopsy) and balloon dilatation. The indications of DBE are for the diagnosis and the treatment of small intestinal diseases. DBE is quite useful for the diagnosis of the origin of obscure gastrointestinal (GI) bleeding in the small intestine and for the endoscopic evaluation and histopathological diagnosis from the biopsy samples of small intestinal lesions such as ulcers, tumors and strictures. It is also useful for the treatment of small intestinal diseases, for example, the management of active GI bleeding and polypectomy of the small intestinal polyps. The technique of DBE is considered to be safe as only few complications related to sedation and original diseases have been reported previously[4,5].

In this paper, we report a case that developed acute pancreatitis after peroral DBE. To our knowledge, this is the first report which describes a case of acute pancreatitis probably associated with peroral DBE.

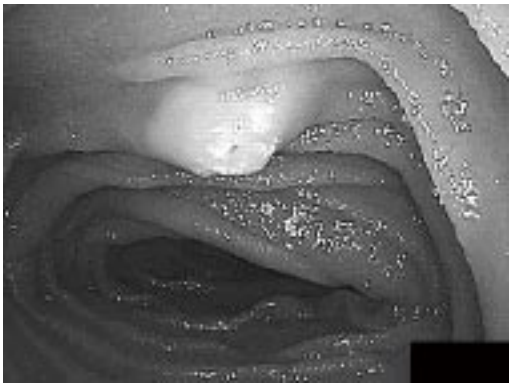

Figure 1 Peroral double-balloon enteroscopy revealed a small yellowish submucosal tumor with white specks on the surface in the upper jejunum.

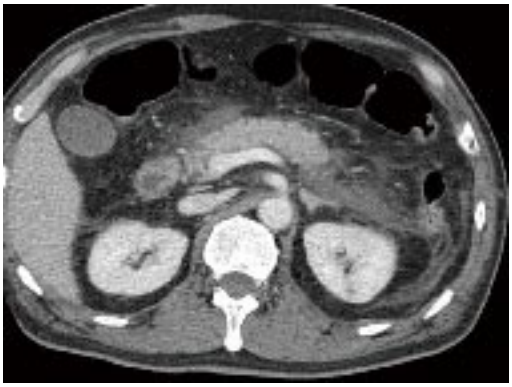

Figure 2 Abdominal CT showed inflammation and swelling of the pancreas, and a blurring of the fat planes in both the peripancreas and the left anterior pararenal space.

CASE REPORT

A 58-year-old Japanese man had tarry stool and syncope and was hospitalized by ambulance during the previous month. Since laboratory tests revealed severe anemia (hemoglobin level: 77 g/L, normal 140-180 g/L), he received red blood cell transfusion. Neither upper nor lower gastrointestinal GI endoscopy showed any localized lesions. Barium meal radiography of the small intestine and computed tomography (CT) also failed to show any lesions. As a result, the source of his GI bleeding was suspected to be a small lesion in the small intestine such as angiodysplasia, small ulcer or erosion, and he was thus referred to our hospital. Thirty days had already passed from the day when he had tarry stool and his hemoglobin level recovered up to 114 g/L. On the day of his admission, written informed consent was obtained from him and he underwent peroral DBE using EN-450T5. The total time of the procedure was 100 min. At the most distal site, the small intestinal mucosa was marked with a tattoo by a submucosal injection of sterilized ink through an injection catheter. There was a small submucosal tumor, which had a yellowish surface with white specks, located in the upper jejunum (Figure 1), which was considered to be a lymphangioma because of its typical image. But it was not considered to be the source of GI bleeding because there was no ulceration or erosion on its surface. After finishing the procedure, the patient began to experience abdominal pain. An abdominal examination revealed moderate epigastric tenderness and silent bowel sounds. His laboratory findings were as follows: white blood cells, 13 100/μL (normal 3 500-9 000 /μL); C-reactive protein, 2.37 mg/dL (normal < 0.10 mg/dL); serum amylase, 702 U/L (normal 50-159 U/L). Abdominal CT revealed an inflammation of the pancreas and the peripancreas (Figure 2). He was thus diagnosed to have acute pancreatitis. The patient was treated by total parenteral nutrition with intravenous rich fluids and gabexate. These treatments resulted in both clinical and laboratory amelioration and he started oral intake on day 16. Since then, his condition was good and he underwent peranal DBE on day 26. No lesions were observed on the anal side of the small intestine although the mark with a tattoo was not detected. It probably disappeared since it has been 26 d from the day of peroral DBE. Hence, his GI bleeding source remained unknown. He was discharged on day 30. His hospitalization was extended for more than 10 d because of pancreatitis after peroral DBE. The grade of his pancreatitis was diagnosed as severe according to the criteria of Cotton *et al*[6].

He had no history of alcohol ingestion, gallstone disease or pancreatitis. Magnetic resonance cholangiopancreatography on day 18 demonstrated no structural alterations and no stones in the pancreatobiliary ductal system. As his abdominal pain started after the procedure, his acute pancreatitis was thus thought to have been related to the peroral DBE.

DISCUSSION

Newly developed methods of enteroscopy, capsule endoscopy and DBE, are quite useful for the detection of the origin of GI bleeding in the small intestine. Capsule endoscopy causes minimum discomfort to patients because the patients are free after loading a recorder and taking a capsule orally. But in Japan, experience with capsule endoscopy is limited as it has not yet been approved for the clinical use at the present time and thus it can be used in only limited facilities as clinical studies. DBE is currently available in Japan. We therefore performed DBE in this case but we could not find a lesion which caused GI bleeding. We might have a greater chance to find a responsible lesion if we could perform DBE when the patient had a active bleeding. We chose EN-450T5 as we considered the possibility of the treatment of a lesion with hemorrhage by argon plasma coagulation and hemostatic clipping. The patient unexpectedly developed acute pancreatitis after the DBE procedure.

Regarding the safety of DBE, May *et al*[4] reported that the only complications observed were related to sedation in 248 enteroscpies (including 153 peroral enteroscopies). Yamamoto *et al*[5] demonstrated that two complications, mainly associated with the original diseases, occurred among 178 procedures (including 89 peroral enteroscopies). One was multiple perforations occurred in a patient with intestinal lymphoma who received chemotherapy and the other was in a patient who was discovered to have Crohn's disease and had postoperative fever and abdomi-

nal pain. In the above two studies, EN-450P5/20 was used and no instances of acute pancreatitis were reported. Up to now, we have performed peroral DBE using EN-450P5/20 on 13 cases (one case reached to the ascending colon), and no previous cases demonstrated pancreatitis. This was the first case in which we performed peroral DBE using EN-450T5. The thicker diameter of EN-450T5 might therefore be associated with the development of pancreatitis.

A few cases developing pancreatitis have been reported as a complication of upper or lower GI endoscopy without ampullary cannulation[7-9] although GI endoscopy is not known to be associated with an increased risk for pancreatitis. The underlying mechanism of pancreatitis in these cases is unclear. In case of upper GI endoscopy, it was possible that trauma to the papilla during duodenal intubation might have led to edema of the papilla and subsequent pancreatitis. In case of colonoscopy, it was possible that over insufflation of the colon might have caused pressure of the pancreas or compression of the colonoscope against the spine might have caused a direct trauma to the pancreas. The mechanisms of developing pancreatitis associated with peroral DBE were thought to be as follows: the one may be a pancreatic duct obstruction due to the direct oppression of the papilla by an overtube and the other may be an increase in the intralumenal pressure of the duodenum by a thick overtube and shortening technique.

Here we reported a case of acute pancreatitis that was thought to be associated with DBE. This case indicates that, when peroral DBE is performed, especially with EN-450T5, we have to keep in mind the possibility of developing pancreatitis. And if a patient complained a strong abdominal pain during and after the procedure, we have to rule out acute pancreatitis by examining serum amylase level and abdominal CT as soon as possible.

Abstract

A 42-year-old woman was admitted to our hospital because of multiple liver tumors detected by ultrasonography. Colonoscopy revealed submucosal tumor in the rectum, which was considered the primary lesion. Endoscopic mucosal resection followed by histopathological examination revealed that the tumor was carcinoid. The resected margin of the tumor was positive for malignant cells. Two courses to transcatheter arterial chemotherapy for liver metastasis were ineffective. Accordingly, the rectal tumor and metastatic lymph nodes were surgically resected. One month after the operation, she received liver transplantation (left lateral segment and caudate lobe) from her son. No recurrent lesion has been observed at two years after the liver transplantation. Liver transplantation should be considered as a treatment option even in advanced case of carcinoid metastasis to the liver. We also discuss the literature on liver transplantation for metastatic carcinoid tumor.

INTRODUCTION

Carcinoid tumors are slow-growing neuroendocrine tumors, and often metastasize to the liver. There is no established treatment for liver metastases and the prognosis is poor[1, 2]. Liver transplantation for metastatic neuroendocrine tumor has already been reported worldwide[3-16], but the procedure is rarely performed in Japan[17]. We report here a case of living-related liver transplantation for liver metastases of rectal carcinoid tumor.

CASE REPORT

A 42-year-old woman was admitted to our hospital because of multiple liver tumors detected by ultrasonography. The medical history included bronchial asthma. There was no history of blood transfusion. Physical examination revealed a hard and swollen liver in the upper abdomen. Laboratory tests showed erythrocyte count of $367 \times 10^4/mm^3$ (normal: $400\text{-}500 \times 10^4/mm^3$), hemoglobin 10.5 g/dL (11.8-15.1 g/dL), leukocyte count $8200/mm^3$ ($4000\text{-}9600/mm^3$), platelet count $25.9 \times 10^4/mm^3$ ($16.0\text{-}35.0 \times 10^4/mm^3$), serum albumin 4.2 g/dL (3.9-5.0 g/dL), total bilirubin (T-Bil) 1.0 mg/dL (0.3-1.2 mg/dL), aspartate aminotransferase (AST) 30 IU/L(13-33 IU/L), alanine aminotransferase (ALT) 39 IU/L (6-27 IU/L), alkaline phosphatase (ALP) 311 IU/L (115-359 IU/L), γ-glutamyl transpeptidase (γ -GTP) 137 IU/L (10-47 IU/L), blood urea nitrogen (BUN) 20.0 mg/dL (8.0-20.0 mg/dL), and creatine (Cr) 0.9 mg/dL (0.6-1.0 mg/dL). Hepatitis B surface and hepatitis C virus antibody were negative. Serotonin and 5-HIAA in serum were within the normal range. Carcinoembryonic antigen, CA19-9, alfa-fetoprotein and protein induced by vitamin K antagonist (PIVKA)-II were normal but neuron-specific enolase (NSE) was elevated 46.1 ng/mL (0-10.0 ng/mL).

Abdominal ultrasonography (US) revealed multiple hyperechoic masses in both lobes of the liver (Figure 1A). Abdominal computed tomography (CT) also revealed multiple liver tumors enhanced mildly (Figure 1B). Abdominal angiography showed hepatomegaly and multiple liver tumors supplied by the hepatic artery. Colonoscopy showed

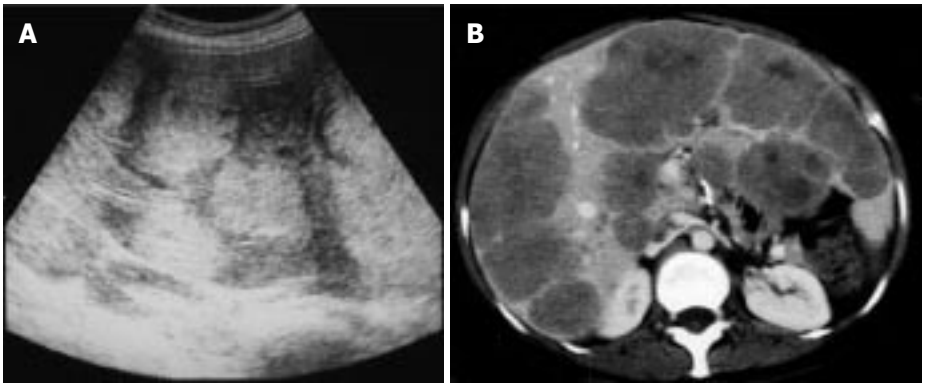

Figure 1 A: Ultrasonography showed multiple hyperechoic masses in the liver; **B**: Dynamic computed tomography showed multiple liver tumors. The surfaces of these tumors showed mild enhancement.

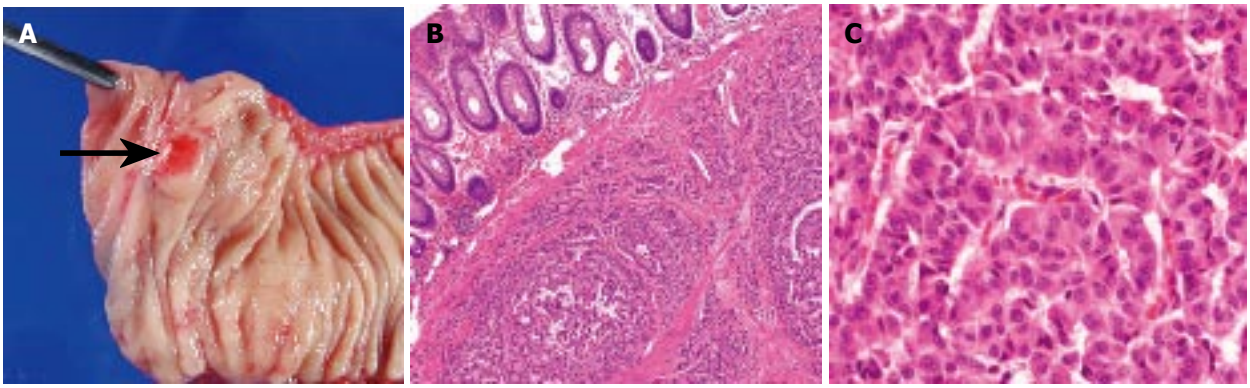

Figure 2 A: Macroscopic findings of the resected rectum. Arrow shows the primary lesion; **B**: The tumor cells showed tubular and alveolar formation, and their nuclei were slightly swelling (**C**). (**B**, **C**: H&E, original magnification, **B**: x 40, **C**: x 400).

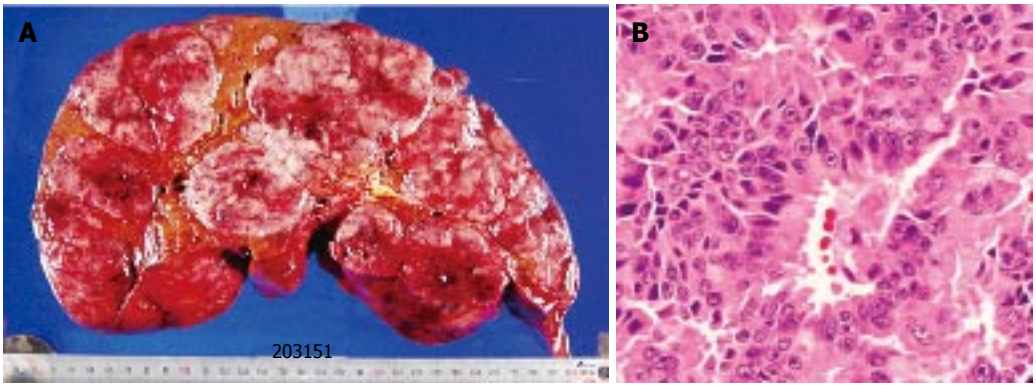

Figure 3 A: The cut surface of the resected specimen showed multiple tumors; **B**: Histopathological findings of the liver tumor were similar to those of the rectal tumor (H&E, original magnification, x 400).

submucosal tumor in the rectum. This tumor appeared as a low echoic mass by endoscopic ultrasonography (EUS). Then we performed endoscopic mucosal resection (EMR) for the submucosal tumor of the rectum, which was histopathologically diagnosed as carcinoid tumor. The resected margin of the tumor was positive for malignant cells. Transcatheter arterial chemotherapy for liver metastasis was applied twice (first: 5-fluorouracil [5-FU] + epirubicin [EPI] + mitomycin C [MMC], second: 5-FU + methotrexate [MTX]), but was ineffective because the liver tumors did not decrease in size and even grow 2 mo after the TACE. Accordingly, the rectal tumor and metastatic lymph nodes were resected surgically. Macroscopically, the rectal tumor was an elevated lesion with a central depression, measuring 58 mm in a diameter (Figure 2A). Histopathological examination showed atypical cells forming tubular and alveolar structures, with slightly swollen nuclei (Figures 2B and 2C). Lymph node metastases and blood vessel invasions were detected. Immunohistochemical examination revealed that most tumor cells were stained with chromogranin A, NSE and synaptophysin. The Ki-67 index was 6.1, but p53 protein was negative.

One month after the operation, there were no recurrence except for the liver. She received a liver transplantation (left lateral segment and caudate lobe) from her son. Standard liver volume (SLV) was 1014.4 g, graft volume (GV) was 450 g, GV/ SLV ratio was 44.4% and graft-to-recipient weight ratio (GR-WR) was 0.98. The volume of the resected liver was 4750 g, and multiple nodules of white and brown colors occupied the whole liver (Figure 3A). The histopathological findings of the liver tumor (Figure 3B) were similar to those of the primary lesion.

No invasion of the portal vein, hepatic vein, and bile duct was noted.

Her clinical course has been good and no recurrence has been demonstrated two years since the liver transplantation.

DISCUSSION

Neuroendocrine tumors have generally been classified by the site of origin. Furthermore, a new histopathological classification was reported by WHO[18]. The WHO classification has been considered by the size of the tumor, the depth of the tumor invasion, angiogenesis, lymphatic invasion, cellular atypia, necrosis, mitoses, Ki-67 index and p53 protein. Based on this classification, neuroendocrine tumors are divided into three types, well-differentiated endocrine tumor (carcinoid), well-differentiated endocrine carcinoma (malignant carcinoid), and poorly-differentiated endocrine carcinoma (small cell carcinoma)[18]. Although the standard therapy for liver metastasis of neuroendocrine origin is surgical resection[19], the prognosis of neuroendocrine tumor with liver metastasis is usually poor[1, 2]. When curative hepatic resection is difficult, transcatheter arterial chemo-embolization (TACE) and intra-arterial chemotherapy are performed and have been reported to be effective[20-23]. Our patient received two courses of intra-arterial chemotherapy but no satisfactory response was observed. Somatostatin analogue and interferon have been used for the treatment of carcinoid tumors[24-27]. These therapies are excellent for improvement of symptoms but the tumor response rate is usually low[24-27].

Liver transplantation has been widely performed in patients with end-stage liver disease and metastatic liver cancers from neuroendocrine tumors[3-6]. The 5-year survival rate of transplant recipients for neuroendocrine tumors metastases to the liver ranges from 0 to 83% (median, 50%) (Table 1). The main cause of death is recurrence of the carcinoid tumors. In Japan, the accumulative living related liver transplantations between 1996 and 2002 are more than 2000. Among these, transplantation was performed in only 6 cases of metastatic neuroendocrine tumors (0.2 %) and the 3-year survival rate is 66.7%[17]. Strictly speaking, the 5-year survival rate of liver transplantation for metastatic carcinoid tumor is 69% but is poor in noncarcinoid neuroendocrine tumors (4-year survival rate, 8%)[6]. Thus, histopathological discrimination is very important to predict the prognosis of neuroendocrine tumors. Our patient had a typical carcinoid tumor which is compatible with well-differentiated neuroendocrine carcinoma, with metastases in the liver and was considered to show good prognosis after transplantation. However, the case was advanced stage with lymph node metastasis, lymphatic and vascular invasion and extensive liver metastasis, and thus was considered a high recurrent risk requiring careful follow-up. Unexpectedly good prognosis of this case could be related to the radical resection of the tumor including primary and metastatic lesion and not classified in poor prognosis such as non-pancreatic primary lesion (rectum) and noncarcinoid apudoma[6]. The prognosis was markedly improved by transplantation and she remains well 2 years and 9 mo after surgery without local recurrence and metastasis. Although much longer follow-up period would provide more meaningful information to elucidate the prognosis of such unusual case, liver transplantation could be life-saving procedure for patients with metastatic neuroendocrine tumor resistant to alternative treatments.

Pelosi *et al*[28] reported that Ki-67 index is a significant predictor of prognosis and survival of patients with pancreatic neuroendocrine tumors. Furthermore, Moyana *et al*[29] reported that MIB-1 and p53 were associated with metastasis of the gastrointestinal carcinoid tumors. Rosenau *et al*[3] pathologically investigated patients who received a liver transplantation for metastatic neuroendocrine tumors. They reported that the survival rate of patients with high Ki-67 index (> 5%) or overexpression of the E-cadherin was low, and suggested that Ki-67 index and E-cadherin expression could be potentially useful prognostic markers after liver transplantation[3]. Our pa-

tient showed moderately positive Ki-67 index (6.1%, rate for carcinoid is around 2-3%) and should be followed as high recurrence risk case.

The Japanese medical insurance system covers liver transplantation for liver cirrhosis and hepatocellular carcinoma (HCC) based on Milan criteria[30]. However, the system does not cover metastatic liver cancer. Liver transplantation is a kind of special treatment for the end-stage liver disease and is also expensive. So, not all the patient in the end-stage liver disease has been covered by medical insurance in Japan. In our patient, distant and lymph node metastases were completely resected, and metastatic neuroendocrine tumors in the liver were removed through hepatectomy and liver transplantation even though the metastasis was far advanced within the liver though localized in the liver. We propose that metastatic neuroendocrine tumors of the liver should be classified as similar to HCC although cases beyond Milan criteria[30], like our case, could be also included in such classification because of its biological low malignant character.

In conclusion, we reported a female patient who underwent successful living liver transplantation for advanced liver metastases of rectal carcinoid tumor. She has been well for the last two postoperative years and remains alive without any recurrence in spite of positivity of poor prognostic parameters. Other parameters, such as oncogene, suppressor gene and cyclin shown in hepatocellular carcinoma[31], apart from those of histopathology and immunohistochemistry, are needed to help in clinical decision making with respect to the indications of transplantation.

Abstract

Autoimmune pancreatitis, a recently recognized type of chronic pancreatitis, is not rare in Japan, but reports of it elsewhere are relatively uncommon. We report the first preoperatively diagnosed case of autoimmune pancreatitis in Hungary, which responded well to steroid treatment and provided radiographic and functional evidence of this improvement. A 62-year-old female presented with a 4-month history of recurrent epigastric pain and a 5-kg weight loss. The oral glucose tolerance test (OGTT) indicated diabetes mellitus and the result of the fecal elastase test was abnormal. Ultrasonography (US) and the CT scan demonstrated a diffusely enlarged pancreas, and endoscopic retrograde cholangiopancreatography (ERCP) an irregular main pancreatic duct with long strictures in the head and tail. Autoimmune pancreatitis was diagnosed. The patient was started on 32 mg prednisolone daily. After 4 wk, the OGTT and faecal elastase test results had normalized. The repeated US and CT scan revealed a marked improvement of the diffuse pancreatic swelling, while on repeated ERCP, the main pancreatic duct narrowing was seen to be ameliorated. It is important to be aware of this disease and its diagnosis, because AIP can clinically resemble pancreatobiliary malignancies, or chronic or acute pancreatitis. However, in contrast with chronic pancreatitis, its symptoms and morphologic and laboratory alterations are completely reversed by oral steroid therapy.

INTRODUCTION

Autoimmune pancreatitis (AIP) is an increasingly recognized type of chronic pancreatitis that is clearly distinct from alcoholic chronic pancreatitis. It is characterized by its special morphology, immunologic features, pathology and steroid responsiveness[1-5]. Since Sarles *et al*[6] first described a case of pancreatitis with hypergammaglobulinaemia more than 40 years ago, several hundred cases have been reported, particularly in the Japanese literature[1-4,7-9]. Its prevalence in other populations is unclear.

We describe here the first preoperatively diagnosed case of AIP in Hungary and discuss the clinical features, diagnosis and treatment of this uncommon disease.

CASE REPORT

A 62-year-old teetotal woman with a 4-month history of recurrent epigastric pain and a 5-kg weight loss was referred to our hospital. There was no personal or family history of pancreatitis. On physical examination, an apple-sized, painless mass was palpated in the epigastrium. With the exception of elevated fasting glucose level, the results of detailed laboratory examinations, including Ca 19-9 antigen, were normal. The oral glucose tolerance test (OGTT) revealed diabetes mellitus. The fecal elastase test result was abnormal (120 μg/g faeces). The antinuclear antibody and rheumatoid factor tests were positive. Abdominal ultrasonography (US) revealed a diffusely enlarged pancreas, and the abdominal CT scan an enlarged, sausage-shaped pancreas (Figures 1A and 1B). On endoscopic retrograde cholangiopancreatography (ERCP), an irregular main pancreatic duct with long strictures in the head and tail was observed (Figure 2A). AIP was diagnosed. The patient was started on 32 mg prednisolone daily and enzyme replacement therapy. After 4 weeks she had become totally asymptomatic. The fasting glucose level, the results of OGTT and the fecal elastase test had normalized, and the repeated US and CT scan demonstrated a marked improvement of the diffuse pancreatic swelling (Figures 1C and 1D). On repeated ERCP, the main pancreatic duct narrowing was seen to be ameliorated (Figure 2B). We ad-

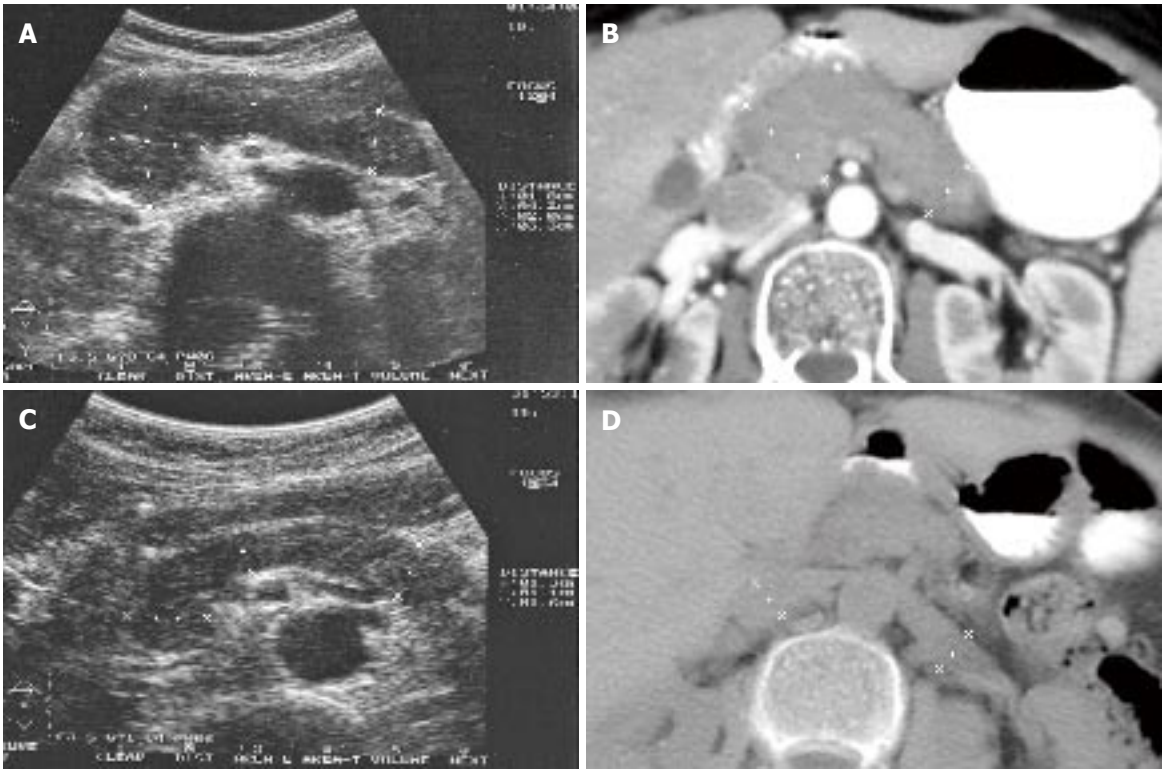

Figure 1 Abdominal ultrasonography (**A**) and CT (**B**) revealed a diffusely enlarged pancreas with sharp margins similar to sausage appearance. Four weeks after the steroid therapy the size of the pancreas became normal (**C** and **D**).

vised tapering and cessation of the steroid.

DISCUSSION

To date, several hundred cases of AIP have been reported, particularly in the Japanese literature[1-5,7-9]. This has led to the proposal of AIP as a distinct clinical entity, and AIP is currently categorized as an established etiology of chronic pancreatitis[10]. The disease has appeared outside Japan only very rarely; few cases have been published in Europe[11-16], most of which were diagnosed postoperatively. It is unlikely that AIP is a disease endemic to Japan. It appears likely that physicians in other countries may overlook this entity due to the lack of their familiarity with it, and regard such patients as cases of ordinary or idiopathic chronic pancreatitis, or pancreatobiliary malignancy.

The diagnosis of AIP is challenging as its symptoms are few and non-specific. Its clinical characteristics are jaundice, abdominal pain, weight loss and diabetes mellitus. Most of the patients are older than 50 years. In consequence of the symptoms and the age of these patients, they are often initially thought to have pancreatic carcinoma, and many of them actually undergo laparotomy[5,17]. AIP may be associated with a number of other autoimmune diseases, such as Sjögren's syndrome, primary sclerosing cholangitis, inflammatory bowel disease, systemic lupus erythematosus or retroperitoneal fibrosis. Laboratory findings suggestive of AIP include hypergammaglobulinaemia, increased levels of total IgG or IgG4, and the presence of autoantibodies such as antinuclear antibody, anti-lactoferrin antibody and anti-CA-II antibody[1-5]. Characteristic radiological features are an enlarged, sausage-shaped pancreas on abdominal US and CT, and narrowing of the main pancreatic duct on ERCP[18]. A common microscopic picture in AIP is periductal lymphoplasmacytic infiltration with pronounced acinar atrophy, marked fibrosis and obliterated phlebitis[19].

The diagnosis of AIP should be based on a combination of the clinical and laboratory findings, pancreatic imaging, and the exclusion of other conditions[4].

The principal treatment is corticosteroid at a recommended starting dose of 30 to 40 mg of prednisolone/day until the symptoms improve; this is followed by a taper of 5 to 10 mg. Steroid treatment usually leads to a rapid improvement in the clinical symptoms and the laboratory and morphological findings. Steroid therapy has also been reported to be beneficial as concerns the pancreatic fibrosis, exocrine and endocrine functions and associated diabetes mellitus[7-9,20]. It has been proposed that the response to steroid therapy should be included in the diagnostic criteria[21]. Steroid therapy may be tried empirically, when AIP is suspected on the basis of the typical pancreatic imaging results alone, if laboratory data and histologic findings are not available or do not fully meet the diagnostic criteria[5, 7] The response to steroid therapy can facilitate confirmation of the diagnosis of AIP.

In our patient, the diagnosis of AIP was indicated by the morphological alterations of the pancreas in US and CT, the narrowing of the main pancreatic duct on ERCP, and the autoimmune abnormalities. Histological findings were not available. The clinical symptoms and the abnormalities observed on US, CT and ERCP responded rapidly to steroid therapy, confirming the diagnosis of AIP.

It is very important to be aware of this disease, because

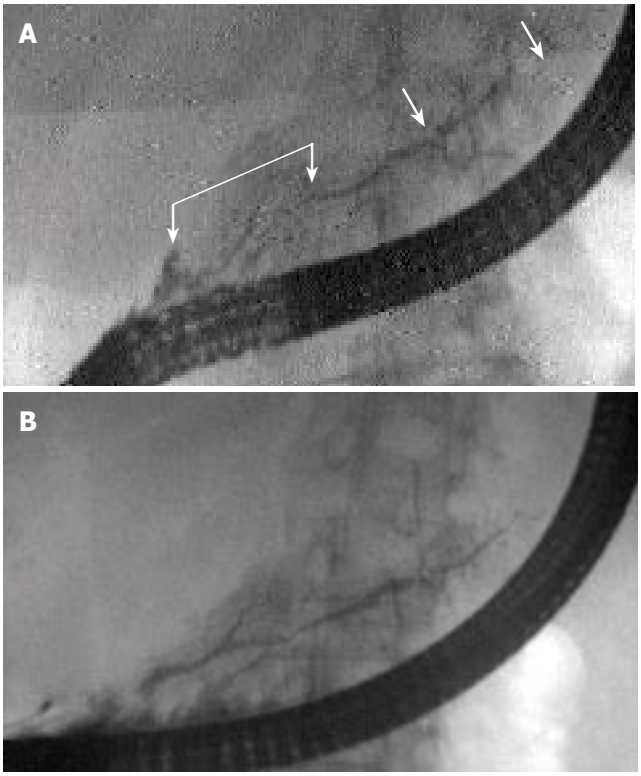

Figure 2 ERCP demonstrated multiple strictures of the Wirsung duct without posttenotic dilation (**A**). Four weeks after the steroid therapy the main pancreatic duct narrowing was seen to be ameliorated (**B**).

AIP may be mistaken for ordinary chronic pancreatitis or pancreatic cancer, leading to pancreatic resection instead of treatment with steroid. As awareness of this disease grows, the reported prevalence of AIP outside Japan may be expected to increase and the possibility of unnecessary surgery may be reduced.

Abstract

We described two members in a family with gastrointestinal stromal tumors (GISTs) without cutaneous hyperpigmentation. The patients were father and son who did not have cutaneous hyperpigmentation. Histological examination showed that these tumors were GISTs expressing CD34 and CD117. Tumor DNA extracted from paraffin-embedded specimens revealed somatic mutation with a deletion mutation at different codons in exon 11 of c-kit gene after direct sequencing analysis. No germline mutation was detected in DNA extracted from peripheral leukocytes obtained from the father and son. We propose that GISTs could be caused by sporadic somatic mutation in a family without germline mutation and hyperpigmentation.

Key words: Sporadic GIST; Somatic c-kit mutation

INTRODUCTION

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of the human gastrointestinal (GI) tract, representing 0.1 to 3 % of all GI tract tumors[1]. It has been suggested that a mutation in the juxtamembrane (JM) domain of c-kit contributes to the development of GIST[2]. Furthermore, germline deletion or point mutation of the c-kit JM domain has been shown in a family with GIST and cutaneous hyperpigmentation[3,4]. GIST-cutaneous hyperpigmentation disease has been used to describe familial multiple GISTs with associated cutaneous hyperpigmentation[4]. Familial GIST is a rare autosomal dominant genetic disorder associated with kit germline mutations. We now report that GISTs could be caused by sporadic somatic mutation in a family without germline mutation and cutaneous hyperpigmentation.

CASE REPORT

Patient 1

A 79-year-old man was referred to our hospital because of a gastric tumor (Figure 1). He complained of epigastria pain and fullness. There was no cutaneous hyperpigmentation. Gastroduodenal endoscopic examination and endoscopic ultrasonography (EUS) showed a gastric submucosal tumor (SMT) about 1.7 cm in size with small ulcer located at anterior wall, greater curvature side of high body. Proton pump inhibitor therapy was administered for 10 months. The SMT enlarged to 5cm in size demonstrated by upper gastrointestinal (GI) series, endoscopic ultrasonography (EUS), and abdominal computed tomography (CT) (Figure 2A). Wedge resection of the gastric SMT at the anterior wall, greater curvature side of high body with spleen preservation was performed with clear resected margin. Histological and immunohistochemical examination revealed low risk gastrointestinal stromal tumor (GIST) with strong positivity of c-kit and CD34 (Figure 2B). The patient lived free of disease for 9 months after surgery.

Patient 2

A 54-year-old man, the son of the patient 1, was referred to our hospital because of a gastric tumor (Figure 1). He complained of epigastria pain, abdominal fullness, body weight loss 7 to 8 kilograms for one month. There was no cutaneous hyperpigmentation. Gastroduodenal endoscopic examination and EUS showed a huge gastric SMT about 10 cm in size located at greater curvature side from high body to antrum with a deep ulcer and easily touch bleeding. Subsequent upper GI series and abdominal CT revealed a gastric SMT about 13×10 cm in size occupying the whole stomach (Figure 2C). Exploratory laparotomy revealed advanced gastric GIST with major vessel involvement. Biopsy of the gastric SMT and feeding jejunostomy

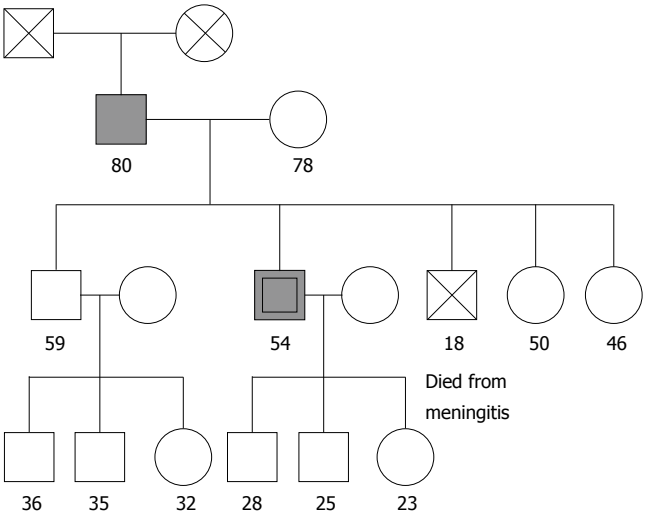

Figure 1 Pedigree of the family with GISTs without cutaneous hyperpigmentation. Hatched symbols indicate family members with GISTs. Double circles denote multiple GISTs. Squares indicate males and circles indicate females.

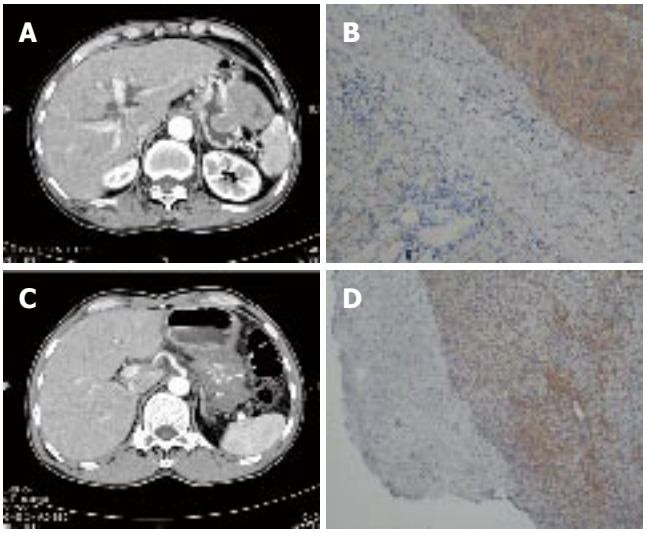

Figure 2 A: Abdominal CT revealed gastric GIST at the anterior wall and greater curvature side of high body of the stomach; **B**: Microscopic findings of the tumor resected. Tumor cells were composed of resicular spindle cells with mild nuclear pleomorphism but no necrosis, expressing strong positive c-kit staining immunohistochemically. (IHC staining, 200X); **C**: Abdominal CT revealed a gastric GIST measuring 13 cm x 10 cm in size occupying the whole stomach. **D**: Microscopic findings of the tumor resected. Tumor comprised proliferation of spindle cells with mild nuclear atypia in the mxyoid stroma but no necrosis, expressing positive c-kit staining. (IHC staining, 200X).

was performed. Histological and immunohistochemical examination revealed advanced high-risk GIST with strong positivity of c-kit and CD34 (Figure 2D). The patient received 400 mg Glivec for 7 months and partial response was illustrated by subsequent abdominal CT. The patient lived with disease for 7 months after surgery.

Genetic examination

To determine whether these GISTs showed a genetic defect, DNA was extracted from paraffin-embedded specimen of tumor tissues. Polymerase chain reaction amplification of genomic DNA for kit and PDGFRA was performed and amplification was analyzed for mutations as previously described[5]. Direct sequencing analysis of DNA from patient 1 showed deletion mutation at codon 560 in exon 11, causing a deletion mutant 560 del V (Figure 3B). While direct sequencing analysis of DNA from patient 2 revealed deletion at codons 557-559 in exon 11, resulting in replacement of WKV by C (Figure 3C). To determine if the mutation is familial, DNA was extracted from peripheral leukocytes obtained from patients 1 and 2. No mutation was detected in exon 11 of c-kit gene (Figure 3A).

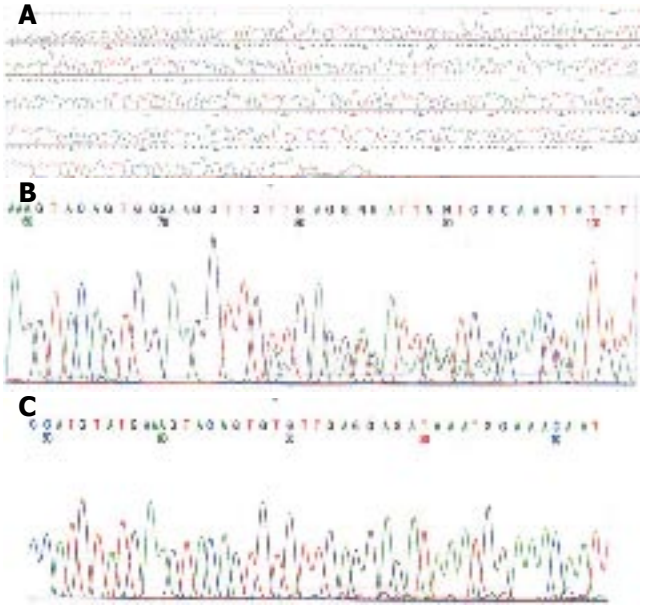

Figure 3 A. Direct sequencing analysis of DNA from peripheral leukocyte obtained from patients 1 and 2 revealed no mutation in exon 11 of c-kit gene; **B**. Direct sequencing analysis of DNA from patient 1 showed deletion mutation at codon 560 in exon 11, causing a deletion mutant 560 del V; **C**. Direct sequencing analysis of DNA from patient 2 revealed deletion at codons 557-559 in exon 11, resulting in replacement of WKV by C.

DISCUSSION

By histological, immunohistochemical examination, and molecular genetic analysis, this study has uncovered sporadic c-kit somatic mutation in a family with GIST without cutaneous hyperpigmentation.

GISTs appear to be related the interstitial cells of Cajal of the mesenteric plexus[7]. These cells are considered as GI pacemaker cells, from the interface between the automatic innervation of the bowel wall and its smooth muscle[8, 9]. GISTs express the cell-surface transmembrane receptor c-kit with a tyrosin kinase activity and kit oncoprotein. There are frequent gain-of-function mutations of c-kit in GISTs. These mutations result in constitutive activation of kit signaling, which leads to uncontrolled cell proliferation and resistance to apoptosis. It has been recently reported that kit activation occurs in all cases of GISTs, regardless of the mutation status of kit. Most GISTs express constitutively activated mutant isoforms of kit kinase or platelet-derived growth factor receptor alpha (PDGFRA), which are potential therapeutic targets for Imatinib mesylate (Glivec).

Gain of function mutations in the JM domain of c-kit contribute to the development of GIST[2]. Because normal kit gene is responsible to normal pigmentation, relationships between GISTs and cutaneous hyperpigmentation have been reported before. GIST-cutaneous hyperpigmentation disease has been used to describe familial multiple GISTs associated with cutaneous hyperpigmentation[3]. Furthermore, germline deletion mutation of the c-kit JM domain has been shown in tumors and normal somatic cells from a family with multiple GISTs who exhibited perineal hyperpigmentation[3]. A single-point germline mutation of c-kit has also been proposed to cause a familial GIST associated with systemic cutaneous hyperpigmentation[4]. A germline PDGRF missense mutation could be a second familial predisposing gene[5].

We described a rare case report regarding two members in a family with GISTs without cutaneous hyperpigmentation. No mutation was detected in DNA extracted from peripheral leukocytes obtained from the father and son. DNA extracted from paraffin-embedded specimens revealed different somatic mutation with a deletion mutation in the exon 11 of c-kit gene after direct sequencing analysis (deletion mutation at codon 560 versus deletion at codons 557-559 in exon 11). So mutation in the tumor is sporadic somatic but not germline. However, the cause of sporadic c-kit mutation in one family is unknown.

In summary, we propose that GISTs could be caused by sporadic somatic mutation in a family without germline mutation and hyperpigmentation.

World J Gastroenterol 2006 March 21; 12(11):1818-1819
World Journal of Gastroenterology ISSN 1007-9327

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

Abstract

Myotonic dystrophy (MD) is characterized by myotonic phenomena and progressive muscular weakness. Involvement of the gastrointestinal tract is frequent and may occur at any level. The clinical manifestations have previously been attributed to motility disorders caused by smooth muscle damage, but histologic evidence of alterations has been scarce and conflicting. A neural factor has also been hypothesized. In the upper digestive tract, dysphagia, heartburn, regurgitation and dyspepsia are the most common complaints, while in the lower tract, abdominal pain, bloating and changes in bowel habits are often reported. Digestive symptoms may be the first sign of dystrophic disease and may precede the musculo-skeletal features. The impairment of gastrointestinal function may be sometimes so gradual that the patients adapt to it with little awareness of symptoms. In such cases routine endoscopic and ultrasonographic evaluations are not sufficient and targeted techniques (electrogastrography, manometry, electromyography, functional ultrasonography, scintigraphy, *etc*.) are needed. There is a low correlation between the degree of skeletal muscle involvement and the presence and severity of gastrointestinal disturbances whereas a positive correlation with the duration of the skeletal muscle disease has been reported.

The drugs recommended for treating the gastrointestinal complaints such as prokinetic, anti-dyspeptic drugs and laxatives, are mainly aimed at correcting the motility disorders.

Gastrointestinal involvement in MD remains a complex and intriguing condition since many important problems are still unsolved. Further studies concentrating on genetic aspects, early diagnostic techniques and the development of new therapeutic strategies are needed to improve our management of the gastrointestinal manifestations of MD.

INTRODUCTION

Myotonic dystrophy (MD) is an autosomal dominant genetic disorder[1]. It is caused by an unstable trinucleotide repeat expansion containing cytosine-thymidine-guanosine $(CTG)^n$, located in the 3' untranslated region of chromosome 19q13.3. The CTG trinucleotide is repeated in the normal population from 5 to 36 times[2,3], but has been found to be expanded up to 2 000 times in MD patients[4,5]. This amplification is correlated to the severity of the disease. Patients can be divided into four groups based on the number of CTG repeats. Group E1 (50-100 CTG repeats) may have either the minor or the classical form of MD, group E2 (500-1 000 CTG repeats) have the classical form of MD, group E3 (1 000-1500 CTG repeats) have the classical form of MD with onset during childhood, and group E4 (more than 1 500 CTG repeats) are affected with the congenital form of MD[6].

Although MD is primarily characterised by myotonic phenomena and progressive muscular weakness, multi-system involvement is often present, taking the form of cardiac conduction abnormalities, cognitive deficits, cataracts and diabetes, as well as endocrine, sexual and reproductive disturbances[1]. Involvement of the gastrointestinal (GI) tract is frequent, and may occur at any level from the pharynx to the anal sphincter. Dysphagia, heartburn, emesis, regurgitation, coughing while eating and dyspepsia are the most common complaints involving the upper digestive tract, while abdominal pain and bloating, changes in bowel habits (diarrhoea or constipation) and dyschezia are common signs of impairment of the lower digestive tract[7-9]. These clinical manifestations have generally been attributed to motility disorders caused by striated and more rarely, smooth muscle damage[10],

although recent studies suggest that neurological alterations may also play a role[11,12].

There appears to be little correlation between the degree of skeletal muscle involvement and the presence and severity of the gastrointestinal disturbance, but some authors have reported a positive correlation with the duration of the skeletal muscle disease[13, 14]. In some patients the impairment of gastrointestinal function is so gradual that they adapt to it with little or no awareness of any disturbance and only a thorough anamnesis may elicit the recall of possible symptoms[12]. In such patients, routine endoscopic and ultrasonographic evaluations are of little value and only highly sensitive, targeted techniques such as electrogastrography, manometry, electromyography, functional ultrasonography, compartmental scintigraphy, *etc.* may help to reveal the true extent of the involvement.

In this review, the available data on the pathophysiologic mechanisms of GI involvement in myotonic dystrophy, their impact on clinical manifestations of the disease, and the tests that can be used to detect them, are discussed in turn for each segment of the gastrointestinal tract.

PHARYNX AND ESOPHAGUS

Because most complaints by MD patients focus on the pharynx and esophagus, which can be quite easily investigated, these are the manifestations that have been most thoroughly studied thus far. MD patients often report dysphagia, sometimes associated with coughing while eating, chest pain, regurgitation and heartburn. Different studies have reported a prevalence of dysphagia ranging from 25% to 80%[9, 12, 15, 16].This is usually considered by both patients and doctors to be the most serious symptom of MD, probably because it is associated with a high incidence of recurrent pulmonary infection[17].

Manometry is useful to detect motility disturbances, which show in the form of asymmetric contractions of the pharynx and weak contractions of the upper esophageal sphincter (UES)[14]. Studies have reported a reduced basal UES pressure in MD patients compared to controls[11] , although the prevalence and duration of UES relaxation during swallowing are similar between the two groups and more significantly, no difference in the residual pressure during relaxation has been found[11, 12,1 8] .

In the esophageal body significant decreases in the peristaltic amplitude and/or simultaneous waves have often been reported[12, 18]. A study of 14 MD patients showed a marked decrease in the median amplitude of the contractions at every level of the esophagus. A higher percentage of non-transmitted and dropped contraction sequences after swallowing has been observed in patients compared to controls, 43% exhibited complete atony of the esophageal body with a scleroderma-like pattern and no detectable esophageal contractions. In this series, although manometry showed impaired esophageal motor function in 71% of the patients, 50% of these were quite asymptomatic[18].

Involvement of the lower esophageal sphincter (LES) is a somewhat more complex matter. Modolell *et al.*[12] failed to detect a significant difference in basal LES pressure between patients and controls, only reporting some cases of incomplete LES relaxation[12]. In contrast, other studies have found a significantly reduced resting tone, competence, and area vector volume of the LES in MD patients than in controls[9, 18]. These data suggest that some alteration in the smooth muscle may take place, leading to a higher risk of developing gastroesophageal reflux disease (GERD)[18].

Esophageal spasm and segmental dilatation can be seen on x-rays, while radiological and scintigraphic techniques are useful for detecting both a lack of tone and a reduced, ineffective or absent peristalsis[12, 15, 19].

Most authors hold that pharyngo-esophageal myotonia, or problems with post-contraction relaxation, should no longer be considered as a typical feature of esophageal involvement[12, 18]. A myotonic response to pharyngeal contractions has been reported by Siegel *et al*[20], but we now know that this is due to limitations in x-ray technology at the time when the study was conducted.

It has been hypothesized that distal esophageal impairment may be myogenic in origin and abnormalities in both the striated and smooth muscle fibers may play a role in MD. However, the histologic data published to date have failed to demonstrate any alteration in the esophageal smooth muscle fibers[19]. Marked atrophy of the esophageal striated muscle, but only small changes in the smooth muscle were observed in a patient reported by Jéquier *et al*[21]. In another case, using electron microscopy to study the esophagus, Ludatscher *et al*[22] detected mild degenerative changes with disoriented filaments of the smooth muscle.

Smooth muscle damage could also explain the reduced LES tonic resting pressure and the elevated frequency of heartburn observed in MD patients. Unfortunately, most of the reported cases did not include an upper digestive tract endoscopic examination or a 24-h pH-metry to determine the presence and degree of GERD[18] .

Recently some authors have suggested that a combined myopathic - neuropathic etiology could provide a more satisfactory explanation for the pharyngo-esophageal symptoms of MD, but at present this remains speculative [12]. One proposed hypothesis is that decrease in the normal amplitude of the peristaltic waves could reflect the inability of the muscle to contract under normal neural control. On the other hand, uncoordinated motor activity in the presence of a normal amplitude contraction could indicate a lack or defect in neural control[12]. This hypothesis is not supported by the study of Eckardt *et al*[19], who failed to detect any neuropathic alterations in MD patients.

However, there are data to suggest that there is no association between the degree of muscular disability and motor abnormalities of the pharynx and esophagus, the presence and severity of dysphagia, or other esophageal symptoms[12]. For example, manometric findings are not significantly different between symptomatic and asymptomatic patients or in patients with different degrees of striated muscular involvement[9, 12, 18, 19]. In particular, in a study of 18 MD patients Modolell *et al*[12] showed that while severe pharyngo-esophageal abnormalities are present in all patients, symptoms are spontaneously reported by only 30% of them. This figure rose but only to 55%, when the patients were specifically questioned on

this point.

These conflicting reports may be explained by the fact that the tongue and pharyngeal muscles can contract sufficiently to push a bolus through the UES into the esophagus, after which the force of gravity is enough to complete the swallowing process. Moreover, because of the slow evolution of the disease, MD patients may develop compensatory mechanisms and thus gradually adapt to the impairment of their esophageal function[18].

STOMACH AND DUODENUM

MD patients frequently complain of dyspeptic symptoms such as early satiety, nausea, vomiting, and epigastric pain[9]. Radiographic, manometric, ultrasonographic and scintigraphic evidence of decreased peristaltic activity causing the delayed emptying of liquids and solids, visceral dilatation, gastric bezoars and even gastroparesis have been reported[10, 13, 23-25].

Kuiper *et al*[23] have described the case of an MD patient who developed symptoms suggestive of gastric retention. Radiological and endoscopic examination revealed polypoid masses, cytologic washing showed them to be food concretions, probably a consequence of abnormal gastric motility[23]. More recently, scintigraphic studies by Ronnblom *et al*[25] indicate a delayed emptying of the stomach in MD patients with dyspeptic symptoms, demonstrated by a prolonged lag phase, a slower emptying rate, and a prolonged T/2.

Bellini *et al*[13] used ultrasound to evaluate gastric emptying abnormalities and their relationship with the severity and duration of the disease in 11 MD patients without dyspeptic symptoms. They found that MD patients and healthy subjects exhibit comparable fasting and maximal antral areas. The findings that (i) the basal and maximal post-prandial values for the gastric antral area between MD patients and controls were quite similar, and (ii) the time required to reach the maximal post-prandial values did not differ in the two groups, are in agreement with the fact that the patients studied were not dyspeptic[13]. Analogous results have been reported for a group of non-dyspeptic patients affected by systemic sclerosis[26].

Indeed, increased antral dimensions have been reported in patients with functional dyspepsia[27,28], suggesting that such abnormalities may play a role in the pathogenesis of the dyspeptic symptoms in MD. In Bellini's study**[13]**, the final emptying time of the MD patients was longer than that of healthy volunteers and was clearly correlated with the disease duration, but was independent of both the CTG expansion size and the patients' disability class.

It is not surprising that patients without dyspeptic symptoms may have delayed gastric emptying. Indeed the association between delayed gastric emptying and upper GI complaints is still under debate[29]. Other abnormalities in gastric motor function, such as impaired accommodation of the proximal stomach[30, 31], abnormal distribution of the gastric contents[31], gastric dysrythmias[32, 33], and a lack of antro-pyloro-duodenal coordination[34], could play a role in the pathogenesis of dyspeptic symptoms in these patients.

Bellini *et al*[13] have confirmed that a direct relationship between disease severity and the impairment of GI motor functioning remains to be demonstrated, since there is no significant difference in gastric emptying between patients with different degrees of skeletal muscle involvement. These results appear to agree with previous studies, demonstrating that skeletal muscular damage and gastric motor disturbances can progress independently[14]. On the other hand, the direct correlation between final emptying time and disease duration suggests that the impairment of gastric emptying may evolve over time.

The delayed gastric emptying in MD could be explained by the muscular disease itself. Unfortunately no definitive conclusions can be drawn on this point because the histological evidence remains limited. Gastric smooth muscle is only rarely affected[7, 8] and as we have already seen in the esophagus, when damage occurs it appears to be similar although earlier and more severe in nature to that occurring in skeletal muscle with severe fatty infiltration[35] . However, a sufficiently large study focusing on the gastric smooth muscle in MD patients is still lacking. It would be important to determine whether the two types of muscle tissue may be damaged to different degrees in the same subjects.

Recent reports suggest that, as in the pharynx and esophagus, muscle involvement alone is not sufficient to explain the altered digestive function in the stomach and duodenum of MD patients. Impaired nervous conduction as well as altered GI hormone secretions could be involved in the motor abnormalities[25]. For example, changes in the electrical impulses controlling duodenal activity could explain the chronic intestinal pseudo-obstruction occasionally reported in MD. Likewise a reduction in the electrical control of gastric activity could be a possible cause of delayed gastric emptying[25].

An electrogastrographic study carried out by Ronnblom *et al*[36] on 10 patients showed that gastric electric cycling activity manifested as bradygastria, tachygastria and a less stable frequency of the gastric signal are reduced compared with control subjects. The presence of an abnormal EGG in MD patients supports the hypothesis that the disease is a systemic disorder, affecting not only the muscles but also other tissues. Ronnblom *et al*[36] then studied the gut hormone profile in the same group of patients and found that the post-prandial secretion of motilin and glucagone-like peptide-1 (GLP-1) is decreased in MD patients. Since motilin triggers the antral phase III activity of the migrating motor complex and accelerates gastric emptying, reduced motilin secretion could cause delayed gastric emptying. In contrast, low post-prandial GLP-1 secretion is probably a result of delayed gastric emptying, i.e. a consequence rather than a cause of the disease. The patients with the most markedly delayed gastric emptying showed abnormal gastric electric activity and an abnormal post-prandial gut hormone profile. Both factors may contribute to altering gastric functioning**.** These findings indicate a partial dysregulation of the GI endocrine system in MD patients rather than a disorder of the entire digestive endocrine system. This conclusion is supported by an immunohistochemistry study carried out earlier by the same authors on the different types of duodenal endocrine cells in MD patients affected with diarrhoea[37].

They reported that the duodenal endocrine cell area containing the cells that produce serotonin, gastrin/CCK, secretin, GIP and somatostatin, is significantly increased. There are various possible explanations for this finding. The increased cell area may be a primary phenomenon or a consequence (via a feed-back mechanism) of the synthesis of defective and biologically inactive peptides or the result of a reduced receptor sensitivity of the effector cells and a malfunctioning effector organ.

If the increase in the number of endocrine cells is a primary disorder, it could play a role in the gastrointestinal manifestations of MD. However, even if it is merely a secondary phenomenon, a possible link can still be hypothesized, because the intestinal peptides may act on many different organs. Further studies are needed to shed light on this intriguing issue. At present, no correlation has been found between the increase in the duodenal cell area and the severity of the disease[37].

Different drugs, particularly prokinetics, have been proposed to treat the dyspeptic symptoms and motor disturbances in MD patients. In their study of 16 patients with delayed gastric emptying of solids and liquids, Horowitz *et al*[14] showed that oral administration of 10 mg of metoclopramide 3 times per day can improve the gastric emptying of both a solid and a liquid meal, but has no effect on esophageal emptying. In another study the same authors tested the efficacy of cisapride (10 mg, 4 times per day) and reported that it improves both gastric emptying and digestive symptoms such as nausea, vomiting, early satiety, abdominal distension and pain[38]. Metoclopramide also seems to be effective in improving gastric emptying in MD patients with gastroparesis[24]. Its effect may be due to the local release of acetylcholine and/or the hypersensitivity of the smooth muscle cells to this transmitter, and/or a reduction in the inhibitory effect of dopamine on gastric motility[14, 24, 39].

Ronnblom *et al*[25] administered erythromycin (100 mg, 2 times per day, before lunch and dinner) to dyspeptic MD patients over a period of 4 wk. The rationale for the use of erythromycin, which has been proved effective in accelerating gastric emptying in diabetic gastroparesis, lies in its agonistic action on the motilin receptors[10]. No effect on gastric emptying and no immediate improvement in symptoms were observed, although by the end of the 4-wk period a slight improvement in nausea and early satiety and a marked improvement in diarrhoea were noted by some patients. The authors reported that overall the treatment is effective possibly due to the positive effects of the drug on other GI symptoms, such as bacterial overgrowth in the ileum, which causes diarrhea by inhibiting the absorption of bile acid[25].

SMALL AND LARGE INTESTINE

Diarrhea, sometimes accompanied with malabsorption, steatorrhea, and crampy abdominal pain, are frequent complaints in MD patients[9]. Paralytic ileus has also been reported[40, 41]. The pain may be located in any part of the abdomen, with no specific characteristics or eliciting factors. Episodic diarrhoea is the single most common complaint (present in up to 33% of cases). It is often disabling and may have a marked impact on the patient's social life, especially when combined with anal incontinence[9].

Diarrhea and possibly malabsorption, have been attributed to reduced peristaltic activity leading to bacterial overgrowth[10]. Anaerobic bacteria seem to be the principal contaminating agents. Their ability to deconjugate bile acids, thereby causing defective uptake in the terminal ileum, could be the main cause of diarrhea[25, 42]. Norfloxacine, either alone or in combination with cholestyramine, can alleviate this symptom in some patients. Other possible mechanisms of diarrhea, such as the reduced secretion of pancreatic amylase, have been hypothesized but not yet been demonstrated, and further evidence is needed to shed light on this issue[42].

Radiological studies have demonstrated reduced or absent peristaltic and/or segmentary activity with delayed intestinal transit[43-45]. Megacolon, sigmoid volvulus and segmental narrowing due to myotonic contractions have also been reported[43, 46-52].

Megacolon with the accompanying risk of ileus, volvulus and rupture, is a significant complication and must be kept in mind during the management of MD patients who are usually at higher risk of complications during anesthesia and surgical operations than normal subjects. The pathophysiological mechanisms underlying megacolon are not entirely clear, but probably smooth muscle damage is not the only factor involved. An electron microscopy study of an MD patient with megacolon showed that the myenteric plexus is degenerated with a paucity of neurons and fragmented axons. Glial cells are increased in number with vacuoles containing electron-dense material. Swelling of the mitochondria, distension of the endoplasmic reticulum and the accumulation of free ribosomes in the cytoplasm are also observed. The neurons are described as being "fewer, and the argyrophilic ones smaller, with less prominent processes and poor staining quality." The number of nerve fibers exhibiting reactivity to substance P and enkephalin in the *muscolaris externa* is decreased, while normal smooth muscle cells are reported[52].

In concurrence with pregnancy or episodes of gastroenteritis, MD patients have been reported to suffer from recurrent intestinal pseudo-obstruction presenting with nausea, vomiting, abdominal cramps, distension and sometimes, constipation[53, 54]. However, such complications may occur during any stage of the disease and may even precede significant skeletal muscle weakness by 15 years. Recently, an MD patient with pseudo-obstruction and partial malrotation of the intestine has been reported[55], although it should be noted that this association has never been observed before and could represent an isolated case[56].

Manometric studies of the small intestine (jejunal manometry) in MD patients have shown low amplitude contractions of the migrating motor complex during phases 2 and 3, with high frequency activity during phase 2 and retrograde propagation and interruption of the contractions during phase 3. Low amplitude post-prandial contractions and myotonic phenomena have also been reported. A disturbance of the mechanoreceptors that link the circular muscle layer with the enteric nerves and

provide the stimulus for the propagation of migrating motor complex phase 3 activity has been hypothesized to explain these phenomena[57].

Very few manometric studies of the colon have been conducted and the results are conflicting. Some report an absence of the normal rhythmic pressure variation in the descending colon[43], while others have failed to detect any motility abnormalities in the sigmoid colon[58]. In any case, intestinal motility disturbances are detectable in both symptomatic and asymptomatic subjects, raising doubts as to the actual role they play in the pathogenesis of MD. The absence of a correlation between disease severity and the presence of symptoms has also been confirmed in the intestinal tract[57].

Only a small number of histologic studies of the muscular layer of the small intestine are now available. They describe the cells as being swollen, fragmented, partially destroyed, or decreased in size, and replaced by fats, quite similar to the abnormalities reported for the skeletal muscles[35, 59]. Biopsies of the mucosa usually show normal histologic patterns[37, 43, 60, 61], although a case of a patient with intestinal villous atrophy and collagenous sprue has been reported by Woods *et al*[62]. The authors' suggestion that this type of malabsorption may be frequent in MD patients has not yet been confirmed.

RECTOANAL REGION

Although constipation often associated with dyschezia is common, since some patients represent a serious problem, the most burdensome and disabling problem affecting MD patients may be fecal incontinence[9, 63, 64]. Up to 66% of MD patients suffer occasional fecal incontinence, while more than 10% report fecal incontinence one or more times a week. The frequency of urinary incontinence seems to have no difference between MD patients and control subjects[9, 65].

Although the procedure is simple and low in invasiveness, manometric studies of the rectoanal region are not often performed in MD patients. Some studies report a decrease in both the resting pressure (based on the tonic activity of the internal anal sphincter) and the squeezing pressure (exerted by the phasic activity of the external anal sphincter)[65-67]. Others have failed to detect any significant modification in the resting pressure and only a slight, statistically insignificant decrease in the squeezing pressure[11].

Lecointe *et al*[11] found that the amplitude and duration of the recto anal inhibitory reflex (RAIR) in response to rectal distension are markedly decreased in MD patients. This could be explained, however, by a prolonged myotonic contraction of the striated external anal sphincter muscles[67], which could obscure the manometric signal indicating the normal internal anal sphincter relaxation response to rectal distension. Due to this myotonic phenomenon, the duration of the rectoanal contractile reflex (RACR) is longer in patients than in controls[11]. According to Hamel Roy *et al*[68], the amplitude of this myotonic response is decreased by pudendal nerve blockade, suggesting the possibility of at least a partial neural reflex response. Pudendal nerve terminal motor latencies are normal in these patients, confirming the absence of a neurogenic lesion[67, 69]. Finally, it was reported that the maximum tolerable volume at rectal distension is significantly lower in MD patients than in controls[11].

Anorectal motility disturbances are as frequent as pharyngo-esophageal disturbances, the degree of involvement of the upper and distal portions of the gastrointestinal tract may be closely correlated both quantitatively and qualitatively[11]. It has been shown that anorectal motility and esophageal motility are altered in a similar number of patients[11].

Although the prevalence of altered motility is high, symptoms such as anal incontinence, diarrhoea and/or abdominal pain have been found in a small number of patients, suggesting that there is a close relationship between smooth and striated muscle motor function in MD but only in the gastrointestinal tract, where smooth and striated muscle abnormalities may be interdependent[11]. Unfortunately, there are no histologic data to back up this intriguing hypothesis.

Eckardt *et al*[66] studied the external anal sphincter using electromyography and have found myopathic potentials with myotonia. Herbaut *et al*.[65] reported a decreased duration and amplitude of the motor units in the external anal sphincter and the puborectalis muscle of MD patients with fecal incontinence, suggesting that there may be a myopathic component to the pathology. In 25% of these patients, polyphasic high-amplitude motor units were also present, indicating the probable presence of a neuropathic lesion. Taken together, the data suggest that both the striated external anal sphincter and the smooth internal anal sphincter may be altered in MD, even if previous histologic examinations have reported pathological findings only in the striated muscle[66]. More recently, Abercrombie *et al*[67] used electron microscopy to study the anal sphincter in two siblings with MD and found that the external anal sphincter is atrophic in both patients, with marked fibrosis and a high variation in the diameter of the fibres as well as the striated muscle almost entirely substituted by smooth muscle cells deriving from the internal sphincter. These cells are all different in size and electron density separated by large amounts of fibrous connective tissue. Some show features suggestive of dedifferentiation into myofibroblasts. The puborectalis biopsies revealed an analogous decrease in the amount of normal striated fibres with pronounced fibrosis. Some of the fibres were hypertrophic with increased central nucleation and many showed sarcoplasmic masses. Moreover, type 1 fibres were markedly prevalent (99%). In the ano-rectal region, no close correlation between motor abnormalities and overt symptoms has been found, although defecatory behaviour is often severely altered in these patients.

Constipation in MD patients is usually treated with prokinetics, laxatives and enemas[15, 70], while medical treatment with procainamide (300 mg twice a day) has been proposed for fecal incontinence[71]. Surgery to treat fecal incontinence has been attempted, but post-anal repair only temporarily improves the defecatory function[67]. Treating and curing defecatory problems in MD patients remain a difficult challenge. Rehabilitation involving a combination

of volumetric rehabilitation, electroanalytical stimulation, kinesitherapy and biofeedback, can be effective in those patients not suffering from severe damage to the pelvic floor muscle[72,73].

CONCLUSIONS

Since MD is a relatively rare disease, most of the papers published are hampered by the bias arising from the low number of patients studied. Many report just one or two cases, and very few involve series of more than 10 patients. Gastrointestinal involvement is frequently observed in MD patients and digestive complaints may be the first sign of the disease. According to Ronnblom *et al*[9], 25% of patients consider their gastrointestinal problems as the most disabling consequence of MD, 28% have digestive symptoms that may appear up to ten years before the typical musculoskeletal features. During this period the impairment of the digestive functions may be so gradual that patients unconsciously adapt to them by compensatory mechanisms, thus masking the symptoms[18, 74]. They may even develop a higher pain threshold (visceral hypoalgesia) similar to that seen in diabetic gastroparesis[75]. For these reasons, patients often do not undergo a thorough examination of the digestive tract, while at the same time they may be subjected to a broad battery of other examinations because of multi-system involvement. Thus, a careful assessment of the digestive tract may be performed only when the symptoms have become severe, although reliable, non-invasive or minimally invasive techniques such as ultrasonography, scintigraphy, breath test and cutaneous electrogastrography are available[13].

Little correlation has been found between the degree of skeletal muscle damage and gastrointestinal disturbances[12, 14], while there does appear to be a relationship between the severity of GI involvement and the duration of the disease[13]. Nevertheless, the pathophysiologic mechanisms of digestive motor disorders certainly suggest that there is damage to the striated muscles in the upper and lower portions of the gastrointestinal tract. Histologic evidence of smooth muscle alterations is scarce and conflicting[12, 14], although some authors have hypothesized that smooth muscle damage may occur earlier and is more severe than striated muscle changes[10].

Moreover, some authors suggest that a common mechanism may be the generation of the motor abnormalities in both the smooth and striated muscles. For example, Lecointe *et al*[11] studied the esophagus and the rectoanal region of MD patients and found that alteration in the smooth muscle is closely related with that in striated muscle, at least in the digestive tract.

A neural factor could also be involved in the digestive symptoms of MD patients. Neural dysfunctions, such as an alteration in the non-adrenergic, non-cholinergic neuronal control of the GI tract, have been suggested to explain the symptoms and instrumental findings that may be present even in the absence of definite histologic damage. Nitric oxide (NO) can mediate non-adrenergic, non-cholinergic nerve-induced relaxation and hyperpolarization of the smooth muscle in the digestive tract[76]. NO is produced from L-arginine via NO synthase, a key enzyme that is expressed in the myenteric plexus, motor neurons and myenteric fetal interneurons[77-80]. Thus, the NO molecule seems to be common in both the striated and smooth muscles, the inhibition of NO synthase could alter the motor parameters in a manner consistent with the observations of Lecointe *et al*[11]. This "neuronal hypothesis" can explain the absence of histologic abnormalities in the smooth muscle of MD patients. In addition, it could explain the degeneration and decreased number of argyrophilic neurons in the colonic myenteric plexus of an MD patient affected with megacolon[52].

Gastrointestinal involvement in MD remains a complex and interesting condition. Given the limited data available, there are very few certainties and many important questions to be solved[81]. The relationship between myotonic dystrophy, gastrointestinal motility and clinical symptoms needs to be investigated in greater depth. Studies should begin early in their disease course, using non-invasive diagnostic techniques and concentrating on the genetic and histologic aspects of each case. Such efforts can improve our understanding of the pathophysiology of the digestive system involvement in MD and speed up the development of new therapeutic strategies to manage this difficult condition.

Abstract

The pathogenesis of inflammatory bowel disease (IBD) is only partially understood. Various environmental and host (e.g. genetic-, epithelial-, immune and non-immune) factors are involved. It is a multifactorial polygenic disease with probable genetic heterogeneity. Some genes are associated with IBD itself, while others increase the risk of ulcerative colitis (UC) or Crohn's disease (CD) or are associated with disease location and/or behaviour. This review addresses recent advances in the genetics of IBD. The article discusses the current information on the crosstalk between microbial and genetic factors (e.g. NOD2/CARD15, SLC22A46A5 and DLG5). The genetic data acquired in recent years help in understanding the pathogenesis of IBD and can identify a number of potential targets for therapeutic intervention. In the future, genetics may help more accurately diagnose and predict disease course in IBD.

Key words: Inflammatory bowel disease; Ulcerative colitis; Crohn's disease; Pathogenesis; Microbial factors; Genetics; NOD2/CARD15; SLC22A4/A5; DLG5

INTRODUCTION

There has been a sharp increase in the incidence of inflammatory bowel disease (IBD) in the late 1900s in Western countries as well as in some Eastern parts of Europe and North America[1-3]. Both Crohn's disease (CD) and ulcerative colitis (UC) stem possibly from a common mechanism with an exact etiology that remains obscure[4,5]. Crohn's disease manifests itself as a chronic granulomatous inflammation of the gastrointestinal tract capable of affecting its entire length with the presence of "skip" lesions[6,7]. It preferentially affects the terminal ileum, as was originally described by Crohn *et al*[8]. Ulcerative colitis, on the contrary, presents as a continuous inflammatory lesion affecting the rectum and colon, lacking granulomatous characteristics.

IBD are multifactorial, polygenic diseases with probable genetic heterogeneity. According to this hypothesis, different genetic backgrounds may explain the various clinical patterns of the disease[4,5]. In addition to genetic predisposition, various environmental and host factors (e.g. genetic-, epithelial-, immune and non-immune) play a major role in the pathogenesis of IBD. Extensive heterogeneity is observed in terms of presentation, extraintestinal manifestations and location in CD, while behavior and response to treatment are heterogeneous in both CD and UC[9]. Furthermore, it is now undisputed that enteric bacterial flora play a key role in the pathogenesis of IBD, both in UC and in CD. The exact mechanism by which the intestinal mucosa loses tolerance to its bacterial neighbors remains elusive. The role of host genetic regulation of the innate immune response in the pathogenesis of CD has been brought to sharp focus by the identification of the NOD2 (CARD15) mutations.

The genetic aspect of research is quite focused on numerous chromosomal loci. The environmental contributors are diverse and an "infectious origin" of inflammatory bowel disease has not been confirmed. This review describes the various environmental, immunologic and genetic components leading to the manifestation of inflammatory bowel disease.

MICROBIAL FACTORS: ARE PATHOGENIC BACTERIA AND/OR ALTERED PERCEPTION OF NORMAL FLORA THE KEYS IN THE BREAKDOWN OF TOLERANCE?

The normal intestine encounters a high concentration of foreign antigens, bacteria and food. In the stomach and proximal small intestine, secretion of acid and bile, phasic 'housekeeping' motility patterns hinder colonization. However, the number of bacteria dramatically increases in the distal small intestine to an estimated 10^{10} - 10^{12} bacterial cells/g content in the colon, which contribute to 60% of the faecal mass[10]. More than 400-500 species of bacteria are represented, belonging to 30 genera. Although this antigenic load is separated from the largest complement of lymphocytes in the body (gut associated lymphoid tissue, GALT) by only a single layer of polarised intestinal epithelium, most people do not have an immune response to foreign antigens and interaction between the mucosal immune system and the fecal bacterial mass regulates physiologic bowel functions. The mucosal immune system has evolved to balance the need to respond to pathogens while maintaining active tolerance to commensal bacteria and food antigens. In IBD, this tolerance breaks down and inflammation supervenes driven by the intestinal microbial flora.

A large part of research has traditionally been devoted to finding a causative biological source of any disease. This has also been the case in IBD, but to date there is no compelling evidence of an etiological role for any single pathogenic microorganism.

PATHOGENIC MICROBES

The history of IBD is dotted by cyclic reports on the isolation of specific infectious agents responsible for CD or UC. Several microorganisms, such as *Mycobacterium paratuberculosis, Listeria monocytogenes, Chlamydia trachomatis, Escherichia coli, Cytomegalovirus, Saccharomyces cerevisiae*, have been proposed as having a potential etiologic role.

The suggested etiologic role of *Mycobacterium paratuberculosis* in CD is also controversial. This bacterium is the causative agent of Johne's disease, a chronic granulomatous ileitis in ruminants, which closely resembles CD. *M. paratuberculosis* was initially isolated from CD tissues some 20 years ago[11] and follow-up studies have tried to culture *M. paratuberculosis* for testing specific DNA sequences in intestinal tissues, or measuring serum antibodies against *M. paratuberculosis* with conflicting or inconclusive results[12-14]. Recently, *M. paratuberculosis* has been identified by *in situ* hybridization to the *M. paratuberculosis*-specific IS*900* gene in tissue specimens of Crohn's disease[15] and in 40% of Crohn's disease granulomas isolated from surgical specimens by laser capture microdissection[16]. Others have localized *M. paratuberculosis* by PCR to macrophages and myofibroblasts within the lamina propria[17]. However, the possibility of an association between *M. paratuberculosis* and CD remains inconclusive.

Additionally, *E. coli* bacteria possessing special adhesive properties have been associated with the development of ulcerative colitis.

A fascinating hypothesis was published in the *Lancet* in 2003[18]: an association between refrigeration and CD. Some so called psychrotrophic bacteria are capable of growing slowly at low temperature (known as "cold chain hypothesis"). Common pathogens are *Yersinia enterocolitica*, *Listeria monocytogenes*, and *Clostridium botulinum*[19].

Several studies have demonstrated members of the *Yersinia* species in intestinal mucosal samples of Crohn's disease. The specific pathogens detected are either *Y. enterocolitica* or *Y. pseudotuberculosis*, and sometimes even both[20,21]. There are numerous aspects of yersiniosis which resembles the inflammatory reaction seen in Crohn's disease, making differential diagnoses of these two conditions, including ileitis or ileocolitis, mesenteric adenolymphitis, reactive arthritis and erythema nodosa. Additionally, granulomas may be observed in histological samples[18].

Recent data also demonstrate a role of mucosa-associated and intramucosal bacteria in the pathogenesis of IBD and colorectal cancer. In the study by Martin *et al*[22], mucosa-associated or intramucosal *E.coli* are present in 43% and 29% of CD, and 17% and 9% of controls, respectively, supporting a role of mucosa-adherent bacteria in the pathogenesis of Crohn's disease.

Finally, a viral etiology has also been proposed as the cause of IBD, particularly CD. An early measle infection during the perinatal period notably increases the risk of Crohn's disease[23]. The finding of paramixovirus-like particles in CD endothelial granulomas suggests an association between perinatal measles and predisposition to CD based on some epidemiological and serologic data[24]. However, these preliminary findings are not confirmed by later studies[25]. Importantly, the progressive decline of measle virus infection in the last decades with the concomitant rise of CD during the same period of time speaks against an etiologic role of measles in CD. The hypothesis that measle vaccination rather than measle infection, might be a risk factor for CD, has also been raised, but again results of additional studies fail to confirm this association[26]. In contrast, a role of cytomegalovirus infection is proposed in UC[27].

NON-PATHOGENIC INTESTINAL FLORA

In the last decade, the focus of interest in microbial etiology of IBD has shifted from infectious to commensal agents. Based on fairly solid data, there is a substantial body of evidence that the normal enteric flora plays a key role in the development of IBD[28]. This is even more evident after the discovery of the genetic factors (e.g. NOD2/CARD15, TLR4 and CD14) responsible for alterations in bacterial perception[29]. The beneficial effect of antibiotics in the treatment of CD, and to a lesser extent UC, has been appreciated for years. Diversion of the fecal stream from inflamed bowel loops has also been known to induce symptomatic improvement in CD patients, while re-emergence of inflammation often occurs upon restoration of intestinal continuity[30].

Changes are observed in the normal flora of IBD patients and dysbacteriosis is commonly reported. Based on the clinical picture of IBD, the intestinal flora

might play a role in the initiation and perpetuation of inflammatory reaction. *Fabia et al*[31] demonstrated that the concentration of anaerobic bacteria and *Lactobacillus* are radically decreased in active IBD patients. On the contrary, patients with inactive IBD show no such decrease. *Swidsinski et al*[32] compared over 300 IBD patients with 40 control individuals and found that abnormalities can be observed in the flora using various laboratory techniques. In addition, a much greater number and concentration of bacteria make up the biofilms covering the epithelium involved in IBD. Furthermore, a direct association has also been reported between bacterial concentration and disease severity.

More recently, probiotics (primarily lactic acid bacteria) defined as live microbial feeds that beneficially affects the host by modulating gut microbial balance, have been demonstrated to improve both human IBD and experimental colitis, primarily by preventing relapses, thus adding an important dimension to the role of gut flora in IBD[33,34].

Probably, the most convincing evidence comes from experimental data. In the majority of IBD animal models, intestinal inflammation fails to develop when they are kept in a germfree environment. This critical observation has led to the widely accepted paradigm "no bacteria, no colitis". However, once normal flora is introduced into their environment, the mutant-strain mice quickly develop colitis[35, 36].

It is worth mentioning that bacterial superinfection (most commonly *Clostridium difficile*, but also *Entamoeba histolytica, Campylobacter spp*, etc.) is also able to elicit relapse of IBD. In the study of Mylonaki *et al*[37], 10.5% of all relapses are associated with enteric infections. In another study[38], 20% of all relapses are correlated to *C. difficile* positivity.

The presence of bacterial antigens as the initiating factor in IBD has also been explored. The data support a role of flagellin proteins in activating the innate immune system. Elevated titers of serum anti-flagellin IgG against these proteins could be detected in CD patients[39]. Furthermore, elevated serum IgG2a titers could also be demonstrated in experimental IBD models, similar to results observed in humans. Recently, anti-CBir1 (anti-flagellin) expression has been independently associated with small-bowel, internal-penetrating and fibrostenosing disease features in CD[40].

Finally, the role of bacteria in the pathogenesis of IBD is further supported by the increased intestinal permeability in CD patients. Although it is not an environmental factor *per se*, it has been postulated as an early predisposing factor for the development of this condition. Increased intestinal permeability is also observed in asymptomatic first-degree relatives of CD patients, possibly encompassing another group of individuals who are at an increased risk of developing this form of IBD[41,42]. Documented observations of increased permeability preceding the onset of symptomatic disease are of further interest[43]. In relating this phenomenon to the UC form, electron microscopy has revealed deficiency of those elements comprising the tight junctions necessary for the wholeness of the intestinal epithelium[44]. Recent data reporting an association between genes important in mucosal transport and integrity (OCTN and DLG5) and IBD further support this assumption.

Table 1 Locations of nine major loci showing linkage to inflammatory bowel disease

IBD locus	Chromosome	Identified genes	Disease
IBD1	16q13	NOD2/CARD15	CD
IBD2	12q14	Not known (VDR, STAT6, MMP18, b2-integrin)	UC
IBD3	6p	Not known (HLA, TNF)	IBD
IBD4	14q11-12	Not known (TCR, LTB4 receptor)	CD
IBD5	5q31-33	SLC22A4/A5	CD
IBD6	19p13	Not known (ICAM1, C3, TBXA2)	IBD
IBD7	1p36	Not known (TNF-R family)	IBD
IBD8	16p12	Not known	CD
IBD9	3p26	Not known (CCR5, CCR9,hMLH1)	IBD
	10q23	DLG5	IBD

The phenomenon of decreased bacterial diversity of the intestinal microflora obtained from stool samples in IBD patients has also been suggested, based on culture-dependent microbiological techniques[45]. Recently, a German group has reported the relative lack of the *Bacteroides* group (usually accounting for 50%-90% of the anaerobic faecal microflora) by utilizing 16sDNA-based single strand conformation polymorphism (SSCP) fingerprint, cloning experiments and real time PCR. Moreover, the bacterial profiles are stable, at least for the observed period of six weeks. This is in concordance with previous findings, suggesting that the mucosa-associated microflora contains only a small number of bacteria of the *Bacteroides/Prevotella* group[52]. However, in a recent study comparing the faecal microflora of healthy controls and CD patients, no differences are noted between patients and healthy controls[46]. This lack of significant difference may be partially explained by the differences in mucosal and faecal microflora.

Why an abnormal response to normal endogenous gut bacteria exists in IBD is not clear, but recent data, especially on the genetic background of CD, suggest an association between gut inflammation and abnormal bacterial sensing.

GENETICS AND GENE FUNCTION

Possible genetic loci influencing the presentation of inflammatory bowel disease have already been identified on more than half of all chromosomes, including the X chromosome[47-49]. First, in 1996 Hugot *et al*[50] reported that the pericentromeric region of chromosome 16 (D16S408) is associated with CD renamed as IBD1[50]. This is confirmed by several studies. To this date, results of numerous studies have revealed a total of nine loci associated with specific linkage requirements, subsequently labeled as IBD1-9[51-55] (Table 1). Furthermore, it is clear that some loci correlate with either UC or CD while others are involved in the pathogenesis of both IBD forms[49].

FAMILIAL STUDIES

Evidence of genetic constituents in the induction of inflammatory bowel disease clearly lies within the results of familial studies. Several studies examining the relationship of IBD within families have reported positive findings in 10%-25% of families[56,57]. This finding goes back at least two decades when Farmer and Michener reported 40% concordance for IBD in first-degree relatives. They observed that sibling-sibling involvement occurs in addition to parent-offspring transmission.

Solid evidence of genetic predisposition showed that as many as 50% of monozygotic twins are affected by Crohn's disease whereas ulcerative colitis is seen in approximately 14%[58]. Monozygotic twins are not equally affected but still display greater concordance for IBD than dizygotic twins. The overall risk for IBD is increased by 5-20 times[59], being highest in twins and in siblings. The genetic component is more prominent in CD than in UC.

Finally, genetics certainly play a role in the observed phenotype of IBD, including disease behavior and location[60].

Genetic anticipation is suggested in early studies with a more severe and earlier presentation of the disease in subsequent generation[61], but this has not been replicated in more recent studies[62,63].

GENES INVOLVED IN THE RECOGNITION OF BACTERIA – NOD2/CARD15, NOD1/CARD4, TLR4 AND CD14

NOD2/CARD15

Three independent groups have identified NOD2 CARD15 on chromosome 16 in IBD1 as a candidate gene for CD[29,64,65].

NOD2/CARD15 is an intracellular element responsible for the indirect recognition of bacterial peptidoglycan through the binding of muramyl dipeptide[66,67]. It is a member of the Ced4-APAF1 protein superfamily and is expressed in various cells, including monocytes, dendritic cells, Paneth cells and intestinal epithelial cells[6]. Structurally, NOD2/CARD15 is composed of three segments: the first being composed of two CARD units, the central portion consisting of nucleotide-binding domain (NBD) and finally, a leucine-rich repeat (LRR) region as is found in TLRs[68]. The most intriguing question that remains to be answered concerns the mechanism whereby mutations in the NOD2/CARD15 gene predispose towards the chronic intestinal inflammation characteristics of CD.

At the molecular level, the binding of NOD2/CARD15 to a bacterial motif (muraryl dipeptide-MDP, a component of both Gram negative and positive bacterial cell walls) causes its binding to a second NOD2/CARD15 molecule, thus forming a dimer. Further interaction with other cytosolic proteins leads to the ultimate activation of nuclear factor κB (NF-κB), eliciting pro-inflammatory reactions[68] (Figure 1). Surprisingly, it is still unclear whether NF-κB expression is elevated or depressed in CD due to conflicting observations and studies. *In vitro* experiments demonstrated that the declined activity of this protein indicates a loss-of-function effect[69,70]. Hisamatsu *et al*[71] showed that

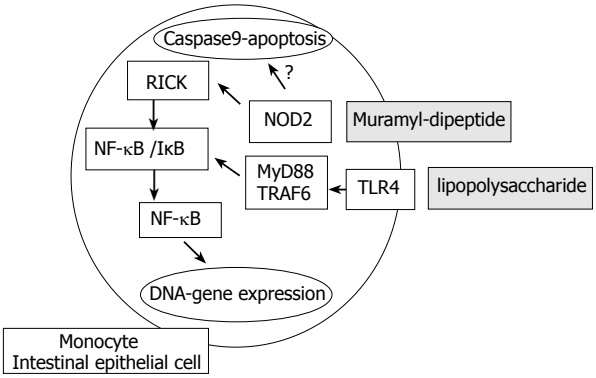

Figure 1 NOD2/TLR4 signaling pathway. NOD2 activation by CARD-CARD dimmer formation results in binding to RICK kinase (RIP-like interacting CLARP kinase). RICK then activates the nuclear factor kB inhibitor (IkB) kinase complex (IKK) via phosphorylation of IKKc. The IKK complex next phosphorylates IkB resulting in nuclear factor kB (NFkB) translocation to the nuclei and transcriptional activation of NFkB responsive genes, such as pro-inflammatory cytokines or defensins. TLR4 induces activation through other molecules (Myd88, IRAK and TRAF6).

CARD15/NOD2 may function as an antibacterial factor in CaCo2 intestinal epithelial cells. Cells stably transfected with a wild-type CARD15/NOD2 gene construct are able to prevent invasion of *Salmonella typhimurium*. This protective effect is lost in cells transfected with gene constructs of mutant CARD15/NOD2. It has also been demonstrated that NOD2/CARD15 expression in intestinal epithelial cells might be upregulated by the proinflammatory cytokine tumor necrosis factor α (TNF-α)[72]. The NF-κB activation is regulated by the LRR region and deletion within this region may theoretically result in its uncontrolled activation. In concordance with this, increased NF-κB activation is observed in the presence of 3020insC mutation by stimulation of MDP[73], which may explain the findings of higher NF-κB tissue levels in samples from IBD patients[74]. Interestingly, mice lacking NOD2 or possessing mutated NOD2 variants do not spontaneously develop Crohn's disease. These findings suggest that NOD2 mutations create an intestinal environment susceptible to IBD[73,75] rather than playing a direct causative role in disease development expression of α- and β-defensins.

Defensins are integral parts of the local intestinal immune system, and are secreted by intestinal epithelium as endogenous antimicrobial proteins. The consequential damage could finally lead to an intensified bacterial invasion and a chronic inflammation of the intestinal mucosa[76]. The possibility exists that NOD2/CARD15 is involved in the regulation of Paneth cell degranulation[77], as NOD2/CARD15 expression is noted in close proximity to the secretory granules of these cells. Kobayashi *et al*[75] and Wehkamp *et al*[78] have shown that carriage of NOD2/CARD15 variants may be associated with reduced α-defensin release from Paneth cells in response to bacterial cell wall components, and the defective defensin release by the Paneth cells could provide the missing link, whereby reduced NOD2/CARD15 activity impairs host defenses against bacteria and underlies persistent intestinal inflammation. Finally, NOD2/CARD15 is involved in the regulation of TLR2 stimuli by peptidoglycans. Defective

NOD2 function results in a pro-inflammatory cytokine bias after stimulation of mononuclear cells with TLR2 stimuli, which may contribute to the overwhelming inflammation in Crohn's disease[79].

Three major mutations have been identified within NOD2/CARD15: one frame shift (3020insC, SNP13) and two missense mutations (R702W-SNP8 and G908R-SNP12).

The presence of NOD2/CARD15 mutations increases the risk for CD by 1.4-4.3-fold in heterozygous patients and 17.6-44.0-fold in homozygous and compound heterozygous patients. Reports on homozygous individuals who are disease-free are available. One such family has been described by van der Linde *et al*[80]. It is estimated that any of these three common mutations involving NOD2/CARD15, is present in heterozygous form in 30-50% of CD patients and 7-20% of controls from North-America and Europe[81-85]. However, various geographical differences are noted. Furthermore, other races display a much lower prevalence of this mutation, sometimes lacking it altogether (e.g. African-American[86], Chinese[87] and Japanese[88]). The prevalence is also lower in other North European countries[89,90].

The association between NOD2/CARD15 and disease phenotype and behavior has also been investigated. The three common mutations are associated with ileal disease and fibrostenosing behavior, but they are relatively less frequent in colonic and fistulous disease[64,66,91,92]. The presence of mutations is not associated with extraintestinal manifestations or the response to infliximab therapy[93]. The mutations are also not associated with UC. In CD, the attributable risk for ileal disease is 40% determined by NOD2/CARD15 and 20% by HLA genes. The numbers are similar for ileo-colonic disease (NOD2/CARD15: 30%, HLA: 40%), while colonic disease is thought to be associated with HLA and other yet unknown genes[91].

It is worth mentioning that NOD2/CARD15 increases the risk for colorectal cancer (CRC). Kurzawski *et al*[94] have found that the presence of SNP13 mutation increases the risk of developing CRC by 2.23-fold in patients with an age >50 years at diagnosis of CRC. This has not been confirmed in a more recent study by Alhopuro *et al*[95].

NOD1/CARD4

A similar protein to NOD2/CARD15 by its structure and function, is located on chromosome 7p. Its particular location is in the midst of a region with strong IBD correlation, being translated into an intracellular bacterial pathogen-associated molecular pattern[96].

Zouali *et al*[97] denounced that NOD1/CARD4 plays a role in IBD following an investigation involving 63 IBD patients. The screening process was conducted on the eleven exons constituting the NOD1/CARD4 gene with the goal of identifying polymorphisms. Indeed, several variants were identified, none of which has proved any association with IBD[97]. On the contrary, McGovern *et al*[96] have located a complex insertion/deletion allele on NOD1, associating it with both an early onset of IBD and extraintestinal manifestations.

Toll-like receptors and CD14

Toll-like receptors (TLRs) expressed in myeloid cells play a major role both in detecting microbes (lipopolysaccharide) and in initiating innate immune responses. Accordingly, a disturbance in its function predisposes to infections with Gram negative bacterial pathogens, possibly influencing the advancement of IBD[98,99]. In contrast, little is known about the expression, distribution and function of TLRs in epithelial cells *per se*. TLR4 is also expressed in the Golgi apparatus of intestinal epithelial cells. Thus, LPS recognition in intestinal epithelial cells may occur in the Golgi apparatus and requires LPS internalization [100]. Recently, it has been suggested that the interaction of LPS with TLR4 / MD2 contributes to the perpetuation of the inflammatory epithelial cell injury via TNFα induced alterations of enterocyte turnover in an autoparacrine/paracrine manner[101]. TLRs may also influence the nature of immune response by skewing T cells toward a Th1 or Th2 profile. Myeloid cells are exquisitely sensitive to TLR ligands and produce significant IL-12p40. They appear to play a key role in the initiation and possibly the Th1/Th2 skewing of inflammatory responses. In this model the inflammation can be normally controlled by myeloid or lymphocyte-derived IL-10 acting through Stat3 in myeloid cells to block further production of IL-12/IL-23 and skewing the responses towards Th1 profile[102].

IBD is characterized by an altered expression pattern of TLRs on the surface of intestinal epithelium and TLR4 expression is up-regulated in patients with CD. In contrast, the expressions of TLR2 and TLR5 are unchanged, while TLR3 that recognizes viral replication is down-regulated[103]. The D299G (Asp299Gly) polymorphism of the TLR4 gene associated with LPS hyporesponsiveness[104] is associated with CD (OR:2.45-2.80) and UC (OR: 2.05)[98,105]. However, other studies have failed to replicate this association[85,106].

Another TLR which binds to and recognizes bacterial DNA, TLR9, may also play an important role in the pathogenesis of IBD. Rachmilewitz *et al*[107] reported that the anti-inflammatory effect of probiotics is transmitted through TLR9 in experimental colitis. More recently, an English group has reported a synergy between TLR9 and NOD2 that is lost in the CD patients carrying NOD2 mutation, indicating impairment in innate immunity[108]. Recently, *Torok et al*[109] reported that the -1237C promoter polymorphism of TLR9 is significantly associated with CD in German patients.

Contradictory data are available on the association between the bacterial receptor CD14 and IBD. Klein *et al*[110] found that the 159 TT genotype is associated with CD but not with UC. In a Japanese study[111], the same genotype is associated with UC (OR: 1.96) but not with CD and also a further study investigating Caucasian patients has failed to demonstrate any association[112].

MUCOSAL INTEGRITY AND TRANSPORT - SLC22A4/OCTN1, SLC22A5/OCTN2 AND DLG5

SLC22A4/OCTN1, SLC22A5/OCTN2

The association between 5q31 and CD is first noted in genome-wide screens (the genes for Th2 cytokines -e.g. IL-3, 4, 5, 9, 13 and IRF1- maps to this region). The

risk haplotype is associated only with a moderate risk for CD (OR: 1.4-1.5). The effect of NOD2/CARD15 is additive while the 5q31 haplotype is an independent risk factor[113-115]. A German study reported that the risk haplotype is also associated with UC while the IBD5 haplotype is not associated with the clinical presentation, nor is it correlated to IBD in Japanese[114]. Based on the available data, IBD5 increases mainly the overall risk for IBD, whereas NOD2/CARD15 mutations are primarily responsible for the determination of phenotype.

One of the most important findings in the genetics of IBD is the identification of OCTN1/SLC22A4 and OCTN2/SLC22A5 genes coding for integral membrane proteins. The function of these proteins is multispecific in bidirectional transmembrane transport of carnitine and organic cations. The SLC22A4 C1672T and SLC22A5 promoter G207C variants increase the risk for CD by 2-2.5-fold when present as a single copy and by 4-fold in homozygous carriers[55,116]. The elevated risk attributed to OCTN TC haplotype and NOD2/CARD15 mutations, is additive with an odds ratio of 7.3-10.5 in double carriers. A more recent Japanese study on SLC22A4/A5 and DLG5 polymorphisms and CD[117], has shown a weak association, concurring with the Ashkenazi population[118], where the frequency of the allele is lower, indicating racial differences. Variant alleles are associated with functional changes. The SLC22A4 variant encodes exchange of a leucine residue on the OCTN1 transmembrane domain for phenylalanine (L503F), a change which reduces carnitine but augments organic cation transporter activity. The SLC22A5 variant impairs heat shock protein-driven promoter transcriptional activation[116]. Carnitine is an essential mediator of fatty acid oxidation, a role subserved by promoting transport of long-chain fatty acids across the mitochondrial membrane. Inhibition of fatty acid oxidation can evoke clinical and pathologic signs of colitis[119], which may explain why impairments in carnitine transport may confer an increased risk for IBD. Another possibility is that the enhanced cation transporter activity of the OCTN1 503F variant may provoke disease by allowing aberrant uptake of toxic substrates.

A possible association between OCTN3 and CD has been reported[120,121]. In contrast, no association has been found between the proton-coupled bivalent metal antiporter located on 2q35 SLC11A1 and IBD[122].

DLG5

The association between DLG5 (Drosophilia Discs Large Homolog 5) at chromosome 10q22-23 is first reported by Stoll *et al*[123]. DLG5 is a member of the membrane-associated guanylate kinase (MAGUK) gene family which encodes cell scaffolding proteins and is also involved in the maintenance of epithelial integrity and regulation of cell growth[124], a role potentially impaired by expression of the CD-associated DLG5 variants causing increased permeability and disease. The impact on the overall risk of developing IBD is much smaller than NOD2/CARD15. The carriage of the 113A allele increases the risk for CD by 1.3-2.1-fold in German, Italian, Canadian patients and is associated with early onset of IBD in Scottish children[123,125,126]. Less common variants have also been identified (C4126A). Interaction between DLG5 and NOD2/CARD15 is also detectable. This however, has not been replicated by the same group in English and Scottish CD patients and by the German group from Munich[127,121].

HLA, CYTOKINE GENES AND OTHER GENETIC FACTORS

HLA genes

Reports on genetic trait of IBD are available, which investigated the genes associated with the immune response. The main region of interest is that of MHC (main histocompatibility complex) genes located on chromosome 6. The human leukocyte antigen (HLA) class II genes are candidates for a role in the pathogenesis of IBD because their products play a central role in the immune response. More than 100 known genes are located in the area, each is highly variable and several polymorphisms are known.

Several studies have addressed the possible association between certain HLA polymorphisms and the risk for IBD. Most of these studies have revealed contradictory results and their findings could not be replicated in different populations. Overall, genes in the HLA region may play a greater role in modifying IBD phenotype rather than in determining overall disease susceptibility[128-130].

The association of UC with HLA genes is stronger than CD[4,130]. In the white Caucasian population, the rare HLA-DRB1*0103 allele is positively associated with UC (OR: 3.42). Others have found that this allele predisposes to extensive disease and is additionally associated with the presence of extraintestinal manifestations[131]. The repeatedly observed association with HLA-DR2 has been confirmed in the cumulative odds ratio of 2.00, while the odds ratio for DRB1*1502 and DR9 is 3.74 and 1.54, respectively. In contrast, the presence of DR4 (OR: 0.54) and DRw6 is preventive for UC[132].

In CD, negative association has been found between DR2 (OR = 0.83) and DR3 (OR = 0.71), while HLA-DR7 and DQ4 seem to be associated with a moderately increased risk (OR = 1.42 and 1.88). The studies on allele DRB3*0301 showed that this allele is positively associated with Crohn's disease (OR = 2.18)[4,31]. Ahmad *et al*[91] investigated 340 polymorphisms in HLA genes and found that the 3 common NOD2/CARD15 alleles, the HLA DRB1*0701 (RR: 1.5) and Cw*802 (RR3.0) are associated with increased risk for CD, while the presence of HLA DRB1*1501 (RR: 0.6) is protective.

Investigating the genotype-phenotype relations, HLA DRB1*0103 allele in both UC and CD is associated with both extensive and severe disease as judged by the need for colectomy[131,133]. However, the low frequency of this allele even in UC patients suggests that this association is unlikely to be clinically useful in predicting disease course. The same allele is associated with late onset, colonic location (38.5% *vs* controls 3.2%) of CD[134], while the presence of HLA-DRB1*04 (OR:1.7) and HLA-DRB1*0701 (OR: 1.9) increased the risk for ileal location[135]. MICA*010 (MHC class I chain-related gene A) and HLA-DRB*0103 are associated with perianal

disease[91].

A number of genetic associations have also been described in extraintestinal manifestations of IBD. Studies comprising both UC and CD patients showed that migratory pauciarticular large-joint arthritis is associated with HLA-DRB1*0103 and B*27 and B*35 class I alleles in linkage disequilibrium. In contrast, chronic small-joint symmetric arthritis is associated with HLA-B*44[136]. Uveitis is correlated to HLA-B*27, B*58 and DRB1*0103, while erythema nodosum to B*15 and TNF-1031C[137]. However, due to the relatively small sample size of these studies, the evidence is lacking to draw a firm conclusion.

Cytokine, multidrug resistance and cell adhesion gene polymorphisms

Interaction between non-pathogenic, commensal bacteria and epithelial cells, M-cells and dendritic cells of the intestinal mucosa is characterized by a cytokine profile of mainly the Th2/Th3 (suppressor) type (IL-4, IL-5, IL-10, TGF-β), which incapacitates the development of an inadequate, progressive, proinflammatory cycle in healthy individuals[138]. Contrary to this, mucosal immune response against pathogenic species is largely mediated by Th1 cells and a specific cytokine milieu (IL-1, TNF-α, interferon-γ). Both ulcerative colitis and Crohn's disease are characterized by an increased expression of "general" proinflammatory cytokines (TNF-α, IL-1, IL-6), which suggests an abnormally intense inflammatory response against commensal bacteria. This loss of immune tolerance to non-pathogenic microbes results in pathologic immune reactivity and a self-supporting inflammatory cascade. In healthy individuals, the tight control of the inflammatory reaction between bowel mucosa and bacterial milieu involves antiinflammatory cytokines (IL-10, TGF-β)[139]. In case of cytokine imbalance, the inflammatory reaction intensifies. However, lack of antiinflammatory cytokines plays only a restricted role in the development and maintenance of IBD, which is suggested by their low therapeutic potential in IBD[140]. In contrast, the widely used chimera or humanized anti-TNF antibody represents one of the most fascinating new therapeutic options in severe and/or penetrating CD cases as well as UC[141-143]. Studies are also underway targeting IL-12[144].

Although the above mechanism is pivotal in the induction of local inflammatory changes from an immunological point of view, lack of reproducibility has challenged many of the other reported genotype-phenotype associations in IBD, such as association between interleukin polymorphisms and IBD.

The association between a low-producing allele, allele 2 of the interleukin (IL)-1RA gene and UC (OR: 1.3), extensive colitis, the need for colectomy[145,146] and development of pouchitis (OR: 3.1) in UC after ileal-pouch anastomosis[147] has been reported in Caucasian population. However, another study investigating 529 IBD patients has failed to confirm these results[148]. IL-10 polymorphisms also lack association with UC. However, the 627A allele is more frequent in patients with left sided colitis[149]. In contrast, the frequency of the high IL-10 producer allele (-1082*G) is decreased in IBD[150].

Bone loss and osteoporosis are well recognized in IBD, but the risk factors have not been clearly identified. Several studies investigated whether genetic markers may predict bone loss and found that variable number of tandem repeats adjacent to IL-6 or within IL-1RA and genes previously implicated in the paracrine stimulation of osteoclasts are associated with bone resorption[151]. A subsequent study from the same group has failed to identify an association with a putatively functional polymorphism in the IL-6 gene. Nemetz *et al*[152] reported that the 511*2 allele of IL-1b is associated with increased *in vitro* production of IL-1b by mononuclear cells in Hungarian CD patients[152].

Furthermore, microsatellite loci of TNF-α are associated with CD[153]. However, only data from a single study suggest that the TNF-308A polymorphism is associated with more intense inflammatory activity and an increased risk of arthritis in CD patients with fistulizing disease[154].

The A6 allele MICA is associated with UC and early onset of disease[155], while the MICA*011 allele increases the risk for UC by almost 2-fold. No association has been found between different polymorphisms of CTLA4, a receptor of activated T cells, which has an inhibitory function in regulating T-cell activation and IBD in different Caucasian and Asian populations[156,157].

Brant *et al*[158] have described a suggestive linkage on chromosome 7q containing the multidrug resistance (MDR)-1 gene, in association with the appearance of UC and CD. This particular gene is a membrane transport protein with several documented human polymorphisms having effects on intestinal absorption and drug pharmacokinetics. The significant mutation designated as Ala-893Ser/Thr is originally identified in knockout mice with spontaneous colitis[159,160]. An additional locus of mutation (C3435T) associated with 50% decreased protein secretion corresponding to UC (OR: 1.6-2.0) especially in extensive colitis (OR: 2.64), showed no manifestation in CD[161,162].

Adhesion molecules mediating cell-cell and cell-extracellular matrix interactions, are pivotal mediators of inflammation in IBD. Catenins and catherins are major contributors of integrity of the intestinal mucosa[163]. Dysregulation in E-cadherin-catenin complex formation leads to decomposition of the mucosal structure characterized by leaky epithelium, as observed in IBD.

Cell surface adhesion molecules conveying leukocyte-endothelial interactions, govern homing of activated inflammatory cells into the bowel mucosa. In order to slow down by rolling along the endothelium, circulating leukocytes in small vessels of the inflamed mucosa interact with adhesion molecules (e.g. CD44) expressed in the endothelium. This is followed by establishing a firm adhesion anchor. Extravasation and migration into the site of inflammation are mediated by integrins (mainly $\alpha_4\beta_2$ and $\alpha_4\beta_7$) and selectins (L-, E- and P-selectin). Vascular endothelium of the inflamed intestine, particularly in CD, is characterized by increased expression of adhesion molecules and integrin ligands, such as E-selectin, ICAM-1, MAdCAM-1, VCAM-1[164,165]. In UC, the soluble E-selectin levels show no preference between active or inactive forms. Also, the sVCAM concentration is far higher in the control group than in the inactive UC patients. Finally, unlike in CD, VEGF levels in UC cases are similar in active, inactive and control subjects[166]. Expression of

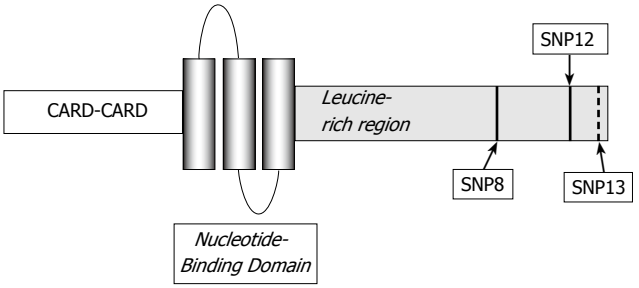

Figure 2 Structure of NOD2/CARD15 protein and locations of the three main mutations.

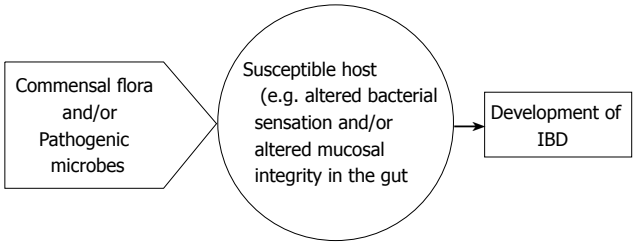

Figure 3 Role of microbial factors and genetics in the pathogenesis of IBD.

certain adhesion molecules (MAdCAM-1, CCL25) is also increased in tissues not primarily involved in the pathological process of IBD (e.g. liver), which might account for the extraintestinal manifestations of the disease[167].

Finally, in Japanese CD patients, the ICAM-1 K469 allele in IBD6 is associated with CD (OR: 2.6) and UC[168]. This association has also been confirmed in Caucasian population[169]. Targeted therapy against certain adhesion molecules (e.g. a4 and ICAM-1) is currently one of the major focuses of pharmaceutical trials in IBD[170,171].

In conclusion, various factors have been implicated in the pathogenesis of IBD, but its mechanism of action is still obscure. Recent data indicate that altered NOD2/CARD15 (or TLR4)-mediated bacterial sensing of normal commensal flora in the gut and mucosal permeability changes may be the key mechanisms (see Figure 2). At present, most efforts are devoted to a better understanding of the genetic changes underlying IBD and to further clarification of how the altered recognition of pathogenic and/or commensal microbial factors by the mucosal immune system leads to inflammation in IBD subjects but not in the general population (Figure 3).

Abstract

AIM: To investigate the interrelationship of Epstein-Barr virus (EBV) and EBV- encoded proteins with *Helicobacter pylori* (*H pylori*) infection and the expression of c-met and c-myc oncogene proteins in gastric carcinoma, and to explore their role in gastric carcinogenesis.

METHODS: One hundred and eighty-five gastric carcinoma tissues were detected by polymerase chain reaction (PCR)-Southern blot for EBV genome and in situ hybridization (ISH) for EBV-encoded small RNA 1 (EBER1). Gastric carcinoma with positive EBER1 signals was confirmed EBV-associated gastric carcinoma (EBVaGC). The status of *H pylori* infection in 185 gastric carcinomas was assessed by rapid urease test and PCR. The samples with positive PCR and urease test were defined as *H pylori* infection. The expression of c-met and c-myc oncogene proteins in tissues of EBVaGC and matched EBV-negative gastric carcinoma (EBVnGC) were examined by immunohistochemistry. RT-PCR and Southern hybridization were used to detect the expression of nuclear antigens (EBNAs) 1 and 2, latent membrane protein (LMP) 1, early genes BARF1 and BHRF1 in EBVaGC cases.

RESULTS: The positive rate of *H pylori* and EBV in 185 gastric carcinomas was 59.45% (110/185) and 7.03% (13/185) respectively. No difference was found in sex, age, pathological differentiation, clinical stages and lymph node metastasis between *H pylori*-positive and *H pylori*-negative gastric carcinomas. However, the positive rate of *H pylori* infection in the antrum gastric carcinomas was higher than that of cardia and body gastric carcinomas. In our series, age, pathological differentiation, clinical stages, lymph node metastasis and location of cancer were not different between EBVnGC and EBVaGC, while the positive rate of EBV in male patients was significantly higher than that of female patients. The positivity of *H pylori* in EBV-associated and EBV-negative gastric carcinomas was 46.15% (6/13) and 81.40%(104/172) respectively. There was no significant correlation between EBV and *H pylori* infection. The c-met overexpression was significantly higher in the EBVaGC group than in the EBVnGC group. However, c-met and c-myc expression did not show significant difference between the two groups. Transcripts of EBNA1 were detected in all 13 EBVaGCs, while both EBNA2 and LMP1 mRNA were not detected. Six of the 13 cases exhibited BARF1 transcripts and 2 exhibited BHRF1 transcripts.

CONCLUSION: The positivity of *H pylori* in EBVnGCs is higher than that of EBVaGCs, but no significant correlation is found between EBV infection and *H pylori* infection. *H pylori*-positive gastric carcinoma is predominant in antrum location, while EBVaGC has a tendency of predominance in cardia/body location. EBV infection is associated with c-met abnormal expression but not with c-myc protein in EBVaGC. c-met overexpression is not induced by LMP1. BARF1 and BHRF1 may play important roles in the tumorigenesis of EBVaGC through different pathways.

INTRODUCTION

Helicobacter pylori (*H pylori*) infection is one of the important environmental risks for gastric carcinoma. In 1994, the

Working Group Meeting of the International Agency for Research on Cancer (IARC) concluded that *H pylori* is a definite carcinogen to gastric carcinoma(GC). Chronic gastritis caused by *H pylori* infection may progress to intestinal metaplasia and even GC[1,2]. The correlation between Epstein-Barr virus (EBV) infection and gastric carcinoma is well known. EBV infection is found in 2%-16% of ordinary gastric adenocarcinoma cases and 80%-100% of gastric lymphoepithelioma-like carcinoma cases[2-5]. However, the pathogenic role of EBV in gastric carcinogenesis remains to be elucidated. Recent studies have shown that the expressions of EBV encoded genes in gastric carcinoma are different from those in Burkitt' s lymphoma and nasopharyngeal carcinoma (NPC), suggesting that the oncogenic mechanism of EBV in gastric carcinoma may be unique[6-8]. The development of gastric carcinoma is a multistep event proceeding from normal to preneoplastic lesions to highly malignant tumors, accompanied by participation of multiple factors and multiple genes. To shed further light on gastric carcinogenesis, we determined the clinicopathologic characteristics and EBV status in 185 patients with gastric carcinoma and correlated with the status of *H pylori* infection, genetic alterations in proto-oncogenes c-myc and c-met.

MATERIALS AND METHODS

Specimens and cases

One hundred and eighty-five surgically resected specimens of gastric carcinoma were collected from the Affiliated Hospital of Qingdao University Medical College, Qingdao Municipal Hospital and Yantai Yuhuangding Hospital. Tumor tissues from each surgical specimen were separately dissected. Partial tissue was used to detect *H pylori* by urease test. DNA was extracted by the standard proteinase K-sodium dodecyl sulfate (SDS) method and purified with phenol-chloroform. Total RNA was extracted with TRIzol reagent (Gibco BRL, Gaithersburg MD, USA) according to the manufacturer's instructions. The tissue sections were used for histopathological diagnosis, *in situ* hybridization (ISH) and immunohistochemical analysis.

Detection of EBV infection

The cases positive for EBV DNA by PCR-Southern blot assay were further confirmed by ISH for EBER1 as previously described[6]. The cases with EBER1 positive signals were classified as EBVaGC group.

Detection of H pylori infection

The resected tissues were used to detect *H pylori* infection by urease test kit. Simultaneously, PCR was used to detect 16 sRNA of *H pylori*. The specific primers were designed as previously described[9]. The sequence of sense primer is 5'-CTGGAGAGACTAAGCCCTCC-3', and that of antisense primer is 5'-ATTACTGACGCTGATTGTGC-3 '. The PCR products were 109 bp. Three microliter DNA was added into a solution containing 200 μmol/L dNTPs, 0.5 μmol/L each primer, 1.5 mmol/L $MgCl_2$ and 1 U Taq DNA polymerase (Promega, USA) in a total volume of 25 μL. PCR was carried out under the following conditions: first denaturation at 94℃ for 5 min; then denaturation for 30 s at 94℃, annealling for 30 s at 55℃, extension for 45 s at 72 ℃ in 35 amplification cycles; and finally extension for 5 min at 72℃. The amplified products were electrophoresed in 2% agarose gel and visualized by ethidium bromide staining and ultraviolet illumination. DNA from the culture of *H pylori* was used as positive control, and that from human leukocyte as negative control.

Immunohistochemistry

Paraffin-embedded sections of tissues from EBVaGC cases and 45 cases of EBVnGC with similar clinicopathological data were immunostained by the standard streptavidin-biotin-peroxidase method. Anti-human mouse polyclonal antibodies against c-met and anti-human mouse monoclonal antibodies 9E10 against c-myc (Santa Cruz Biotechnology Inc) were used as primary antibodies. Phosphate buffered saline (PBS), instead of the primary antibody, was used for negative control sections. The sections of breast carcinoma tissue with highly expressed c-met and c-myc served as the positive controls. The percentage of positively stained tumor cells in each tumor section was evaluated by counting at least 1 000 cells in 10 randomly selected high-power fields. Brown staining for c-myc was located in nuclei, staining for c-met protein was located in both membrane and cytoplasm. The section was considered as expressing the protein if cellular staining ⩾5%, following the methods described previously [10,11]. c-met positivity was divided into three grades: 5%-30%, 30%-50% and >50%. Positive cells >30% (++) was regarded as overexpression.

RT-PCR and Southern hybridization analysis for EBV genes expression

According to the methods previously described[12], RT-PCR and Southern hybridization were used to detect the expression of nuclear antigens (EBNAs) 1 and 2, latent membrane protein (LMP) 1, early genes BARF1 and BHRF1 in EBVaGC cases. cDNAs from EBV-immortalized lymphoblastoid cell lines (LCL) were used as positive controls, and those from EBV-negative Ramos cells as negative controls. The integrity of RNA was checked by parallel amplification of endogenous control gene glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA.

Statistical analysis

Qualitative data were analyzed by χ^2 test or the Fisher's exact test (two-tail). Quantitative data were expressed as mean±SD and compared between the 2 groups by Student' s *t*-test or *t'*-test. $P<0.05$ was considered statistically significant. Software SAS 6.12 was employed to process the data.

RESULTS

Detection of H pylori infection

H pylori infection in 185 gastric carcinomas was assessed by rapid urease test and PCR. The samples

with positive PCR and urease test were defined as *H pylori*- positive. No difference was found in sex, age, pathological differentiation, clinical stages or lymph node metastasis between *H pylori*-positive and *H pylori*-negative gastric carcinomas. However, the location of tumor was significantly different between the two groups (χ^2=13.817, P=0.003). The positive rate of *H pylori* infection in the antrum gastric carcinomas was higher than that of cardia and body gastric carcinomas (q=4.528, P=0.005; q=3.681, P=0.010) (Table 1).

Detection of EBV infection

The positive rate of EBV in 185 gastic carcinomas was 7.03% (13/185). Age, pathological differentiation, clinical stages, lymph node metastasis and location of cancer were not different between EBV-negative gastric carcinomas (EBVnGC) and EBVaGC (P=0.669, 0.141, 0.259, 0.818, 0.064, respectively), while sex was significantly different between the two groups (χ^2=3.940, P=0.047) (Table 2).

Relationship of EBV and H pylori

The positivity of *H pylori* in EBV-positive and EBV-negative gastric carcinomas was 46.15% (6/13) and 81.40%(104/172) respectively. There was no significant correlation between EBV and *H pylori* infection (χ^2=1.027, P=0.317, r=-0.075) (Table 3).

Immunohistochemistry of c-met and c-myc

Forty-five cases of EBVnGC with similar clinicopathological data were chosen as the control group. No statistical difference was found in age, sex, tumor location, histological subtype, stage, or lymphnode metastasis between the two groups [12]. Immunostaining results of c-met and c-myc are shown in Figure 1. The c-myc and c-met expression was 61.5% (8/13) and 76.9% (10/13), and c-met overexpression was 69.2% (9/13) in EBVaGC group, while they were 55.6 (25/45), 64.4% (29/45) and 37.8% (17/45) respectively in EBVnGC group. The difference in c-met overexpression between EBVaGC and EBVnGC was significant. However, the difference in c-myc and c-met expression between the two groups was not significant (Table 4).

Expression of EBV-associated genes in EBVaGC

We investigated the expression of EBV-associated genes in 13 EBVaGC cases by RT-PCR and

Southern hybridization analysis (Figure 2). The transcripts of EBNA1 were detected in all 13 cases, while neither EBNA2 nor LMP1 mRNA was detected. Six of the 13 cases exhibited BARF1 transcripts and 2 exhibited BHRF1 transcripts. GAPDH mRNA was amplified to check pertinent RNA extraction. The result showed that the RNA was in integrity.

DISCUSSION

H pylori is believed to be a carcinogen of gastric carcinoma. Recently, it was found that EBV is also linked with the development of partial gastric carcinomas. In this study, we simultaneously detected the status of EBV and *H pylori* infection in gastric carcinomas. No statistical relationship was found between *H pylori* infection rate and sex, age, pathological differentiation, clinical stages and lymph node metastasis. However, the positive rate of *H pylori* infection in the antrum gastric carcinomas was higher than that of cardia and body gastric carcinomas. These results are consistent with those of previous studies[1,13]. In our series, age, pathological differentiation, clinical stages, lymph node metastasis and location of cancer were not different between EBVnGC and EBVaGC, while the positive rate of EBV in male patients was significantly higher than that of female patients. Eleven cases of EBVaGC were low differentiated adenocarcinoma, and 8 cases of EBVaGC were body or cardia cancer. Although no statistical difference was found, it revealed a tendency that included predominance of cardia/body location and low differentiated adenocarcinoma. It remains controversial whether there is a significant clinicopathologic difference between EBVaGC and EBVnGC. Several reports showed that EBVaGC was characterized by male predominance, preferential location in proximal stomach, and a high prevalence of low differentiated adenocarcinoma[14,15]. Wu *et al*[2] found EBV-positive lymphoepithelioma-like carcinoma (LELC) showed less node metastasis and higher survival rate, and tended to be at cardia/body location in contrast to EBV-negative gastric carcinomas, while no significant clinicopathologic difference was found between EBV-positive ordinary gastric carcinoma and EBV-negative gastric carcinoma.

In the present study, no significant correlation between EBV and *H pylori* infection was found in gastric carcinomas. Currently, only a few studies have investigated the effect and interaction of EBV and *H pylori* infection in gastric carcinomas, but no conclusive results have been

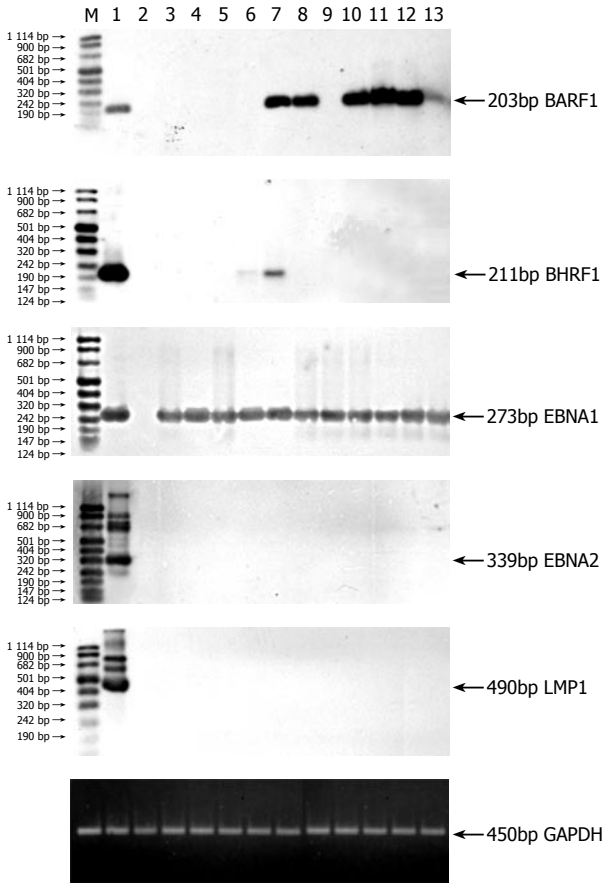

Figure 2 Detection of EBV-associated gene expression by RT-PCR and Southern hybridization in EBVaGC. M: DIG-labeled DNA molecular weight marker VIII (Roche); lane 1: EBV-positive LCL (positive control); lane 2: EBV-negative Ramos cells (negative control); lanes 3-13: EBV-positive gastric carcinoma samples.

reported[2,16-18]. Levine *et al*[16] documented that specific IgG antibody levels against *H pylori* in 39 EBV-negative gastric carcinomas were significantly higher than those of 5 EBV-positive gastric carcinomas. It was thus inferred that an inverse relationship between specific IgG titer against *H pylori* and EBV status existed. In the present study, the positivity of *H pylori* in EBVnGCs was higher than that of EBVaGCs, but no reverse correlation is found between EBV infection and *H pylori* infection. Wu *et al*[2] found EBV was detected in 11 (100%) gastric LELC and 19 (13.7%) of 139 non-LELC. Compared with the EBV-negative gastric carcinomas (68.4%) and EBV-positive non-LELC (68.3%), EBV-positive gastric LELC had a significant lower positive rate of *H pylori* IgG (36.4%). This finding implicates that there is a tendency for gastric LELC, with the high frequency of EBV and predominant proximal location, to have less association with *H pylori* infection than the other two groups, and also suggests that EBV may play a role in *H pylori*-seronegative gastric carcinomas, especially those located at the proximal stomach. Same results were found in other two reports[19,20]. Our result showed that in ordinary non-LELC gastric carcinomas, *H pylori*-positive gastric carcinoma is predominant in antrum location, while EBVaGC has a tendency of predominance in cardia/body location. Several studies found equal *H pylori* infection and distribution of intestinal metaplasia and atrophic gastritis among EBV-positive and -negative gastric carcinomas, indicating that EBV and *H pylori* may play roles together in the pathogenesis of gastric carcinomas. Chronic atrophic gastritis and subsequent intestinal metaplasia caused by *H pylori* infection enhances the susceptibility of EBV to gastric mucosal epithelia, and then EBV facilitated the carcinogenesis of gastric carcinoma[17,18].

Many studies have been focused on the relationship between EBV and the oncogenes or tumor suppressor genes in the carcinogenic mechanism of EBV. c-met protein is a receptor for hepatocyte growth factor (HGF), also known as scatter factor (SF), a tyrosine kinase encoded by the proto-oncogene c-met. HGF/SF-met signaling has been shown to affect a wide range of biological activities in mammalian cells, including cellular proliferation, migration, invasion, morphogenesis, and angiogenesis[21,22]. The oncogene c-myc also has numerous biological activities, such as transformation, immortalization, blockage of cell differentiation and induction of apoptosis[23]. Amplification and abnormal expression of oncogenes of the c-myc and /or c-met are involved in the development of tumor. In this study, EBVaGC had a higher rate of c-met overexpression than EBVnGC, however the difference in c-myc and c-met expression between the two groups was not significant, indicating that EBV infection induces c-met over-expression. The results are inconsistent with previous studies[11,24-30]. The study about the amplification and expression of c-met oncogene and EBV infection in tumor tissues has been little reported, majoring in lymphoproliferative disorder such as Hodgkin's disease (HD). Kijima *et al*[24] found the amplification and overexpression of c-met in EBV-positive and -negative gastric carcinomas did not differ significantly. Teofili *et al*[25] also reported c-met expression was independent of the presence of EBV in HD patients. However, Weimar *et al*[26] found a strong correlation between the expression of the c-met proto-oncogene and EBV infection in patients with HD. Six out of eight EBV-positive samples from HD patients expressed c-met protein, while none of the 10 EBV-negative samples from HD expressed c-met. Furthermore, circulating B lymphocytes,c-met-negative, express c-met after infection by EBV. In the same way, no consistent results were found in the study of c-myc expression in EBV-associated tumor. Several studies showed that EBV facilitates the development of tumor by inducing c-myc and inhibiting p53 expression[27-29]. However, Park *et al*[30] found that significant increase of c-myc gene copy numbers was only found in 12 out of 31 non-Hodgkin's malignant lymphomas (MLs) (38.7%), in which 6 cases were EBV positive and 6 cases were EBV negative, indicating c-myc gene amplification did not correlate with EBV infection. Ishii *et al*[11] found c-myc expression in early stage of EBVaGC was higher than that of EBVnGC, while the c-myc expression in advanced stage of EBVaGC was lower than that of EBVnGC. It was inferred that EBV might cause the host cell to induce c-myc expression and inhibit p53 overexpression in the initial development of the cancers (early stage), but then influence c-myc expression negatively in advanced

stage cancers, making them less likely to have a natural regression via apoptosis. In the present study, most of the samples were advanced stage gastric carcinomas. Apparently, it could not infer whether EBV induces c-myc expression in early stage EBVaGC, but it was certain that EBV does not inhibit c-myc expression in advanced stage EBVaGC.

Some *in vitro* and *in vivo* studies have shown that EBV-encoded genes, such as LMP1, EBNA, BHRF1 and BARF1, can interact with oncogenes and tumor suppressor genes in the carcinogenesis of tumor[28,31,32]. LMP1 are the essential genes for cell transformation. LMP1 can induce c-met expression through the activation of Ets-1 transcription factor *in vitro*, which may contribute in part to the highly metastatic potential of NPC[31]. The expression of c-myc can be induced by LMP1 and EBNA2 *in vitro* and *in vivo*[28, 29, 32, 33]. Our study and other studies failed to detect LMP1 and EBNA2 mRNA in EBVaGC[6-8], suggesting that LMP1 and EBNA2 may not be essential for EBVaGC formation and may not be related with c-met and c-myc expression in EBVaGC. EBV early gene BHRF1 shows partial sequence homologous to the human bcl-2 proto-oncogene, which is involved in inhibiting cell apoptosis. BHRF1 protein can inhibit apoptosis of B lymphocytes and epithelial cells and promote cell growth and transformation[34,35]. BARF1 shares homology with the cellular proto-oncogene c-fms and is able to immortalize epithelial cells and fibroblast cells and B lymphocyte *in vitro*[8,36,37]. Furthermore, it can activate the expression of bcl-2[38]. We demonstrated that 6 of 13 EBVaGC cases exhibited BARF1 mRNA and 2 exhibited BHRF1 mRNA. Zur Hausen *et al*[8] also detected 9 BARF1-positive cases and 2 BHRF1-positive cases in 10 EBV-related gastric adenocarcinomas. Because EBVaGC lacks the expression of LMP1[6-8], BARF1 and BHRF1 might provide an alternative way for the pathogenesis of EBVaGC independent of LMP1. *In vitro* studies showed that BARF1 can activate the expression of c-myc in BARF1 transformed cells, and EBNA1 and c-myc cooperate in lymphomagenesis[38,39]. In our study no correlation was found between c-met and c-myc expression with the expression of BARF1 or BHRF1 in 13 EBVaGCs. So further study is needed to elucidate the relationship of EBV infection and EBV-encoded proteins with expression of c-met and c-myc.

In summary, this study shows that *H pylori* infection is closely linked to the distal location gastric carcinoma, but EBVaGC is predominant proximal location. No correlation exists between EBV infection and *H pylori* infection in the development of gastric carcinomas. EBV infection is associated with c-met abnormal expression but not with c-myc protein in EBVaGC. c-met overexpression is not induced by LMP1. BARF1 and BHRF1 may play important roles in tumorigenesis of EBVaGC through different pathways.

Abstract

AIM: To evaluate the long-term outcome of standard 5-FU based adjuvant or neoadjuvant radiochemotherapy and to identify the predictive factors, especially anemia before and after radiotherapy as well as hemoglobin increase or decrease during radiotherapy.

METHODS: Two hundred and eighty-six patients with Union International Contre Cancer (UICC) stage II and III rectal adenocarcinomas, who underwent resection by conventional surgical techniques (low anterior or abdominoperineal resection), received either postoperative ($n = 233$) or preoperative ($n = 53$) radiochemotherapy from January 1989 until July 2002. Overall survival (OAS), cancer-specific survival (CSS), disease-free survival (DFS), local-relapse-free (LRS) and distant-relapse-free survival (DRS) were evaluated using Kaplan-Meier, Log-rank test and Cox's proportional hazards as statistical methods. Multivariate analysis was used to identify prognostic factors. Median follow-up time was 8 years.

RESULTS: Anemia before radiochemotherapy was an independent prognostic factor for improved DFS (risk ratio 0.76, $P = 0.04$) as well as stage, grading, R status (free radial margins), type of surgery, carcinoembryonic antigen (CEA) levels, and gender. The univariate analysis revealed that anemia was associated with impaired LRS (better local control) but with improved DFS. In contrast, hemoglobin decrease during radiotherapy was an independent risk factor for DFS (risk ratio 1.97, $P = 0.04$). During radiotherapy, only 30.8% of R0-resected patients suffered from hemoglobin decrease compared to 55.6% if R1/2 resection was performed ($P = 0.04$). The 5-year OAS, CSS, DFS, LRS and DRS were 47.0%, 60.0%, 41.4%, 67.2%, and 84.3%, respectively. Significant differences between preoperative and postoperative radiochemotherapy were not found.

CONCLUSION : Anemia before radiochemotherapy and hemoglobin decrease during radiotherapy have no predictive value for the outcome of rectal cancer. Stage, grading, R status (free radial margins), type of surgery, CEA levels, and gender have predictive value for the outcome of rectal cancer.

INTRODUCTION

An improved therapeutic strategy for stage II and III rectal adenocarcinomas is urgently needed because up to 30% of patients still develop recurrent disease after curative surgical resection[1]. Several studies are ongoing aiming at evaluation of new multimodality treatment strategies[2]. However, pelvic radiotherapy *per se* is nowadays undisputed and accepted as standard therapy in all trials concerning locally advanced rectal cancer. The current standard treatment is the result of two independent, multi-institutional, prospective randomized trials more than 12 years ago by the Gastrointestinal Tumor Study Group

(GITSG 7175) in 1985[3] and the North Central Cancer Treatment Group (NCCTG 79-47-51) in 1991[4]. Both studies demonstrated that combined radiotherapy and chemotherapy following surgical resection of stage II and III rectal cancer can improve the overall survival. These results have prompted the National Institute of Health to publish the NIH Consensus recommending postoperative radiochemotherapy for stage II and III tumors.

Anemia has been shown to have impact on the rate of local control or distant metastasis of other tumor entities[5, 6]. To identify such prognostic factors and to evaluate the outcome of preoperative or postoperative radiochemotherapy, we conducted a retrospective study including 286 patients with stage II and III rectal carcinoma treated with radiochemotherapy in the Department of Radiotherapy at the University Hospital Freiburg from 1989 until 2002.

MATERIALS AND METHODS

Patient cohort

The retrospective study enrolled patients with stage II or III rectal cancer who were treated with pre- or postoperative adjuvant radiochemotherapy between January 1989 and July 2002. Pretreatment evaluation included complete blood test, chemistry profile, determination of carcinoembryonic antigen (CEA), chest radiography, liver ultrasonography and computer tomography (CT) of abdomen and pelvis[7]. Tumor location was divided in to the lower third (less than 7 cm from the anal verge), the middle third (less than 12 cm) and the upper third (12 or more than 12 cm) according to Phang *et al*[8]. However, there are other definitions[9], and even the anatomic length of the rectum is unclear[10]. If patients suffered from other diseases leading to a Karnofski lower than 80, these patients were counted as having "other serious disease(s)". Concerning survival a complete set of data were available. But due to the missing data about hemoglobin during radiotherapy, the effect of anemia (haemoglobin <120 g/L in women or <130 g/L in men) was analyzed using a subgroup of 192 patients with complete patient documentation.

Multi-modal therapy

According to the surgical reports from the different hospitals, all patients were treated with standard surgical technique. Total mesorectal excision (TME) was performed in all patients with abdominal-perineal resection (APR) but less consequently and not quality-controlled in patients with low anterior resection (LAR). If proximal and distal surgical margins were microscopically free of tumor, the patients were defined as "radically resected" (R0). According to the patient documentation analyzed, the circumferential margins were not systematically assessed. The scheduled radiotherapy delivered 45 - 56 Gy in 25 - 31 sessions using 6 / 18 MeV linear accelerator. The treatment included two parallel opposing right and left portals (using wedges with 40 or 50 % absorption) and a dorsal field. These three (or four, if external iliac lymph nodes were included) field box arrangements were used, representing the generally approved radiotherapeutic scheme during the retrospective study[11]. The upper margin was fixed 1.5 cm cranial of the promontorium whereas the lower margin was chosen depending on the exact tumor localization. The lower margin including the perineal scar (if the tumor was located less than 8 cm from the anal verge or if abdominoperineal resection was performed), was marked by the tuber ischiadicum (between 8 and 12 cm above the anal verge), or covered by the lower border of the obturator foramen (12 cm above the anal verge). The width of posteroanterior portals covered the pelvic inlet with 2 cm margin. Radiotherapy was administered with cycles 1 and 2 instead of cycles 3 and 4 as recommended by the NIH[12], renewed by the 1996 Patterns of Care Rectal Cancer Committee[13]. In the NCCTG study, cycles 1 and 2 of 5-FU plus semustine were given, followed by pelvic radiotherapy plus chemotherapy.

Depending on their R status, patients were treated with combined modality therapy either according to the NIH recommendations[12] or to the protocol[14] of the Arbeitsgemeinschaft Radioonkologie (ARO) of the German Cancer Society. Patients with no evidence of microscopical residuals of the disease (R0 resection) were treated according to the NIH protocol[12]. Following R1 or R2 resection, patients were treated according to the ARO protocol. When the NIH protocol was used, the concurrent bolus 5-FU was given at a daily dose of 500 mg/m² for 3 d during cycles 1-3, the following three cycles were given for 5 d. When the ARO protocol was used, patients received 350 mg/m² 5-FU iv continuously during 24 h for 14 d. Additionally, bolus of 200 mg/m² leucovorin and 4 mg/m² mitomycin C, was given daily for 1 h. In both protocols radiotherapy and chemotherapy were started simultaneously.

Statistical analysis

The data were analyzed using SAS. The statistical methods included Student's *t*-test, Chi-square test, and Kruskal-Wallis-test. Survival was analyzed using univariate and multivariate methods (step down analysis). Kaplan-Meier curves[15] were used to estimate the distribution of overall survival (OAS), cancer-specific survival (CSS) and disease-free survival (DFS). For analysis, the rates of treatment failure were adjusted, local-relapse-free survival (LRS) and distant-relapse-free survival (DRS) were determined as life table analysis referring to freedom of locoregional relapse and freedom of distant recurrence (metastasis). LRS was defined as the rate of local control. Log-rank test (Cox-Mantel) was used to compare the survival distributions between different patient subgroups[16]. Multivariate analysis and proportional hazard models[17] were used to determine the prognostic factors with significant impact on survival, including hemoglobin effect, grading, staging, adjuvant therapy, surgical method and tumor marker.

RESULTS

Two hundred and eighty-six patients (186 men and 100 women) fulfilled the inclusion criteria and were enrolled in the study (Table 1). Their age ranged from 30 to 84

Table 1 Patient characteristics

years (median 62 years). The distribution of stages was as follows: 92 patients (32.2%) were assigned to stage II (lymph node negative) and 194 (67.8%) to stage III (lymph node positive). One hundred and forty-six patients (51.0%) were treated with low anterior resection (LAR), 140 patients (49.0 %) with abdominoperineal resection (APR). According to the surgical reports from different hospitals, all patients were treated with standard surgical technique. Total mesorectal excision (TME) was performed in all patients with APR but less consequently and not quality-controlled in patients after LAR. Two hundred and thirty four patients (81.8 %) were defined as R0 (Table 1). Sixteen patients were known to have oncological diseases in their histories. Other severe diseases referred to cardial ($n = 62$), pulmonary ($n = 5$), hepatic or gastric ($n = 18$), psychiatric diseases ($n = 8$), or diabetes ($n = 6$).

Survival and life table analysis

The calculated overall 5-year survival (OAS) of all stage II and III patients was 47% (Figure 1 and Figure 2), the 10-year survival was 36.3%. The cancer-specific survival (CSS) and disease-free survival (DFS) decreased from 60.0% and 41.4% respectively to 52.0% and 34.9 % between 5 and 10 years (Table 3). Local-relapse-free survival (LRS) was 67.2% (5 years) and 65.7% (10 years), distant-relapse-free survival (DRS) was 84.3% (5 and 10

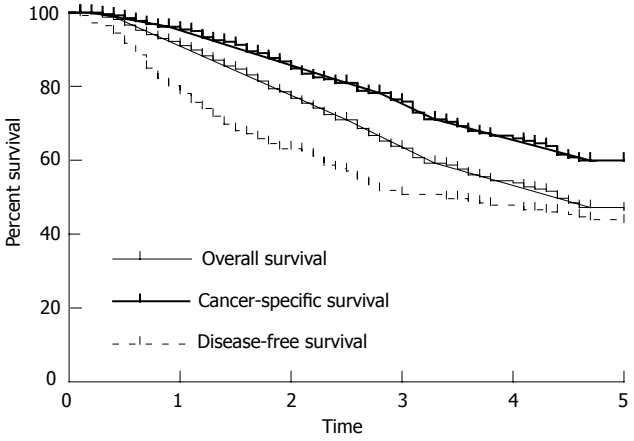

Figure 1 Kaplan-Meier curves of OAS, CSS and DSF.

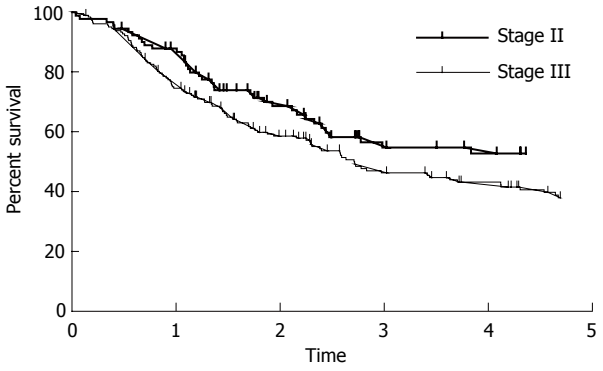

Figure 2 Log-rank test of staging (5-year disease-free survival, $P = 0.015$).

Table 2 Anemia and hemoglobin values during radiotherapy (subgroup analysis of 192 patients)

Anemia after RT			
No	102 (62.2)	8 (28.6)	110 (57.3)
Yes	62 (37.8)	20 (71.4)	82 (42.7)
Hemoglobin during RT			
Hb increase	106 (64.6)	10 (35.7)	116 (60.4)
Hb decrease	58 (35.4)	18 (64.3)	76 (39.6)

years). The mean overall survival time was 4.4 years and the mean disease-free survival time was 2.73 years. The mean follow-up time was 8 years.

Survival and patient characteristics

Complete data about hemoglobin were available from 192 patients. When this subgroup (Table 2) was analyzed, anemia was found in 52.1% of the patients. Of the patients who received adjuvant radiotherapy, 64.6% showed increased hemoglobin during radiotherapy compared to 35.7% of the patients who were treated neoadjuvantly. Patients showed more frequently anemia if they were older than the median age or if R0 resection was performed. Anemia after radiotherapy was less frequently seen if postoperative radiotherapy was given instead of preoperative radiotherapy (37.8% *vs* 71.4%, respectively) or if low anterior resection (LAR) instead of abdominoperineal resection (APR) was performed (36.8% *vs* 51.4%, respectively), while 43.8% of the patients with stage III tumors showed increased hemoglobin during radiotherapy compared to 30.0% of the patients with stage II tumors (Table 7). Furthermore, patients less frequently suffered from increased hemoglobin if they received postoperative radiochemotherapy or their tumors underwent R0-resection. Decrease of hemoglobin was found to be an independent risk factor for DFS with a risk ratio of 1.97 (CI 1.02 - 3.43). Conversely anemia before radiotherapy had a risk ratio of 0.76 (CI 0.57 - 0.99) (Table 6).

Tumor grading was found to be an independent prognostic factor for CSS and DFS (Table 3). The overall 5-year survival rate of patients with stage III tumors was about 10% compared to patients with stage II tumors (50.6% *vs* 40.7%; $P = 0.023$) (Table 3). Patients with stage II tumors showed a 5-year overall survival of 57 % (CSS: 65.8%; DFS: 53.3%) whereas patients with stage III tumors showed a 5-year overall survival of 42.6% (CSS: 57.2 %; DFS: 36.3%). Univariate analysis showed that the N stage was found to be significant for OAS and CSS ($P = 0.06$). The patients' gender was found to be an independent factor for LRS. The 5-year LRS for female was significantly worse than that for males (56.8% *vs* 73.1%). No dependency between tumor location and outcome could be seen (Table 5). Tumor adherence to adjacent structures predicted survival (OAS $P < 0.001$, CSS $P = 0.004$, DFS $P < 0.001$, DRS $P = 0.019$) regardless of the surgical method, but was not significant for LRS ($P = 0.13$).

Survival and treatment characteristics

The overall survival did not vary depending on the radiotherapy treatment type (either pre- or post-operative radiotherapy) (Table 4). Neither gross nor microscopic evidence of disease could be achieved in 37 of 53 (69.8%) preoperatively irradiated patients, and in 197 of 233 (84.5%) of postoperatively irradiated patients. Sphincter-saving surgery could be performed in 24.6% of patients receiving preoperative radiotherapy and in 56.8% of the patients receiving postoperative radiochemotherapy.

Multivariate analysis showed that R status (R0 *vs* R1/2) was an independent prognostic factor for disease-free survival (risk ratio 3.45, CI 1.56 -7.96) whereas surgical method (low anterior or abdominoperineal resection) was an independent prognostic factor for local control, determined as LRS (risk ratio 1.3, CI 1.01-1.60) (Table 4). Chi-square test showed no significant relationship between surgical method and staging ($P = 0.93$) or R status ($P = 0.07$) but a significant relationship between R status

side effects (Table 1), while 89 (31.1%), 55 (19.2%), 13 (4.5%), and 3 (0.7%) patients had RTOG grade I, II, III or IV side effects, respectively. Diarrhoea, dysuria and skin reaction were the leading problems whereas other side effects were rarely reported.

DISCUSSION

Concerning the outcome of rectal cancer, patients with younger age, lower stage, tumor grading GII or better, no elevated tumor markers, and a higher distance from the anal verge may fare better[8, 18, 19]. There is also some evidence that R0 resection, no adherence to adjacent structures, and lower anterior resection (LAR), performed with quality-controlled total mesorectal excision (TME), are beneficial factors for the local control whereas positive lymph nodes are risk factors mainly for distant metastases. The impact of radiotherapy is still debated. Moreover, valid data from other tumor entities suggest that anemia may have predictive value for local relapse or distant recurrence[5, 6]. At the Department of Radiotherapy, University Hospital Freiburg from 1989 to 2002, 286 patients with stage II or III cancer were treated and qualified for our retrospective study analyzing patient- or treatment-related variables and their impact on treatment outcome. This study, however, has some limitations mainly due to lack of data about the quality of surgery and incomplete patient documentation. Therefore, the extent and quality of total mesorectal excision could not be assessed. The impact of anemia on 192 patients with complete data about hemoglobin during radiochemotherapy was analyzed.

The overall 5-year survival rate (47.0%) and disease-free survival rate (41.1%) were lower than those of other large randomized trials[3, 4]. It is known that the outcome of therapeutic interventions obtained in studies usually exceed "the reality" of population-based reports of cancer treatment[21]. The rate of distant recurrence (16.7%) was slightly lower in our patient cohort than that reported in literature (Table 4), which may be due to the modified sequence of radiochemotherapy. This scheme of early radiochemotherapy can achieve significantly improved rates of local recurrence and distant metastasis[22], suggesting that early radiotherapy as performed in our study is more effective concerning local control and consequently more effective concerning distant outcome.

The Mayo study and other studies are influenced by a local relapse rate of about 30 %[3, 4]. These studies could reflect the situation before the "era" of trained and quality-controlled total mesorectal excision. Similarly, we found that a local recurrence rate of 32.8% (local-relapse-free survival of 67.2%) is consistent with current literature[23]. After conventional and non-standardized surgery, local recurrence was 15%-55%[24-26]. However, it was reported that the 5-year local control rate was higher than 90 %, even without chemotherapy or any adjuvant treatment[27-29].

Tumor adherence to the adjacent structures can predict local recurrence and survival[30-32]. Consistent with these data, the Freiburg patient cohort including 286 cases showed that all survival rates (OAS, CSS, DFS) were associated with tumor adherence. This may be due to the effect of sample size or support the contention that out-spread of the gross tumor should be estimated as an important indicator for systemic tumor progression leading to worse outcome. According to this, it has been recently shown that even among N2 patients (4 or more positive lymph nodes), T stage influences overall 5-year survival[22]. Furthermore, T and N classifications can predict survival, but only N stage is correlated with local recurrence[30]. On the contrary, in our retrospective study N stage was significant for overall survival ($P=0.009$) and cancer-specific survival ($P=0.05$), whereas a trend for local recurrence ($P=0.09$) and disease-free survival ($P=0.06$) could be seen.

When an average radiation dose of 50 Gy is used for preoperative or postoperative radiochemotherapy, patients classified as N0 have better results than N positive ones[33]. Similarly, analysis of eligible patients has confirmed the effect of N stage[19]. Notably our data suggest that N positive patients are even more substantially at risk for local failure rather than for distant metastasis. Apparently, spread-out to lymph nodes indicates a more aggressive nature of local tumor growth. Concerning treatment intervention, these results support the hypothesis that sterilization of tumor cells in lymph nodes could be achieved in many patients, preventing them from distant metastasis. As a consequence, this contradicts to any efforts to minimize radiation fields. Only if adequately included in the radiation field, the tumor cells in regional

lymph nodes can be killed.

In the present study, when anemia and hemoglobin were analyzed, conflicting results were obtained from the multivariate analysis. When hemoglobin values decreased during radiotherapy it meant to be a risk factor for patients, possibly indicating bad performance status, prolonged convalescence, side effects of therapy or progressive disease (Table 7). But anemia had a risk ratio of 0.76 for DFS (Table 6), suggesting that rectal cancer patients with anemia before radiotherapy have better results than patients without anemia. Considering the adjuvant setting at a time interval of 3 - 5 wk between surgery and radiochemotherapy, anemia can be regarded as a consequence of a more radical surgical intervention. This hypothesis is supported by the analysis of 192 patients with complete data about hemoglobin during radiochemotherapy: 60.0% of patients after R0-resection had anemia compared to 55.6% of patients after R1/2-resection. After radiotherapy only 42.5% patients after R0-resection still had anemia compared to 44.4% patients after R1/2-resection. Only 30.8% patients after R0-resection suffered from hemoglobin decrease during radiotherapy compared to 55.6 % patients after the R1/2-resection, suggesting that R status is an independent prognostic factor for disease-free survival. According to our data, anemia before radiochemotherapy or hemoglobin decrease during radiotherapy does not imply any predictive value for the outcome of rectal cancer. It should be considered as a readout of age, stage, type of surgical resection, or performance status. Taken together, if there is any hemoglobin effect on the outcome of rectal cancer, it is completely biased by the extent of surgical intervention, which is one of the most important predictors for the outcome of rectal cancer.

Multivariate analysis of our data revealed that tumor grading was the most important prognostic factor for CSS and DFS. In a retrospective study of 214 patients with primary rectal carcinoma, Luna-Perez *et al*[33] have identified well-differentiated cancer as a prognostic factor for achieving local control. Martijn *et al*[31] also found that tumor grading has a prognostic value, which is consistent with our study. We found that there was no significant difference in survival rate regarding tumors in the lower, middle or upper third. Thus, the hypothesis that tumor location influences response rate or survival is not supported by our data. Phang *et al*[8] reported that survival is affected by tumor distance from the anus. Lower distance significantly can worsen survival and distant recurrence rate but not the rate of local recurrence. Finally, an independent detrimental influence on local recurrence has been proved by a retrospective study of 197 patients, using conventional resection technique[32].

By analyzing the influence of the resection type, we revealed a better control rate of local relapse (34%) if the patients were treated by low anterior resection (LAR) compared to abdominoperineal resection (APR). Out data are consistent with a study of Stocchi *et al*[30] showing a better rate for LAR (28%) but not with a study of Kuru *et al*[32] who identified anterior resection as a negative independent prognostic factor for local control. However, Stocchi *et al*[30] stated that the overall rate of local recurrence (16%) is unexpectedly low in their study, considering the high-risk patient cohort and the data from literature. Unlike this, our data (32.8 % local recurrence in five years) could obviously reflect the "surgical reality today"[34] or, more accurately, the surgical results in the era (Table 6) before comprehensive surgical quality control of TME[36].

In the Freiburg cohort male gender was found to be an independent prognostic factor for local recurrences. No difference was found in OAS, CSS, DFS and DRS. It was reported that DFS and local recurrence do not differ significantly in gender, but differ significantly in OAS with a risk ratio 1.2 ($P=0.03$) for men. Furthermore, increased grade III or IV toxicity in females has been described. As in our study, no interaction between sex and age was seen. Therefore sex as an indicator for higher age can be ruled out. Studies evaluating psycho-oncological aspects have identified gender-related factors which influence cancer treatment and outcome[38]. However, if sex difference has any significant impact on outcome, this effect seems to be inconsistent and may be influenced by local differences in lifestyle or environmental factors.

Among the patients-related factors, age is known to be crucial, because administration of adjuvant chemotherapy to patients aged over 70 years remains a difficult choice for the clinicians with respect to the expected benefit versus toxicity. Sargant *et al*[39] and Popescu *et al*[40] showed that old patients (with good performance status and renal and hepatic function) share the same benefit from adjuvant chemotherapy as younger patients without increasing toxicity. CEA and CA 19-9 levels are reliable tumor markers for rectal cancer[18, 41, 42]. In our study, the prognostic value of CEA could be shown by uni- and multivariate analysis. Additionally, the increase of CEA during radiotherapy indicated a decreased survival rate. Our results are consistent with that of Behbehani *et al*[43], who demonstrated that patients with preoperatively elevated CEA levels have a 2-year DFS of 23% whereas patients without CEA elevation have a 2-year DFS of 71%.

Our retrospective review of the Freiburg patient cohort did not detect any difference between preoperative and postoperative radiochemotherapy. Cancer-specific survival was 62.6% and 59.0%, respectively. Our data correspond to Rinkus *et al*[34] who reviewed 292 patients showing no significant difference in survival between preoperative versus postoperative radiotherapy (combined with chemotherapy in 66% and 48% of the cases, respectively).

It was reported that preoperative radiation can significantly decrease local failure rate. The 5-year survival curve does not differ significantly between both strategies. Until now the German trial (Protocol CAO/ARO/AIO 94) is the only prospective study with patients randomized to conventional preoperative and postoperative radiochemotherapy[20]. This study showed that preoperative radiochemotherapy could improve local control and reduce toxicity but overall survival was not different between pre- and postoperative radiochemotherapy. However, our retrospective, non-randomized data might be biased as preoperative radiochemotherapy was mainly given if the tumor was inoperable. Therefore these patients were in more

advanced tumor stages. Supposing an advantage of preoperative radiochemotherapy, as shown by Sauer *et al*[20], this may explain why preoperative and postoperative radiochemotherapy seem to be equivalent according to our data.

In conclusion, new therapeutic strategies are urgently needed, preferably based on a better understanding of beneficial or disadvantageous factors determining the outcome of rectal cancer. Tumor stage, grading, R status (free radial margins), type of surgery, CEA levels, and gender are predictive factor for the outcome of rectal cancer. However, anemia before radiochemotherapy or hemoglobin decrease during radiotherapy does not imply any predictive value for the outcome of rectal cancer. It should be considered as an indicator for higher age, stage, type of surgical resection, or performance status. Any hemoglobin effect of radiotherapy on outcome of rectal cancer is completely biased by the extent of surgical intervention.

Abstract

AIM: To investigate whether Src, JAK2 and phosphatidylinositol 3-kinase (PI3K) pathways are involved in the proliferation of human colonic tumour cells induced by glycine-extended gastrin (G-gly), the precursor of the mature amidated gastrin and to elucidate the molecular interaction between these three kinases in response to this peptide.

METHODS: Using the human colonic tumour cell line HCT116 as a model, we first measured the activation of PI3K, p60-Src and JAK2 in response to G-gly by *in vitro* kinase assays. Then we investigated the involvement of these kinases in G-gly-induced cell proliferation by MTT test.

RESULTS: G-gly stimulation induced p60-Src, JAK2 and PI3K activation in HCT116. The different pathways were involved in proliferation of human colon cancer cells induced by G-gly. Furthermore, we found that both Src and JAK2 were necessary to PI3K regulation by this peptide. However, we did not find any cross-talk between the two tyrosine kinases.

CONCLUSION: Our results suggest that the p60-Src/PI3K and JAK2/PI3K pathways act independently to mediate G-gly proliferative effect on human colonic tumour cells.

INTRODUCTION

Hyperproliferation of the colonic mucosa is associated with an increased risk of tumour development, and corresponds to an early stage in the adenoma-carcinoma sequence. It is now well established that glycine-extended gastrin (G-gly), the precursor of the mature amidated gastrin, plays an important role in colonic mucosa hyperproliferation. Proliferative effects of G-gly were first described in a pancreatic tumour cell line, AR4-2J[1]. Afterwards, numerous studies have confirmed its mitogenic effects, especially on colonic mucosa, and *in vitro* studies have shown that G-gly is a growth factor for non transformed cell lines from colon origin or human colon cancer cells[2-5]. Trophic effects of G-gly have also been confirmed *in vivo* and MTI/G-gly transgenic mice overexpressing G-gly, as well as gastrin-deficient mice perfused with this peptide, display hyperproliferation of the colonic mucosa[6]. Furthermore, perfusion of G-gly into rats results in proliferation of colonic mucosal cells forming aberrant crypt foci and increases the sensitivity to azoxymethane, a colon carcinogen[7].

The p85/p110 PI3K is a lipid kinase composed of two constitutively associated subunits: p85, the regulatory subunit; and p110, the catalytic subunit. Upon stimulation, PI3K phosphorylates the D3 position of phosphoinositides leading to second messengers, namely phosphatidylinositol 3, 4 biphosphate and phosphatidylinositol 3, 4, 5 triphosphate[8]. The PI3K pathway is involved in the regulation of many cellular processes including prolifera-

tion and survival. During the last years, many studies have shown the implication of the PI3K in colon carcinogenesis. In particular, the PI3K has been found to play an important role in colon cancer development and progression by promoting cell growth and allowing cells to escape apoptosis[9]. Activation of this pathway is also involved in the progression of human colon adenocarcinoma[10].

Different groups including ours, have demonstrated the involvement of the phosphatidylinositol 3-kinase in G-gly functions. We have reported the activation of lipid kinase in response to this peptide in a pancreatic tumoral cell line, AR4-2J[11]. Afterwards, Hollande *et al*[12] have described the involvement of the phosphatidylinositol 3-kinase in adhesion and migration of gastric epithelial cells regulated by G-gly. More recently, we described the overexpression of the regulatory subunit p85 as well as an overactivation of the downstream effector Akt, in the hyperproliferative colonic mucosal epithelium of MTI/G-Gly mice[13]. Moreover, in the same study, we have demonstrated the involvement of the PI3K pathway as well as Src and JAK2 pathways in the proliferation of isolated normal murine colonic epithelial cells in response to G-gly.

Our aim here was to investigate whether these three kinases are involved in G-gly-induced proliferation of human colonic tumour cells and to elucidate the molecular interaction between Src, JAK2 and PI3K in response to the peptide. In HCT116, a human colon tumour cell line, we first measured the activation of these kinases by G-gly as well as their involvement in G-gly-induced cells proliferation. The results indicate that both p60-Src and JAK2 are necessary to PI3K regulation by the peptide. However, we did not observe any cross-talk between the two tyrosine kinases, suggesting that the p60-Src/PI3K and JAK2/PI3K pathways act independently.

MATERIALS AND METHODS

Materials

Polyclonal anti-JAK2 antibody was purchased from Upstate Biotechnology Inc. Monoclonal anti-p60-Src antibody was obtained from Oncogene Science. Rabbit polyclonal antibody specific to p85, the regulatory subunit of the phosphatidylinositol 3-kinase, was kindly provided by Drs. Y. Le Marchand-Brustel and J. F. Tanti (Nice, France). DFO, LY 294002, PP2 and AG490 were from Calbiochem. [γ-32P] ATP (7000 Ci/mmol) was from ICN. Phosphatidylinositol was purchased from Sigma.

Cell culture

HCT116, human colonic tumour cells, were grown in DMEM containing 4.5g/L glucose-glutamax, supplemented with 10% fetal calf serum at 37 ℃ in a 50mL/L CO_2 atmosphere.

Proliferation assay

Approximately 75 000 cells/well were plated into 96-well plates. Forty-eight hours after plating, cells were treated for 48 h with G-gly (10 pmol/L) with or without inhibitors (10μmol/L). MTT colorimetric assay (MTT, Sigma) was used to measure proliferation as previously described[13].

Immunoprecipitation and Western-blot analysis

HCT116 cells were serum-starved for 18 h before peptide addition. After stimulation, the cells were lysed, and the soluble fractions containing identical levels of proteins were immunoprecipitated and analyzed by Western-blot with the indicated antibodies as described previously[14]. Band intensity was analyzed using the image analyzer Biocom (France).

Src kinase assay

Src kinase activities were determined on anti-p60-Src-immunoprecipitates as previously described[15]. Briefly, kinase assay was carried out at 37 ℃ for 10 min in kinase buffer (12.5 mmol/L MnCl2, 1.25 mmol/L DTT, 25 mmol/L Hepes, pH 7.4) containing 3.75 μmol/L ATP, 10 μCi/point ATP[γ-32P]. Proteins were separated by SDS–PAGE and the gel was autoradiographied. The gels were then treated with 1N KOH at 50 ℃ for 1h and autoradiographied. Band intensity was analyzed using the image analyzer Biocom (France).

JAK2 kinase assay

JAK2 kinase activities were determined on anti-JAK2-immunoprecipitates as previously described[14]. Briefly, kinase assay was carried out at 37 ℃ for 10 min in kinase buffer (10 mmol/L MnCl2, 5 mmol/L MgCl2, 0.1 mmol/L Vn2+, 10 mmol/L Tris, pH 7.4) containing 3.75 μmol/L ATP, 10 μCi/point ATP[γ-32P]. Proteins were separated by SDS–PAGE and the gel was autoradiographed. Band intensity was analyzed using the image analyzer Biocom (France).

Phosphatidylinositol 3-kinase assay

Cell lysates were immunoprecipitated with the indicated antibodies. PI3K assay was performed on immunoprecipitates as described previously[16]. Briefly, phosphatidylinositol used as an exogenous substrate, was prepared in 5 mmol/L HEPES and then sonicated for 15 min at 4 ℃. The samples were incubated for 15 min at room temperature with phosphatidylinositol (0.2 mg/mL) and 50 μmol/L ATP[γ-^{32}P] (10 μCi/point). The reaction was stopped by adding HCl 4N and lipids were extracted using agitation in chloroforme/methanol (1/1) solution for 45 s. After centrifugation, the upper phase containing the lipids was analyzed. The phospholipids were separated by thin layer chromatography and analyzed by autoradiography. Spot intensity was analyzed using the image analyzer Biocom (France). When indicated, the cells were pretreated for 1h with 1μmol/L desferrioxamine (DFO).

Statistical analysis

Statistical analysis was carried out by Student's *t* test using GraphPad Prism.

RESULTS

Glycine-extended gastrin activated phosphatidylinositol 3-kinase

We first tested whether the p85/p110 phosphatidylinositol 3-kinase (PI3K) was activated in HCT116 cells after G-gly stimulation. Cells were treated with the peptide for varying

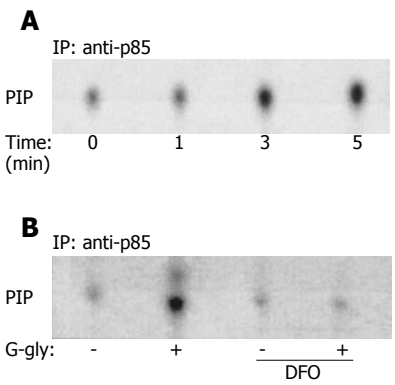

Figure 1 G-gly-induced PI3K (**A**) and G-gly (**B**) activation. HCT116 cells were stimulated with G-gly (10 pmol/L) for the indicated time. PI3K activity was determined in an immune complex kinase assay as described in Methods. The specificity of G-gly activation was accessed by pretreating the cells with ferric chelator DFO (1μmol/L). Representative autoradiograms from at least three separate experiments are shown.

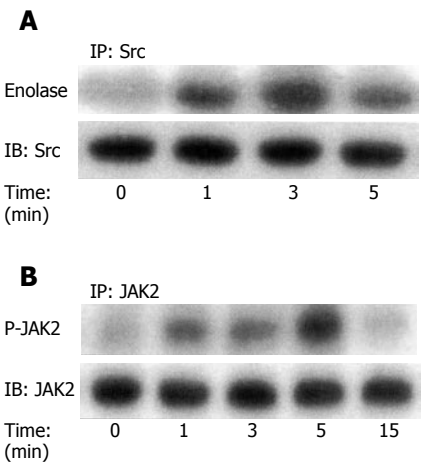

Figure 2 G-gly-induced p60-Src (**A**) and JAK2 (**B**) activation. HCT116 cells were stimulated with G-gly (10 pmol/L) for the indicated time. p60-Src and JAK2 activities were determined in an immune complex kinase assay as described in Methods. Immunoprecipitated proteins were also analysed by Western-blot using the anti-p60-Src and anti-JAK2 antibody respectively. Representative autoradiogram from at least three separate experiments is shown.

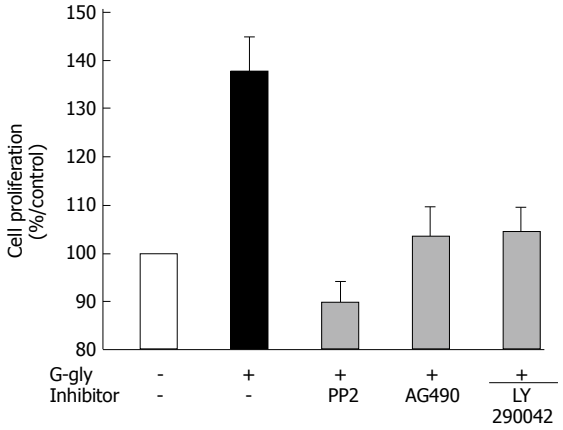

Figure 3 Role of PI3K, Src or JAK2 pathways in human colonic tumour cell proliferation induced by G-gly. Serum-starved HCT116 cells were treated with G-gly for 48h in the presence or absence of the indicated inhibitor (10 μmol/L). The proliferation was determined as described in Methods. Each point represents data from triplicate and is representative of 5 independent experiments. Data are presented as means ± SE.

lengths of time. Lipid kinase assay was performed *in vitro* on anti-p85 immunoprecipitates using inositol phosphate as an exogenous substrate. Lipids were then separated by thin layer chromatography. Increase in phosphatidylinositol phosphorylation was detected within 3-5 min after treatment with G-gly. This stimulation similar to our previous observation in pancreatic tumour cells[11], indicated that PI3K activation was also an early event of G-gly signalling in colon cancer cells. The ferric ion chelator, desferrioxamine (DFO) could inhibit both the binding of G-gly to its receptor and biological activity[17]. To test the specificity of the activation by G-gly, we performed PI3K assays after pretreatment of the cells with DF0 for 1h. DFO could completely inhibit PI3K activation in response to the peptide (Figure 1).

Glycine-extended gastrin activated tyrosine kinases p60-Src and JAK2

To investigate whether glycine-extended gastrin could regulate p60-Src activation, serum-starved HCT116 cells were treated with G-gly for various times and lysed. Tyrosine kinase assays were performed in anti-p60-Src immunoprecipitates using enolase as an exogenous substrate. Our results indicated that p60-src was very rapidly and transiently activated in HCT116 cells in response to G-gly. The activation of p60-Src was detected 1 min after peptide addition. The stimulation was maximal at 3 min and decreased after 5 min (Figure 2A).

To test whether JAK2 was activated by G-gly, lysates from cells stimulated for various times were immunoprecipitated with anti-JAK2 antibodies and *in vitro* kinase assays were performed on immunoprecipitates as described in "Methods". We observed a rapid and transient increase in JAK2 autophosphorylation in response to G-gly stimulation. The maximal activation obtained within 5 min after peptide addition decreased toward the basal level at 15 min (Figure 2B).

Involvement of JAK2, Src and phosphatidylinositol 3-kinase pathways in glycine-extended gastrin-induced proliferation

In order to identify the role of PI3K, Src and JAK2 pathways in the proliferation of human colonic tumour cells induced by G-gly, we measured HCT116 proliferation in the presence or absence of specific inhibitors for each pathway, LY290042, PP2 and AG490 respectively. Stimulation of HCT116 cells for 48h by G-gly induced a significant increase of cell proliferation (mean ± SE; 1.38 ± 0.07; $P<0.05$; $n=5$) (Figure 3). Treatment of the cells with PP2, AG 490 or LY 290042 completely inhibited G-gly-induced HCT116 proliferation while inhibitors alone did not affect basal cell proliferation (data not shown). The result indicated that these three pathways could mediate G-gly proliferative effects not only on normal colonic epithelial cells but also on human colonic tumoral cells.

Involvement of both p60-Src and JAK2 upstream of PI3K activation in response to G-gly

In order to determine whether p60-Src was involved in PI3K activation by G-gly, we first tested whether PI3K activity was detected in association with p60-Src. After peptide treatment for various times, PI3K assays were carried out on anti-p60-Src immunoprecipitates. In response to G-gly, we observed an increased PI-kinase activity co-precipitated with maximal p60-Src after 5 min of peptide stimulation (Figure 4A). To test the PI3K specificity, we

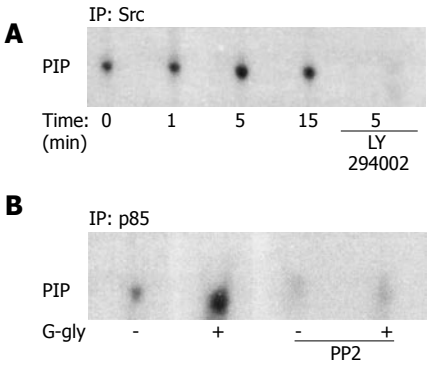

Figure 4 Involvement of p60-Src (**A**) and PI3K (**B**) activation in response to G-gly. HCT116 cells pretreated with or without 10 μmol/L of LY290042 and anti-p85 antibody were stimulated (+) or not (-) with glycine-extended gastrin (10 pmol/L) for the indicated time. After immunoprecipitation of cell lysates with anti-p60-Src and anti-p85 antibody, precipitates were assayed for PIK activity using inositol phosphate as an exogenous substrate. Lipids were separated by thin layer chromatography and autoradiographied. The result shown is representative from five and three separate experiments.

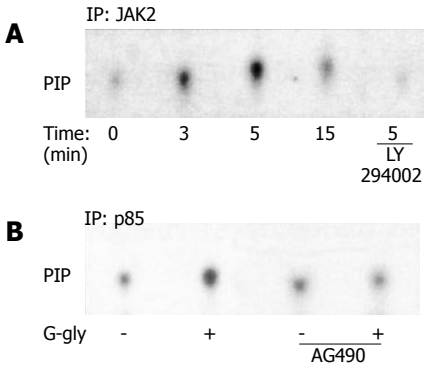

Figure 5 Involvement of PI3K (**A**) and JAK2 (**B**) activation in response to G-gly. HCT116 cells pretreated with or without 10μmol/L of LY290042 and were 10μmol/L of AG 40, stimulated (+) or not (-) with glycine-extended gastrin G-gly (10 pmol/L) for the indicated time. After immunoprecipitation of cell lysates with anti-JAK2 and anti-p85 antibody, precipitates were assayed for PIK activity using inositol phosphate as an exogenous substrate. Lipids were separated by thin layer chromatography and autoradiographied. The result shown is representative from five separate experiments.

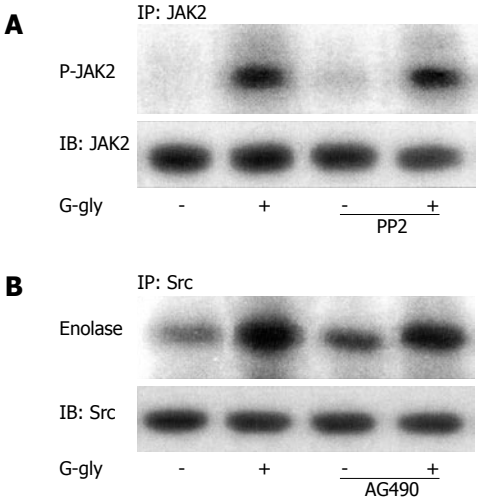

Figure 6 No involvement of p60-Src (**A**) and JAK2 (**B**) activation in response to G-gly. Cells pretreated with or without PP2 and AG 490 (10 μmol/L), were stimulated (+) or not (-) by G-gly (10 pmol/L) for 5 min. JAK2 and p60-Src kinase activities were determined by immune complex kinase assay using anti-JAK2 and anti-p60-Src antibodies as described in Materials and Methods. Proteins were separated by SDS-PAGE and JAK2 autophosphorylation was detected by autoradiography. A representative autoradiogram from at least three separate experiments is shown.

added the PI3K inhibitor, LY 294002, in the *in vitro* lipid kinase assay. Under these conditions, G-gly induced-PI-kinase activity was completely blocked. These results demonstrated that glycine-extended gastrin was associated with p60-Src and PI3K. In order to confirm that an Src family member could act upstream of the PI3K pathway activated by G-gly, we pretreated the cells for 1h with PP2 before G-gly stimulation. PI3K activation was inhibited in PP2 pretreated cells, indicating the role of Src in PI3K activation (Figure 4B).

We then examined the role of JAK2 in PI3K activation by G-gly. After peptide treatment for the time indicated, the cells were lysed and PI3K assays were performed on anti-JAK2 immunoprecipitates. Increased PI-kinase activity was associated with JAK2, detectable at 1 min and maximal after 5 min of peptide stimulation (Figure 5A). The inhibition of PI-kinase activity observed when LY 294002 was added in the *in vitro* lipid kinase assay indicated that glycine-extended gastrin was associated with JAK2 and PI3K. To confirm the involvement of JAK2 upstream of the G-gly-induced PI3K pathway, the cells were pretreated for 1h with AG 490 prior to G-gly addition. The PI3K activation in response to G-gly was inhibited in the presence of JAK2 inhibitor, indicating the role of this tyrosine kinase upstream in PI3K activation (Figure 5B).

No cross-talk between p60-Src and JAK2 pathways in response to G-gly

To investigate the possible association between p60-Src and JAK2, solubilized proteins were immunoprecipitated with an anti-JAK2 antibody and the precipitates were analyzed by immunoblot using an anti-p60-Src antibody. No p60-Src protein associated with JAK2 was detected in control cells or in cells stimulated with G-gly, whereas comparable amounts of JAK2 proteins were detected in immunoprecipitates (data not shown).

Independently of any association, we studied whether Src-family kinases were involved in JAK2 activation by G-gly. We tested the effect of PP2 on JAK2 activity. Cells were pretreated for 1h with PP2 5 min before stimulation with G-gly. JAK2 kinase assay was performed on JAK2 immunoprecipitates. PP2 did not inhibit G-gly-induced JAK2 activation, indicating that Src kinases were not involved in upstream of JAK2 activation by G-gly (Figure 6A). Similarly, using AG490, we tested a possible role of JAK2 upstream in p60-Src activation. The presence of AG490 in the incubation medium did not significantly change p60-Src activation by G-gly (Figure 6B). Indeed, in this human colon tumoral cell line, activation of the two tyrosine-kinases, p60-Src and JAK2, in response to G-gly was entirely independent.

DISCUSSION

The p85/p110 phosphatidylinositol 3-kinase (PI3K) is a

lipid kinase which plays an important role in human colon cancer. Its specific inhibitor, LY 294002, has been shown to inhibit cell growth and to induce apoptosis. Treatment of human colon cancer cell lines *in vitro* with LY 294002 or transplanted *in vivo* abolishes tumour cell growth and leads to apoptosis[9]. In addition, Philp *et al*[18] have identified somatic mutations in the gene of the p85 subunit leading to a constitutive active form of PI3K. These mutations are present in primary human colon tumours and cancer cells, suggesting that PI3K is involved in human colonic tumorigenesis

Non-amidated gastrin precursors, including G-gly, are produced by colorectal cancers and exert growth factor effects on these tissues[19, 20]. They are expressed in 80% - 90% of colorectal tumours and polyps in human beings[21-24]. Identification of signalling pathways involved in colonic mucosa hyperproliferation is important for the understanding of tumour processes. In a previous study we have identified that Src, JAK2 and PI3K pathways are overactivated in the colonic epithelium of mice overexpressing G-gly and involved in G-gly-induced proliferation of normal colonic epithelial cells isolated from control mice[13].

In the current study, we used the human colon tumour cell line, HCT116, to investigate whether these three kinases interact to regulate the growth of human tumoral colon cells. The results indicate that both p60-Src and JAK2 are necessary to PI3K regulation by the peptide. Theses results are in accordance with previous reports showing that JAK2 are involved upstream of the PI3K pathway of other cellular models. Pretreatment of human neutrophils with the JAK2 inhibitor, AG 490 could abolish the stimulation of the p85/p110 PI3K in response of the granulocyte-macrophage colony-stimulating factor. In addition, Attoub *et al*[25] have shown that leptin can induce a transient elevation of the PI3K lipid products in JAK2 immunoprecipitates prepared from MDCK cells. Similarly, Src family kinases are involved upstream of the PI3K/AKT pathway[26, 27]. Previous studies suggest that the IRS proteins could serve as scaffolding intermediates between tyrosine kinases and PI3K[28]. This mechanism is likely involved in PI3K activation by G-gly. In HCT116 cells we observed a basal association between JAK2 and IRS1 and the tyrosine phosphorylation of IRS-1 in response to G-gly (data not shown). In addition, we have previously reported that tyrosine phosphorylation of IRS-1 in pancreatic tumour cells, leading to the rapid recruitment of the regulatory subunit of PI3K, might represent a common mechanism for PI3K activation by different factors including insulin and G-gly[11]. Obviously, we cannot exclude other hypotheses such as interaction between the SH2 domain of p85 and phospho-tyrosine of p60-Src or JAK2. Different studies have previously described the involvement of Src family kinases upstream of JAK2 activation. For example, cell transformation by the oncogene v-Src[29] or the overexpression of certain members of the Src family-kinases as Lck[30] can lead to a constitutive activation of JAK2. However, we did not find any cross-talk between the two tyrosine kinases, suggesting that the p60-Src/PI3K and JAK2/PI3K pathways act independently. The involvement of two different mechanisms upstream of the lipid kinase might be a way to amplify the PI3K signal. However, in our study, the level of PI3K activity associated with JAK2 or p60-Src was not different from that observed in anti-p85 immunoprecipitates. As for many other signalling molecules, it seems that the cellular localization of PI3K is important for the function of the enzyme. Therefore the recruitment of PI3K to different cell compartments by the two independent tyrosine-kinases allows the enzyme to play a complementary role. The finding that p60-Src and JAK2 do not associate in response to G-gly stimulation, demonstrates that the p60-Src/PI3K and JAK2/PI3K pathways act independently and indicates that they might be involved in different cell compartments. The analysis of the cellular localization of phosphatidylinositol 3-kinase, might be crucial to understand the role of this signalling molecule in different biological effects of G-gly.

Our previous studies indicate that gastrin precursors contribute to the initiation phases of colon carcinogenesis by upregulating the signalling pathways involved in cellular proliferation and cell survival. The results of this study demonstrate that G-gly is also able to regulate proliferation of tumoral colonic cells and support the idea that gastrin precursors are not only involved in the initiation steps of the colon tumour process but also involved in the later stages of tumour progression after genetic alterations, by conferring a growth advantage to the cells *via* the constitutive activation of numerous signalling pathways.

Abstract

AIM: To investigate the expression of different cytokeratins (CKs) in gastric epithelium of adult patients with chronic gastritis infected with *Helicobacter pylori* (*H pylori*) *cagA*+ strains.

METHODS: The expression of CK 7, 8, 18, 19 and 20 was studied immunohistochemically in antral gastric biopsies of 84 patients. All the CKs were immunostained in *cagA*+*H pylori* gastritis (57 cases), non-*H pylori* gastritis (17 cases) and normal gastric mucosa (10 cases).

RESULTS: In *cagA*+ *H pylori* gastritis, CK8 was expressed comparably to the normal antral mucosa from surface epithelium to deep glands. Distribution of CK18 and CK 19 was unchanged, i.e. transmucosal, but intensity of the expression was different in foveolar region in comparison to normal gastric mucosa. Cytokeratin 18 immunoreactivity was significantly higher in the foveolar epithelium of *H pylori*-positive gastritis compared to both *H pylori*-negative gastritis and controls. On the contrary, decrease in CK19 immunoreactivity occurred in foveolar epithelium of *H pylori*-positive gastritis. In both normal and inflamed antral mucosa without *H pylori* infection, CK20 was expressed strongly/moderately and homogenously in surface epithelium and upper foveolar region, but in *H pylori* -induced gastritis significant decrease of expression in foveolar region was noted. Generally, in both normal antral mucosa and *H pylori*-negative gastritis, expression of CK7 was not observed, while in about half *cagA*+ *H pylori*-infected patients, moderate focal CK7 immunoreactivity of the neck and coiled gland areas was registered, especially in areas with more severe inflammatory infiltrate.

CONCLUSION: Alterations in expression of CK 7, 18, 19 and 20 together with normal expression of CK8 occur in antral mucosa of *H pylori*-associated chronic gastritis in adult patients infected with *cagA*+ strains. Alterations in different cytokeratins expression might contribute to weakening of epithelial tight junctions observed in *H pylori*-infected gastric mucosa.

INTRODUCTION

Cytokeratins (CKs), a family of important cytoskeleton structural proteins, have specific spatial and temporal dynamic locations along the epithelial axis of the gastrointestinal tract (GIT), and their expression is linked to the degree of epithelial differentiation[1-4]. Cytokeratins 7, 8 (intermediate-sized and basic), 18 and 19 (smallest in size and acidic) are exclusively expressed in nearly all simple epithelia, pseudostratified respiratory epithelium and

transitional epithelium. CK8 and CK18 pair together and have a similar distribution, while CK19 can be detected in a broad range of epithelial tissues, including many simple epithelia, diverse stratified epithelia, and cultured keratinocytes. CK20 (intermediate sized and acidic) is expressed in gastric foveolar epithelium, intestinal villi and crypt epithelium, cutaneous and oral Merkel cells[4]. Various changes in CK expression and distribution profile have been noted in inflammatory[5], preneoplastic[6-10] and neoplastic[2,11-13] disorders along GIT, including gastric mucosa. Structural changes in the gastric epithelium of adult and pediatric *H pylori*-infected patients with chronic gastritis have been recently demonstrated using cytokeratin immunohistochemistry[14-19].

Results of previous studies postulated that only a subset of individuals infected with *H pylori* develop severe gastritis and/or metaplasia, peptic ulcer or gastric cancer [14,20]. Bacterial strain, environmental and host factors can converge in the gastroduodenal milieu and control the final outcome of *H pylori* infection. However, to the best of our knowledge, relationship between *cagA*+ *H pylori* and changes in CK expression in the gastric epithelium has not yet been studied in patients with chronic gastritis. Since we have previously demonstrated high seroprevalence of antibodies to *cagA* in *H pylori*-infected patients in Serbia and Montenegro[21], this study aimed to identify and describe immunohistochemical pattern of antral CK expression in *H pylori* –associated chronic gastritis of adult patients infected with *cagA*+ strains.

MATERIALS AND METHODS

Subjects

We conducted an outpatient-based prospective study at the Clinic for Gastroenterology and Hepatology (Clinical Center of Serbia, University of Belgrade). All patients gave informed consent for participation in the study and the study protocol was approved by the local Ethics Committee. Adult patients with dyspeptic symptoms and histological signs of gastritis entered the study. Dyspepsia was defined as upper abdominal or retrosternal pain, discomfort, nausea, vomiting or other symptoms referable to the upper abdominal tract lasting for at least one month[22]. Exclusion criteria were in concordance with the recommendations from European *H pylori* Study Group[20].

Ninety-one patients entered the study. After histological examination, we excluded 17 patients (15 with and 2 without *H pylori* infection) due to the presence of intestinal metaplasia (IM) in the antral mucosa. Since specific IM- related changes in CK expression were reported, we aimed to identify changes related exclusively to the presence of *H pylori* infection. Therefore, data from 74 patients (57 *H pylori*-positive and 17 *H pylori*-negative) with chronic gastritis were analyzed. Control group (CG) consisted of 10 asymptomatic healthy volunteers with no histological changes in the gastric mucosa (mean age 32± 11 years, 3 males, 7 females). In the *H pylori*-positive group mean age was 44±13 years (26 males, 31 females), while in the non-infected group mean age was 47±17 years (5 males, 12 females). Esophagogastroduodenoscopy with biopsies from antral and corpus mucosa was performed in all patients and blood was taken for serology and immunoblot.

H pylori infection was diagnosed by rapid urease test (RUT), histology, immunohistochemistry and serology. A patient was defined as *H pylori* positive if histology and at least one of the other applied diagnostic methods were positive.

Routine endoscopy and H pylori status

Each patient underwent upper endoscopy and testing for the presence of *H pylori* by RUT and histology. Six biopsies were taken, 3 from the antrum and 3 from the corpus (2 for histology and 1 for RUT). Biopsies selected for histological examination were stained with hematoxylin-eosin, alcian blue pH 2.5/periodic acid Schiff (AB/PAS) and high iron diamine/alcian blue pH2.5 (HID/PAS). Both Giemsa and immunohistochemical stainings (polyclonal antibody to *H pylori*, dilution 1:10, DAKO A/S, Glostrup, Denmark) were applied for the detection of *H pylori*.

H pylori serology and immunoblot assay

Blood samples were taken from all patients after endoscopic examination and sera were separated by centrifugation and stored at -20 °C until analyzed. The presence of anti-*cagA* antibodies was detected using the *Helicobacter pylori* Vira blot test kit™ (Viramed Biotech AG, Lich, Germany). The concentration of anti-*H pylori* IgG antibodies was analyzed using Pyloriset EIA-G III™ (Orion Diagnostica, Finland)[23]. Both tests were performed according to the manufacturer's instructions.

Immunohistochemistry

Immunohistochemical reactions were performed on consecutive sections of one selected antral biopsy of each patient to detect cytokeratins 7, 8, 18, 19 and 20. Only well-oriented biopsies allowing assessment of full mucosal thickness, were selected for immunohistochemical study. The sections were stained with monoclonal antibodies to CK7 (dilution 1:25, DAKO A/S, Glostrup, Denmark), CK8 (dilution 1:20, DAKO Carpinteria, CA, USA), CK18 (dilution 1:25, DAKO A/S, Glostrup, Denmark), CK19 (dilution 1:50, DAKO A/S, Glostrup, Denmark) and CK20 (dilution 1:25, DAKO A/S, Glostrup, Denmark). Immunohistochemical staining was performed according to the manufacturer's instructions using streptavidin-biotin/HRP detection system (DAKO LSAB+/HRP kit, Glostrup, Denmark), followed by counterstaining with hematoxylin. For negative controls, no staining was detectable when the pre-immune serum was used instead of primary antibodies. In addition, human fetal esophagus of the 13th gestation week was used as positive control for evaluation of CK7 immunoreactivity.

Histological and immunohistochemical evaluation

Mucosal biopsies were evaluated by an experienced pathologist blinded to clinical and endoscopic data. In addition, an experienced gastrointestinal pathologist and a cytologist independently evaluated immunohistochemistry. Differences in immunohistochemical evaluation were resolved by re-examination and consensus. Chronic gastritis was diagnosed and graded according to the

updated Sydney system[24]. Biopsies showing intestinal metaplasia classified according to previous proposals [13] were not included in this study. Mucosal distribution (surface epithelium, foveolar region, glandular necks and deep glands) and intensity of cytoplasm staining (without staining, weak or moderate/strong staining) were registered together with the expression pattern (focal or diffuse) for each analyzed CK, while an additional semi-quantitative assessment of percentages of immunoreactive cells in each mucosal compartment was performed and graded for CK7 in 3 groups (<10%, 10-20%, and >20% immunoreactive cells).

Statistical analysis

Results were analyzed using non-parametric tests, Kruskall-Wallis, chi-square or Fisher's exact test for independent samples. $P < 0.05$ was considered statistically significant.

RESULTS

Results of our study showed that presence of intestinal metaplasia could be detected in 18.6% (17/91) of dyspeptic patients with histological signs of gastritis (15 with and 2 without *H pylori* infection). These patients were excluded from further analysis, since we aimed to investigate the influence of *H pylori* infection on normal gastric epithelium. Out of the remaining 74 patients, 57 (77%) were infected with *H pylori,* while infection was not found in 17. All infected patients harbored *cagA*+ bacterial strain in the gastric mucosa.

Histology evaluation

Histological examination of antral and corpus mucosa in *H pylori*-infected individuals revealed signs of antral gastritis in 5 (9%), while pangastritis was diagnosed in the remaining 52 (91%) patients. In the *H pylori* negative group antral gastritis was diagnosed in 7 (42%) patients and histological signs of pangastritis were found in 10 (58%). Histological changes in the gastric mucosa were graded using Sydney classification both for antral (Table 1) and corpus mucosa (data not shown).

In the antrum of *H pylori*-infected individuals, inflammatory infiltrate density and activity of inflammation were higher than in the uninfected group ($P < 0.001$ for both histological parameters). Presence of atrophic changes was not different between the two groups, while moderate density of *H pylori*-colonization was most frequent in infected patients.

Immunohistochemical evaluation of CK expression and distribution

Cytokeratin 8 was identified immunohistochemically in antral mucosa of both *H pylori* positive and negative patients with gastritis and controls (Table 2). Diffuse immunoreactivity to CK8 was the predominant expression pattern in surface epithelium, foveolae and glandular neck (moderate/strong immunoreactivty was observed in 90% of controls, 70.6% of *H pylori* negative and 63.1% of *H pylori*+ gastritis and weak in only 11.8% with and 12.3% without *H pylori* infection). On the other hand, deeper glandular structures did not express CK8 in about 10-30% of cases. No significant difference was found in any of the examined antral mucosa regions between the three groups (Figure 1).

Normal antral mucosa was in general immunostained transmucosal (from the surface to the gland region) when antibodies to CK18 and CK19 were applied (Tables 3 and 4), while in foveolar region inconsistent CK18 immunoreactivity with the expression rate of only 10% was observed. In the foveolar epithelium of *H pylori*+ patients more intense diffuse ($P < 0.05$) and focal ($P < 0.01$) CK18 immunoreactivity was detected when compared to *H pylori*-negative gastritis and controls (Figure 2). As opposed to these results, lower antral CK19 patchy immunoreactivity was noted in foveolar epithelium of *H pylori*+ gastritis compared to *H pylori*-negative gastritis and controls ($P < 0.05$) (Figure 3).

All examined antral biopsies showed positive immunostaining of CK20 (Table 5) restricted to the surface and upper foveolar epithelium. In the surface epithelium strong and homogenous CK20 immunoreactivity was predominant (moderate/strong diffuse immunoreactivity was observed in 90% of controls, 70.6% of *H pylori* negative and 64.9% of *H pylori*+ gastritis, as opposed to the patchy staining observed in 10%, 29.4% and 35.1% of individuals, respectively). No significant differences were noted between controls and patients with gastritis irrespective of the presence of *H pylori* infection. In the antral mucosa of the majority of *H pylori* negative patients with gastritis and controls CK20 was expressed strongly/moderately in all foveolar cells while in *H pylori* positive gastritis patients a significantly higher percentage of patients had focal expression of CK20 (Figure 4). Further analysis revealed different CK20 expressions in upper foveolar region related to the presence of gastritis but not

Cytokeratin 18 immunoreactivity was significantly higher in the foveolar epithelium of *H pylori*-positive gastritis compared with *H pylori*-negative gastritis.

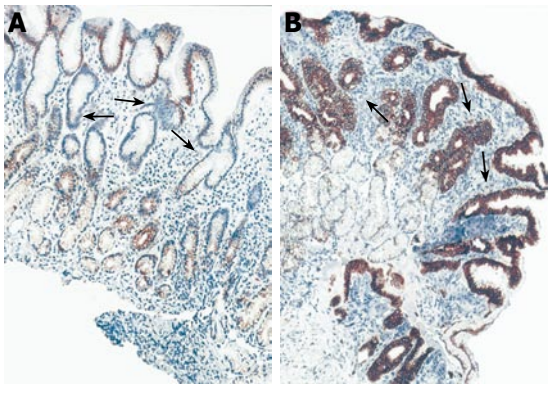

Figure 3 CK19 immunoreactivity in antral mucosa of patients with cagA+ *H pylori* chronic gastritis (**A**) and non-*H pylori* chronic gastritis (**B**). Decrease in CK19 immunoreactivity was found in foveolar epithelium of antral mucosa of *H pylori*-positive gastritis compared to non-*H pylori* chronic gastritis. Original magnification: x20 (**A**, **B**)

H pylori infection. Namely, patchy staining pattern was detected in 44% of *H pylori*+ and 29% of *H pylori* negative gastritis patients and only 10% of controls ($P < 0.05$).

The main findings of CK7 immunoreactivity are listed in Table 6. In both controls and *H pylori*-negative gastritis patients almost no immunoreactivity of CK7 was found in the antral mucosa, with the exception of some inconsistent and faint CK7 immunoreactivity observed in single cells of glandular necks and deep glands in about 2/3 of cases (Figure 5). However, moderate focal CK7 immunoreactivity in the same area was more frequently observed in *H pylori*-positive gastritis compared to both *H pylori*-negative gastritis and control group ($P < 0.01$). Namely, about half in *H pylori*-infected patients (28/55,

In the cagA+ *H pylori* chronic gastritis, CK20 expression was decreased in upper foveolar epithelium in comparison to non-*H pylori* chronic gastritis and control subjects with normal gastric mucosa. Numerous CK20 strong immunoreactive endocrine cells could be observed (►) in the glandular epithelium. Original magnification: x20 (A-C)

50.1%) moderate focal immunoreactivity of CK7 in more than 10% of cells in neck and coiled gland areas was registered, especially in individuals with more severe inflammatory infiltrate (Figure 6).

DISCUSSION

H pylori-induced proinflammatory cytokine expression and inflammation affects various gastric cell populations controlling gastric acid secretion[25], including somatostatin-producing D cells[26], gastrin-producing G cells[27], and parietal cells[28]. In addition, in the course of *H pylori*-induced gastritis, acute foveolitis of the pit proliferative zone with characteristic morphological change of epithelial cells, which is often described as the malgun (clear) cell change[29] occurs. It is postulated that malgun cell change in the course of *H pylori* gastritis reflects epithelial genomic damage and repair processes. In addition, various structural changes of mucosal epithelial cells in *H pylori* gastritis have been reported in both adult[14-16, 19] and pediatric patients[18].

Strain-specific *H pylori* gene, *cagA*, has been recognized as a marker of strains that confer increased risk for peptic

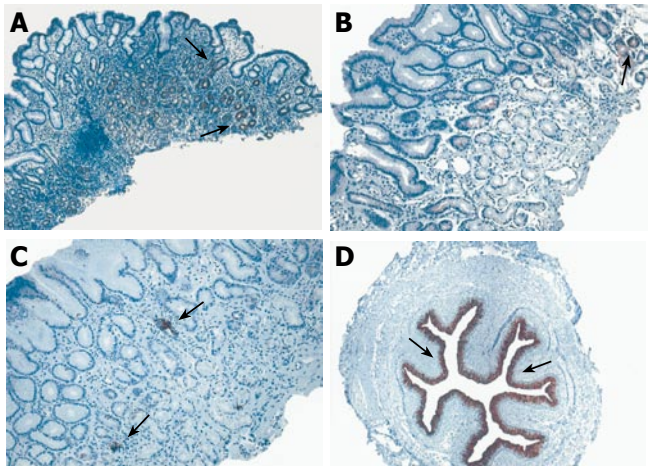

Figure 5 CK7 immunoreactivity in antral mucosa of patients with cagA+ *H pylori* chronic gastritis (**A**), non-*H pylori* chronic gastritis (**B**), control subjects with normal gastric mucosa (**C**), and control specimen of human fetal esophagus (**D**). Moderate focal CK7 positivity (→) in the pits and the glands of antral mucosa in patients with cagA+ *H pylori* chronic gastritis could be observed. CK7 positive cells covering a single gland (→) of antral mucosa could be found in patients with non-*H pylori* chronic gastritis. Normal antral mucosa with a few single cells or cell clusters (→) were strongly decorated with antibody to CK7. Strong CK7 immunoreactivity was displayed in the stratified columnar epithelium (→) of human fetal esophagus of the 13th gestation week. Original magnification: x10 (**A-D**).

ulcer disease and gastric cancer[25]. Since the seroprevalence of *cagA*+ *H pylori* strains was high in chronic gastritis patients of Serbia and Montenegro[21] and there is no evidence that bacterial strain is related to alterations in cytokeratin expression in gastric epithelium, we aimed in the current study to evaluate the changes in distribution and expression pattern of different CKs in the course of *cagA*+ *H pylori* -associated chronic gastritis in adult patients.

In normal antral gastric mucosa, results of our study revealed broad panmucosal (from the surface to the gland) expressions of CKs8,18 and 19, while CK20 immunoreactivity was strong and homogenous in the tip

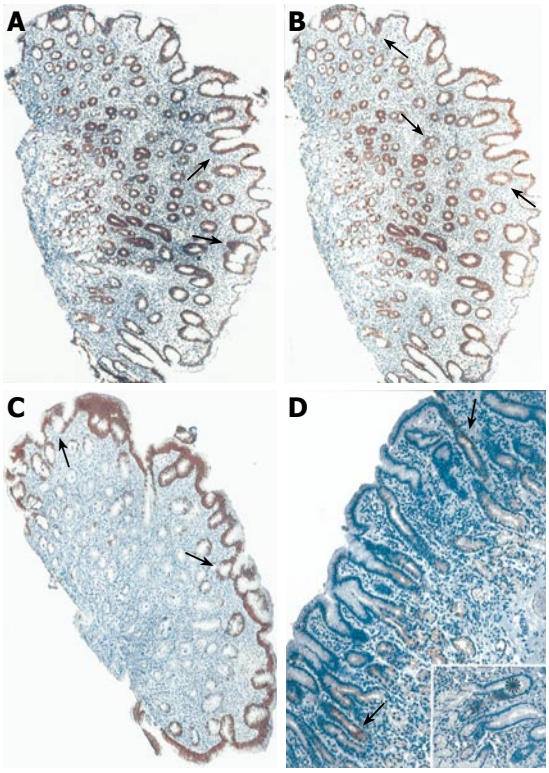

Figure 6 Typical expression pattern of CK18 (**A**), CK19 (**B**), CK20 (**C**) and CK7 (**D**) in antral mucosa of patients with cagA+ *H pylori* chronic gastritis. Strong diffuse cytokeratin 18, moderate focal CK19 and CK20 (**C**) immunoreactivities were demonstrated in upper foveolar epithelium (→) of the antral mucosa. Moderate focal CK7 positivity (→) was revealed in the pits and the glands of antral mucosa. CK7 immunoreactivity was prominent (*) in some cell clusters of the foveolar epithelium (insert). Original magnification: x10 (**A**-**C**), insert x20.

and upper portion cells of foveolae. As opposed to other examined cytokeratins, CK7 was mostly undetectable. Similar results were obtained for gastritis patients without *H pylori* infection and overall these findings are in line with previous reports[1,2,14,15,17].

Several immunohistochemical studies in the past few years demonstrated that altered gastric cytokeratin expression is closely related with *H pylori* infection in adult patients[1,2,14-17,19]. However only two studies by Schwerer *et al*[15] and Louwers *et al*[17] have investigated multiple CKs simultaneously. To the best of our knowledge, all other studies are focused on particular CK. None of these studies however have provided data concerning bacterial strain.

According to previous observations, CK7 is present in fetal but largely absent in normal adult and is transiently *de novo* expressed in metaplastic and neoplastic epithelial cells[2,11]. Our results suggest that CK7, largely absent in normal adult antral mucosa, is expressed in *H pylori* chronic gastritis patients, which is in line with reports in adults describing slight[17] and markedly increased CK7 expression in *H pylori*-associated chronic gastritis in children[18]. As opposed to these findings, a study by Schwerer and Baczako[14] when investigating CK7 expression in normal foveolar epithelium found that *H pylori* can induce gastritis and intestinal metaplasia with CK7 immunoreactivity detected only in intestinal metaplasia.

Study by Kirchner *et al*[2] using animal experimental model of gastritis-cancer sequence in Mongolian gerbils revealed signs of mild gastritis 2 mo after *H pylori* infection together with CK7 expression in epithelial cells of basal glands followed by loss of specific differentiation and changes to duct-like appearance, while after 6, 12 and 24 mo moderate to severe gastritis with loss of differentiated gastric glands and switch to CK7 positive duct-like structures in large mucosal segments was observed. These results may provide evidence that non-neoplastic stomach with non-atrophic *H pylori* gastritis constantly exhibits low score of CK7 positive cells in antrum and corpus, thus supporting our findings. Furthermore, there is evidence that CK7 expression in metaplastic and neoplastic stomach is related to dedifferentiated epithelial cells that can phenotypically be linked to fetal cells at the beginning of gastric pit development[2]. The dedifferentiated cells exhibit low proliferation and beta-catenin accumulation similar to stem cells. Therefore, observations of Kirchner *et al*[2] imply that metaplasia, gastric intraepithelial neoplasia, early gastric cancer and dedifferentiated epithelial cells defined by CK7 expression are related with each other in *H pylori* induced gastritis. Based on the above stated findings, we speculate that CK7 *de novo* expression in gastric mucosa of patients infected with *cagA*+ *H pylori* strains represents the proliferative/regenerative cells rather than pure dedifferentiated cells because CK7 positive flat duct-like

structures have not been identified.

Our results did not reveal any significant difference in CK8 expression between patients with *cagA*+ *H pylori*-induced gastritis and normal mucosa. These findings are supported by results of other authors[15,17], but not by study of Baek *et al*[19] that described under-expressed CK8 in the gastric mucosa of *H pylori* infected-individuals as a result of oxidative stress-induced cytoskeleton damage.

Higher expression of CK 18 in foveolar epithelium together with a decrease in CK19 expression was noted in patients with *cagA*+ *H pylori*-induced gastritis. These findings differ from previous studies, since two independent studies have revealed unchanged CK18 and CK19 expression in gastric mucosa of *H pylori*-infected patients[15,17]. Normal stomach expresses less CK19 in the upper mucosal compartment in comparison to other mucosal compartments[1]. CK19 expression is thought to be inversely related to cell proliferation, strong CK19 expression implying weak proliferation and vice versa[1]. Intestinal metaplasia of the stomach however exhibits more intense CK19-immunoreactivity than gastric cancer tissue[1]. If CK19 immunoreactivity is negatively correlated with cell proliferation and differentiation in fetal, normal and pathologically transformed adult gastric mucosa, our results may suggest good differentiation and enhanced proliferation of upper foveolar cells in patients with *cagA*+ *H pylori*-induced gastritis.

Botta *et al*[3] studied CK20 immunoreactivity in fetal and neonatal human gut, including stomach and demonstrated that CK20 expression is progressive increased during gestation, suggesting that the degree of CK20 positivity is related to the epithelial maturation stage in gastric mucosa. CK20 expression in adults is restricted to the surface foveolar epithelium and is not detectable in gastric pit or glandular region. Previous investigations revealed that CK20 expression is significantly lower in foveolar epithelium of *H pylori*-induced chronic gastritis[15-17] supporting our results, while available studies suggest that this is a reversible change and CK20 expression is normalized within 6 mo after eradication of *H pylori* infection[15].

Taken together, all these findings imply alterations in epithelial cell maturation in the course of *H pylori*-induced chronic gastritis.

Our results suggest that bacterial strain is of importance in inducing alterations of CK expression. It is well known that *cagA* present in 50-60% of all strains is a part of *H pylori* genome termed *cag* pathogenicity island (*cag*PAI) and that proteins encoded by *cag*PAI are responsible for both NFkB and MAPK activation in gastric epithelial cells. It has also been demonstrated that infection with *cagA*+ strains is more likely to result in peptic ulceration, atrophic gastritis and gastric carcinoma[25]. Therefore, presence of *cag*PAI in *H pylori* genome might play a role in signal transduction leading to *H pylori*-induced host gene expression, thus regulating inflammation, proliferation and carcinogenesis. In addition, bacterial strain-related differences in host gene expression have been reported, implying that protein expression profile including CKs, depends on bacterial strains and is related to the presence of *cagA*+ *H pylori* strains. Amieva *et al*.[31] reported that *cagA* appears to target *H pylori* host cell intercellular junctions and to disrupt junction-mediated functions. Since predominant genotype of *H pylori* in Serbia and Montenegro has been reported to be the *cagA*+ genotype[21], it is very important to further investigate the presence and reversibility of different epithelial alterations induced by different *H pylori* strains.

Abstract

AIM: Gastric inhibitory polypeptide is secreted from intestinal K-cells in response to nutrient ingestion and acts as an incretin hormone in human physiology. While animal experiments suggested a role for GIP as an inhibitor of gastric secretion, the GIP effects on gastric acid output in humans are still controversial.

METHODS: Pentagastrin was administered at an infusion rate of 1 μg . kg^{-1} . h^{-1} over 300 min in 8 patients with type 2 diabetes (2 female, 6 male, 54 ± 10 years, BMI 30.5 ± 2.2 kg/m^2; no history of autonomic neuropathy) and 8 healthy subjects (2/6, 46 ± 6 years., 28.9 ± 5.3 kg/m^2). A hyperglycaemic clamp (140 mg/dl) was performed over 240 min. Placebo, GIP at a physiological dose (1 pmol . kg^{-1} . min^{-1}), and GIP at a pharmacological dose (4 pmol . kg^{-1} . min^{-1}) were administered over 60 min each. Boluses of placebo, 20 pmol GIP/kg, and 80 pmol GIP/kg were injected intravenously at the beginning of each infusion period, respectively. Gastric volume, acid and chloride output were analysed in 15-min intervals. Capillary and venous blood samples were drawn for the determination of glucose and total GIP. Statistics were carried out by repeated-measures ANOVA and one-way ANOVA.

RESULTS: Plasma glucose concentrations during the hyperglycaemic clamp experiments were not different between patients with type 2 diabetes and controls. Steady-state GIP plasma levels were 61 ± 8 and 79 ± 12 pmol/l during the low-dose and 327 ± 35 and 327 ± 17 pmol/l during the high-dose infusion of GIP, in healthy control subjects and in patients with type 2 diabetes, respectively ($P = 0.23$ and p 0.99). Pentagastrin markedly increased gastric acid and chloride secretion ($P < 0.001$). There were no significant differences in the rates of gastric acid or chloride output between the experimental periods with placebo or any dose of GIP. The temporal patterns of gastric acid and chloride secretion were similar in patients with type 2 diabetes and healthy controls ($P = 0.86$ and $P = 0.61$, respectively).

CONCLUSION: Pentagastrin-stimulated gastric acid secretion is similar in patients with type 2 diabetes and healthy controls. GIP administration does not influence gastric acid secretion at physiological or pharmacological plasma levels. Therefore, GIP appears to act as an incretin rather than as an enterogastrone in human physiology.

INTRODUCTION

Gastric inhibitory polypeptide (GIP) is secreted from intestinal K-cells in response to nutrient ingestion and acts to augment insulin secretion from pancreatic beta-cells[1-4]. Together with glucagon-like peptide 1 (GLP-1) it confers approximately 60 % of total postprandial insulin secretion, thus acting as an incretin hormone[5, 6]. Since the insulinotropic effect of GIP appears to be dependent on the prevailing plasma glucose concentrations[7], the term "glucose-

dependent insulinotropic polypeptide" was coined later to denominate the peptide in accordance with its major physiological role[8]. In addition, GIP administration augments glucagon secretion under certain circumstances[7, 9]. While there is little doubt regarding GIP effects on endocrine pancreatic secretion, the case is different for its role in the regulation of gastrointestinal functions. In fact, original studies in canine gastric preparations pointed to an inhibition of gastric acid secretion by GIP[10, 11] and subsequent *in vivo* experiments demonstrated an increase in gastric acid output following antibody blockade of endogenous GIP in dogs, suggesting a physiological importance of GIP in the stomach[12]. These inhibitory effects of GIP on gastric acid secretion were ascribed to the local antral release of somatostain[13].

In humans, a significant inhibition of gastric acid output was only reported during the administration of highly supraphysiological doses of GIP[14, 15], whereas no effects were observed at physiological GIP plasma levels[15, 16].

While GIP is the major mediator of the incretin effect in healthy subjects[1, 5], the incretin activity of GIP is almost absent in patients with type 2 diabetes[17-19]. It is yet unclear, whether this is due to a general impairment in beta-cell function in type 2 diabetes or whether the reduced insulinotropic effect of GIP reflects a specific defect, for example of the GIP receptor, in patients with type 2 diabetes[20, 21]. In the latter case, one would expect a loss of GIP action not only with respect to insulin secretion, but also regarding other physiological actions like the inhibition of gastric acid secretion. Therefore, in the present study, the effects of GIP on pentagastrin-stimulated gastric acid secretion at both physiological and supraphysiological plasma levels were investigated in patients with type 2 diabetes and healthy controls. The effects of GIP on insulin secretion have been reported in a separate communication[22].

MATERIALS AND METHODS

Study protocol

The study protocol was approved by the ethics committee of the medical faculty of the Ruhr-University, Bochum on 01-24-2002. Written informed consent was obtained from all participants.

Study design

At a screening visit a clinical examination was performed and laboratory parameters were screened. If the subjects met the inclusion criteria (see below), they were recruited for the following procedure: Pentagastrin-stimulated gastric acid secretion was assessed over 300 min. A hyperglycemic clamp aiming at a steady capillary plasma glucose concentration of 140 mg/dL (7.8 mmol/L) was performed over 240 min. Placebo (1 % human serum albumin in 0.9 % NaCl), GIP at a low infusion rate (1.0 pmol/(kg · min)), and GIP at a high infusion rate (4.0 pmol/(kg · min)) were administered consecutively, each over 60 min. Boluses of placebo, GIP at a low dose (20 pmol/kg) and GIP at a high dose (80 pmol/kg) were administered intravenously at the beginning of each infusion period (at 0, 60, and 120 min, respectively).

In order to exclude a time-dependent order effect on gastric secretion, five of the control subjects were studied on an additional occasion with the administration of placebo only (1 % human serum albumin in 0.9 %NaCl from 0 to 180 min) instead of GIP. Boluses of placebo were administered at 0, 60, and 120 min.

Table 1 Characteristics of the participants (mean±SE)

Parameter (unit)	Healthy controls	Patients with type 2 diabetes	Significance (*P*-value)
Sex (female/male)	2/6	2/6	1.0
Age (years)	46±6	54±10	0.07
Body mass index (kg/m^2)	28.9±5.3	30.5±2.2	0.43
Waist-to-hip ratio (cm/cm)	0.97±0.08	1.00±0.05	0.40
Blood pressure			
Systolic (mmHg)	118±13	138±21	0.044
Diastolic (mmHg)	79±10	92±10	0.026
HbA_{1c} (%)[1]	6.0±0.5	8.3±2.2	0.013
Diabetes duration (years)	-	9 ± 4	-
Total-cholesterol (mg/dL)	223±52	210±35	0.57
HDL-cholesterol (mg/dL)	49±22	34±14	0.15
LDL-cholesterol (mg/dL)	145±37	164±31	0.32
Triglycerides (mg/dL)	161±110	167±92	0.90
Creatinine (mg/dL)	0.86±0.13	1.05±0.29	0.12

Statistics: ANOVA or χ^2 test. [1]Normal range: < 6.5

Subjects/patients

Eight patients with type 2 diabetes and eight healthy control subjects without a family history of diabetes were studied. Patient/subject characteristics are presented in Table 1.

Subjects with anemia (hemoglobin < 11 g/dl), elevation in liver enzymes more than double the respective upper normal limits, or with elevated creatinine concentrations (> 1.3 mg/dl) were excluded. Among the patients with type 2 diabetes, 2 were treated with metformin, whereas the other 6 were on a dietary regimen. All antidiabetic treatment was withdrawn at least 48 hours prior to the experiments. None of the participants had a history of gastrointestinal disease or was taking any kind of medication with a known influence on gastric secretion. In addition, none of the patients had a history or any clinical signs of autonomic or sensory neuropathy. No abnormalities in the responsiveness of both the patellar and Achilles tendon reflexes, as assessed using a reflex hammer, were found. The results of a vibration perception threshold performed at both medial malleoli were within the normal limits

Peptides

Synthetic GIP was purchased from PolyPeptide Laboratories GmbH, Wolfenbüttel,
Germany, and processed for infusion as described[18]. Pentagastrin was purchased from Cambridge Laboratories, UK, Lot-No. 1TT.

Experimental procedures

The tests were performed in the morning after an overnight fast. Two forearm veins were punctured with a teflon cannula, and kept patent using 0.9 % NaCl (for blood sampling and for glucose and peptide administrations, respectively). Both ear lobes were made hyperemic using Finalgon® (Nonivamid 4 mg/g, Nicoboxil 25 mg/g). A

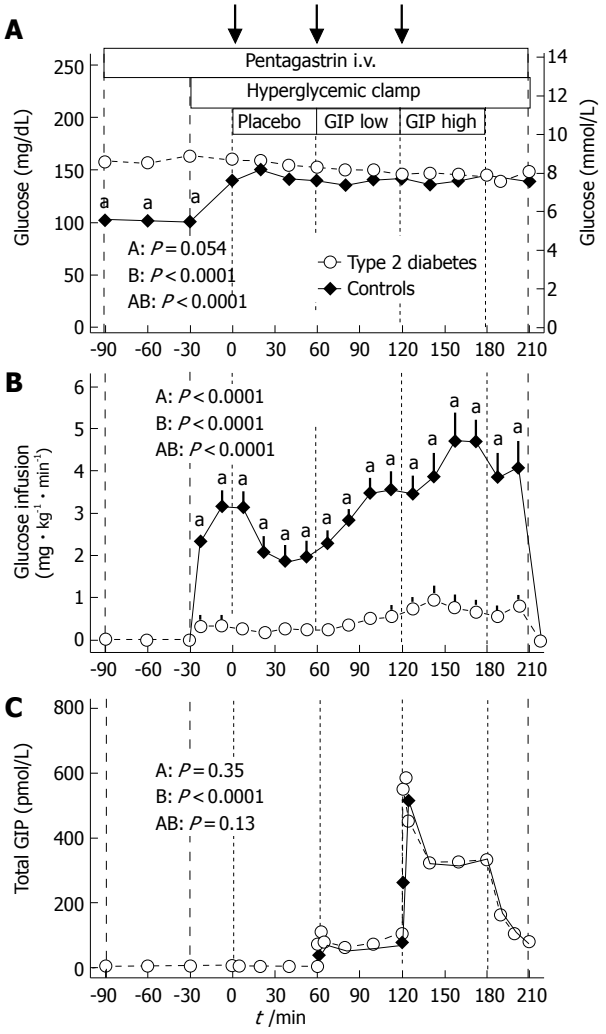

Figure 1 Plasma concentrations of glucose (**A**), glucose infusion rates (**B**) and plasma concentrations of total GIP (C) during hyperglycemic clamp experiments with the intravenous infusion of pentagastrin (1 μg . kg^{-1} . h^{-1}; -90 to 210 min), placebo (0 - 60 min), GIP at a low dose (1 pmol . kg^{-1} . min^{-1}; 60-120 min), and GIP at a high dose (4 pmol . kg^{-1} . min^{-1}; 120 -180 min) in eight patients with type 2 diabetes (open circles) and eight healthy controls (filled diamonds). Arrows indicate bolus administrations of placebo, 20 pmol GIP/kg and 80 pmol GIP/kg, respectively. Data are presented as means ± SEM; *P*-values were calculated using repeated measures ANOVA and one-way ANOVA and denote **A:** differences between the groups, **B:** differences over time and AB: differences due to the interaction of group and time. $^{a}P < 0.05$ patients with type 2 diabetes at individual time points.

nasogastric tube (Total length: 144 cm, diameter 6 mm, Sherwood Medical, Gosport, UK) was positioned for removing gastric acid by intermittent suction at 15 min intervals (HICO Gastrovac, Hirtz & Co., Germany). Basal gastric acid output was assessed over 15 min following a 30 min equilibration period. From -90 to 210 min, pentagastrin was administered intravenously at an infusion rate of 1 μg · kg body $weight^{-1}$ · h^{-1}. All participants remained in a semi-recumbent position, turned to their left side throughout the experiments.

A hyperglycemic clamp test aiming at a steady capillary plasma glucose concentration of 7.8 mmol/l (140 mg/dl) was started by injecting 40 % glucose as a bolus at -30 min and maintained by infusing glucose (20 % in water, weight/vol.) until 210 min, as appropriate, based on glucose determinations performed every 5 min and until 210 min. At 0 min, an intravenous infusion of placebo (1 % human serum albumin in 0.9 % NaCl) was started and maintained until 60 min. At 60 min, an intravenous infusion of GIP was started with an infusion rate of 1.0 pmol · kg^{-1} · min^{-1}. At 120 min, the GIP infusion rate was increased to 4.0 pmol · kg^{-1} · min^{-1} and maintained until 180 min. At 0 min an intravenous bolus of placebo was administered. GIP was injected as a bolus at 60 min (20 pmol/kg) and at 120 min (80 pmol/kg). Venous blood samples were drawn frequently, as seen in Figure 1.

Blood specimen

Venous blood was drawn into chilled tubes containing EDTA and aprotinin (Trasylol®; 20 000 KIU/ml, 200 μl per 10 ml blood; Bayer AG, Leverkusen, Germany) and kept on ice. After centrifugation at 4 ℃, plasma for hormone analyses was kept frozen at -28 ℃. Capillary blood samples collected from the ear lobe (approximately 100 μl) were stored in NaF (Microvette CB 300; Sarstedt, Nümbrecht, Germany) for the immediate measurement of glucose.

Laboratory determinations

Glucose was measured with a Glucose Analyser 2 (Beckman Instruments, Munich, Germany). GIP immunoreactivity was determined as described[18] using a C-terminal assay involving antiserum R65, which reacts fully with intact GIP (1-42) and the truncated metabolite (3-42), but not with so-called 8-Ku GIP, of which the chemical nature and molecular relation to GIP is uncertain. The assay has a detection limit of less than 2 pmol/l and an intra-assay variation of approximately 6 %. Human GIP (Peninsula Laboratories, Europe, Ltd.) was used as standard, and radiolabeled GIP was obtained from Amersham Pharmacia Biotech Ltd. (Aylesbury, UK).

Gastric volume output was measured in 15-min fractions to the nearest 0.5 ml. Acidity was determined by titration to pH 7.0 using phenol red as an indicator dye. Chloride concentration was measured by a Corning EEL 920 chloride meter (CIBA Corning Diagnostics, Fernwald, Germany).

Statistical analysis

Results are reported as mean ± SEM. Statistical calculations were carried out using repeated-measures analysis of variance (RM-ANOVA), using Statistica Version 5.0 (Statsoft Europe, Hamburg, Germany). This analysis provides p-values for differences between groups (A), differences over time (B), and for the interaction of groups with time (AB). If a significant interaction of treatment and time was documented ($P < 0.05$), values at single time points were compared by one-way ANOVA. A *P*-value < 0.05 was taken to indicate significant differences.

RESULTS

Fasting plasma glucose concentrations were significantly higher in patients with type 2 diabetes compared to control subjects ($P < 0.001$; Figure 1). During the hyperglycemic clamp period, similar glucose levels were obtained in both groups. As expected, glucose infusion rates required to

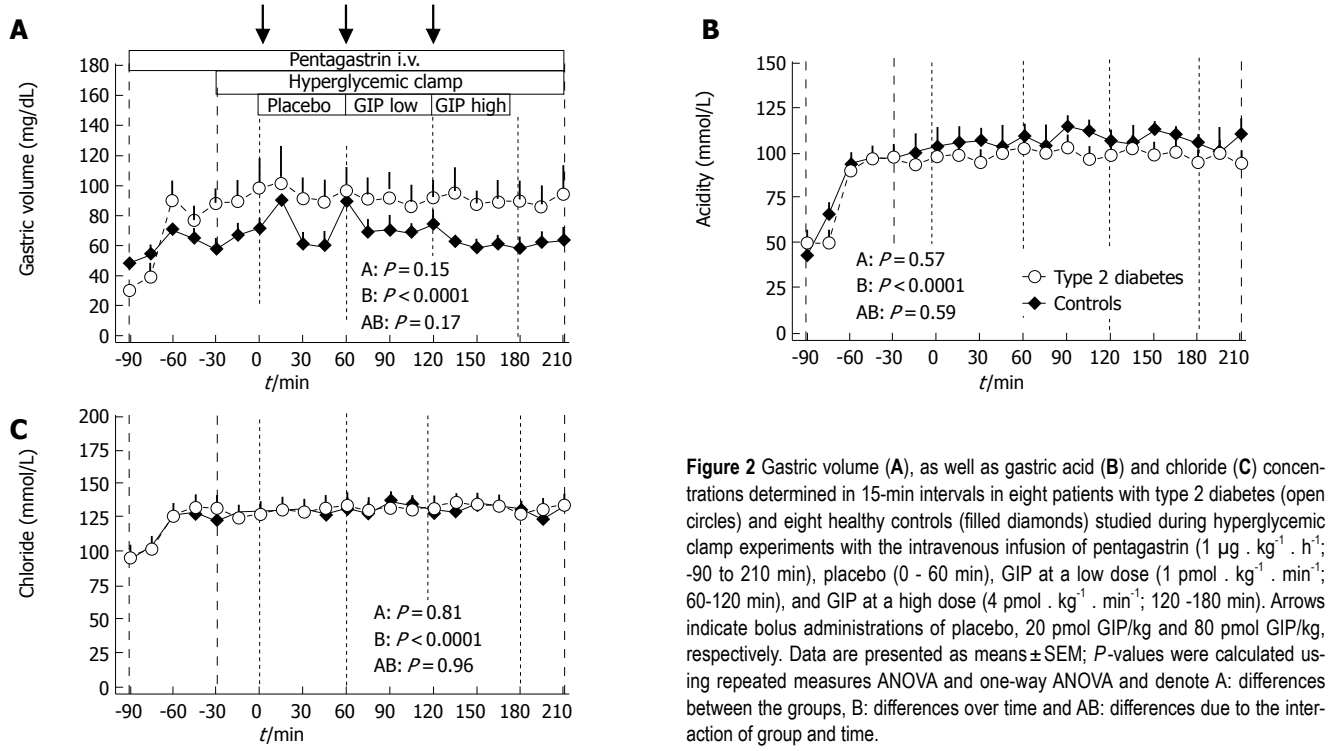

Figure 2 Gastric volume (**A**), as well as gastric acid (**B**) and chloride (**C**) concentrations determined in 15-min intervals in eight patients with type 2 diabetes (open circles) and eight healthy controls (filled diamonds) studied during hyperglycemic clamp experiments with the intravenous infusion of pentagastrin (1 μg . kg^{-1} . h^{-1}; -90 to 210 min), placebo (0 - 60 min), GIP at a low dose (1 pmol . kg^{-1} . min^{-1}; 60-120 min), and GIP at a high dose (4 pmol . kg^{-1} . min^{-1}; 120 -180 min). maintain the hyperglycaemic clamp conditions were much higher in the controls than in the patients with type 2 diabetes ($P < 0.0001$).

GIP plasma levels increased to steady-state levels of 61 ± 8 and 79 ± 12 pmol/l during the low-dose and 327 ± 35 and 327 ± 17 pmol/l during the high-dose infusion of GIP, in healthy control subjects and in patients with type 2 diabetes, respectively ($P = 0.23$ and $P = 0.99$).

Basal gastric acid output was 1.9 ± 0.4 mmol/15 min and 1.6 ± 0.4 mmol/15 min (in healthy controls and in patients with type 2 diabetes, respectively; $P = 0.56$). The secretion of both gastric acid and chloride was markedly increased during the administration of pentagastrin ($P < 0.001$; Figures 2 and 3). In contrast, intravenous glucose administration had no effects on gastric acid or chloride output (Figure 2 and 3; Table 2). There were no differences in the rates of gastric acid or chloride output between the experimental periods with the administration of placebo, the low GIP dose, and the high GIP dose (Figure 3; Table 2). The lack of GIP effect on gastric secretion was confirmed in the five control experiments with the administration of placebo only and with GIP ($P = 0.87$ for acid output and $P = 0.59$ for chloride output, respectively; details not shown). The temporal pattern of

gastric acid and chloride secretion was similar in patients with type 2 diabetes and healthy controls ($P = 0.86$ and $P = 0.61$, respectively; Figure 3).

DISCUSSION

The present experiments were undertaken to investigate the influence of GIP on pentagastrin-stimulated gastric acid secretion in patients with type 2 diabetes and in healthy controls. No effects of GIP on gastric acid output were observed at both physiological and pharmacological plasma concentrations.

A role for GIP in the regulation of gastric acid secretion was suggested from initial experiments in dogs[10-13]. Moreover the reduced rates gastric of acid secretion observed after jejuno-ileal shunt operation, when GIP plasma levels are increased, lent support to the concept of GIP as a negative regulator of gastric secretion[23]. In humans however, inhibitory effects of GIP on gastric acid secretion were only described, when supraphysiological GIP doses were used[14, 15], whereas GIP plasma levels that resembled those typically reached following meal ingestion failed to inhibit gastric acid secretion[15, 16]. In the present experiments, no effect of GIP on gastric acid output was observed even at supraphysiological plasma concentrations. The differences between the present and some of the previous studies[14, 15] may be explained by the use of different GIP preparations. In fact, both studies demonstrating inhibitory effects of GIP on gastric acid secretion in humans employed porcine GIP[14, 15], which differs from human GIP in two amino acid positions[24]. Moreover, some earlier peptide preparations contained impurities with cholecystokinin (CCK)-33 and -39, thereby limiting the interpretation of those studies[25]. Therefore, all aspects considered, the role of GIP in the regulation of gastric acid secretion in humans appears negligible.

The present data give rise to reconsider the role of GIP in human physiology. In fact, the peptide was initially considered to act as an enterogastrone[10, 11]. This term was proposed to describe (hormonal) factors from the duodenum that are secreted in response to nutrient ingestion and inhibit upper GI-functions at their typical plasma concentrations[26]. Such effects have been demonstrated for GLP-1 as well as for peptide-YY (PYY)[27-30]. In contrast, GIP does not appear to have any effects on gastric emptying[31] or gastric acid secretion in humans, and therefore does not fulfil the criteria for an enterogastrone. Rather, GIP acts as an incretin hormone, as demonstrated by numerous previous experiments[1, 5, 32]. Of note, a potent augmentation of insulin secretion by GIP was observed in the present experiments as well[22], thereby affirming the activity of the GIP preparations used.

The lack of GIP effect on gastric acid output represents another interesting difference in the biological actions of GIP and the other incretin hormone GLP-1, which is known as a potent inhibitor of gastric secretion[27, 33]. In fact, even though both hormones are secreted almost simultaneously[5, 34] and act in concert to augment glucose-stimulated insulin secretion[5, 32], they do exhibit a number of characteristic differences: Thus, GLP-1 suppresses pancreatic glucagon release[35, 36], whereas GIP has no effect or, at normoglycemic fasting conditions, even stimulates glucagon release[7, 9]. In addition, GLP-1 dose-dependently decelerates gastric emptying, thereby reducing the rise in glycemia following meal ingestion[30, 33, 37, 38]. In contrast, GIP administration has no effect on the velocity of gastric emptying[31]. Taken together, GLP-1 apparently possesses both incretin and enterogastrone activity, whereas GIP mainly acts as incretin hormone.

Another purpose of the present experiments was to compare gastric acid secretion in patients of type 2 diabetes and healthy controls. Since hyperglycemia itself has been shown to inhibit gastric acid output[39], hyperglycaemic clamp conditions were applied to match plasma glucose concentrations in both groups. Under these conditions, no differences occurred in the rates of gastric acid or chloride output. It is important to point out that in the present study only patients without a history or clinical signs of neuropathy were included. In fact, a number of previous studies have demonstrated reduced rates of gastric acid secretion in diabetic patients with overt autonomic neuropathy[40] [41-43]. In contrast, no abnormalities in gastric secretion were reported in patients with diabetes without signs of neuropathy[41, 43]. Therefore, it appears that, unless neuropathy develops, gastric acid secretion is similar in patients with type 2 diabetes and non-diabetic controls, when plasma glucose levels are matched.

In conclusion, gastric inhibitory polypeptide has no effect on gastric acid secretion in patients with type 2 diabetes and healthy controls. Therefore, GIP seems to act as an incretin rather than as an enterogastrone in human physiology.

ACKNOWLEDGMENTS

The excellent technical assistance of Birgit Baller and Lone Bagger is greatly acknowledged.

Abstract

AIM: To develop the effective technology for reconstruction of a liver organ *in vitro* using a bio-artificial liver.

METHODS: We previously reported that a radial-flow bioreactor (RFB) could provide a three-dimensional high-density culture system. We presently reconstructed the liver organoid using a functional human hepatocellular carcinoma cell line (FLC-5) as hepatocytes together with mouse immortalized sinusoidal endothelial cell (SEC) line M1 and mouse immortalized hepatic stellate cell (HSC) line A7 as non parenchymal cells in the RFB. Two x 10^7 FLC-5 cells were incubated in the RFB. After 5 d, 2 x 10^7 A7 cells were added in a similar manner followed by another addition of 10^7 M1 cells 5 d later. After three days of perfusion, some cellulose beads with the adherent cells were harvested. The last incubation period included perfusion with 200 nmol/L swinholide A for 2 h and then the remaining cellulose beads along with adherent cells were harvested from the RFB. The cell morphology was observed by transmission electron microscopy (TEM) and scanning electron microscopy (SEM). To assess hepatocyte function, we compared mRNA expression for urea cycle enzymes as well as albumin synthesis by FLC-5 in monolayer cultures compared to those of single-type cultures and cocultures in the RFB.

RESULTS: By transmission electron microscopy, FLC-5, M1, and A7 were arranged in relation to the perfusion side in a liver-like organization. Structures resembling bile canaliculi were seen between FCL-5 cells. Scanning electron microscopy demonstrated fenestrae on SEC surfaces. The number of vesiculo-vacuolar organelles (VVO) and fenestrae increased when we introduced the actin-binding agent swinholide-A in the RFB for 2h. With respect to liver function, urea was found in the medium, and expression of mRNAs encoding arginosuccinate synthetase and arginase increased when the three cell types were cocultured in the RFB. However, albumin synthesis decreased.

CONCLUSION: Co-culture in the RFB system can dramatically change the structure and function of all cell types, including the functional characteristics of hepatocytes. Our system proves effective for reconstruction of a liver organoid using a bio-artificial liver.

INTRODUCTION

Liver regeneration technology has made many advances in recent years. Efforts now are being made toward development of embryonic stem cells (ES cells), differentiation of hemopoietic stem cells, and development of isolation and culture methods for somatic stem cells originating from different organs. Hemopoietic stem cells, hepatoblasts originating from fetal liver, hepatocytes, and pancreatic duct epithelial cells have been included in the list of candi-

date cells for liver regeneration[1]. Development of immortalized cells by introduction of the simian virus 40 (SV40) large T antigen gene or human telomerase reverse transcriptase (hTERT) is also under investigation[2]. To date, however, no technique for regenerating and reconstructing parenchymal organs using these cells has been established. Conventional cell culture methods have achieved this goal clinically for skin, cornea, and bone tissue[3,4].

Reconstruction of organs such as the liver requires maintenance of viable cells at a high density and coculture under conditions favorable to several different cell types that constitute a liver. To make a culture system is important in reconstructing a liver organoid. Conventional stationary culture techniques are not well suited to the culture of cells in a layered form, i.e., in a structural and functional organoid a simple air/CO_2 incubator does not deliver adequate oxygen supply to layered cells. Furthermore, high-density culture cannot be maintained with the limited nutrients available in conventional cultures. For these reasons, construction of a bioreactor that allows 3-dimensional growth in a high-density perfusion culture has been advocated for reconstructing a liver organoid. In our study a radial-flow bioreactor (RFB) developed in Japan was used as a candidate model for high-density perfusion culture. Filled with a porous carrier, this bioreactor permits culture at a cell density 10 times higher than that allowed by a hollow-fiber culture system[5, 6]. Another important point is to select a cell source. Clinically, cells using bio-artificial liver are required to be highly functional and supplied quickly in large quantities. Therefore we established a functional human hepatocellular carcinoma cell line (FLC-5), which can express drug-metabolized enzymes (e.g., human-type carboxyl esterase or cytochrome) and liver-specific proteins such as albumin. *In vitro* this cell line retains its three-dimensional form, developing distinct microvilli on the surface. These cells can be cultured in serum-free ASF104 medium (Ajinomoto, Tokyo). A liver organoid cannot be reconstructed with hepatocytes only. At minimum, coculture of hepatocytes with nonparenchymal cells, such as sinusoidal endothelial cell (SEC) and hepatic stellate cell (HSC) is required. So we established immortalized SEC line M1[7] and an immortalized HSC line A7[8] by isolating nonparenchymal cells from an H-2Kb-tsA58-transgenic mouse liver transfected with the SV40 large T antigen gene[9].

Reconstruction of the liver sinusoid is important for activity of the liver organoid as a functional unit. Also, the open pores on the surfaces of SEC in fenestrae have an important functional role in the liver sinusoid. Fenestrae are the most remarkable characteristics of SEC, as first described by Wisse in 1970[10] using transmission electron microscopy (TEM). Diameters of these pores vary between species, ranging from 100 to 200 nm[11]. These fenestrae facilitate the transport of materials and solutes from the luminal to the abluminal side of the liver parenchymal cells and *vice versa*[12]. The process and mechanism of formation of these pores remain largely unclarified[13, 14]. The presence of actin filaments at the margin of these pores has been demonstrated by electron microscopic studies[15, 16]. Swinholide A, a most potent microfilament-disrupting drug available, has been demonstrated to increase the number of SEC fenestrae[13]. However, when immortalized SEC was treated in a monolayer culture or as a monoculture in the RFB, an increase in number of fenestrae could not be observed when the Swinholide A was introduced. The potential for drug-induced increase also has been reported to disappear in long-term cultures[7].

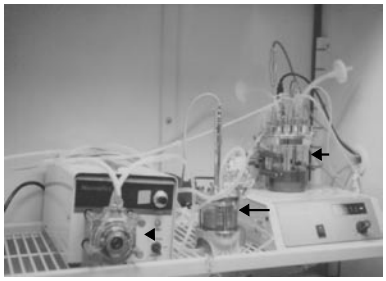

Figure 1 The system of radial-flow bioreactor. A 15-mL radial-flow bioreactor (large arrow), a mass flow controller (arrow head), and a reservoir (small arrow) are connected each other. Culture medium is perfused in the RFB. Medium conditions (PH, oxygen, CO_2 and temperature) are controlled by computer.

In developing a high functioning organoid using a bioartificial liver, the function, form and reactivity of pharmacological agent should be near *in vivo*. In the present study, we reconstructed a functional liver organoid using immortalized cell lines in the RFB.

MATERIALS AND METHODS

Cell culture and medium

We used the three cell lines mentioned above, FLC-5, M1, and A7. As reported, culture of M1 cells was possible in serum-free conditions while supplementation of ASF104 medium with 2% fetal bovine serum (FBS) was required for culture of A7 cells. Therefore, in coculture experiments, ASF104 medium was enriched with 2% FBS.

Coculture in radial-flow bioreactor

As reported elsewhere, the RFB system is composed of a 15-mL radial-flow chamber (RA-15; ABLE, Tokyo), a mass flow controller (RAD925, ABLE), a reservoir (Figure 1), a computer, and a tissue incubator as described previously[17] (Figure 1). The culture medium was oxygenated within the reservoir, and the pH was adjusted automatically to 7.4. Oxygen pressure in the culture medium was measured both within the reservoir and at the outlet of the bioreactor. Relative oxygen consumption was monitored on the basis of the oxygen pressure gradient. During the study the temperature within the reservoir was kept constantly at 37 ℃. Two $\times 10^7$ FLC-5 cells were inoculated into the reservoir. The bioreactor was perfused in a closed circuit for 2 h to aid cells in adhering to the porous carrier cellulose beads (Asahi Kasei, Tokyo). Subsequently the bioreactor was switched to the open-circuit mode, and incubation was continued with addition of fresh culture medium to the reservoir. After 5 d, 2×10^7 A7 cells were added in a similar manner followed by another addition of 10^7 M1 cells 5 d later. Retinol (10^{-6}mol/L) was added during the first 2 d. After three days of perfusion cellulose beads with the adherent cells were harvested, and cells deposited at the bottom of the bioreactor also were recovered. Beads with attached cells were fixed in 1.2% or 2.0% glutaraldehyde as described below.

Swinholide A experiments

We cultured the three cell lines as described above. The

last incubation included perfusion with 200 nmol/L swinholide A (Sigma catalog number S9810; S) for 2 h. The cellulose beads along with adherent cells were harvested from the bioreactor. Beads with attached cells were fixed in glutaraldehyde and prepared for morphologic observation as follows.

Electron microscopy

For scanning electron microscopy (SEM), cultured cells were fixed with 1.2% glutaraldehyde in 0.1 mol/L phosphate buffer (PB) at pH 7.4 and postfixed with 1% OsO_4 in 0.1mol/L PB. The fixed cells were rinsed twice with PBS, subsequently dehydrated in ascending concentrations of ethanol, critical point-dried using carbon dioxide, and coated by vacuum- evaporated carbon and ion-spattered gold. Specimens were observed under JSM-35 scanning electron microscope (JEOL, Tokyo) at an accelerated voltage of 10 kV.

For transmission electron microscopy (TEM), cultured cells were fixed with 2.0% glutaraldehyde in 0.1mol/L PB for 1 h and postfixed with 1% OsO_4 in 0.1mol/L PB for 1 h at 4 ℃. Specimens were dehydrated in ethanol and subsequently embedded in a mixture of Epon-Araldite. Thin sections (60 nm) were cut with a diamond knife mounted on an LKB ultratome, and stained with aqueous uranyl acetate. Specimens were examined under a JEOL 1200EX electron microscope.

Amino acid analysis of supernatants

For analysis of amino acid fractions by high-performance liquid chromatography (HPLC), supernatants were collected from FLC-5 alone and from cocultures of the three cell types in the bioreactor. Supernatants were mixed with 5% sulfosalicylic acid and allowed to stand at 4 ℃ for 15 min. After centrifugation to precipitate protein, supernatants were injected into amino acid analysis columns (L-8500, Hitachi, Tokyo).

Quantitative TaqMan RT-PCR

We measured mRNA expression for the urea cycle enzymes, carbamoyl phosphate synthetase (CPS1), ornithine carbamoyltransferase (OCT), argininosuccinatesynthetase (ASS), argininosuccinatelyase (ASL), and arginase (ARG), as well as mRNA expression for albumin, hepatocyte nuclear factor (HNF)-1 and HNF-4, by quantitative TaqMan reverse transcription polymerase chain reaction (RT-PCR). RT-PCR was performed on the ABI PRISM 7700 sequence detection system using random hexamers from TaqMan reverse transcription reagents and the RT reaction mix (Applied Biosystems, Rockville, M) to reverse-transcribe RNA. TaqMan universal PCR Master Mix and Assays-on-Demand gene expression probes (Applied Biosystems) were used for PCR. A standard curve for serial dilution of 18S rRNAs was generated similarly. A relative standard curve method (Applied Biosystems) was used to calculate the amplification difference in urea cycle-related enzymes between cocultured and control cells, and elongation factor 1 (EF1), for each primer set and between albumin, HNF-1, HNF-4, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH). Specificity was evaluated using GAPDH mRNA as an internal control (4310884E; Perkin-Elmer Applied Biosystems). Each amplification was performed in triplicate, and averages were obtained.

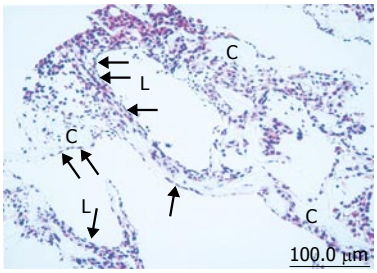

Figure 2 Light microscopic image of coculture in the RFB. High-density and layered cells attached on the cellulose beads (C). Sinusoid-like lumen structure (L) could be observed. SEC was observed with flat shape on surface of the lumen and perfusion side (arrow).

Based on DNA sequences in GenBank, primers and the TaqMan probe for albumin, HNF-1, and HNF-4 were designed using the primer design software Primer Express TM (Perkin-Elmer Applied Biosystems, Foster City, CA). AmpliTaq DNA polymerase extended the primer and displaced the TaqMan probe through its 5'-3' exonuclease activity. Probes were labeled with a reporter fluorescent dye either 6-carboxy-fluorescein (FAM) or 2, 7 dimethoxy-4,5-dichloro-6-carboxy-fluorescein (JOE) at the 5' end and a quencher fluorescent dye [6-carboxytetramethyl-rhodamine (TAMRA)] at the 3' end.

Primers/probes were as follows: ornithine transcarbamoylase (OTC) forward primer 5'-CCAGGCAATAAAAGAGTCAGGATT-3', reverse primer/ 5'-TTATCAAAG TCCCCTGGTTAGAGATACT-3', probe/ 5'-(FAM)- TTCAAATGCTCCTACACCCTGCCCTG-(TAMRA)-3'; arginosuccinase (ASL) forward primer/ 5'-TGGCCAAGGAGGTCGTCA-3', reverse primer 5'-TTCCTCGTCGTCCGGAAG-3', probe 5'-(FAM)-TGTCTTCCAGACCCGGAGACCGAA-(TAMRA)-3'; albumin forward primer/ 5'-CGATTTTCTTTTTAGGGCAGTAGC-3', reverse primer/ 5'-TGGAAACTTCTGCAAACTCAGC-3', probe/ 5'-(FAM)-CGCCTGAGCCAGAGATTTCCCA-(TAMRA)-3'; HNF-1 forward primer/ 5'-AGCGGGAGGTGGTCGATAC-3', reverse primer/ 5'-CATGGGAGTGCCCTTGTTG-3', probe/ 5'-(FAM)-TCAACCAGTCCCACCTGTCCCAACA-(TAMRA)-3'; HNF-4 forward primer/ 5'-GGTGTCCATACGCATCCTTGA-3', reverse primer/ 5'-TGGCTTTGAGGTAGGCATACTCA-3', probe/ 5'-(FAM)-CCTTCCAGGAGCTGCAGATCGATGAC-(TAMRA)-3'; GAPDH forward primer/ 5'-CTCCCCACACACATGCACTTA-3', reverse primer/ 5'-CCTAGTCCCAGGGCTTTGATT-3', probe/ 5'-(VIC)-AAAAGAGCTAGGAAGGACAGGCAACTTGGC-(TAMRA)-3'.

RESULTS

Structure of cells cultured in bioreactor

In the bioreactor, cells cultured in high density assumed layered form on the cellulose beads. Lumen-like structure was observed. Endothelial cells were exits with flat shape at the surface of the lumen and the perfusion side (Figure 2). Multiple layers of FLC-5 cells adhered to the cellulose beads, while A7 and M1 cells were predominantly localized to the side where perfusion occurred. Layered cells were seen in a hole of porous cellulose beads. Sinusoid-like lumen was observed at perfusion side in the cellulose beads

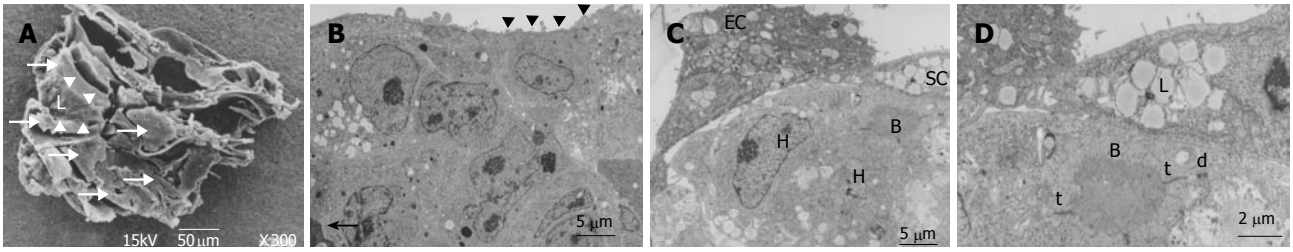

Figure 3 Transmission electron microscopic images of cocultures in the RFB. **A**: The cells are arrayed on the cellulose beads. Several cell clusters could be seen in a gap of cellulose beads (arrow). Vascular lumen structure surrounding cell clusters could be seen in the beads (small arrow). Culture media flow through inside of lumen structure; **B**: The cells are arrayed in layers on cellulose beads. Part of a cellulose bead (arrow) is visible at the bottom of the layer. A process of a sinusoidal endothelial cell (arrowhead) is seen at the perfusion side. Scale bar: 5 μm; **C**: Sinusoidal endothelial cells (EC) can be seen at the perfusion side. Hepatic stellate cells (SC) containing fatty vitamin A droplets are seen overlying the FLC-5 cells (H). FLC-5 cells (H) below EC and SC show bile-canaliculus-like structures (B). Scale bar: 5 μm. **D**: Bile canaliculus-like structures (B) containing electron dense bile components. Tight junctions (t) and desmosomes (d) are visible, as are fatty vitamin A droplets (L). Scale bar: 2 μm.

They form a thin layer (arrowhead), showing the typical appearance of a sinusoid-like vascular structure. Scale bar: 5 μm; **B**: Transmission electron microscopic image showing sinusoidal endothelial cell growth at the perfusion side forming a thin layer (arrowhead) overlying the A7 cells (SC). Scale bar: 1 μm; **C**: Transmission electron microscopic view showing tight junctions (arrow) between sinusoidal endothelial cells (EC). Scale bar: 200 nm.

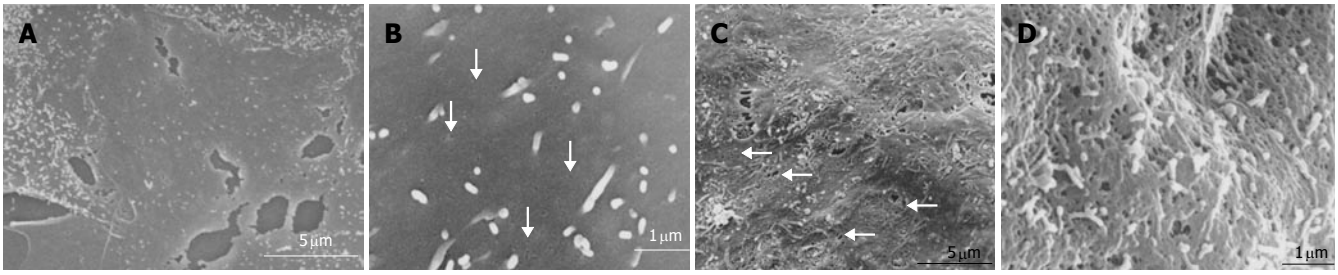

Figure 5 Scanning electron microscopic image of the surface of sinusoidal endothelial cells. **A**: Low-magnification scanning electron microscopic images of the surface of sinusoidal endothelial cells cultured on plastic dishes. The sinusoidal endothelial cells formed a thin layer on the plastic dish substrate. Scale bar: 5 μm; **B**: High-magnification scanning electron microscopy images of the surface of sinusoidal endothelial cells cultured on plastic dishes. Fenestrae could not be detected on the surface of endothelial cells. Only small pits are seen (arrow). Scale bar: 1 μm; **C**: Low-magnification scanning electron microscopic view of the surface of sinusoidal endothelial cells cocultured in the RFB. Fenestrated pores could be observed (arrow). Scale bar: 5 μm; **D**: High-magnification scanning electron microscopic view of the surface of sinusoidal endothelial cells cocultured in the RFB. Pores have a diameter of 100 - 200 nm. Scale bar: 1 μm.

(Figure 3A). TEM showed that cocultured cells assumed layered form from cellulose beads to the perfusion side (Figure 3B). M1 and A7 cells containing vitamin A-laden fat droplets were seen mainly at the perfusion side, while dense layers of FLC-5 cells were observed beneath (Figure 3C). At sites where the three cell lines were in contact with each other bile canaliculus-like structures were present between neighboring FLC-5 cells. Lumens of these structures contained electron-dense bile components, tight junctions and desmosomes also could be observed (Figure 3D). This side showed growth of endothelial cells with the formation of sinusoid-like vascular structures (Figures 4A and 4B). Tight junctions were seen between endothelial cells (Figure 4C). Fenestrae which are characteristic of SEC *in vivo*, were absent in monocultures of M1 cells on plastic dishes (Figures 5A and 5B). Because a long time subculture would change the character of M1 cells, pores were represent on the surface of M1 cells co-cultured in the RFB system (Figure 5C). The pores had a diameter of 100 to 200 nm, being similar in morphology and size to those of fenestrae shown by SEC *in vivo* (Figure 5D).

Morphology of M1 cells incubated with swinholide A

Cells incubated for 2 h with 200 nmol/L of the actin-disrupting agent swinholide A showed the increased number of pores (Figure 6), while some pores were dilated (about

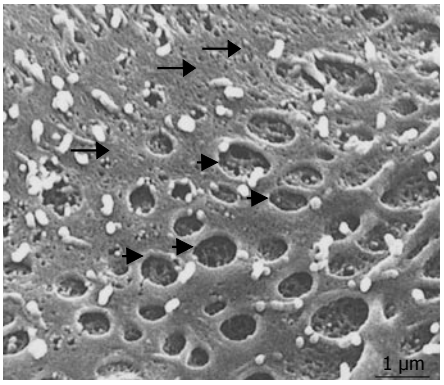

Figure 6 Scanning electron micrographs of the surface of swinholide A - treated SEC cells in the RFB culture system. Large open pores have a fenestra-like appearance (short arrow). Small pores were detectable in the nonfenestrated area (long arrow). Scale bar: 1 μm.

1 μm). Small pores (tens of nanometers in size) that probably resembled coated pits were abundant in the nonfenestrated areas.

TEM investigation showed that treatment with swinholide A resulted in fenestrated pores with a diameter between 100 and 200 nm. The pores fused with each other formed labyrinthine structures (Figure 7A). In addition, vacuoles with a diameter of about 200 nm, similar to previously described vesiculo vacuolar organelles (VVO), were noted. These structures typically were seen in areas where relatively regular overlap was seen in FLC-5, A7, and M1. The number of VVO increased when cells were treated with 200 nmol/L swinholide A, which was associated with partial fusion (Figure 7B).

Amino acid fractions from supernatants

At the end of culture, the supernatant was subjected to amino acid analysis. Urea production was not seen in monocultures of FLC-5 cells in the RFB, while FLC-5 cells cocultured with M1 and A7 cells produced 523 nmol urea /mL in the culture medium, suggesting that the urea cycle was activated in the coculture RFB system (Figure 8). Several amino acids were increased in the medium.

We compared mRNA expression of CPS1, OTC, ASS, ASL, and ARG in FLC-5 monolayer cultures with those of monocultures in the RFB system. In addition, mRNA expression in cocultures in the RFB also was assessed. We could not detect OTC in any type of culture. Expression of other urea cycle enzymes showed no notable difference between monolayer culture of FLC-5 and monoculture of FLC-5 in the RFB. However, ASS and ARG expressions in co-culture in the RFB were about 7 and 3 times greater than those in FLC-5 monolayer culture (Figure 9).

Albumin synthesis and expression of nuclear factors

We compared mRNA expression of albumin and HNF-1 and HNF-4 as transcription regulation factors between experimental conditions. Expression of mRNA encoding the three proteins was less in FLC-5 co-cultures in the RFB system than in FLC-5 RFB monocultures or in FLC-5 cells in monolayer culture (Figures 10A-10C). In a previous study, albumin production was enhanced in the RFB using the immortalized cell line[17]. However it was different cell line in this study.

DISCUSSION

Introduction of a functional human hepatocellular carcinoma cell line (FLC) in our system can allow the cells to be cultured at high density in a layered array and maintain viability for long periods[17,18].

Immortalized cells can be used for artificial liver. The reason is that it can supply cells in large quantities and quickly. Immortalized cells lose several characteristics in

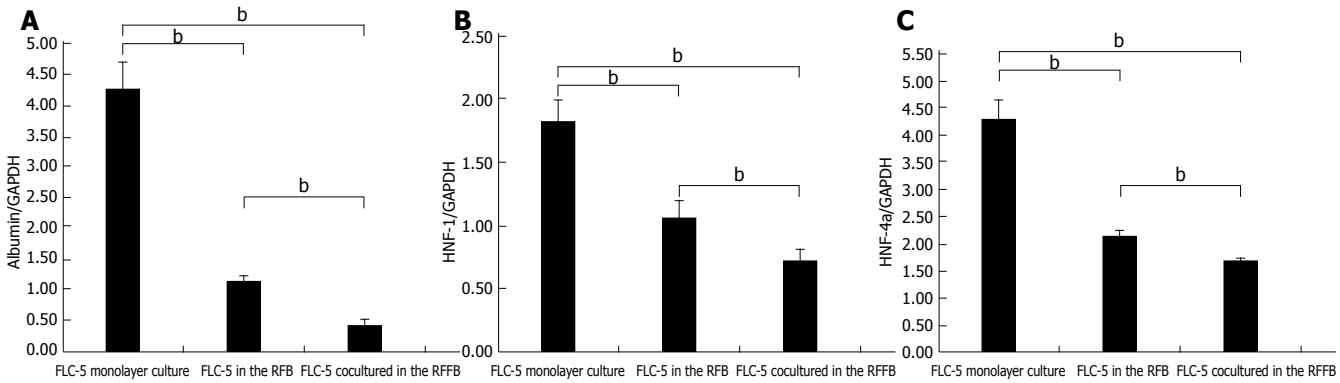

Figure 10 Expression of mRNA for albumin (**A**), HNF-4 (**B**) and HNF-1 (**C**) as transcription regulation factors in each condition. Messenger RNA expression for these three proteins decreased in cocultured FLC-5 in the RFB compared with FLC-5 monocultures in the RFB and FLC-5 cultured in a monolayer. Mean value ± SD. The ratio of mRNA for each protein versus GAPDH is shown. Differences with respect to each condition were statistically significant ($^bP < 0.01$) according to Student's *t*-test.

morphology and function. However, three cell lines were studied in our RFB culture system, including their fine structure according to electron microscopy. Layers of FLC-5, A7, and M1 were arranged respectively from the carrier attachment side to the perfusion side. In some areas, liver-like architectures, sinusoid-like lumen structure, bile-canaliculi and functional complex, were observed, comparable to *in vivo* tissue relationship. The M1 cell line well covered the perfusion side, mimicking vascular structures, indicating that this cell type forms an arrangement similar to that *in vivo*. Furthermore, M1 cells in monolayer culture did not express fenestrae, probably reflecting a long culture or subculture time[19]. In a previous study, we found that M1 cells also lack fenestrae in monocultures in the RFB[7]. In contrasts, fenestrated pores were seen in M1 cells cocultured according to the present RFB experimental design. Coculture and cell to cell contact have an influence on these morphological changes. Because fine structures *in vivo* could be observed better than monoculture in the RFB.

The electron microscopic observations in the present study clearly showed that if an appropriate environment for cell growth was provided in a perfusion culture system, the individual cell types could arrange themselves according to their *in vivo* characteristics, even in a high-density layered culture.

This study also examined the numerical dynamics of fenestrae. For this we exposed the cocultures to the actin-disrupting drug swinholide A[13]. When the cells were treated with swinholide A, the number of pores with a diameter of about 100 to 200 nm increased 2 h after swinholide A treatment. Furthermore, by TEM, cytoplasmic vesicles about 200 nm in diameter could be seen and were much larger than the caveolae in the cytoplasm, and their number increased in the presence of swinholide A. These vacuolar-like vesicles probably represent the vesiculo vacuolar organelle (VVO) as described by Feng *et al*[20]. The VVO is an organelle contributing to transport of macromolecules between luminal and abluminal sides of endothelial cells, thus increasing transcellular permeability. Vascular permeability factor and vascular endothelial growth factor (VPF/VEGF) can induce formation of VVO[21]. FLC-5 used in this study, could express VPF/VEGF (data not shown). The presence of vascular factors may partially explain why VVO is noted in cocultures and why fenestrae could be observed in our experiments[22]. VVO is thought to be formed by fusion of caveolae, when multiple VVOs fuse together, a structure extending from the luminal to the abluminal sides of endothelial cells is formed. In the present study, fused VVOs also were seen in swinholide A - treated specimens by transmission electron microscopy, suggesting that this fusion represents a process culminating in formation of the labyrinthine structures in SEC[23]. The mechanism of pore formation in immortalized SEC and under cocultured perfusion conditions remains unknown from the present study. However, pore formation may result from multiple effects or factors working in concert upon endothelial cells, such as cytoskeletal dynamics represented by actin and/or the influence of a yet unknown factor secreted by other cell types present in the cocultures such as VEGF. The observation that hepatic endothelial cells maintain one of their typical morphological features (i.e. an abundant number of membrane-bound coated-pits, uncoated vesicles/vacuoles and fenestrae) is an indication that the bioreactor mimics a nearby physiological cultivation environment for the various liver cell types. However, the mechanism by which the bioreactor and its culture environment bring about and maintain these membrane-bound vesicles and fenestrae in endothelial cells remain to be elucidated and consequently open up new directions for future experiments.

To assess hepatocyte function, we compared mRNA expression for urea cycle enzymes and albumin synthesis by FLC-5 in monolayer culture compared to these single-type cultures and cocultures in the RFB. Previously, we have demonstrated hepatocyte functions such as albumin synthesis and cytochrome expression are enhanced in the RFB[24, 25]. Urea production is among the most primitive functions of liver cells. We could not detect urea in medium from monolayer cultures or monocultured FLC-5 in the RFB. In contrast, FLC-5 cells cocultured in the RFB exhibit ability to produce urea, and mRNA expression for ASS and ARG is enhanced. The medium used in this experiment, ASF 104 contained arginine, so urea production was observed in cocultures in the RFB although OTC was not expressed. One report showed that urea produc-

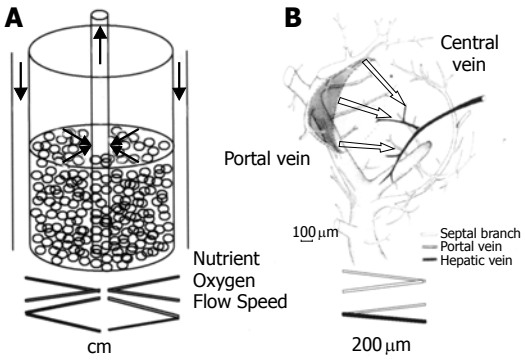

Figure 11 RFB and intact organ. **A**: In the RFB system, culture medium flows from outside the column toward the center of the reactor. Medium flows faster at the center than at the periphery. Biases in distribution of oxygen and nutrition at inflow and outflow are minimized. **B**: In the hepatic lobe, blood flows from the portal vein to central vein. The RFB system is similar to the organization of the hepatic primary lobe[31]. Figure 11B is reproduced from Figure 9 in reference 31.

tion in OTC-deficient mice could be detected under the same condition[26]. Glutamic acid, glutamine and alanine were also increased in supernatant co-cultured in the RFB, indicating that amino acid metabolism becomes active.

It was reported that three-dimensional spherical culture induces albumin synthesis, a particularly important hepatocytic function[27, 28]. However, in the present study, mRNA expression of albumin was decreased under coculture conditions in the RFB. Nuclear transcriptional factors HNF-4 and HNF-1, which regulate albumin synthesis, were decreased under coculture conditions in the RFB. Albumin in supernatant was also decreased during culture (data not shown). The results suggest that the culture environment (cell-to-cell communication, cell polarity, shear stress, and other factors) can control manifestations of intracellular nuclear transcription factors and therefore dramatically influence albumin production by liver cells. Immortalized cells can be used for artificial liver. The reason is that it can supply cells in large quantities and quickly. But immortalized cells may change the characteristics of its original cells. In this study, albumin synthesis was decreased. It was not useful for artificial liver. In future study, we have to try other cell sources (ES cell, oval cell, and other immortalized cell lines).

Finally, several points should be noted concerning our culture system. First, controlling the mixture ratio of the three cell types used is very difficult since each type possesses its own potential for active growth. Thus, growth rates vary between cell types and are difficult to control. For examples, A7 cells grew less rapidly and tended to be less than the other two cell types in the coculture system. Second, the hepatic lobule spans about 140 μm *in vivo*, extending from the portal to the central area, toward which portal blood flows in a radial manner. According to Matsumoto *et al*[29], the liver is an organ composed of numerous groups of microscopic three-dimensional units (minimal radial-flow bioreactors) extending from the inflow side (composed of combinations of parabola-shaped inflow fronts) to the central vein[30]. According to this model, the liver microcirculation as observed *in vivo* could not be reproduced faithfully with a radial-flow bioreactor, since the distance between inflow and outflow sides in the bioreactor is about 1.5 cm (Figure 11). Third, bile canaliculus-like structures are formed between hepatocytes. Since we did not use the bile duct cells in this study, whether different cell types can reconstruct bile ducts remains to be elucidated[31]. Finally, although several questions remain, the results of the present study suggest that liver reconstruction is possible *in vitro*. Such organ reconstruction technology is expected to contribute greatly to the development of sophisticated artificial livers and other organs for transplantation. Our culture system may be a very important tool to maintain liver organ.

ACKNOWLEDGMENTS

Abstract

AIM: To demonstrate bone marrow stromal cells (BMSCs) can be used as an attractive target for genetic modification in the treatment of malignant diseases.

METHODS: Using a hamster model of biliary cancer, we investigated the therapeutic effects of interleukin-2 (IL-2) gene-modified BMSCs. Syrian golden hamsters were injected via the femoral vein with 5×10^5 cells of the KIGB-5 biliary cancer cell line (n=20). One week later, the hamsters were injected intraperitoneally with BMSCs containing Ad/hIL-2 and Ad/ΔE1, unmodified BMSCs, or RPMI only (control) and observed for 12 wk (n=5 /each group).

RESULTS: All hamsters treated with BMSCs containing Ad/hIL-2 survived with no evidence of the disease during this period. In contrast, hamsters in the other three groups showed disseminated metastases involving the lungs as early as 4 wk.

CONCLUSION: Ad/IL-2 therapy is effective in the treatment of biliary cancer.

Key words: Bone marrow stromal cell; Adenovirus/hIL-2; Biliary cancer

INTRODUCTION

Cholangiocarcinoma arising from bile duct epithelium is the second most common primary liver cancer in the world[1]. In the United States, 2000-3000 new cases of cholangiocarcinoma are diagnosed per year[2]. At present, only surgical excision of all detectable tumors can improve 5-year survival[3-5]. However, most patients are not candidates for surgery and undergo only endoscopic or percutaneous biliary drainage procedures, such as plastic or metal stents. Systemic chemotherapy and radiation therapy are not able to enhance the survival of patients with cholangio carcinoma[6-11].

Introduction of specific genes into the body by infusion of vehicle cells that have been modified *ex vivo* offers a potential therapy for a number of diseases. Vehicle cells most commonly used for gene transfer include hematopoietic stem cells, peripheral blood lymphocytes and bone marrow stromal cells (BMSCs). Among these, BMSCs have several advantages including ease of culture and gene transduction, as well as specificity to hematopoietic organs such as bone marrow, spleen, and liver. These qualities make BMSCs ideal for gene transfer in hematologic diseases[12].

BMSCs have been shown to support hematopoiesis and have the potential to differentiate into cells of multiple lineages, including osteogenic, chondrogenic and adipogenic cells[13-15]. Human BMSCs can be easily obtained and grown in conventional *ex vivo* culture. In addition, BMSCs can be infused safely and have been shown to home to the bone marrow, spleen, lung, liver and kidney. Using a murine lymphoma model, we found that immunocell therapy with ad/hIL-2 encoded stromal cells shows promising therapeutic results[16]. Here we further investigated immunocell therapy for biliary cancer induced by the KIGB-5 cell line in Syrian golden hamsters, and found that Ad/hIL-2 genetically-modified BMSCs could provide adoptive immunocell therapy for biliary cancer.

MATERIALS AND METHODS

Animals

Female Syrian golden hamsters aged 6-8wk, purchased from Harlan (Indianapolis, Indiana, USA) were housed in the specific pathogen-free unit of the Animal Resource Center at the Asan Institute for Life Sciences and Technology.

Cholangiocarcinoma cell line

The KIGB-5 cell line, a gallbladder carcinoma cell line derived from Syrian golden hamsters, was established and kindly provided by Dr. Tajima (Nagasaki University, Nagasaki, Japan). This cell line was maintained in complete RPMI-1640 (GIBCO BRL, Grand Island, NY, USA) supplemented with 100 mL/L fetal bovine serum (FBS) (GIBCO BRL, Grand Island, NY, USA), 100 U/mL penicillin (Sigma, St. Louis, MO, USA), 0.1 mg/mL streptomycin (Sigma), and 10^{-5} mol/L β-mercaptoethanol (Sigma)[17]. The 293 cell line, derived from human embryonic kidney, was maintained in high glucose DMEM (GIBCO BRL) and 100 mL/L FBS (GIBCO BRL).

BMSC culture

Bone marrow cells were obtained by flushing the femurs and tibias of 6-8 wk old Syrian golden hamsters with RPMI-1640 medium (GIBCO BRL) using 2mL syringes with 23-guage needles. After a single-cell suspension was prepared, the cells were plated at a concentration of 5.0×10^5 /mL in 75 cm^2 plastic tissue culture flasks, and cultured in McCoy's 5A medium (Sigma) supplemented with 125 mL/L FBS, 125 mL/L horse serum (HS), 200mmol/L L-glutamine, 0.05 mg/mL hydrocortisone, 1 ng/mL recombinant human basic fibroblast growth factor (rh bFGF, Invitrogen Corporation, Groningen, Netherlands), and 0.5ng/mL rh IL-1α (Invitrogen) at 37 ℃ in 50 mL/L CO_2 and 950 mL/L air. The cultures were fed weekly by replacing 500 mL/L of the supernatant with fresh culture medium. When the cells became confluent, they were trypsinized and harvested for passage. Gene transduction was performed on cells after 5 passages.

Preparation of recombinant adenovirus

Three replication-deficient adenoviral vectors were used, namely Ad/Lac-Z containing the β-galactosidase gene, Ad/ΔE1 and Ad/hIL-2 harboring the human IL-2 gene. Each of these vectors was constructed from human adenovirus serotype 5 by homologous recombination. The expression of the inserted genes was driven by a CMV promoter. The recombinant adenoviruses were propagated into human 293 embryonic kidney cells, and the adenoviral titers were determined by a plaque-forming assay with these cells. Recombinant adenoviruses were diluted to a titer of 5.0×10^8 PFU/mL in viral supernatant and stored at -70 ℃.

Stromal cell transduction

Stromal cells (SCs) were seeded at a density of 1.0×10^5 /mL in 75 cm^2 plastic tissue culture flasks and allowed to grow. The medium was removed, the cells were washed twice with PBS, and the modified adenovirus was added at various multiplicities of infection (MOI). The cells were cultured at 37℃ for 24h in a humidified atmosphere of 50 mL/L CO_2.

The transduction efficiency of the recombinant adenoviruses was determined by an X-gal assay. BMSCs were transduced with Ad/Lac Z for 24h at 0, 10, 20, 50, 100 MOI. After one round of transfection the transduction efficiency was determined by the percentage of blue-stained cells, after subtraction of the percentage of non-specifically stained, uninfected BMSCs[7]. Stained positive cells were 5-10% at 10 MOI, 10-15% at 20 MOI, 40-50% at 50 MOI, 60-65% at 100 MOI (Figure 1).

From the results of the preliminary experiments we decided to use 50 MOI for further experiments.

X-gal assay

BMSCs were seeded in 12-well plates and transfected 24 h later with Ad/Lac Z. The cells were cultured for 24 h at 37 ℃ in a humidified atmosphere containing 50 mL/L CO_2. The media were removed and the cells were washed with PBS. Fixing solution was added to the transfected cells at room temperature for 5 min and removed. The cells were stained with 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside(X-gal) overnight at 37℃ in a humidified atmosphere containing 50 mL/L CO_2.

Stromal cell transplantation

To test for homing of gene-transduced stromal cells, 6-8 wk old Syrian gold hamsters were infused intraperitoneally (IP) or injected via the femoral vein with transduced stromal cells mixed in 0.1 mL PBS at a dose of 2.5×10^6 cells per animal. After one week, the hamsters were sacrificed and the bone marrow, spleen, liver, kidneys, and lungs were obtained. Single cells prepared from these organs using collagenase (GIBCO BRL) were cultured for four days and stained with X-gal to test for homing of the transfected cells.

RT-PCR

Total RNA was extracted using Trizol (Life Technologies, Invitrogen) following the manufacturer's instructions. The extracted RNA was resuspended in diethylpyrocarbonate-treated water at a concentration of 0.5 μg/μL. Two ug of each total RNA preparation was reverse-transcribed into cDNA using Moloney murine leukemia virus reverse transcriptase (Boeringer, Manheim, Germany) in 20 μL reaction mixture containing 50 mmol/L DTT, 1 μg oligo (dT) and 0.125 mmol/L dNTPs, as described by the manufacturer. The cDNAs were stored at -20℃ or directly used for subsequent amplification. Amplification of human IL-2 mRNA was performed using primers: 5' -TTGCATTGCACTAAGTCTTGC-3' (forward) and 5' -CAATGGTTGCTGTCTCATCAG-3' (reverse), whereas amplification of GAPDH mRNA was performed using primers: 5'-ACCACAGTCCATGCCATCAC-3' (forward) and 5'-TCCACCACCCTGTTGCTGTA-3' (reverse). PCR was performed in reaction mixtures containing 10 mmol/L Tris-HCl (pH 8.3), 1.5 mmol/L $MgCl_2$, 50 mmol/L KCl, 200 μmol/L of each dNTP, 1 μmol/L of each primer, 0.5 units of Taq polymerase, and 1×concentration of PCR buffer, in a total volume of 50 μL. The amplification pro-

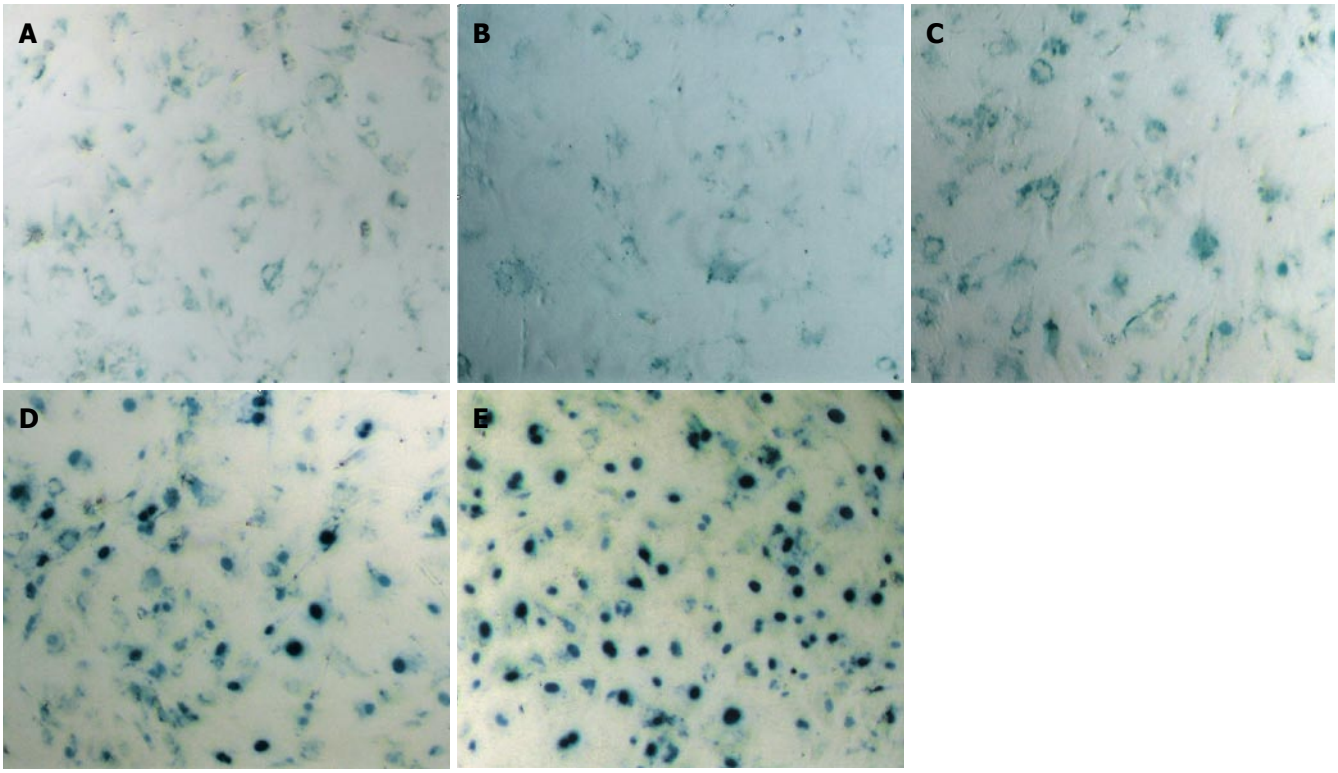

Figure 1 X-gal assay of hamster BMSCs transfected with Ad/ Lac Z at 0 (**A**), 10 (**B**), 20 (**C**), 50 (**D**), and 100 (**E**) MOI.

tocol consisted of 32 cycles of denaturation at 94℃ for 30 s, annealing at 55℃ (IL-2) or at 65℃ (GAPDH) for 30 s, and extension at 72℃ for 40 s (IL-2) or 80 s (GAPDH), using a Perkin-Elmer 9600 thermal cycler. The PCR products were separated on 15 g/L agarose gels stained with ethidium bromide.

hIL-2 ELISA

BMSCs were seeded at a concentration of 2.5×10^5 cells/mL and transduced with Ad/hIL-2 for 1, 2, 3, or 5 d .The supernatants were collected each day, filtered and tested for the presence of IL-2 by ELISA (Endogen, Woburn, MA, USA).

Preparation of cholangiocarcinoma-bearing hamster model

KIGB-5 cells were cultured for 6-7 passages, washed three times and resuspended in PBS. Each hamster was infused through the femoral vein with 5.0×10^5 KIGB-5 cells. After seven days, the tumor-bearing hamsters were divided into four groups and injected intraperitoneally with PBS ($n = 5$), unmodified BMSCs ($n = 5$), BMSCs+Ad/hIL-2 ($n = 5$) or BMSCs+Ad/ΔE1 ($n = 5$). Hamsters were sacrificed 4, 8, and 12 wk after tumor inoculation, and the number of metastatic lesions in each was assessed.

RESULTS

Evaluation of BMSC homing

Following transduction of BMSCs with Ad/LacZ at 50 MOI for 24 h, 2.5×10^6 cells were transplanted into each hamster. After one week, the hamsters were sacrificed and various organs including bone marrow, spleen, kidneys, liver, and lungs, were obtained. Single cell preparations were made from each of these organs and examined by X-gal assay. We found that the BMSCs made in our laboratory homed primarily into the bone marrow, spleen and liver, with fewer in the lungs and kidneys (Figure 2).

Expression of human IL-2

The Ad/hIL-2 construct was designed to express human IL-2 protein in BMSCs. To confirm hIL-2 expression in BMSCs transduced with Ad/hIL-2, we tested these cells by RT-PCR and ELISA. Both showed IL-2 expression in transduced BMSCs (Figure 3).

Gross and microscopic findings of metastatic lesions

Following injection of KIGB-5 cells into hamsters, we observed gross metastatic lung lesions after 8 wk (Figure 4).

Hamsters subsequently injected with RPMI, unmodified BMSCs, or BMSCs containing Ad/ΔE1 had multiple metastatic lung lesions 8 and 12 wk after tumor cell injection, but no metastatic lesions were observed in the liver or other organs. In contrast, no evidence of metastatic tumors was observed in hamsters treated with BMSCs containing Ad/hIL-2. These findings were further confirmed by microscopic examination (Figure 5).

DISCUSSION

Cholangiocarcinoma is an extremely aggressive tumor most frequently detected at an advanced stage. Fewer than 50% of patients with cholangiocarcinoma have a chance of curative surgery. Patients with advanced disease have a

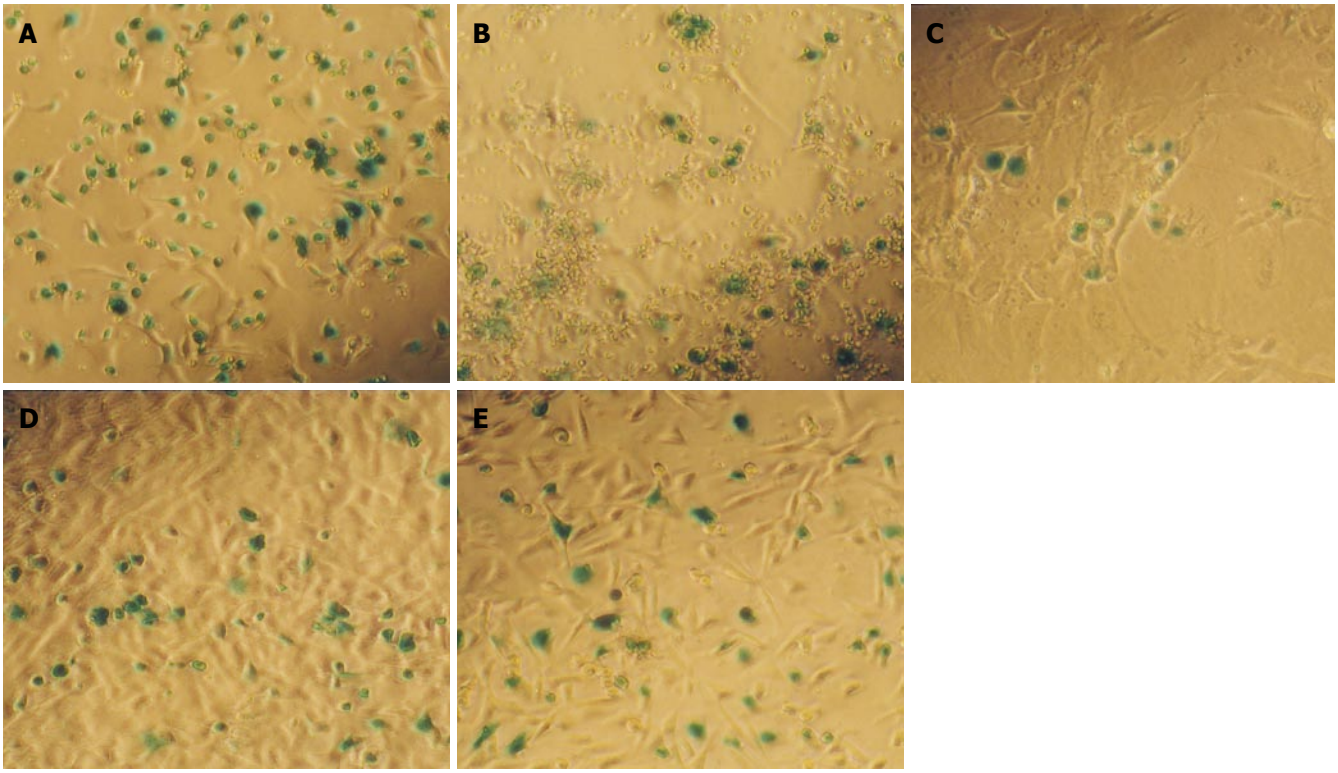

Figure 2 X-gal assay of post -transfection in BM (**A**), spleen (**B**), kidney (**C**), lung (**D**), and liver (**E**).

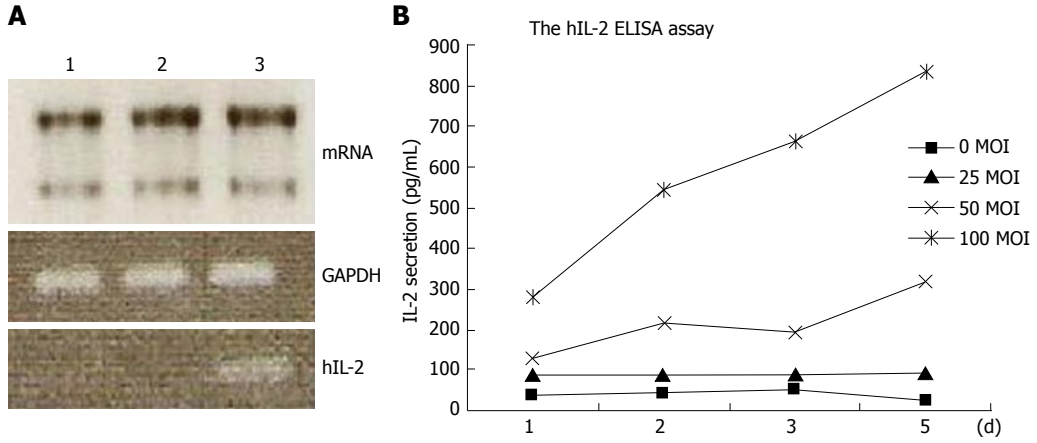

Figure 3 Expression and quantitative analysis of human IL-2. **A:** RT-PCR of in vitro cultured BMSC. Lane 1: $1x10^6$ stromal cells; lane 2: $1x10^6$ stromal cells containing 20 MOI Ad/ΔE1; lane 3: $1x10^6$ stromal cells containing 20 MOI Ad/hIL-2; **B:** ELISA assay of IL-2 secretion from in vitro cultured BMSCs (2.5 X 10^5/mL) of Syrian golden hamster after transduction with Ad/hIL-2 at MOI of 0(◆), 25(■), 50(▲), and 100 (●). Culture supernatants were harvested on different days and tested for hIL-2 secretion levels by ELISA.

median survival time of less than 6 mo and respond poorly to conventional chemotherapy[18]. Patients who undergo curative surgery have a 5 year-survival rate ranging from 16% to 32% because of early lymph node metastases[19, 20].

There have been no clinical trials using adoptive immunotherapy (IL-2 cytokine or dendritic cell and tumor lysates) for biliary cancer. We previously showed that BMSCs can be targeted to bone marrow in mice as well as to other organs, including spleen, liver, kidneys and lungs. Moreover, BMSCs containing Ad/hIL-2, with a low calculated dose of IL-2, are therapeutically effective for malignant lymphoma, because animals treated with this recombinant demonstrate 100% survival with no evidence of the disease, whereas control mice show extensive metastases[16]. These findings encouraged us to investigate whether Ad/hIL-2 would be effective in hamsters bearing biliary cancer induced by the KIGB-5 cell line. IL-2 is a cytokine with multiple biologic effects, including enhancement of the cytotoxic activity of cytotoxic T lymphocytes (CTLC). Previous clinical trials have shown that IL-2 has anti-tumor modulating effects in melanoma, renal cell carcinoma and hematologic malignancies[22]. In each of these models, the IL-2 dose is extremely high and has moderate to severe clinical side effects whereas the response rate ranges from 20-25%[21, 22].

Adenoviruses can bind efficiently to epithelial cells and efficiently transfer genes into both replicating and non-replicating cells, although the transfection efficiency varies depending on cell type. Therapy with BMSCs containing Ad/hIL-2 has potential advantages for gene delivery *in vivo* due to their ability to home to specific organs and to secrete IL-2 into the local microenvironment. This may en-

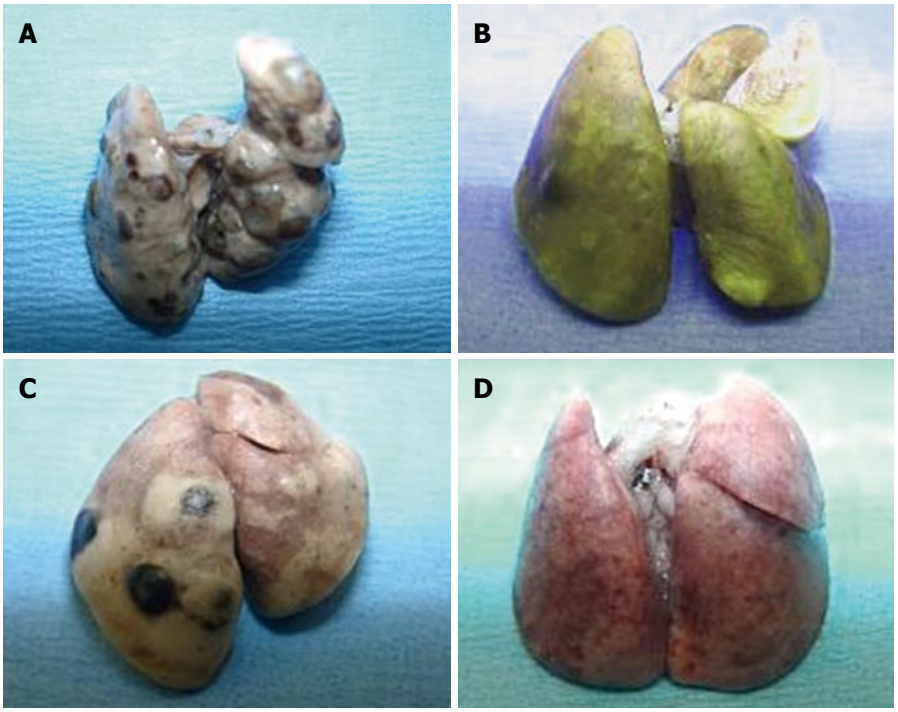

Figure 4 Gross findings of metastatic lung lesions in Syrian hamsters 8 wk after injection of KIGB-5 tumor cells in RPMI control (**A**), BMSCs (2.5×10^6 cells/d) (**B**), BMSCs containing 50 MOI Ad/ΔE1 (2.5×10^6 cells/day) (**C**), and BMSCs containing 50 MOI Ad/hIL-2 (2.5×10^6 cells/d) (**D**). Hamsters injected with RPMI, BMSCs, or BMSCs containing Ad/ΔE1 showed multiple metastatic lung lesions 8 wk after tumor injection, whereas hamsters injected with BMSCs containing Ad/IL-2 showed no evidence of disease.

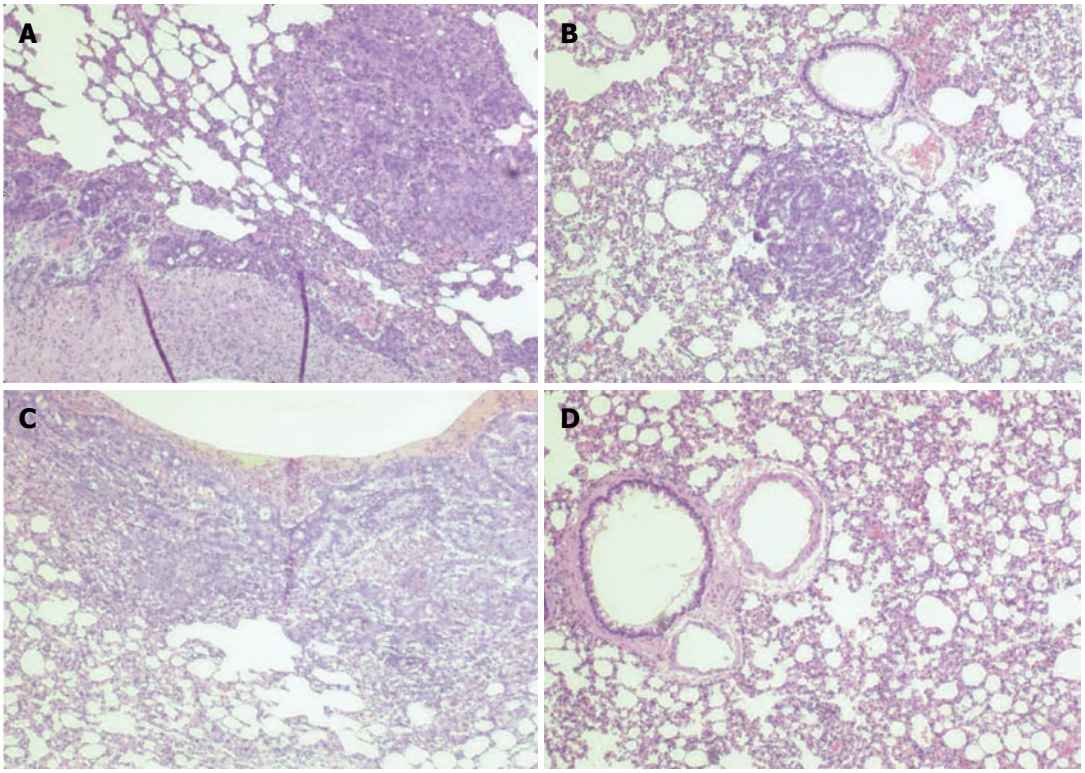

Figure 5 Microscopic findings in Syrian hamsters 8 wk after injection of KIGB-5 tumor cells in RPMI control (**A**), BMSCs (2.5×10^6 cells/d) (**B**), BMSCs containing 50 MOI Ad/ΔE1 (2.5×10^6 cells/d) (**C**), and BMSCs containing 50 MOI Ad/hIL-2 (2.5×10^6 cells/d) (**D**). Hamsters injected with RPMI, BMSCs, or BMSCs containing Ad/ΔE1 showed multiple metastatic lesions in both lungs, whereas hamsters injected with BMSCs containing Ad/IL-2 showed no evidence of disease.

hance cytotoxicity against tumor cells while reducing side effects.

Using BMSCs containing Ad/Laz ((β-galactosidase gene), we observed strong positive X-gal staining in the bone marrow, spleen, liver, lungs and kidneys. The transduction efficiency of these BMSCs was 70% at 50 MOI and 90% at 100 MOI. At 50 MOI, BMSCs containing Ad/hIL-2 showed effective anti-tumor effects. These animals showed no evidence of the disease, whereas the control animals developed widespread metastases during the 12 wk observation period. In addition, hamsters treated with BMSCs containing Ad/hIL-2 showed no evidence of side effects until the time of sacrifice. These findings suggest that BMSCs containing Ad/hIL-2 can implant into various organs and that locally-transplanted IL-2 stimulates and activates T4 and T8 cells leading to an attack on tumor cells via paracrine effects, thus killing tumor cells at metastatic sites.

One limitation of this study is that BMSCs were infused prior to the formation of measurable tumor mass

in hamsters, thus not allowing us to determine whether the effect of IL-2 was dependent on tumor burden. However, given that BMSCs containing Ad/hIL-2 could suppress cholangiocarcinoma development in hamsters, this therapy may be effective as an adjuvant treatment after curative resection in minimizing residual disease after debulking surgery. These findings suggest that treatment with BMSCs containing Ad/hIL-2 may be one of the potential modalities for cholangiocarcinoma, especially for eradicating residual metastatic biliary cancer.

ACKNOWLEDGMENTS

The authors thank Dr. Tajima for providing the KIGB-5 cholangiocarcinoma cell line.

Abstract

AIM: To determine the role of c-Jun N-terminal kinase (JNK) activity in ethanol-induced apoptosis and the modulation of this signaling cascade by S-Adenosyl-methionine (AdoMet).

METHODS: Primary hepatocyte cultures were pretreated with 100 μmol/L SP600125, a selective JNK inhibitor, 1 mL/L DMSO or 4 mmol/L AdoMet and then exposed to 100 mmo/L ethanol. Hepatocyte apoptosis was determined by the TUNEL and DNA ladder assays. JNK activity and its inhibition by SP600125 and AdoMet were determined by Western blot analysis of c-jun phosphorylation and Bid fragmentation. SP600125 and AdoMet effects on the apoptotic signaling pathway were determined by Western blot analysis of cytochrome c release and pro-caspase 3 fragmentation. The AdoMet effect on glutathione levels was measured by Ellman's method and reactive oxygen species (ROS) generation by cell cytometry.

RESULTS: The exposure of hepatocytes to ethanol induced JNK activation, c-jun phosphorylation, Bid fragmentation, cytochrome c release and pro-caspase 3 cleavage; these effects were diminished by SP600125, and caused a significant decrease in ethanol-induced apoptosis ($P < 0.05$). AdoMet exerted an antioxidant effect maintaining glutathione levels and decreasing ROS generation, without a significant effect on JNK activity, and prevented cytochrome c release and pro-caspase 3 cleavage.

CONCLUSION: The JNK signaling cascade is a key component of the proapoptotic signaling pathway induced by ethanol. JNK activation may be independent from ROS generation, since AdoMet which exerted antioxidant properties did not have a significant effect on JNK activity. JNK pathway modulator agents and AdoMet may be components of promising therapies for alcoholic liver disease (ALD) treatment.

INTRODUCTION

Ethanol abuse increases the risk of developing liver damage, such as fatty liver, hepatitis, cirrhosis and the development of viral hepatitis and hepatocarcinomas[1-3]. Alcoholic liver disease (ALD) is a common health problem in Western countries, therefore the diagnostic evaluation and clinical management of ALD are major issues of concern. Clinical management depends on the extent of ALD and, although alcohol abstinence and supportive care are the classical treatments for ALD, the development of new therapies to improve ALD outcome are being examined. Among these new therapeutic agents are small c-jun N–terminal kinase (JNK) inhibitors, such as SP600125 and S-Adenosyl methionine (AdoMet), the principal biological methyl donor and also a glutathione (GSH) precursor in the liver[4-6]. However, an incomplete knowledge of the molecular mechanisms regulated by these agents in ALD development has complicated the validation of these new therapeutic approaches.

The JNK signaling pathway, a member of the mitogen-activated protein kinases family, regulates cell differentiation, proliferation, inflammation, cell survival and cell death in response to stress signals[7,8]. Acute ethanol exposure induces JNK activation, promoting hepatocyte apoptosis[9-11], which has been strongly correlated with liver disease and postulated as the "nexus of liver injury and fibrosis"[12]. Small molecule JNK inhibitors, such as SP600125[13], have been proved to exert a protective effect in reperfusion liver injury and are suggested as optional treatment for liver disease[14-16]. Thus, the JNK signaling transduction pathway has emerged as an interesting element in liver disease development, opening the possibility that its modulation may represent an important approach for ALD treatment. Besides specific small molecule inhibitors, JNK activity may be modulated by other therapeutic agents, such as antioxidants[17-19]. Indeed, in diverse aspects of cellular function, JNK is implicated as a redox stress cell sensor[20]. Alcohol ingestion promotes oxidative stress[21-24] and causes changes in intrahepatic GSH[25,26]. This events may be related to JNK activation induced by ethanol. AdoMet, which has been shown to inhibit hepatocyte apoptosis[27], is increasingly used for liver disease treatment, although its protective mechanisms still remain unclear. A possible hepatoprotective mechanism has been attributed to AdoMet effects on the regulation of cytosol and mitochondrial GSH levels[28-30]. The up-regulation of GSH levels may have a down-regulatory effect on JNK signaling, since GSH acts as a key cell signaling modulator[31,32].

Although JNK has been identified as a pro-apoptotic signaling pathway involved in ALD development, the mechanism by which JNK induces programmed cell death remains far less clear[9,14,16], limiting the identification and validation of JNK-activity modulator agents as a potential ALD treatment. In this study, we determined the effect of the small JNK inhibitor SP600125 and AdoMet on the apoptotic pathway activated by ethanol and a possible modulating effect of AdoMet on JNK activity as part of its hepatoprotective mechanism. We found that JNK activation played a critical role in ethanol-induced apoptosis by means of its effect on Bid fragmentation, a key pro-apoptotic target of JNK. Even though AdoMet increased GSH concentration and protected against ethanol-induced apoptosis, we did not find an effect of AdoMet on JNK activity. These results strongly suggest that JNK activation induced by ethanol is independent of ROS generation, and that the AdoMet protective effects lie mainly at mitochondrial level.

MATERIALS AND METHODS

Materials

Anti-JNK-P and DeadEnd™ Colorimetric TUNEL System were obtained from Promega (Madison, WI). Antibodies against JNK and c-jun-P were purchased from Cell Signaling. c-jun, Bid, caspase 3 and cytochome c antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Anti-actin monoclonal antibody was kindly provided by Dr. Manuel Hernández (CINVESTAV, IPN México). JNK inhibitor SP600125 and caspase 8 inhibitor Z-IETD-fluoromethyl ketone were purchased from Calbiochem (San Diego, CA). Collagenase, ethanol, dimethyl sulfoxide (DMSO), AdoMet in p-toluene sulfonate salt form, 2', 7' -dichloro-dihydrofluorescin diacetate (DCFH-DA) and all other reagents were purchased from Sigma Chemical Company (St. Louis,MO). Electrophoresis reagents and Protein assay kit were from Bio-Rad (Richmond, Calif.)

Animals

Male Fisher 344 rats with an average weight of 200 g were obtained from the Lab Animal Facility UPEAL, CINVESTAV. Animal care was performed according to the guidelines established by the Institutional Animal Care Committee

Hepatocyte isolation and treatments

Rat hepatocytes were isolated from male Fisher rats (weighing 180-200 g) by collagenase perfusion as previously described[33]. Viable hepatocytes were separated by Percoll gradient centrifugation at 1500 r/min for 2 min at 4 °C. Subsequently, cell viability was examined by trypan blue exclusion, and was over 90%. Hepatocytes were plated in Dulbecco's modified Eagle's medium (Gibco-BRL) supplemented with 100 mL/L bovine serum (Gibco-BRL). After 2 h incubation, the medium was changed to William's E medium containing 100 mL/L bovine serum, 1.5 U/mL insulin, 20 nmol/L dexamethasone, 100 μg/mL strep tomycin and 100 U/mL penicillin. Cells were cultured overnight at 37 °C in a humidified atmosphere containing 50 mL/L CO_2. The day after plating, cells were washed with Hank's balanced salt solution (HBSS), and incubated in William's E medium (supplemented with 1 mL/L of fetal calf serum, 100 μg/mL streptomycin and 100 U/mL penicillin) with either 100 μmol/L SP600125, 25 μmol/L Z-IETD-FMK or 1 mL/L DMSO as a vehicle control for 2 h. Another set of cultures was pre-incubated with 4 mmol/L AdoMet for 1 h. Then 100 mmol/L ethanol was added and the dishes were sealed with parafilm to prevent evaporation. The cells were incubated for different periods of time at 37 °C before collection.

Cell viability assessment

Cell viability was determined using the MTT (methyl thiazole tetrazolium) assay as previously described[34]. Briefly, at indicated times after pretreatments and ethanol exposure, media were removed and MTT solution (0.4 mg/mL in media, filter sterilized) was added and the cells were incubated for 2 h at 37 °C. Plates were washed twice with PBS. The resultant formazan product was dissolved by addition of 500 μL DMSO to the plate. Optical density was measured at $A_{595\ nm}$ and cell survival was expressed as percentage of absorbance.

DNA gel electrophoresis

After different pretreatments and 24 h of ethanol exposure, hepatocytes (detached and attached) were harvested and washed in ice-cold PBS by centrifugation at 4°C at 1500 r/min for 5 min in an Eppendorf microcentrifuge. Approximately 8×10^5 cells were resuspended in lysis buffer (200 mmol/L EDTA; 100 mmol/L Tris, pH 8.0;

8 g/L sodium lauryl sarcosine; 20 μg/mL DNase-free RNasa) and incubated at 37 ℃ for 2 h, followed by addition of proteinase K (200 μg/mL) and another overnight incubation at 50 °C. DNA was electrophoresed on 18 g/L agarose gel at 35 mv, stained with ethidium bromide and visualized under UV light[35].

TUNEL assay

The TUNEL assay was performed using a DeadEnd colorimetric apoptosis detection system kit. Rat hepatocytes were cultured on Falcon Chamber slides pre-coated with poly-L-lysine. After different pretreatments and 24 h ethanol exposure, slides were fixed by immersion in 40 g/L paraformaldehyde in PBS for 25 min at room temperature. Then, the TUNEL assay was performed as previously described[36] following the manufacturer's instructions. One hundred cells were counted in three randomly selected microscopic fields and cell apoptotic rate was expressed as a percentage of the total cells counted.

Isolation of mitochondria

Mitochondria were isolated from 4.8×10^6 cells. Cells were washed twice with HBSS, scrapped and centrifuged for 10 min at 1 500 r/min at 4 ℃ in an Eppendorf microcentrifuge. Cell pellets were resuspended in permeabilizing buffer (210 mmol/L D-manitol, 10 mmol/L HEPES, 0.2 mmol/L EGTA, 50 mmol/L succinate, and addition just before use of 70 mmol/L sacarose, 1.5 g/L bovine serum albumin and 80 μg/mL digitonine, pH 7.2) and incubated at 4 ℃ for 20 min. Permeabilized cells were centrifuged at 170 r/min for 10 min at 4 ℃. The supernatant was centrifuged at 13 000 *g* for 10 min at 4 ℃, the second supernatant obtained contained the cytosolic fraction. The pellet resultant from the first centrifugation after the permeabilization step was incubated with 1 mL/L Triton X-100 in PBS for 20 min at 4 ℃ and centrifuged at 13 000 *g* for 10 min at 4 ℃, thus the supernatant contained the mitochondrial fraction. Supernatants were precipitated with 50 g/L sulfosalicylic acid and resuspended in PBS[37]. Protein concentration in the supernatant was determined by the Lowry method.

Immunoblot analysis

Cellular protein was extracted at 4 ℃ in kinase lysis buffer (20 mmol/L Hepes pH 8.0, 136 mmol/L NaCl, 1 mmol/L EDTA, 1 mmol/L EGTA, 10 mmol/L KCl, 2 mmol/L $MgCl_2$, 50 mmol/L sodium fluoride, 1 mmol/L phenylmethylsulfonyl fluoride, 1 mmol/L sodium orthovanadate, 2 g/L SDS) or Chaps buffer for samples to determine Bid and pro-caspase cleavage (50 mmol/L Tris-HCl, 2 mmol/L EDTA, 1 g/L Chaps, 1 mmol/L phenylmethylsulfonyl fluoride and Complete (BioRad) 25×). Cell lysates were centrifuged at 12 000 *g* for 10 min at 4 ℃. The supernatant protein concentration was determined by Lowry method. Whole cell extracts and cytosolic or mitochondrial fractions were resolved on SDS-PAGE and transferred onto nitrocellullose membrane. Blots were incubated overnight at 4 ℃ with antibodies against JNK, phospho JNK, c-jun, phospho c-jun, Bid, caspase 3 (Bid antibody detected full length Bid and caspase 3 antibody recognized the precursor of pro-caspase 3 form) and cytochome c. Then, blots were incubated with horseradish peroxidase-conjugated antibody and developed by chemiluminescence.

Intracellular GSH content determination

Hepatocytes were incubated under control conditions in William's E medium only, or were pretreated with 4 mmol/L AdoMet for 1 h and then exposed to ethanol, or only exposed to ethanol. After the indicated times, cells were harvested and washed with HBSS buffer (pH 7.4). Cells (3×10^6) were sonicated for 1 min in ice-cold 50 g/L sulfosalicylic acid, incubated for 20 min on ice and centrifuged at 12 000 *g* at 4 ℃ for 30 min. The resultant thiol extract was assayed by the method of Ellman with previously reported modifications[38,39]. The pellet obtained from the centrifugation was washed twice with 50 g/L sulfosalicylic acid and resuspended in 0.5 mol/L NaOH. Protein concentration was determined by the method of Lowry. The GSH content (including other eventual thiols) was expressed as nmol per mg of protein.

Measurement of intracellular reactive oxygen species (ROS)

The level of intracellular ROS was measured by the change in fluorescence resulting from oxidation of DCFDA. After treatment for indicated times, hepatocytes were washed with HBSS and incubated with 5 μmol/L DCFH-DA for 30 min at 37 ℃. Hepatocytes were harvested and resuspended in HBSS, and then 5 g/L propidium iodide was added to detect dead cells. Intracellular ROS levels were measured on a Benckton Dickinson FACS Calibur. Ten thousand events were recorded for the analysis[40].

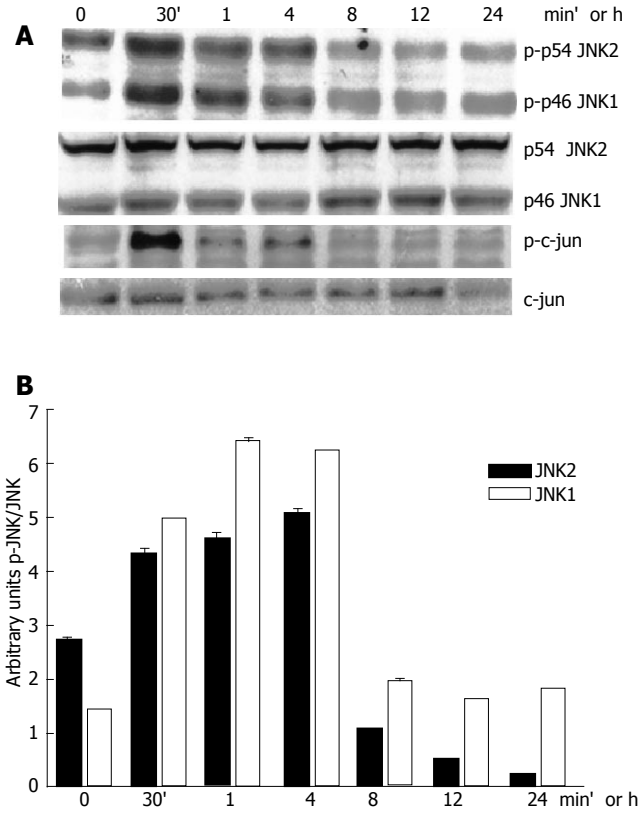
Statistical analysis

Data were analyzed using one-way ANOVA to determine differences between all independent groups. Differences between 2 groups were tested using two-tailed unpaired Student's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

Inhibition of ethanol-induced JNK activation by SP600125

We first confirmed that 100 mmol/L ethanol exposure promoted JNK activation in our system. Ethanol induced JNK phosphorylation. We detected that the JNK1 basal activity was lower than JNK2, while JNK1 activity increment was higher than that for JNK2. Maximal JNK activation induced by ethanol was detected after 30 min and remained above control levels until 8 h after, as detected by c-jun phosphorylation, one of the most commonly measured parameters of JNK activity (Figure 1A-B). Next, we determined the effect of 100 μmol/L SP600125 on JNK activity. JNK activity significantly decreased in SP600125-pretreated hepatocytes compared to hepatocytes exposed to ethanol only ($P<0.05$), as determined by a decrease in c-jun phosphorylation (Figure 2A-B). The Western blot and densitometric analyses shown are representative of three individual experiments.



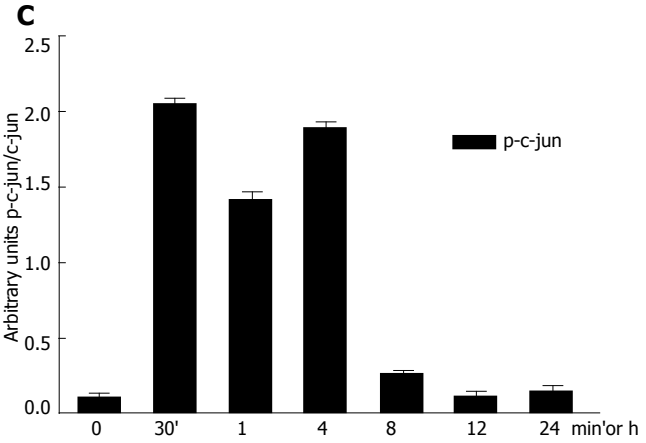


Figure 1 Inhibition of 100 mmol/L ethanol-induced JNK activation by SP600125. **A:** Western blot; **B:** JNK; **C:** P-c-jun densitometric analysis.

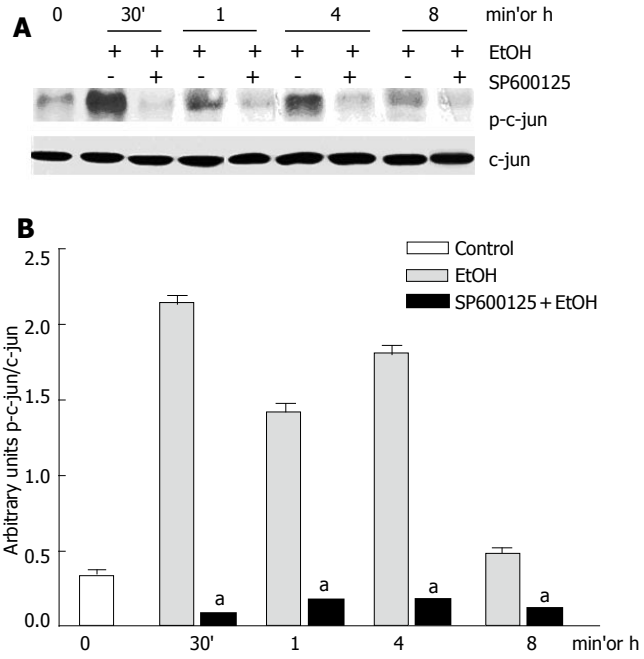

Figure 2 c-jun phosphorylation inhibition by 100 μmol/L SP600125. **A:** Western blot; **B:** Densitometric analysis. Each bar represents mean±SEM of $n = 3$. [a]indicates a significant difference ($P < 0.05$) between c-jun phosphorylation in hepatocytes exposed to ethanol only and SP600125-pretreated hepatocytes.

Inhibition of ethanol-induced apoptosis by SP600125 and AdoMet

Once we identified an effect of both ethanol and SP600125 on JNK activity, we determined the effect of SP600125 and AdoMet on the apoptosis process induced by ethanol. Ethanol-induced apoptosis was significantly reduced ($P < 0.05$) in hepatocyte cultures pretreated with 100 μmol/L SP600125 or 4 mmol/L AdoMet, but not in hepatocytes pretreated with 1 g/L DMSO, the vehicle for SP600125, as shown by the DNA laddering assay (Figure 3A) or TUNEL assay (Figure 3B). A 24-h exposure to 100 mmol/L ethanol produced approximately 47% cell death in non-pretreated hepatocytes as compared to 23% and 25% cell death observed in SP600125- and AdoMet-pretreated cultures, respectively. Cells pretreated with DMSO but not stimulated with ethanol showed 5% cell death (Figure 1C).

Protection of SP600125 and AdoMet on ethanol hepatocyte injury

In order to determine whether or not the survival of hepatocytes exposed to 100 mmol/L ethanol was modulated by SP600125 and AdoMet, we determined survival rates after different periods of 100 mmol/L ethanol exposure. Cell metabolic activity, determined by the MTT assay, significantly decreased after 12 h in cells only exposed to ethanol ($P < 0.05$) compared to the cells pre-incubated with AdoMet, SP600125 or incubated under control conditions. Cell metabolic activity, measured as the percentage of tetrazolium salt reduction, decreased from 75% observed in pretreated hepatocytes to 40% observed in hepatocytes exposed to ethanol only (Figure 4).

AdoMet effect on GSH intracellular levels from ethanol-incubated hepatocytes

The JNK signaling pathway activation may be modulated by antioxidants. AdoMet, a GSH precursor in liver, prevented ethanol-induced apoptosis as aforementioned. We tested if, through an antioxidant effect, AdoMet may be related to an inhibitory action of JNK activity as a possible hepatoprotective mechanism. We first determined the effect of 4 mmol/L AdoMet pretreatment on GSH intracellular levels in ethanol-incubated hepatocytes. Pre-incubation with 4 mmol/L AdoMet significantly prevented GSH decrease induced by the exposure of cultured hepatocytes to 100 mmol/L ethanol ($P < 0.05$), and moreover, maintained GSH levels above those found in control hepatocyte cultures. A significant increase in GSH concentra-

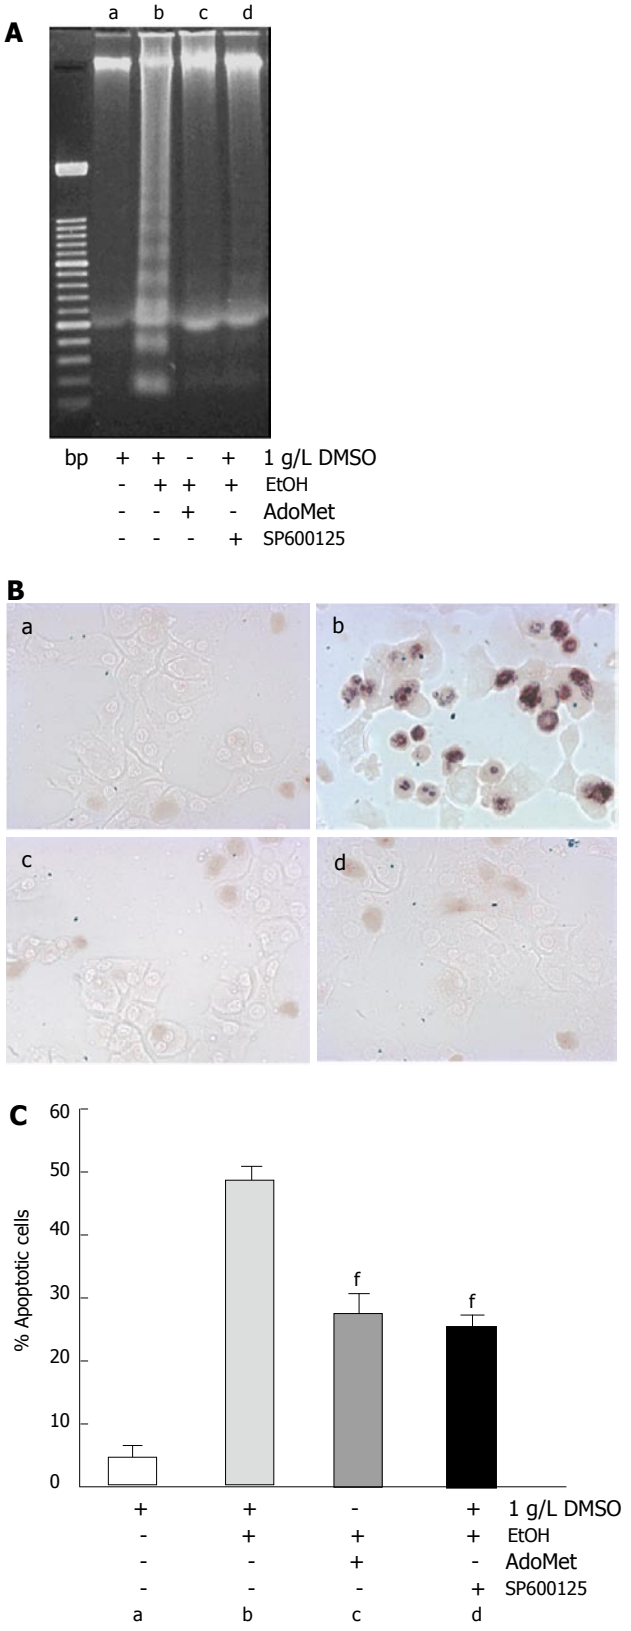

Figure 3 Effect of SP600125 and AdoMet in apoptosis induced by ethanol. **A:** DNA ladder assay; **B:** 40x TUNEL assay; **C:** data from TUNEL assay; a: control; b: ethanol; c: AdoMet+ ethanol; d: SP600125 + ethanol. The data represent mean ±SE of $n = 3$. [f]indicates a significant difference ($P < 0.05$) between SP600125 or AdoMet-pretreated cells and cells only pretreated with DMSO and exposed to ethanol.

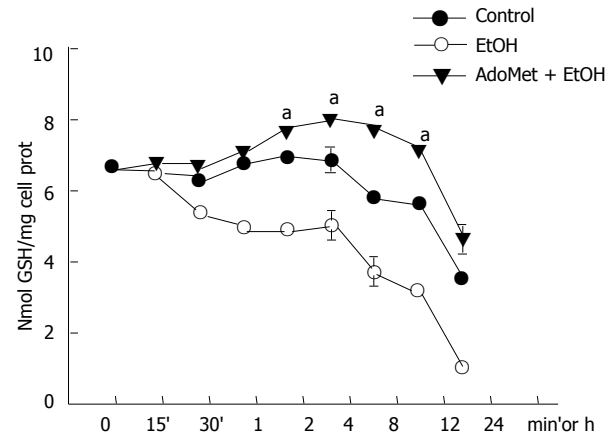

Figure 5 Prevention of GSH decrease in hepatocyte cultures exposed to ethanol by AdoMet. Data represent percentage change of ROS levels in mean±SEM of $n = 3$. [a]represents a significant difference ($P < 0.05$) in ROS generation between pretreated cells and cells exposed to ethanol only.

tion was observed between 8 and 12 h in hepatocytes pretreated with AdoMet compared to hepatocytes incubated in control medium (Figure 5) ($P < 0.05$). Furthermore, ROS generation in hepatocytes pretreated with 4 mmol/L AdoMet and then exposed to ethanol was maintained as in control cells in comparison to hepatocyte cultures exposed to ethanol only, in which a significant ROS generation was observed (Figure 6) ($P < 0.05$).

Effect of AdoMet on JNK activity

Once we determined that AdoMet had antioxidant effects, we tested if AdoMet exerted an inhibitory action on JNK activity. We first measured AdoMet effect on c-jun phosphorylation. AdoMet pretreatment slightly decreased JNK activity induced by ethanol treatment by 25.4% with respect to the cultures exposed to ethanol only, contrasting with the effect of the selective JNK inhibitor which produced a c-jun phosphorylation inhibition of approximately 68.8% with respect to ethanol- treated samples. So, the decrease on c-jun phosphorylation induced by AdoMet was

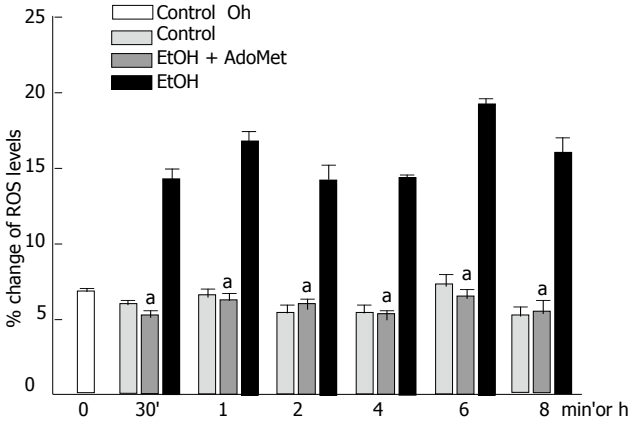

Figure 6 Decrease of ethanol-induced ROS generation in hepatocyte cultures by AdoMet. ROS generation in hepatocytes pretreated with Ado Met and ethanol was significantly reduced compared to hepatocyte cultures exposed to ethanol only ($^aP<0.05$).

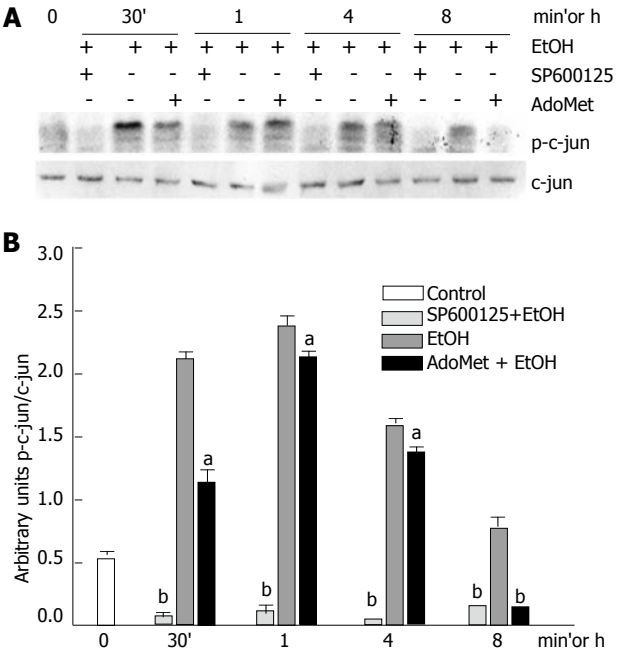

Figure 7 Effect of AdoMet on JNK activity. **A:** Western blot; **B:** densitometric analysis. Data represent mean±SEM of $n = 3$. ($^aP < 0.05$) or ($^bP < 0.01$) indicates a significant difference in c-jun phosphorylation between SP600125- or AdoMet-pretreated cells and non-pretreated cells exposed to ethanol.

not comparable to the decrease produced by SP600125, a selective JNK inhibitor (Figure 7).

Effects of SP600125 and AdoMet on Bid fragmentation, another JNK target

We next determined the effects of SP600125 and AdoMet on Bid cleavage. Bid is a proapoptotic member of the Bcl-2 family, which may represent another important JNK target. We observed that 100 mmol/L ethanol hepatocyte exposure promoted Bid cleavage between 4 h and 24 h. SP600125 hepatocyte pretreatment significantly prevented Bid fragmentation compared to cells stimulated with ethanol only between 4 h to 24 h ($P < 0.05$). Bid has been reported as a caspase 8 target. Indeed, we found that pre-

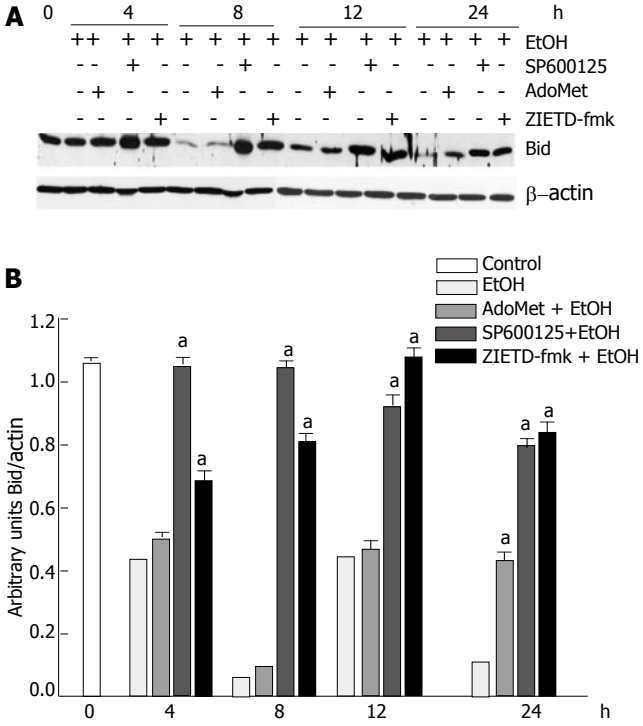

Figure 8 Preventive effect of SP600125 and AdoMet on Bid cleavage, a component of the JNK signaling pathway. **A:** Western blot; **B:** densitometric analysis. The data represent mean± SE for $n = 3$. ^{a} indicates a significant difference in Bid fragmentation between SP600125- or Z-IETD-fmk-pretreated cells and cells exposed to ethanol only ($P < 0.05$).

incubation with 25 μmol/L Z-IETD-fmk, a selective caspase 8 inhibitor, significantly decreased Bid fragmentation induced by ethanol (Figure 8) ($P < 0.05$). These results suggested that Bid cleavage induced by ethanol not only depends on JNK, but also on caspase 8 activity. Nevertheless, even if AdoMet exerted antioxidant properties, it did not prevent Bid fragmentation induced by ethanol. Western blot and densitometric analyses shown are representative of three independent experiments.

Decrease in ethanol-induced cytochrome c release and caspase 3 activation by SP600125 and AdoMet

Apoptosis induced by 100 mmol/L ethanol involves Bid fragmentation, which is responsible for cytochrome c release with the subsequent activation of caspase 3. We determined the effect of SP600125 and AdoMet on these apoptotic components. Pretreatment of hepatocyte with SP600125 prevented Bid cleavage induced by ethanol and decreased cytochrome c release from mitochondria between 8 h and 24 h after ethanol exposure. Even though AdoMet did not have an effect on Bid fragmentation, it decreased cytochrome c release from mitochondria (Figure 9). Cytochrome c release contributes to pro-caspase 3 fragmentation, so we observed that cytochrome c release prevention by SP600125 and AdoMet also decreased pro-caspase 3 fragmentation (Figure 10). These results indicated that the hepatoprotective effects of SP600125 and AdoMet converge at mitochondrial level, but AdoMet antiapoptotic action mainly lies in an inhibition of the mitochondrial apoptotic pathway.

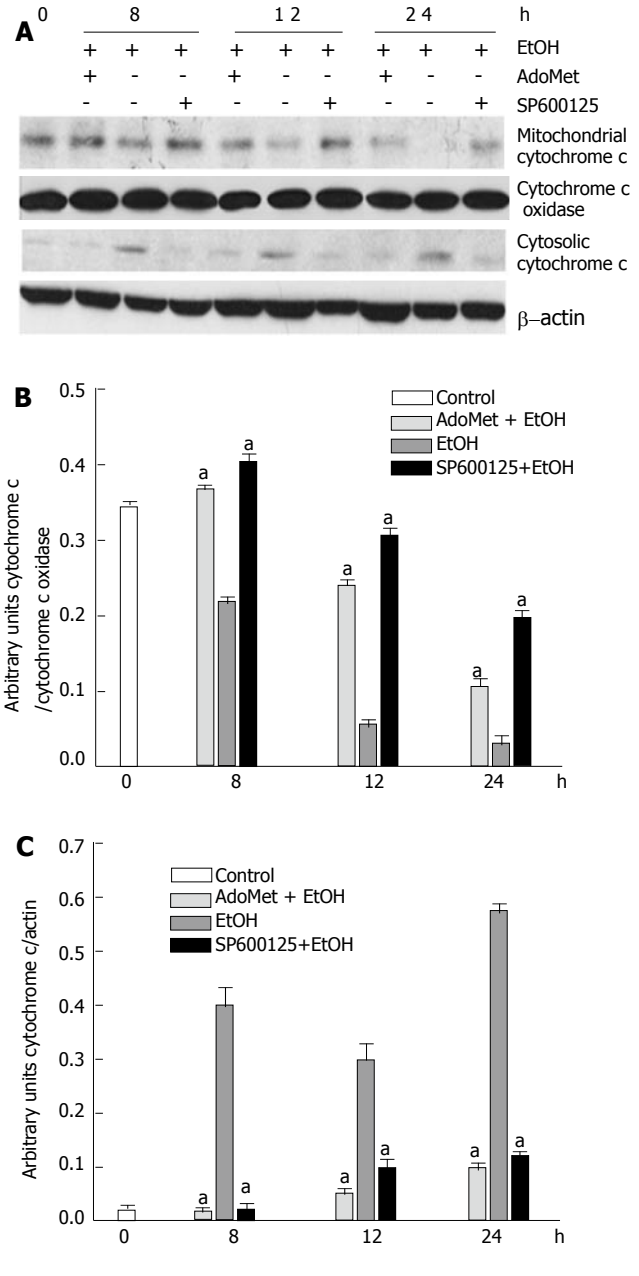

Figure 9 Prevention of cytochrome c release by AdoMet and SP600125. **A:** Western blot; **B:** mitochondrial cytochrome c; **C**: cytosolic cytochrome c densitometric analysis. [a]represents a significant decrease ($P < 0.05$) in cytochrome c release in AdoMet- and SP600125-pretreated hepatocytes in comparison with non-pretreated cells.

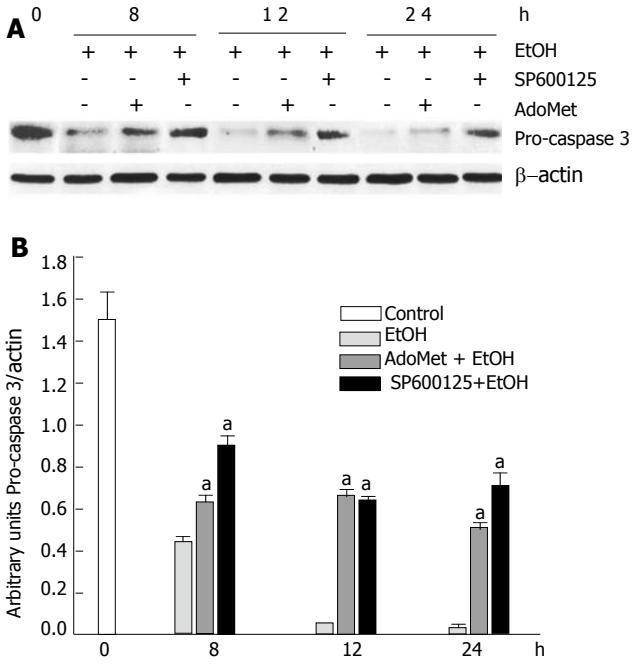

Figure 10 Decrease of ethanol-induced pro-caspase 3 fragmentation by SP600125 and AdoMet. **A:** Western blot; **B:** densitometric analysis. [a]indicates a significant difference ($P < 0.05$) between SP600125- and AdoMet-pretreated hepatocytes compared to non-pretreated hepatocytes.

DISCUSSION

This study points out that modification of the JNK signaling transduction pathway by selective JNK inhibitors and mitochondrial function preservation by AdoMet are among several key factors that must be considered to develop successful therapies for ALD treatment. We determined the role of JNK activity in the apoptotic process induced by ethanol in primary hepatocyte cultures and the possible modulator effect of JNK activity by AdoMet, an agent increasingly used in ALD treatment.

JNK activity is related to proapoptotic responses, but it is also linked to antiapoptotic signals and cell proliferation[41,42], thus the functions and components of this signaling cascade still remain controversial. We exposed hepatocytes to 100 mmol/L ethanol, considering previous reports which indicate that ethanol levels in the peripheral blood of some alcoholic patients have been exceeded 100 mmol/L[43]. In the present study, the exposure of primary hepatocyte cultures to 100 mmol/L ethanol promoted JNK activation. We detected that JNK1 basal activity was lower than JNK2 basal activity, while the JNK1 activity increment was higher than JNK2. These findings are in agreement with previous reports[9,44] and strongly suggest that JNK1 activity is related to the proapoptotic function of this signaling pathway activation by ethanol. We determined ethanol JNK activation by measuring c-jun phosphorylation, the most common parameter of JNK activity. In our system, JNK activity was significantly inhibited by a 2-h pretreatment with 100 μmol/L SP600125, a concentration previously reported for the selective inhibition of JNK[15]. Indeed, c-jun phosphorylation was significantly decreased by 100 μmol/L SP600125 in comparison with cells pretreated with 1 g/L DMSO only, as a vehicle control. We measured a decrease in c-jun and not in JNK phosphorylation because previous reports have indicated that SP600125 specifically inhibits c-jun phosphorylation and does not down-regulate p-JNK levels[14,15]. In our study, selective JNK inhibition by SP600125 allowed us to confirm that JNK functioned as a proapoptotic signaling pathway in hepatocyte cultures exposed to 100 mmol/L ethanol for 24 h, since in SP600125-pretreated hepatocyte cultures, DNA ladder and positive TUNEL cells significantly decreased. Our results, in agreement with previous reports[9,15], indicated that JNK might be a key pathway involved in apoptosis induction by ethanol. However, other signaling events must be involved in the apoptotic pathway induced by ethanol, since apoptotic cells in SP600125-pretreated hepatocytes were not completely abolished,

suggesting that JNK activity contributes to but is not the only factor required for the apoptotic process induced by ethanol. MAPK p38 is also a key candidate in this process, since there are several reports indicating that TNF-alpha, which plays a critical role in ALD development, induces p38 activation[45]. Recently, Bid, a pro-apoptotic member of the bcl-2 family, has been reported as a JNK target in different systems[46,47]. We observed that the incubation of primary hepatocyte cultures with 100 mmol/L ethanol induced Bid cleavage, which was decreased by SP600125. These results strongly suggested Bid as a key target of the pro-apoptotic JNK activity induced by ethanol. Even though maximal JNK activity, measured by c-jun phosphorylation, was observed between 30 min and 4 h after ethanol treatment, Bid fragmentation was not observed until 8 h after ethanol exposure, when c-jun phosphorylation was slightly above control. This slow kinetic of JNK-stimulated Bid cleavage may indicate that several steps separate JNK activation from Bid fragmentation[48]. Since JNK is not a protease, it is likely that one of these steps corresponds to a protease induction by JNK[49,50]. Thus, the exact target of JNK involved in Bid fragmentation is yet to be established[51]. Bid cleavage was also decreased when cultures were exposed to Z-IETD-fmk, a selective caspase 8 inhibitor, indeed it has been reported that Bid is a caspase 8 target[52]. Fas-mediated apoptosis has been related to FasL induction by c-jun activation, and downstream to caspase 8 and Bid fragmentation. Our result suggests that Bid fragmentation in the apoptosis process induced by ethanol lies at least in two distinct pathways, and not only depends on JNK activity. In accordance with this result, a previous report indicates that Bid fragmentation by JNK does not depend on transcription, and in addition, SP600125 does not affect Fas-mediated apoptosis[16]. JNK and other kinases that regulate JNK activity are known to be responsive to redox changes[20], and oxidative stress is critically involved in ALD development[22-24]. We observed that treatment of hepatocyte culture with 100 mmol/L ethanol induced a peak of ROS generation between 6 h and 8 h after ethanol exposure, which coincided with a significant decrease in GSH levels. These redox alterations may be resulted from two of the main components of alcohol metabolism, alcohol dehydrogenase (ADH) and cytochrome P450 2E1, since it has been reported under similar culture conditions that 4-methyl pyrazole, an ADH inhibitor, led to the reduction of H_2O_2 generation[21, 53]. Besides, different non-enzymatic free radical pathways and the mitochondrial dysfunction after the reduction of GSH content are involved in ROS generation induced by ethanol. Therefore, JNK activation in response to ethanol may be related to the oxidative metabolism of ethanol in the liver and to the resultant alterations in intracellular redox state, primarily reflected by GSH changes. AdoMet, an increasingly used agent for liver disease treatment, has wide physiological and pharmacological actions, including its effect on GSH metabolism. However, its hepatoprotective mechanisms have not been completely elucidated[27,54]. We observed that AdoMet, as SP600125, significantly reduced ethanol-induced apoptosis. AdoMet has been identified as a GSH precursor, a major cell antioxidant, and JNK activity has been reported to be down-regulated by antioxidant agents. Thus, our study suggested that AdoMet may down-regulate JNK activity as part of its hepatoprotective mechanism through an antioxidant effect. We found that 4 mmol/L AdoMet was able to prevent GSH decrease induced by ethanol in primary hepatocyte cultures and even maintained intracellular GSH levels above those found in non-treated cells. Furthermore, AdoMet pretreatment also diminished ethanol- induced ROS generation. These results indicated that AdoMet might be related to the repletion of GSH levels. There are contradictory results about the effect of AdoMet on GSH levels; while a previous study found no effect of AdoMet on GSH levels[27], present results are in agreement with others which reported an increment of GSH levels resulted from AdoMet pretreatment[29,55]. Even though AdoMet exerted a redox state regulating effect, surprisingly, it only decreased c-jun phosphorylation by 25.5% in comparison to the inhibition induced by SP600125, which corresponded to 62.8%. We also tested the effect of AdoMet on Bid fragmentation and did not observe an inhibitory effect of AdoMet until 24 h after ethanol exposure. At this time, JNK activity was below control levels, so it is possible that this decrease was not related to JNK activity. These results indicated that even though AdoMet exerted an antioxidant action, it did not have a significant effect on JNK activity, at least on c-jun or Bid, the measured JNK targets. Thus, we suggest that JNK activation may be independent of oxidative stress, in accordance with previously reported results in which cell pretreatment with N-acetyl-cysteine failed to prevent JNK activation[10]. Other reports suggest that JNK activation may be independent of ethanol metabolism, since ethanol activates JNK in HepG2 cells which do not express detectable levels of Cyp2E1 and express low levels of alcohol dehydrogenase activity[56]. However, further studies are required to determine the regulatory mechanisms of JNK activity independent of ROS generation. Even though AdoMet did not have a significant effect on JNK activity as it was measured by its action on c-jun and Bid, it preserved the mitochondrial metabolic activity as it was measured by the MTT assay. In hepatocytes exposed to ethanol only, the mitochondrial function was significantly reduced compared to AdoMet-pretreated hepatocytes. Downstream AdoMet prevented cytochrome c release and pro-caspase 3 fragmentation. In agreement with previous reports which indicated that AdoMet maintained mitochondrial membrane stability and corrected the reduction of GSH content both in cytosol and mitochondria[29,30,56], these results suggest that the AdoMet protective effect mainly lies at mitochondrial level.

In summary, our results point out that ALD is a complex and multifactorial process, and that the mechanisms involved in ALD development must be thoroughly explored for the design of successful therapeutic strategies. We found that AdoMet, although protected against ethanol apoptosis induction and exerted an antioxidant effect, did not show any inhibitory action on Bid fragmentation, a key proapoptotic target of JNK. This finding is in agreement with the suggestion that the mechanisms which lead to JNK activation are independent of ROS generation. We conclude that the JNK signaling pathway modulation by selective inhibitors

and mitochondrial integrity maintenance by AdoMet are promising components of therapeutic approaches for ALD.

ACKNOWLEDGMENTS

We are very grateful to Sergio Hernández García for his valuable technical assistance. We are also grateful to Victor Hugo Rosales García for his assistance in the performance of flow cytometry experiments and to the Lab Animal Facility UPEAL, CINVESTAV for the animal handle and care. We also thank Isabel Pérez Montfort for correction of the English version of the manuscript.

Abstract

AIM: To evaluate the potential of *S*-nitroso-*N*-acetylcysteine (SNAC) in inhibition of lipid peroxidation and the effect of oral SNAC administration in the prevention of nonalcoholic fatty liver disease (NAFLD) in an animal model.

METHODS: NAFLD was induced in Wistar male rats by choline-deficient diet for 4 wk. SNAC-treated animals (n=6) (1.4 mg/kg/day of SNAC, orally) were compared to 2 control groups: one (n=6) received PBS solution and the other (n=6) received NAC solution (7 mg/kg/d). Histological variables were semiquantitated with respect to macro and microvacuolar fat changes, its zonal distribution, foci of necrosis, portal and perivenular fibrosis, and inflammatory infiltrate with zonal distribution. LOOHs from samples of liver homogenates were quantified by HPLC. Nitrate levels in plasma of portal vein were assessed by chemiluminescence. Aqueous low-density lipoprotein (LDL) suspensions (200 μg protein/mL) were incubated with $CuCl_2$ (300 μmol/L) in the absence and presence of SNAC (300 μmol/L) for 15 h at 37 ℃. Extent of LDL oxidation was assessed by fluorimetry. Linoleic acid (LA) (18.8 μmol/L) oxidation was induced by soybean lipoxygenase (SLO) (0.056 μmol/L) at 37 ℃ in the presence and absence of N-acetylcysteine (NAC) and SNAC (56 and 560 μmol/L) and monitored at 234 nm.

RESULTS: Animals in the control group developed moderate macro and microvesicular fatty changes in periportal area. SNAC-treated animals displayed only discrete histological alterations with absence of fatty changes and did not develop liver steatosis. The absence of NAFLD in the SNAC-treated group was positively correlated with a decrease in the concentration of LOOH in liver homogenate, compared to the control group (0.7±0.2 nmol/mg vs 3.2±0.4 nmol/mg protein, respectively, P<0.05), while serum levels of aminotransferases were unaltered. The ability of SNAC in preventing lipid peroxidation was confirmed in *in vitro* experiments using LA and LDL as model substrates.

CONCLUSION: Oral administration of SNAC prevents the onset of NAFLD in Wistar rats fed with choline-deficient diet. This effect is correlated with the ability of SNAC to block the propagation of lipid peroxidation *in vitro* and *in vitro*.

INTRODUCTION

Nonalcoholic steatohepatitis (NASH) is considered a particular type of a large spectrum of nonalcoholic fatty liver disease (NAFLD), which includes fat alone and fat with nonspecific inflammation[1,2]. Although several predisposing factors such as obesity and diabetes, are related to NAFLD, the pathogenesis of NAFLD and its progression to fibrosis and chronic liver disease are still unclear[3-5]. One of the main hypotheses is that the mechanism of hepatocyte injury in NASH is associated with oxidative stress

and lipid peroxidation resulting from the imbalance between pro-oxidant and antioxidant chemical species[6]. Such an imbalance is associated with increased β-oxidation of fatty acids by mitochondria, peroxisomes, and cytochrome P450 2E1 (CYP2E1) pathways. These oxidative processes produce free electrons, H_2O_2, and reactive oxygen species (ROS) while depleting the potent antioxidants, glutathione and vitamin E[1]. The increased levels of free fatty acids present in the fatty liver provide a perpetuating and propagating mechanism for oxidative stress via lipid peroxidation, with secondary damage to cellular membranes and key organelles such as mitochondria[6]. Lipid peroxidation usually leads to the formation of peroxyl radicals, which are central species in the peroxidation chain reaction. Enzymatic lipid peroxidizing systems include lipoxygenases (LOXs), which are a family of nonheme iron-containing dioxygenases and able to induce enzymatic peroxidation of polyunsaturated fatty acids using atmospheric oxygen (O_2) as a second substrate. In contrast to lipid monooxigenases like cytochrome P-450, whose main catalytic activity is the hydroxylation of substrates, LOXs are able to introduce peroxides in lipid substrates, forming reactive fatty acid hydroperoxides (LOOH). In general, LOXs contain an essential iron atom, which is present as Fe^{2+} in the inactive enzyme form. Enzymatic activation occurs through hydroperoxide-driven oxidation of Fe^{2+} to Fe^{3+}. Among LOXs, 15-LOX is of particular interest, which can also oxidize esterified fatty acids in biological membranes and lipoproteins and has been implicated in the pathogenesis of atherosclerosis[7-9]. Site-specific oxidation of lipidic substrates can also be performed in model systems when metal ions (Cu(I)/Cu(II)) or Fe(II)/Fe(III)) are used to generate radicals in the absence of chelant species[10].

Nitric oxide (NO) can act as a potent inhibitor of the lipid peroxidation chain reaction by scavenging propagatory lipid peroxyl radicals and by inhibiting many potential initiators of lipid peroxidation, such as peroxidase enzymes[11]. However, in the presence of superoxide ($O_2^{\bullet -}$), NO forms peroxynitrite ($OONO^-$), a powerful oxidant, which is able to initiate lipid peroxidation[12]. An excess of NO is expected to exert a protective effect against lipid peroxidation, while an excess of $O_2^{\bullet -}$, or equimolar concentrations of NO and $O_2^{\bullet -}$ are expected to induce lipid peroxidation[13]. Thus, the balance between NO and $O_2^{\bullet -}$ may have important implications in NAFLD, where oxidative stress seems to have a pivotal role in the onset and/or progression of the disease[12,13]. NO is believed to coexist in cells with S-nitrosothiols (RSNOs) which are considered endogenous NO carriers and donors in mammals[14]. NO covalently bound to the sulfur atom in RSNOs resists oxidant inactivation by oxyhemoglobin and has the same physiological properties of free NO, including its protective action on oxidative stress[15]. RSNOs have been considered potential therapeutic agents in a variety of pathologies in which NO may be involved[16] and S-nitroso-N-acetylcysteine (SNAC) is a relatively stable RSNO and a potent vasodilator[17]. SNAC is among the RSNOs, which can be synthesized through the S-nitrosation of the corresponding free thiol (in this case, N-acetylcysteine, NAC). Free thiols (R-SH) play also an important role *in vivo* as antioxidants. Hydrogen abstraction from thiol group is particularly fast compared to hydrogen abstraction from carbon atoms or alkoxyl radicals[18-21]. At physiological pH values, thiyl radicals ($R\text{-}S^{\bullet}$) formed can react with excess thiol anions ($R\text{-}S^-$) to give disulphide radical anions ($R\text{-}SS\text{-}R^{\bullet -}$), or can dimerize giving rise to inter or intramolecular RS-SR cross-links in a termination process. Compared to free thiols, RSNOs can be more powerful terminators of radical chain-propagation reactions by reacting directly with $ROO^{\bullet}$ radicals, yielding nitro derivatives (ROONO) as end products as well as dimmers RS-SR.

The aim of this study was to evaluate the role of SNAC as an NO donor, in the prevention of NAFLD in an animal model where NAFLD was induced by a choline deficient diet. Our results show, for the first time, that SNAC is able to block the onset of NAFLD in this animal model. This result was correlated with *in vitro* experiments which have confirmed the ability of SNAC to prevent the oxidation of low-density lipoprotein (LDL) and linoleic acid (LA) as model substrates, by Cu(II) ions and soybean lipoxygenase (SLO), respectively.

MATERIALS AND METHODS

Materials

N-acetyl-L-cysteine (NAC), linoleic acid, sodium nitrite, hydrochloric acid, human lyophilized LDL, soybean lipoxygenase, sodium dodecil sulfate (SDS), phosphate buffer saline (PBS, pH 7.4) and copper (II) chloride (Sigma, St. Louis, MO) were used in this study. All experiments were carried out using analytical grade water from a Millipore Milli-Q gradient filtration system.

SNAC synthesis

SNAC was synthesized through the S-nitrosation of N-acetyl-L-cysteine (Sigma Chemical, St. Louis, MO) in an acidified sodium nitrite solution[17]. Stock SNAC solutions were further diluted in PBS. Solutions were diluted to 2.4 x 10^{-4} mol/L in PBS (pH 7.4) before administration.

Nitrate quantification

Nitrate (NO_3^-, a stable metabolite of NO) levels in plasma of portal vein of the animals were assessed by chemiluminescence using a Sievers nitric oxide analyzer (NOA-280, Boulder, CO) according to a method described elsewhere[22]. Higher nitrate concentrations were found in the plasma of animals which received SNAC orally (10.8 μmol/L) then intraperitoneally (4.2 μmol/L). This result was used as a criterion to choose oral administration as a protocol to achieve greater SNAC absorption.

Effect of NAC and SNAC on in vitro LDL oxidation

Oxidation of LDL was induced through the addition of $CuCl_2$ (300 μmol/L) to oxygenated aqueous LDL suspensions (200 μg/mL) in the absence and presence of SNAC (300 μmol/L). Aqueous LDL suspensions were prepared by diluting solid LDL to 200 μg protein/mL with EDTA-free PBS and incubated with $CuCl_2$ (300 μmol/L) for 15 h at 37 ℃. The extent of LDL oxidation was assessed by measuring the fluorescence intensity of LDL suspensions. Oxidation of LDL resulted in derivatization of lysine residues of apolipoprotein B by lipid peroxide decomposition

products, leading to fluorescent free and protein-bound Schiff base conjugates as previously described[23,24]. In all cases, fluorescence spectra of such conjugates were firstly recorded in the range 430-600 nm, in order to characterize the shape and position of the emission peak. All the spectrofluorimetric measurements were performed using a Perkin-Elmer LS-55 luminescence spectrometer with a temperature-controlled cuvette holder thermostatized at 37℃. Spectra of the solutions were obtained in 1 cm quartz cuvette. The excitation and emission wavelengths were 360 and 433 nm, respectively. Native LDL (200 μg/mL) served as the control.

Effect of NAC and SNAC on in vitro LA oxidation

Oxidation of LA was induced through the addition of SLO to aqueous LA dispersions. LA was dispersed in SDS solution (0.01 mol/L). The final LA concentration was 18.8 μmol/L. LA was aliquoted into a quartz cuvette, flushed with O_2 for 1 min and SLO (0.056 μmol/L) was added with a syringe to start the oxidation. The oxidation reactions were monitored in the absence or presence of NAC and SNAC (56 and 560 μmol/L) at 37℃ through the increase in absorbance at 234 nm, due to conjugated diene formation. A Hewlett Packard spectrophotometer, model 8453 (Palo Alto, CA, USA) with a temperature-controlled cuvette holder, was used to monitor the spectral changes in the range 200-600 nm in the dark and at 37℃. Spectra of the solutions were obtained in 1 cm quartz cuvette referenced against air, under stirring (1 000 r/min). Each point in the kinetic curves of absorbance *vs* time was the average of two experiments with the error bars expressed by their standard deviations (SD).

Animals

Male Wistar rats, weighing 300 to 350 g, were housed in cages with a controlled light/dark cycle, receiving free water. Fatty liver was induced in the animals by choline deficient diet for four weeks. The animals were randomly divided into three groups: control group ($n = 6$) fed with choline deficient diet plus oral administration of vehicle (0.5 mL of PBS), SNAC group ($n = 6$) fed with choline-deficient diet plus oral administration of SNAC solution (0.5 mL of SNAC solution, reaching 1.4 mg/kg/day), and NAC group ($n = 6$) fed with choline-deficient diet plus oral administration of NAC solution (0.5 mL of NAC solution, reaching 7 mg/kg per day). After four weeks of treatment, plasma samples were collected, animals were sacrificed, and their livers were collected for histological examination and lipid peroxidation analysis. All procedures for animal experimentation were in accordance to the Helsinki Declaration of 1975 and the Guidelines of Animal Experimentation from the School of Medicine of the University of São Paulo.

Biochemical analysis

Serum alanine aminotransferase (AST), aspartate aminotransferase (ALT), cholesterol and triglycerides were analyzed by standard methods[25].

Histological analysis

Fragments of liver tissue previously fixed by immersion in formaldehyde saline (10%) solution were processed and submitted to hematoxylin-eosin (HE) and Masson trichrome staining for histological analysis. Scharlach red (O-tolylazo-o-tolylazo-β-naphthol) fat staining[26] was used for more accurate evaluation of fatty change. Histological variables were blindly semiquantitated from 0 to 4+ with respect to macro and microvacuolar fatty change, its zonal distribution, foci of necrosis, portal and perivenular fibrosis as well as inflammatory infiltrate with zonal distribution.

Lipid peroxidation

Samples of liver homogenates were extracted with a mixture of acetonitrile : hexane (4 : 10, v/v). The contents were vortexed for 2 min and centrifuged at 2 500 r/min for 10 min for phase separation. The hexane phase containing cholesteryl ester derived hydroperoxides (LOOH), was collected and evaporated under nitrogen. The residue was dissolved in methanol : butanol (2 : 1, v/v), filtered through a 22 μm Millex filter (Millipore, São Paulo, Brazil) and analyzed by HPLC (Perkin-Elmer series 200, Beaconsfield, Buckinghamshire, England) using an LC18DB column (Supelco, Bellefonte, PA, USA). LOOHs were eluted in methanol : butanol 2 : 1 (v/v) at a flow rate of 1.0 mL/min through a pump (Perkin-Elmer series 200) and an LC-240 fluorescence detector (Perkin-Elmer) with the excitation source switched off. A solution of 100 mmol/L borate buffer pH 10/methanol 3 : 7 (v/v) containing microperoxidase (25 mg/L) was used as the reaction solution for the postcolunm reaction[27]. Peaks were identified using external standards prepared from their respective oxidation products as previously described[27] and quantified using the package Turbochrom Navigator software (Perkin-Elmer). Results were expressed as nmol of lipid hydroperoxides/mg of protein.

Statistical analysis

All data were expressed as mean ± SE or as mean ± SD. Statistical significance was evaluated using the one-way ANOVA test for comparisons among three groups (Control *vs* NAC *vs* SNAC-LOOH quantification) and t-test for the comparison between two means (Control *vs* SNAC - biochemical analysis). $P < 0.05$ was considered statistically significant.

RESULTS

Figure 1 shows the micrographs of liver tissue extracted from animals treated with choline-deficient diet, which received vehicle or SNAC solutions for four weeks. A moderate macro and microvacuolar steatosis in periportal zone could be seen in the control group (Figure 1A) while in the SNAC-treated group the animals did not develop liver steatosis (Figure 1B). Scharlach staining showed a fatty change (positive staining) in the control group (Figure 1C), whereas in the SNAC-treated group no fat change was detected (negative staining) (Figure 1D). In both animal groups, necroinflammatory activity was minimal and no fibrosis was detected. In the NAC-treated group there was a macro and microvacuolar steatosis in periportal zone (data not shown).

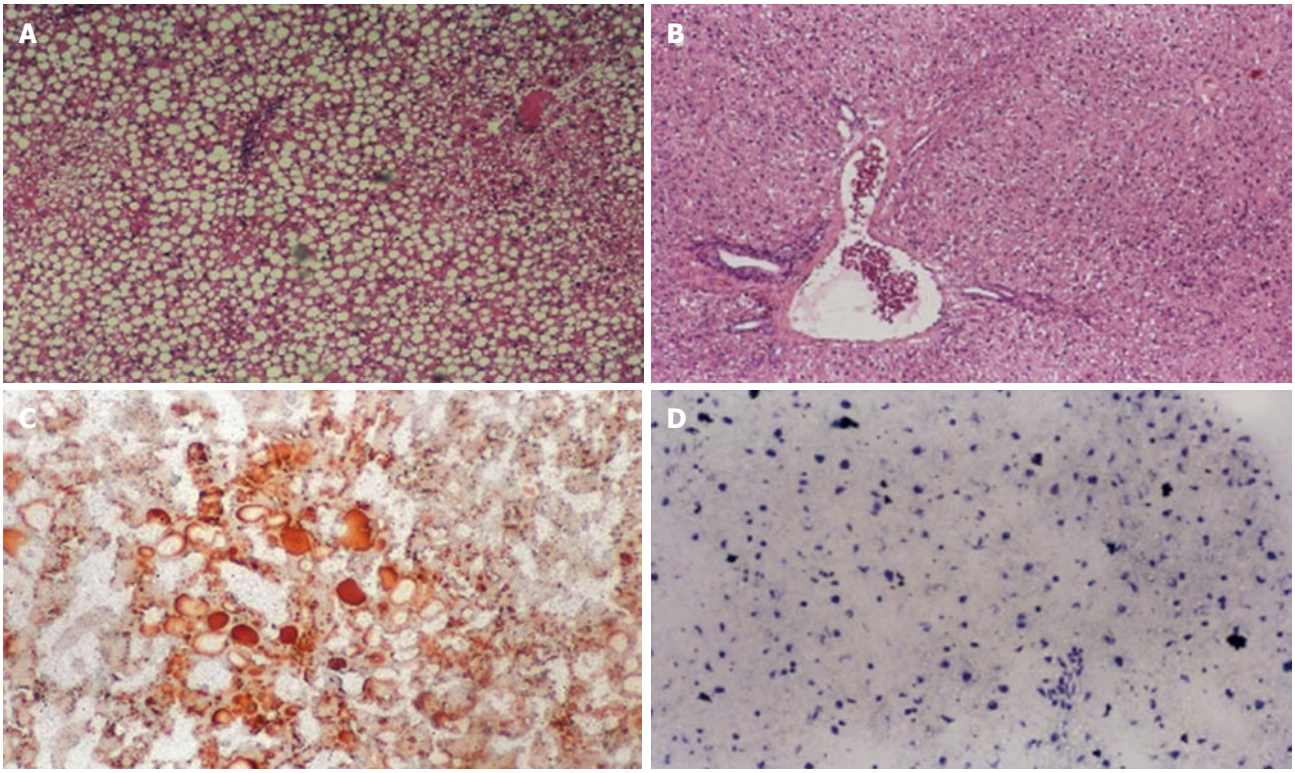

Figure 1 Histological features of liver tissue of rats fed with choline-deficient diet. **A**: Control group showing a moderate macro and microvacuolar steatosis in periportal zone; **B**: SNAC-treated animals showing normal liver in periportal zone (hematoxylin-eosin stain-HE); **C**: Control group showing positive Scharlach staining; **D**: SNAC-treated animals showing negative Scharlach staining.

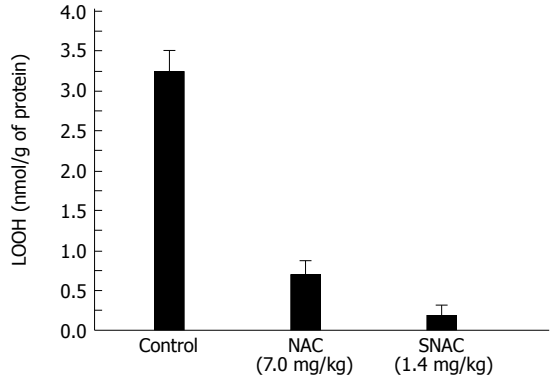

Figure 2 Concentration of hydroperoxides (LOOH) in liver homogenates of the control group, NAC and SNAC-treated animals.

Table 1 Levels of alanine aminotransferase (AST), aspartate aminotransferase (ALT), cholesterol and triglycerides in serum of rats fed with choline-deficient diet (mean±SD)

Group	Number of animals	AST (U/L)	ALT (U/L)	Cholesterol (U/L)	Triglyceride (U/L)
Control[1]	6	108±3	40±1	36±1	88±3
SNAC[2]	6	95±4	37±8	35±1	70±1

Normal values in U/L for AST: 10-34; ALT: 10-44; mg/dL: cholesterol and triglyceride: 45-89. [1]Control - animals fed with choline-deficient diet. [2]SNAC –animals fed with choline-deficient diet and treated daily with oral SNAC administration.

Figure 2 shows that SNAC prevented the rise of LOOH concentration in the liver of the SNAC-treated group, compared to the control group (0.3 ± 0.1 *vs* 3.2 ± 0.4 nmol/mg protein, respectively). The protective effect of NAC was also expressed by a reduction of hydroperoxide formation that could be seen in the *ca.* 4.6-fold reduction in LOOH formation (0.7 ± 0.2 nmol/mg protein *vs* 3.2 ± 0.4 nmol/mg protein, respectively).

On the other hand, the levels of AST and triglycerides were increased to a similar extent in the control and SNAC-treated groups. SNAC treatment of the choline-deficient fed rats did not lead to changes in ALT and cholesterol levels (Table 1)

Figure 3 shows the emission spectra of human LDL suspension (200 μg/mL) in PBS. The two emission peaks at *ca.* 410 and 440 nm (Figure 3A) could be assigned to the partial oxidation of the freshly prepared LDL suspension. It could be seen that these two peaks increased after incubation of LDL with $CuCl_2$ (300 μmol/L) (Figure 3B) reflecting the oxidation of LDL catalyzed by Cu (II) ions. However, incubation of LDL with $CuCl_2$ under the same condition, but in the presence of SNAC (300 μmol/L) completely blocked the growth of the 410 and 440 nm peaks (Figure 3C). In fact, the peak at 440 nm was extinguished in this case.

Figure 4 shows the effect of SNAC on the kinetics of LA oxidation by SLO. This effect could be evaluated through the analysis of two kinetic parameters: initial rate and extent of the peroxidation reaction until the achievement of the chemical equilibrium. Kinetic curves were ob-

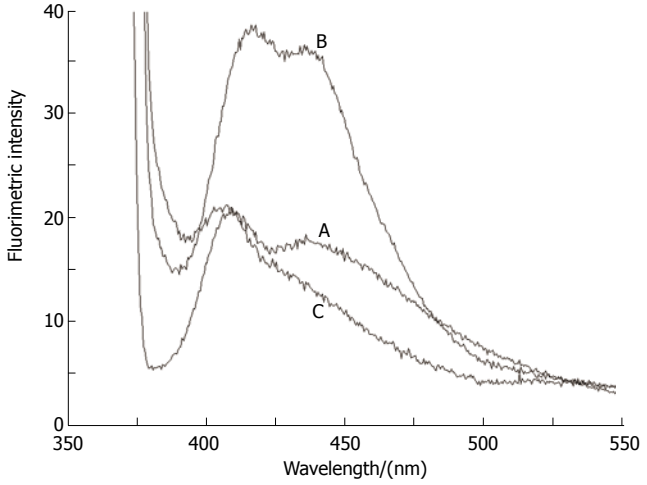

Figure 3 Emission spectra of human LDL (200 μg/mL) suspended in aerated PBS. **A**: Freshly prepared suspension; **B**: after incubation with $CuCl_2$ (300 μmol/L) for 15 h; **C**: after co-incubation with $CuCl_2$ (300 μmol/L) and SNAC (300 μmol/L). The excitation and emission wavelengths were 360 and 433 nm, respectively.

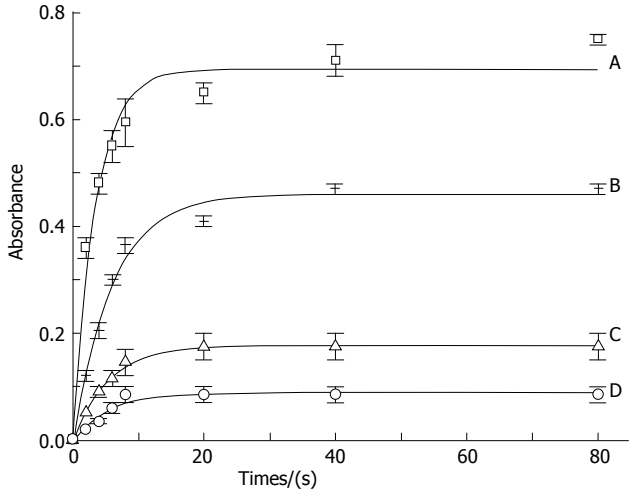

Figure 4 Kinetic curves of linoleic acid (18.76 μmol/L) peroxidation catalyzed by SLO (**A**) (0.056 μmol/L), SLO co-incubated with NAC (**B**) (560 μmol/L), SLO co-incubated with SNAC (**C**) (56 μmol/L) and SLO co-incubated with SNAC (**D**) (560 μmol/L). Absorbance changes were monitored at 234 nm at 37 ℃.

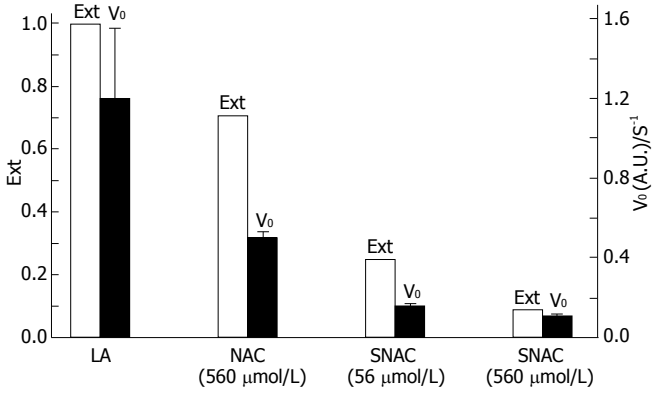

Figure 5 Barr graph showing the extent (Ext) and initial rates (V_0) of the peroxidation reaction of linoleic acid (LA) by SLO. Data were extracted from the curves of Figure 4.

tained from the corresponding spectral changes in the UV, monitored through the band with maximum at 234 nm. This band was characteristic of conjugated dienes and could thus be taken as a marker of LA peroxidation. While the initial rates of reactions correspond to the inclination of the initial sections of the curves (*ca.* 10 s), and the extents of reactions corresponded to the absorbance values at the plateaus. It could be seen that both parameters were maximum when LA (18.76 μmol/L) was incubated with SLO (0.056 μmol/L) (Figure 4A). Co-incubation with NAC (560 μmol/L) reduced the extent and rate of oxidation (Figure 4B), but this reduction was much more pronounced in the co-incubation with SNAC at a concentration ten times lower than NAC (56 μmol/L) (Figure 4C). The reduction was further increased in the presence of SNAC (560 μmol/L) (Figure 4D). These effects could also be evaluated in the bar graph of Figure 5, where the initial rates of reaction and the extents of reaction were extracted from the kinetic curves of Figure 4. It could be seen in Figure 5 that both the rates and the extents of reaction in the presence of SNAC were reduced to about half of those obtained in the presence of NAC at a concentration ten times higher.

DISCUSSION

Choline-deficient diet is a classical general model of NAFLD, where Cyp2E1 is up regulated and the animals develop steatosis, steatohepatitis and hepatic fibrosis[28]. The results obtained in this animal model show a strong inhibitory effect of SNAC on fatty change, which is the initial step of NAFLD. The protective effect of SNAC observed here could be analyzed according to the suggested role of oxidative stress in the pathology of NAFLD[29-31]. Although the exact role of antioxidants in the prevention of NAFLD is not well established yet, a number of studies have shown that markers of oxidative stress are increased, while levels of endogenous antioxidants (e.g. vitamin E and glutathione, GSH) are decreased in NAFLD[29, 30]. The microsomal enzymes CYPs 2E1 and 4A are believed to be involved in the fatty acid oxidation in the liver of humans with NASH, contributing to the pathogenesis of this disease[31]. In the present case, formation of lipid hydroperoxides (LOOH), which are one of the main products of the lipid peroxidation process, was observed to be expressively reduced in the liver tissue of the SNAC-treated animals, indicating that SNAC acts as a potent inhibitor of lipid/lipoprotein oxidation. This result is in accordance with the reactivity of NO from SNAC and the ability of NO to block the propagation of radical chain reactions by forming nitrated lipid derivatives as end products[32-36].

SNAC-induced inhibition of LDL oxidation by Cu(II) as a model system, was confirmed in the *in vitro* experiments (Figure 3). The emission peaks at 410 and 440 nm in the fluorescence spectra of LDL suspensions were assigned to adduct formation (Schiff bases) between oxidation products of the lipid content of LDL particles (mainly malondialdehyde, MDA) and amino groups of the apolipoprotein (mainly Apo-B-100), which are well known markers of LDL oxidation[37,38]. The inhibition of their formation in the co-incubation of LDL with Cu (II) and SNAC, showed that SNAC could block LDL oxidation under this condition. The protective effect of SNAC was also confirmed *in vitro* using LA as a second model compound

in which peroxidation was catalyzed by SLO (Figures 4 and 5). The co-incubation of LA with SNAC (56 μmol/L) and its correspondent reduced thiol, NAC (560 μmol/L) highlighted the much more potent effect of SNAC in the inhibition of LA peroxidation, once SNAC at a concentration ten times lower than NAC exerted a much more important antioxidant effect. The fact that an increase in SNAC concentration to 560 μmol/L did not lead to a proportional reduction in the kinetic parameters associated with LA peroxidation, is probably due to the relatively fast initial steps of LA peroxidation.

As SNAC does not react directly with aldehydes or ketones, the protective effect observed here must be associated with the termination of lipid radical chain propagation reactions, through the inactivation of alkoxyl ($LO^{\bullet}$) and peroxyl ($LOO^{\bullet}$) intermediates, which have already been demonstrated to be converted into inactive ROONO products by NO[32-36] *in vivo*. A general equation for these reactions can be written as:

$$2RS\text{-}NO + LO^{\bullet} / LOO^{\bullet} \rightarrow LONO / LOONO + RS\text{-}SR \quad (1)$$

where RSNO can be any primary S-nitrosothiol and RS-SR is the corresponding oxidized thiol yielded as a dimmer. The same RS-SR dimmers are formed if the RSNOs release NO primarily according to[39]:

$$2\ RSNO \rightarrow RS\text{-}SR + 2NO \quad (2)$$

Free NO released in equation 2 is also capable of reacting with $LO^{\bullet}/LOO^{\bullet}$ species[35], leading to the same termination products of equation 1.

Although NAC (the precursor of SNAC) has also an important antioxidant action due to the ease of hydrogen abstraction from its thiol group (data not shown), the protective action of SNAC cannot be assigned to its conversion into NAC. Such a reaction does not take place in an oxidative environment. Under such conditions, the anti-oxidant effect of SNAC can be assigned mainly to the lability and reactivity of NO, according to equations 1 and 2. This statement is supported not only by the greater antioxidant action of SNAC compared to NAC in the *in vitro* experiments with LDL and LA, but also by the *in vivo* results showing that the daily oral administration of NAC at a concentration five times higher than SNAC, did not prevent the development of liver steatosis in the present animal model and led to a lower reduction in the LOOH level in the liver tissue. The protective action of NAC in this animal model is not entirely dissimilar to that obtained with other more classical anti-oxidants. However, ascorbic acid which reduces liver steatosis in rats on choline-deficient diet, is not able to inhibit the onset of this pathology, and α-tocopherol (vitamin E) does not even reduce fat accumulation in the hepatic tissue in the same animal model[40].

The important protective action of an NO donor in this model suggests that NAFLD can be associated with an impairment of endogenous NO production in the liver. Since the production of endothelium-derived NO has already been demonstrated to be impaired in other diseases related to oxidative stress, like atherosclerosis[41, 42], the effects of NO in NAFLSD can involve other mechanisms in addition to those associated solely with oxidative stress. NO is also known to be a signal transduction mediator and accumulating data suggest that S-nitrosation and nitrosilation reactions performed by NO may be a ubiquitous posttranslational modification involved in signal transduction regulation[43]. The absence of correlation between the reduction of LOOH concentration and the occurrence of macro and microvacuolar steatosis in the NAC-treated group, is an evidence that protective mechanisms other than the inhibition of lipid peroxidation, are operative when SNAC is administered to choline deficient animals. Such mechanisms are probably associated with the biochemical/signaling actions of NO and can be specifically linked to the biochemistry of RSNOs. In contrast to other NO donors which are already in widespread clinical use, like organic nitrates, nitrites and sodium nitroprusside, few clinical studies have been reported for RSNOs. Therefore, the use of RSNOs as exogenous NO sources in the treatment of NAFLD can bring new perspectives for understanding the pathogenesis of this disease.

In conclusion, oral administration of SNAC as an exogenous NO source, can block the onset of NAFLD and the reduction of LOOH production in liver tissue as a result of this treatment can be associated with the ability of SNAC to block the lipid peroxidation. These findings have clinical implications, regarding novel therapeutic strategies for the treatment of NAFLD.

Abstract

AIM: To study the effect of WeiJia on chronic liver injury using carbon tetrachloride (CCl_4) induced liver injury animal model.

METHODS: Wistar rats weighing 180-220g were randomly divided into three groups: normal control group (Group A), CCl_4 induced liver injury control group (Group B) and CCl_4 induction with WeiJia treatment group (Group C). Each group consisted of 14 rats. Liver damage and fibrosis was induced by subcutaneous injection with 40% CCl_4 in olive oil at 3 mL/kg body weight twice a week for eight weeks for Groups B and C rats whereas olive oil was used for Group A rats. Starting from the third week, Group C rats also received daily intraperitoneal injection of WeiJia at a dose of 1.25 μg/kg body weight. Animals were sacrificed at the fifth week (4 male, 3 female), and eighth week (4 male, 3 female) respectively. Degree of fibrosis were measured and serological markers for liver fibrosis and function including hyaluronic acid (HA), type IV collagen (CIV), γ-glutamyl transferase (γ-GT), alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were determined. Alpha smooth muscle actin (α-SMA) and proliferating cell nuclear antigen (PCNA) immunohistochemistry were also performed.

RESULTS: CCl_4 induction led to the damage of liver and development of fibrosis in Group B and Group C rats when compared to Group A rats. The treatment of WeiJia in Group C rats could reduce the fibrosis condition significantly compared to Group B rats. The effect could be observed after three weeks of treatment and was more obvious after eight weeks of treatment. Serum HA, CIV, ALT, AST and γ-GT levels after eight weeks of treatment for Group C rats were 58±22 μg/L (P<0.01), 57±21 μg/L (P<0.01), 47±10 U/L (P<0.01), 139±13 U/L (P<0.05) and 52±21 U/L (P>0.05) respectively, similar to normal control group (Group A), but significantly different from CCl_4 induced liver injury control group (Group B). An increase in PCNA and decrease in α-SMA expression level was also observed.

CONCLUSION: WeiJia could improve liver function and reduce liver fibrosis which might be through the inhibition of stellate cell activity.

Key words: WeiJia; Carbon tetrachloride; Liver fibrosis

INTRODUCTION

Hepatic fibrosis is one of the processes that occur when the liver is damaged through viral activity, toxins, autoimmune diseases, metabolic disorder or genetic defects. It is a result of chronic liver injury that ultimately leads to cirrhosis and its complications of portal hypertension, liver failure and hepatocellular carcinoma. Millions of people die each year worldwide[1-5]. Efficient and well-tolerated antifibrotic drugs are lacking and current treatment of hepatic fibrosis is limited to withdrawal of the noxious agent[6].

Advance in pathophysiology, molecular biology, ge-

netically engineered animals, liver transplantation *etc*. has increased our understanding of the molecular mechanism in liver fibrogenesis. Hepatic stellate cell (HSC) was identified as the primary cell type to mediate fibrogenesis which is the major source of extracellular matrix deposition[7-9]. Antifibrotic drug development was focused on fibrogenic cells generating the scarring response in the past decade.

WeiJia is a protein peptide mixture extracted from neonate porcine liver. It is a Category-I new drug on the market approved by the State Food and Drug Administration (SFDA) for the treatment of severe hepatitis and shows promising results in clinical studies[10-12]. Studies also showed that WeiJia can act as a therapeutic agent in the treatment of cirrhosis[13, 14]. As progressive hepatic fibrosis would lead to cirrhosis, it is likely that WeiJia might also play a role in treatment of hepatic fibrosis. In this study, carbon tetrachloride (CCl_4) induced liver injury animal model was used to evaluate the potential of WeiJia as a therapeutic agent for hepatic fibrosis.

MATERIALS AND METHODS

Materials

Wistar rats, weighing 180-220g were bought from Experimental Animal Centre, Daping Hospital, Third Military Medical University, Chongqing. WeiJia was from LifeTec Enterprise Limited, Hong Kong; analytical grade CCl_4, alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ-glutamyl transferase (γ-GT) testing kits and DAB were from Sigma (St. Louis, MO, USA); hyaluronic acid (HA) and type IV collagen (CIV) RIA kits were from Shanghai Naval Medical Research Institute; alpha smooth muscle actin (α-SMA) and proliferating cell nuclear antigen (PCNA) monoclonal antibodies were from Dako Ltd. (Glostrup, Denmark)

Animal treatment

Wistar rats were randomly divided into three groups: normal control group (Group A), CCl_4 induced liver injury control group (Group B) and CCl_4 induction with WeiJia treatment group (Group C). Each group consisted of 14 rats (8 male, 6 female). Liver damage and fibrosis was induced by subcutaneous injection with 40% CCl_4 in olive oil at 3 mL/kg body weight twice a week for eight weeks for Group B and C rats whereas olive oil alone was used for Group A rats. Rats were allowed to feed *ad libitum*. Starting from the third week, Group C rats also received daily intraperitoneal injection of WeiJia at a dose of 1.25 μg/kg body weight. All studies were conducted according to the guidelines described in the NIH Guide for the Care and Use of Laboratory Animals.

Sample collection

Half of the rats (4 male, 3 female) in each group were sacrificed at the fifth week and the other half were sacrificed at the eighth week. Amobarbital sodium (0.5%) was injected intraperitoneally into the rats at 4 mL/kg and blood was collected from the heart after anesthesia. Blood (5 mL) was collected and 1.2 mL serum was obtained after centrifugation and stored at 4 ℃ before analysis. Liver tissues (1 cm×1 cm×1 cm) from the right liver lobe were dissected and immobilized in 4% paraformaldehyde. Tissue was then embedded in paraffin wax and sectioned (4 μm thick) before analysis.

Serum chemistry

Liver fibrosis blood tests for HA and CIV were performed using competitive RIA method. Blood serum level of γ-GT, ALT and AST were measured by standard clinical chemical methods using an automatic analyzer type ALCYON 300i (Abbott Laboratories Ltd, USA).

Histological examination

Tissue was sectioned, haematoxylin and eosin (HE) staining, Van Gieson (VG) staining and immunohistochemistry were performed and examined under light microscope. All histological examinations were performed by experienced pathologist without prior knowledge of the animal treatment groups in the study. Images were acquired through Nikon Eclipse E400 (Nikon Corporation, Japan) and analyzed with analySIS 3.0 software.

Degree of fibrosis was measured on HE stained sections. Stage of liver fibrosis was graded with the METAVIR scale, which grades fibrosis on a five-point scale: F0 (no fibrosis), F1 (portal fibrosis without septa), F2 (portal fibrosis with a few septa), F3 (numerous septa without cirrhosis) and F4 (cirrhosis). METAVIR scale is a widely used scale that has excellent inter-observer reliability[15, 16].

Ballooning degeneration and steatosis for HE stained sections were graded according to a four point scale where Grade 0: negative, Grade (1): up to 33%, Grade (2): 33%-66% and Grade (3): > 66% cells show ballooning degeneration and steatosis[17].

The collagen content of the sections was determined by VG staining. Five random fields were chosen in each section and the amount of total collagen was detected as the area stained by VG and expressed as percentage relative to the total area.

α-SMA and PCNA immunohistochemistry were also performed. Sections were deparaffinized, rehydrated and incubated in 3% hydrogen peroxide at room temperature for 10 min to block endogenous peroxidase. After rinsing with distilled water, sections were incubated in phosphate buffered saline (PBS, 0.01 mol/L, pH 7.4) for 5 min and epitope retrieval was induced with heat in a microwave oven. Non-specific binding sites were blocked with 10% normal goat serum (NGS) / 10% bovine serum albumin (1 ∶ 1 dilution) for 30 min at room temperature followed by incubation with monoclonal mouse anti α-SMA or PCNA as primary antibodies at 1 ∶ 100 dilution in PBS containing 10% NGS and 0.3% Tween 20 overnight at 4 ℃. Sections were then washed with PBS for 3 times, each 5 min before applying the secondary antibody. Goat anti-mouse antibody conjugated with horseradish peroxidase (HRP) at 1 ∶ 200 dilution in PBS containing 10% NGS was applied and the sections were incubated for 30 min at 37 ℃. Sections were then washed with PBS for 3 times, each 5 min and stained with DAB for 1 to 5 min. Staining was stopped by washing with tap water. Sections were counterstained with haematoxylin, dried and visualized under light microscope.

Expression of α-SMA was determined according to four categories and each category was assigned a number.

Table 1 Liver fibrosis serum markers test for rats in different treatment group

Group	5th wk		8th wk	
	HA μg/L	CIV μg/L	HA μg/L	CIV μg/L
A	43±19	19±10	37±17	46±16
B[b]	324±92	206±70	130±52	136±28
C[a]	66±20[c]	74±19[c]	58±22[c]	57±21[1]

$n=7$ for each group, [a]$P<0.005$ *vs* Group B, [b]$P<0.001$ *vs* Group A, [c]$P<0.05$ *vs* Group A, [1]$P>0.1$ *vs* Group A.

Table 2 Degree of fibrosis for rats in different treatment group

Group	5th wk					8th wk				
	F0	F1	F2	F3	F4	F0	F1	F2	F3	F4
A	7					7				
B[b]		3	4					1	6	
C[a,d]		5	2				3	3	1	

$n=7$ for each group, [a]$P>0.05$ *vs* Group B at fifth week, [b]$P<0.01$ *vs* Group A, [d]$P<0.01$ *vs* Group B at eighth week.

Grade (1): no expression (-, 2^0=1); Grade (2): individual positive cells expressed in diseased area (+, 2^1=2); Grade (3): a few positive cells gathered together and expressed in the diseased area (++, 2^2=4) and Grade (4): wide spread of positive cells (+++, 2^3=8). Result is expressed in numbers according to different categories.

Expression of PCNA was determined using a double blind method. For each section, 5 random fields at high resolution were chosen and positive cells were recorded by two analysts. Result is expressed as the mean positive cells recorded by the two analysts.

Statistical analysis

Comparison of the degree of liver fibrosis between samples was performed by WILCOXON method. Other data were analyzed by SPSS11.0 software and reported as mean ± standard deviation using one-way ANOVA. Student's t-test was used for comparison between groups. P values of 0.05 or less are considered statistically significant.

RESULTS

WeiJia is an SFDA-approved Category-I new drug for the treatment of severe hepatitis. WeJia showed an overall efficacy of 88.9% in relieving symptoms and improving physical conditions of chronic hepatitis patients in a treatment period of six weeks in previous clinical study. Studies also showed that WeiJia can act as a therapeutic agent in the treatment of cirrhosis[13, 14]. As progressive hepatic fibrosis would lead to cirrhosis, it is likely that WeiJia might also play a role in the treatment of hepatic fibrosis. Thus the effect of WeiJia on liver fibrosis was investigated through an animal model in this study.

Rats were induced with CCl_4 followed by the treatment with WeiJia. Animals without CCl_4 induction or without WeiJia treatment were used as control for comparison. The effect of CCl_4 and WeiJia on rat liver fibrosis was determined through histological examination and serological markers test.

Biochemical tests of fibrosis

Serum levels of biochemical markers were determined to evaluate the severity of fibrosis. Levels of extracellular matrix constituents HA and CIV were measured which wer expected to increase as a result of remodelling and recurrent scarring in liver fibrogenesis. HA has correlation with stage 3 and 4 fibrogenesis. Together with CIV and other markers, differentiation of stage 1 and 2 fibrosis from stage 3 and 4 fibrosis can be obtained[18, 19]. HA and CIV serum levels for different treatment groups are shown in Table 1. Significant elevation of serum HA and CIV levels were observed upon CCl_4 induction ($P<0.001$ *vs* Group A). Their levels were significantly reduced upon treatment with WeiJia ($P<0.005$ *vs* Group B). Though there was still significant difference between the levels of Group C and Group A rats at the fifth week, there was no apparent difference for CIV level at the eighth week between the two groups, indicating prolonged treatment with WeiJia could alleviate the severity of fibrosis. Decrease of the CIV and HA levels were observed for Group B rats at the 8th wk when compared to their level at the 5th wk indicating some recovery processes took place. However, such recovery processes were not potent enough to revert or alleviate the severity of fibrosis as their enzyme levels were still significantly higher than that of Group A rats.

Histopathological study

The great elevation of HA and CIV levels upon CCl_4 induction indicated the successful generation of liver fibrosis animal model. The result was further confirmed by histopathology study. HE staining for sections of normal control group (Group A) showed structural integrity without necrosis, inflammation or fibrosis development. VG staining for collagen was negative too. However, CCl_4 induced liver injury control group (Group B) showed significant fibrosis ($P<0.01$) with the loss of structural integrity and formation of nodules that lacked a central vein. Steatosis and ballooning degeneration ($P<0.01$) were observed on the fifth week whereas increased collagen fibres and complete fibrous septa were observed on the eighth week. Nevertheless, CCl_4 induction with WeiJia treatment group (Group C) showed that WeiJia could significantly alleviate CCl_4 induced alterations as seen in Group B rats. No obvious changes for fibrosis were observed on the fifth week ($P>0.05$). However, the condition for ballooning degeneration and steatosis were significantly relieved at this stage ($P<0.05$). After prolonged treatment, a significant reduction in inflammation, steatosis ($P<0.05$), necrosis, fibrosis ($P<0.01$) and collagen fibres ($P<0.05$) were observed on the eighth week. Representative HE stained images of sample on the eighth week are shown in Figure 1. There was no apparent difference between male and female rats. The degree of fibrosis, ballooning degeneration and steatosis and collagen expression are summarized in Table 2, Table 3 and Table 4.

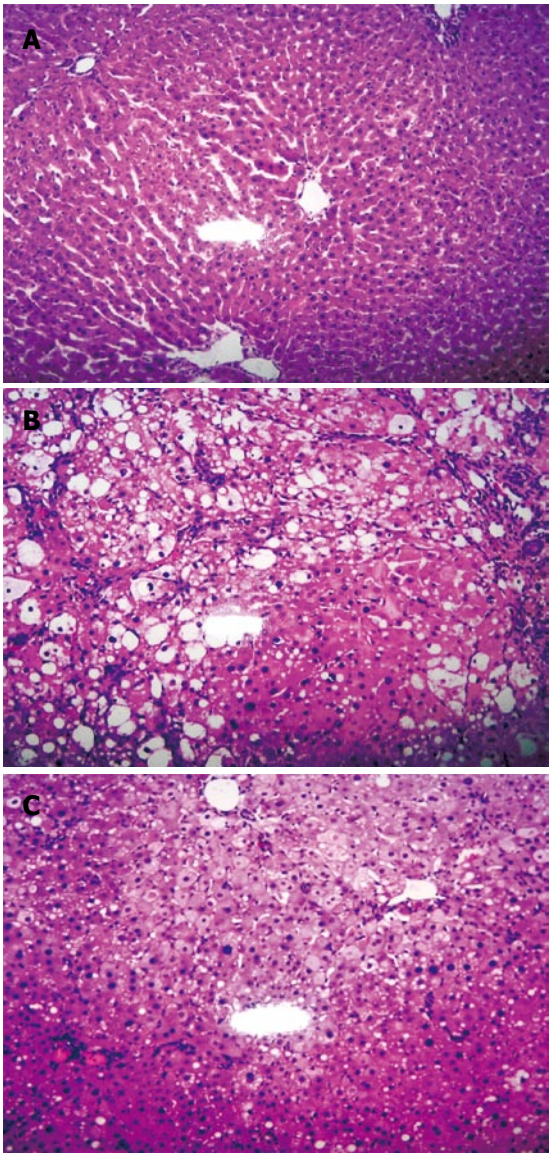

Figure 1 Effect of different treatments on rat liver fibrosis induced by CCl_4 (HE staining, ×100). **A**: Normal control Group A rats, treated with vehicle for eight weeks; **B**: CCl_4 induced control Group B rats, treated with CCl_4 for eight weeks; **C**: CCl_4 induced and WeiJia treatment Group C rats, treated with CCl_4 for two weeks followed by both CCl_4 and WeiJia treatment for six weeks.

$n = 7$ for each group, [a]$P < 0.005$ *vs* Group A, [b]$P < 0.001$ *vs* Group B, [c]$P < 0.05$ *vs* Group B, [d]$P > 0.1$ *vs* Group B, [e]$P > 0.05$ *vs* Group A, [f]$P < 0.01$ *vs* Group A, [g]$P < 0.05$ *vs* Group A.

Liver function test

The effect of CCl_4 on liver and the role of WeiJia in treating liver fibrosis were also determined through liver function test. Serum levels of ALT, AST and γ-GT were measured and compared with control groups as shown in Table 5.

Significant increase in serum levels of ALT, AST and γ-GT upon CCl_4 induction were observed ($P<0.005$ Group B *vs* Group A). A significant decrease in the levels of ALT and AST were observed after WeiJia treatment ($P<0.05$ Group C *vs* Group B). However, the decrease was not significant for γ-GT ($P>0.1$ Group C *vs* Group B). This indicates that there was no strong correlation between the degrees of fibrosis and γ-GT as γ-GT is an indicator for primary or metastatic malignancy involving liver[20].

It has been known that ALT and AST are useful serum markers for inflammation and necrosis of the liver. ALT is especially useful in acute and cholestatic diseases whereas AST is more sensitive in chronic and infiltrative lesion of the liver. Though the levels of these enzymes decreased after WeiJia treatment, they were still significantly different when compared to Group A ($P<0.05$), except the levels of ALT and γ-GT at the fifth week. Studies have indicated that the ratio rather than the absolute values of the two enzymes provides high specificity in monitoring fibrosis[21-23]. By comparing the ratio of the two enzymes, there was no significant difference between rats treated with WeiJia and that from Group A. The results indicate that WeiJia could alleviate the adverse effect on liver function caused by liver injury.

Immunohistochemical study

As WeiJia treatment could alleviate the effects caused by CCl_4 induction, it is important to understand how WeiJia mediates its effect. It was suggested that the proliferative rate of regenerating hepatocytes may be an important pathogenetic factor in chronic liver disease[24]. Recent studies have also shown that HSC are the primary cell type in mediating fibrogenesis[7-9]. Thus the expression of PCNA and α-SMA were determined to evaluate the cell proliferation and HSC activation in liver injury respectively. Results are summarized in Table 6.

Table 6 Expression of PCNA and α-SMA of rats in different treatment group

Group	5th wk		8th wk	
	PCNA	α-SMA	PCNA	α-SMA
A	17.4±7.0	1.4±0.5	16.6±7.8	1.3±0.5
B	27.9±8.3[a]	4.9±2.3[b]	21.0±5.4[c]	4.6±1.5[b]
C[g]	43.4±14.0[e]	3.7±2.1[1]	31.0±10.0[e]	2.6±1.0[e]

$n=7$ for each group, [a]$P<0.05$ *vs* Group A, [b]$P<0.01$ *vs* Group A, [c]$P>0.05$ *vs* Group A, [1]$P>0.1$ *vs* Group B, [e]$P<0.05$ *vs* Group B, [g]$P<0.05$ *vs* Group A.

Normal hepatocytes are generally quiescent and replicate in a limited and regulated manner[25-27]. High proliferative rates were reported in hepatocellular carcinoma, cirrhosis and acute hepatic failure[28-32]. Nevertheless, recent evidences showed that the replicative activity of hepatocytes diminishes in advanced cirrhosis in humans and in chronic liver injury in mouse, reaching a state of replicative senescence[33-35].

Only limited expression of PCNA was found in normal control Group A whereas increased PCNA expression was observed upon CCl_4 induction in active hepatocytes nuclei. Significant difference was found at the fifth week ($P<0.05$, Group B *vs* Group A). However, expression of PCNA in Group B at the eighth week was not significantly different from that of Group A. PCNA expression increased further with WeiJia treatment ($P<0.05$ Group C *vs* Groups A and B).

In normal liver, HSCs are nonparenchymal quiescent cells for vitamin A storage. In pathological conditions as in liver fibrosis, HSCs lose retinoids and synthesize a large amount of extracellular matrix components including collagen, proteoglycan and adhesive glycoproteins. Morphology of these cells also changes from the star-shaped stellate cells to that of fibroblasts or myofibroblasts[36]. α-SMA is a good indicator for HSC activation.

Only limited α-SMA expression was observed in normal control group A. Upon CCl_4 induction, increased amount of α -SMA expression by activated HSC was observed ($P<0.01$ Group B *vs* Group A). The expression was reduced with WeiJia treatment. However, significant reduction was only observed at the eighth week ($P<0.05$ Group C *vs* Group B). Though WeiJia could reduce α -SMA expression, its level was still significantly different from that of Group A ($P<0.05$ Group C *vs* Group A). The results indicated that WeiJia could mediate the alleviation of CCl_4 induced injury through the proliferation of regenerating hepatocytes and the reduction of stellate cell activity.

DISCUSSION

WeiJia is an effective therapeutic agent for severe hepatitis. However, its action mechanism is not clear. WeiJia was also shown to be effective in cirrhosis treatment. Thus we hypothesize that it may also play a role in fibrosis treatment. In this study, its effect on liver fibrosis was evaluated through CCl_4 induced liver injury animal model. This study also provides some information for understanding the mechanism of WeiJia.

It was found that treatment of WeiJia could relieve CCl_4 induced liver necrosis, ballooning degeneration, steatosis and inflammation. The effect was significant at an early stage of treatment at the fifth week. An improved liver function was also observed at this stage of treatment. The results suggest that WeiJia protects liver cells from damage induced by CCl_4 and the therapeutic effects of WeiJia on severe hepatitis might be related to the protective effect of this medication.

Upon liver injury, the body will attempt to repair the damage through increasing the expression of hepatocyte growth factor (HGF), transforming growth factor beta (TGF-β) and other cytokines to enhance hepatocytes proliferation and initiate tissue repairing process. Replicative activity of hepatocytes diminishes in advanced cirrhosis in humans and in chronic liver injury in mouse [33-35]. PCNA expression in Group B was the response of hepatocyte to liver damage. The level of PCNA expression in Group C was significantly higher than that in Group B suggesting that liver cells of rats in Group C have stronger replicative activity. The increase in PCNA expression in WeiJia treated rats with CCl_4 induced liver damage demonstrated that WeiJia has protective effect on liver cells.

Uncontrollable remodelling and regeneration would lead to the development of fibrosis due to excessive deposition of extracellular matrix. The data from this investigation also showed that WeiJia was effective in fibrosis treatment. In addition to inflammation and necrosis, CCl_4 induction also resulted in collagen deposition and liver fibrosis as observed through histopathologic examination. Treatment with WeiJia reduced ballooning degeneration, steatosis and accumulation of collagen. The effect was significant at an early stage of treatment at the fifth week. An improved liver function was also observed at this stage of treatment with the increase in PCNA expression. Significant reduction of fibrosis was only observed after a longer period of treatment at the eighth week. Nevertheless, the results indicate that early treatment with WeiJia might prevent the progression of liver injury to fibrosis through increased liver regeneration and reduced liver necrosis.

It is believed that HSC activation is a critical step in hepatic fibrosis. Levels of serological markers (HA, CIV) and α-SMA expression clearly indicated that HSC was activated by CCl_4 induced liver injury. WeiJia treatment led to a significant reduction of theses proteins, indicating that the mechanism of WeiJia in reducing hepatic fibrosis may be through the inactivation of HSC.

In conclusion, WeiJia is shown to be an effective therapeutic agent that could alleviate liver fibrosis through the stimulation of liver regeneration and inhibition of HSC activation.

Abstract

AIM: To study the effects of interleukin-10 (IL-10) on the expression of α-smooth muscle actin (α-SMA), nuclear factor-κB(NF-κB) and Fas/Fas ligand (FasL) in hepatic stellate cells of experimental rats with hepatic fibrosis.

METHODS: Sixty clean SD rats were randomly divided into control group (group N), liver fibrotic group (group C) and IL-10 treatment group (group I). Control group received intraperitoneal injection of saline (2ml•kg^{-1}), twice a week. Fibrotic group was injected intraperitoneally with 50% carbon tetrachloride (CCl_4) (2 ml•kg^{-1}), twice a week. IL-10 treatment group was given IL-10 at a dose of 4 μg•kg^{-1} 20 minutes before CCl_4 administration from the third week. Hepatic stellate cells (HSCs) were isolated from these rats at the seventh and eleventh weeks during the course of liver fibrosis, respectively. The expression of α-SMA and NF-κB in HSCs was measured by S-P immunohistochemistry. The expression of Fas and FasL mRNA was measured by RT-PCR. Furthermore, liver tissues were harvested from three groups at the same time.

RESULTS: The CCl_4- induced experimental rat hepatic fibrosis model was established successfully. The purity of extracted hepatic stellate cells was about 95% and the yield of hepatic stellate cells was 1.2-2.3×10^6/g liver tissue averagely. The positive expression of α-SMA and NF-κB was 36.5% and 28.5% respectively in group N. The positive levels of α-SMA and NF-κB were increased significantly in group C compared to group N (P<0.01). The positive signals decreased significantly (P<0.05) in group I. In the 11th week, the HSCs of group I became round with visible pyknotic nuclei. The expression of NF-κB in group C was significantly increased in a time-dependentmanner (P<0.01), but there was no difference in the α-SMA expression (P>0.05). The mRNA of Fas and FasL in group C was significantly increased in a time-dependent manner compared to that in control group. After treated with IL-10, the expression level of Fas and FasL was higher in group I than in group C.

CONCLUSION: The positive expression of α-SMA and NF-κB in hepatic stellate cells is decreased by ectogenic IL-10 in liver fibrosis induced by CCl_4. The expression of Fas and FasL is increased in the course of liver fibrosis, and is further increased by IL-10. IL-10 could inhibit the activation of HSCs and cause apoptosis of activated HSCs.

INTRODUCTION

Liver fibrosis is a model of wound-healing responses to chronic liver injury and is the excessive accumulation of extracellular matrix proteins in most types of chronic liver diseases[1]. The cellular and molecular mechanisms of liver fibrosis have greatly advanced since hepatic stellate cells (HSCs) were identified as the main collagen-producing cells in the liver. HSCs are the central event in hepatic fibrosis[2-3]. In normal liver, HSCs reside in the Disse's space and are the major storage sites of vitamin A. Following chronic injury, HSCs activate or transdifferentiate into myofibroblast-like cells, acquiring contractile and fibrogenic properties, secreting cytokines and expressing α-smooth muscle actin(α-SMA)[4-5]. The mechanisms involved in cytokine secretion by HSCs include activation of the transcription nuclear factor-κB (NF-κB). NF-κB, a key transcription factor induces genes involved in inflammation, responses to infection, and stress[6]. DNA binding activity of NF-κB is demonstrated in activated but not in quiescent HSCs, and activation of HSCs is associated with the nuclear translocation of

NF-κB. Inhibition of NF-κB by proteosome inhibitors or by adenovirus expressing the IkB superrepressor can markedly blunt cytokine secretion by activated HScs. Using differential display, investigators have shown that intercellular adhesion molecule 1 (ICAM-1) is expressed in HSCs activated in culture or *in vivo*, but not in quiescent HSCs[7]. The ICAM-1 gene contains a NF-κB binding site and its transcription is stimulated by NF-κB[8,9]. This observation provides functional support for a critical role of NF-κB in the activation of HSCs. As liver injury resolves, the number of activated stellate cells decreases through 1 of 2 potential pathways, namely spontaneous reversion or clearance by apoptosis[10,11]. To date, spontaneous reversion of myofibroblasts to quiescent cells has only been documented in culture, but not *in vivo*. In contrast, there is evidence that HSCs undergo apoptosis during resolution of liver injury *in vivo*. Some data demonstrate that apoptosis of HSCs in the course of activation is accompanied with increased expression of FasL by HSCs themselves[12]. Fas/FasL system is the key pathway for apoptosis of HSCs. Our work team found that ectogenic IL-10 could decrease liver fibrosis, but its mechanism still remains unclear. In the present study, α-SMA, NF-κB and Fas/FasL were selected as the targets to study the effects of interleukin-10 on activation and apoptosis of HSCs.

MATERIALS AND METHODS

Materials

Sixty clean male Sprague-Dawley rats, weighing 400-500g (provided by Shanghai Experimental Animal Center), were divided randomly into 3 groups. The control group (group N) included 8 rats, the fibrotic group (group C) included 28 rats and the IL-10 intervention group (group I) included 24 rats. All the rats were bred under clean conditions (room temperature: 22℃±2℃; humidity: 55%± 5%) in a 12 h light/dark cycle with free access to drinking water and food. High voltage disinfectant animal food was provided by BK Company in Shanghai, China.

Reagent

Recombined rat interleukin-10 was provided by Jingmei Biotechnology Corporation. Collagenase type IV and Nycodenz were provided by Sigma Corporation. Pronase E was provided by Merk Corporation. DNase I was provided by Sino-American Biotechnology Corporation. DMEM was provided by Gibco Corporation. Mouse anti-rat α-SMA and NF-κB monoclonal antibodies were provided by Santa Cruz Biotechnology Inc. SP immunocytochemistry kit was provided by American Zymed Company. RNA isolation kit was provided by Gentra Company (USA) and PCR kit was provided by Promega Company. The primers were synthesized by Beijing Sanbo Company.

Animal models

The rats of group N were injected intraperitoneally with saline (2ml·kg^{-1}), twice a week. The rats of groups C and I were intraperitoneally injected with 50% CCl_4 (dissolved in castor oil) (2ml·kg^{-1}), twice a week. From the third week, the rats of group I were injected intraperitoneally with IL-10 (4μg·kg^{-1}) (dissolved in saline) 20 minutes before they were injected with CCl_4[13]. All injections were performed on Monday and Thursday with the body weights determined before each injection. By the end of the experiment, 12 rats in group C and 8 in group I died. No animals died in group N. In the seventh and eleventh weeks, 3 rats in group N and 5 rats in the other two groups were sacrificed to collect their hepatic stellate cells. The liver tissue was collected from 1 rat in each group at this time point and fixed in 10% formalin and embedded with paraffin.

Isolation and culture of hepatic stellate cells

Nonparenchymal cells were isolated from rats of the experimental groups by sequential perfusion with collagenase and pronase E as described previously [14,15]. Buoyant HSCs were separated from the resulting cell suspension by elutriation over a Nycodenz gradient. In brief, the liver of rats was routinely perfused through a portal vein catheter with Ca^{2+}-free D-Hanks solution, then with pronase E and type IV collagenase dissolved in Ca^{2+} containing D-Hanks solution. The liver was homogenized and incubated with pronase E, type IV collagenase and DNase I dissolved in Ca^{2+} containing D-Hanks solution for 20 min at 37℃ with constant stiring. This suspension was centrifuged by 11% Nycodenz density gradient centrifugation for 15 minutes at 1500r/min after filtered. The cells were aspirated from the interface, washed twice in DMEM solution, and then resuspended in DMEM containing 20% calf serum. The HSCs were seeded onto plastic tissue culture bottle at 1×10^6 cells/mL and incubated at 37℃ with 50mL/L CO_2 in air.

Immunocytochemistry measurement

The HSCs cultured for 24 hours were fixed by 4% paraformaldehyde at 4℃ for 24 hours, then incubated in PBS containing 3%H_2O_2 to remove endogenous perxoidase activity and then in PBS containing 0.1mol/L citrate to saturate nonspecific binding sites. After incubation with 1∶100 mouse anti-rat α-SMA and NF-κB monoclonal antibody, the reaction was carried out with the instant S-P immunocytochemistry reagents. The primary antibody was replaced with PBS as blank contrast. The plates were incubated in a buffer containing 3,3-diaminobenzidine tetrahydrochloride (DAB) and H_2O_2 to produce a brown reaction product, then imaged under microscope.

Result assessment

Two hundred cells were calculated under the microscope. The reactions were graded and scored according to their intensities and percentage of the positive cells as follows: zero score for negative reaction, 1 score for pale yellowish staining, 2 scores for dense yellow staining and 3 scores for brown staining. The eventual result was produced by the two scores for staining intensity and positive cell percentage.

Reverse transcription- polymerase chain reaction (RT-PCR) for Fas and FasL

Total RNA was isolated from HSCs using Gentra

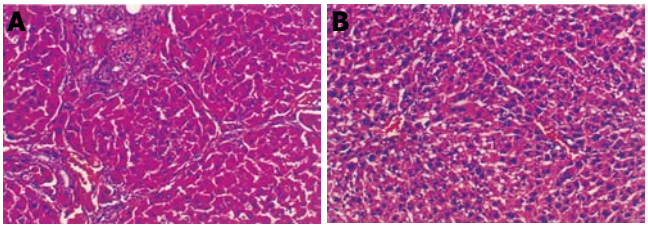

Figure 1 Liver of rats in groups C (**A**) and I (**B**) (week 11, H-E staining, ×100)

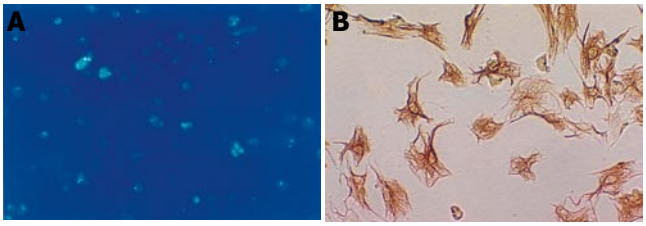

Figure 2 Autofluorescence (**A**) and desmin staining (**B**) of HSCs.

reagent (USA) according to the protocol provided by the manufacturer. The A260/A280 of total RNA was between 1.8 and 2.0. After treated with DNase-I, 1-2μg of total RNA was reversely transcribed into complementary DNA (cDNA) with oligo (dT) using cDNA synthesis kit. Then 2 μL of cDNA product was used as the template to amplify specific fragments in a 25μL reaction system. PCR was performed with an initial denaturation at 94℃ for 5 min, followed by 25 cycles at 94℃ for 45 s, annealing at 55℃ for 30 s (FasL at 58℃), at 72℃ for 60 s, with a final extension at 72℃ for 7 min. The primer sequences used are sense: 5' -GAATGCAAGGGACTGATAGC-3' and antisense: 5' -TGGTTCGTGTGCAAGGC TC-3' for Fas; sense: 5' -GGAATGGGAAGACACATATGGAACTGC-3' and antisense: 5'-CATATCTGGCCAGTAGTGCAGTAAT TC-3' for FasL; sense: 5'-GAGCTATGAGCTGCCTGA CG-3' and antisense: 5'-AGCACTTGCGGTCCAC GATG-3' for β-actin (660bp); sense: 5' -GAGCTATGAGCTGC CTGACG-3' and antisense: 5' -AGCACTTGCGGTCCACGATG-3' for β-actin (410bp).

Electrophoresis and semi-quantitative analysis

The PCR products were run on 2% agarose gel electrophoresis and visualized with ethidium bromide staining. The expected product sizes were Fas (414bp), FasL (239bp), β-actin (660bp and 410bp). Bioimagine system was used to detect the density of bands of PCR products. The values of Fas and FasL expression were calculated from percentage of the ratio of band density of PCR products and the band density of β-actin.

Statistical analysis

All data were expressed as mean ± SD. The significance for the difference between the groups was analyzed with SPSS10.0 by one-way ANOVA. $P<0.05$ was considered statistically significant.

RESULTS

Animal model

Liver fibrosis was remarkable during the treatment with CCl_4. In the seventh week, steatosis and ballooning degeneration of hepatocytes were obvious, plentiful inflammatory cells infiltrated into the Disse's space, collagen fibers increased and extended to the parenchyma. In the eleventh week, collagen fibers formed widely, complete fibrous septa were seen and pseudolobular structures were also present occasionally. In the IL-10 treatment group, the CCl_4-caused alterations as described above seemed to be markedly alleviated, less profound steatosis and necrosis were noted in the seventh week, and no distinct change was found in the eleventh week compared to the normal group (Figures 1A, 1B).

Hepatic stellate cell identification

HSCs were isolated successfully. The yield of HSCs was $1.2\text{-}2.3\times10^6$/g liver tissue. HSCs were identified according to their typical autofluorescence at 328-nm excitation wavelength (Figure 2A) and by immunohistochemistry with monoclonal antibody against desmin. Greater than 95% of the isolated HSCs were stellate cells (Figure 2B). The cells' viability was determined by trypan blue exclusion staining with viability over 90%.

Expression of α-SMA and NF-κB in HSCs

The granular positive products of α-SMA were localized in cytoplasm of HSCs, and the NF-κB was in cytoplasm and nuclei. In control group, the expression was weak and pale yellowish, the positive rate of α-SMA and NF-κB was 36.5% and 28.5%, respectively. In group C, the expression increased obviously with the development of liver fibrosis (positive rate was 100% and the granular positive products were dense yellow or brown). The distribution of NF-κB was found mainly in nuclei. In group I, the changes were less pronounced than in group C. Especially in the eleventh week, the HSCs became round with visible pyknotic nuclei, the vigour of cells was weak (Figures 3A-3E). Comparison of α-SMA and NF-κB positive expression levels among 3 groups is shown in Table 1 and in Figures 4A, 4B. In group I, IL-10 treatment resulted in decreased immunoreactivties of α-SMA and NF-κB ($P<0.05$). With the development of liver fibrosis, the intensities of NF-κB increased gradually, but that of α-SMA did not change significantly.

Expression of Fas and FasL in HSCs

The Fas and FasL mRNA could be measured in HSCs of control group. The mRNA of Fas and FasL in fibrotic group was increased in a time-dependent manner compared to that in control group. After treated with IL-10, the expression level of Fas and FasL mRNA was higher in fibrotic group than in control group. The expression of Fas and FasL mRNA was increased in the course of liver fibrosis and was further increased by IL-10 (Figures 4C, 4D). Comparison of Fas and FasL mRNA expression levels among 3 groups is shown in Table 2 and in Figures 4E, 4F.

DISCUSSION

Liver fibrosis results from the excessive secretion of matrix proteins by HSCs. In normal liver, HSCs are nonparenchymal, quiescent cells whose main function is to store vitamin A[16]. In response to liver injury, HSCs undergo an "activation" process in which they produce cytokines and chemokines, express receptors of cytokines and chemokines, and synthesize ECM[17]. Activation of HSCs is the central event of liver fibrosis, which consists of 2 major phases: initiation and perpetuation[18]. The earliest changes in stellate cells are likely to result from paracrine stimulation by all neighboring cell types, including Kupffer cells, sinusiodal endothelium, etc. Perpetuation of stellate cell activation involves several discrete changes in cell behavior, such as proliferation, chemotaxis, fibrogenesis, contractility, matrix degradation, of which contractility of HSCs may be a major determinant during liver fibrosis. The activated HSCs show common phenotypic features of smooth muscle cells and myofibroblasts, shape of well-developed stress fibers of actin cytoskeleton. The microfilament protein α-SMA has been explored as a marker for activated HSCs. Quiescent cells are negative *in vitro* or *in vivo* and activated HSCs are clearly positive[19]. This suggests a close relationship between α-SMA induction and liver fibrosis. Our data show that α-SMA is expressed in activated hepatic stellate cells in the course of liver fibrosis. After the treatment with IL-10, the expression of α-SMA decreased, indicating that ectogenic IL-10 may release activated HSCs.

NF-κB exists in cytoplasm as an inactive form associated with regulatory proteins called inhibitors of kB (IkB)[20]. Phosphorylation of IkB, an important step in NF-κB activation, is mediated by IkB kinase (IKK). Appropriate stimuli induce selective IkB phosphorylation, which is then degraded by the proteasome pathway. Free NF-κB migrates to nuclei by virtue of its nuclear localization signal and induces transcription of multiple kB-dependent genes. Newly synthesized IkB both in cytoplasm and in nuclei inactivates NF-κB. NF-κB regulates the transcription of a number of proinflammatory molecules involved in acute responses to injury and chronic liver inflammation, including TNF-a, IL-6, ICAM-1 etc[21]. The induction of NF-κB during liver regeneration after partial hepatectomy appears to be a required event to prevent apoptosis and allow for normal cell cycle progression. NF-κB is a key transcription factor involved in activation of HSCs[22,23]. Inhibition of the IKK/NF-κB pathway is sufficient to increase the rate at which activated hepatic stellate cells undergo

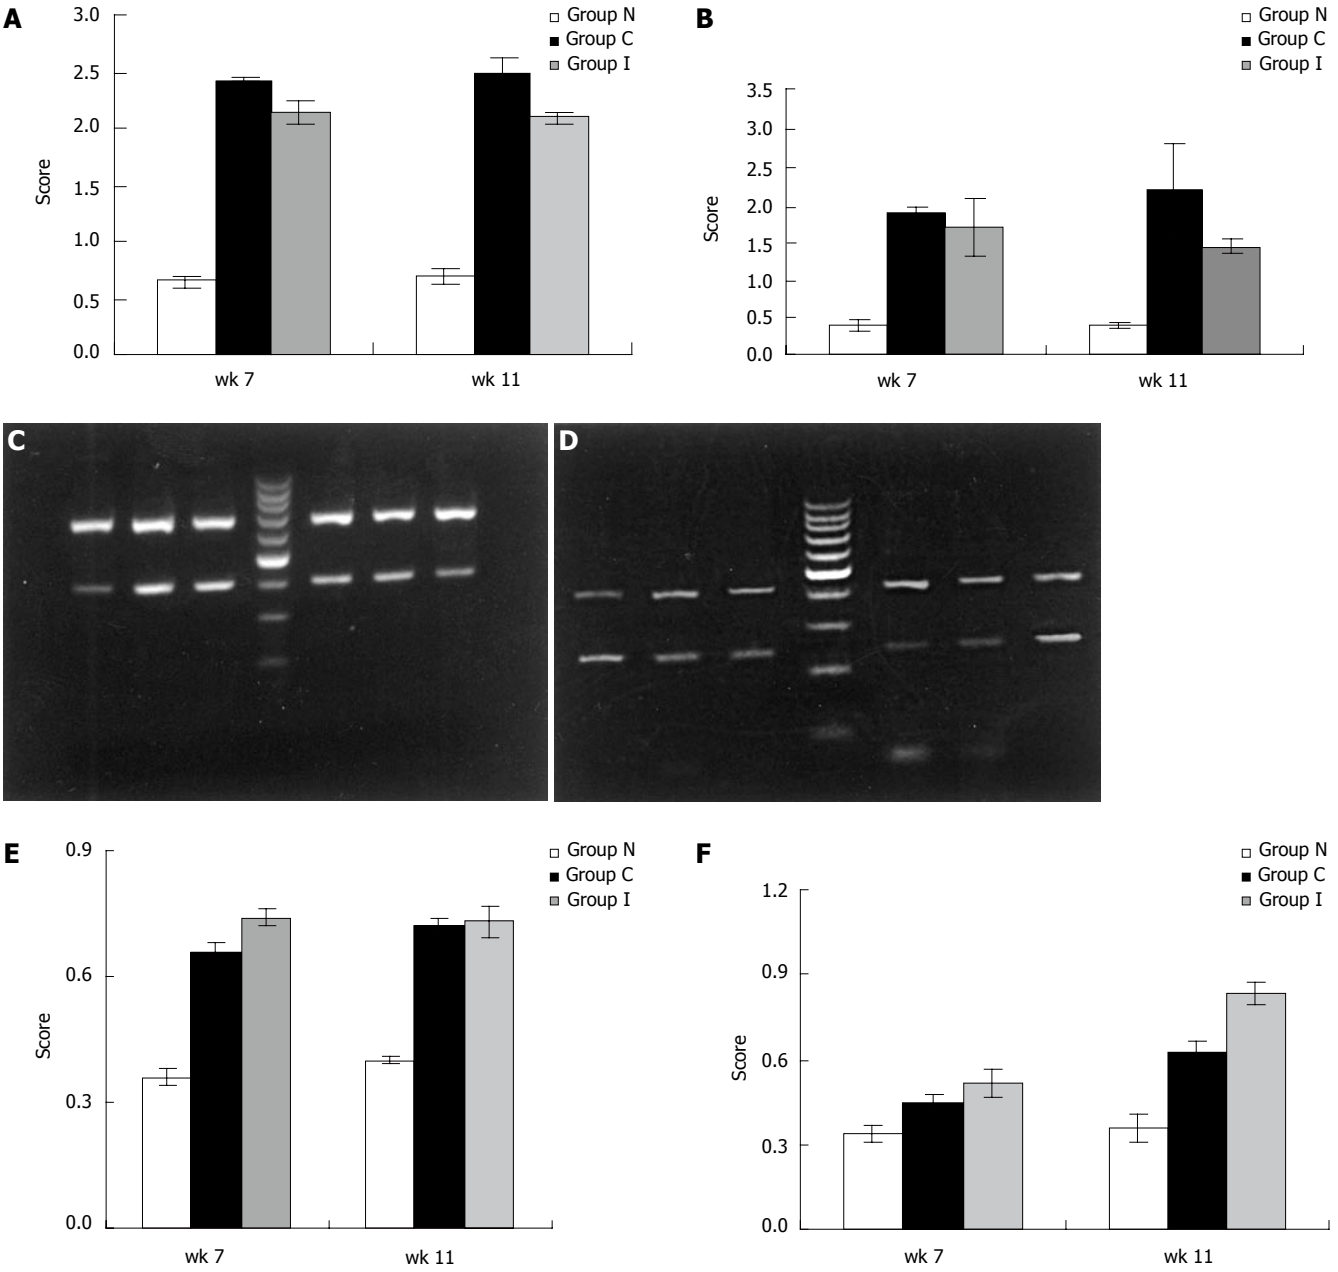

Figure 4 Expressions of α-SMA (**A**), NF-κB (**B**), Fas mRNA (**C**), FasL mRNA (**D**), Fas (**E**), and FasL (**F**) in HSCs.

apoptosis *in vitro* and *in vivo*. Drugs selectively targeting IKK have potential as antifibrotics[24]. Although in some studies IL-10 has been demonstrated to block NF-κB activation, our data suggest that IL-10 could decrease the NF-κB expression. The molecular target for IL-10-induced inhibition of NF-κB has not been established. There is evidence that IL-10 regulates NF-κB by dual mechanisms[25]. Firstly, IL-10 blocks IKK activity, thus inhibiting phosphorylation and degradation of IkBa. The preserved IkBa continues to bind to NF-κB in cytoplasm, prohibiting NF-κB nuclear translocation and NF-κB-dependent transcription. Secondly, IL-10 can directly block NF-κB DNA binding by a mechanism that is independent of NF-κB nuclear translocation.

Apoptosis associated with liver disease is increasingly viewed as a nexus through which many key pathways converge[26]. Pathologic apoptosis in liver may not only result from inflammation and fibrosis, but also in turn amplify these responses. In particular, HSCs contribute to apoptosis and inflammation. As the liver injury resolves, apoptosis of activated HSCs may be involved in the reversion of liver fibrosis[27]. Fas is known as an important mediator of apoptosis and acts as an inducer of apoptosis in Fas-expressing cells in response to ligand binding (FasL)[28]. Saile *et al*[29] reported that resting HSCs display no sign of apoptosis and spontaneous apoptosis becomes detectable in parallel with HSC activation, suggesting that apoptosis might represent an important mechanism terminating proliferation of activated HSCs. They also demonstrated that apoptosis of HSCs in the course of activation is accompanied with increased expression of FasL by the HSCs themselves. The activated HSCs possess more Fas and FasL, compared with HSCs in the resting and transitional phase. The apoptosis of HSCs could largely be

inhibited by blocking Fas, indicating that Fas/FasL system plays a major role in initiation of apoptosis. Thus, driving activated HSCs into apoptosis may be a way to resolve fibrosis. Our data show that with the development of liver fibrosis, the Fas/FasL system mRNA expression increases. In addition, IL-10 could promote the expression of Fas and FasL mRNA-activated HSCs, implying that IL-10 may promote activated HSCs into apoptosis through binding of FasL to Fas on the cell membranes of HSCs.

IL-10 is pleiotropic[30-31] and has multiple effects on diverse cell types. One of the most important properties of IL-10 is its anti-inflammatory action, which restrains the immune response under various stimuli, otherwise the individuals would have deleterious consequences. Evidence of *in vivo* function of IL-10 indicates that in the absence of IL-10 (in genetically IL-10 deficient animals), an exaggerated inflammatory response can lead to inflammatory states[32]. In our study, the ectogenic IL-10 could alleviate liver fibrosis induced by CCl_4 in rats. During the course of liver fibrosis, the positive expression of α-SMA in HSCs was decreased by IL-10, suggesting that activation of HSCs can be inhibited by IL-10. The mechanisms may involve blocking NF-κB activation. At the same time, the expression of Fas and FasL mRNA was further increased by IL-10, suggesting that IL-10 may induce apoptosis of HSCs. In brief, IL-10 could inhibit activation and promote apoptosis of HSCs, which may be related with its mechanism against fibrosis.

Abstract

AIM: To investigate the prognostic significance of *PECAM-1*, *ICAM-3* and *HLA-DR* antigens in patients with primary non-Hodgkin's gastric lymphoma.

METHODS: We immunohistochemically studied *PECAM-1*, *ICAM-3* and *HLA-DR* antigen expression in 36 B-cell MALT-type primary gastric lymphoma patients. Ten non-malignant and ten healthy gastric tissue specimens were used as controls. Clinicopathological and survival data were correlated with the staining results.

RESULTS: *HLA-DR* antigen expression was detected in 33 gastric lymphoma patients (91.7%) and 6 non-malignant patients (54.5%). *PECAM-1* stained tumor cells of 10 patients (27.8%), endothelial cells of 9 patients (25%) and inflammatory infiltrate of 4 patients (40%) with benign gastric disease. *ICAM-3* expression was observed on the tumor cells of 17 patients (47.2%), while 5 non-malignant patients (50%) were stained positive as well. None of the healthy controls was stained for any of the genes studied. In the multivariate analysis, *HLA-DR* antigen and *PECAM-1* were proved to be statistically significant independent prognostic factors associated with a favourable and an unfavourable prognosis respectively ($P = 0.009$ and $P = 0.003$). In the univariate analysis, *PECAM-1*(+)/*ICAM-3*(-) and *HLA-DR*(-)/*ICAM-3*(-) patients exhibited a significantly decreased overall survival compared to those with the exactly opposite gene expression patterns ($P = 0.0041$ and $P = 0.0091$, respectively). Those patients who were *HLA-DR*(+)/*ICAM-3*(+)/*PECAM-1*(-) ($n = 8$) had a significantly higher survival rate compared to the rest of the group ($n = 24$) ($P = 0.0289$).

CONCLUSION: *PECAM-1*, *ICAM-3* and *HLA-DR* are representative markers of tumor expansion potential and host immune surveillance respectively. Their combined use may help us to identify high-risk patients who could benefit from more aggressive therapeutic protocols.

Key words: *PECAM-1*; *ICAM-3*; *HLA-DR*; Non-Hodgkin's gastric lymphoma; Prognosis

INTRODUCTION

Primary gastric B-cell non-Hodgkin's lymphomas are uncommon tumors, constituting less than 2% of all primary gastric malignancies[1]. Numerous clinicopathologic studies have identified stage and grade as the most important prognostic factors[1,2]. Still there are a number of patients with favourable stage and grade that exhibit an aggressive phenotype. A second line of molecular prognostic markers has been introduced lately to better describe this clinical entity.

Several different molecules (*bcl-2*, *p53*, *PCNA*, *c-fos*, *c-myc* and *Ki67*) and biologic pathways have been implicated in the initiation and progress of primary non-Hodgkin's gastric lymphoma[3]. Immunohistochemical tracing of these molecules in gastric lymphoma patients has already been employed not only for the diagnosis but for the determination of prognosis as well[4].

HLA-DR antigen is a class II MHC membrane-bound glycoprotein, which plays an important role in the regulation of the immune response[5]. Although it is normally expressed exclusively by antigen presenting cells of the immune system[6], it shows variable expression in malignancies[7,8]. During oncogenesis, it is modified to affect tumor

Table 1 Demographics and clinicopathological characteristics of 36 patients with primary gastric lymphoma

Characteristics	Frequency	Percentage (%)
Age of disease presentation (yr)	58.39 ± 15.39 (median: 59, range: 33-82)

cell behavior by decreasing or enhancing specific anti-tumor immune mechanisms[9].

Cell adhesion molecules are membrane glycoproteins that play a major role in neoplastic disease by interfering with cell-matrix and cell-cell interactions. They are also believed to participate in host immune surveillance by providing antigen non-specific recognition between Th-cells, APCs, Tc-cells, NK-cells and their potential targets. *ICAM-3* and *PECAM-1* are considered to be representative members of the immunoglobulin Ig superfamily of cell adhesion molecules (*CAMs*). *ICAM-3* is constitutively highly expressed by leukocytes especially in lymphomas and myelomas[10]. It is postulated that it may constitute the critical ligand for the initiation of lymphocyte immune responses [11] with possible antitumoral properties. Tumor expansion is angiogenesis dependent[12,13], a function which is orchestrated by a constant interaction between tumor cells and host cells. This "cross talk" can lead either to cell cycle arrest and tumor regression or to tumor progression[14,15]. *PECAM-1* (platelet/endothelial cell adhesion molecule) is considered to be an accurate measure for the assessment of vascular proliferation on tumor sections[12] determining prognosis in a variety of tumors[16,17]. Moreover, *PECAM's-1* expression by immunocompetent cells[11] as well as its regulatory role in the extravasation of leukocytes[18], suggests a potential pathway through which lymphoid tumors may escape immune surveillance.

Although the above molecules appear to represent interacting pathways responsible for the antitumoral response and tumor progression, up to day very little information is available on their role in the pathogenesis and prognosis of primary gastric lymphoma[19-21]. The aim of this study was to analyze the immunohistochemical expression of *ICAM-3* (*CD50*), *PECAM-1* (*CD31*) and *HLA-DR* antigens in a group of patients operated for primary non-Hodgkin's gastric lymphoma with respect to their clinicopathological characteristics and clinical outcome.

MATERIALS AND METHODS

We retrospectively recruited 36 B-cell MALT-type non-Hodgkin's primary gastric lymphoma patients (76.6%). All of them were diagnosed and treated during the period from 1991 to 1997 at the First Department of Propaedeutic Surgery of the Hippokration Hospital, Athens Medical School. Follow-up time measurements were specifically interrupted by death of the affected individuals from any cause. In this regard, follow-up time ranged between 15 d and 135.5 mo, with a mean of 60.5 ± 38.8 mo and a median of 68.5 mo. Favorable treatment outcome was defined as undetectable disease at the most recent follow-up. Unfavorable treatment outcome was defined as tumor recurrence, either locally or distantly, or death due to the tumor. Four patients had inadequate 5-year survival data and were excluded from the survival analysis. All reported deaths were attributed to the underlying disease, thus the overall survival corresponded to tumor-associated survival. Our study also included 10 gastric tissue specimens of non-malignant origin (Analytically this group consisted of 4 patients with gastritis and 6 patients with non malignant ulcer of the stomach, none of whom was submitted to any kind of surgery) and 10 healthy control tissue specimens. The characteristics of gastric lymphoma patients as well as information regarding adjuvant therapy are summarized in Table 1.

All patients were diagnosed by endoscopic biopsy and preoperatively evaluated by bone marrow biopsy, chest radiography, abdominal CT and indirect laryngoscopy. The mean age of disease presentation was 58.39 ± 15.39 years (median: 59 years).

Staging was performed according to the Japanese Classification of Gastric Carcinoma by the Japanese Gastric Cancer Association[22]. Seventeen patients (47.2%) were stage I, 7 (19.4%) stage II, 6 (16.7%) stage III and 6 (16.7%) stage IV. Histopathologic examination was undertaken according to the working formulation[23]. Fifteen (41.7%) were found to be low grade lymphomas (grade I), 7 (19.4%) intermediate grade lymphomas (grade II) and 14 (38.9%) high grade lymphomas (grade III). The presence of *H pylori*-associated MALT-type lymphoma was not determined in the majority of cases and this information was not included in our statistical analysis. Ten patients (27.7%) received a total gastrectomy and 20 (55.5%) a subtotal gastrectomy, while there was no information regarding the type of surgery for 6 (16.8%) patients. All patients had macroscopically clear margins, while microscopically

involved resection margins were detected in 5 patients (13.9%). Intraoperative staging consisted of biopsies of the liver and any enlarged abdominal lymph nodes. Splenectomy was performed only if the spleen was directly invaded.

Adjuvant chemotherapy was administered to 25 patients (69.4%), 3 of whom (8.3%) received a combination of adjuvant chemo/radiotherapy. Eight patients (22.3%) did not receive any kind of supplemental therapy, while no data were retrieved for three more (Table 1).

Immunohistochemistry

Immunohistochemical studies were performed on formalin-fixed and paraffin-embedded sections using the streptavidin- biotin- peroxidase method (Novostain Super ABC Novocastra laboratories Ltd, Newcaste, UK) with monoclonal antibodies specific for *HLA-DR* (DAKO, Glostrup, Denmark, dilution 1:70) and *PECAM-1* (Oncogene Research Products, Calbiochem, Boston, dilution 1:50) and *ICAM-3* (Oncogene Research Products, Calbiochem, Boston, dilution 1:1000). The assignment was performed on surgical specimens obtained during the surgical excision of the tumors.

The staining technique used was the same as previously described[24, 25]. The sections were deparaffinized in xylene and rehydrated in graded ethanol. Antigenic determinants masked from the formalin-fixation and parafin-embedding were exposed to saponin. Briefly, the endogenous peroxidase activity was blocked using a hydrogen peroxide solution. The primary antibody was then applied overnight at 4℃ followed by incubation with a polyvalent antibody for 30 min and then a streptavidin-peroxidase reagent for 30 min at room temperature. Diaminobenzidine tetrahydrochloride (DAKO) was used as the chromogen, and hematoxylin for counterstaining. Appropriate positive and negative controls were used.

All slides were evaluated by two independent reviewers. The percentage of *HLA-DR* (+) tumor cells was estimated, compared to the total area covered by the tumor in 10 randomly selected low power fields (x40). The proportion of *HLA-DR* (+) stromal cells close to and far from the tumor (macrophages, leukocytes, activated T-cells, necrotic tissue) was also assessed, as well as *HLA-DR* expression in normal gastric mucosa and stroma, for all the slides containing benign gastric tissue. HLA-DR antigen expression was located mainly in the cytoplasm but on some occasions membrane staining was seen. According to our initial estimation paraffin sections expressing *HLA-DR* in less than 5% of the tumor were considered negative. Tumor sections in which most of the tumor was found positive for *HLA-DR* expression in 10 randomly selected low power fields, were characterized as >75% positive.

A semi-quantitative grading system for *ICAM-3* and *PECAM-1* was used with the following criteria:

Negative (-): no immunoreaction or < 5% of tumor cells stained; (+) : 5-10% of tumor cells stained; (+ +) :10-50% of tumor cells stained; (+ + +) : >50% of tumor cells stained.

Tumor vascularity was assessed using the method described by Horak *et al*[12] and penfold *et al*[26]. Microvessels identified with PECAM-1 staining were counted on three 400 × fields (A=0.302 mm^2) within areas of maximum vascularity and the mean microvessel count was calculated for each area.

Statistical analysis

Data were expressed as mean ±SD. Survival analysis was performed using the Kaplan-Meier method with the log rank test. To determine independent prognostic factors we used the Cox proportional hazards model, which estimates the odds ratio in 95% confidence intervals. Univariate analyses comparing subgroups of patients were performed with the chi-square test (Pearson, Mantel-Haenzel test for linear association). The results of the morphometric examination were studied in various levels of the variables examined by the Student's *t*-test or the one-way ANOVA. The Levene test for homogeneity of variance was performed before the application of *t*-test or ANOVA. Non-parametric tests such as the Mann-Whitney test and the Kruskal –Wallis one-way ANOVA were applied in every case where the requirements of the t-test or the one-way ANOVA were not met. For all statistical tests, $P < 0.05$ was considered statistically significant.

RESULTS

PECAM-1 was immunohistochemically expressed on the tumor cells of 10 gastric lymphoma patients (27.8%) (mean expression = 26.5% ± 8.8% for *PECAM-1* positive cells) (Figure 1A). *PECAM-1* (+) endothelial cells were found in the vessels of 9 gastric lymphomas (25%) (Figure 1B). The tumor stromal *PECAM-1* (+) vessel counts/mm^2 varied between 1.987/mm^2 and 8.609/mm^2 (mean ± SD: 4.6358 ± 2.0679) and were significantly higher ($P = 0.027$) than *PECAM-1* (+) vessel counts located at the tumor margin (mean ± SD: 2.1341 ± 2.7460, range: 0 - 8.609). Similarly, the number of centrally located *PECAM-1* (+) vessels/mm^2 was significantly higher in gastric lymphoma patients with lymph node involvement (7.285 *vs* 3.753, $P = 0.002$). Four gastric lymphoma patients (11.11%) expressed *PECAM-1* on their tumoral and neovascular endothelial cells. *PECAM-1* was also expressed by the inflammatory infiltrate of 2 (50%) gastritis and 2 (33.33%) non-malignant ulcer patients. Nevertheless, its immunohistochemical expression was not detected on the endothelial cells of any of the above patients. *PECAM-1* upregulation did not correlate with patients' age, gender, tumor stage and grade or type of surgical treatment, as well as tumoral diameter, surface or thickness.

ICAM-3 positive staining was observed in 17 gastric lymphoma patients (47.2%) (mean expression = 34.118% ± 14.5% for *ICAM-3* positive lesions) (Figure 2A). *ICAM-3* was also stained in 1 (25%) gastritis and 4 (66.66%) non-malignant ulcer specimens. It was mainly expressed in patients with more advanced local disease as demonstrated by the increased tumor surface (70.074 cm^2 *vs* 29.7 cm^2, $P = 0.033$) and thickness (8.786 mm *vs* 5.531 mm, $P = 0.034$) (Table 2). Furthermore, *ICAM-3* expression level differed significantly in gastric lymphomas with different histologic grade ($F = 4.833$, $P = 0.014$) (Figure 2B and Table 3). *ICAM-3* expression level correlated with

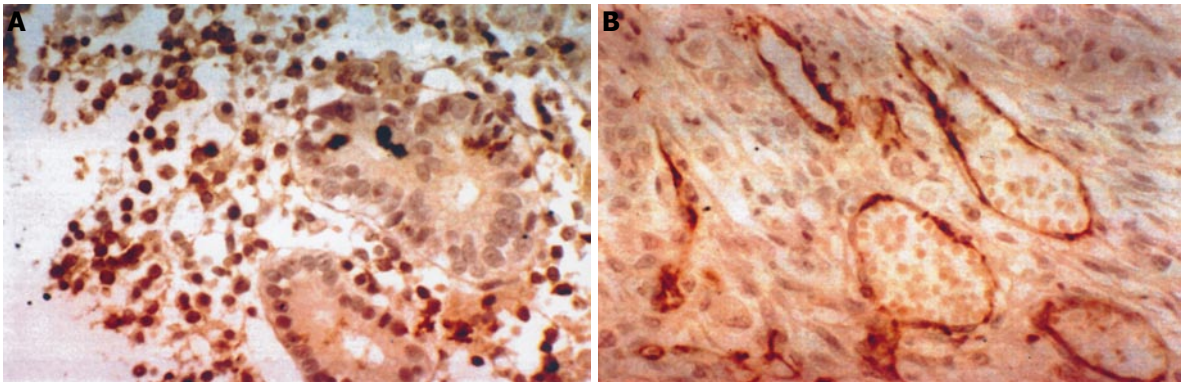

Figure 1 Positive membrane immunostaining (**A**) and endothelial staining (**B**) for *PECAM-1* in diffusely growing lymphocytes (magnification 1X400). Gastric glands were identified as negatively stained.

Table 2 Differences in tumor thickness, surface and diameter according to *ICAM-3* expression status in patients with non-Hodgkin primary gastric lymphoma (mean ± SD)

	ICAM-3 Tumor Expression		
	ICAM-3 (+) (*n* = 14)	*ICAM-3* (-) (*n* = 16)	*P*
Mean tumor thickness (mm)	8.79 (± 4.67)	5.53 (± 2.81)	<0.05
Mean tumor surface (cm^2)	70.07 (± 9.18)	29.70 (± 28.96)	<0.05
Mean tumor diameter (cm)	7.89 (± 7.89)	5.59 (± 2.78)	NS[1]

[1] NS: Non-significant.

Table 3 *ICAM-3, PECAM-1* and *HLA-DR* antigen quantitative expressions according to tumor grade (mean ± SD)

Gene expression (%)	Grade I (*n* = 15)	Grade II (*n* = 7)	Grade III (*n* = 14)	*P*
ICAM-3 (+) tumor cells	26.67 ±22.09	3.57 ±9.45	11.07± 5.95	< 0.05
PECAM-1 (+) tumor cells	6 ±10.55	10.71±13.36	7.14± 5.28	NS[1]
HLA-DR (+) tumor cells	40 ±25.98	55.71 ±26.21	31.43± 6.63	NS[1]

[1] NS: Non-significant

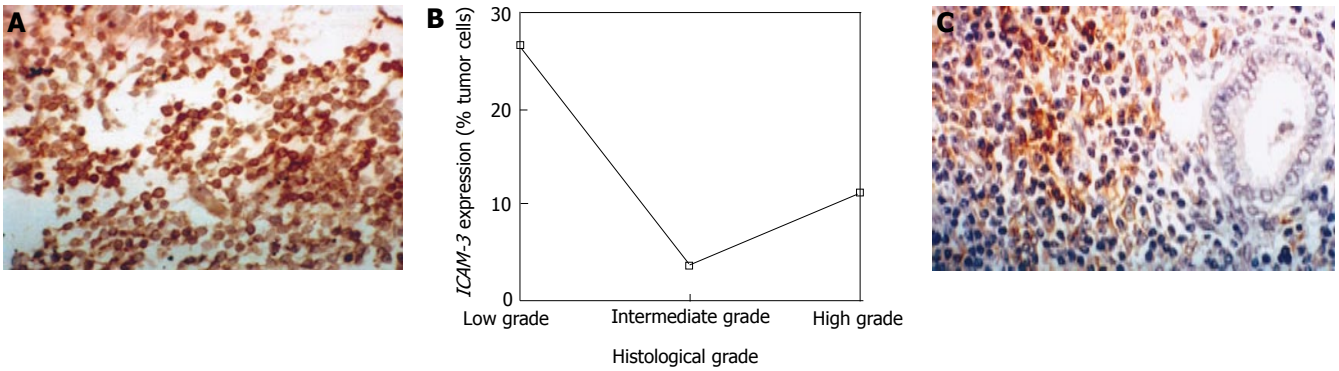

Figure 2 Positive membrane immunostaining for *ICAM-3* in diffusely growing lymphocytes (magnification 1X400) (**A**) and fluctuations of the mean *ICAM-3* expression level according to tumor grade (**B**) and positive intracytoplasm immunostaining for *HLA-DR* antigen in gastric lymphoma lymphocytes (magnification 1X200) (**C**) with gastric glands indicated as negatively stained.

increased tumor diameter ($r = 0.400$, $P = 0.028$), tumor surface ($r = 0.462$, $P = 0.012$), tumor thickness ($r = 0.526$, $P = 0.003$) and higher tumor grade ($r = -0.362$, $P = 0.030$), but not with age, gender, stage or type of surgical treatment.

HLA-DR antigen expression on tumor and peritumoral stromal cells was observed in 91.7%($n = 33$) of gastric lymphoma patients (Figure 2C).The proportion of *HLA-DR* positive tumor and peritumoral stromal cells was equally distributed in gastric lymphoma patients with different stage, grade, gender and type of surgery. *HLA-DR* was also expressed on stromal cells in 2 (50%) gastritis and 4 (66.6%) non malignant gastric ulcer control cases.

Several patients co-expressed two or more of the markers studied. The patterns of different protein co-expression are demonstrated in Table 4. None of the 10 healthy controls expressed any of the molecules studied.

Survival analysis

Univariate analysis showed that *ICAM-3* expression was associated with improved 5-year survival rate (78.6% *vs* 55.6%, $P = 0.1701$). *PECAM-1* expression on gastric lymphoma tumor cells was associated with significantly decreased 5-year survival rate (28.6% *vs* 76%, $P = 0.0078$) (Figure 3A). Although the presence of *PECAM-1* (+) vessels within the tumor was associated with decreased overall

Table 4 *ICAM-3*, *PECAM-1* and *HLA-DR* antigen expressions in gastric lymphoma tumor cells [1]

Gene expression	Frequency	Percentage (%)
ICAM-3(+)/*PECAM-1*(+)/*HLA-DR* tumor(+)	4	11.1
ICAM-3(+)/*PECAM-1*(+)/*HLA-DR* tumor(-)	1	2.8
ICAM-3(+)/*PECAM-1*(-)/*HLA-DR* tumor(-)	4	11.1
ICAM-3(+)/*PECAM-1*(-)/*HLA-DR* tumor(+)	8	22.2
ICAM-3(-)/*PECAM-1*(+)/*HLA-DR* tumor(+)	4	11.1
ICAM-3(-)/*PECAM-1*(+)/*HLA-DR* tumor(-)	1	2.8
ICAM-3(-)/*PECAM-1*(-)/*HLA-DR* tumor(+)	10	27.8
ICAM-3(-)/*PECAM-1*(-)/*HLA-DR* tumor(-)	4	11.1

[1]While *PECAM-1* and *ICAM-3* were positive when more than 5% of the tumor cells were stained positive, *HLA-DR* antigen positivity depicted in Table 4 represents the 15% cut-off level used in our survival analysis.

Table 5 Five-year survival rate according to patients´ gender, tumor stage, histologic grade and microscopic resection margins

Characteristics	Number of cases	5-yr survival rate (%)	*P*
Gender			NS[1]
Male	20	65	
Female	12	66.7	
Stage			NS
I	16	62.5	
II	9	66.7	
III	1	100	
IV	6	66.7	
Histologic grade			NS
Low	13	76.9	
Intermediate	7	71.4	
High	12	50	
Microscopic margins			NS
Positive	5	60	
Negative	27	66.7	

[1] NS: Non-significant.

survival rate (55.6% *vs* 69.6%), this difference was not proved to be statistically significant ($P=0.4067$). Nevertheless, patients who showed *PECAM-1* expression both on their endothelial cells ($n=4$), presented a decreased overall survival rate compared to the rest of the group (25% *vs* 71.4%, $P=0.0403$).

Different levels of proportional *HLA-DR* antigen expression were sequentially evaluated for their prognostic value. *HLA-DR* antigen expression in more than 15% of the tumor cells ($n=26$, 72.2%) was associated with an increased 5-year survival rate (75% *vs* 37.5%, $P=0.0469$) (Figure 3B). A corresponding though non-significant increase in the overall survival rate was also observed in those gastric lymphoma patients expressing *HLA-DR* antigen in more than 15% of their peritumoral stromal cells ($n=19$, 52.8%) (66.67 % *vs* 64.29 %, $P=0.8593$).

A univariate analysis was also performed to identify high-risk groups of patients with regard to gene co-expression. For the needs of this analysis, the 15% *HLA-DR* antigen expression level was considered a measure of *HLA-DR* positivity between tumor cells. Those patients who were *PECAM-1*(+)/*ICAM-3*(-) ($n=5$) presented a significantly decreased overall survival rate compared to those who were *PECAM-1*(-)/*ICAM-3*(+) ($n=12$) (20% *vs* 83.3%, $P=0.0041$) (Figure 4A). Furthermore, gastric lymphoma patients who were *HLA-DR* (+)/*ICAM-3*(+) ($n=10$) presented a significantly improved overall survival rate compared to those who were *HLA-DR*(-)/ *ICAM-3*(-) ($n=4$) (90% *vs* 25%, $P=0.0091$) (Figure 4B). When all three genes were studied together, all *HLA-DR*(+)/*ICAM-3*(+)/*PECAM-1*(-) gastric lymphoma patients ($n=8$) were alive 5 years postoperatively (100% 5-year survival rate), compared to a 54.2% survival rate for the rest of the group ($n=24$) ($P=0.0289$) (Figure 5).

Univariate analysis revealed that patients´ gender, tumor stage, histologic grade and marginal status were not associated with their overall survival rate as demonstrated in Table 5.

To identify the independent prognostic factors that would predict survival, multivariate analysis was performed. The analysis included *HLA-DR* antigen and *PECAM-1* upregulation (which was proved to be statistically significant prognostic markers in univariate analysis), age of the patients, tumor stage and tumor grade. Four patients were excluded from the process due to inadequate 5-year survival data. Multivariate Cox regression analysis revealed that *PECAM* and *HLA-DR* antigen expressions were the only statistically significant independent prognostic variables in the group of gastric lymphoma patients ($P=0.005$ and $P=0.016$, respectively). Similar results were obtained when *PECAM-1* and *HLA-DR* antigen expressions were the only covariates submitted to multivariate analysis ($P=0.003$ and $P=0.009$, respectively). The results of multivariate analysis are depicted in Table 6 and Table 7.

DISCUSSION

Primary non-Hodgkin's gastric lymphoma represents a rare malignant tumor comprising 2-5% of all cases of malignant gastric tumor[27, 28]. The 5-year survival rate ranges between 57%[29] and 96% for IE and IIE patients[30], while it has been considered as low as 25% when all stages are grouped together. Several molecular markers like *P27*, *cyclin E*[31] and *bcl-6*[32] have been recently assessed for their prognostic value. Still, most of them have no independent prognostic value.

In malignant lymphoma patients, clinical outcome and prognosis appear to depend largely on host immune response and vascular invasion. The current study attempted to clarify the prognostic value of *HLA-DR* antigen, *ICAM-3* and *PECAM-1* since they represent specific markers of regional immune reactions, cell-cell interactions and transendothelial migration.

HLA-DR antigen expression is a marker of host immune response in human malignant neoplasms. Its expression in tumor cells has been reported to be related with a favorable prognosis in patients with different types of cancer such as breast cancer[33] and squamous cell laryngeal carcinoma[34]. In our multivariate analysis, *HLA-DR* antigen expression was found to be a statistically significant independent prognostic factor associated

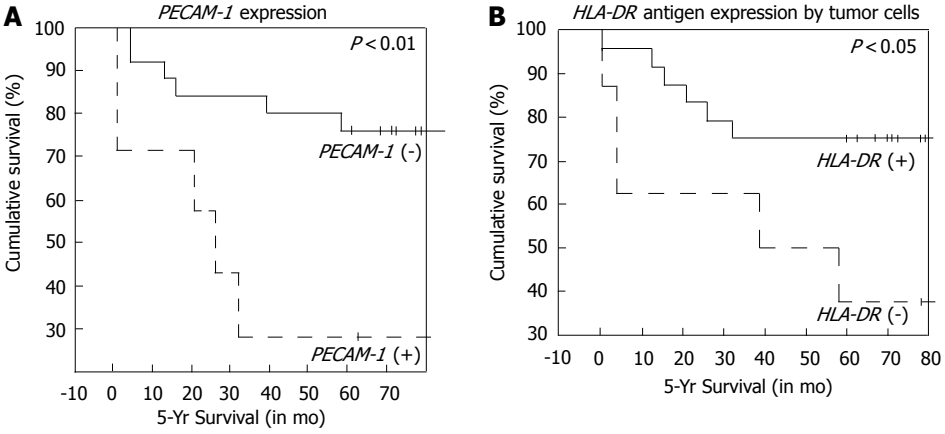

Figure 3 Five- year survival according to *PECAM-1* (**A**) and *HLA-DR* antigen (**B**) expression (*HLA-DR* positive patients had expression of *HLA-DR* antigen in more than 15% of their tumor cells).

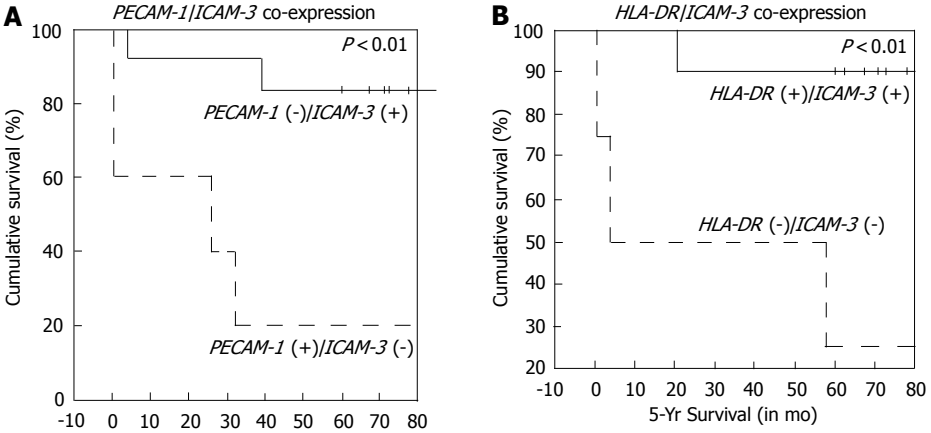

Figure 4 Decreased 5 –year survival rate in *PECAM-1*(+)/*ICAM-3*(-) (**A**), and increased 5-year survival rate in *HLA-DR*(+)/*ICAM-3*(+) (**B**) gastric lymphoma patients.

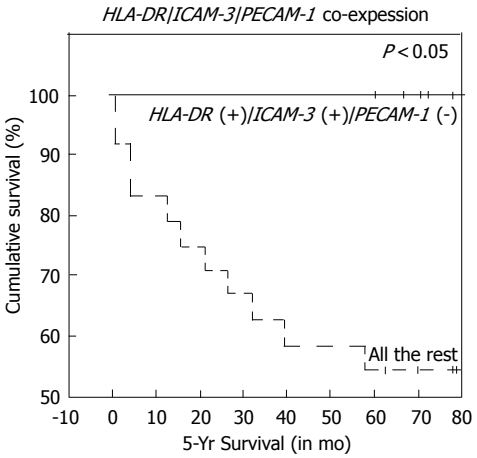

Figure 5 One hundred percent 5-year survival rate in *HLA-DR*(+)/*ICAM-3*(+)/*PECAM-1*(-) gastric lymphoma patients.

with a favorable clinical outcome ($P = 0.0199$). This is in agreement with previous reports[33, 34]. The expression of HLA-DR antigen in tumor cells has a modulating effect on the host immune response, possibly by helping in the presentation of tumor associated antigens to T-lymphocytes[35], thus enabling the immune system to inhibit cancer growth. Regarding peritumoral stroma cells, the presence of tumor infiltrating leukocytes (TIL) invading the site of malignancy, suggests that the immune system is capable of reacting with tumors. The presence of such immune infiltrates has been documented in numerous reports and is often associated with improved prognosis[36, 37]. In our primary gastric lymphoma group of patients, *HLA-DR* antigen expression in peritumoral stromal cells was associated with an increased (though non-significant) survival rate.

Cell adhesion molecules are membrane glycoproteins that play a major role in neoplastic disease. Four primary groups of cell adhesion molecules have been described including the integrin receptor family, the immunoglobin superfamily, selectins and cadherins[38]. *PECAM-1* constitutes a significant representative of the immunoglobulin superfamily and has been applied with considerable accuracy as an angiogenesis marker in several kinds of human neoplasia[16, 17, 39, 40].

A significant number of gastric lymphoma patients expressed *PECAM-1* in their tumor cells ($n = 10$, 27.8%). Since *PECAM-1* is constitutively expressed not only on the surface of endothelial cells, but on platelets, leukocytes, monocytes, neutrophils and selected T cell subsets as well[11], our findings can be attributed to the lymphoid origin of the malignancy. *PECAM-1* positive staining on gastric lymphoma tumor cells was found to be a statistically significant independent prognostic factor, associated with unfavorable prognosis ($P = 0.0029$). Although there are several reports[17, 39] correlating increased angiogenesis with an unfavorable prognosis, this is the first report

Table 6 Multivariate Cox regression analysis I (Age, grade, stage, *PECAM-1* and *HLA-DR* antigen expression were included)

Variable	*P* value	Exp (B)	95% CI for Exp (B)
Age	NS	1.0085	0.9541-1.0660
Stage	NS	2.0919	0.2317-18.8828
Grade	NS	0.2272	0.0475-1.0855
PECAM-1 tumor expression	$P<0.01$	19.9490	2.7865-142.8178
HLA-DR tumor expression	$P< 0.05$	0.1373	0.0258-0.7299

Table 7 Multivariate Cox regression analysis II (Only *PECAM-1* and *HLA-DR* antigen expressions were included, since they were the only statistically significant factors found in the univariate analysis)

Variable	*P* value	Exp (B)	95% CI for Exp (B)
PECAM-1 tumor expression	$P<0.01$	10.3520	2.2196-48.2812
HLA-DR tumor expression	$P< 0.01$	0.1308	0.0286-0.5989

on the clinical outcome of gastric lymphoma patients based on *PECAM-1* expression by tumor cells. As a key participant in cell adhesion cascade, *PECAM-1* can lead to the extravasation of leukocytes[18], constituting a possible regulator of the metastatic process in lymphoid tumors. Its presence on the surface of tumor cells can be therefore associated with altered cellular adhesivity, enabling malignant cells to dissociate from their primary sites, leading to tumor growth and metastasis[41-43].

The detection of *PECAM-1* (+) vessels within the tumor was related to an unfavorable, though non-significant clinical outcome. This difference reached statistical significance only for gastric lymphoma patients ($n=4$) who showed *PECAM-1* expression both in their tumor cells and in their endothelial cells ($P=0.0403$). Although the fact that *PECAM-1* expression in tumor endothelial cells has been associated with unfavorable prognosis in several tumors[2, 16, 17, 40, 44-46], tumors with *PECAM-1* (+) endothelia exhibit an extended[47] overall survival rate.

Vascular density at the tumor margins is significantly lower than that within tumor stroma[12]. Additionally, gastric lymphoma patients with lymph node involvement present a significantly higher number of *PECAM-1* (+) stromal vessel counts (7.285 *vs* 3.753, $P=0.002$). It appears that the density of *PECAM-1* (+) stromal microvessels/mm^2 correlates with the lymphatic metastatic pathway. Several studies have reported that *PECAM-1* is a non-specific angiogenesis marker, which stains both lymphatic (weaker staining) and blood vessel endothelial cells[48, 49]. New proliferating capillaries in the tumor stroma have fragmented basement membranes[50], while endothelial cells at the tips of growing capillaries secrete collagenases and plasminogen activators [51]. These properties facilitate the metastatic process and may explain the association between tumor stromal vessel counts and lymph node metastasis as observed in our study.

Antigen-dependent and/or independent interactions between target cells and lymphocytes are required for the initiation of a specific immune response. In addition to antigen-specific interactions, "accessory" cell-surface molecules, ICAMs[52,53], mediate an antigen-independent, non-specific adhesion between the reactant cells, which is considered the primary step in activation of lymphocytes[54]. These events often take place in a host against malignant cells. Recent work has indicated that resting leukocytes express a third ligand, ICAM-3, which appears to be the major ligand for *LFA-1* in initiating phases of immune response[10,55]. Although it is poorly investigated, *ICAM-3* upregulation has been well documented in lymphoid tumors[56,57]. In our gastric lymphoma group of patients, *ICAM-3* upregulation was associated with a non- significantly improved 5-year survival rate. The fact that *ICAM-3* expression level is associated with increased tumor surface and thickness provides evidence that its regulation is directly proportional to the tumor burden.

Furthermore, *ICAM-3* expression when studied in combination with *PECAM-1* and/or *HLA-DR*, improved their prognostic accuracy. From our univariate analysis, three distinct gene expression patterns were distinguished. Two of them [*PECAM-1*(+)/*ICAM-3*(-) and *HLA-DR*(-)/*ICAM-3*(-)] were associated with a significantly decreased 5-year survival rate, when compared to the exactly opposite gene expression patterns [*PECAM-1*(-)/*ICAM-3*(+) with $P=0.0041$ and *HLA-DR*(+)/*ICAM-3*(+) with $P=0.0091$, respectively]. Furthermore, gastric lymphoma patients who were *HLA-DR* (+) / *ICAM-3* (+) / *PECAM-1* (-) had 100% 5-year survival rate. Similar results have been reported by Hosch *et al*[58], who observed that the co-expression of *HLA* class *I* molecules and *ICAM-1* is a significant predictor of increased disease-free survival in patients with primary esophageal carcinomas. It appears that the lack of expression for both *HLA-DR* and *ICAM-3* [*HLA-DR*(-)/*ICAM-3*(-)] in gastric lymphoma patients is associated with a compromised host immune response against the tumor as well as with an unfavourable prognosis compared to those who were *HLA-DR*(+)/*ICAM-3*(+) ($n=10$, $P=0.0091$). On the contrary, gastric lymphomas expressing both *HLA-DR* and *ICAM-3* but not *PECAM-1* have not only a more potent host immune surveillance, but a negative expansion potential and a growth disadvantage as well.

In our study, *PECAM-1* and *HLA-DR* antigen expressions were proved to be statistically significant independent prognostic factors in a group of patients with primary B-cell MALT-type non-Hodgkin's gastric lymphoma, suggesting that upregulation of both *PECAM-1* and *HLA-DR* antigen is closely related to the clinical phenotype exhibited by the affected cases. Furthermore, it appears that *ICAM-3*, *PECAM-1* and *HLA-DR* represent complementary biologic pathways associating host immune surveillance with non-specific intercellular interactions and endothelial transmigration. Their combined study in gastric lymphoma patients may amplify their prognostic accuracy and provide a better description of the biologic behaviour of these tumors.

Abstract

AIM: To assess the causes of ileocecal mass in patients with amebic liver abscess.

METHODS: Patients with amebic liver abscess and ileocecal mass were carefully examined and investigated by contrast-enhanced CT scan followed by colonoscopy and histological examination of biopsy materials from lesions during colonoscopy.

RESULTS: Ileocecal masses were found in seventeen patients with amebic liver abscess. The cause of the mass was ameboma in 14 patients, cecal tuberculosis in 2 patients and adenocarcinoma of the cecum in 1 patient. Colonic ulcers were noted in five of the six (83%) patients with active diarrhea at presentation. The ileocecal mass in all these patients was ameboma. Ulcers were seen in only one of the 11 (9%) patients without diarrhea. The difference was statistically significant from the group with diarrhea ($P < 0.005$).

CONCLUSION: Ileocecal mass is not an uncommon finding in patients with amebic liver abscess. Although, the ileocecal mass is due to ameboma formation in most cases, it should not be assumed that this is the case in all patients. Colonoscopy and histological examination of the target biopsies are mandatory to avoid missing a more sinister lesion.

Key words: Amebiasis; Ameboma; Colon; Colonoscopy; Diagnosis

INTRODUCTION

Intestinal amebiasis occurs throughout the world[1]. It is estimated that out of all people infected with *E. histolytica*, 40 million develop colitis or extra-intestinal abscesses and of these 40 000 die annually[1]. Extra-intestinal amebiasis is also not uncommon and the liver is the most common extra-intestinal organ to be involved[1-3]. A post-mortem study reported that the liver is involved in 37% of cases[4]. Involvement of the colon is also common in patients with amebic liver abscess (ALA)[5, 6]. A recent study showed that colonic ulcers are observed in 55% of patients with ALA. These ulcers are more common in patients with active diarrhea or history of diarrhea in the recent past[6]. Some of the patients with ALA also have a palpable ileocecal mass on abdominal examination. The cause of the ileocecal mass in these patients still remains unclear.

Formation of an ameboma has been noted to be an uncommon complication of amebiasis[7-18]. It has been estimated that ameboma occurs in only about 1.5% of all cases[8]. Although there have been recent reports dealing with the problem of ameboma[14, 17], in regions where ALA is not very common, ameboma has been confused with cancer of the colon[9, 13, 14, 18]. However, in regions where ALA is common, the reverse may happen and if diagnostic facilities are not widely available as in the case of several developing countries, cancer of the colon or tuberculosis may be confused with ameboma, especially in patients with concurrent ALA and its clinical signs and symptoms of high fever, local pain and tenderness. We therefore report our findings in patients with amebic liver abscess(es) and associated cecal mass. We believe that this is the largest collection of patients with ameboma.

MATERIALS AND METHODS

Consecutive patients with ALA having a palpable ileocecal mass were studied. The diagnosis of ALA was made on the basis of the clinical features of fever, right upper abdominal pain, tender hepatomegaly with a typical ultrasonic finding of a single or multiple hypoechoeic lesion(s) in the liver and antiamebic antibody titer >160 in serum (immunofluorescent assay).

A detailed clinical history was obtained from all patients and recorded. Patients were asked specifically about loose stools (three or more in a day for more than 48 h), with or without blood during the last eight weeks. Whole stool samples were observed and three fresh samples were examined for the presence of trophozoites and cysts of *E. histolytica*.

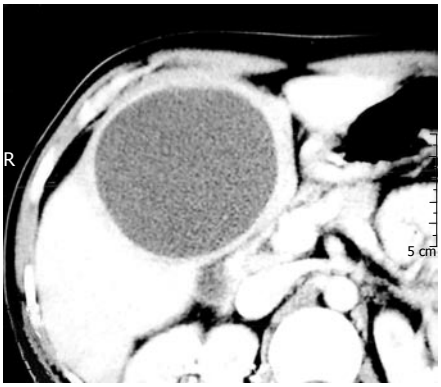

Figure 1 Hypodense round lesions in the liver due to amebic liver abscess.

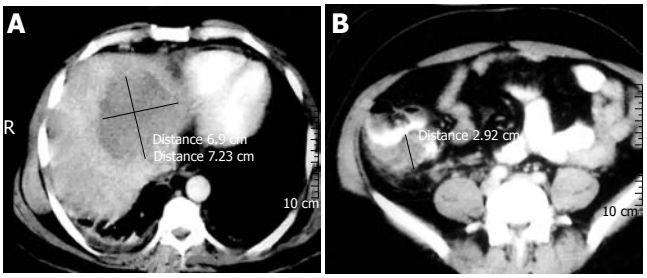

Figure 3 Contrast-enhanced CT scan of the abdomen with the presence of ALA in the liver (**A**) and ileocecal mass (**B**).

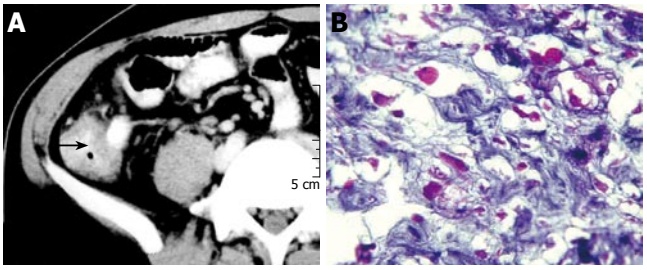

Figure 2 Contrast-enhanced CT scan of the abdomen showing the ileocecal mass with thickening of the cecal wall (**A**) and histological examination of the biopsies showing trophozoites of E. *histolytica* (**B**) (H & E X 800).

Contrast-enhanced CT scan was performed for all patients and apart from the abscess in the liver, the ileocecal area was carefully studied.

Colonoscopy was carried out in all but one patient within two days of instituting anti-amebic treatment after stool samples were obtained for microscopic examination. In one patient colonoscopy could be performed on the fifth day of instituting anti-amebic therapy.

Colonic preparation was done for all patients using a polyethylene glycol-electrolyte-based solution (*Peglec*, Tablets India Ltd, Chennai). The procedure was performed under conscious sedation with intravenous diazepam (5-10 mg) and pentazocine (25-50 mg). The findings observed during colonoscopy were recorded. The site, size, number and presence of inflammation around the ulcers were recorded if ulcers were noted. Multiple biopsies were obtained from the ulcer margins for histopathological examination. When the cecum was reached, the area was carefully inspected and multiple biopsies were obtained from any lesion that was encountered.

Patients who were too sick, those who did not give consent, those with ruptured ALA, those requiring urgent needle or catheter drainage and those with severe comorbid illnesses, were excluded from the study. Patients who received anti-amebic treatment during the preceding eight weeks were also excluded.

The protocol for the study was cleared by the Ethical Committee of the Hospital and a detailed informed consent was obtained from all participating patients.

RESULTS

A total of 17 patients with ALA and ileocecal mass were studied. There were 16 males and one female. The mean (SD) age of these patients was 37.9 (9.9) years (range 24 to 62 years). Two patients presented with active lower gastrointestinal bleeding.

Contrast-enhanced CT scan demonstrated rounded hypodense lesions in the liver due to ALA (Figure 1). In all the patients, thickening of the cecal wall was noted (Figure 2A). Lymphnodal enlargement was not evident and a definite diagnosis could be made on the basis of the CT findings in none of the patients.

Diarrhea was present in six patients. The other 11 patients did not complain of diarrhea. Ulcers were noted in the colon of five of the six (83%) patients with active diarrhea. The ileocecal mass in all these patients was due to ameboma formation (Figure 2B). Ulcers were seen in only one of the 11 (9%) patients without diarrhea. The difference between the two groups was statistically significant ($P < 0.005$, Fisher's exact test).

At colonoscopy, sixteen patients showed mass lesions in the cecum. The patient who underwent colonoscopy on the fifth day of starting anti-amebic therapy showed evidence of amebic liver abscess (Figure 3A) and thickening of the cecal wall on contrast-enhanced CT scan (Figure 3B), but colonoscopy showed multiple round and oval, deep ulcers of varying sizes confined to the cecum and the adjoining ascending colon (Figure 4A). Colonic biopsies obtained from the ulcers showed trophozoites of *E. histolytica* (Figure 4B).

The colonoscopic appearance in all patients, except for one who underwent delayed examination, showed mass lesions in the cecum and the colonoscopic appearance was similar in all of them. The final diagnosis of ileocecal mass was made after histological examination of the tissue obtained at colonoscopy. The final diagnosis was ameboma in 14 patients, ileocecal tuberculosis in two patients (Figure 4C) and adenocarcinoma of the cecum in one patient.

The patient with cancer of the colon was a 32-year-old man who was admitted due to massive lower GI bleeding. At the time of hospitalization, the pulse rate was 160/min. The systolic blood pressure was 70 mm Hg. The hemoglobin was 5 g/dL. The patient was in shock and managed with intravenous fluids and blood transfusion. After haemodynamic stability was achieved, emergency colonoscopy was performed, which showed that the bleeding originated from the ascending colon. The bleeding stopped spontaneously on the next day. An ultrasound examination of the abdomen showed a large hypoechoic

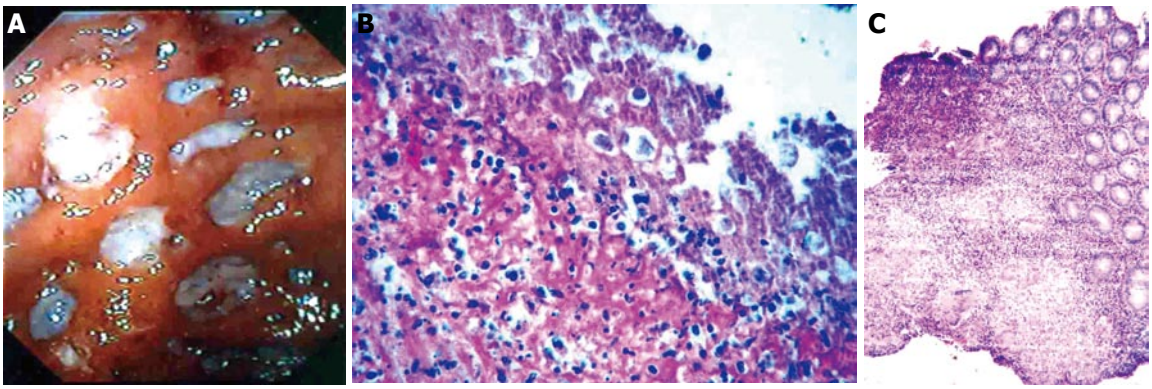

Figure 4 Colonoscopy findings in a patient showing deep round and oval ulcers in the cecum (**A**), histological examination of the biopsies obtained from ulcers in the cecum showing the presence of trophozoites of E. *histolytica* (**B**) and from a patient with amebic liver abscess and cecal mass showing the presence of multiple epithelioid cell granulomas and Langhans giant cells (**C**) (H & E X 40).

Figure 5 Colonoscopic appearance of the mass lesion in a patient with cecal cancer.

lesion in the left lobe of the liver, consistent with the diagnosis of amebic liver abscess. CT scan showed similar findings. In addition to the lesion in the liver, there was thickening of the wall of the cecum. No other abnormality was detected. Aspiration of the liver abscess yielded an anchovy sauce-like material. Cytological examination of the aspirate revealed acute inflammatory cells. No amebic trophozoites or malignant cells were seen. Indirect hemagglutination test for presence of antibody against *E. histolytica* was positive in titres of 1:160.

Repeat colonoscopy following bowel preparation showed irregular, nodular friable growth in the cecum (Figure 5). Multiple biopsies were obtained from the growth. Histological examination of the biopsies revealed adenocarcinoma. The patient was advised to undergo right hemi-colectomy but did not consent to be operated. The amebic liver abscess responded to needle aspiration and metronidazole.

A 62- year old lady who was diagnosed to have ALA five months ago received anti-amebic therapy at another hospital and was reported to have been cured of the disease. She however, visited our hospital with diarrhea, high fever and a mass in the right lower quadrant. Ultrasonography and CT scan of the abdomen showed features of ALA. CT scan also showed thickening of the cecal wall. Colonoscopy showed a friable nodular mass in the cecum. A provisional diagnosis of cancer of the cecum was made. Histological examination of biopsies obtained from the cecal mass during colonoscopy, however, showed trophozoites of *E. histolytica* and the mass was finally diagnosed as an ameboma.

All the patients received metronidazole. Nine patients required needle aspiration of ALA. All patients were cured of ALA. The ileocecal masses due to ameboma formation disappeared after treatment with metronidazole in all the patients. Repeat colonoscopy did not reveal any abnormality in 12 patients and mild hyperemia in the remaining two patients with ameboma. The two patients with ileocecal tuberculosis received anti-tuberculous treatment and were well during follow-up. The cecal masses were no longer palpable after follow-up of 6 and 7 months respectively.

DISCUSSION

Although ALA is rare in developed countries, it is not an infrequent disease in developing countries. However, the occurrence of ileocecal mass due to ALA is rare, except for a case report[11]. If an ileocecal mass is detected in a patient with ALA, an ameboma should be diagnosed.

It has been estimated that out of all cases with amebiasis, ameboma formation occurs in only about 1.5% of patients[8]. However, it is important to note that in regions where ALA is not very common, ameboma has been confused with cancer of the colon[9, 13, 14, 18]. More importantly, in regions where ALA is common, the reverse may happen and cancer of the colon or tuberculosis may be confused with ameboma, especially in patients with concurrent ALA and its clinical signs and symptoms of high fever, local pain and tenderness. This was evident in one patient in this series who had carcinoma of the cecum but was clinically thought to have an ameboma due to the young age and concurrent occurrence of ALA. Two other patients in this series were clinically thought to have ameboma of the cecum on the basis of the colonoscopic findings, but showed tuberculosis of the cecum on histological examination of colonoscopic biopsies. In an elderly patient, a clinical diagnosis of cecal cancer was considered and it was only on histological examination of the biopsies that the diagnosis of ameboma could be made.

It is generally considered that ameboma formation occurs due to untreated or partially treated amebic colitis[1,7]. However, in the present series, only one patient

had a history of anti-amebic treatment five months ago for ALA. None of the other patients received any anti-amebic treatment in the recent past. Moreover, all of them had evidence of ALA at the time when they were found to have an ileocecal mass, suggesting that ameboma formation can occur even in the acute or subacute phase.

CT findings of cecal ameboma with pericolonic lessions have been reported recently[17]. The ileocecal valve shows a large abscess within the mesentry causing compression of the adjacent terminal ileum and cecum. Even then a differential diagnosis of lymphoma, neoplasm, enterocolitis and inflammatory bowel disease are considered. It was reported that due to concentric thickening of the cecal wall and mass like appearance, a clinical diagnosis of ameboma could only be established after histopathological examination of colonoscopic biopsies[14]. It is therefore evident that all patients with ileocecal masses, even with concurrent ALA, should undergo colonoscopy and biopsies should be obtained from any suspicious lesions in order not to miss tuberculosis or cancer.

Although in the present series, we encountered only amebomas, cancer of the cecum and tuberculosis as the cause for the ileocecal mass, lymphomas as well as enterocolitis, acute appendicitis, Crohn's disease, abscess and fungal infections should also be considered as a probable diagnosis.

The simultaneous occurrence of ALA and colonic tuberculosis in this part of the world is not surprising because both diseases are commonly encountered in this region[6, 19-21]. This situation may hold true for most developing countries and the two diseases may also occur simultaneously even in developed countries, especially in immigrants, people living in confined areas and patients with immunodeficiency virus infection. The ileocecal mass in patients with cecal tuberculosis is due to proliferative lesions in the cecum resulting in a tumor-like presentation[19]. The cause of the lesions could not be therefore diagnosed on the basis of CT or colonoscopic findings.

As noted in an earlier study[6], the frequency of colonic ulcers is higher in patients with active diarrhea at presentation as opposed to those who had no diarrhea at the time of admission. What was interesting to note is that, in all patients with active diarrhea, the ileocecal mass is due to ameboma formation. Whether active diarrhea in such patients signifies ameboma can only be ascertained if a larger number of patients with similar presentation are studied.

Abstract

AIM: To investigate the expression and activity of NAD(P)H quinone oxidoreductase 1 (NQO1) in human liver specimens obtained from patients with liver damage due to acetaminophen (APAP) overdose or primary biliary cirrhosis (PBC).

METHODS: NQO1 activity was determined in cytosol from normal, APAP and PBC liver specimens. Western blot and immunohistochemical staining were used to determine patterns of NQO1 expression using a specific antibody against NQO1.

RESULTS: NQO1 protein was very low in normal human livers. In both APAP and PBC livers, there was strong induction of NQO1 protein levels on Western blot. Correspondingly, significant up-regulation of enzyme activity (16- and 22-fold, $P < 0.05$) was also observed in APAP and PBC livers, respectively. Immunohistochemical analysis highlighted injury-specific patterns of NQO1 staining in both APAP and PBC livers.

CONCLUSION: These data demonstrate that NQO1 protein and activity are markedly induced in human livers during both APAP overdose and PBC. Up-regulation of this cytoprotective enzyme may represent an adaptive stress response to limit further disease progression by detoxifying reactive species.

Key words: NQO1; Quinone oxidoreductase; Acetaminophen; APAP; Primary biliary cirrhosis; PBC; Nrf2; Diaphorase

INTRODUCTION

Although NAD(P)H quinone oxidoreductase 1 (NQO1) has been historically associated with generation of hydroquinones from reactive quinones, additional substrates including nitrosoamine, nitro and azo chemical moieties have been identified. NQO1 is also capable of scavenging superoxide anions generated during oxidative stress and regenerating reduced forms of protective endogenous antioxidant compounds.

There is very low expression of NQO1 mRNA and protein in normal human livers, with slightly greater mRNA levels observed in biliary epithelial cells[1, 2]. NAD(P)H quinone oxidoreductase 2 (NQO2) mRNA is greater in hepatocytes compared to NQO1 mRNA and is in turn thought to play a more critical role in maintaining low levels of quinones in hepatocytes[2]. Consequently, it has been suggested that human NQO1 does not play a major role in hepatic xenobiotic metabolism under normal conditions[3].

Instead, NQO1 may be more important during periods of hepatic oxidative stress and damage. NQO1 mRNA protein and activity are markedly increased in mouse liver following bile duct ligation, a model of obstructive cholestasis (José Manautou, unpublished observations). Similar elevations in rodent NQO1 mRNA also occur after exposure to centrilobular hepatotoxicants such as acetaminophen (APAP), carbon tetrachloride and bromobenzene[4, 5]. Although different regions of the liver lobule are injured in cholestasis and drug-induced hepatocellular necrosis, oxidative stress contributes to the pathogenesis of both diseases. We hypothesize that up-regulation of NQO1 may represent a common response to liver injury with an oxidative stress component.

The present study was undertaken to determine if NQO1 expression and activity are similarly altered in two types of human liver disease, injury by APAP overdose and primary biliary cirrhosis (PBC). The results showed that protein levels and activity of human hepatic NQO1 were elevated during APAP overdose and PBC. Immunohistochemical analysis highlighted injury-specific patterns of NQO1 staining. APAP livers showed loss of

centrilobular cells and NQO1 staining in midzonal and periportal hepatocytes. Conversely, PBC livers exhibited prominent staining of hyperplastic biliary epithelium and hepatocytes at the periphery of cirrhotic nodules.

MATERIALS AND METHODS

Chemicals

2,6-dichlorophenol-indophenol (DCPIP), dicumarol, sucrose, Tris-hydrochloride, nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) were all obtained from Sigma Chemical Co. (St. Louis, MO).

Human liver specimens

Archival samples of frozen and formalin-fixed, paraffin-embedded adult livers (normal, primary biliary cirrhosis and APAP overdose) were obtained from the Liver Tissue Procurement and Distribution System at the University of Minnesota which was funded by NIH Contract #N01-DK-9-2310. Diagnosis was first established by the University of Minnesota and confirmed by histological examination of tissue sections at the University of Connecticut in a blinded fashion. Patient characteristics are provided in Table 1.

NQO1 protein expression

Livers were homogenized in sucrose-Tris buffer (0.25 mol/L sucrose, 10 mmol/L Tris–HCl, pH 7.4) and centrifuged at 105 000 r/min for 60 min at 4°C. The resulting supernatant contained the cytosolic fraction. Protein concentrations were determined by the method of Lowry using Bio-Rad protein assay reagents (Bio-Rad Laboratories, Hercules, CA). Anti-NQO1 monoclonal antibodies (clones A180 and B771) were kindly provided by David Ross (University of Colorado, Health Science Center, Denver, CO). Cytosolic proteins (40 μg protein/lane) were electrophoretically resolved using polyacrylamide gels (12% resolving, 4% stacking) and transblotted overnight at 4ºC onto PVDF-Plus membrane (Micron Separations, Westboro, MA). Immunostaining was performed as previously described[1]. NQO1 protein-antibody complexes were detected using an ECL chemiluminescent kit (Amersham Life Science, Arlington Heights, IL) and exposed to Fuji medical X-ray film (Fisher Scientific, Springfield, NJ). Equal protein loading was confirmed by Coomassie blue staining of blots (data not shown). Antibody specificity was confirmed using 2.5 μg recombinant human NQO1 (rNQO1)(Sigma Chemical Co. St. Louis, MO) as a positive control.

NQO1 activity assay

NQO1 activity was calculated by measuring the colorimetric oxidation of NADPH to NADP+ using DCPIP as substrate. The disappearance of NADPH was measured at 600 nm for over 1 min as described by Ernster with modifications by Benson[6, 7]. NQO1 activity was measured in 1-mL reactions (27°C) containing liver cytosol, 200 μmol/L NADPH, 40 μmol/L DCPIP and Tris-HCl buffer (25 mmol/L Tris-HCl, pH 7.4, 0.7 mg/mL bovine serum albumin). Parallel reactions were performed in the presence of 20 μmol/L dicumarol. The rate of dicumarol-sensitive NQO1 activity was determined as the difference between the uninhibited and dicumarol-inhibited rates and was normalized to total cytosolic protein as previously described[6].

NQO1 immunohistochemistry

Immunohistochemistry was performed on tissue sections cut from archival paraffin blocks as previously described[1]. Negative control staining was performed by incubating the sections without primary antibody. The sections were photographed on an Olympus BX50 microscope equipped with a QImaging MicroPublisher 3.3 RTV camera. Images were acquired with QCapture Pro software.

Statistical analysis

NQO1 activity was presented as mean nmol reduced DCPIP/min/mg protein ± SE (n = 3-5). Differences in NQO1 activity between normal livers and either APAP or PBC livers were determined using Student's t test. $P < 0.05$ compared to normal livers was considered statistically significant.

RESULTS

NQO1 expression and activity in normal human liver were very low as previously described[1]. Immunoblot analysis demonstrated marked induction of NQO1 protein in liver cytosol isolated from APAP and PBC specimens (Figure 1A). This increase in protein corresponded to a significant up-regulation of NQO1 activity from 3 ± 2 nmol DCPIP/min/mg protein in normal livers to 45 ± 16 nmol DCPIP/min/mg protein ($P < 0.05$) and 62 ± 32 nmol DCPIP/min/mg protein ($P < 0.05$) in APAP and PBC livers, respectively (Figure 1B).

Immunohistochemical staining demonstrated minimal NQO1 expression in hepatocytes and biliary epithelium of normal liver tissue (Figures 2A and 2B). Histology of APAP livers showed centrilobular necrosis and cell loss with lymphocytic accumulations and minimal biliary hyperplasia (Figures 2C and 2D). NQO1 staining was cytosolic and concentrated in midzonal and portal hepatocytes surrounding regions of centrilobular cell loss.

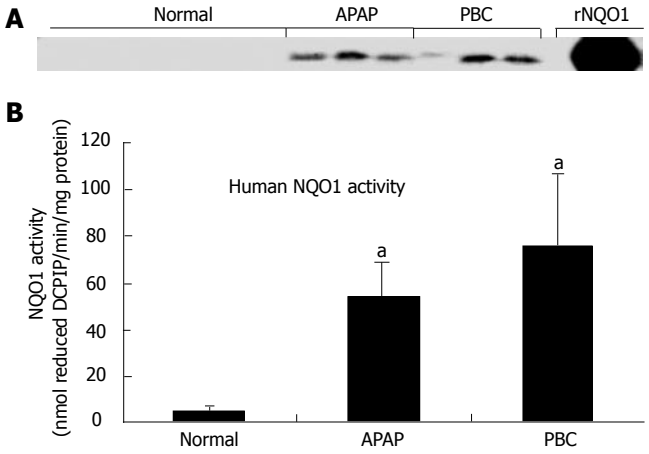

Figure 1 NQO1 protein (**A**) and activity (**B**) in cytosolic fractions from normal, APAP and PBC human liver specimens. The data are presented as nmol reduced DCPIP/min/mg protein ± SE (n = 3-5, $^{a}P < 0.05$ *vs* normal liver specimens).

Conversely, sections from PBC livers exhibited necrosis, fibrosis and nodular regeneration with lymphocytic-histiocytic infiltration and mild bile stasis (Figures 2E and 2F). Hepatocytes on the periphery of nodules were stained positive for cytosolic NQO1 protein. Positive staining was also observed in hyperplastic biliary epithelium in PBC livers (Figures 2G and 2H). No signal was detected in negative control sections (data not shown).

DISCUSSION

This is the first report documenting strong induction of NQO1 protein and activity in livers from individuals with two very different types of liver injury; exposure to toxic amounts of APAP or chronic PBC. Drug-induced liver injury is the most common cause of acute liver failure, with APAP exposure accounting for more than 40% of cases[8]. Ingestion of supratherapeutic amounts of APAP results in degeneration and necrosis of centrilobular hepatocytes. Conversely, PBC is a progressive disease primarily attributed to autoimmunity. Chronic inflammation and destruction of bile ducts during PBC cause biliary hyperplasia, marked fibrosis, and cirrhosis in later stages. The specificity of NQO1 up-regulation during liver damage is unknown. Increased NQO1 expression in APAP and PBC livers is similar to that in non-viral human hepatocellular carcinoma[9]. Conversely, livers from patients with type B or C hepatitis-induced hepatocellular carcinoma, focal nodular hyperplasia or cholangiocarcinoma do not demonstrate altered NQO1 levels[2, 10]. Together, these and previously reported data suggest differential regulation of NQO1 in human liver disease of varying etiologies.

Transcription factor NFE-2-related factor 2 (Nrf2) is the key regulatory pathway for NQO1 expression. Oxidative stress causes translocation of Nrf2 to the nucleus and binding to antioxidant response elements in the promoter region of numerous detoxification genes, including NQO1[11]. Subsequent gene activation leads to production of NQO1 and other proteins involved in cytoprotection. With the use of Nrf2-null mice, NQO1

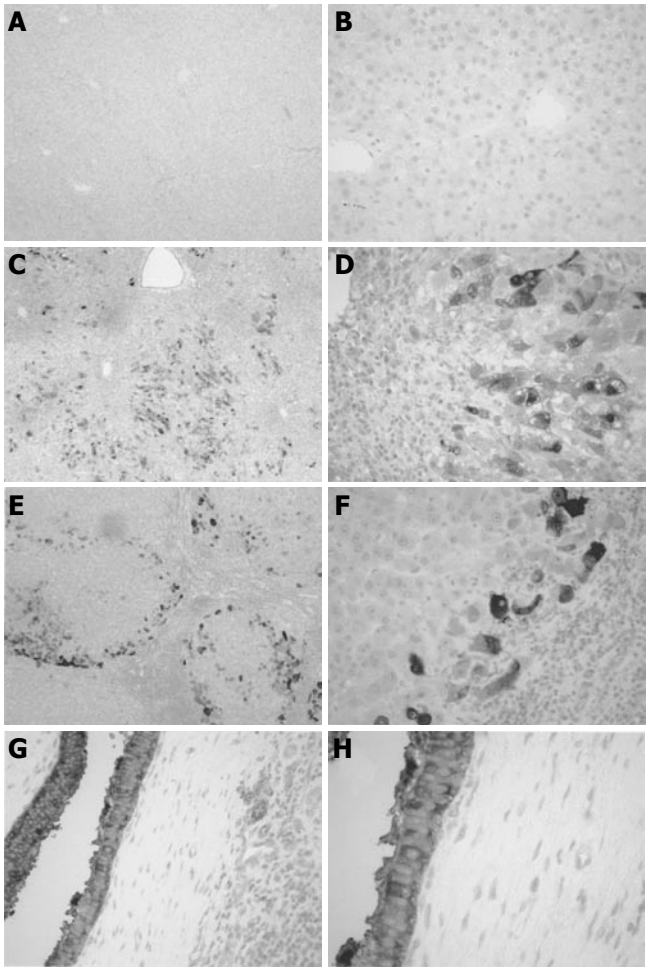

Figure 2 Immunoperoxidase staining of NQO1 in normal (**A**, **B**), APAP (**C**, **D**), and PBC (**E**, **F**) human liver specimens as well as in PBC hyperplastic biliary epithelium (**G**, **H**).

expression and induction have been shown to be Nrf2-dependent[12]. Activation of the Nrf2 signaling pathway during different types of human liver disease may be responsible for NQO1 up-regulation in drug-induced damage, cirrhosis and carcinoma.

As an Nrf2 target gene, NQO1 plays a role in cellular antioxidant defense beyond general drug metabolism, which includes dismutation of superoxide[13]. Therefore, NQO1 may be a scavenger of superoxide anions that are generated during both APAP toxicity and PBC[14]. Similarly, NQO1 also limits oxidative stress and lipid peroxidation by converting endogenous antioxidants (such as vitamin E) back to their more active, reduced forms[13, 15].

Loss of NQO1 function heightens susceptibility of rodents and humans to a number of diseases as demonstrated in transgenic mice lacking NQO1 and humans with a naturally-occurring NQO1 polymorphism. NQO1-null mice exhibit increased susceptibility to menadione-induced hemolytic anemia while patients possessing a C → T substitution at residue 609 of NQO1 have lower levels of NQO1 protein and exhibit an increased risk of benzene toxicity, urothelial tumors, acute myelogenous leukemia, and numerous additional cancers[13, 16, 17].

Since the pathogenesis of APAP hepatotoxicity is

mediated by an electrophilic quinone, NQO1 might possess the ability to convert the APAP metabolite back to parent compound[18]. Limited data suggest that inhibition of NQO1 by dicumarol potentiates APAP toxicity in mice[19]. Conversely, administration of Nrf2 activating compounds, such as oltipraz, protects hamsters against APAP hepatic damage by inducing detoxification pathways including NQO1[20, 21].

The relative constitutive level of hepatic NQO1 among rodents and humans may also explain in part the different susceptibility to APAP hepatotoxicity across species. NQO1 activity is markedly higher in rat liver compared to mouse and human livers. Along the same line, rats exhibit a greater resistance to APAP-induced liver damage compared to mice and humans. Although additional variations in APAP metabolism between rodents and humans are known, differences in basal NQO1 activity among these species may also be a determinant of susceptibility to APAP.

In conclusion, NQO1 is upregulated in APAP–induced and cholestatic human hepatic injury, suggesting that this Nrf2 gene may limite the progression of these liver diseases.

ACKNOWLEDGEMENTS

The authors thank David Ross and David Siegel for providing the monoclonal NQO1 antibody and procedure for NQO1 immunohistochemistry and Jonathan Maher for technical assistance. Lauren Aleksunes is a Predoctoral Fellow Howard Hughes Medical Institute.

Abstract

AIM: To evaluate the prevalence of *Giardia lamblia* (*G. lamblia*) infection in patients with irritable bowel syndrome (IBS) and dyspepsia and to establish which is the most accurate test to diagnose the infection in this setting.

METHODS: One hundred and thirty-seven patients who consecutively attended the Outpatient Gastroenterology Clinic for the first time between January 2002 and December 2003 due to symptoms of IBS and/or dyspepsia were recruited. All patients underwent clinical evaluation, first-step haematology and chemistry tests, serologic assays for celiac disease, lactose-H_2 breath test, abdominal ultrasonography, and esophagogastroduodenoscopy. *Helicobacter pylori* status was evaluated. In patients with symptoms of IBS older than 45 years, colonoscopy was also performed. In all patients, duodenal biopsies and stool samples were examined for trophozoites and cysts of *G. lamblia* by several methods.

RESULTS: *G. lamblia* was identified in 9 patients. The following diagnoses were also made: IBS (100/137, 73%), functional dyspepsia (62/137, 45%), organic dyspepsia (33/137, 24%), and lactose intolerance (75/137, 55%). A significant association was found between giardiasis and *H pylori* infection ($\chi^2 = 6.632$, OR = 12.4, CI = 1.5-68.1). There were no symptoms that reliably allowed the recognition of giardiasis. Direct search of the parasite in duodenal biopsy and stool sample examinations gave concordant results in all cases while histological examination of duodenal biopsies displayed a low sensitivity (e.g., 22.2%).

CONCLUSION: In this consecutive series, diagnosis of *G. lamblia* infection accounted for 6.5% of patients with IBS and dyspepsia. Duodenal biopsies for diagnosis of giardiasis may be unnecessary if stool sample examination is performed.

Key words: Dyspepsia; Giardiasis; *H pylori*; Irritable bowel syndrome

INTRODUCTION

Giardia lamblia is a cosmopolitan parasite with worldwide distribution and the most common protozoan isolated from gastrointestinal tract[1]. The prevalence of infection varies from 2%-7% in industrialized countries to 40% in tropical/subtropical regions with poor sanitation and hygienic conditions[2-5].

Giardiasis typically occurs following the ingestion of water or foods contaminated with fecal material containing cysts, and the infective dose may be as low as 10 cysts. The clinical aspects of giardiasis are largely nonspecific. The infection can be asymptomatic or patients may present with extraintestinal symptoms, such as fever, maculopapular rashes, pulmonary infiltrates, lymphadenopathy, polyarthritis and urticaria. However, the most common symptoms are diarrhea, abdominal pain, bloating, flatulence and weight loss resulting from malabsorption[6]. Since these symptoms may overlap those of patients with other gastrointestinal disorders[7-9], it is not clear when the infection should be suspected. Classically, diagnosis of giardiasis is performed by microscopic examination of stool samples and/or duodenal biopsies and further methods include immunocromathography and immunofluorescence on stool samples. There are

few studies comparing the diagnostic proficiency of the methods using either stool or duodenal biopsy samples.

The aim of this study was to evaluate the prevalence of *G. lamblia* infection in patients with irritable bowel syndrome (IBS) and dyspepsia and to establish the most accurate test for its diagnosis in this setting.

MATERIALS AND METHODS

Patient recruitment

Four hundred and thirty-five consecutive patients attending our hospital for the first time between January 2002 and December 2003 on two days of the week (Monday and Wednesday) due to symptoms of IBS who satisfied Rome II criteria[10] and/or dyspepsia were considered for the study. Patients with alarm features (such as weight loss, dysphagia, vomiting, bleeding), familiarity for gastrointestinal neoplasia and inflammatory bowel disease were excluded as well as patients who took nonsteroidal anti-inflammatory drugs and proton pump inhibitors in the last 15 days and antibiotics in the last 30 days. Patients with symptoms lasting more than one year were also excluded. Finally, 137 patients (48 M, 89 F; median age 39 years, range 19-77 years) were enrolled.

All patients underwent routine blood investigations, including erythrocyte sedimentation rate, C-reactive protein, thyroid hormones, antigliadin, antiendomysial and antitransglutaminase antibodies. Furthermore, urinalysis, microscopic examination of stools, esophagogastroduodenoscopy with duodenal biopsy, evaluation of *Helicobacter pylori* (*H pylori*) infection, abdominal ultrasonography, and lactose-H_2 breath test were performed. Patients with symptoms of IBS older than 45 years ($n=46$) underwent also colonoscopy.

Laboratory tests for G. lamblia infection

The presence of the parasite was evaluated by three different approaches: direct search of the parasite in the duodenal biopsy samples with or without use of fixation and dyes, histological examinations of other aliquots of the above bioptic samples, and parasitological evaluations of stool samples.

Search of the parasite in duodenal biopsy samples Duodenal biopsies were obtained during the upper gastrointestinal endoscopy, immediately submitted to microbiology laboratory where they were put into a sterile plastic container filled with 10 mL of sterile saline. The samples were processed within 2 h of arrival in the laboratory. Wet mount preparations were obtained by cutting the original biopsy into 0.5 mm pieces on a glass slide, with the help of a razor blade and a plastic pipette tip. Then such pieces were suspended in 2 drops of sterile saline and a cover glass was put on them. Microscopic examination for motile organisms was carried out using low and high dry power (× 200 and × 400). Permanent stains were prepared as reported above. However the biopsy pieces were air dried, fixed and the giemsa (Giemsa Plus, Trend Scientific) or trichrome staining (Trichrome Stain, Scientific Device Laboratory Inc., Des Plaines, IL, USA) were carried out following the manufacturer's instructions. Also the vital staining with acridine orange was used on unfixed specimens examined by confocal microscopy to help identify the parasite and address both the mobility and some details of its cytostructure.

Histology of bioptic samples Duodenal biopsies obtained during the upper gastrointestinal endoscopy were also submitted to the Pathology laboratory, where the specimens where paraffin-included, stained with hematoxylin-eosin and examined for Giardia trophozoites as well as for inflammatory infiltrate particularly of plasma cellular type.

Stool parasitology Liquid or semi liquid fecal specimens were immediately submitted to the microbiology laboratory, a wet mount with saline and Lugol's iodine (Dobell reactive) was prepared and microscopic examination for motile organisms and Giardia cysts was carried out using low and high dry power (× 200 and × 400). Moreover, both liquid and solid fecal samples were processed using the formalin/ether enrichment method followed by microscopy for Giardia cysts. Coproantigens were also evaluated in the stool specimens by immunochromatographic technique (Xpect, Remel Europe, Dartford Kent, UK), an EIA method (Prospect, Remel Europe, Dartford Kent, UK), and commercial direct fluorescent antibody assay (Merifluor, Meridian Bioscience Inc., Cincinnati, USA). Laboratory tests for Giardia coproantigens were carried out and the results were evaluated following the manufacturer's instructions.

The microbiologist (GM) and pathologist (AA) were blinded to the clinical and laboratory data.

H pylori status

Patients were classified as *H pylori* positive when the urease quick test (Yamanouchi Pharma, Milan, Italy) was positive. Patients underwent C-13 urea breath test (Cortex, Milan, Italy) when the urease quick test was negative and were considered free of the infection when the two tests were both negative for *H pylori*.

Statistical analysis

The relation between presence of giardiasis and *H pylori* infection was evaluated with χ^2 test and odds ratio (OR). Data were given together with 95% confidence interval (CI).

RESULTS

G. lamblia infection was found in 9 of the 137 patients (6.5%). According to the clinical and laboratory evaluations, the following diagnoses were also made: IBS, lactose intolerance, functional and organic dyspepsia, colon diverticulosis, celiac disease, inflammatory bowel disease, gastric cancer, colon cancer, and collagenous colitis (Figure 1). All patients with giardiasis (7 M, 2 F; median age: 38 years, range 26-61 years) had nonspecific (mostly mild) symptoms largely overlapping those complained by patients without giardiasis (Table 1). Indeed, according to the clinical and laboratory findings, these patients were considered affected also by other functional and organic disorders (Table 1). In patients with giardiasis, blood examination was normal with only one patient

Table 1 Characteristics of 9 patients with *G. lamblia* infection among the 137 complaining of symptoms of irritable bowel syndrome (IBS) and/or dyspepsia (FD: functional dyspepsia; OD: organic dyspepsia) or displaying lactose intolerance (LI)

Patient	Age (yr)	Sex	Symptoms	IBS	LI	FD	OD
1	61	M	Abdominal pain, constipation/diarrhea	+	-	+	-
2	38	F	Abdominal pain, diarrhea, pirosis	+	+	-	+
3	33	M	Abdominal pain, diarrhea	+	-	-	-
4	26	F	Abdominal pain and bloating, constipation	+	+	-	-
5	48	M	Abdominal pain, diarrhea	+	+	-	-
6	47	M	Abdominal pain, diarrhea, pirosis	+	-	+	-
7	37	M	Abdominal pain and bloating, diarrhea	+	-	-	+
8	26	M	Abdominal pain and bloating, diarrhea	+	+	+	-
9	39	M	Abdominal pain, diarrhea	+	-	-	-

Table 2 Comparison of the laboratory tests for *G. lamblia* infection in the study population (n = 137)

Patient	Age (yr)	Sex	Direct search in duodenal biopsy	Stool sample examination	Histology of duodenal biopsy
1	61	M	+	+	-
2	38	F	+	+	-
3	33	M	+	+	+
4	26	F	+	+	-
5	48	M	+	+	-
6	47	M	+	+	-
7	37	M	+	+	+
8	26	M	+	+	-
9	39	M	+	+	-

In the remaining 128 patients, all the three tests were negative for the presence of *G lamblia*.

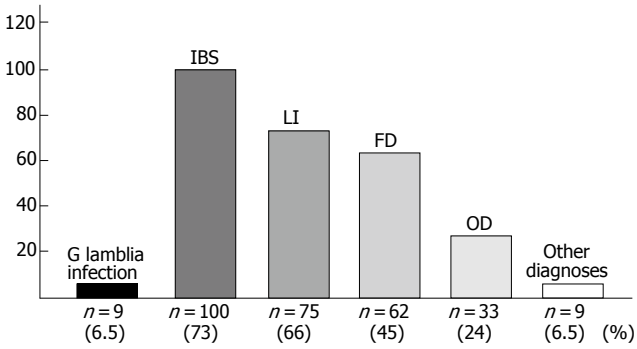

Figure 1 Diagnostic categories in the 137 patients complaining of symptoms of irritable bowel syndrome (IBS) and/or dyspepsia (FD: functional dyspepsia; OD: organic dyspepsia). LI: lactose intolerance; Other diagnoses included: colon diverticulosis (n = 3), celiac disease (n = 2), inflammatory bowel disease (n = 1), gastric cancer (n = 1), colon cancer (n = 1), and collagenous colitis (n = 1).

showing a moderate eosinophilia (1.190/μL; normal range: 0-500/μL). Direct search of the parasite in duodenal biopsy (Figures 2A, 2B) and stool sample (microscopic) examination (Figures 2C, 2D) were concordantly positive (9 of 137 patients) and negative (128 of 137 patients) for *G. lamblia*, while histological evaluation of duodenal biopsy was positive in only two cases (2 of 137 patients) and negative in the remaining (135 of 137 patients) (Table 2). Using as reference the former two tests, the sensitivity and specificity of the histological examination of duodenal biopsy for the diagnosis of giardiasis were 22.2% and 100%, respectively.

Fifty-eight patients (42%) were infected with *H pylori* (18 M, 40 F; median age 40 years, range 20-65 years). A significant association was found between giardiasis and *H pylori* infection. Eight of 58 patients (14%) with *H pylori* infection had giardiasis while 1 of 79 (1%) without *H pylori* infection had giardiasis (χ^2 = 6.632, OR = 12.4, CI = 1.5-68.1).

DISCUSSION

This study aimed at investigating the impact of *G. lamblia* infection on patients who complained of symptoms referring to IBS and dyspepsia. In order to prevent information and observational bias, we properly excluded patients who have had a previous gastroenterological consultation, those with symptoms lasting more than one year and those who had been recently taking drugs that might interfere with complaints and laboratory investigations. Furthermore, to minimize the presence of serious illness, patients complaining of alarm symptoms were excluded. In the consecutive series of 137 patients with symptoms of IBS and/or dyspepsia, the prevalence of giardiasis was 6.5% (9/137). Possibly due to the selection of a symptomatic study population, this figure is slightly higher than the average in the general population in a Western country[2-5]. Nevertheless, no comparisons can be made with the incidence of giardiasis in the asymptomatic population coming from our geographical area.

Furthermore, an important finding of this prospective study is that no symptoms could reliably discriminate patients with giardiasis from those without the parasite. Giardiasis may be present in patients with other gastrointestinal disorders as observed in this study, it seems that symptoms of one disease may overcome/overlap those of the other. Nevertheless, the prevalence of giardiasis in patients suffering from IBS and/or dyspepsia can be considered as the cause of 1BS and/or dyspepsia.

Another important finding of this study involves the diagnostic procedures to be taken into account when dealing with *G. lamblia* infection. The data showed that histological examination of duodenal biopsies for *G. lamblia* was unsuitable due to an unacceptable rate of false negative results (e.g., 22.2% sensitivity). At the same time, it has been shown that stool examination is as accurate as the direct search of the parasite in the duodenal samples.

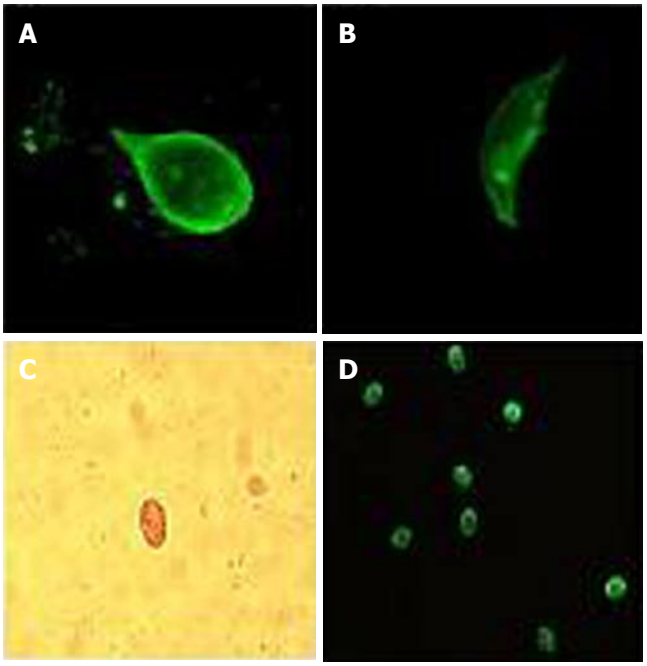

Figure 2 Confocal microscopy images (**A** and **B**) of *G. lamblia* trophozoite (x1000) in duodenal bioptic sample, using acridine orange as a vital stain. **A:** a dorsal projection showing the peculiar tear-shaped cell with flagella. **B:** an unusual flank projection shows the nuclei on the back of the ventral disk. **C:** *G. lamblia* cysts (x200) microscopic images after a wet mount with Lugol's iodine of fecal specimens. **D:** *G. lamblia* cysts (x200) in stool sample following formalin/ether enrichment of filtered samples and staining with a direct fluorescent antibody.

Consequently, when a skilled microbiologist and appropriate techniques are available, duodenal biopsy seems unnecessary in accurate identification of *G. lamblia*, thus invasive and expensive tools such as upper gastrointestinal endoscopy could be avoided.

This study also showed that giardiasis was significantly associated with *H pylori* infection, possibly reflecting that the two infections share a number of risk factors[11]. This association may have several clinical implications in regard to the transmission mode[12,13], the possibility of a synergy in metronidazole resistance[14], and the experimental evidence of a common pathogenesis scenario, leading to gastrointestinal metaplasia[15].

In conclusion, the prevalence of giardiasis in patients suffering from symptoms of IBS and dyspepsia is non-negligible, and duodenal biopsies for the parasite may be unnecessary if stool examination is performed.

Abstract

AIM: To describe the clinical and histological characteristics of a group of adults with small-bowel nodular lymphoid hyperplasia (NLH).

METHODS: Patients were searched for five years in pathology records of our institution. The biopsy material was reassessed using strict histopathological criteria. Clinical data were obtained from medical records.

RESULTS: Small-bowel NLH was diagnosed in 18 cases. The female: male ratio was 2 : 1. The most frequent symptoms were diarrhea (72%), involuntary weight loss (72%) and abdominal pain (61%). Nine patients (50%) had immunodeficiency. Small-bowel bacterial overgrowth was found in three (17%) cases. At small-bowel NLH diagnosis, three (17%) had associated lymphoma: two intestinal and one extra-intestinal lymphomas. In two patients with villous atrophy and anti-endomysial antibodies the diagnosis of celiac disease was established. *Giardia lamblia* infection was found in only one patient with hypogammaglobulinemia (Herman's syndrome).

CONCLUSIONS: NLH is uncommon in adult patients. Associated diseases are immunodeficiency and lymphoid tissue malignancies.

Key words: Nodular lymphoid hyperplasia; Hypogammaglobulinemia; Lymphoma

INTRODUCTION

Nodular lymphoid hyperplasia (NLH) of the gastrointestinal (G1) tract is characterized by markedly hyperplasic, mitotically active germinal centers with well-defined lymphocyte mantles[1]. The nodules are found in mucosa and/or submucosa anywhere in the gastrointestinal tract and may resemble small adenomatous polyps on gross examination[2,3]. Approximately 20% of adults with common variable immunodeficiency (CVI) are found to have NLH. It has been suggested that NLH is a risk factor for both intestinal and extra intestinal lymphoma[4]. It has also been reported in patients with human immunodeficiency virus infection[5]. In children, NLH tends to have a benign course and usually regresses spontaneously but in adults it is rare and poorly described.

In a previous report by Canto *et al*[6] NLH was diagnosed in 11 Mexican subjects. In five of them a diagnosis of Herman's syndrome was established. Patients were collected from the pathology database of our institute from 1973 to 1988. Since this time, an increased number of duodenal biopsies have been taken for the approach of patients with chronic diarrhea who were referred to our institution from different places. In this work we described the clinical characteristics of 18 new patients with NLH seen at the Instituto Nacional de Ciencias Médicas y Nutrición "Salvador Zubirán", a National Institute of Health located in Mexico City, which is a referral center for gastrointestinal diseases.

MATERIALS AND METHODS

Patients

From January 1998 to December 2002, patients with the histological diagnosis of NLH were identified from the pathology database. Medical records were reviewed and a pathologist (STH) reassessed slides or paraffin-embedded biopsies. NLH was considered when the following histological criteria were observed: hyperplasic lymphoid follicles, mitotically active germinal centers with well-defined lymphocytes mantles, and lymphoid follicles localized at mucosa and/or submucosa.

Histology

The original duodenal mucosal biopsy specimens were

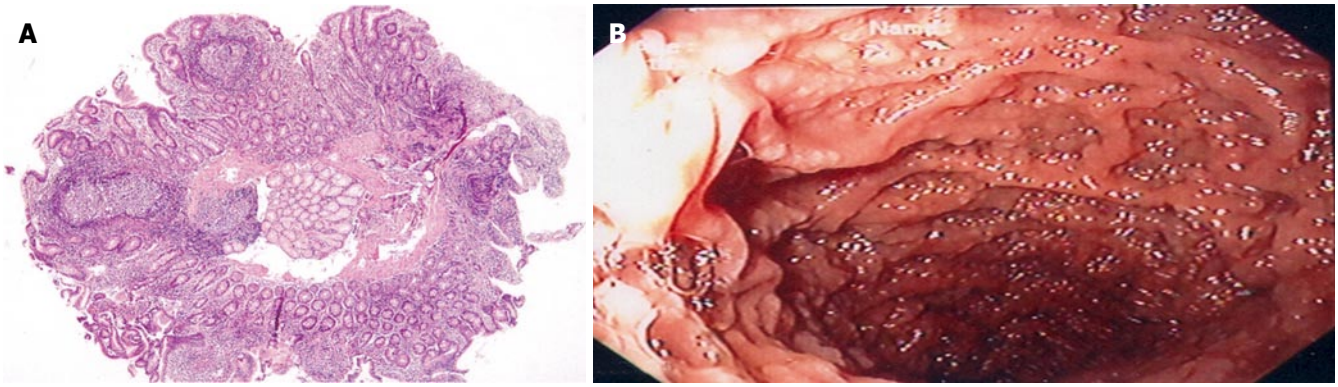

Figure 1 Histological (**A**) and endoscopic (**B**) characteristics of NLH. Hyperplasic follicles with active germinal centers localized at *mucosa* and *submucosa*, Brunner's glands at center and a pseudo-polypoid pattern of duodenum mucosa were observed.

used for reassessment. The histopathological evaluation was performed on hematoxylin-eosin-stained samples, including counting and localization of lymphoid follicles, type and severity of inflammation in *lamina propria*, and presence of villous atrophy. If the quality of the original sections was too poor for the reassessment, new sections from the original paraffin wax-embedded biopsy blocks were made.

Clinical and laboratory data

Age, duration and type of symptoms, body mass index (BMI) and associated diseases were evaluated. The following tests were recorded at the time of diagnosis: hemoglobin, mean cell volume, total proteins, albumin, globulins, β-carotene, electrolyte profile, prothrombin time, partial thromboplastin time, human immunodeficiency virus antibody, liver enzymes, stool analysis for ova and parasites, microscopic examination and culture of sterile collected duodenal fluid.

Statistical analysis

Clinical and histopathological data were expressed as absolute and/or relative frequencies and mean±SD. The Mann-Whitney U or χ^2 tests were used to compare groups. $P<0.05$ was considered statistically significant. SPSS software (version 10) was used.

RESULTS

Patients

Eighteen out of 550 duodenal biopsies had the histological diagnosis of NLH. After re-evaluation of the histological material all of them were included in the analysis. Twelve were women and 6 were men, yielding a female: male ratio of 2:1. Their median age at diagnosis was 41 years (18 to 76 years). Duration of symptoms from the onset to diagnosis varied from 1 to 48 mo (median = 18 mo). The median body mass index at diagnosis was 19 kg/m^2 (11 to 26 kg/m^2).

Clinical data

Diarrhea and weight loss were the predominant symptoms in 13 (72%) patients. A mean of 6 ± 4 bowel movements per day and a weight loss of 11.6 ± 6.9 kg in the last six months were presented. Eleven (61%) had abdominal pain (Table 1).

Table 1 Symptoms and signs of patients with NLH

Symptom or sign	*n* (%)
Diarrhea	13 (72)
Involuntary weight loss	13 (72)
Abdominal pain	11 (61)
Lymphadenopathy	4 (22)
Pallor	4 (22)
Chronic cough	2 (11)
Edema	2 (11)
Arthralgia	1 (6)
Neuropathy	1 (6)

Histopathology

A mean of 2.5 (range 2-6) hyperplasic lymphoid follicles was observed in a single field 4 × magnification with light microscopy. Hyperplasic lymphoid follicles were localized in mucosa of 13 cases (69%) and in mucosa and submucosa of five cases (31%) (Figure 1).

Patients with 3 or more hyperplasic follicles had lower β-carotene levels (46.7 ± 25 mg/dL *vs* 108 ± 42.6 mg/dL, $P<0.05$) and mixed localization of follicles (mucosa and submucosa) (8 *vs* 1, $P<0.05$) than patients with ⩽2 follicles. Subjects with mixed localized lymphoid follicles showed a statistically significant lower hemoglobin (11.9 ± 1.4 g/L *vs* 14 ± 13 g/L, $P=0.03$) and serum β-carotene (44 ± 21.9 mg/dL *vs* 111.2 ± 38.7 mg/dL, $P<0.02$) as well as a tendency to prolong thromboplastin time (17.3 ± 7.2 *vs* 11.5 ± 2.5, $P<0.07$) than those with exclusively mucosa-localized follicles.

Villous atrophy (partial or total) was observed in seven cases (38%) and it was associated with weight loss (7 *vs* 2, $P<0.02$), lientery (4 *vs* 0, $P<0.07$) and low globulin level (2.3 ± 0.87 g/L *vs* 3.2 ± 5.2 g/L, $P<0.06$). This group had also lower hemoglobin (12.3 ± 1.3 g/L *vs* 14.2 ± 14 g/L, $P<0.03$) and cholesterol serum level (170 ± 38.1 mg *vs* 200 ± 17.1 mg, $P<0.03$) than those without atrophy (Table 2).

Associated diseases

NLH was associated with hypogammaglobulinemia in 9 (50%) patients, CVI in 8 cases and selective IgA deficiency

Table 2 Findings in duodenal mucosa biopsy specimens from patients with NLH

Abnormality	*n* (%)
Localization of lymphoid follicles	
• Mucosa	13 (69)

Crypt hyperplasia	1 (9)

in 1 case. In this group the mean level of globulins was 1.6 ± 3.5 g/L which was quite different from that in subjects with normal globulins (3.2 ± 4.5 g/L, $P < 0.001$).

Giardia lamblia infection was found in only one case. *E. coli*, *Streptococcus sp,* and *Klebsiella sp* were respectively isolated from duodenal fluid in three (17%) (10^6 bacterial colonies per milliliter). These patients showed a markedly prolonged prothrombin time (18.5 ± 7.4 s *vs* 11.4 ± 1.9 s, $P < 0.014$). Anti-endomysium antibodies were tested in 16 subjects and two (12.5%) were positive. Both had villous atrophy thus the diagnosis of celiac sprue was established.

Lymphoma was found in three (17%) cases: one with nodular sclerosing-Hodgkin´s disease on the mediastinum, one with jejunum non-Hodgkin's lymphoma (diffuse large B-cell lymphoma) and one with gastric lymphoma. Patients with lymphoma were older (58 ± 10 years old) and only one of them presented diarrhea as a predominant symptom. No AIDS-associated NLH was found in this series (Table 3).

MNGIE: mitochondrial neurogastrointestinal encephalomyopathy.

DISCUSSION

Nodular lymphoid hyperplasia (NLH) is a well-characterized condition frequently associated with increased risk of gastrointestinal tumors, mainly gastrointestinal lymphoma. As a pathological entity it seems to be rare. It has been described in immunocompromised and immunocompetent subjects, normal children and adults and patients with AIDS[1-5].

This series represent the whole experience of the National Institute of Health in Mexico, which is a tertiary referral center for gastrointestinal diseases. In previous works Canto *et al*[6] and Castañeda *et al*[7] have described some cases with NLH seen at the same institution. In these two papers 12 patients are included in a period of 18 years contrasting with the 18 cases found by us in only a 5-year period. This difference could be explained by the selection criteria used. While Canto *et al*[6] selected the cases based on the radiological and histological findings. We included only the cases who met the strict histological criteria from a large database of subjects with duodenal biopsy. On the other hand, upper GI endoscopy with biopsy and duodenal fluid aspirate was performed in each patient with chronic diarrhea. NLH was found in 18 cases (4%). This low frequency can be explained by our selection criteria. Again we only included subjects with a duodenal biopsy with or without small bowel radiology. It was reported that NLH is most frequently located in jejunum-ileum[1-3].

The pathogenesis of NLH is unknown but is likely the result of an accumulation of plasma-cell precursors due to a maturational defect in the development of B-lymphocytes in order to compensate for functionally inadequate intestinal lymphoid tissue[8]. The role of functionally inadequate intestinal lymphoid tissue is suggested by the common occurrence of hypogammaglobulinemia and recurrent infections (particularly by *Giardia lamblia*)[9]. Nine patients had disgammaglobulinemia, but we were able to demonstrate *Giardia lamblia* infection only in one. It should be noted that we only used stool analysis for ova and parasites and microscopic duodenal fluid examination. It is possible that some cases could be missed because we did not perform fecal ELISA for *giardia-specific* antigen, which is the most sensitive and specific method for *giardia* detection[10]. Another plausible explanation is the high frequency of auto-medication used in our patients. Mexican subjects with chronic diarrhea are empirically treated with antibiotics including metronidazole.

Histological diagnosis of NLH can demonstrate the hyperplasic lymphoid follicles with mitotically active germinal centers at mucosa and/or submucosa. The number of follicles is not a diagnostic criterion[1,2]. We found a mean of 2.5 hyperplasic lymphoid follicles in a single 4× magnification field. Patients with three or more localized hyperplasic follicles in mucosa or submucosa showed markers of poor intestinal absorption such as low serum hemoglobin and β-carotene and a marked prolonged prothrombin time, suggesting that fat malabsorption may in turn lead to deficiencies of fat-soluble vitamins. These patients also had chronic diarrhea and a marked weight loss.

The association between NLH and other malignant and benign diseases has been clearly described[9,12-15]. In our series, seven cases had CVI and one had selective IgA deficiency. CVI is a heterogeneous form of immunodeficiency associated with decreased serum immunoglobulin levels, recurrent sinopulmonary infections, gastrointestinal disorders, and increased frequency of malignancies[12,13]. The association between NLH, hypogammaglobulinemia and *Giardia lamblia* infection is known as Herman's syndrome[8]. We only found one case with disgammaglobulinemia, NLH and *Giardia lamblia* infection. The only real difference with

Canto's work was the low detection of giardiasis in our series, a feature which is needed to establish the diagnosis of Herman's syndrome.

The risk of malignancy has been well recognized in subjects with NLH[14]. Three of our cases had lymphoma. Lymphoma has been reported in patients with and without immunodeficiency[15,16]. The link between the extra intestinal lymphoma and NLH is less clear. We found one patient with Hodgkin's disease localized on the mediastinum. Jonsson *et al*[4] have reported a case of extra intestinal lymphoma associated with NLH. Hyperplasic tissue completely disappeared after chemotherapy with remission of lymphoma and then reappeared at relapse.

To the best of our knowledge, no relationship between NLH and celiac disease has been reported. In our series, intestinal atrophy, increased intraepithelial lymphocytes and anti-endomysium antibodies were found in two patients. One of them was asymptomatic on gluten-free diet, and complete resolution of anatomical changes was found in duodenal-specimens taken two months later. In the other case, no clinical response was found six weeks after implementation of a gluten-free diet. This patient lost her follow-up and we do not know her current histological status. Moderate to severe intestinal atrophy and increased intraepithelial lymphocytes have been reported in patients with CVI known as "pseudo-celiac" pattern[17]. In contrast to the typical changes seen in patients with celiac disease, CVI cases showed mild inflammatory infiltrate at the *lamina propria* with normal enterocyte maturation. We identified partial villous atrophy in five patients with negative anti-endomysium antibodies. Perhaps these 5 patients correspond to the pseudo-celiac pattern previously described.

Abstract

AIM: To characterize hyperlactatemia in patients with non-acetaminophen acute liver failure (ALF) in an attempt to clarify the mechanisms implicated and the role as a prognosis factor.

METHODS: In the setting of liver transplantation, 63 consecutive patients with non-acetaminophen acute liver failure were studied in relation to tissue oxygenation, hemodynamic and metabolic parameters. Before and after transplantation, the number of infected patients and outcome were registered.

RESULTS: Acute ALF showed higher levels of lactate than subacute ALF (5.4 ± 1 mmol/L versus 2.2 ± 0.6 mmol/L, $P = 0.01$). Oxygenation parameters were within the normal range. Lactate levels showed good correlation with respiratory quotient ($r = 0.759$, $P < 0.005$), mean glucose administration ($r = 0.664$, $P = 0.01$) and encephalopathy ($r = 0.698$, $P = 0.02$), but not with splanchnic arteriovenous difference in PCO2, pH and the presence of infection ($P = 0.1$). Portal vein lactate was higher ($P < 0.05$) than arterial and mixed venous lactate, suggesting its production of hyperlactatemia in the intestine and spleen. The presence of infection was an independent predictor of survival.

CONCLUSION: Hyperlactatemia is not a prognosis factor due to byproduct of the overall acceleration in glycolysis.

INTRODUCTION

Up to now hyperlactatemia, a common finding in the setting of acute liver failure (ALF), has been attributed mainly to severe circulatory disturbance, abnormal vasomotor tone, plugging of small vessels by platelets and/or interstitial edema[1] and it has been proposed as a bad prognosis factor. Several studies suggest that splanchnic circulation abnormalities during ALF may result in inadequate distribution of blood flow and occlusion of the microvasculature, leading to tissue hypoperfusion, although oxygen delivery is increased in a macro circulation[2,3]. Inadequate balance between splanchnic oxygen delivery and demand results in splanchnic hypoxia of tissues that consume oxygen avidly[4]. In this condition, as cellular oxygen concentrations decrease, ATP concentrations cannot be maintained by oxidative phosphorylation. In an attempt to maintain cellular function, the cells shift over to anaerobic glycolysis with accumulation of lactic acid and hydrogen ions as ATP is hydrolyzed.

However, other mechanisms may be implicated in hyperlactatemia in the context of ALF. Although lactate is the end-product of anaerobic glycolysis and blood concentrations rise in response to hypoxia, well-oxygenated tissues may also produce lactate due to aerobic glycolysis[5]. On the other hand, since the liver is the principal organ responsible for removal of whole body lactate clearance, hyperlactatemia may be the result of a deficit of lactate clearance by the insufficient liver.

We undertook the present study to characterize hyperlactatemia in patients with non-acetaminophen ALF who were considered candidates for liver transplantation in an attempt to clarify the mechanisms implicated in high

lactate levels as well as the role as a prognosis factor.

MATERIALS AND METHODS

Patients

A total of 63 patients with diagnosis of non-acetaminophen ALF were admitted to the Liver Intensive Therapy Unit in our hospital and submitted to liver transplantation. All patients were prospectively evaluated and included in the study. Four of them were considered hyperacute, 39 acute while 20 subacute hepatic failure based on the criteria of the Kings College Hospital Group[6].

This prospective study was approved by the Clinic Hospital Research Ethic Committee. Informed consent for the study was obtained from each patient or patient's family.

General management

All patients were managed in the Liver Intensive Therapy Unit, in a standard manner[7]. They were maintained on 10%-20% glucose solution infusion (keeping blood glucose levels between 90 and 120 mg/dl). Prophylaxis for upper gastrointestinal bleeding and close microbiological surveillance (all patients received norfloxacin and nystatin) were performed. Coagulation profile was corrected only in the presence of overt bleeding. Those in grade III and IV coma (43 patients) were treated with standard sedation and mechanical ventilation. An epidural transducer (Ladd Research Laboratories, Burlington, VT) was inserted into the epidural space to enable early recognition and treatment of intracranial hypertension (>25 mmHg), mannitol (0.5 to 1 mg/kg) for over 30 min and pentobarbital infusion as a following step were used to control intracranial pressure (ICP). Systemic arterial hypotension (systolic <100 mmHg) was managed by dopamine infusion according to the hemodynamic conditions in an attempt to maintain cerebral perfusion pressure (CPP) (>60 mmHg). No artificial liver support techniques were used and no patient was treated with N-acetylcysteine or epoprostenol.

Anesthesia and hemodynamic management

In 20 patients who remained awake (encephalopathy grades I and II), anesthesia was induced following our standard policy. All patients were mechanically ventilated (Servo 900C, Siemens) and the fraction of inspired oxygen was adjusted to achieve an arterial PaO_2 of 180 - 220 mmHg. Ventilatory parameters were regulated to maintain the end tidal CO_2 around 32 mmHg and P_aCO_2 below 35 mmHg. In all patients vasopressor dopamine at 3 μg/kg was started at the beginning of the surgical procedure and maintained through the transplant and increased to 8 μg/kg if necessary to achieve a mean arterial pressure greater than 75 mmHg. After graft reperfusion, arterial hypotension was treated by intravenous bolus of 10 μg of epinephrine. Fiberoptic pulmonary artery floatation catheter (7.5 French, Edwards Laboratories, Irvine, Calif.) was introduced through the right internal jugular vein and an arterial catheter (18 gauge, Arrow, Reading, PA) was placed via the left radial artery. At the beginning of the surgical procedure portal vein catheter (Certofix ® Mono S330 16G Braun) was placed by introducing it through a branch of the superior mesenteric vein and advanced to the portal vein until it was felt, in order to register portal pressure and to obtain blood samples for oxygen and metabolic parameters in splanchnic area. Not all patients received portal vein cannulation because it was not considered technically possible by the surgeon in 11 patients (4 with subacute ALF and 7 with acute ALF).

Variables analyzed in the setting of LTx

Before the surgical transplant procedure was started, the following parameters were measured. Mean arterial pressure (MAP, mmHg), cardiac index (CI, L/min/m^2) and systemic vascular resistance index (SVRI, dyn.sec.cm^{-5}.m^2) were obtained.

Systemic parameters including oxygen content difference [D(a-v)O_2, ml/dl], oxygen delivery (DO_2, mL/min/m^2), oxygen consumption (VO_2, mL/min/m^2), oxygen extraction ratio (VO_2/DO_2, %), mixed venous/arterial gradient of PCO_2 (VACO2, mmHg), arterial/mixed venous gradient of pH (AVpH, U) as well as respiratory quotient (RQ) were calculated.

Splanchnic parameters including arterial/portal venous oxygen content difference [D(a-v)O2, ml/dl], oxygen extraction ratio (VO_2/DO_2), portal veno/arterial gradient of PCO2 (VACO2, mmHg), and arterial/portal venous gradient of pH (AVpH, U) were obtained. All these variables were calculated following standard formulas.

Plasma lactate levels were measured with three blood samples simultaneously drawn from arterial catheter (La), the distal part of pulmonary catheter (Lv) and portal vein catheter (Lp). Blood lactate level was determined using a Kodak Ektachem 700XR (Rochester, NY. USA) analyzer[8].

The need of catecholamine administration and the mean glucose administration in the last 48 hours before transplant were recorded. The need of vasopressor drugs administered during the transplant procedure was also registered. The degree of encephalopathy and intracranial pressure were recorded.

Explanted liver pathology

Weight and structural characteristics of all explanted livers were studied.

Infectious complications

Diagnosis of infection was made by the presence of the white blood cell count greater than 12×10^9/L or less than 4×10^9/L, the presence of immature neutrophils, temperature higher than 38 ℃ or lower than 36 ℃ and microbiological confirmation. Also, chest infection was confirmed by radiology. All these parameters were recorded daily during the ICU admission before transplantation and the ten following days. The number of infected patients and episodes and pathogens microbiologically confirmed was registered, respectively.

ICU stay and immediate outcome

The mean stay in ICU during the first admission of patients after transplantation and immediate outcome (first admission in the hospital) were recorded.

Table 1 Clinical and demographic characteristics of the patients

Age (yr)	32.7±11
Sex (M/F)	26/37
Etiology (*n*, %)	
Viral hepatitis	18 (30)
Cryptogenic (non-A, non-B, non-C)	32 (52)
Drug toxicity	7 (11)
MAOi	3
Rifampin+Isoniacid	2
Isoflurane	1
α metil-dopa	1
Metabolic disease	4 (6)
Encephalopathy	
I-II (subacute form: 20 p)	20 (31.7)
III-IV (acute form:39 p) (hyperacute form: 4 p.)	43 (68)

Statistical analysis

Statistical analysis was performed using two-sided paired *t*-test for comparison of paired data and two-sided unpaired *t*-test for comparison of groups. The Bonferroni correction test was applied as appropriate. Categorical data were compared with the chi-square test for relationship between encephalopathy and infection. Correlation between lactate and the hemodynamic and oxygenation variables was assessed by linear regression analysis. Variables reaching significance in the univariate analysis between survivors and non-survivors were included in the multivariate analysis. Multivariate analysis was carried out by stepwise logistic regression analysis to determine discriminants of survival. All values were expressed as mean±SD. $P<0.05$ was considered statistically significant.

RESULTS

Demographic and clinical characteristics of the patients are shown in Table 1. No patient needed blood transfusion before the transplant.

Systemic hemodynamic and oxygenation parameters

Systemic hemodynamic parameters showed a hyperdynamic circulatory status with high CI (4.53±1.4 L/min/m^2) and low SVRI (1029±420 dyn.sec.cm^{-5}.m^2). Oxygenation parameters remained between normal ranges (DO_2 623±36 mL/min/m^2, VO_2 96.4±21 mL/min/m^2 and VO_2/DO_2 18.4±3.1%).

Blood lactate levels

The production of lactate in the intestine or in the spleen (Table 2), in accordance with Murphy *et al*[9], was suggested by the increased difference between portal, arterial and mixed venous lactate ($P<0.05$). Acute ALF showed significant higher levels (acute: 5.4±1 mmol/L, subacute: 2.2±0.6 mmol/L, $P=0.01$).

Lactate levels did not correlate with any of the hemodynamic or oxygenation parameters studied, except for the respiratory quotient (Figure 1 A). The grade of encephalopathy and the amount of glucose administered 48 hours before transplant (Figure 1 B and Figure 1 C) correlated well with blood lactate levels.

Table 2 Plasma lactate levels at different sites (mean±SD)

	Total (*n* = 52)	Acute (*n* = 36)	Subacute (*n* = 16)	*P*
La (mmol/L)	4.1±1.8 (1.1-15.2)	5.4±1	2.2±0.6	0.01
Lv (mmol/L)	4.3±2 (1.4-16.3)	4.7±2	2.4±1.4	0.03
Lp (mmol/L)	5.3±1.1a (2.1-17.6)	6.8±1.8a	2.9±0.9	<0.01
pH (units)	7.36±0.07 (7.28-7.42)	7.33±0.02	7.36±0.04	NS
VA_{CO2}(mmHg)	12.4±7 (8.3-13.4)	13.8±5	9.6±9	NS
AvpH (units)	0.06±0.03 (0.02-0.07)	0.08±0.02	0.07±0.04	NS

La: arterial lactate; Lv: mixed venous lactate; Lp: portal vein lactate; L(a-p): transplanchnic arterial/portal difference of lactate; $V_{A\ CO2}$: portal/arterial gradient of CO^2; AV_{pH}: arterial/portal gradient of pH; $^aP<0.05$ *vs* La, Lv and Lp.

Splanchnic oxygenation parameters

The splanchnic VA_{CO2} and AV_{pH} levels were in normal range and did not correlate with plasma lactate levels ($r=0.203$ and $r=0.164$, respectively). No differences were found (Table 2) when we compared patients with high (acute ALF) and low lactate levels (subacute ALF).

In order to maintain hemodynamic stability, only five patients with acute ALF needed administration of dopamine prior to the transplant. Only one of the patients demonstrated a high level of lactate (8.2 mmol/L). There was no significant correlation between lactate levels and the dosages of dopamine and epinephrine ($r=0.020$ and $r=0.13$ respectively) through the transplant. The total dose of epinephrine administered after graft reperfusion in patients with low (subacute ALF) and high lactate level (acute ALF) was similar in both groups (42.6±12 μg and 54.1±18 μg, respectively).

Explanted liver pathology

No relationship was found between lactate levels and liver weight. Interestingly, although the rate of massive necrosis was similar, liver weight of subacute ALF patients was significantly lower than that of acute ALF patients (762±22 g and 932±38 g, $P<0.05$).

Infectious complications

Twenty-one patients (33.3%) were infected in the perioperative period. Bacterial infection was found in 16 patients (25.4%), fungal infection in 5 patients (7.9%) and viral infection in 2 patients (3.1%). The incidence of infectious episodes of acute (13 patients, 30.2%) and subacute (8 patients, 40%) hepatic failure showed no difference. The level of lactic acidosis (Figure 2) no correlated with the presence of infection ($P=0.1$). Sixteen patients were infected before the transplant, 11 of them requiring mechanical ventilation because of pulmonary infection (confirmed on chest radiograph and microbiologically), showed significantly higher arterial lactate levels compared with mixed venous lactate level (5.2±1.1 and 4.5±0.8 mmol/L, $P=0.03$), suggesting lactate production within the lungs.

ICU stay and immediate outcome of patients with ALF

During the stay in ICU, 13 patients died (8 patients with acute and 5 subacute liver failure). Bleeding was not controlled in 2 patients. Furthermore, 3 patients needed

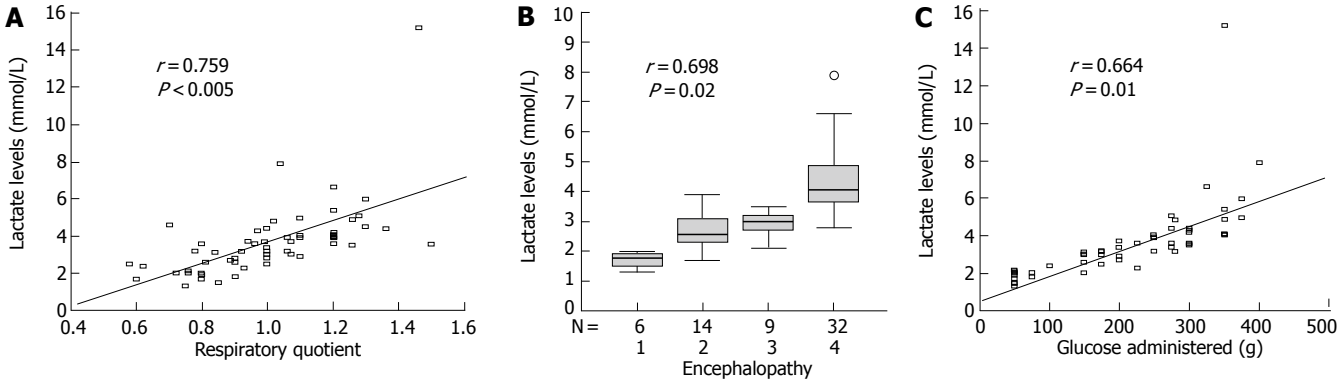

Figure 1 Correlation between arterial lactate level (nmol/L) and respiratory quotient ($n = 61$) (**A**), arterial lactate level (nmol/L) in patients with different grade of encephalopathy ($n = 61$) (**B**), correlation between arterial lactate level (nmol/L) and total amount of glucose (g) administered 48 hours before the transplant (**C**).

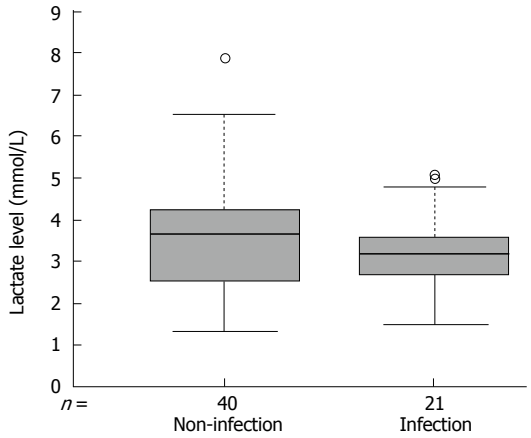

Figure 2 Arterial lactate levels in 21 infected and 40 non-infected patients. Box plot indicates that there is no significant difference between the infected and non-infected patients.

retransplantation because the primary graft did not function and one of them died after retransplantation because of infection complications.

The mean stay in ICU was 14.6 days (range 4 - 38 d). The ICU stay correlated well with infection complications ($P < 0.01$) but not with plasma lactate levels. The mean plasma lactate level was similar in nonsurvivors and survivors (4.3 ± 0.7 mmol/L and 3.9 ± 10 mmol/L, respectively, ($P = 0.69$). Univariate analysis showed that infectious complications (71.4% *vs* 22.4%, $P = 0.02$) and subacute ALF (30% *vs* 18.6%, $P = 0.08$) were the potential risk of non-survivors compared to survivors. Multiple logistic regression revealed that the presence of infection was the only discriminator of survival. Encephalopathy grade and splanchnic VACO2 and AVpH did not significantly improve the prediction of immediate survival.

DISCUSSION

Hyperlactatemia observed in the context of non-acetaminophen ALF seemed to be related to aerobic glycolysis but not to tissue hypoperfusion. Additionally, the incidence of infection in these patients, which appeared as an independent predictor of survival, did not correlate with the degree of hyperlactatemia.

It is important to emphasize that the foremost cause of ALF in our series was acute viral hepatitis that differs substantially in other series. Since acetaminophen exerts a direct toxic effect on cellular respiration, this type of cytotoxicity may be different from other types of ALF.

Currently, the presence of hyperlactatemia in patients with ALF is assumed as the consequence of underlying overt tissue hypoxia. In these patients, oxygen delivery may be impaired. Combined measurement of VACO2 and AVpH may serve as a good indicator of tissue hypoxia with a closer relation to cardiac output than blood lactate, because it is less affected by changes in fuel substrate utilization or enzymatic alterations [10-12]. In our study no differences were found in splanchnic VACO2 and AVpH between patients with high (acute ALF) and low lactate levels (subacute ALF).

If hyperlactatemia is attributable to tissue hypoperfusion, the increase in oxygen delivery should reduce lactate levels. However, several reports[13-15] have failed to identify this evidence in patients with ALF due to acetaminophen overdose.

In our patients selected to receive liver transplantation, plasma lactate levels did not correlate with hemodynamic or oxygenation parameters, except for RQ and the amount of glucose administered, suggesting that aerobic glycolysis is responsible of lactate hyperproduction. Since patients with ALF may exhibit hyperinsulinemia due to pancreatic hypersecretion and/or decreased hepatic clearance of insulin, they need glucose infusion in order to maintain blood glucose level. Previous studies[16-18] showed that infusion of glucose results in a dose-dependent rise in splanchnic lactate levels. Moreover, peripheral tissues of cirrhotic patients produce an exaggerated lactate production in response to glucose administration[19]. In our study, 7 patients who did not require glucose administration (subacute liver failure), showed normal lactate levels (<1.3 mmol/L). A complete round of the Cori cycle is proton-neutral because the H+ produced by lactate from glucose is subsequently removed during synthesis of glucose from lactate in the liver. In the context of liver failure, the possibility to handle lactate to glucose (gluconeogenesis) is handicapped and consequently the possibility to develop "lactic acidosis" without the presence of high muscular lactate overproduction is not significant. In our patients the arterial blood pH stayed within normal ranges (7.28 to 7.41). If hyperlactatemia is not related

to the mortality, infection, or operative hemodynamic management difficulty, the usage of dichloroacetate (which acts by stimulating pyruvate dehydrogenase) is not a priority unless its benefit to avoid postoperative severe alkalosis (lactate metabolism by the graft consume H^+) is considered. However, it seems that this treatment fails to attenuate metabolic alkalosis after transplant[20].

Clemmesen *et al*[5] have suggested a hypermetabolic condition secondary to an excessively high glycolysis in relation to the small liver mass, but we have not shown any correlation between liver weight and splanchnic lactate level in patients with ALF. Wendon *et al*[21] demonstrated that there is a significant correlation between arterial lactate and survival in acetaminophen related ALF, but in our study no relationship was found between plasma lactate and outcome. Inadequate splanchnic blood flow and tissue hypoperfusion could contribute to bacterial translocation and sepsis, however in these patients several factors can predispose to infection such as comatose state, steroid therapy, mechanical ventilation and intravenous catheters. Patients with ALF are susceptible to infection as a result of multiple immunologic defects (excessive cytokine production from cells, such as monocytes and macrophages in response to a number of stimuli including bacterial lipopolysaccharide)[22]. In our patients the Gram-positive organisms were predominant. The presence of Gram-negative organisms such as pseudomonas was not uncommon, showing a high incidence in this group of patients. These results suggest that selective bowel decontamination can be used in the treatment of such patients[23]. We did not find any correlation between lactate levels and infection incidence although there is evidence that cytokines may promote augmented production of lactate[24] by several organs, enhancing cellular glucose uptake and glycolytic metabolism. However, in agreement with other studies[25], arterial lactate is higher than venous mixed lactate in patients with pulmonary infection.

In summary, the presence of high plasma lactate levels in patients with non-acetaminophen ALF, is not related to tissue hypoperfusion and is not a prognostic factor in the treatment of ALF.

Abstract

AIM: To evaluate the frequency, clinical and paraclinical features of hepatopulmonary syndrome (HPS) and to determine their predictive values in diagnosis of this syndrome in patients in Iran.

METHODS: Fifty four cirrhotic patients underwent contrast enhanced echocardiography to detect intrapulmonary and intracardiac shunts by two cardiologists. Arterial blood oxygen, O_2 gradient (A-a) and orthodoxy were measured by arterial blood gas (ABG) test. The patients positive for diagnostic criteria of HPS were defined as clinical HPS cases and those manifesting the intrapulmonary arterial dilation but no other criteria (arterial blood hypoxemia) were defined as lHPS cases. HPS frequency, sensitivity, positive and negative predictive values of clinical and paraclinical features were studied.

RESULTS: Ten (18.5%) and seven (13%) cases had clinical and subclinical HPS, respectively. The most common etiology was hepatitis B. Dyspnea (100%) and cyanosis (90%) were the most prevalent clinical features. Dyspnea and clubbing were the most sensitive and specific clinical features respectively. No significant relationship was found between HPS and splenomegaly, ascites, edema, jaundice, oliguria, and collateral veins. HPS was more prevalent in hepatitis B. $PaO_2 < 70$ and arterial-alveolar gradient had the highest sensitivity in HPS patients. Orthodoxy specificity was 100%.

CONCLUSION: Clubbing with positive predictive value (PPV) of 75% and dyspnea with negative predictive value (NPV) of 75% are the best clinical factors in diagnosis of HPS syndrome. $PaO_2 < 70$ and P (A-a) $O_2 > 30$ and their sum, are the most valuable negative and positive predictive values in HPS patients.

Key words: Hepatopulmonary syndrome; Cirrhosis; Contrast enhanced echocardiography

INTRODUCTION

Ascites by elevating the diaphragm and confounding the ventilation/perfusion might lead to mild hypoxemia in most patients due to chronic hepatic involvement, not regarding the etiology. When cirrhotic patients have no sign of any cardiovascular diseases, severe hypoxemia($PO_2 < 60$mmHg) strongly recommends hepatopulmonary syndrome[1-3]. Hepatopulmonary syndrome is one of the pulmonary complications of cirrhosis which affects the treatment and disease prognosis and is a factor for arterial blood oxygen reduction. The diagnosis of this syndrome is confirmed by presence of cirrhosis in liver biopsy, absence of cardiovascular diseases, arterial blood oxygen reduction found in arterial blood gas (ABG) tests and pulmonary vein dilation in imaging[4]. Many studies have been performed on evaluating the prevalence, etiology, clinical features, early diagnosis, treatment and prognosis of this syndrome worldwide. The aim of this study was to evaluate the clinical and paraclinical characteristics and their predictive values in diagnosis of this syndrome.

MATERIALS AND METHODS

This study was performed in 54 randomly chosen cirrhotic patients referred to Gasteroenterology Department of Taleghani Hospital in 2004. In the patients who entered the study, cirrhosis was confirmed by biopsy, clinical and paraclinical evaluations. Echocardiography and pulmonary function tests were done for all patients and plain chest x-ray was taken. Those with cardiovascular and known respiratory diseases were excluded from this study. The patients with ascites underwent large volume paracentesis. These 54 patients underwent contrast enhanced echocardiography performed by two cardiologists from Cardiovascular Department of Talaghani Hospital. The procedure was performed by injecting agitated saline into patient's right hand cubital vein. Left and right sides of the heart were evaluated by echo after 5 beats. Presence of opacity after 5 beats in the left heart was determined as intrapulmonary shunt. If opacity was present immediately after injection, it was a sign of intracardiac shunt. ABG test was performed in patients at supine. After one hour in vertical position, the oxygenation saturation, arterial blood oxygen, (A-a) O_2 gradient and orthodoxy were evaluated. Physical examination was performed to detect clinical features including clubbing in fingers and toes, central and peripheral cyanosis, presence of spider angioma, telangiectasia, jaundice, collateral veins in abdomen, ascites, consciousness, splenomegaly, dyspnea, peripheral edema, palmar erythema, oliguria or anuria and pleural effusion for the underlying etiology. All patients were tested for hepatitis B, hepatitis C, biliary, autoimmune, metabolic, cardiac, alcoholic and idiopathic etiologies. Complete blood count (CBC), liver function test (LFT), creatinine, prothrombin time (PT), partial thromboplastin time (PTT), albumin and other routine tests were measured in all patients. Ascitic fluid was tested for protein, albumin and white blood cells.

The patients presenting the three diagnostic criteria of hepatopulmonary syndrome, including hepatic cirrhosis, arterial blood deoxygenation ($PO_2 < 80$ mmHg) and intrapulmonary arterial dilation were defined as clinical hepatopulmonary cases. Those presenting intrapulmonary arterial dilation but no other two criteria (arterial blood hypoxemia) were defined as subclinical hepatopulmonary cases. The study was carried out in accordance with the Helsinki Declaration and approved by the Ethics Committee of the Research Center for Gastroenterology and Liver Disease, Shaheed Beheshti University of Medical Sciences. The data were presented by descriptive statistics. The variables were compared by χ^2 test. Sensitivity, specificity, positive and negative predictive values of clinical and paraclinical features in diagnosis of hepatopulmonary syndrome were evaluated. $P < 0.05$ was considered statistically significant.

RESULTS

Among the 54 patients who participated in the study, 10(18.5%) met the clinical hepatopulmonary syndrome criteria and 7(13%) with intrapulmonary arterial dilation (but no other criteria) were defined as subclinical hepatopulmonary cases. Most frequent age group was 71-80 years. Figure 1 shows the age distribution. The most common etiology was HBV, but there was no significant relation. Figure 2 shows the prevalence of HPS etiologies.

Table 1 Characteristics and diagnostic values of signs and symptoms in hepatopulmonary syndrome

Symptoms and signs	Frequency in HPS (%)		Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	*P*
	Pos	Neg					
Cyanosis	90	15.9	90	80.1	60	97	<0.0001
Clubbing	80	9.1	80	90.9	75	95	<0.0001
Dyspnea	100	25	100	75	50	100	<0.0001
Palmar erythema	80	29.5	80	70.5	38	94	0.003
Spider angioma	80	29.5	80	70.5	38	94	0.005

HPS: hepatopulmonary syndrome, PPV: positive predictive value, NPV: negative predictive value.

Table 2 Child class in hepatopulmonary syndrome and subclinical patients

Child classification	HPS positive	HPS negative	Total
Class A	0	5	5
Class B	2	27	29
Class C	8	12	20
Total	10	44	54

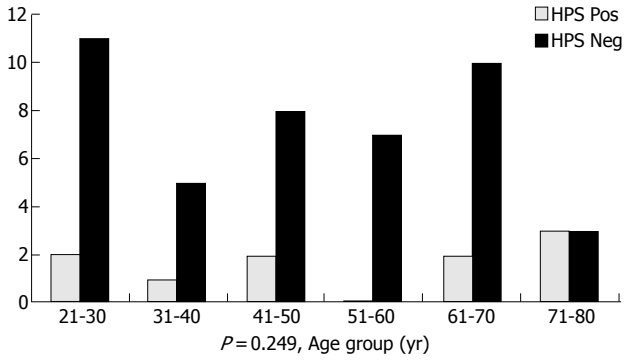

Figure 1 Age distribution in patients with hepatopulmonary syndrome.

By paying attention to the frequency of clinical features in HPS patients, dyspnea (100%) and cyanosis (90%) were the most prevalent. Dyspnea and clubbing were the most sensitive and specific clinical features. Table 1 presents the characteristics and diagnostic values of signs and symptoms in HPS patients.

No significant relation was found between splenomegaly, ascites, edema, jaundice, oliguria, collateral veins and hepatopulmonary syndrome. Table 2 presents the patients with or without hepatopulmonary syndrome. HPS was more common in class C. Table 3 presents the diagnostic value of arterial blood gas in HPS. PaO_2 and arterial–alveolar oxygen gradients were most sensitive in diagnosis of HPS. Orthodoxy specificity was 100%.

DISCUSSION

Hepatopulmonary syndrome includes the triad of liver

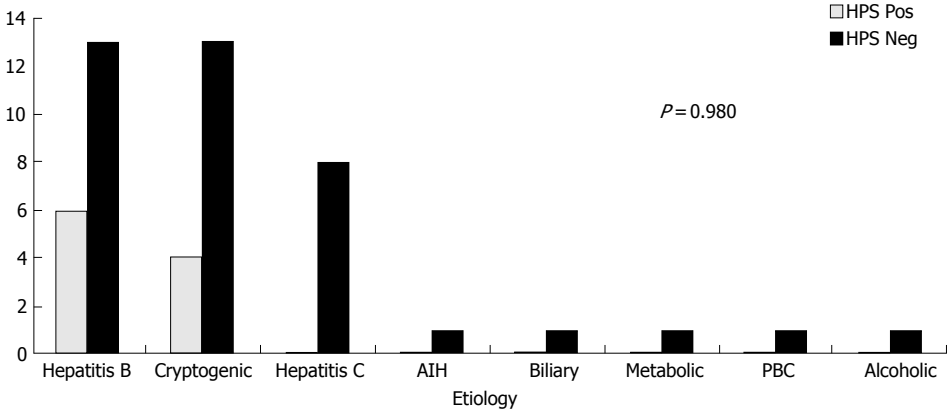

Figure 2 Causes of liver disease in patients with hepatopulmonary syndrome.

Table 3 Diagnostic value of arterial blood gases in hepatopulmonary syndrome

Laboratory results	Frequency (%)		Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	*P*
	Pos	Neg					
$Pa0_2$<70 and (A-a)0_2>30	100	4.5	100	92	85	100	<0.0001
$Pa0_2$<70	100	4.5	100	95	83	100	<0.0001
$a0_2$<65	70	4.5	70	98	77	95	<0.0001
$Pa0_2$<60	30	4.5	30	92	66	87	0.039
(A-a)0_2>15	100	75	100	25	23	10	0.1
(A-a)0_2>20	100	63.6	100	36	26	100	0.24
(A-a)0_2>30	100	31.8	100	70	88	89	0.001
(A-a)0_2>40	90	11.4	90	88	65	75	<0.0001
Orthodoxy>10	60	0	60	100	15	93	<0.001

disease, arterial blood deoxygenation and pulmonary vein dilation. Although the mortality of this syndrome is high, its influence on patient survival is unknown. In our study, the prevalence of hepatopulmonary syndrome was 18.5% and the prevalence of pulmonary vein dilation was 13%. Our findings are compatible with those of other studies in this field[1-5].

In our study, age and Child class C were significantly associated with HPS, suggesting that this syndrome is related with development of cirrhosis. Studies have shown a relation between HPS and cyanosis, clubbing and orthodoxy, although spider angioma is significantly related to intrapulmonary vein dilation[1]. The same results were observed in our study also. Cyanosis, clubbing and orthodoxy had positive and negative predictive values of 75% and 100% in hepatopulmonary syndrome.

Previous studies showed that the most common underlying etiologies of HPS were cryptogenic cirrhosis and cirrhosis due to hepatitis B[3,4]. The reported positive predictive values were 37% and 53% for (A-a) O_2 gradients and 93% and 94% for PaO_2[3,4]. Orthodoxy has been reported to be 88%, but in our study it was 66% and no significant statistical relation was found[6-7]. These clinical results strongly lead to diagnosis of HPS and the above tests can be used in screening patients.

In conclusion, hepatopulmonary syndrome and intrapulmonary vein dilation are relatively frequent in patients with portal hypertension. Clubbing with the highest positive predictive value (75%) and dyspnea with the highest negative predictive value (100%) are the best clinical features in HPS patients. Further studies are needed to confirm our results.

Abstract

AIM: To determine the prevalence of *Helicobacter pylori* (*H pylori*) among dyspeptic patients and to assess the relationship between *H pylori* infection, blood group, HIV infection and life style of the patients.

METHODS: In a hospital-based cross-sectional study, patients attending Outpatient Department of University of Gondar Hospital were enrolled. Socio-demographic information was collected using questionnaires. Serum was analyzed for anti-*H pylori* IgG antibodies using a commercial kit. HIV serostatus was determined by enzyme-linked immunosorbent assay (ELISA). Blood grouping was performed by slide agglutination tests.

RESULTS: A total of 215 dyspeptic patients were included in the study. One hundred and sixteen patients (54%) were females and 99 (46%) were males. Anti-*H pylori* IgG antibodies were detected in sera of 184 (85.6%) patients. The prevalence was significantly higher in patients aged 50 years and above. Twenty point five percent of the patients were found to be seropositive for HIV. No significant association was found between sex, ABO blood groups, consumption of spicy diets, socio-economic status and seropositivity for *H pylori*. However, alcohol consumption was significantly associated with *H pylori* serology.

CONCLUSION: The prevalence of *H pylori* infection is associated with a history of alcohol intake and older age. The effect of different diet, alcohol and socioeconomic status as risk factors for *H pylori* infection needs further study.

http://www.wjgnet.com/1007-9327/12/1957.asp

INTRODUCTION

Helicobacter pylori (*H pylori*), a flagellate Gram negative rod, infects over half of the world's population[1] and plays a pivotal role in the etiology of a number of gastroduodenal diseases and development of gastric malignancy[2-4]. *H pylori* has been recognized as grade one carcinogen[5] and the National Institute of Health Consensus Development Conference Statement recommended that all patients who are found to have gastric or duodenal ulceration and concurrent *H pylori* infection should receive treatment aimed at eradicating the bacterium[6].

Low socio-economic status, low level of education, consumption of alcohol, gender and occupation are the risk factors for *H pylori* infection[7]. In addition, blood group antigens, which mediate attachment of *H pylori* to gastric mucosa, are associated with a risk of developing peptic ulcer and gastric cancer[1]. About 95% of patients with duodenal ulcers and perhaps 80% of patients with peptic ulcers are infected with this bacterium and its eradication greatly diminishes the recurrence of these ulcers[8]. However, there have been very few studies on the prevalence of *H pylori* in Ethiopian patients[9,10]. Therefore,

the aim of this study was to determine the prevalence of *H pylori* among dyspeptic patients and to assess the relationship between *H pylori* infection, blood group, HIV infection and life style of patients attending Gondar University Hospital in Northwest Ethiopia.

MATERIALS AND METHODS

The study was conducted at the Hospital of Gondar University, Northwest Ethiopia, from February 2003 to June 2003. Patients who presented with complaints of dyspepsia were included in the study. Institutional ethical clearance was obtained from the Research and Publication Committee of Gondar University.

Socio-demographic and relevant clinical information was collected by a questionnaire. A senior internist examined the patients and filled the questionnaires. The variables included sex, age, ethnicity, smoking, stress, nutrition, alcohol consumption, exercise and socio-economic factors. After informed consent was obtained from each patient and appropriate pre-test counseling was provided about 5mL of venous blood was collected in vacutainer tubes and sera were separated by centrifugation immediately after clotting. Serological status of *H pylori* infection was tested with commercial *H pylori* serology kits (HEXAGON H.PYLORI, Germany) following instructions of the manufacturer. The kit was used for the detection of *H pylori* IgG antibodies in serum. It could detect anti-*H pylori* antibodies with a highsensitivity (97%) and specificity (95%) when compared with ELISA (HEXAGON H.PYLORI, Germany). Blood grouping was performed by slide agglutination test using monoclonal anti-A, anti-B, anti-AB and anti-D (Rho) antibodies. Testing for the presence of HIV antibodies was determined by ELISA following the manufacturer's instructions (Vironostica HIV Uni-Form II plus O, Organon Teknika, Boxtel, The Netherlands). HIV serology test was carried out anonymously with all clinical and laboratory data identified by a code number. Data entry and analysis were performed using SPSS version 10 statistical package. χ^2 test was used to compare the categorical data and logistics regression was used to avoid the confounder effect and to calculate the risk ratio. Odds ratio (OR) and 95% confidence interval (CI) were used to measure the strength of association. $P<0.05$ was considered statistically significant.

RESULTS

A total of 215 dyspeptic patients were included in the study. Table 1 shows the socio-demographic characteristics of the study population in relation with *H pylori* serostatus. The mean age of the subjects was 35 years (range 14-74 years). A substantial majority (55.8%) of the patients were young adults aged 20-40 years. Females constituted 54% of the patients. Fifty three percent of the patients were farmers followed by students (13.5%). Regarding the marital status, 62.8% were married, 18.1% were singles and 10.2% were divorced. Fifty nine point one percent of the

Others	5 (31.3)	11 (68.7)	

patients came from Gondar town and the remaining 48.1% came from rural areas.

Among the patients, 184 (85.6%) were found to be positive for anti-*H pylori* antibodies. The sex specific prevalence in males was 88.9% which was not significantly different from that of females (82.8%). The prevalence of *H pylori* was significantly higher in patients aged 50 years and above (100%) when compared to patients aged < 50 years (82.2%) ($\chi^2=8.54$, $\gamma=1$, $P<0.05$). *H pylori* seroprevalence was not associated with residence, marital status, occupation and ethnic group of the patients ($P>0.05$) (Table 1).

The prevalence of HIV among the patients was about 20.5% (44/215). The HIV seropositivity was not associated with *H pylori* seropositivity as only 19.6% (36/184) of the patients who were positive for *H pylori* were also positive for HIV while 25.8% (8/31) patients who were negative for *H pylori* were positive for HIV (Table 2). Analysis of demographic factors for HIV infection showed a significant association by residence ($\chi^2=5.78$, $P<0.01$) and occupation ($\chi^2=24.78$, $\gamma=7$, $P<0.001$) of the dyspeptic patients (Table 3)

Analysis of blood group showed that 201 (93.5%) of the total subjects were rhesus positive (Rh+) and 14 (6.5%) were rhesus negative (Rh-). Among the total subjects blood group O was the most common blood group (43.3%) in the patients followed by blood groups B (28.4%), A (22.3%) and AB (6.0%), respectively. However, no statistically significant association was seen between *H pylori* infection and blood group of the patients (Table 4).

Table 4 Relationship between ABO blood groups and seropositivity of antibodies against *Helicobacter pylori* infection

Blood group	Serum anti HP+ [*n* (%)]	Serum anti HP- [*n* (%)]
O	76 (84.4)	14 (15.6)
B	59 (88.1)	8 (11.9)
A	41 (85.4)	7 (14.6)
AB	8 (80)	2 (20)
Total	184 (85.6)	31 (14.4)

Table 5 Relationship between *Helicobacter pylori* infection and life style in dyspeptic patients attending Gondar University Hospital (Northwest Ethiopia, 2003)

		Serum anti-HP+ *n* (%)	Serum anti-HP- *n* (%)	*P* value
Alcohol intake	Yes	128 (90.1)	14 (9.9)	<0.01
	No	56 (76.7)	17 (23.3)	$\chi^2=7.05$
Diets	Coffee	24 (82.8)	5 (17.2)	$\gamma=1$
	Spicy food	108 (89.3)	13 (10.7)	=0.2
	Others	52 (80)	13 (20)	$\chi^2=3.15$
				$\gamma=2$

History of diet, alcohol consumption and socio-economic status were obtained from the patients. It was observed that seropositivity for anti-*H pylori* antibodies was significantly associated with history of alcohol consumption (OR=2.78, 95% CI: 1.19-6.5, $P<0.01$) (Table 5). Although there was a higher prevalence of *H pylori* infection in those with low socioeconomic status than in those having average income, the association was not statistically significant. Likewise, no statistically significant interaction was observed in the prevalence of *H pylori* infection and consumption of coffee and spicy foods (Table 5).

DISCUSSION

The prevalence of *H pylori* IgG antibody among dyspeptic patients was 85.6%. This finding is higher than an earlier report from 136 patients with non ulcer dyspepsia from Addis Ababa, showing a prevalence of 65% for *H pylori*[9]. However it is comparable with a recent report from blood donors in Addis Ababa, where a seroprevalence of 89% has been observed[10]. When compared to studies from other countries like England, France, Scandinavia, Italy, Belgium and USA, the seroprevalence found in this study is much higher[11]. This may be explained by the association between *H pylori* and low socioeconomic status as evidenced by unsafe drinking water[12] and other factors like low educational level which would have an impact on personal hygiene and environmental sanitation[13].

Prevalence of *H pylori* increases with age. It is interesting to note that in patients aged 50 years and above its prevalence is 100%. Similar results have been reported in

other studies indicating the high frequency of infection in the elderly[13]. This tendency is believed to be attributable to the environmental factors specific to these age group rather than aging[13]. The lack of significant association between sex, residence of patients and *H pylori* is in line with previous reports from elsewhere[14,15].

In the present study, more than one fifth of the patients (20.5%) were found to be seropositive for HIV and the seroprevalence of HIV in *H pylori*-infected patients was also very high (19.6%). This high prevalence of HIV in dyspeptic patients reflects the severe magnitude of HIV infection in the general population in Northwest Ethiopia. Recent studies showed that 51.4% tuberculosis patients[16] and 5% cataract patients[17] were seropositive for HIV in the region substantiating our present observation. Co-infection with HIV can debilitate the defense mechanism of patients and increase morbidity and mortality.

Blood group O is associated with duodenal ulcer disease, while gastric ulcer and gastric carcinoma are associated with blood group A[18]. Since the identification of *H pylori*, no pathogenic mechanism has been identified to support this earlier finding. Lewis B blood group antigen has recently been shown to function as a receptor for *H pylori* adhesins, mediating bacterial adherence to the gastric epithelial surface, which is essential for bacterial colonization[19]. Furthermore, substitution of the Lewis B antigen with blood group A and B determinants results in failure of *H pylori* binding[19]. Reduced exposure of the Lewis B epitope in persons of blood groups A and B could result in lower *H pylori* infection rates and a predominance of *H pylori* infection in persons of blood group O[20]. This is consistent with the reported association of blood group O with duodenal ulcer disease, but at variance with the association of blood group A with gastric ulcer and carcinoma, which is also related with *H pylori* infection. The present study did not demonstrate any significant difference in *H pylori* serological status of dyspeptic patients with varying blood groups, which is consistent with similar studies from other countries[18,20-22].

Histories of alcohol (local alcoholic drinks like "Tella", "Teji" "Araki" and beer) consumption appears to be a risk factor for *H pylori* infection, which is in line with study from Finland[23]. However, different results have been reported in other countries[24]. The reason for this contradictory result might be due to the difference in the type of alcoholic beverages consumed and the life time history of alcohol consumption. Socioeconomic status does not appear to be a risk factor for *H pylori* infection, although a higher proportion of patients with low income are found to be positive for *H pylori* antibody. This result is in line with reports form Zambia and United Kingdom[25,26]. Spicy foods and coffee are considered to be risk factors for *H pylori* infection. However, no statistically significant interaction was observed in the present study, but it has been reported in Japan[27].

In conclusion, the prevalence of *H pylori* infection is very high and associated with history of alcohol intake and older age. Different diet, alcohol and socioeconomic status as risk factors for *H pylori* infection need further study.

ACKNOWLEDGMENTS

The authors acknowledge the Research and Publication Office of University of Gondar for financing and thank Drs. Moges Tiruneh, Yenew Kebede and Mr. Andargachew Mulu from Department of Medical Microbiology for their valuable comments and Mr. Getu Degu for statistical consultation. Our thanks also go to Mrs. Birhanemeskel Tegene, Abebaw Getahun and Tessema Zewudie for their technical assistance.

Abstract

AIM: To investigate electroacupunture(EA) at the acupoints of Stomach Meridian of Foot-Yangming(SMFY), Gallbladder Meridian of Foot-Yangming(SMFY) on gastric mucosal intestinal trefoil factor (ITF) gene expression detection in stress-induced rats with gastric mucosal lesion, and to explore the regulatory mechanism and significance of EA-related gastric mucosal protective effect.

METHODS: Forty rats were randomly divided into 4 groups: Blank group, Model group, Model group+EA at acupoints of SMFY group("SMFY group"), and Model group+EA at acupoints of GMFY group(GMFY group). All rats (except blank group) were made model by water immersion and restraint stress (WRS). Then the gastric mucosa tissue in each rat was taken off after assessment of gastric mucosal lesion index(GUI), and the expression of ITF mRNA of the tissues was detected by reverse transcription-polymerase chain reaction(RT-PCR) method.

RESULTS: Compared with Model group(54.3 ± 1.34), the GUI value in SMFY group (31 ± 2.21) decreased significantly($P < 0.01$), so did that in GMFY group (39.8 ± 1.62, $P < 0.05$), meanwhile GUI value in SMFY group was significantly lower than in GMFY group($P < 0.01$). Compared with Model group (0.65 ± 0.01), EA had a tendency to improve the expression of gastric mucosal ITFmRNA gene: such tendency existed in GMFY group (0.66 ± 0.01) but with no signficant difference($P > 0.05$), in SMFY group(0.76 ± 0.01) with an extremely obvious difference ($P < 0.01$), furthermore the expression in SMFY group was significantly higher than in GMFY group ($P < 0.01$).

CONCLUSION: The gastric mucosal protective effect by EA at the acupoints of SMFY and GMFY was related to the expression variance of ITF, indicating certain meridian specificity exists. It could be one proof for the TCM theory "Relative particularity between SMFY and stomach".

Key words: EA; Relative particularity between Stomach Meridian of Foot-Yangming; Gastric mucosal damage; Stress; Intestinal trefoil factor; Gene expression

INTRODUCTION

Acupuncture is one of the traditional Chinese medicine(TCM) therapeutic techniques that can be traced back at least 2500 years, gaining popularity in the West as an alternative and complementary therapeutic intervention[1-4]; while "Relative particularity between Foot Yangming meridian and stomach", is one of important TCM theories. Such theory was proved by our previous research results[5-7]: acupuncture at acupoints of Sibai (ST 2), Liangmen (ST 21), and Zusanli (ST36), could regulate gastric motion and gastric secretion. Recently, a group of new peptides have been discovered, called trefoil factor family (TFF) or trefoil peptides because of their uniquely distinctive cysteine-rich "three-leaf" secondary structure[8], which probably protects these peptides from the degradation by luminal acid and proteases within the gastrointestinal tract[9]. Intestinal trefoil factor (ITF) belongs to the growing family of trefoil peptides[10]. Most of the researches to date have revealed important roles for ITF in protection and repair against injury to the gastrointestinal mucosa[11-14].

To our knowledge, there existed still no evidence of ITF gene expression in stress-induced gastric mucosal lesion in rats by the treatment of acupuncture. In our present study, ITFmRNA was detected to probe gastric

mucosal protective mechanism of the factor, and to prove the classical TCM theory "Relative particularity between Stomach Meridian of Foot-Yangming(SMFY) and stomach".

MATERIALS AND METHODS

Reagents

Trizol reagent was obtained from Invitrogen Co. (USA). One tube RT-PCR kit was from Promega Co. (USA). Primers for rat ITF and GAPDH were designed by ourselves in accordance with gene sequence in GenBank, synthesized and purified by Gibco BRL Biological Engineering Co. All other reagents were analytically pure.

Animals

Forty spraque-dawley rats weighing 180-250 g, male and female mixture, were used. They were housed three to four per cage at temperature 22 ℃ ± 2 ℃ with a 12/12 h light/dark (0:00 a.m. to 20:00 p.m.) cycle under controlled environment. Rats were fed standard laboratory chow, and water was given *ad libitum*. The rats were kept for 7 d in laboratory for habituation. This study was carried out according to the protocol approved by the Ethical Committee of Hunan University of Traditional Chinese Medicine, Changsha, China.

Animal groups and model

All rats were randomly divided into 4 groups(ten rats in each). The design of the experimental animal groups is shown in Table 1.

Table 1 Design of experimental animal groups

Group/code	Treatment
Group A: Blank group	Untreated rats as normal control group
Group B: Model group	having no EA or other treatment for 7 d, then WRS rat model was established.
Group C: SMFY group	After EA at points of SMFY for 7 d, WRS rat model was established
Group D: GMFY group	After EA at points of GMFY for 7 d, WRS rat model was established

Acupuncture method

Acupoints location was defined by reference of rat-acupoint-atlas[15] and analogy to human body. According to the induction stated above, three pairs of acupoints consisting of Sibai (ST 2), Liangmen (ST 21), Zusanli (ST36), in the Foot Yangming Meridian, were designed, which represent acupoints of different level(head, trunk, limb); thus 3 pairs of acupoints of the Foot Shaoyang Meridian in the same horizontal level were selected: Yangbai(GB 14), Riyue(GB 24), Yanglingquan(GB 34). Acupoint location: Sibai acupoint, at the depression of the infraorbital foramen; Liangmen acupoint, at intersection of the midline between anterior midline and midclavicular line and the middle horizontal line of omphalos and xiphoid.

Pairs of stainless-steel needles of 0.25 mm in diameter were inserted into the acupoints stated above of experimental rabbits(Groups C and D). The needles were connected to the output of an electronic pulse generator, a medical EA stimulator (Model G6805-1, made by Shanghai Medical Electro-apparatus Factory, China), which achieves intermittent-and-irregular wave(intermittent wave:4 Hz, irregular wave:20 Hz, intensity of 6-15 V, the depth of acupuncture of 0.5 cm, constant time of 20 min), while there was a light vibration in the rats' lower limbs.

Induction of gastric mucosal lesion index

Seven days after corresponding treatment, each rat was immobilized in a restraint cage and immersed for 10 h to the height of the xiphoid in a water bath kept at 20 ℃ ± 1 ℃, and then sacrificed under anesthesia with 10% urethane intraperitoneally (1 ml/100 g). The abdomen was opened, and the stomach was removed, opened along the great curvature and the gastric mucosa was carefully examined under a dissection microscope to determine gastric mucosal lesion index(GUI) by the score systems suggested by Guth[16]. Briefly, the stomach mucosa was examined with magnifier for the presence of erosions and scored as follows: (1) for small, round hemorrhagic erosion; (2) hemorrhagic erosions less than 1 mm in length; (3) hemorrhagic erosions between 1-2 mm in length; (4) hemorrhagic erosions between 2-3 mm in length; (5) hemorrhagic erosions longer than 4 mm in length. The score value was multiplied by 2 when the width of erosion was larger than 1 mm. The extent of the lesion (lesion index) is expressed as the sum of the length of these breaks per stomach.

RNA extraction

After the treatment stated above, each rat's gastric mucosal tissue was collected and put in freezing-and-storing tubes and kept in the nitrogen tank quickly. Five samples of each group were selected randomly for experiment. Expression of EGFR mRNA was evaluated with RT-PCR. Total RNA was isolated from gastric mucosal samples using a guanidinium isothiocyanate/phenol chloroform single step extraction kit from Stratagene(Gibco BRL, USA), precipitated in ethanol and resuspended in sterile RNAase-free water for storage at -80 ℃ until use. Total RNA was quantified spectrometrically at 260 nm, and the quality of isolated RNA was analysed on agarose gels under standard conditions.

Reverse transcription reaction

Total RNA (10 μL, about 0.5 μg/sample) was reverse transcribed (RT) using oligo(dT)18 primers 1 μL (30 pmol/L), 5×RT buffer 4 μL(Promega Co.), dNTPs(10 mmol/L) 1 μL, RNasin(20 MU/μL, Promega Co. Madison, America) 0.5 μL, M-MULV reverse transcriptase (200 MU/μL, Promega Co., Madison, America) 1 μL, and DEPC water 2.5 μL in a 20 μL reverse transcription reaction system, and such system was performed at 42 ℃ for 30~60 min, then cooled and centrifuged for several seconds so that target mRNA of total RNA sample was transcribed into target cDNA.

Polymerase chain reaction (PCR)

An aliquot of the same RT product from each sample (1/20

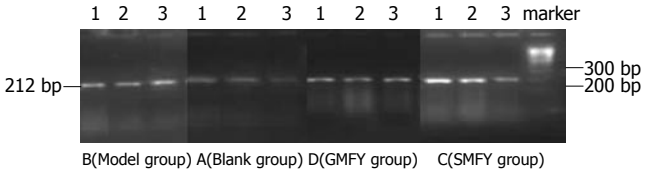

Figure 1 Electrophoresis of ITFmRNA RT-PCR product in gastric mucosal tissue (1, 2 and 3 are randomly selected from each group).

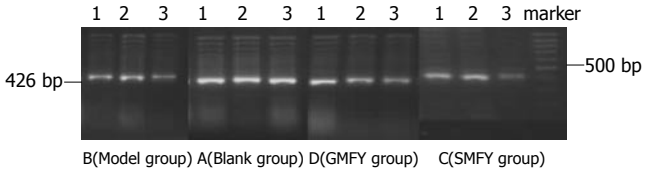

Figure 2 Electrophoresis of GAPDH mRNA RT-PCR product in gastric mucosal tissue (1, 2, and 3 are randomly selected from each group).

of the total volume) was used in the PCR amplification reactions for ITF and GAPDH. The PCR reaction system compound contained 4 μL cDNA, 10×PCR buffer(Promega Co., Madison, America)5 μL, dNTPS (10 mmol/L) 1 μL, oligonucleotide primers sense/ antisense (10 mmol/L) 1 μL (the related primer sequence as stated below), Taqase(5 MU/μL Promega Co.) 1 μL, ddH_2O 32 μL in a total volume of 50 μL. Reaction mixtures were incubated for predenaturation at 94 ℃ for 2 min, followed by 35 cycles for ITF (denaturation at 94 ℃ for 30 s, annealing at 58 ℃ for 1 min, and extension at 72 ℃ for 1 min) and 35 cycles for GAPDH (denaturation at 94 ℃ for 30 s, annealing at 58 ℃ for 30 s, and extension at 72 ℃ for 30 s), and a final extension at 72 ℃ for 5 min.

PCR primer design

By use of the relatively quantitative method to measure ITF-mRNA, rat GAPDH was selected as internal control substance. The primer sequences and sizes of amplification products are as follows: ITF sense, 5' -ACAACCCTGCTGCTGGTCCT -3'; antisense, 5' -TCTGTCTCTTGCAGAGGTTTG-3' (212 base pairs); GAPDH sense, 5'-TGCTGAGTATGTCGTGGAGTC-3'; antisense: 5'- AAGGCCATGCCAGTGAGCTTC-3' (426 base pairs).

RT-PCR product electrophoresis

Five microliter PCR products were analyzed on 10 g/L agarose gel containing ethidiumbromide with TBE buffer at 80 V for 40 min and photographed under UV illumination. The band intensities were quantified by densitometry. ITF and GAPDH PCR products were respectively 212 base pairs(Figure 1), and 426 base pairs(Figure 2). ITF and GAPDH were determined by computer-assisted densitometric scanning. Signals were quantified by density analysis of the digital images using Eagle Eye Ⅱ image software (Stratagene Co.) and ITF/ GAPDH quotient indicated the relative expression of ITF.

Table 2 Effect of EA on GUI and ITF-mRNA expression in gastric mucosal tissue (mean ± SD)

G	GUI score (n = 10)	ITF mRNA/GAPDH mRNA (n = 5)
A(Blank group)	0.3±0.48	0.45±0.01
B(Model group)	54.3±1.34[b]	0.65±0.01[b]
C(SMFY group)	31±2.21[bd]	0.76±0.01[bd]
D(GMFY group)	39.8±1.62[bcf]	0.66±0.01[bf]

[b]$P<0.01$ *vs* blank group, [c]$P<0.05$ *vs* Group B, [d]$P<0.01$ *vs* Group B, [f]$P<0.01$ *vs* Group C.

Experiments were performed in triplicate.

Statistical analysis

The data were expressed as mean±SD of 10 rats per group. Comparison between groups was assessed using one-way analysis of variance (ANOVA) on ranks. Differences were considered statistically significant if the P value was less than 0.05. Software SPSS 10.0 was used in all statistical tests.

RESULTS

Gastric mucosal injury condition and GUI

There were some dots and strips injury detected by the magnifier(10×). The GUI in Model group was highest, while in Blank group lowest, with significant difference between them ($P<0.01$). It demonstrated the ulcer model was successful. Compared with Model group, GUI in SMFY group and GMFY group reduced significantly ($P<0.05$ or $P<0.01$), and the GUI in SMFY group was lower than that in GMFY group($P<0.01$, Table 2).

Effect of ITF-mRNA expression on gastric mucosal tissue

The expression of ITF mRNA using RT-PCR was detected in the intact gastric mucosa of Blank group as a weak signal but it was well-defined among other groups: Model, SMFY, and GMFY groups($P<0.01$). Compared with Model group, EA at acupoints of SMFY group could upregulate significantly the expression of ITF-mRNA expression in gastric mucosal tissue($P<0.01$), while there did not exist difference of expression between GMFY group and model group($P>0.05$), but obvious difference between SMFY group and GMFY group was found ($P<0.01$, Table 2).

DISCUSSION

According to classical TCM theory, SMFY, running from head, via chest and abdomen, along anterior lateral lower limb to foot, is a crucial meridian for its good bidirectional modulation of digestive diseases. Previously, we studied the effect of single acupoint of SMFY on gastric function as well as the whole SMFY's functional mechanism. Acupuncture at acupoints of head and face, trunk, or lower limb (such as acupoint "Sibai", "Tianshu", "Liangmen", "Zusanli", "Shangjuxu"), could produce certain ameliorative effect through the following mechanisms: augmentation of gastric antrum anrea, reinforcement of

pressure power of gastric pyloric sphincter, promotion or inhibition of related gastrointestinal peptide secretion[17-19]. All of these have provided experimental evidence for the theory "Relative particularity between SMFY and stomach".

The cytoprotective functions in protecting gastrointestinal tract against ongoing damage may be accomplished in several ways, and evidences for participation in both the early phase of epithelial repair known as restitution (marked by increased cell migration but no proliferation), and in the subsequent, protracted phase of glandular renewal (marked by proliferation, differentiation and migration) have been published[20-22]. ITF is one of the most recently described members of the trefoil peptide family, a peptide of 59 amino acids, expressed normally by mucus secretory cells of the small and large intestine[9,23]. It is secreted onto the luminal surface of the gastrointestinal tract, and may act in conjunction with the mucin glycoprotein products of goblet cells to promote reestablishment of mucosal integrity after injury through mechanisms distinct from those that may act at the basolateral pole of the epithelium[11,24].

This study assessed for the first time ITF expression by RT-PCR analyses in rat gastric mucosa after exposure to water immersion and restrained stress. It showed that expression of ITF in gastric mucosa was enhanced shortly after the stress, leading us to hypothesize that this process might be mediated by ITF. Meanwhile, it was proved that EA had a tendency to improve the expression of gastric mucosal ITFmRNA gene, and such expression of SMFY group was strongly higher than model group and GMFY group, indicating that the expression discrepancy of ITFmRNA may be the underlying mechanism of different effect of EA at acupoints of SMFY and that of GMFY, thus it could be one proof for the TCM theory "Relative particularity between SMFY and stomach".

Abstract

Brunner's gland adenoma (BGA) is a very rare benign tumour of the duodenum, which is usually asymptomatic and discovered incidentally at endoscopy. Occasionally, this lesion may be large, causing upper gastrointestinal haemorrhage or intestinal obstruction. The case had a large Brunner's gland adenoma, presenting melena that was managed by endoscopic excision.

Key words: Brunner's gland adenoma; Endoscopic resection; Giant brunneroma

INTRODUCTION

Brunner's glands, described by the anatomist Brunner in 1688, are submucosal mucin-secreting glands. They are predominantly localized in the duodenal bulb and proximal duodenum and progressively decrease in size and number in the distal portions. Brunner's glands exert a physiological "anti-acid" function by secreting alkaline fluid composed of mucin which protects the duodenal epithelium from the acid chime of the stomach[1]. Furthermore, they produce and secrete "enterogastrone", an enteric hormone inhibiting gastric acid secretion.

Brunner's gland adenoma (BGA), firstly described by Curveilheir in 1835, is a benign tumour arising from the Brunner's glands that exceptionally may evolve towards a malignant transformation[2-4]. BGA is an extremely rare tumour with an estimate incidence of 0.008% reported in a single series of 215 000 autopsies[1]. At present, < 200 cases have been reported in the world medical English literature.

Here, one case of large BGA managed by endoscopic resection is reported together with a review of the pertinent literature.

CASE REPORT

A 58-year old female was referred to our Gastroenterology Unit due to episodes of epigastric discomfort over the past few months. Past medical history included appendicectomy performed during childhood, cholecystectomy for gallstones performed 4 years previously and a self-limiting single episode of melena occurred two months previously. The patient denied weight loss or use of non steroidal anti-inflammatory drugs (NSAIDs).

Clinical examination and routine blood tests were normal. Esophago-gastro-duodenoscopy (EGDS) demonstrated normal esophagus and stomach. A large pedunculated polyp, 3 cm × 4 cm in size, completely occupying the duodenal bulb was found. Healing microerosions were present on the mucosa. Histological examination of the multiple biopsy specimens obtained during EGDS, suggested "Brunner's gland hyperplasia" in a context of mild chronic gastritis without evidence of *Helicobacter pylori* (*H pylori*) infection.

Abdominal CT-scan confirmed the presence of a polypoid mass originating in the mucosa of the duodenal bulb and extending to the second portion of the duodenum for about 4 cm, without evidence of duodenal wall infiltration (Figure 1). Endoscopic resection was carried out to remove the duodenal mass. Histological examination revealed closely packed Brunner's glands and ducts embedded in a fibrous stroma with a moderate degree of lymphocyte and monocyte infiltration (Figures 2A and 2B). A diagnosis of Brunner's adenoma was made. During the 6-month follow-up, the patient remained symptom-free and no further episodes of melena occurred. EGDS did not find any residual lesion.

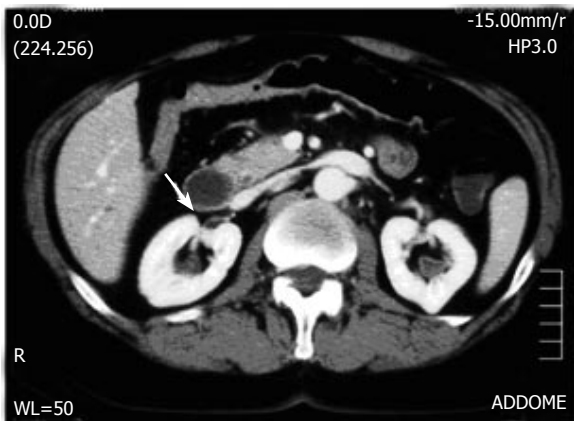

Figure 1 Evidence of polypoid mass in duodenal bulb extending to second duodenal portion (arrow).

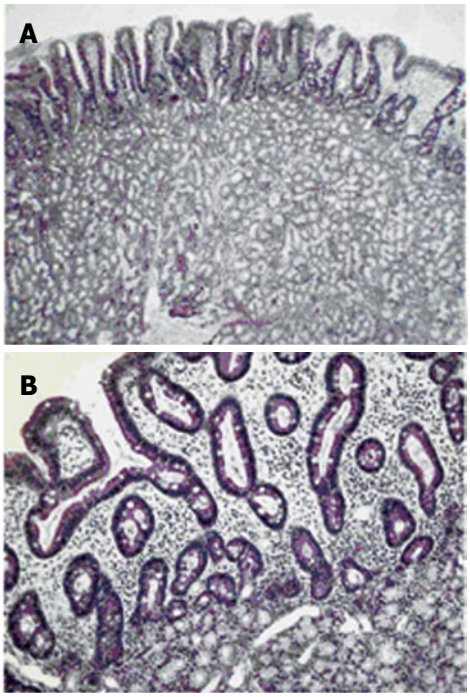

Figure 2 Gland hyperproliferation extending beyond muscolaris mucosae reaching lower portion of duodenal villi with irregular and squat profile of these structures (**A**) (H&E, original magnification X4) and detail of interface between Brunner's gland proliferation and duodenal mucosa with absence of muscularis mucosae and irregular profile of villi (**B**) (E&E, original magnification X20).

DISCUSSION

BGA has a tendency to be predominant in the fifth or sixth decade of life with equal gender distribution [5]. Clinical presentation is variable. However, the majority of cases are asymptomatic or present with non specific, vague symptoms such as abdominal pain or discomfort, nausea or bloating. BGA is usually an incidental finding during imaging studies or EGDS[5].

In symptomatic patients, the most common clinical presentations are gastrointestinal bleeding (37%) and obstructive symptoms (37%)[5]. Gastrointestinal bleeding manifests in the majority of cases as chronic loss of blood with iron deficiency and anaemia[6]. Less frequently, when erosion or ulceration of the tumour occurs, patients can present with melena or haematemesis. These findings are usually described in BGA occurring beyond the first portion of the duodenum, probably because these lesions are subjected to more stress and vascular damage from gastrointestinal motility[6]. In our case, the patient referred to our unit for a self-limiting episode of melena and showed a large polyp at EGDS with a short peduncle localised in the duodenal bulb with an ulcer scar on the surface.

Aetiology and pathogenesis of BGA still remain to be elucidated. Due to the "anti-acid" function of Brunner's glands, it has been postulated that an increased acid secretion could stimulate these structures to undergo hyperplasia[7]. Franzin *et al* [8] have reported an association between BGA and hyperchlorhydria in patients with chronic gastric erosions and duodenal ulcers, but Spellberg *et al*[9] have not found regression of the lesion with acid secretion inhibitors[9]. A second hypothesis suggests that this lesion is of inflammatory origin due to the presence of a dense inflammatory cell infiltration[10]. Since lymphocytes are usually present in the normal submucosa of the intestinal tract, the presence of inflammatory foci in the BGA is not sufficient to sustain the "inflammatory hypothesis". Finally, it has been suggested that *H pylori* infection may play a role in the pathogenesis of BGA. In a recent study involving 19 100 subjects, *H pylori* infection was found in five out of seven (71%) BGA cases[11]. In our patient, *H pylori* infection was not found. The extreme rarity of BGA and the high prevalence of *H pylori* infection in general population do not allow us to draw a clear pathogenetic link. At present, the most accredited pathogenetic hypothesis remains that BGA is a duodenal dysembryoplastic lesion or hamartoma[12].

The duodenal bulb is the most frequent localization of BGA (57%) [13]. In the majority of cases, these lesions develop into a polypoid mass, usually pedunculated (88%), being 1 to 2 cm in size[14] while few cases reaching several centimetres as the "giant BGA" have been reported[6,15-18]. On the other hand, lesions < 1 cm are referred to as Brunner's gland hyperplasia[19].

Diagnosis of BGA is not always easy at present. Radiological findings (X-ray and computed tomography) are often non specific[12]. Indeed, the duodenal filling defect can mimic several other lesions, such as leiomyoma, lipoma, lymphoma, aberrant pancreatic tissue or carcinoid tumours[20]. Computed tomography is useful only to confirm the absence of extra-luminal extension of BGA[20]. Diagnosis can be obtained by histological examination of the excised mass. Traditional endoscopy of pinching biopsies is usually negative since the biopsy forceps are unable to reach the tumoral tissue localized completely in the submucosa layer [21]. In our case, diagnosis was made on endoscopic biopsy samples of duodenal mass, because Brunner's gland hyperproliferation was extended beyond muscularis mucosae reaching lower portion of duodenal villi (Figure 2).

Endoscopic or surgical removal of BGA has been suggested to prevent the development of complications (haemorrhage, severe anaemia, obstruction or intussusception). Endoscopic polypectomy represents the ideal approach, which is more cost-effective and less invasive of the abdominal surgery [22, 23]. However, the success depends on site and size of the BGA and presence of a peduncle. Several cases of successful endoscopic resections have been reported [12, 24-26]. In our case, even though the lesion was large (3 cm × 4 cm) with a short peduncle occupying entirely the duodenal bulb (Figure 1), endoscopic polypec-

tomy was effective for the treatment of BGA, without complication and recurrence of the lesion during the 6-month follow-up.

Abstract

Hepatocellular carcinoma (HCC) is a so highly invasive tumor that metastasizes hematogenously and lymphogenously to distant site. Frequent sites are lung, regional lymph node, bone, and adrenal gland. But metastasis to the gastrointestinal (GI) tract is rare, and most common site is stomach. Metastasis to the small intestine is extremely rare. Moreover, metastatic HCC of the small bowel causing intussusception has not been reported until now. Here, we report a case of metastasis of HCC to the small bowel manifested by intussusception.

Key words: Hepatocelluar carcinoma; Small bowel metastasis; Intussusception

INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly malignant tumor with frequent metastasis. Extrahepatic metastases have been reported in 25 to 65 percent of autopsy series, with lung, bones, and regional lymph nodes as the most commonly involved sites[1-5]. Metastasis of HCC to the gastrointestinal (GI) tract is rare and most common site of metastasis is reported stomach by direct invasion of tumor[4,5]. The distant hematogenous metastasis of HCC to the small intestine is extremely rare[6].

The majority of adult intussusceptions arising in the small bowel are due to benign lesions, and metastatic melanoma is the most frequent malignancy causing small bowel intussusception[7]. Intussusception caused by the metastatic HCC to the small bowel has not been reported until now. We report a case of metastasis of HCC to the small bowel manifested by intussusception.

CASE REPORT

A 65-year-old man was referred to emergency room with complaint of sudden onset, cramping periumbilical pain for 2 d. The pain was continuous with frequent exacerbation, and was associated with nausea and vomiting. The patient had been assigned a diagnosis of hepatitis B virus associated cirrhosis 3 years previously. Two months before, he was diagnosed as HCC with multiple bones and regional lymph nodes metastases according to the large enhanced hepatic mass on computed tomography scan with elevated level of serum alpha-fetoprotein (629 μg/L). On physical examination, the abdomen was distended, with provocable pain in the periumbilical area and increased bowel sound. Complete blood cell count revealed anemia (Hb 72 g/L) and leukocytosis (15.1×10^9/μL). Liver function tests and renal function test were not remarkable. Plain radiography of abdomen demonstrated presence of marked distension of bowel loops with air fluid level and absence of colonic gas, which were known as a characteristic finding of small bowel obstruction (Figure 1). Computed tomography scan showed ill defined hepatic mass with regional lymph node enlargement and a "target mass" lesion in the right lower abdomen (Figure 2). Abdominal ultrasound showed 10 cm long intussusception in the mid small bowel level (Figure 3A) and a small mass which was suspected of leading point of intussusception was also observed at the head of intussusception (Figure 3B).

After five days of conservative management, segmental small bowel resection and end-to-end anastomosis was performed. At surgery, intussusceptional segment was located at the level of jejunum 110 cm distal from the Treitz

Figure 1 Plain radiography of abdomen showed stepladder appearance.

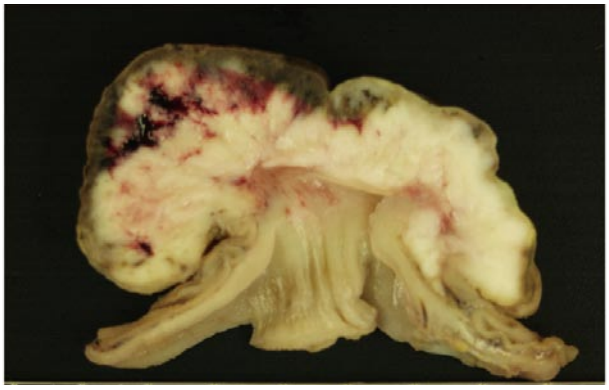

Figure 4 Surgical specimen showed that mass arising from submucosa grown into lumen and had dimpling portion on the top of tumor.

Figure 2 Computed tomography scan showed a "target mass" lesion (arrow) in the right lower abdomen, representing the intussuscepted mesenteric fat and vessel.

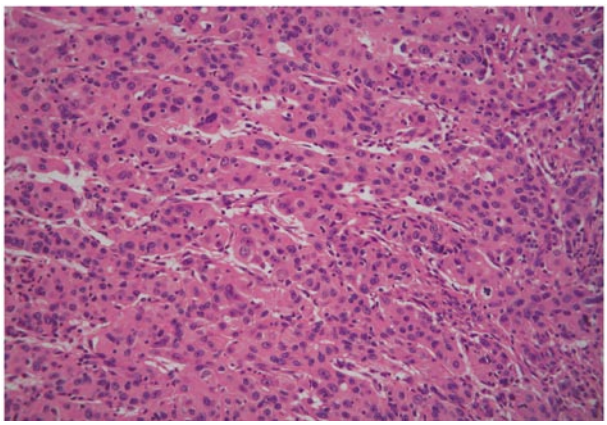

Figure 5 Histological examination demonstrated a poorly differentiated adenocarcinoma with hepatoid feature of trabecular pattern (HE X 100).

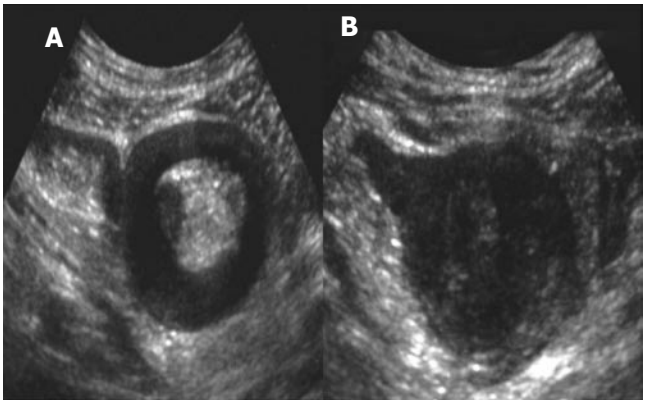

Figure 3 Abdominal ultrasound showed, **A:** "pseudo kidney sign" at the body of intussusception, **B:** Lobulated mass lesion at the head of intussusception, which was suspected of leading point of intussusception.

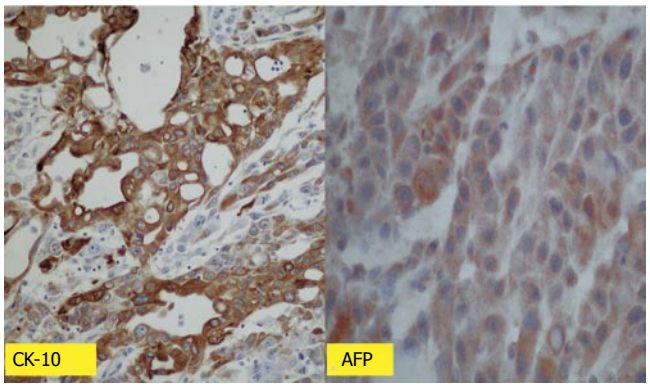

Figure 6 Strongly positive staining for alpha-fetoprotein and cytokeratin 18 (Immunoperoxidase × 100).

ligament and 8 cm sized protruding mass was grown into the lumen of small intestine within intussusceptional segment. Other three masses which measured 0.5 cm, 0.8 cm, and 3 cm respectively were also grown into the lumen at the level of jejunum 170 cm distal from the Treitz ligament.

Macroscopic examination of the surgical specimen showed multiple luminal protruding submucosal mass with extension to the subserosa (Figure 4). The largest mass measured 3.0 cm × 2.0 cm × 0.8 cm. In microscopic examination, the atypical epithelial cells were poorly differentiated carcinoma with hepatoid feature of the trabecular pattern (Figure 5). There tumor cells were positive for alpha-fetoprotein and cytokeratin 18 on the immunohistochemical staining (Figure 6). These evidences supported HCC metastasis to small bowel.

DISCUSSION

HCC is so highly invasive that extrahepatic metastasis is frequently observed [2,5]. The most common site of metastasis is lung, followed by regional lymph node, adrenal gland and bone. HCC metastasis to gastrointestinal tract is a rare condition, being found only in 4-12% of cases in autopsy series[5]. These metastatic lesions are usually asymptomatic, and most are discovered on postmortem examination[8]. Reports of premoterm diagnosis of GI tract involvement in HCC are extremely rare and are associated with poor prognosis[8,9]. Chen *et al* reported that median survival following the diagnosis of GI tract involvement in HCC was only one month[8].

The modes of metastasis of HCC are known as hematogenous, lymphatic spread and local infiltration[8]. The presumed mode of metastasis of HCC to GI tract is mostly direct invasion to adjacent GI tract via adhesion to the serosal side by bulky mass. Lin *et al.* reported that nine of eleven patients with HCC represented direct invasion of HCC to adjacent GI tract[9]. In Park's series, the mode of spread was direct invasion from a contiguous HCC (66.7 %), hematogenous metastasis (17%), peritoneal seeding (6%)[10]. Characteristic features of HCC with direct involvement of GI tract were large, located at the subcapsular area, and had exophyting growth pattern[9,10]. HCC has a high incidence of venous invasion and thrombosis formation. Hematogenous spread of HCC to the GI tract may be caused by tumor thrombi via the portal system and disseminated by hepatofugal portal spread to the GI tract. In previous reports, most of patients with hematogenous metastasis of HCC to the GI tract showed main portal vein thrombosis[8,9]. But in some cases, vascular involvement was not observed. In our case, the presumed mode of metastasis to small intestine was hematogenous spread. However despite of bulky mass with multiple bone metastases, main portal vein thrombosis was not observed.

The most commonly involved site of the GI tract in HCC was reported to be the stomach[9]. The small intestine can often be involved in tumors such as melanoma, carcinoma of the lung, cervix of the uterus, the breast, and colon[11,12]. HCC metastasis to small intestine was rarely reported. Few cases with the involvement of the duodenum have been reported, but in those cases, the duodenum was directly invaded by tumor in the liver[6, 8-10]. In our case, HCC metastasized to jejunum by hematogenous spread and formed multiple polypoid masses.

Metastatic tumors in the small intestine predominantly involve the bowel wall, the subserosa, the serosa or the mesentery. But submucosal involvement is rare. According to Farmer and Hawk, metastatic masses to small bowel are divided into three types: (1) spherical mesenteric masses encroaching on or extension into the intestine, (2) intramural masses, often with ulceration; and (3) bulky polypoid masses extending into the bowel lumen [11]. Polypoid lesions are resulted from mucosal or submucosal involvement rather than intramural involvement. In the present case, histological examination showed that polypoid mass sprouted from submucosa and extended to serosa. This finding suggested that the main metastatic site of HCC was the submucosa of the small intestine.

Intussusception, although common in children, is rare in adults and represents 1% of cause of small bowel obstruction in adult [13]. Adult intussusception presents with a variety of acute, intermittent, and chronic symptoms mimicking partial small bowel obstruction[14]. Thus, the diagnosis of intussusception is difficult to make before surgery and computed tomography scan is the most useful diagnostic tool. In distinction to intussusception in children, intussusceptions in adults are mainly resulted from organic lesion. The most common cause of benign lesion was postoperative band and malignant lesions were mainly consisted of metastatic tumor[13]. In previous report, melanoma was the most common tumor of small intestine and lymphoma, followed by sarcoma, squamous cell carcinoma[13]. In our case, cause of small bowel intussusception was diagnosed as metastatic HCC by pathologic examination.

We reported an extremely rare case of metastatic HCC to small intestine, which caused small bowel intussuception in adult. Up to our knowledge, this is the first case report of small bowel intussuception resulting from HCC metastasis.

Abstract

Little is known about the long-term survivors of acute arsenic intoxication. We present here a clinical case report of a man with chronic hepatitis B virus (HBV) infection who developed hepatocellular carcinoma four years after acute arsenic poisoning. HBsAg was detected in serum in 1990 when he voluntarily donated blood. In 1991, the patient suffered from severe psychological depression that led him to attempt suicide by massive ingestion of an arsenic-containing rodenticide. He survived with polyneuropathy and paralysis of the lower limbs, and has been wheelchair-bound since then. During participation in a follow-up study conducted among HBV carriers, abdominal ultrasound detected a two-centimeter liver mass consistent with hepatocellular carcinoma. The tumor was confirmed by computed tomography (CT) and magnetic resonance image (MRI). Because of his significant comorbidity, the patient received palliative treatment with transarterial lipiodol chemoembolization (TACE) on three occasions (1996, 1997 and 1999). At his most recent visit in May 2005, the patient was asymptomatic, liver enzymes were normal and the tumor was in remission on ultrasound.

INTRODUCTION

Arsenic is a recognized human carcinogen established by the International Agency for Research on Cancer[1]. Chronic arsenic intoxication has been associated with skin lesions (such as hyperpigmentation, hyperkeratosis and carcinoma) and liver disease (non-cirrhotic portal hypertension, hepatocellular carcinoma and angiosarcoma). Moreover, chronic arsenic exposure is associated with a higher frequency of diabetes mellitus, ischemic heart disease and hypertension[2-4]. Epidemiological studies mainly involving cohorts of chronic arsenic-exposed subjects suggest that chronic arsenic intoxication increases the risk of developing liver cancer as compared with non-exposed populations[5,6].

Patients who survive the initial effects of acute arsenic exposure may develop peripheral neuropathy and encephalopathy[7]. Hepatic injury is uncommon but is associated with severe liver disease and high mortality[8]. Little is known about the long-term survivors of acute arsenic intoxication.

We present here a clinical case report of a Caucasian man with chronic hepatitis B virus (HBV) infection who developed hepatocellular carcinoma four years after acute arsenic poisoning.

CASE REPORT

The man born in 1947 was obese with no HBV carriers

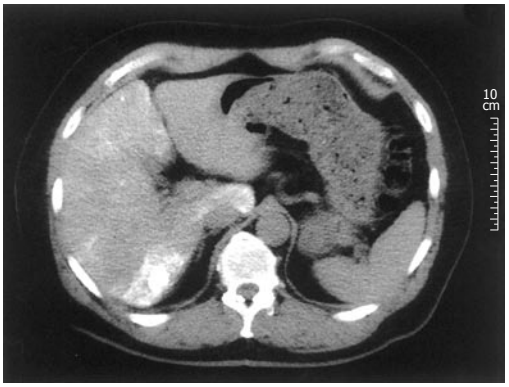

Figure 1 Non-contrast CT one month after arterial chemoembolization with iodized oil (Lipiodol) and doxorubicine emulsion. CT shows a 2-cm nodule with dense Lipiodol enhancement in segment VI (arrow), consistent with hepatocellular carcinoma.

Figure 2 Follow-up contrast-enhanced CT five years later from 1995 shows a small hypervascular lesion (arrow) in segment VI consistent with residual tumor. Tumoral Lipiodol retention was absent and the size of the lesion was significantly decreased.

in his family and no previous hepatitis or parenteral drug use. He was a heavy smoker and alcohol consumer before 1987. HBsAg was detected in serum in 1990 when he voluntarily donated blood.

In 1978 he had self-limited cardiac arrhythmia because of stress and in 1991 arrhythmia due to atrial fibrillation that reverted with cardioversion. In 1991, the patient suffered from severe psychological depression that led him to attempt suicide by massive ingestion of an arsenic-containing rodenticide. He developed acute renal failure and generalized paralysis and was hospitalized for 11 days in the intensive care unit, requiring assisted ventilation and chelation therapy with dimercaprol. He survived with polyneuropathy and paralysis of the lower limbs, and has been wheelchair-bound since then. In 1994 and 1995 he suffered from several transient ischemic attacks that were managed with chronic decoagulation therapy. In 2000 diabetes was diagnosed. He also required long-term treatment for sleep apnea-hypoapnea syndrome with automatic continuous positive airway pressure.

In November 1995 he was invited to participate in a follow-up study conducted in HBV carriers[9]. The viral serology results were negative for HBsAg, anti-HBs, HBeAg, IgM-anti-HBc, and positive for anti-HBe, IgG-anti-HBc. Serum HBV-DNA was negative by PCR technique, while anti-HDV, anti-HCV and anti-HIV were all negative. ALT was 1.36 μKat/mL (normal <0.5 μKat/mL), AST and alpha-fetoprotein were normal. Abdominal ultrasound detected a pattern suggestive of chronic liver disease and a liver mass two centimeters in diameter consistent with hepatocellular carcinoma. The tumor was confirmed by computed tomography (CT) scanning and magnetic resonance imaging. Because of his comorbidity, the patient was not considered eligible for liver transplant or hepatectomy. Palliative treatment with transarterial lipiodol chemoembolization (TACE) was performed on three occasions (1996, 1997 and 1999) (Figure 1) with clinical, analytical and imaging follow-up studies (Figure 2). At his last visit in May 2005, he was asymptomatic, liver enzymes were normal and the tumor was in remission on ultrasound imaging.

DISCUSSION

To the best of our knowledge, this patient is the first known case of liver tumor developed after acute arsenic exposure. Standard chelation treatment for acute intoxication could not remove arsenic from intracellular sites because of its lipophobic nature, suggesting that this treatment cannot protect cells from long-term clinical consequences[10]. As has been described, the presence of intracellular arsenic may be related to the development of diabetes, arterial hypertension, ischemic arterial disease and liver cancer in such patients. It should also be taken into consideration that intraindividual variability in arsenic methylation can increase susceptibility to arsenic-induced cancer[11].

Given the fact that the patient was obese and had occult HBV infection (his anti-HBc and anti-HBe positive status could indicate integration of the virus in the host genome) prior to arsenic intake, we are not sure that some hepatic injury is not due to these risk factors[12,13]. The presence of these risk factors may enhance the hepatic lesion and the development of liver cancer.

Angiosarcoma is the type of liver tumor most often related with chronic arsenic exposure[5]. In our case, histological confirmation of the liver tumor could not be performed due to the anticoagulant treatment (Sintrom®). However, the features of the tumor on CT and TACE are consistent with hepatocellular carcinoma, particularly when the tumor characteristics are considered after lipiodol uptake during and after TACE[14]. Even though the most effective therapy for hepatocellular carcinoma is liver transplantation or partial hepatectomy[15], our patient remains asymptomatic after nine years of TACE treatment. This fact is consistent with the increasing survival rates of patients receiving this palliative treatment[16].

In conclusion, this is the first patient with occult HBV infection who developed hepatocellular carcinoma after acute arsenic exposure, and his tumor remitted after palliative treatment with TACE. The clinical implication of our observation is that periodical liver studies should be undertaken in patients who survive after acute arsenic exposure.

Abstract

Mucinous cystadenoma of the appendix is a rare condition and represents one of the three entities with the common name mucocele of the appendix. It is characterized by a cystic dilatation of the lumen with stasis of mucus inside it. Histopathologically mucocele is divided into three groups: focal or diffuse mucosal hyperplasia, mucinous cystadenoma and mucinous cystadenocarcinoma. This condition is often associated with other neoplasia, especially adenocarcinoma of the colon and ovaries. We here describe a 57 year old male patient who presented with abdominal discomfort, constipation, fresh blood in stool and frequent urination. He had a big cystadenoma of the appendix associated with adenocarcinoma of the colon and hepatocellular carcinoma of the liver. The patient underwent right haemicolectomy, sigmoid colon resection and segmental resection of the liver. Now 3 years later he has no evidence of disease relapse. According to this, we stress the need of accurate preoperative diagnosis and intraoperative exploration of the whole abdomen in these patients.

INTRODUCTION

Mucocele of the appendix is a common name for three different entities with similar clinical presentations. Its main characteristic is cystic dilatation of the appendiceal lumen with mucus inside it. Focal or diffuse mucosal hyperplasia and mucinous cystadenoma are of benign nature, but could lead to complications due to rupture, invasion to adjacent organs or recurrence. Mucinous cystadenocarcinoma is a malignant disease and pseudomyxoma peritonei is its worst complication. On the other hand, this condition is often associated with other intra-abdominal neoplasia. According to this, it is necessary to apply strict oncologic principles for resection in order to minimize the possible complications. A correct preoperative diagnosis may help to avoid iatrogenic rupture during surgery and missing the possible associated intra-abdominal tumors. We describe here a case of correct preoperative diagnosis of big appendiceal mucinous cystadenoma associated with adenocarcinoma of the sigmoid colon and hepatocellular carcinoma of the liver.

CASE REPORT

The patient was male, 57 years old with pain in ileo-cecal region for 6 mo prior to administration. He had abdominal discomfort, constipation, fresh blood in stool and frequent urination. On physical examination he had palpable tumor mass in the lower right quadrant of abdomen, enlarged liver and subicterus of sclera. Laboratory findings showed inflammatory syndrome with sideropenic normocytic anemia, elevated alkaline phosphatase, carcinoembryonic antigen, carboanchidratic 19-9 antigen and alpha-feto protein. He had negative markers for hepatotropic viruses (B and C). Transabdominal sonography showed the presence of a large bilocular cystic tumor in the right lower quadrant of abdomen with outlined capsule and maximal dimensions of 106 mm × 74 mm, slightly enlarged liver with focal hyperechogenous tumor in the 6th and 7th liver segments (maximal diameter of 67 mm) and "pseudokidney" sign in the left lower quadrant of abdomen. CT scan displayed tumor of the right liver lobe (Figure 1). Barium enema showed extra luminal compression and medial displacement of cecum and terminal ileum with appendix not filled with the contrast and 4-cm long tubular stenosis of the proximal part of

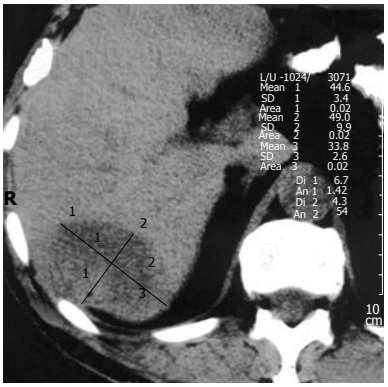

Figure 1 Abdominal CT showing presence of the right lobe tumor of the liver.

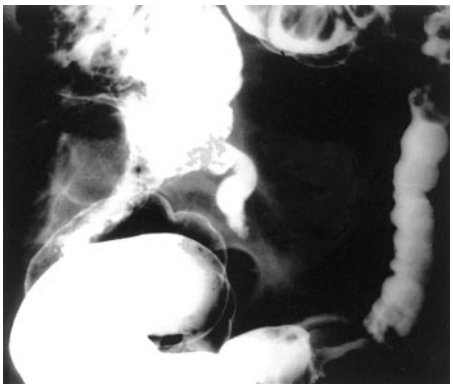

Figure 2 Barium enema displaying extraluminal compression and medial dislocation of the cecum due to cystadenoma of the appendix and tubular stenosis of the sigmoid colon due to the adenocarcinoma.

sigmoid colon (Figure 2). According to that we suspected that it was the mucocele of the appendix with neoplasia of the sigmoid colon and hepatic tumor. The patient underwent right haemicolectomy with ileo-transverso termino-lateral anastomosis and sigmoid colon resection with colo-recto termino-terminal anastomosis as well as paraaortal and paracaval lymphadenectomy. Segmetal resection of the liver (the 6th and 7th segments) was done and the whole tumor was resected. Histology showed big mucocele of the appendix caused by mucinous cystadenoma with severe displasia (Figure 3 and Figure 4), adenocarcinoma of the sigmoid colon (T3,N1,M0,L1,V0; Dukes C; Astler-Coller C-2) and carcinoma hepatis hepatocellulare (well-differentiated alveolar type). Adjuvant therapy with 5-fluorouracile and Leucovorine was administrated in five cycles. Now, three years later, the patient is doing well and has gained 17 kilograms with no evidence of disease relapse and his laboratory findings including tumor markers are within the normal range.

DISCUSSION

Mucocele of the appendix is a descriptive term that implies a dilated appendiceal lumen caused by abnormal accumulation of mucus. Mucocele is found in 0.2-0.3% of all appendectomy specimens. The male:female ratio is 1:4 and the mean age of patients is around 55 years[1,2]. Post-imflammatory obstruction was initially thought to be the main reason for the majority of mucoceles, but recent evidence suggests that neoplasia is the basis of most of these cases. The understanding of the nature of appendiceal mucocele and its terminology has been

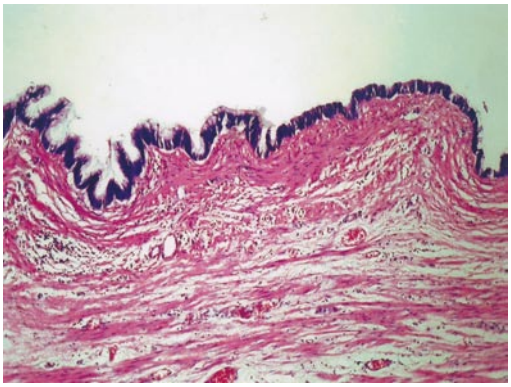

Figure 3 Cystadenoma mucinosum appendicis with obvious dysplastic epithelial lining and focally evident mucinous cytoplasmatic production (H&E, 64x).

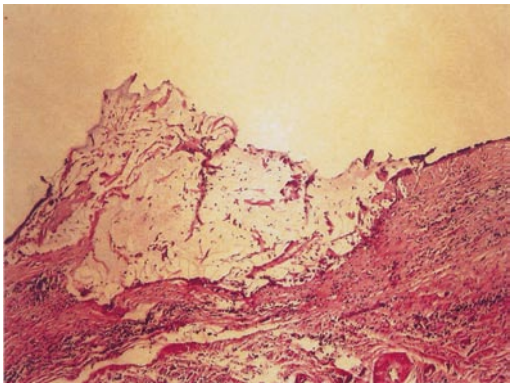

Figure 4 Cystadenoma mucinosum appendices with small extracellular mucinous deposit just beneath focally eroded adenomatous epithelium (H&E, 13x).

greatly changed since the initial description of Rokitansky in 1842[3] and Higa *et al*[4] in 1973. Appendiceal mucocele can be histologically divided into three groups: focal or diffuse mucosal hyperplasia without epithelial atypia, mucinous cystadenoma with some degree of epithelial atypia and mucinous cystadenocarcinoma. A large series of hyperplasia were found in 24.7% cystadenoma, 63% cystadenocarcinoma and 12.3 % of all cases[1,2,4]. Our case could be regarded as mucinous cystoadenoma with severe dysplasia.

Peritoneal (and/or retroperitoneal and pleural) pseudomyxoma is regarded as a worst complication of this disease which could have metastatic characteristics in case of mucinous adenocarcinoma. It is well known that this entity is often associated with colorectal carcinoma (11-20%), ovarian mucinous cystadenoma, uterine myoma, carcinoma of the pancreas and carcinoid tumor of the appendix[4]. Our patient is interesting because of the two associated tumors while one of them (hepatocellular carcinoma) has not so far been mentioned in literature in association with mucinous cystadenoma.

Clinical symptomatology of these patients is not specific. Abdominal pain is present in 64% of the patients and palpable ileo-cecal mass in 50% of them. Disease course is asymptomatic in 25% of the patients even when they have large tumors. Urinary infection and haematuria

are often associated (20%)[5]. Intestinal obstruction caused by intussusception and intestinal bleeding are rare complications[6]. Our patient had a long history of abdominal pain, blaunting, subicterus and urinary discomfort, constipation and rectal bleeding. Some of these symptoms are due to associated tumors.

Laboratory findings are usually non specific, but the elevation of tumor marker level often indicates neoplastic origin and/or associated tumors, which was seen in our patient.

Correct and complete preoperative diagnosis was rare in the past, but modern techniques of imaging allow us today to recognise most of the complications and associated conditions[7]. Sonography usually shows a cystic encapsulated lesion with liquid content adjacent to cecum. CT/NMR scan shows a low density, encapsulated, thin-walled mass that does not contain contrast medium and communicates directly with the cecum. Other solid or cystic abdominal and peritoneal tumors could also be visualised by these methods. Barium enema could point out a failure of the appendix to fill with contrast medium and signs of the extra luminal compression in the ileocecal region[8,9]. The "sign of volcano" is a pathognomonic colonoscopy finding[8,9]. We could not perform total colonoscopy due to neoplastic stenosis of the sigmoid colon.

Fine needle aspiration biopsy is not recomended because of great risk of pseudomyxoma dissemination.

Classical surgical approach is the best therapy option with intraoperative abdominal cavity exploration because of the already stressed associated tumors. Appendectomy is advised for focal or diffuse mucosal hyperplasia and cystadenoma when the appendiceal base is intact. Cecal resection is performed for cystadenoma with a large base and right colectomy is recommended for cystadenocarcinoma. Other surgical procedures depend upon the existence of associated tumors. In cases of disseminated pseudomyxoma peritonei, ultrasonic surgical aspirator can be used[10, 11]. Laparoscopic approach to cystadenoma of the appendix is safe if surgery can be performed without grasping the lesion and if the specimen is removed through the abdominal wall using a bag[12].

The five-year survival rate is 100% in cases of benign mucocele and about 45% in malignant cases. Radiotherapy, chemotherapy and new therapeutic modalities (radioimmunotherapy and matrix metalloproteinase inhibitors) have still to be proven by prospective analysis[13].

In conclusion, accurate preoperative diagnosis and intraoperative exploration of the whole abdomen can improve the prognosis of patients with appendiceal mucocele.

ACKNOWLEDGMENTS

The authors thank Professor Božina Radević, PhD, surgeon, Institute for Cardiovascular Diseases Dedinje, Belgrade and Professor Ivan Boričić, PhD, pathologist, Institute for Pathology, Belgrade, for their kind help.

TO THE EDITOR

Rituximab is a chimeric monoclonal antibody against CD20 antigen expressed on most B cells and is used for the treatment of malignant lymphomas expressing the CD20 antigen[1]. It temporarily eliminates normal B-lymphocytes without a substantial decrease in serum immunoglobulin levels[2]. Recently, several serious viral infections have been reported in association with rituximab use. Cytomegalovirus (CMV) is one of the agents that may be a cause of morbidity and mortality in immunocompromised individuals[2, 3]. In the face of exogenous or endogenous causes of immunosuppression, cytomegalovirus can result in retinitis, colitis, pneumonitis, or encephalitis. Presented here is a case of a patient with non-Hodgkin's lymphoma (NHL) who developed gastritis and enterocolitis due to CMV infection after treatment with rituximab.

A 65-year old female patient was admitted with complaints of epigastric pain and diarrhea. Prior to her admission she was treated for diffuse large cell type NHL, stage IIIB bulky disease with six courses of a regimen consisting of cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) and rituximab, and a good partial response was achieved. Due to the presence of bulky disease at presentation, she also received radiotherapy (RT) to the parailiac and inguinal regions at a dose of 3000 centigray (cGy), one month after chemotherapy. Two weeks after radiotherapy, she presented with epigastric pain and diarrhea without blood and mucous. Microscopic examination of stool specimens was unremarkable. Her blood and stool cultures were negative. Her chest X-ray was also normal. Initial investigations revealed normal hemoglobin concentration and platelet count as well as mild leucopenia. The number of white blood cells was 3.6×10^9/L (3.0×10^9/L neutrophils). Serum levels of glucose, amylase, liver transaminases, urea and electrolytes were normal. Based on the preliminary diagnosis of radiation enteritis, antidiarrheal therapy was initiated. The patient did not benefit from this, and her epigastric pain aggravated. A computerized tomography scan of the abdomen revealed gastric wall thickening as well as findings consistent with colitis of the ascending and transverse colon. Subsequent upper gastrointestinal endoscopic evaluation demonstrated multiple linear exudative gastric ulcers, the largest being 4 cm in diameter, from which multiple biopsy specimens were obtained. Histological examination revealed hyperchromatic epithelial cells with nuclear viral inclusions (owl's eye). These cells were positive for monoclonal antibodies against CMV. However, peripheral blood CMV viral load was negative. She failed to respond to acid suppression therapy and her clinical condition deteriorated further. Repeat upper gastrointestinal endoscopy and histological examination of biopsy specimens were consistent with the previous results. Consequently, treatment with intravenous gancyclovir (2×5 mg/kg) was initiated with a diagnosis of CMV gastritis and enterocolitis. Dramatic clinical improvement was achieved within one week and treatment was continued for 3 weeks. Her symptoms resolved completely and a subsequent endoscopy only showed signs of healing ulcers.

Pelvic or abdominal RT is a known cause of acute enteritis characterized by abdominal cramping and diarrhea in approximately 50% of treated patients, and the incidence is higher with concomitant chemotherapy[4]. Acute intestinal side effects of RT occur at doses of approximately 1000 cGy. Since the curative doses for most abdominal or pelvic tumors range between 5000 and 7000 cGy, enteritis is more often than not likely to occur[5]. Our patient received 3000cGy of RT and probably developed RT-induced enteritis. However, antidiarrheal therapy with oral opiates failed to alleviate the patient's complaints, which only resolved after anti-CMV therapy.

Cytomegalovirus enterocolitis should be considered in the differential diagnosis in patients receiving rituximab

whose symptoms fail to resolve after conventional anti-diarrheal therapy, irrespective of peripheral blood CMV viral load.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc.*, from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Published by
The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm×210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission
Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission
Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm×210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office
World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page
Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract
An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc.* should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words
Please list 3-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text
For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations
Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm×76 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables
Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations
Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments
Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system (http://www.aushome.cn/cgi-bin/index.pl), the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.aushome.cn/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Format

Standard journal article (list all authors and include the PubMed ID [PMID] where applicable)

1 **Das KM,** Farag SA. Current medical therapy of inflammatory bowel disease. *World J Gastroenterol* 2000; 6: 483-489 [PMID: 11819634]

2 **Pan BR**, Hodgson HJF, Kalsi J. Hyperglobulinemia in chronic liver disease: Relationships between *in vitro* immunoglobulin synthesis, short lived suppressor cell activity and serum immunoglobulin levels. *Clin Exp Immunol* 1984; 55: 546-551 [PMID: 6231144]

3 **Lin GZ,** Wang XZ, Wang P, Lin J, Yang FD. Immunologic effect of Jianpi Yishen decoction in treatment of Pixu-diarrhoea. *Shijie Huaren Xiaohua Zazhi* 1999; 7: 285-287

Books and other monographs (list all authors)

4 **Sherlock S,** Dooley J. Diseases of the liver and billiary system. 9th ed. Oxford: Blackwell Sci Pub, 1993: 258-296

Chapter in a book (list all authors)

5 **Lam SK.** Academic investigator's perspectives of medical treatment for peptic ulcer. In: Swabb EA, Azabo S. Ulcer disease: investigation and basis for therapy. New York: Marcel Dekker, 1991: 431-450

Electronic journal (list all authors)

6 **Morse SS.** Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1):24 screens. Available from: URL: http//www.cdc.gov/ncidod/EID/eid.htm

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, *p*(B)= 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*

Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*

Biology: *Helicobacter pylori, H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

It is the policy of *WJG* to acquire copyright in all contributions. Papers accepted for publication become the copyright of *WJG* and authors will be asked to sign a transfer of copyright form. All authors must read and agree to the conditions outlined in the Copyright Assignment Form (which can be downloaded from http://www.wjgnet.com/wjg/help/9.doc).

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.

EDITORIAL and LETTERS TO THE EDITOR are free of change.

Abstract

Acute pancreatitis is generally believed to be a disease in which the pancreas is injured by digestive enzymes that it normally produces. Most of the potentially harmful digestive enzymes produced by pancreatic acinar cells are synthesized and secreted as inactive zymogens which are normally activated only upon entry into the duodenum but, during the early stages of acute pancreatitis, those zymogens become prematurely activated within the pancreas and, presumably, that activation occurs within pancreatic acinar cells. The mechanisms responsible for intracellular activation of digestive enzyme zymogens have not been elucidated with certainty but, according to one widely recognized theory (the "co-localization hypothesis"), digestive enzyme zymogens are activated by lysosomal hydrolases when the two types of enzymes become co-localized within the same intracellular compartment. This review focuses on the evidence supporting the validity of the co-localization hypothesis as an explanation for digestive enzyme activation during the early stages of pancreatitis. The findings, summarized in this review, support the conclusion that co-localization of lysosomal hydrolases with digestive enzyme zymogens plays a critical role in permitting the intracellular activation of digestive enzymes that leads to acinar cell injury and pancreatitis.

Key words: Acute pancreatitis; Digestive enzymes; Pancreatic acinar cells

van Acker G JD, Perides G, Steer ML. Co-localization hypothesis: A mechanism for the intrapancreatic activation of digestive enzymes during the early phases of acute pancreatitis. *World J Gastroenterol* 2006; 12(13): 1985-1990

INTRODUCTION

Acute pancreatitis is an inflammatory disease of the pancreas which, in its severe forms, leads to varying degrees of pancreatic necrosis. Passage of a biliary tract stone into or through the terminal biliopancreatic ductal system is the most frequent inciting cause for clinical acute pancreatitis and studies performed using an opossum model of biliary acute pancreatitis have suggested that the offending stone triggers pancreatitis by obstructing drainage from the pancreatic duct[1]. Other studies performed using that same model have indicated that the earliest changes of pancreatitis occur within the acinar cells of the pancreas and that periductal as well as perilobular changes, including cell injury and inflammation, occur at later times[2].

The morphological changes of acute pancreatitis suggest that an autodigestive process has occurred and, indeed, activated digestive enzymes can be detected within the pancreas during clinical acute pancreatitis. Activated digestive enzymes can also be detected within the pancreas during the very early stages of most experimental pancreatitis models. Since the pancreas normally synthesizes and secretes many potentially harmful digestive enzymes, it is generally believed that it is the premature, intrapancreatic activation of those pancreas-derived enzymes which, ultimately, leads to cell injury and acute pancreatitis. However, for the most part, the potentially harmful digestive enzymes that are synthesized and secreted by the pancreas are present, within the gland, as inactive pro-enzymes or zymogens and activation of those zymogens normally occurs only when they reach the duodenum. How, then, might these zymogens be prematurely activated within the pancreas during the early stages of acute pancreatitis and how might that activation lead to acinar cell injury/necrosis?

Not surprisingly, these questions have prompted the performance of many studies, using various experimental models of acute pancreatitis, over the past several decades and several hypotheses have been advanced which address these questions. One of those hypotheses is the so called "co-localization hypothesis" which suggests that, during the early stages of acute pancreatitis, pancreas derived

digestive zymogens become co-localized with lysosomal hydrolases in acinar cell cytoplasmic vacuoles and that, as a result of this co-localization, lysosomal hydrolases such as cathepsin B, activate trypsinogen. According to this hypothesis, trypsin then activates the other digestive enzyme zymogens and the activated digestive enzymes gain access to the cell interior leading to the cell injury/necrosis which typify acute pancreatitis[3].

This review will summarize current evidence that supports the co-localization hypothesis. To place this hypothesis in its proper context, we will begin by briefly summarizing current concepts regarding the physiological synthesis, intracellular trafficking, and secretion of certain types of proteins by the exocrine pancreas. This will be a highly selective review which will primarily draw upon work performed by many collaborators in the authors' laboratory over the past 25 years and the contributions of those individuals are gratefully acknowledged.

PANCREATIC ACINAR CELL BIOLOGY

Protein assembly

On a "gram of protein-per-cell" basis, pancreatic acinar cells synthesize more protein than any other cell in the body. Digestive enzymes, which are secreted from the pancreas and designed to act within the gastrointestinal tract, account for most of the protein mass synthesized by acinar cells but acinar cells also synthesize many other types of proteins, including the hydrolytic enzymes that are designed to digest un-needed material within intracellular lysosomes. Both types of enzymes, secretory digestive enzymes and lysosomal hydrolases, are assembled on ribosomes attached to the rough endoplasmic reticulum (ER). As they are assembled, they elongate within the cisternae of the rough ER until a signal peptide is added and, at that point, they are cleaved freeing them to assume their tertiary structure within the ER. Many secretory digestive enzymes are synthesized as pro-enzymes or zymogens which are inactive until they are proteolytically processed following secretion. Many of the lysosomal hydrolases are also synthesized as inactive pro-enzymes but their post-translational processing and activation is accomplished within the cell.

Intracellular trafficking of secretory proteins[4]

Following their assembly within the ER, the enzymes destined for secretion are carried within small transport vesicles to the Golgi stacks where they are sorted and some are post-translationally modified. Those that are destined to be secreted in a constitutive manner are then transported to the cell surface where they exit the cell. Most of the secreted digestive enzymes and their zymogens, however, are subject to regulated discharge - i.e. they are stored within the cell until their secretion is accelerated in response to extracellular stimuli. Following their assembly and transport to the Golgi, these proteins traverse the Golgi stacks and they are then packaged within condensing vacuoles which evolve into zymogen granules as they mature and migrate towards the luminal surface of the cell. There, by mechanisms which are regulated by neurohormonal secretagogue stimuli, fusion/fission of the zymogen granule membrane with the luminal plasmalemma occurs and this leads to the formation of a fusion pore which permits the granule contents to be discharged into the extracellular (i.e. ductal) space. In an overall sense, this regulated pathway allows for the massive and rapid discharge of intracellularly stored proteins which, in the case of pancreatic acinar cells, consists primarily of digestive enzymes[5].

Intracellular trafficking of lysosomal hydrolases[6]

The lysosomal hydrolases are a group of more than 50 dissimilar acid hydrolases which function to degrade un-needed cellular material as well as material taken up by cells via either endocytosis or phagocytosis. As noted for other proteins, lysosomal hydrolases are assembled within the cisternae of the rough ER and, in common with other newly synthesized proteins, the nascent lysosomal hydrolases are transported to the Golgi complex which they traverse from its *cis* to its *trans* surface, passing through the *medial* and *trans*-Golgi subcompartments. In contrast to proteins destined for either secretion or transport to other intracellular sites, the lysosomal hydrolases are sorted from other newly synthesized proteins as they traverse the Golgi stacks by a complex mechanism in which *N*-acetylglucosamine phosphates are added to mannose residues and then the *N*-acetylglocosamine groups are removed, leaving the remaining mannose residues phosphorylated at the 6-position. Those mannose-6-phosphorylated lysosomal hydrolases are then bound to receptors in the *trans*-Golgi that specifically recognize mannose-6-phosphate residues. The mannose-6-phosphate receptors along with their associated lysosomal hydrolases are then shuttled to the pre-lysosomal compartment where, as a result of the acidic pH of this compartment, dissociation of the hydrolase/receptor complexes occurs, thereby liberating the hydrolases within the pre-lysosomal compartment and allowing the now unoccupied receptors to return to the Golgi where they are free to bind and transport additional mannose-6-phosphorylated lysosomal hydrolases. Of potential significance however, is the fact that, even under physiological conditions, sorting of lysosomal hydrolases from secretory proteins in the Golgi is incomplete and, as a result, a fraction of the newly synthesized lysosomal hydrolases enters the secretory pathway[7-9]. This fraction of the lysosomal hydrolases is subject to regulated secretion from the cell along with other secretory proteins[10]. Another fraction of lysosomal hydrolases may also be secreted from the cell by being enclosed within so-called secretory lysosomes[11]. Lysosomal hydrolases may also be constitutively secreted from the cell without ever being packaged within lysosomes.

Many of the lysosomal hydrolases are initially synthesized as inactive or only partially activated pro-enzymes. Their complete activation is achieved through post-translational processing of the pro-peptide as it undergoes intracellular transport to pre-lysosomes[12]. Together, pre-lysosomes, lysosomes, endosomes, phagosomes, and autophagosomes function as an

interconnected network of organelles which contain a wide variety of acid hydrolases capable of degrading nucleic acids, proteins, carbohydrates, and lipids.

Activation of digestive enzyme zymogens

Some of the digestive enzymes (e.g. amylase, lipase, DNAase, RNAase) are synthesized and secreted from pancreatic acinar cells as active enzymes but others, including most of the potentially harmful digestive enzymes (e.g. trypsin, chymotrypsin, phospholipase, elastase, carboxypeptidase) are synthesized as inactive pro-enzymes or zymogens. Under physiological conditions, activation of these zymogens does not occur until they reach the duodenum where the brush border enzyme enterokinase (enteropeptidase) catalytically activates trypsinogen and trypsin then catalyzes the activation of the other zymogens. In most instances, activation involves cleavage of the zymogen and release of an "activating peptide" which, prior to its release, had maintained the zymogen in its inactive state. Thus, quantitation of free activating peptide levels may provide information regarding the extent of zymogen activation prior to that measurement[13].

Protective mechanisms

In a general sense, the acinar cells of the pancreas are protected from the injury which might be inflicted by premature, intracellular activation of trypsinogen and other digestive enzyme zymogens by virtue of 3 features. The first, as noted above, is the fact that most of the potentially harmful digestive enzymes are normally present within acinar cells as inactive zymogens. The second is the fact that potent inhibitors of trypsin are synthesized and co-transported through the cell along with trypsinogen and those inhibitors are available to dampen any trypsin activity that might arise as a result of intracellular trypsinogen activation. The third protective feature of pancreatic acinar cells is the fact that, throughout their intracellular trafficking within the cell, digestive enzymes and their zymogens are sequestered from the remainder of the cell by being enclosed within membrane bounded organelles. Very recently, two reports have appeared that suggest that acinar cells may have yet another protective feature. Pancreatic acinar cells express proteinase-activated receptor-2 (PAR2) which is a tethered ligand receptor that is activated by trypsin and, as shown by Namkung *et al*[14] and Sharma *et al*[15], activation of pancreatic PAR2 triggers events that protect the pancreas from pancreatitis.

THE CO-LOCALIZATION HYPOTHESIS

History

The so-called "co-localization hypothesis" grew out of studies, performed more than two decades ago, that employed the diet-induced and the secretagogue-induced models of acute experimental pancreatitis[16-20]. Those studies had shown that digestive enzyme synthesis and intracellular transport continue during the early stages of pancreatitis, but secretion of newly synthesized digestive enzymes from acinar cells is blocked. Those studies had also shown that, prior to the appearance of evidence reflecting acinar cell injury, the normal segregation of digestive enzyme zymogens from lysosomal hydrolases is perturbed and, as a result, both types of enzymes become co-localized within intra-acinar cell cytoplasmic vacuoles. That co-localization phenomenon could be demonstrated using techniques of immunolocalization as well as using techniques of subcellular fractionation. Finally, those studies had shown that digestive enzyme zymogens, including trypsinogen, are activated within acinar cells at very early stages during the evolution of experimental pancreatitis-i.e. prior to the appearance of cell injury. Since the lysosomal hydrolase cathepsin B is known to be capable of activating the digestive zymogen trypsinogen[21,22] and, since trypsin can activate the other digestive zymogens, these various observations suggested the following 3-tiered hypothesis: (a) that perturbation of normal intracellular trafficking of digestive zymogens and lysosomal hydrolases, is a very early event during the evolution of pancreatitis and that, as a result of this perturbation, digestive enzyme zymogens become co-localized with lysosomal hydrolases within acinar cell cytoplasmic vacuoles; (b) that, as a result of this co-localization phenomenon, the lysosomal hydrolase cathepsin B (and, most likely, other lysosomal hydrolases) activates trypsinogen and trypsin activates the other zymogens; and (c) that the organelles containing intracellulary activated digestive zymogens become fragile and they release their content of activated enzymes within the cell interior where those enzymes trigger changes leading to cell injury/death[23].

Challenges

Subsequent to its initial proposal, the co-localization hypothesis was challenged on two grounds. The first was the fact that, while most lysosomal hydrolases have a pH optimum of roughly 5.0, the site of co-localization during the early stages of pancreatitis appears to have a neutral pH. Subsequent studies characterizing the pH optimum for cathepsin B, however, indicated that considerable (although perhaps not optimal) activity was also present at pH 7.0[24] and, thus, this concern regarding the co-localization hypothesis appears to be unwarranted. The second challenge to the hypothesis, however, proved to be more substantial because it focused on the issue of causality. Its advocates suggested that the co-localization phenomenon, although real, might be a response to the early injury of pancreatitis. They argued that the co-localization of digestive enzymes with lysosomal hydrolases might simply be a reaction to injury, rather than causing this injury[25]. Some even suggested that cell injury-induced co-localization might be a protective response which could allow lysosomal hydrolases to inactivate and degrade those prematurely activated digestive zymogens[26].

THE EVIDENCE THAT CO-LOCALIZATION LEADS TO ZYMOGEN ACTIVATION IN PANCREATITIS

The remainder of this review will be devoted to an

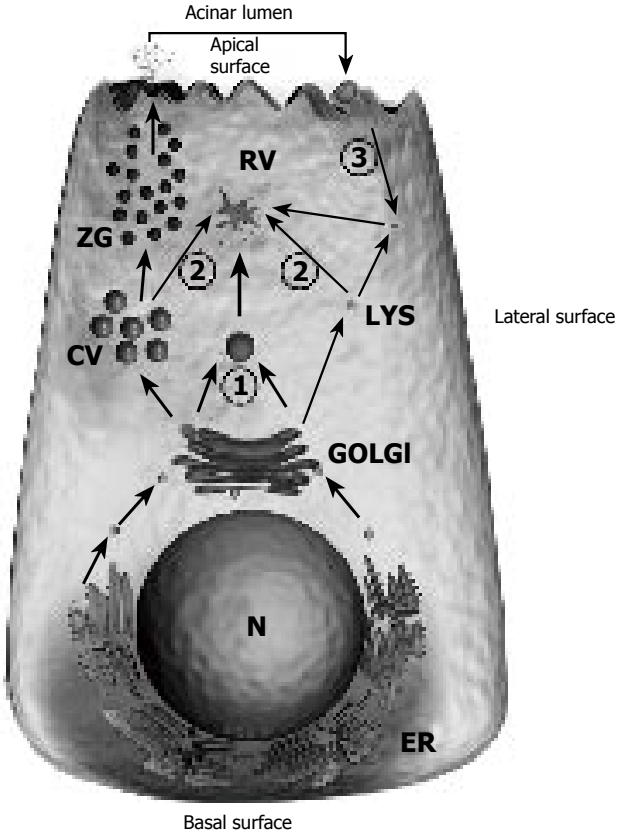

Figure 1 Acinar cell demonstrating mechanisms of co-localization. Arrows represent physiological and pathological pathways. Co-localization can occur as a result of (1) missorting of lysosomal hydrolases from digestive zymogens in the Golgi, (2) fusion of zymogen granules with lysosomes and (3) reuptake into the lysosomal compartment of secreted digestive zymogens. Note the ruptured co-localization vacuole (RV) and release of activated digestive enzymes inside the cell. (ER = endoplasmic reticulum, N = nucleus, LYS = lysosomes, CV = condensing vacuoles and ZG = zymogen granules).

examination of the evidence which suggests that the co-localization phenomenon is not simply a reaction to injury or a protective response but that it is, in fact, an early and critical event which leads to zymogen activation and acinar cell injury in pancreatitis. Ideally, studies addressing these issues would be performed using clinically derived material and patients with acute pancreatitis but, unfortunately, those studies are not possible since patients with acute pancreatitis are only identified after the very early phases of the disease have been completed and access to the pancreas of patients with early acute pancreatitis is generally not possible. Thus, by necessity, studies testing the co-localization hypothesis have all been performed using various models of acute pancreatitis in experimental animals.

Validation of the co-localization hypothesis would require fulfillment of the following 6 postulates: (1) The co-localization phenomenon should be observed in all experimental models of acute pancreatitis. (2) Lysosomal hydrolases should be capable of activating digestive enzyme zymogens such as trypsinogen. (3) During the evolution of pancreatitis, the co-localization phenomenon should occur prior to zymogen activation and cell injury. (4) The co-localization phenomenon and digestive zymogen activation should occur within the same intracellular compartment. (5) Digestive zymogen activation should be dependent upon the presence of lysosomal hydrolase activity. (6) Prevention of co-localization should interfere with zymogen activation but prevention of zymogen activation should not interfere with co-localization.

The evidence supporting fulfillment of these 6 postulates will now be summarized.

The co-localization phenomenon occurs in all models of experimental pancreatitis

As noted above, early studies performed using the diet-induced and the secretagogue (caerulein)- induced models of experimental pancreatitis and employing the techniques of both subcellular fractionation and immunolocalization, indicate that the co-localization phenomenon occurs in both of those models[16-20,9]. Subsequent studies using the rabbit model of duct obstruction[27], the closed duodenal loop model[28], and the taurocholate model of retrograde duct injection[29], indicate that the co-localization phenomenon occurs in each of those models as well. In each of these models, co-localization is an early event which can be demonstrated to occur prior to the appearance of cell injury/necrosis.

The mechanism(s) responsible for the co-localization phenomenon in each of these models appears to be different (Figure 1). In the diet-induced model, it reflects fusion of zymogen granules with lysosomes (i.e. crinophagy) while, in the secretagogue-model, it reflects both crinophagy and defective sorting of lysosomal hydrolases away from secretory proteins because of a defect in processing lysosomal hydrolases prior to their passage through the medial Golgi compartment. In the opossum model, co-localization occurs because previously secreted digestive zymogens are taken up by acinar cells via endocytosis and then transported to the endosome/lysosome compartment.

Lysosomal hydrolases such as cathepsin B can activate trypsinogen

Studies independently performed and reported by at least 3 groups of investigators have shown that cathepsin B can activate trypsinogen under in-vitro conditions[21,22,24]. The most recent of those studies evaluated the pH profile of this activation process and found that a considerable degree of activation could occur at pH 7.0[24].

The co-localization phenomenon occurs prior to acinar cell injury/necrosis

If the co-localization phenomenon is a reaction to cell injury, it should occur after changes indicative of that injury are already demonstrable while, if it is the cause of cell injury, it should occur prior to the appearance of that injury. Time-dependence studies using the secretagogue-induced model have been performed to evaluate this issue[30]. In these studies, pancreatic tissue was homogenized and subcellular fractionated to obtain zymogen granule-enriched and lysosome-enriched fractions at selected times after the start of caerulein administration. Redistribution of cathepsin B from the lysosome-enriched to the zymogen granule-enriched fraction was noted within

15 minutes after the start of caerulein administration and, at roughly this same time, evidence of trypsinogen activation (i.e. increased trypsin activity and increased pancreatic levels of trypsinogen activation peptide) was also first detected. In contrast, hyperamylasemia, pancreatic edema and acinar cell injury/necrosis were only detected at later times. Thus, these studies indicate that the co-localization phenomenon occurs prior to, and not after, cell injury in pancreatitis.

Co-localization and zymogen activation occur within the same intracellular compartment during pancreatitis

Studies addressing this issue have been performed using antibodies directed against the lysosomal hydrolase cathepsin B and antibodies directed against the peptide released during the process of trypsinogen activation (i.e. trypsinogen activation peptide, TAP). During the early stages of secretagogue-induced pancreatitis, both types of antibodies were found localized in the same cytoplasmic vacuoles[31,9,20]. Similar observations have been made in studies using antibodies directed against lysosomal membrane proteins[32]. In both cases, the site of co-localization appeared to be in the area of the *trans*-Golgi network. Taken together, these immunolocalization studies support the conclusion that co-localization and activation occur within the same intracellular compartment.

Zymogen activation and pancreatitis severity are dependent upon cathepsin B activity

This issue has been addressed in two ways. In one, cathepsin B inhibition was achieved using the cell permeant and highly specific cathepsin B inhibitor CA-074me. The effect of this inhibitor in two dissimilar models of pancreatitis (secretagogue-induced and taurocholate-induced) was evaluated[33] and, in both models, inhibition of cathepsin B was found to prevent trypsinogen activation. That inhibition was also found to reduce the severity of pancreatitis. The second approach to this issue involved the use of genetically modified mice that did not express cathepsin B and, in those mice, both trypsinogen activation and the severity of pancreatitis were found to be reduced[34]. These observations support the conclusion that cathepsin B (either alone or, perhaps with other lysosomal hydrolases) plays a critical role in trypsinogen activation during pancreatitis and that, in pancreatitis, trypsinogen activation is closely related to the severity of the disease.

Prevention of the co-localization phenomenon interferes with zymogen activation but inhibition of zymogen activation does not prevent co-localization

The co-localization of digestive zymogens with lysosomal hydrolases in both the secretagogue-induced and the taurocholate-induced models of pancreatitis is dependent upon the activity of phosphoinositide-3-kinase (PI3K) and co-localization can be prevented in those models by administration of the PI3K inhibitors wortmannin and LY49002. In a recently reported study, administration of those PI3K inhibitors was found to reduce trypsinogen activation[35]. These findings indicate that prevention of co-localization, by administration of PI3K inhibitors, can reduce zymogen activation in these models of pancreatitis.

As noted above, CA-074me is a potent in-vivo cathepsin B inhibitor and administration of CA-074me to animals can prevent trypsinogen activation during pancreatitis. To further evaluate the possible causative role of co-localization in zymogen activation, mice subjected to secretagogue-induced pancreatitis were given CA-074me and the effect of inhibiting trypsinogen activation (via inhibition of cathepsin B) on the co-localization phenomenon was evaluated (Van Acker *et al*, submitted for publication). Under these conditions, co-localization of lysosomal hydrolases with digestive enzymes was still observed even though zymogen activation had been prevented. Taken together, these findings are consistent with the conclusion that zymogen activation is dependent upon the co-localization phenomenon and they are inconsistent with the theory that zymogen activation leads to the co-localization phenomenon.

SUMMARY

Acute pancreatitis is generally believed to be a disease in which the pancreas is injured by digestive enzymes that it normally produces. Most of the potentially harmful digestive enzymes produced by pancreatic acinar cells are synthesized and secreted as inactive zymogens which are normally activated only upon entry into the duodenum but, during the early stages of acute pancreatitis, those zymogens become prematurely activated within the pancreas and, presumably, that activation occurs within pancreatic acinar cells. The mechanisms responsible for intracellular activation of digestive enzyme zymogens have not been elucidated with certainty but, according to one widely recognized theory (the "co-localization hypothesis"), digestive enzyme zymogens are activated by lysosomal hydrolases when the two types of enzymes become co-localized within the same intracellular compartment.

This review has been focused on the evidence supporting the validity of the co-localization hypothesis as an explanation for digestive enzyme activation during the early stages of pancreatitis. Indeed, there is considerable evidence that, under appropriate conditions lysosomal hydrolases such as cathepsin B are capable of activating digestive enzyme zymogens such as trypsinogen. Normally, that activation does not occur because, under physiological conditions, newly synthesized lysosomal hydrolases are segregated from digestive enzyme zymogens as the two types of enzymes traffic through acinar cells. However, during pancreatitis, that segregation is perturbed and lysosomal hydrolases become co-localized with digestive enzyme zymogens within cytoplasmic vacuoles. Evidence supporting the co-localization hypothesis as an explanation for intracellular zymogen activation include the following: (a) the co-localization phenomenon is observed in virtually all of the experimental models of pancreatitis that have been studied; (b) lysosomal enzymes such as cathepsin B can activate digestive zymogens such as trypsinogen and trypsin can activate the other zymogens; (c) the co-localization phenomenon occurs prior to the appearance of cell injury/necrosis during pancreatitis; (d) co-localization and zymogen activation occur within the

same intracellular compartment; (e) zymogen activation is dependent upon the presence of lysosomal enzyme (i.e. cathepsin B) activity; and finally, (f) preventing the co-localization phenomenon prevents zymogen activation during pancreatitis but preventing zymogen activation does not, necessarily, prevent the co-localization phenomenon. Taken together, these findings support the conclusion that co-localization of lysosomal hydrolases with digestive enzyme zymogens plays a critical role in permitting the intracellular activation of digestive enzymes that leads to acinar cell injury and pancreatitis.

Abstract

The inflammatory bowel disease, Crohn's disease and ulcerative colitis, are polygenic disorders with important environmental interactions. To date, the most widely adopted approach to identifying susceptibility genes in complex diseases has involved genome wide linkage studies followed by studies of positional candidate genes in loci of interest. This review encompasses data from studies into novel candidate genes implicated in the pathogenesis of inflammatory bowel disease. Novel techniques to identify candidate genes-genome wide association studies, yeast-two hybrid screening, microarray gene expression studies and proteomic profiling, are also reviewed and their potential role in unravelling the pathogenesis of inflammatory bowel disease are discussed.

INTRODUCTION

Following the identification of the NOD2/CARD15 gene in 2001[1,2], the impetus has grown to identify novel genetic determinants of susceptibility and phenotype in the inflammatory bowel diseases, Crohn's disease and ulcerative colitis. The inflammatory bowel disease are now considered to be non-Mendelian polygenic disorders with important environmental interactions[3], and as such the accepted approach to identifying candidate genes in complex disease genetics has been adopted, namely genome wide scanning followed by studies of positional candidate genes in subchromosomal regions of association (loci).

A number of candidate genes and susceptibility loci have been discussed elsewhere in this issue, so in this review we first summarise recent data with regards to genome wide scanning and candidate gene studies, which may lead to gene identification. Novel techniques to identify candidate genes - genome wide association studies, yeast- two hybrid screening, microarray gene expression studies and proteomic profiling, are subsequently discussed.

GENE FINDING APPROACHES

Genome wide scan approach

Genome-wide linkage analysis using highly polymorphic microsatellite markers identified during the course of the Human Genome Project has led to success in identifying genetic determinants both in single gene disorders and in complex genetic diseases. To date, successful genome scans have typically involved several hundred microsatellite markers and a large number of multiply affected inflammatory bowel disease families (typically sibling pairs), with the aim of examining whether the degree of sharing variant alleles between affected individuals exceeds that as expected by chance alone[4].

To date, fourteen genome wide scans have been carried out in patients with inflammatory bowel disease. The most widely accepted guidelines for assessing the results are those defined in 1995 by Lander and Kruglyak who proposed criteria for reporting areas of linkage[5], with areas of 'suggestive linkage' having LOD scores of 2.2 and above and P values of less than 7×10^{-4}, areas of 'significant linkage' having LOD scores above 3.6 and P values of less than 2×10^{-5}, and areas of 'highly significant linkage' having LOD scores of 5.4 and above and P values of less than 3×10^{-7}. Areas of' confirmed linkage defined as areas of significant linkage have been replicated in an independent cohort, with a nominal P value of less than 0.01. Using these criteria, loci with confirmed linkage have been identified on chromosomes 1[6], 3 (IBD9)[7,8], 5 (IBD5)[9-11], 6 (IBD3; HLA)[10,12], 12 (IBD2)[13], 14 (IBD4)[9,14], 16 (IBD1)[13,15] and 19 (IBD6)[10] (Figure 1).

These confirmed regions of linkage need to be further narrowed by fine mapping of these areas, as each spans a large genomic region. The classical positional cloning approach is used by Hugot and colleagues to identify NOD2/CARD15 as the gene confers the critical mutations in IBD1 on chromosome 16[1]. Alternative strategies for fine mapping these regions or providing a short-cut to the critical genes are discussed in the following.

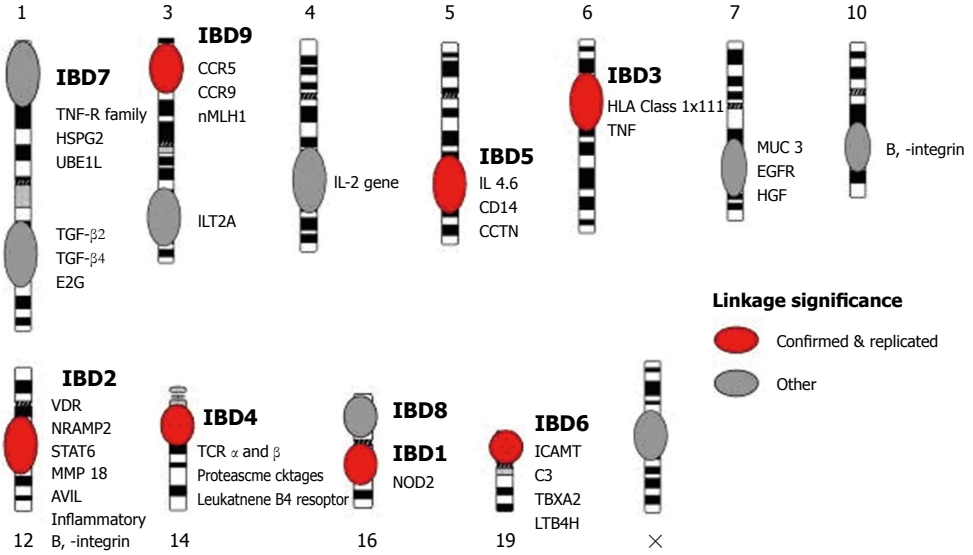

Figure 1 Confirmed and suggested linkage intervals from genome wide scans in inflammatory bowel diseases with the potential candidate genes coloured in red.

Significance levels defined by Lander and Kruglyak [95].

Positional candidate gene approach

The positional candidate gene approach to identifying association involves the use of data concerning the chromosomal location of the candidate gene as well as functional or expression data. In inflammatory bowel disease genes involved in the regulation of the innate immune system, mucosal integrity and cell-cell interactions are all clearly plausible candidate genes. By comparing the allelic frequencies of variants in these genes between patients with IBD and matched controls (case control analysis), or by investigating intra-familial association/ linkage, genes containing critical disease causing mutations may be identified.

Using this approach, Ogura and colleagues[2] identified the frameshift mutation in the NOD2/CARD15 gene (Leu1007fsinsC). Stoll and colleagues[16] also identified the DLG5 (Drosophila Discs Large Homolog 5) gene located on chromosome 10q23 by candidate gene approach allied to its position as being associated with inflammatory bowel disease in the German population[16].

However, whilst these approaches have had notable success, especially with the identification of the NOD2/CARD15 gene within the IBD1 locus, there have been difficulties in identifying candidate genes within other loci, notably the IBD5 locus as discussed elsewhere. Due to the tight linkage disequilibrium across the IBD5 locus and the wealth of candidate genes in the region[17], it has been impossible to identify with certainty the causative mutations in this region. Although Peltekova and colleagues[18] have suggested that the OCTN1/2 genes contain the causative mutations, considerably larger cohorts of inflammatory bowel disease patients (around 3000 patients) are needed to confirm these findings using genetic studies alone and functional and expression data can help delineate this region[19].

NOVEL GENES AND LOCI CURRENTLY UNDER INVESTIGATION

Genes involved in initiation and regulation of the innate immune system

The function of the immune system is to be able to recognise the vast number of antigens that are present in our environment, to mount an appropriate response to invasive pathogens and also to limit damage during inflammation and immune response to these pathogens. Dysregulation of the immune system can lead to immune-mediated diseases such as inflammatory bowel disease. Following the discovery of NOD2/CARD15, attention has focussed on the innate immune system[20]. From an evolutionary prospective, the innate immune response is more ancient than the adaptive immune response present in nearly all taxa[21]. As a further measure of the importance of the innate immune response in plants, genes involved in plant disease resistance occupy >1% of the genome of primitive species, such as *Rockcress*[22].

Toll like receptors (TLRs) are transmembrane proteins which play a pivotal role in mediating the innate immune response to viral, bacterial and fungal pathogens[23]. TLRs were initially identified in *Drosophila* and they are widely conserved across animal species[24]. In mammals TLRs are integral membrane glycoproteins which recognise conserved products unique to microbial metabolism and signal via a number of downstream signalling molecules (MyD88, Il-1R-associated kinases, TGF-β, and TNF- receptor associated factor 6)[25]. To date 11 members of the TLR family have been identified in mammals[24].

TLR4

TLR4 functions as a sensor for lipopolysaccharide (LPS), part of the cell membrane of Gram negative bacteria[26], and as such has been considered a strong functional candidate gene in the pathogenesis of inflammatory bowel disease as well as in other immunoinflammatory diseases. Variant alleles of the TLR4 Asp299Gly polymorphism have been associated with decreased bronchial responsiveness to LPS in humans and reduced activation in transfection experiments[27]. The Asp299Gly polymorphism has been associated with Crohn's disease and ulcerative colitis both in a cohort of Belgian patients[28] and in cohorts from Greece[29] (Table 1).

An association was observed between ulcerative colitis

Table 1 Number of patients studied and Toll-like receptor 4 Asp299Gly allele frequency (as a percentage of each group) in healthy controls, ulcerative colitis and Crohn's disease patients

	Healthy controls (%)	Ulcerative colitis (%)	Crohn's disease (%)	*P* value for controls versus Crohn's disease (NS: not significant)
Franchimont *et al*, Belgium (28)	139 (5.0)	163 (10.0)	334 (11.0)	0.007
Arnott *et al*, Scotland (32)	189 (8.8)	246 (6.8)	234 (10.3)	NS
Torok *et al*, Germany (30)	145 (4.0)	98 (9.0)	102 (7.0)	NS
Gazouli *et al*, Greece (29)	100 (3)	85 (3.5)	120 (7.9)	0.026
Brand *et al*, Germany (31)	199 (7.5)		204 (14.2)	0.038
Oostenbrug *et al*, Netherlands (33)	296 (4.6)	179 (5.9)	393 (6.7)	NS

These data from 6 European case control studies looking at the allelic frequencies of the Asp299Gly polymorphism of the TLR4 gene illustrate the contrasting results from these studies, and furthermore suggest a degree of genetic heterogeneity between the different populations.

and the TLR4 Thr399Ile polymorphism but not the Asp299Gly variant in one German cohort[30]. However, in a further cohort of German patients Asp299Gly variants were associated with Crohn's disease[31]. No association between inflammatory bowel disease and the TLR4 Asp299Gly polymorphism has been observed in cohorts of patients from Scotland[32]. In the light of these discordant data-sets, it is difficult to ascertain whether these two polymorphisms represent the critical disease causing mutations in the TLR4 gene[33]. Recent data from two independent mouse models have shown that treatment with TLR4 antagonists may prevent the development of colitis, further suggesting that this innate immune receptor may be central to the pathogenesis of inflammatory bowel disease[34].

TLR5

TLR5 functions by recognising flagellin, a common bacterial antigen that is present in enteric bacteria[35, 36]. Strong serological response to flagellin in multiple animal models of colitis has been observed by Lodes and colleagues[37], who demonstrated that colitis can be induced by transferring flagellin-specific T cells to immunodeficient animals. Further evidence implicating TLR5 polymorphisms in the pathogenesis of inflammatory bowel disease suggests that carriage of a dominant negative TLR5 polymorphism (TLR5-stop) appears to protect against Crohn's disease and results in a significant reduction in flagellin-specific circulating concentrations of IgA and IgG[38]. These data linking a genetic defect in TLR5 to an alteration in the acquired immune response are intriguing and of great pertinence as recent studies report synergism between NOD2/CARD15 and TLR5 signalling[39].

NOD-LLR protein family

NOD (nucleotide- binding oligomerization domain) - LLR (leucine rich region) proteins are part of the CATERPILLER (CARD, transcription enhancer, R [purine]- binding, pyrin, lots of purine repeats) family, and these proteins are key regulators of innate immunity and apoptosis in mammals and plants[40]. NOD- LLR proteins play a central role in recognising pathogens on the cell surface and in the cytosol, and a family of greater than twenty human proteins possessing a NOD domain has been identified[41]. NOD-LLR proteins are comprised of three distinct functional domains: the amino terminal effector domain involved in signalling, the centrally located NOD domain and the LLR ligand-sensing domain[42]. Three of the human NOD-LLR proteins have effector domains, namely caspase-recruitment domains (CARD): NOD1/CARD4, NOD2/CARD15 and Apaf-1.[40]

With the established role of NOD2/CARD15 in the pathogenesis of Crohn's disease, attention has focused on NOD1/CARD4 identified by two groups in 1999[43,44]. NOD1/CARD4 has a similar structure to NOD2/CARD15 with it having only one CARD domain, a central NOD domain and a LLR[45]. NOD1 detects intracellular diaminopimelic acid, a tripeptide motif found in many Gram negative bacteria and unique to Gram negative proteoglycans[46,47]. NOD1/CARD4 plays a role in colonic epithelial defence against the intracellular pathogens *E. coli* and *Shigella flexeneri*[48,49]. Its effector domain is associated with RipK2(a CARD-containing interleukin-1 beta-converting enzyme-associated kinase), thus mediating NFκB activation[43,44,50].

Linkage to the area that encompasses the NOD1/CARD4 gene, chromosome 7p14, was first found on a genome wide scan of the UK population in 1996[13]. This initial finding is replicated in two further genome wide scans involving patients in North America (USA and Canada)[6,10]. In a pan-European study involving 381 inflammatory bowel disease families from France, Sweden, Belgium, Spain, Denmark, Italy and Ireland (235 CD and 58 UC), no association between susceptibility to IBD and the E266K variant which lies within the CARD domain of NOD1/CARD4 was observed[51].

However, a further recent UK study of 556 IBD trios (294 CD and 252 UC) a significant association was observed between a complex insertion deletion allele (CCCCCCAC/ CCCCCCCCC) of NOD1/CARD4 at nucleotides 30, 258, 950 (Ensembl build 35) which is partially identified by rs6958571 and is located within intron 9, and predisposition to inflammatory bowel disease ($P = 0.002$)

and, also to ulcerative colitis ($P=0.01$)[52]. By creating a sliding two marker haplotype using this insertion deletion allele and the rs2907748 (T→ C) variant at nucleotides 30,246,263, the association was strengthened with *P* values of 3×10^{-6} for inflammatory bowel disease, 7×10^{-4} for Crohn's disease and 3×10^{-5} for ulcerative colitis. The deletion allele was significantly associated with an early age of onset of IBD (<25 years) and there was no evidence of an epistatic effect when NOD1/CARD4, NOD2/CARD15 and IBD5 are investigated.

Interestingly allelic variation of the same insertion deletion polymorphism (CCCCCCAC/ CCCCCCCCC) at nucleotides 30, 258, 950, which appear to alter the protein binding of NOD1/CARD4, is also associated with susceptibility to childhood onset of asthma and elevated serum IgE levels[53]. Further genetic and functional data with regards to NOD1/CARD4 are required to discover whether these variants play a role in the pathogenesis of inflammatory bowel disease in racially diverse populations.

CCL20

CC chemokine ligand (CCL) 20 is responsible for the chemoattraction of immature dendritic cells (DC) expressing the CCR6 receptor in the epithelium and Peyer's patches in the bowel mucosa[54]. The ligand- receptor pair of CCL20 and CCR6 also play a role in the chemoattraction of effector/memory T-cells and B-cells under homeostatic and inflammatory conditions, in diseases including cancer and rheumatoid arthritis[55]. Microarray and real-time PCR analysis of endoscopic colonic biopsies of patients with IBD have revealed increased levels of CCL20 mRNA in histologically inflamed biopsies when compared to non-inflamed IBD biopsies and inflamed non-IBD colonic biopsies[56,57].

Using microarray analysis of peripheral blood mononuclear cells in 8 patients with ulcerative colitis and 8 healthy controls, Choi and colleagues showed that the CCL20 gene is upregulated in ulcerative colitis samples[58]. Five SNPs in the promoter region of CCL20 are identified and analysed in a case control study of 118 ulcerative colitis patients and 300 healthy controls in the Korean population. Three of the CCL20 variants are significantly associated with ulcerative colitis ($P<0.0038$) and further replication data in ethnically diverse cohorts of patients with IBD are required.

Other loci

The identification of other genetic variants in loci identified by genome wide scan continues to yield other potential determinants of inflammatory bowel disease. These genes may play a role that is limited to specific populations and disease phenotypes. However, their identification can unravel the pathogenesis of inflammatory bowel disease and may reveal new therapeutic targets.

Other loci of current interest include the IBD2 locus on chromosome 12 first described in the UK[13] and subsequent analysis suggests that this locus is most strongly associated with colonic disease[59]. In the Flemish population the IBD4 region on chromosome 14 appears to be an important determinant of Crohn's disease[60] and this association has been replicated in the USA[14] and by the International IBD genetics consortium[61]. Fine mapping of the IBD2 and the IBD4 loci are required to establish which genes in these regions contain critical disease causing mutations.

NOVEL TECHNIQUES TO IDENTIFY CANDIDATE GENES

Genome wide association studies

With the advent of the HapMap project[62] and plans to include information on around 300 million genotypes, genome-wide association studies have been proposed as a powerful tool in identifying common variants that contribute to complex genetic traits[63]. Genome wide association studies compare the frequency of alleles and genotypes between cases and controls on a genome-wide scale, thus creating a comprehensive unbiased method to identify candidate genes. Advances in technology lowering the price of genotyping on a large scale and genome wide linkage disequilibrium mapping using data from the HapMap project have made this method available. However, significant concerns remain about the power of these studies and it has been proposed that levels of significance of $P<5\times10^{-8}$ are required to constitute significance in genome wide association studies[64].

Using this approach Tamiya and colleagues[65] placed 27 039 microsatellite markers across the human genome at 100kb intervals in 470 patients with rheumatoid arthritis and 470 controls. Forty seven candidate regions were identified and the previously implicated major histocompatibility complex gene HLA- DRB1 in the chromosomal region 6p21.3 was shown to be associated with rheumatoid arthritis. In the UK, the Wellcome Trust has provided initial funding for a phase I study including 1 000 patients with Crohn's disease and 3 000 controls, 675 000 SNPs will be genotyped to cover the entire genome and results are expected in 12 months.

Yeast two- hybrid screening

The yeast two-hybrid assay is an elegant means of investigating protein-protein interactions, which have become increasingly important in our understanding of biological systems and pathways. The yeast two- hybrid model can also be used to characterize interactions already known to occur, thus helping delineate the protein domains responsible for interaction and the environmental conditions involved[66].

The yeast two-hybrid assay is performed in the budding yeast, *S cerevisiae* using two fusion proteins: the target protein of interest, known as 'bait' is fused to a DNA binding domain attached to its N-terminus. The second protein, the 'prey' is fused to an activation domain. If the bait protein interacts with the prey, these bring the binding domain and the activation domain of transcriptional activator together, which in turn switches on the expression of the reporter genes. The reporter genes are constructed to allow growth of the yeast in a selective medium when the interaction occurs. When investigating 'protein- protein' interactions, a single bait protein is used to search for interaction with a library of proteins fused to the activation domain. The choice of library is determined

by the tissue of interest, e.g. intestinal cell library for inflammatory bowel disease[67].

Schizophrenia is a disease of polygenic genetic susceptibility where the yeast two hybrid systems have been successfully used to identify candidate genes. The disrupted-in- schizophrenia 1 (DISC1) gene was identified in 2 000[68] and confirmed in other cohorts,[69,70] was used as bait. DISC1 encodes a novel protein of unknown function and full-length human DISC1 protein was used to screen human adult and foetal brain libraries for interacting proteins, using the yeast two-hybrid system[71]. Twenty-one proteins from a variety of locations have been identified implicating DISC1 in several aspects of central nervous system signalling and confirming data from other yeast two- hybrid scans using DISC1 as bait[72,73]. From these data the authors are able to identify a number of potential DISC1 interactions and to speculate that DISC1 may be at the centre of an extensive protein interaction network.

Yeast two- hybrid as an investigative tool in inflammatory bowel disease

Barnich and colleagues[74] used NOD2/CARD15 gene as 'bait' to screen a bone marrow library and identified GRIM19, a protein with homology to the NADPH dehydrogenase which interacts with endogenous NOD2[74]. GRIM19 is required for NFκB activation following NOD2-mediated recognition of bacterial muramyl dipeptide and the authors hypothesised that GRIM19 is a key component of the CARD15/NOD2 signalling pathway which currently remains under detailed investigation[75-77]. In our own protein yeast two- hybrid studies a series of 12 candidate genes which interact with CARD15/NOD2 (*Nimmo, Satsangi,* unpublished data) have been identified.

GENOMICS

Microarray expression studies

Gene expression technology using microarray allows a comprehensive picture of gene expression at the tissue and cellular level, thus helping understand the underlying physiological and pathological processes. Microarray technology has developed from spotted nylon array technology used to identify genomic inserts in bacterial colonies by hybridisation with preidentified cDNAs[78]. In the seminal microarray experiment in 1995, a two-colour fluorescent pattern of differential gene expression is generated when comparing 48 genes in the root and the shoot of *Arabidopsis*[79].

Since 1995 there has been a rapid increase in the number of papers published using microarray technology from 7 in 1995-1996 to 139 in 1999 and to 3 000 in 2003[80]. The initial optimism set out by Mark Schena, one of the authors of the *Arabidopsis* microarray experiment suggesting that all human diseases can be studied by microarray technology, With the ultimate goal of this work to develop effective treatments and cures for every human disease by 2 050 has not yet fully been born out by the published data. However, a number of exciting and novel observations have been generated.

Microarray design

RNA isolated from the tissue sample or cells can be used to generate cRNA or cDNA[78]. The probe set is then designed with transcripts targeting the genes of interest and care needs to be taken to prevent cross- hybridization. It is worth noting at this point that the probe refers to the reporter sequence placed at a particular position on the array which interrogates the sample and not the other way around. The probes are hybridised on the chip with the target unknown cRNA or cDNA. Following this process which can take several hours, the unbound target is washed off and the arrays are fluorescently labelled, so that they can be analyzed by confocal laser scanning. Expression of the entire human genome can be analyzed on one chip and complex computational and statistical techniques have been developed to analyze expression data because of the large amount of data microarrays[81].

Clinical data generated by microarray

Probably the most provocative and clinically relevant data generated by microarray have been in the field of cancer research. An example of the potential of microarray has demonstrated by Alizadeh and colleagues[82]. By comparing expression analysis on a 'lymphochip' panel of 3186 genes between patients with diffuse large B- cell lymphoma (DLBCL) prior to treatment, the investigators are able to group these patients into two discrete groups: germinal centre DLBCL and activated DLBCL. When the clinical progress of these two groups of patients were examined, the germinal cell DLBCL had a higher five year survival rate than the activated DLBCL (75% $n=25$ versus 16% $n=37$ respectively, $P \leqslant 0.01$). Gene expression profiles have also been successfully used to predict prognosis in 295 patients with breast cancer[83]. However, a meta- analysis of 84 studies found that DNA microarrays have a variable performance in measuring prognosis in a number of different cancers[84].

Microarray experiments in subjects with inflammatory bowel disease

Microarray has been used to compare synovial tissue obtained from patients with severe rheumatoid arthritis and macroscopically affected bowel of patients undergoing surgery for Crohn's disease[85]. A number of inflammatory genes were commonly expressed in diseased tissues. In 2000 Dieckgraefe and colleagues[86] published a study using microarray technology to compare patients with ulcerative colitis undergoing colectomies for disease refractory to medical management and a control group. Six thousand five hundred genes were analysed and the results confirmed an increase in a number of genes previously implicated in the pathogenesis of ulcerative colitis (IL-1, IL-1 RA and IL8) and suggested that multiple members of the chemokine subfamily may play a role in disease pathogenesis.

In a further microarray experiment using surgically resected inflammatory bowel disease tissue, 7 070 genes were examined and 170 genes were differentially expressed in ulcerative colitis and Crohn's disease with almost an equal number up regulated and down regulated[87]. Twenty percent of the differentially regulated genes were common to both forms of inflammatory bowel disease and when the locations of these genes were mapped several were found to lie within IBD2 locus on chromosome 12.

More recently Langman and colleagues[88] used microarray to analyze biopsies taken from patients with Crohn's disease, ulcerative colitis and control patients, 22 283 genes were analysed. They found that genes involved in cellular detoxification and biotransformation (pregnane X receptor and MDR1) are significantly down regulated in the colon of patients with ulcerative colitis.

Endoscopic investigation of inflammatory bowel disease with the ability to take pinch mucosal biopsies has allowed investigators to take microarray tissue from a larger range of patients including those with less severe disease compared to patients requiring rescectional surgery. In a study of 24 patients with ulcerative colitis, Okahara and colleagues[89] investigated the difference in gene expression between endoscopic biopsies taken from inflamed and non inflamed areas using a 1300 gene microarray, and found that migration inhibitory factor- related protein 14 (MRP14), growth-related oncogene gamma (GROγ) and serum amyloid A1 (SAA1) were upregulated whereas TIMP1 and PDZ and LIM domain 1 (elfin) were down regulated in the inflamed biopsies when compared to the non- inflamed biopsies.

In a study involving endoscopic biopsies of patients with Crohn's disease, ulcerative colitis and controls, Costello and colleagues[90] found that 500 and 272 transcripts are differentially regulated in CD and UC, respectively. Candidate genes are confirmed by real-time PCR and immunohistochemistry, and a number of genes involved in immune regulation were identified.

Further microarray studies in inflammatory bowel disease

Microarray has been useful in studies thus far and continues to be a powerful tool in investigation of the pathogenesis of inflammatory bowel disease. Further studies need to be designed in order to allow the collection of accurate clinical data describing the phenotype and activity of inflammatory bowel disease at the time of sample collection as these data are critical in analysis and interpretation of the results. The confounding problems associated with the heterogeneous mixture of cells, which is inevitable in the analysis of entire biopsy samples, can be reduced by using laser capture micro-dissection, in order to analyze only the cells of interest. By obtaining painstakingly accurate clinical information at the time of biopsy collection and narrowing down cell heterogeneity, the amount of background 'noise' that has hampered previous microarray studies can be reduced[91]. Minimum standards of information reported on microarray data have been proposed with the aim of establishing a standard for recording micoarray-based gene expression data[92], and replication of results with real-time PCR helps to validate these studies.

PROTEOMICS

Proteomic analysis is another relatively new investigative tool that has not been used to any large extent in the field of inflammatory bowel disease. Proteomics refers to the study of the total protein content in cells and the products of genes, so as to identify differences between normal and diseased tissue[93]. This is achieved by combining the techniques of protein electrophoresis and mass spectrometry. Expression profiles of proteomes may be generated from samples of serum or secreted fluid, and may be able to differentiate disease progression, response to therapy and to identify novel therapeutic targets.

Preliminary data have been generated in our unit by comparing serum of patients with severe ulcerative colitis who responded to corticosteroid therapy and matched patients who were resistant to and failed corticosteroid therapy[94]. Proteomic profiles of corticosteroid resistant and responsive groups are significantly different at 19 protein biomarkers: 12 proteins were up-regulated and 7 proteins were down-regulated in the corticosteroid resistant group. These results suggest that protein profiling may be useful in predicting patient response to corticosteroid therapy and identification of these proteins is currently underway.

CONCLUSION

The application of novel technologies has catalyzed the search for novel determinants in inflammatory bowel disease. Proof of the principle for genome wide studies is provided by the NOD2/CARD15 discovery and investigation of genes at other loci is underway. Rigorous attention to statistical design and phenotypic classification of disease is of paramount importance in gene discovery.

With the advent of new powerful investigative tools such as microarray and proteomic analysis, large amounts of data can be generated from small studies in inflammatory bowel disease. Among the clinical challenges in harnessing the power of these new investigative tools will be to accurately define clinical phenotype in patients studied, given the heterogeneity inevitable in these studies.

Abstract

Prognosis of locally advanced gastric cancer remains poor, and several multimodality strategies involving surgery, chemotherapy, and radiation have been tested in clinical trials. Phase III trial testing the benefit of postoperative adjuvant chemotherapy over treatment with surgery alone have revealed little impact on survival, with the exception of some small trials in Western nations. A large trial from the United States exploring postoperative chemoradiation was the first major success in this category. Results from Japanese trials suggest that moderate chemotherapy with oral fluoropyrimidines may be effective against less-advanced (T2-stage) cancer, although another confirmative trial is needed to prove this point. Investigators have recently turned to neoadjuvant chemotherapy, and some promising results have been reported from phase II trials using active drug combinations. In 2005, a large phase III trial testing pre- and postoperative chemotherapy has proven its survival benefit for resectable gastric cancer. Since the rate of pathologic complete response is considered to affect treatment results of this strategy, neoadjuvant chemoradiation that further increases the incidence of pathologic complete response could be a breakthrough, and phase III studies testing this strategy may be warranted in the near future.

Key words: Surgery; Radiation; Anticancer drug; Adjuvant chemotherapy; Neoadjuvant chemotherapy

INTRODUCTION

Despite its declining incidence in Western Europe[1] and the United States[2], gastric carcinoma remains the second most common cause of cancer death worldwide with over 600 000 deaths per year[3]. The curative treatment of gastric carcinoma remains primarily surgical. Although developments in surgery have been slowed in the West by the large percentage of patients presenting at advanced stages[4] radical gastrectomy with extended lymphadenectomy[5,6] has been performed in Japan and other East Asian countries[7] as well as at specialized centers in the West[8-12] and is now recognized as a reasonably safe procedure in experienced hands[13,14]. However, the survival benefit of extended lymphadenectomy is yet to be proven in a large-scale randomized trial[15,16], and the prognosis of patients with locally advanced gastric cancer remains dismal even after potentially curative resection. Consequently, multimodal treatment strategies involving surgery, chemotherapy, and radiation have been explored to improve on the survival of the patients with resectable advanced cancer. The current review focuses on the development and states of the art of chemotherapy given as a component of such multimodal treatments. It is not within the scope of this review to describe in detail the chemotherapeutic regimens given concurrently with radiation.

Postoperative adjuvant chemotherapy

One straightforward strategy against resectable advanced gastric cancer is to do the best that can be done by surgery and then supplement it with chemotherapy to eliminate micrometastases that may have developed before the surgery or viable cells that may have been disseminated during the surgical procedure. Based on the fractional cell kill hypothesis [17], it would be expected that the highest tolerable drug doses given at the shortest possible interval after surgery would maximize the rate of cell kill[18, 19]. The authors have shown through an in vivo model of peritoneal carcinomatosis that either oral S-1 (1M tegafur-0.4M gimestat-1M otastat potassium)[20] or intraperitoneal paclitaxel[21] can control viable intraperitoneal cancer cells at an early stage of the metastatic process, although the therapeutic effect proved limited once they have developed into gross metastases. This strategy has long been a standard of care in other cancer types including colorectal cancer, reflecting the results of several randomized phase III trials. In the case of gastric carcinoma, however, the results of phase III trials testing this strategy have been inconsistent. An early success was reported from Japan in the 1970s, where a treatment by twice weekly intravenous administrations of

0.08 mg/kg mitomycin for 5 weeks reportedly improved the 5-year survival of curatively resected Stages I~IV gastric carcinoma by 13.5%[22]. This was the result of a large-scale nationwide trial in which 714 patients had been enrolled. Survival analysis, however, showed that the number of patients receiving chemotherapy was 242, whereas the number treated by surgery alone was 283. Details of a large number of patients who had been excluded from the survival analysis have not been reported, and the reliability of the study is questionable from the current point of view. Nevertheless, the result was taken seriously at the time, and several trials in the decade to follow explored the benefits of new combinations, mostly with oral fluoropyrimidines, as well as of new routes of delivery versus intravenous mitomycin, the gold standard. It was only in late 1980s after a long dispute that the Gastric Cancer Surgery Study Group in the Japan Clinical Oncology Group (JCOG) declared that treatment with surgery alone should once again be considered as the standard of care for curatively resected gastric cancer. Since that time, several new phase III trials have been launched in Japan with surgery alone as a standard arm. However, these new generation studies have repeatedly produced negative results. The failure to prove a survival benefit may be attributed to inadequate eligibility criteria that allowed the inclusion of early-stage cancers[23], faulty study design[24], and selection of ineffective antineoplastic agents[25]. The first JCOG study to be reported was a phase III study testing the impact of intravenous mitomycin (1.4 mg/m^2) and fluorouracil (166.7 mg/m^2) twice weekly for 3 week followed by oral UFT for 18 months[23]. From subset analyses of this negative study that enrolled 579 patients, Nakajima suggested that T1 stage cancer should be excluded from future trials, whereas T2 stage cancer could be a promising target for postoperative adjuvant chemotherapy. However, eligibility criteria of the next JCOG trial testing intravenous mitomycin 1.33 mg/m^2, fluorouracil 166.7 mg/m^2, and cytosine arabinoside 13.3 mg/m^2 given twice weekly for 3 wk followed by oral fluorouracil 134 mg/m^2 daily for the next 18 mo were based on surgical rather than histopathologic findings, and this again resulted in the inclusion of several T1 stage cancers. Consequently, the excellent survival achieved by surgery alone left little room for improvement by adjuvant chemotherapy, and the study, designed unfortunately to detect a large difference of 15% in 5-year survival, wasdestined to be under-powered[24]. Another JCOG phase III trial testing the survival benefit of a combination chemotherapy with intraperitoneal CDDP (70 mg/m^2) on d1, intravenous CDDP at 70 mg/m^2 on d14, and continuous 5FU at 700 mg/m^2 on d14~16 followed by one year of oral UFT (267 mg/m^2) over surgery alone for T3~T4 stage cancer had been powered to detect a difference of 12% in 5-year survival[25]. Survival curves in this study that were found to be almost identical suggest that this trial failed because of an inadequate regimen rather than a flaw in the statistical considerations, since intraperitoneal CDDP had already proven ineffective as was reported in 1994 by a much smaller Austrian study[26].

After the aforementioned JCOG trials, a trial testing oral UFT (350 g/m^2) to be continued for 16 months was conducted for pathological T2/N1 and T2/N2 stage cancer (NSAS-GC). Although there were several new participants in the study in addition to the members of JCOG (33 institutions in all), the patient accrual was poor with only 199 patients participating in 4 years, whereas 488 were needed to detect an 8.8% difference in 5-year survival. The trial was eventually discontinued in order to carry out the next randomized trial testing a new and more promising drug, S-1[27], in the adjuvant setting (ACTS-GC). Nevertheless, a planned interim analysis at the median follow-up of 3.8 years revealed significant improvements in overall and relapse-free survival in the chemotherapy arm[28]. Patient characteristics had been well-balanced between the arms, and the study had been carefully conducted. However, this was considered too small a study to definitively prove the benefit of postoperative chemotherapy in gastric cancer. In the meantime, ACTS-GC, a nationwide trial comparing postoperative adjuvant chemotherapy by oral S-1 with surgery alone for Stages II and III gastric cancer, completed a planned enrollment of 1000 patients in the year 2005. It is hoped that the results of this trial will in the near future provide a decisive answer regarding the survival benefit of adjuvant chemotherapy with oral fluoropyrimidines following formal D2 dissection. Since the result of ACTS-GC could turn out to be negative after all, another confirmative phase III trial testing the benefit of UFT is currently planned by JCOG so that the enrollment may be completed before the interim analysis for the ACTS-GC study due to take place in 2008. Although the response rate of S-1 in cancer with measurable lesions was higher than that of UFT, there is currently no guarantee that S-1 is more effective than UFT in the adjuvant setting.

In the meantime, two randomized trials in the West have shown the advantage of adjuvant chemotherapy, one with mitomycin and tegafur[29], and the other with epidoxorubicin, 5FU and leucovorin[30]. However, prognosis of those patients treated with surgery alone in these trials had been so dismal that the patients enrolled for the trial might have been treated with or inadequately staged by suboptimal surgery. On the contrary, an adjuvant postoperative chemotherapy regimen consisting of EAP (etoposide, doxorubicin, cisplatin) followed by intravenous 5FU/LV had no survival benefit in a trial by the Italian Medical Oncology Group. Interestingly, the 5-year survival rate of the surgery alone group in that trial was relatively good at 44% [31]. Survival benefit was not proven in other modern adjuvant trials exploring the FAM (5-FU, doxorubicin, mitomycin) regimen[32] or 5FU/LV and cisplatin[33], though meta-analyses of the Western trials demonstrated some potential of this strategy[34-38]. A meta-analysis of the three Japanese randomized trials with serosa-negative cancer as a target[23, 24, 27] also suggested a survival advantage[39]. Thus, attempts to confirm a definitive survival advantage of postoperative adjuvant chemotherapy should be continued.

There is a significant difference between the Japanese and Western principles for the selection of chemotherapeutic regimens to be used in the postoperative adjuvant setting. In the West, any regimen found to be active in the treatment for unresectable/metastatic cancer could also be regarded as a candidate to be tested in the adjuvant setting. For instance, the EAP regimen tested in the Italian Trials in the Medical Oncology group study[33] had caused

concern due to its severe toxicity[40]. A Swiss study currently exploring the impact in both a neoadjuvant and adjuvant setting of a combination of 5-FU, cisplatin and docetaxel which has revealed a superior response rate compared with 5FU and cisplatin among advanced gastric cancers [41] but has also been recognized as highly toxic. The Gruppo Onocologico Italia Merideionale (GOIM) recently conducted a trial to explore the efficacy and tolerability of the addition of epirubicin to a combination of etoposide, leucovorin and 5FU (ELF), and found this regimen (ELFE) to be active for advanced gastric cancer[42]. Here again, the next step they took was to test this regimen in the adjuvant setting in a phase III study with surgery alone as a control arm[43]. Since most of the patients treated with potentially curative surgery still have dismal prognosis in the West, investigators there do not hesitate to introduce toxic regimens that were nevertheless found to be active against advanced cancer into trials for postoperative adjuvant chemotherapy.

The situation is different in Japan where regimens used in adjuvant settings tend to be relatively mild. This is because a larger proportion of patients to be treated with postoperative adjuvant chemotherapy will survive by surgery alone, so that treatment-related toxicities and impairment of patient's quality of life are less likely to be tolerated. For these reasons, adjuvant chemotherapies in Japan have centered around oral fluoropyrimidine-based regimens with mild toxicities. The aforementioned regimen of intravenous mitomycin, fluorouracil, and cytosine arabinoside followed by oral fluorouracil, for example, induced Grade III leucopenia in 1.6% and Grade III gastrointestinal symptoms in 0% of patients treated in the adjuvant setting[24]. A highly regarded combination of oral S-1 (80 mg/m^2 for 21 d with 14 d of rest) and cisplatin (60 mg/m^2 on d8) that achieved a response rate of >70%[44], for instance, had been frequently used in Japan for unresectable/metastatic cancer, but has not been considered as a candidate for postoperative adjuvant chemotherapy. Use of mild regimens demonstrating moderate reponse rates are regarded by some investigators as old-fashioned[45], but as described earlier, the possibility that these regimens may still prove useful in pT2 stage cancers treated with adequate surgery cannot be currently denied.

Finally, a positive result in a trial testing adjuvant chemoradiation needs to be mentioned. In the United States, an Intergroup Trial (SWOG-9008/INT0116) was launched in 1991 to test the effect of combined radiation and fluorinated pyrimidine in the adjuvant setting[46]. The treatment consisted of five consecutive days of bolus 5FU (425 mg/m^2) /LV (20 mg/m^2) before and after 45 Gy of radiation given for 5 weeks, with intravenous 5FU (400 mg/m^2) /LV (20 mg/m^2) on the first four and last three days of radiotherapy. The trial enrolled 556 patients, and the median overall survival in the surgery-only group was 27 mo as compared with 36 mo in the chemoradiotherapy group, showing a significant survival benefit for chemoradiation. Since radiation was delivered to the gastric bed and regional lymph nodes, the object of chemoradiation would seem to have been to combat any locoregional residual disease, and it was indeed for this pattern of recurrence that a significant decrease in the incidence was observed among the treatment group. The extent of lymph node dissection being D0 in 54% of the patients enrolled, some skepticism arose as to whether chemoradiotherapy might have effectively compensated for the suboptimal surgery in terms of local control[47, 48]. These observations point to the importance of quality control in surgery even when multimodality treatments are being discussed[26]. Although postoperative chemoradiation has not been seriously explored in Japan where investigators believe that local control can be achieved through extended lymphadenectomy, this may be a useful option in countries where systematic lymphadenectomy has not become a standard practice.

Future perspective regarding postoperative adjuvant chemotherapy

A breakthrough in clinical trials testing postoperative adjuvant chemotherapy may be achieved through a customized approach in which the candidates for adjuvant chemotherapy are more meticulously selected. Detection of minimal residual disease may be one of the options, since chemotherapy given to a patient with no residual disease would only be needlessly harmful. This detection can be done through immunostaining or polymerase chain reaction of protein, gene mutation, or mRNA expression that may be present in cancer cells while absent in non-cancer cells that may be included in the samples[49]. Although the prognostic value of micrometastasis detected in the lymph node through immunostaining remains controversial[50, 51], detection of free cancer cells in peritoneal washing samples by a conventional cytologic examination is a strong prognostic factor predicting the risk for peritoneal carcinomatosis[52]. Enhanced detection through reverse-transcriptase polymerase chain reaction was found to be even more potent as a prognostic factor[53-55].

Identification of patients at risk will have little value unless effective drugs are available. Adequate selection of anticancer drugs could be achieved through *in vitro* chemosensitivity testing in which the rates of growth in relation to a control of viable cancer cells from the surgical specimens are tested in culture media containing various antineoplastic drugs. A retrospective study has shown that patients treated with postoperative adjuvant chemotherapy using a certain drug had a better outcome when the result of *in vitro* chemosensitivity testing for that drug had been positive[56]. Prospective studies to confirm this phenomenon are currently underway by several study groups in Japan. However, a randomized trial comparing patients whose treatments are selected based on chemosensitivity testing and those who were treated with empirical treatments is still needed to definitively assess the benefit of this costly and time-consuming procedure[57,58].

Neoadjuvant chemotherapy for resectable gastric cancer

Due to the consistently poor outcome of patients treated with a strategy of surgery followed by chemotherapy, preoperative chemotherapy has for several years attracted the attention of investigators in the West[59]. This is considered effective for patients in advanced T and N stages, and may result in downstaging of the tumors and consequently improving the curative resection rate. Since the best response is likely to be achieved within a few months from

the initiation of therapy, 2 to 3 courses of preoperative chemotherapy are usually performed in most clinical trials. Naturally, a high response rate is required for the chemotherapeutic regimens to be used in this setting in order to achieve downstaging. Chemotherapeutic regimens with high response rates usually are associated with greater toxicity and may not be feasible in the postoperative adjuvant setting, since chemotherapy performed immediately after gastric surgery is often marred by surgery-related gastrointestinal symptoms. Preoperative delivery of chemotherapy would be much less problematic, and this underscores the major appeal of neoadjuvant therapy[60]. Another theoretical benefit of neoadjuvant chemotherapy concerns micrometastases that are undetected at the initiation of treatment. Patients with locally advanced cancer are more or less likely to harbor distant micrometastases which could remain untreated for several weeks when the surgery-first strategy is selected.

It appears so far that survival rates are excellent among patients who respond to neoadjuvant chemotherapy[60]. However, whether a group of patients as a whole benefits from this strategy needs to be carefully elucidated, and several phase III trials are ongoing after producing promising phase II results[61-63]. Of these, a MAGIC trial exploring pre- and postoperative ECF regimens (a combination of epirubicin, CDDP, and continuous infusion of 5FU) has enrolled patients as planned and has proved the significant benefit of chemotherapy (improvement of 13% in a 5-year survival rate)[64]. Although three cycles each of ECF were to be performed before and after surgery, compliance with chemotherapy was unexpectedly lower after surgery (only 42% of patients completed postoperative chemotherapy), so that the result of MAGIC trial is considered mainly to reflect the effect of preoperative ECF. Tumor diameter, depth of invasion, and nodal status of the surgical specimens were significantly decreased or improved in the chemotherapy group, indicating that downstaging actually took place in a significant proportion of patients. Despite the toxicity of neoadjuvant chemotherapy, the mortality and morbidity in surgery following chemotherapy seems to have been comparable to what it would have been without preoperative chemotherapy.

In Japan, two phase II studies await survival analysis after enrollment as planned: one is exploring a combination of CPT-11 and CDDP[65] performed against gastric cancer with bulky nodal metastasis, and the other is testing CDDP and oral S-1[44] against linitis plastica type (type 4) and large type 3 cancers. A phase III trial comparing neoadjuvant chemotherapy by CDDP and S-1 with surgery alone for types 3 and 4 cancers will soon be launched. The concept of chemotherapy in the neoadjuvant setting is similar between Japan and Western countries in that regimens with high response rates have usually been selected. It has been proven in other types of cancer that only neoadjuvant chemotherapy using a regimen with a high pCR (pathological complete response) rate can really affect survival[66]. A high incidence of PR (partial response) was reported in a phase II trial of chemotherapy with CDDP and S-1, but CR was seldom observed as a result of treatment with this combination[44]. Thus, there is a theoretical concern that the expected survival benefit may not be obtained by a neoadjuvant chemotherapy relying on this regimen, although the consequences of neoadjuvant chemotherapy followed by gastrectomy plus extended lymphadenectomy with sufficient nodal clearance remain of interest.

The pCR rate can be enhanced by the addition of radiation, which has been shown to have a beneficial impact on the surgical outcome in esophageal and rectal cancer. Anticancer drugs in this case are in part considered as radiosensitizers, and 5FU, cisplatin, and paclitaxel have been used alone and in combination[67-69]. A pCR was achieved in 20% of patients who received two cycles of continuous 5FU, paclitaxel, and cisplatin followed by 45 Gy radiotherapy with concurrent 5FU and paclitaxel[70]. Although chemotherapy performed concurrently with radiation may be somewhat inadequate against potential micrometastases that may exist outside the field of radiation, a three- step strategy with intense induction chemotherapy prior to the preoperative chemoradiation and surgery may overcome this weakness. The validity of this strategy needs to be proven by a well-designed phase III trial.

CONCLUSIONS

Since the prognosis of locally advanced gastric cancer remains poor, several multimodality strategies involving surgery, chemotherapy, and radiation have been tested in clinical trials. Postoperative adjuvant chemotherapy with highly active regimens generally had disappointingly little impact on survival for advanced cancer, although there is a hard evidence that locoregional control could be improved by postoperative chemoradiation where systemic removal of the regional lymph nodes has not been conducted.

Moderate chemotherapy with oral fluoropyrimidines may be effective against T2 N+ stage cancer, although another confirmative trial is needed to prove this point. For more advanced disease, investigators have turned to neoadjuvant chemotherapy in the hope that downstaging might facilitate an R0 resection and that distant micrometastasis could be eliminated. A large randomized study testing pre- and postoperative ECF has confirmed the survival benefit of this strategy, and several phase III trials exploring other promising regimens are ongoing. The outlook is even brighter with neoadjvant chemoradiation that further increases the incidence of pathologic CR, and phase III studies testing this strategy are warranted.

Abstract

AIM: To investigate the expression of midkine in esophageal squamous cell carcinoma (ESCC) and analyze its relationship with clinicopathological features.

METHODS: RT-PCR and immunocytochemical staining were used to detect the expression of midkine mRNA and protein in EC109 cells, respectively. Then the expression of midkine in 66 cases of ESCC samples were detected by immunohistochemistry using monoclonal antibodies against human midkine.

RESULTS: Midkine was expressed in EC109 cell by RT-PCR and immunocytochemistry. The immunoreactivity was detected in 56.1% (37/66) of the ESCC samples. The expression of midkine was found in cytoplasm of tumor cells. Notably, the intensity of midkine was stronger at the area abundant in vessels and the invading border of the tumors. Midkine was more intensely expressed in well differentiated tumors (76.9%) than in moderately and poorly differentiated tumors (43.1% and 41.2%, respectively) ($P < 0.05$). There was no statistically significant correlation between midkine expression and gender, age, clinical stage, lymph node metastasis or survival in ESCC.

CONCLUSION: Midkine is overexpressed in ESCC. It may play a role in tumor angiogenesis and invasion. The expression of midkine is correlated with tumor cell differentiation in ESCC. The more poorly tumor cells differentiate, the weaker midkine expresses.

INTRODUCTION

Midkine is a novel heparin-binding growth factor, originally identified as the product of a retinoic acid-responsive gene. Midkine and pleiotrophin (PTN; also called HB-GAM) are the only members of a family distinct from other heparin-binding growth factor families[1,2]. In the last few years, midkine has been found to be overexpressed in various human malignant tumors, such as esophageal[3-5], gastric[4,5], colorectal[4-6], liver[4,7,8], lung[9], thyroid[10], urinary bladder[11] and prostate carcinomas[12], as well as neuroblastomas[13] and astrocytomas[14,15]. Especially in neuroblasmas[13] and bladder carcinomas[11], the level of midkine expression correlates negatively with the patients' prognosis. Furthermore, it has also been reported that midkine is extensively expressed in the early stages of carcinogenesis[6,12]. All of these studies suggested that midkine may play an important role in carcinogenesis, development and metastasis of tumors, and that it could serve as a novel tumor marker.

In the present study, we investigated midkine expression in esophageal squamous cell carcinoma (ESCC). First, we detected midkine mRNA and midkine protein expression in EC109 cells (a cell line of well differentiated human esophageal squamous cell carcinoma) by means of RT-PCR and immunochemical staining, respectively. Then we examined midkine expression in 66 cases of ESCC tissues by immunohistochemical staining using monoclonal antibody against human midkine, and analyzed the correlation between midkine expression and clinicopathological features.

MATERIALS AND METHODS

Cell lines

EC109 cells, a well differentiated human ESCC cell line, established by National Laboratory of Molecular Oncology, Cancer Institute and Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College

in 1976, and generously supplied by Department of Immunology, the School of Oncology, Peking University, were maintained in RPMI1640 with 100 mL/L heat-inactivated fetal bovine serum in humidified 50 mL/L CO_2 atmosphere at 37 ℃.

RT-PCR

Total RNA was extracted from EC109 cells with a single method using the Trizol reagent according to the manufacturer's protocol. Complementary DNA (cDNA) of EC109 cells was synthesized from 5 μg of total RNA using M-MLV reverse transcriptase. PCR was performed in a total of 20 μL reaction mixture, comprising Taq DNA polymerase, dNTPs, buffer, 10 μmol/L of each gene-specific forward and backward primers and 2 μL of cDNA. β-actin mRNA levels were used as internal controls. The sequences of PCR primers are as follows: for midkine, 5' AAAGAATTCGAGATGCAGCAC CGAGG 3' (forward) and 5' AAACTCGAGCCAG GCTTGGCGTCTAGTC3' (backward); for β-actin, 5' AACTGGGACGACATGGAGAA 3' (forward) and 5' GGTAGTCAGTCAGGTCCC3' (backward). Expected RT-PCR product sizes were 477 bp for midkine and 318 bp for β-actin. PCR conditions consisted of an initial denaturation step for 5 min at 94 ℃, followed by 35 cycles of amplification (denaturation for 30 s at 94 ℃, annealing for 30 s at 62.5 ℃, and extension for 30 s at 72 ℃) and a final extension for 10 min at 72 ℃. Then 7 μL of PCR product was electrophoresed on 15 g/L agarose gels to visualize cDNA products.

Immunocytochemical staining of EC109 cells

Dako EnVision system was used for imm-unocytochemical staining of midkine. EC109 cells were fixed with acetone/methanol (1∶1, V/V). Endogenous peroxidase activity was blocked by incubating the sections with 30 mL/L hydrogen peroxide for 10 min at room temperature. After washed with PBS, the slides were blocked with 50 mL/L horse serum for 1 h at 37 ℃, followed by incubation with mouse anti-human midkine antibody overnight at 4 ℃. After washed with PBS, the slides were incubated with EnVision for 1.5 h at 37 ℃ and then further washed for 3 times with PBS. After that the sections were reacted with DAB for 5 to 7 min to allow visualization. Finally, the slides were counterstained with hematoxylin, dehydrated, and evaluated under a light microscope.

Patients

Sixty-six specimens of ESCC were obtained from patients who underwent surgery at Beijing Cancer Hospital from Aug. 1998 to Dec. 2000. None of the patients received chemo- or radiotherapy prior to resection. These patients included 56 males and 10 females, aged from 38 to 76 years with a median age of 57.5 years. All the cases had been pathologically proven to be ESCC, including 26 well, 23 moderately and 17 poorly differentiated tumors; and 35 metastatic lymph node specimens.

Immunohistochemical staining of tumor tissues

Mouse monoclonal antibody against human midkine was prepared by our laboratory[16]. Secondary antibody of EnVision kit was purchased from Dako Inc. The sections were stained using standard EnVision, peroxidase method. Four-micrometer-thick tissue sections were dewaxed with xylene and rehydrated with graded ethanol, then briefly immersed in water. Endogenous peroxidase activity was blocked by incubating the sections with 30 mL/L hydrogen peroxide for 10 min at room temperature. Then heat-mediated antigen retrieval was performed by heating the sections (immersed in 0.01 mol/L citrate buffer, pH 6.0) in a microwave oven for 10 min. After washed with PBS, the slides were blocked with 50 mL/L milk to prevent nonspecific binding for 1 h at 37 ℃, followed by incubation with mouse anti-human midkine antibody overnight at 4 ℃. After washed with PBS, the slides were incubated with EnVision for 1.5 h at 37 ℃ and then further washed for 3 times with PBS. Finally, the sections were reacted with DAB for 5 to 7 min to allow visualization, and counterstained with hematoxylin, dehydrated, and evaluated under a light microscope. The sections known to be midkine positive were stained under the same conditions as above and served as positive controls. For negative controls, sections were processed as above but the primary antibody was replaced by PBS. Anti-midkine immunoreactivity was confined primarily to the cytoplasm. One hundred cells from 5 randomly selected representative fields (× 400) of each section were counted. It was consid-ered positive when all immunoreactivity levels were more than 10% with anti-midkine antibody.

Statistical analysis

The χ^2 test was used to examine the differences of midkine expression between groups, and Cox regression was employed to analyze the correlation between midkine expression and patients' post-operation survival time by SPSS 11.0 software. $P<0.05$ was considered as statistically significant.

RESULTS

Midkine expression in EC109 cells

Midkine mRNA transcription was detected in EC109 cells by means of RT-PCR (Figure 1). After amplification of RT-PCR, we observed that there were two strands located in the gaps from 400 bp to 500 bp and from 300 bp to 400 bp, respectively. The sizes of RT-PCR product indicated by strands were conformed with expected RT-PCR product sizes of 477 bp for midkine and 318 bp for β-actin. The positive signals of midkine protein immunocytochemical staining were located in cytoplasm. Expression of midkine protein was observed in EC109 cells (Figure 2).

Expression of midkine protein in ESCC tissues

Midkine expression was confined primarily to the cytoplasm, shown as brown granules (Figure 3A). Midkine was expressed in 37 of 66 ESCCs (56.1%), while it was present at a very low level in just a few normal esophageal epithelia adjacent to tumor tissues. Midkine positive tumor cells were distributed in foci, and the intensity of midkine was stronger at the area abundant in vessels and the invading border of tumors (Figure 3B). In addition, Midkine ex-

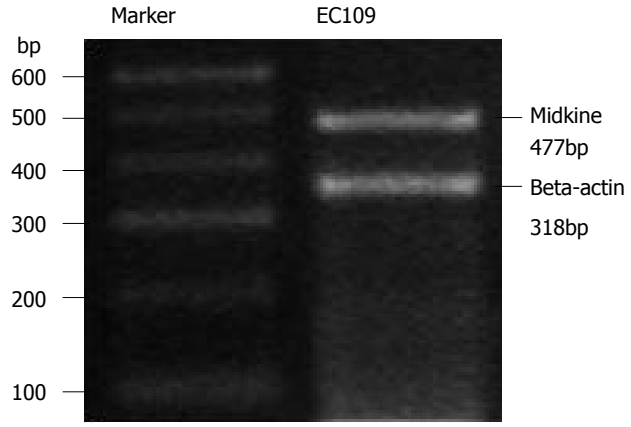

Figure 1 Amplification of midkine mRNA in EC109 cells by RT-PCR.

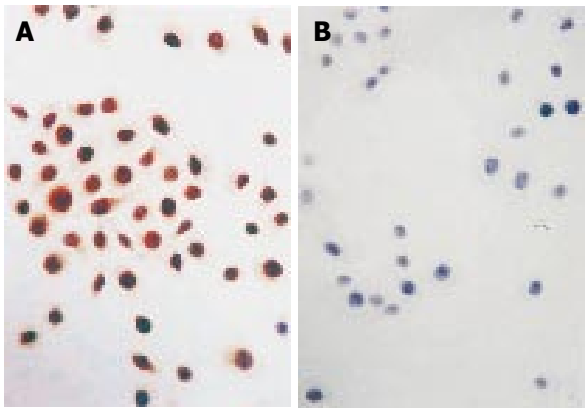

Figure 2 Midkine expression in EC109 cells (Immunoperoxidase method ×400). **A**: Positive in EC109 cells; **B**: Negative control.

pression was also found in epithelial cells and smooth muscle cells of vessels in tumor stromal elements.

Correlation between midkine protein expression and clinicopathological features

Midkine was expressed in 20 of 26 well differentiated ESCCs (76.9%), more than that in moderately (10/23, 43.1%) and poorly (7/17, 41.2%) differentiated tumors ($P<0.05$). There was no statistically significant correlation between midkine expression and gender, age, clinical stage, lymph node metastasis or post-operation survival time in ESCC ($P>0.05$, Table 1).

DISCUSSION

Many studies have shown that growth factors not only promote tissue proliferation but also induce malignant transformation, and they play important roles in the development of neoplasm[17]. Over-expression of growth factors has been found in many human tumors. Midkine, a novel heparin-binding growth factor, is strongly expressed in mid-gestational period. While in normal adult tissues, its expression is highly restricted. It is normally highly expressed in small bowel epithelium, moderately expressed in the thyroid and lowly expressed in lung, stomach, colon and kidney[18]. In the last few years, Midkine has been found

to be over-expressed in various human malignant tumors, such as esophageal[3-5], gastric[4,5], colorectal[4-6], liver[4,7,8], lung[9], thyroid[10], urinary bladder[11] and prostate carcinomas[12], as well as neuroblastomas[13] and astro-cytomas[14,15]. Especially in neuroblasmas[13] and bladder carcinomas[11], the level of midkine expression correlates negatively with the patients' prognosis. It has also been reported that midkine is extensively expressed in the early stages of carcinogenesis[6,12]. Further studies showed that midkine had several cancer-related activities. Midkine could transform NIH3T3 cells[19] and enhanced the plasminogen activator/plasmin levels in bovine endothelial cells[20]. It also promotes cell growth[21,22], cell survival[23] and migration of various cells such as neutrophils and macrophages[24]. These biological activities of midkine supported the possible involvement of midkine in carcinogenesis and tumor advancement.

To further investigate the role of midkine in carcinogenesis and tumor advancement, we examined midkine expression in ESCC. First, we found that midkine was expressed in EC109 cell by means of RT-PCR and immunocytochemistry. Further, we examined midkine expression in 66 ESCC samples using immunohistochemistry. Our data showed that midkine was over-expressed in ESCC with the positive rate of 56.1% (37/66), while it was present at a very low level in just a few normal esophageal epithelium adjacent to tumor tissues. And the intensity of midkine was stronger at the area abundant in vessels and the invading border of tumors. Midkine expression was also found in epithelial cells and smooth muscle cells of vessels in tumor stromal tissues. These characteristics of distribution were confirmed in Kato's study[10], suggesting

Table 1 Intensity of midkine expression in relation to clinicopathological variables in esophageal squamous cell carcinoma

Variable		*n*	Positive *n*	Negative *n*	Positive rate (%)	χ^2 value	*P* value

	Negative	31	19	12	61.3		

[a]$P<0.05$ as compared between well differentiated and moderately or poorly differentiated tumors.

that midkine may play a role in tumor angiogenesis and invasion. It has been demonstrated that midkine could promote the endothelial cells growth and it is a novel molecular mediator in tumor angiogenesis[25].

Our study also showed that the expression of midkine was correlated with tumor cell differentiation in ESCC. Midkine was more intensively expressed in well differentiated tumors (76.9%) than in moderately (43.1%) and poorly (41.2%) differentiated tumors ($P<0.05$). The phenomenon that the more poorly tumor cells differentiated, the weaker midkine was expressed was also observed in other studies on midkine expression in esophageal cancer and vulvar tumors[2,26].

In summary, our study showed that midkine was overexpressed in ESCC. It may play a role in tumor angiogenesis and invasion. The expression of midkine was correlated with tumor cell differentiation in ESCC: the more poorly tumor cells differentiated, the weaker midkine was expressed. Since midkine is a secretory protein, midkine level in blood can be detected when it over-expresses in tumors. It has been reported that an elevated serum midkine level can be detected in many malignant tumors, and serum midkine level decreases after the removal of tumors[27, 28]. In addition, the elevated midkine level even can be detected in urine[29]. These studies suggest that midkine could serve as a tumor marker which can be conveniently detected.

Abstract

AIM: To study the SSTR1, 2, 3, 4, 5 expression and their relationships with clinico-pathological factors, cell proliferation, Bcl-2 and p53 expression in colorectal cancer cells.

METHODS: Immunohistochemical staining of five SSTR subtypes, Ki-67, Bcl-2 and p53 was performed by the standard streptavidin-peroxidase (SP) technique for the paraffin sections of 127 colorectal cancers. and expression of five SSTR subtypes in 40 specimens of normal colorectal mucosae was detected with the same method.

RESULTS: Positive staining for five SSTR subtypes was observed in colorectal cancer cells and normal colorectal mucosae. SSTR1 was the most predominant subtype in both colorectal cancer and normal colorectal mucosa, and the second was SSTR5 or SSTR2. As compared with normal colorectal mucosa, SSTR4 was more frequently expressed in colorectal cancer cells (2.5% *vs* 18.9%, $P < 0.05$); the expression of SSTR2, 4, 5 in moderately to well differentiated colorectal adenocarcinoma was significantly higher than that in poorly differentiated ones ($P < 0.05$), the SSTR1 expression in colorectal cancer with positive lymph node metastasis was significantly higher than that with negative lymph node metastasis (72.2% and 54.5%, $P < 0.05$). In addition, in the ulcerative type of colorectal cancer, SSTR2 expression was obviously decreased ($P < 0.05$); the correlation did not reach a statistical significance between the five SSTR subtypes expression and Dukes'stages ($P > 0.05$), but the frequency of SSTR1 expression increased with Dukes' stage, while SSTR3 and SSTR5 expression decreased with Dukes' stage. Moreover, there was no correlation between expression of the five SSTR subtypes and other clinicopathological factors such as age, sex, tumor site, tumor depth, distant metastasis. The proliferative indexes in colorectal cancer cells with negative expression of SSTR2 and SSTR3 were significantly higher than that with positive expression ($P < 0.05$). The Bcl-2 expression in colorectal cancer cells with positive expression of SSTR1, 2, 3, 5 was significantly lower than that with negative expression ($P < 0.05$). There was no correlation between five SSTR subtypes and p53 expression.

CONCLUSION: The most predominant SSTR subtype is SSTR1, and the second is SSTR2 or SSTR5. Five SSTR subtypes play different roles in the development of colorectal cancer. SSTR2 and SSTR3 can inhibit the proliferation and promote apoptosis of tumor cells.

INTRODUCTION

Somatostatin analogue (SSTA) may inhibit the growth of various tumor cells by direct interaction with specific somatostatin receptors (SSTR) on tumor cells. However, conflicting clinical results were obtained in patients with colorectal cancers treated with SSTA[1]. Many authors think the rationale for the clinical efficacy of SSTA in the management of colorectal cancer may be related to the direct inhibitory effect of SSTA, consequently, with the expression of SSTR subtypes on tumor cells[2,3]. To date, five SSTR subtypes, SSTR1-SSTR5, have been cloned in human tissues, however, few researches on their expres-

cance were reported, and the results were inconsistent[3-6]. In this study, we used an immunohistochemical method to detect the expression of five SSTR subtypes protein in colorectal cancer cells and to explore correlation between each subtype expression and clinicopathological factors, cell proliferation or apoptosis. It will provide the basis for the treatment of colorectal cancer with SSTA.

MATERIALS AND METHODS

Patients and samples

A total of 127 cases of colorectal adenocarcinoma were involved in this study. The patients with colorectal carcinomas, who underwent surgical resection at the Second Hospital Affiliated to Fujian Medical University (Quanzhou, China) from January 1, 2003 to June 30, 2004, had received neither chemotherapy nor radiation therapy before surgery. There were 73 men and 54 women, and their mean age was 58.5 (SD, 13.9; range, 24-84) years. specimens were obtained from right colon (31), left colon (27), rectum (69). According to the Chinese Dukes' Staging criteria, 15 cases were stage A, 31 cases were stage B, 46 cases were stage C and 14 cases were stage D. Among 127 patients, 102 were moderately to well differentiated and 25 poorly differentiated adenocarcinomas. Meantime, 40 specimens of morphologically normal colorectal mucosae were examined from the same patients at a minimal distance of 10 cm from the diseased area.

All specimens were routinely fixed in neutral-buffered formalin and embedded in paraffin. Serial 4 μm sections were cut from archived paraffin blocks and subjected to immunohistochemical study. In each case, standard hematoxylin-eosin staining was employed for routine histological examination.

Reagents

Goat anti-human SSTR2, SSTR3, SSTR4 and SSTR5 polyclonal antibody were purchased from Santa Cruz Biotechnology Co. (California, U.S.A.). Rabbit anti-human SSTR1 polyclonal antibody, mouse anti-human Ki-67 monoclonal antibody (MBI.1), mouse anti-human Bcl-2 monoclonal antibody (100/D5), mouse anti-human p53 monoclonal antibody (DO-7), SP staining kit and DAB kit were supplied by Maixin-Bio Co., Fuzhou, China.

Methods

The immunohistochemical staining for five SSTR subtypes, Ki-67, Bcl-2 and p53 expression in colorectal cancer cells and five SSTR subtypes expression in normal colorectal mucosae were carried out by the standard streptavidin-peroxidase (SP) technique. Briefly, after deparaffinization and rehydration, the antigen retrieval of the sections was achieved by incubation in 0.01mol/L citric acid buffer (pH 6.0) and boiled for 1 min in a pressure cooker, and then cooled and washed in tap water. The sections were incubated with hydrogen peroxide for 10 min and washed in PBS. Nonspecific reactions were blocked by incubating the sections in a solution containing normal serum. The sections were incubated with a primary antibody (anti-SSTR1, SSTR2, SSTR3, SSTR4, SSTR5, Ki-67, Bcl-2 or p53 antibodies) overnight at 4℃. The working dilution of anti-SSTR2, SSTR3, SSTR4, SSTR5 antibodies was 1:400. Rinsed with PBS, then the sections were incubated for 10 min at room temperature with biotinylated secondary antibody. After washing, streptavidin biotin complex conjugated to horse-radish peroxidase was applied for 10 min at room temperature. Again after three rinses with PBS, the sections were incubated with diaminobenzidine substrate, then rinsed with distilled water and counterstained with hematoxylin, finally dehydrated and cover slipped. The sections were prepared for microscopic observation. The known positive colorectal cancer tissues were used as positive control. As negative control, PBS was used to replace primary antibody.

Scoring criteria for SSTR subtypes expression

Intensity and percentage of positive cells were used to evaluate each tissue section. The mean percentage of positive tumor cells to normal epithelial cells in at least five areas at 400 magnification was determined and assigned to one of five categories: 1) 0, < 5%; 2) 1, 5% to 24%; 3) 2, 25% to 49%; 4) 3, 50% to 74%; and 5) 4, ≥ 75%. The intensity of SSTR subtype immunostaining was scored as 0 (achromatic), 1(light yellow), 2(yellow), and 3(brown). The percentage of positive cells and staining intensity were multiplied to produce a weighted score for each case. Cases with weighted scores less than 1 were defined as negative; all others were defined as positive.

Evaluation of staining for p53 and Bcl-2

For p53 or Bcl-2 expression, cases with ≤ 10% positively-stained tumor cells were defined as negative; otherwise, the definition was positive.

Determination of the Ki-67 proliferative index

At least 5 high-power fields were chosen randomly in each section, and 500 cells were counted for each field. The Ki-67 proliferative index was defined as the number of Ki-67-positive nuclei divided by the total number of colorectal cancer cells counted and was expressed as a percentage.

Statistical analysis

The statistical software package SPSS 11.5 was used. Clinicopathological variables associated with SSTR subtypes expression as well as the correlation between SSTR subtypes and p53 or Bcl-2 expression were analyzed by either the χ^2 test or Fisher's exact test. The correlation between SSTR subtypes and proliferative index was analyzed by t test. $P < 0.05$ was considered significant.

RESULTS

Expression of five SSTR subtypes

Positive-staining for all SSTR subtypes was identified in the cytoplasm and membrane of colorectal cancer cells and normal colorectal mucosa with brown-yellow granules (Figures 1-5). The positive rates of SSTR1, SSTR2, SSTR3, SSTR4 and SSTR5 expression were respectively 64.6% (52/127), 36.2% (46/127), 18.9% (24/127), 18.9% (24/127), 38.6% (49/127) in colorectal cancer and 52.5% (21/40), 40% (16/40), 30% (12/40), 2.5% (1/40), 32.5% (13/40) in normal colorectal mucosa (Table 1). SSTR1 was

Table 1 SSTR expression in colorectal cancer

Tissue	*n*	Expression *n* (%)				
		SSTR1	SSTR2	SSTR3	SSTR4	SSTR5
Normal mucosa	40	21(52.5)	16(40.0)	12(30.0)	1(2.5)	13(32.5)
Colorectal cancer	127	52(64.6)	46(36.2)	24(18.9)	24(18.9)[a]	49(38.6)

[a]$P<0.05$ *vs* normal mucosa.

the most predominant subtype in both colorectal cancer and normal colorectal mucosa, and the second was SSTR5 or SSTR2. As compared with normal colorectal mucosa, SSTR4 was more frequently expressed in colorectal cancer cells (2.5% *vs* 18.9%, $P < 0.05$), and the positive rates of other subtypes expression were not different between colorectal cancer and normal colorectal mucosa ($P > 0.05$).

Correlation between SSTR expression and clinicopathological factors

The expression of SSTR2, 4, 5 in moderately to well differentiated colorectal adenocarcinoma was significantly higher than that in poorly differentiated colorectal adenocarcinoma ($P < 0.05$)(Table 2). The SSTR1 expression in colorectal cancer with positive lymph node metastasis was significantly higher than that with negative lymph node metastasis (72.2% and 54.5%, $P < 0.05$). The correlation did not reach a statistical significance between the five SSTR subtypes expression and Dukes' stages ($P > 0.05$), but the frequency of SSTR1 expression increased with Dukes' stage, while SSTR3 and SSTR5 decreased with Dukes' stage. In addition, in the ulcerative type of colorectal cancer, SSTR2 expression was obviously decreased ($P < 0.05$); however, there was no correlation between expression of the five SSTR subtypes and other clinicopathological factors such as age, sex, tumor site, tumor depth, distant metastasis.

Correlation between SSTR expression and proliferative index and Bcl-2 or p53

The proliferative indexes in colorectal cancer cells with negative expression of SSTR2 and SSTR3 were significantly higher than that with positive expression ($P < 0.05$, Table 3). A positive cytoplasmic immunoreactivity for Bcl-2 was detected in 67 of 127 cases (52.8%). The Bcl-2 expression in colorectal cancer cells with positive expression of SSTR1, 2, 3 ,5 were significantly lower than that with negative expression ($P < 0.05$, Table 3). In contrast, nuclear accumulation of p53 was demonstrated in 81 of 127 cases (63.8%). There was no correlation between five SSTR subtypes and p53 expression.

DISCUSSION

Five SSTR subtypes belong to G proteins family, and different SSTR subtypes can be expressed in various patterns in different normal tissues or tumors. Evaluation of five SSTR subtypes expression in tumors may help understand carcinogenesis, and progression of tumors, as well as diagnosis and treatment. There are some controversies on the dominant SSTR subtype and the correlation between five SSTR subtypes expression and clinicopathological factors in colorectal cancer cells. Buscail *et al* found that SSTR2 expression was lost in colorectal cancer[3]. However, some subsequent studies demonstrated that there was no difference between SSTR subtypes expression between normal colorectal mucosae and colorectal cancer[5-7]. Also some results indicated the most frequent subtype was SSTR2 or SSTR5 in colorectal cancer[3,6,8]. The expression of SSTR2 or SSTR5 was significantly lower in Dukes' C and D stages of colorectal cancer than that in Dukes' A and B stages. The decrease of SSTR2 or SSTR5 expression may be related to tumor local invasion and metastasis, which may provide a growth advantage in colorectal cancer. It is possible that SSTR2 or SSTR5 acts as a tumour suppressor[3,6]. But recent research showed there was no correlation of SSTR mRNA expression with Dukes' stages[7].

In this study, only the frequency of SSTR4 expression in colorectal cancer cells was higher than that in the colorectal mucosae. SSTR1 was expressed predominantly in colorectal cancer cells, followed by SSTR5 and SSTR2. There was no correlation between five subtypes expression and Dukes' stages. The differences of our results from previous findings may be accounted for by different research methods. SSTR subtypes can express not only in colorectal cancer cells but also in other constituents of cancer tissue, such as vessels[9]. Thus, the PCR method tends to overestimate the real contribution of the various messengers for receptors owing to the outstandingly sensitive technique, and mRNA levels do not necessarily reflect the presence of the SSTR protein in certain cancers. To detect protein expression of SSTR by receptor autoradiography can not completely reflect protein levels of five SSTR subtypes, because there are major differences in binding affinity of SSTA to various SSTR subtypes[1]. In addition, the discrepancy may be relevant to different reagents and the small sample size of our study. Cascade reaction induced by activation of SSTR2 and SSTR5 can inhibit proliferation of tumor cells. In our study, the expression of SSTR2, SSTR4 and SSTR5 reduced in poorly differentiated colorectal cancer, and the SSTR3 and SSTR5 expression showed a tendency to reduction with Dukes' stages. The loss of these receptors can weaken inhibition on the proliferation of tumor cells, and may provide a growth advantage in colorectal cancer. It suggests SSTR2, 3, 4, 5 may be related to the development of colorectal cancer.

This study also demonstrated that the Ki-67 proliferative index in colorectal cancer cells with positive expression of SSTR2 or SSTR3 was significantly lower than that with negative expression of SSTR2 or SSTR3. This further proved that somatostatin *in vivo* can directly inhibit colorectal cancer cell proliferation by activating SSTR2 and SSTR3. The transplantable models of pancreatic primary tumor and hepatic metastases were established in hamsters which were xenografted with human pancreatic cancer cell line transferred with the SSTR2 gene, and the following effects were induced: growth of tumors with SSTR2 positive expression was delayed and the Ki-67 proliferative index was decreased significantly[10,11]. Activation of SSTR2 and

[a]$P < 0.05$.

SSTR3 can inhibit the proliferation of cancer cell through the following mechanisms: SSTR2 and SSTR3 can inhibit adenylate cyclase activity, which results in reduction of intracellular cAMP concentration; they also can stimulate tyrosine phosphatase activity, modulate the mitogen activated protein kinases (MAPK) and upregulate the expression of the cyclin-dependent kinase inhibitor $p27^{Kip1}$ so that cell cycle arrest is induced; the effects on K^+ and Ca^{2+} channels lead to increased intracellular K^+ concentration and reduced intracellular Ca^{2+} concentration[12-15]. This study further verified that five SSTR subtypes play different roles in development of colorectal cancer. SSTR2 and SSTR3 can obviously inhibit the cell proliferation of colorectal cancer and have an important effect on the progression of colorectal cancer.

The activation of some SSTR subtypes not only directly inhibits the proliferation of tumor cells, but also is relevant to apoptosis. Bcl-2 is an apoptosis suppressor gene and important parameter of apoptosis. In this study, Bcl-2 expression in colorectal cancer cells with positive expression of SSTR1, SSTR2, SSTR3 or SSTR5 significantly decreased, indicating the four SSTR subtypes can promote the apoptosis of tumor cells and affect the progression of colorectal cancer by down-regulating the Bcl-2 expression or counteracting the anti-apoptosis effect of Bcl-2. They promote apoptosis via different mechanisms: Apoptosis is mediated by SSTR1 via a block in the G1/S progression in the cell cycle[16]. SSTR2 activation can promote apoptosis through the following pathways, it sensitizes cancer cells to apoptosis induced by tumor necrosis factor, induces caspase-8 activation cascade, stimulates mitochondrial cytochrome c released into the cytosol and downregulates the Bcl-2 expression[17]. In the mouse models of pancreatic primary tumor and hepatic metastases, which were xenografted with human pancreatic cancer cell line transferred with the SSTR2 gene, it has been demonstrated that activation of caspase-3 and apoptotic index increased, expression of anti-apoptosis protein Bcl-2 decreased in tumor cells expressing SSTR2[10,18]. Apoptosis can be signaled by SSTR3 which can activate phosphoprotein phosphates and lead to cellular acidification and activation of acidic endonuclease[19].

In conclusion, five SSTR subtypes play different roles in the development of colorectal cancer. SSTR2 and SSTR3 can inhibit the proliferation and promote apoptosis of tumor cells. The expression of SSTR2, SSTR4 and SSTR5 is correlated with malignant degree of colorectal cancer cells. Though SSTR1 is the predominant SSTR subtype, its ex-

pression is correlated with lymph node metastasis. SSTA, which has a high affinity to SSTR2, SSTR3 and/or SSTR5 should be a treatment choice for patients with colorectal carcinomas.

Abstract

AIM: To test the hypothesis that enhancement of the activity of heme oxygenase can interfere with processes of fibrogenesis associated with recurrent liver injury, we investigated the therapeutic potential of over-expression of heme oxygense-1 in a CCl_4-induced micronodular cirrhosis model.

METHODS: Recombinant adeno-associated viruses carrying rat HO-1 or GFP gene were generated. 1×10^{12} vg of adeno-associated viruses were administered through portal injection at the time of the induction of liver fibrosis.

RESULTS: Conditioning the rat liver with over-expression of HO-1 by rAAV/HO-1 significantly increased the HO enzymatic activities in a stable manner. The development of micronodular cirrhosis was significantly inhibited in rAAV/HO-1-transduced animals as compared to controls. Portal hypertension was markedly diminished in rAAV/HO-1-transduced animals as compared to controls, whereas there are no significant changes in systolic blood pressure. This finding was accompanied with improved liver biochemistry, less infiltrating macrophages and less activated hepatic stellate cells (HSCs) in rAAV/HO-1-transduced livers.

CONCLUSIONS: Enhancement of HO activity in the livers suppresses the development of cirrhosis.

INTRODUCTION

Heme oxygenase (HO) is a rate-limiting enzyme that cleaves pro-oxidant heme into equimolar amounts of carbon monoxide (CO), biliverdin/bilirubin, and free ferrous iron [1,2]. Up to date, three isoforms of HO have been identified. Among of them, HO-1 and HO-2 are expressed in livers. HO-2 expresses constitutively in hepatocyte and functions as an important enzyme in catalyzing the endogenous and exogenous heme. In contrast, HO-1 is an inducible form of HO in livers [3]. Although expression of HO-1 in the liver is primarily restricted to a subpopulation of Kupffer cells [3,4], the protein is expressed in both parenchymal and particularly non-parenchymal liver cells, and therefore results in higher enzymatic activities of HO under stress conditions [4]. The cytoprotective effects of enhanced HO activities in liver might be through the mechanisms associated with its catalytic products. All of its three catalytic products can contribute the protective effects of HO [5-7].

HO-1 was induced in the livers with cirrhosis [8]. It was thought to be an adoptive response to oxidative stresses, inflammatory insults of persistent or recurrent liver injury as well as the responsiveness to the increase of intrasinusoidal resistance. HO-1 was mainly expressed in Kupffer cells, sinusoidal endothelial cells, stellate cells and in a part of hepatocyte in livers with cirrhosis [8,9]. HO-1 was also expressed in vascular system that might contribute to the development of hemodynamic changes in the rats with cirrhosis [9]. In addition, higher levels of CO production might be associated with the development of hepatopulmonary syndrome in patients with cirrhosis [10]. Thus, it becomes controversy whether the expression of HO-1 or enhancement of HO activities contribute to the pathophysiological changes in the development of cirrhosis, or whether HO-1 functions as homeostatic molecule in controlling of disease progression. To elucidate the role of

HO-1 in the context of recurrent hepatocellular injury and the development of cirrhosis, here we take the advantage of adeno-associated viral vector to increase the overall HO enzymatic activity of the liver in a stable manner and to investigate the effects of HO-1 in the disease progression in carbon tetrachloride (CCl_4)-induced cirrhosis model.

MATERIALS AND METHODS

Generation of recombinant adeno-associated viral vectors (rAAVs)

rAAVs were produced and purified as previously described [11]. In brief, a full-length HO-1 gene originally cloned from the spleen of a LEW rat or the reporter gene GFP was inserted into the vector plasmid to construct pSNAV1/GFP or pSNAV1/HO-1. rAAV/GFP or rAAV/HO-1 was generated in BHK-21 cells (American Type Culture Collection, Manassas, VA) by transfection of vector plasmid and subsequent rescue rAAVs (serotype 2) by co-infection with recombinant HSV1-rc/ΔUL2, which is essential for viron packaging. A large scale of rAAV was purified as described [12].

Animal model and gene delivery protocol

Inbred LEW rats (230-250 g) were purchased from the Animal Institute of Medical School Hannover, Germany and were maintained in the Laboratory Animal Unit of the University of Hong Kong. The study was approved by the Committee on the Use of Live Animals for Teaching and Research, the University of Hong Kong. Micronodular liver cirrhosis in LEW rats was induced using a protocol described previously [13]. In brief, phentobarbital sodium (35 mg/L) was given one week before the first dose of CCl_4 in order to increase the sensitivity of the rat liver to CCl_4 and was present in drinking water in the whole period of induction. A total of 9 doses of CCl_4 (0.2 mL/kg per wk) were given to the rats intragastrically. rAAVs (1×10^{12}v.g.) was given through the portal vein of rats at the time pentobarbital was given in drinking water and 7 d before the first dose of CCl_4.

Liver biochemistry, histology, immunohistochemistry and ELISA

Serum samples were collected at the end point of experiments. The activities of alanine aminotransferase (ALT) and total bilirubin in the plasma were measured in the Department of Clinical Biochemistry, the University of Hong Kong. Liver samples were snap frozen and stored at -75 ℃ until further applications. Five micrometers of frozen sections were used for hematoxylin and eosin staining, Masson's trichrome staining, and immunohistochemistry. The area of fibrotic tissues in the cross section of livers was measured by the computer software (MetaMorph imaging system, Universal Imaging Corporation, PA) after Masson's trichrome, collagen 1α and fibronectin staining. All measurements were done in a double-blind manner with at least 20 areas/liver (fibrotic area, original 200×) in the 5 livers/group. Mouse anti-rat ED1 (infiltrating macrophage), anti-ED2 (tissue residential macrophage), anti-HO-1 (OSA-111) monoclonal antibodies and polyclonal anti-TGF-β1, anti-desmin, anti-collagen 1α, and anti-fibronectin antibodies (Serotec Ltd., Oxford, UK; Stressgene, Victoria, British Columbia, Canada; Chemicon, Temecula, CA; Santa Cruz, CA) were applied in this study for immunohistochemistry using the standard horseradish peroxidase protocol. Serum macrophage migration inhibitory factor (MIF) level was detected by ELISA according to the instruction of manufacturer (Chemicon).

Measurement of portal and systolic blood pressure

Animals were anesthesized with ketamine (100 mg/kg, ip) and Rompun (0.2 mg/kg, ip). Portal pressure and systolic blood pressure were measured by directly introducing 24G Angiocath® (BD Biosciences, San Jose, CA) into the portal vein or abdominal aorta and connecting with a saline filled strain gauge transducer. The signals were monitored by Colin BP-408 Mark III (Japan) and were set to zero before the measurement.

HO enzymatic activity

The HO enzymatic activity was measured by the production of microsomal bilirubin in the liver. Frozen samples of livers were homogenized in ice-cold sucrose and Tri-HCl buffer. Microsomal pellet was obtained after centrifugation and was then re-suspended in $MgCl_2$-potassium phosphate buffer. Sample protein was further incubated with the reaction mixture containing rat liver cytosol, hemin, glucose-6-phosphate, glucose-6-phosphate dehydrogenase and NADPH (Sigma-Aldrich, St. Louis, MO) for 60 minutes at 37 ℃. The generated bilirubin was measured using spectrophotometry. The level of bilirubin production was demonstrated by the ratio of sample/normal liver.

RNase protection assay

The mRNA level of target genes was determined by RNase protection assay according to the instruction of manufacturer (RiboQuant kit, BD Biosciences Pharmingen, San Diego, CA). In brief, total RNA of transduced and non-transduced liver samples were extracted and purified using Rneasy kit (Qiagen, Hilden, Germany). Three micrograms of RNA/samples were hybridized with complimentary [^{32}P]UTP labeled riboprobes overnight. The probes were digested with Rnase and were loaded on a denatured polyacrylamide gel. The radioactive signals were then detected by exposure to X-ray film (BioMax, Kodak, Rochester, NY) and quantified by phosphorimaging (Strom, Molecular Dynamics, Sunnyvale, CA).

Statistical analysis

Data were demonstrated as mean ± SEM. One-way ANOVA was used to compare the difference of means between the experimental groups with the Bonferroni's *t*-test. $P<0.05$ was considered statistically significant.

RESULTS

rAAV-mediated stable HO enzymatic activity in rat liver

To enhance HO activity in a stable manner, we administered the rAAV carrying rat HO-1 cDNA to the liver through portal injection. After the injection, a large num-

ber of HO-1 positive non-parenchymal cells were found in both rAAV/GFP and rAAV/HO-1-transduced livers on d 7 (17.7 ± 0.5 cells/mm^2 versus 10.8 ± 0.7 cells/mm^2, n = 3). However, the number of positive cells decreased dramatically to a level similar to normal livers in rAAV/GFP transduced liver on day 30, whereas there was a significantly larger number of HO-1-positive non-parenchymal cells in rAAV/HO-1-transduced livers (3.9 ± 0.8 cells/mm^2 *vs* 5.8 ± 1.0 cells/mm^2, n = 3, P < 0.05; Figures 1A and 1B). No HO-1 positive hepatocyte was found in both rAAV/GFP and rAAV/HO-1 treatment groups on d 7. The expression of HO-1 in hepatocyte was first detected sporadically on d 14 after portal injection of rAAV/HO-1, whereas there was no HO-1 positive hepatocyte in rAAV/GFP-transduced livers (data not shown). More HO-1 positive hepatocytes could be detected in rAAV/HO-1-transduced livers on d 30 (2.2 ± 0.3 cells/mm^2, n = 3, P < 0.05), whereas they remained undetectable in rAAV/GFP-transduced livers (Figures 1A and 1B). To evaluate the biological activity of transduced HO-1 in the livers, we determined the enzymatic activity of HO by measuring the generated bilirubin of microsomal protein isolated from the livers. There was a significant increase of HO activity of the rAAV-transduced livers on d 7 (the earliest time point that we detected). Both rAAV/GFP and rAAV/HO-1 transduced livers showed increased amount of generated bilirubin in isolated microsomal proteins. Impressively, the amount of generated bilirubin (0.9 fold over the basal level of normal rat liver) remained elevated in the rAAV/HO-1 treatment group and sustained for over 3 mo of observation time. In contrast, the amount of generated bilirubin decreased to the level of normal rats in the rAAV/GFP treatment group on d 14. (Figure 1C). This suggests the specificity of rAAV/HO-1 in the induction of stable HO activity in rat liver.

Enhancement of HO activity suppressed the development of cirrhosis in rats

Intragastrically administration of CCl_4 to adult LEW rats for 9 wk resulted in the formation of micronodular cirrhosis. To further evaluate the effects of elevated HO activity on the development of cirrhosis, we examined various parameters relating to cirrhosis after over-expression of HO-1 in rat liver by rAAV gene transfer (Figure 2A). Histological examination showed massive amount of fibrotic tissues accumulated in the portal tract areas of non-transduced or rAAV/GFP-transduced livers and led to the formation of micronodular cirrhosis accompanied with portal hypertension and lower systolic blood pressure in the majority of rats. rAAV/HO-1 gene transfer markedly diminished the amount of accumulated fibrotic tissues as shown in Masson's trichrome (MT) staining and immunohistochemistry. No micronodular cirrhosis was formed and only minimal fibrotic tissues could be found in the portal tract areas of rAAV/HO-1-transduced livers (Figure 2B). Analysis of fibrotic areas using the computer software showed that there was significantly less fibrotic element deposition in the rAAV/HO-1-transduced liver (7.9% ± 0.9% by MT staining, 3.1% ± 2.6% by collagen 1α

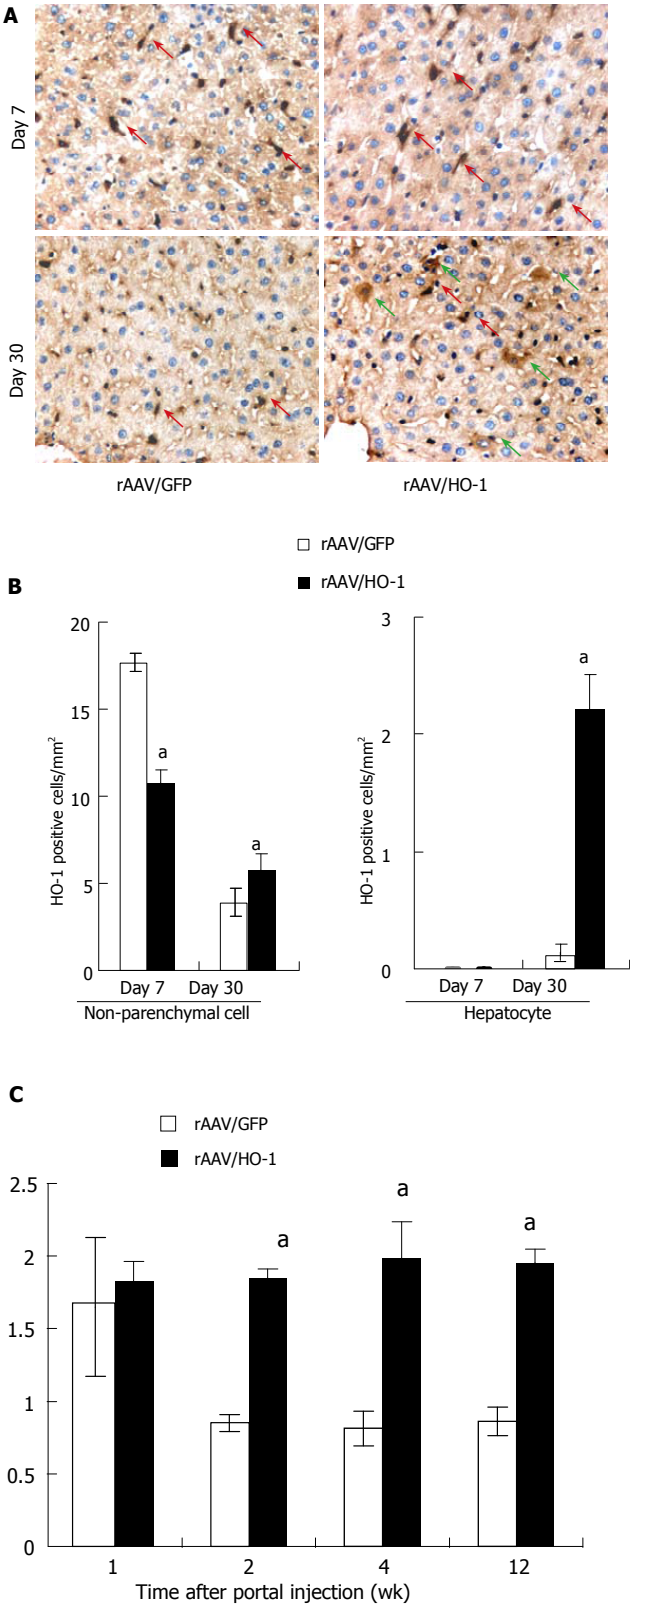

Figure 1 **A:** The expression patterns of HO-1 in the livers after portal injection of rAAV/HO-1 in LEW rats. Red arrow indicated the HO-1-positive non-parenchymal cells; green arrow indicated the hepatocyte; **B:** The quantification of the HO-1 positive cells in the liver after administration of rAAV/HO-1. Data were presented as number of HO-1 positive cells per mm^2; n = 3-5, mean ± SE, ^aP<0.05; **C:** The HO enzymatic activity of rAAV/GFP or rAAV/HO-1 transduced livers. The data were demonstrated as the amount of generated bilirubin of microsomal protein from liver tissues and were shown as the fold changes over the normal rat liver, mean ± SE, n = 3, ^aP < 0.05.

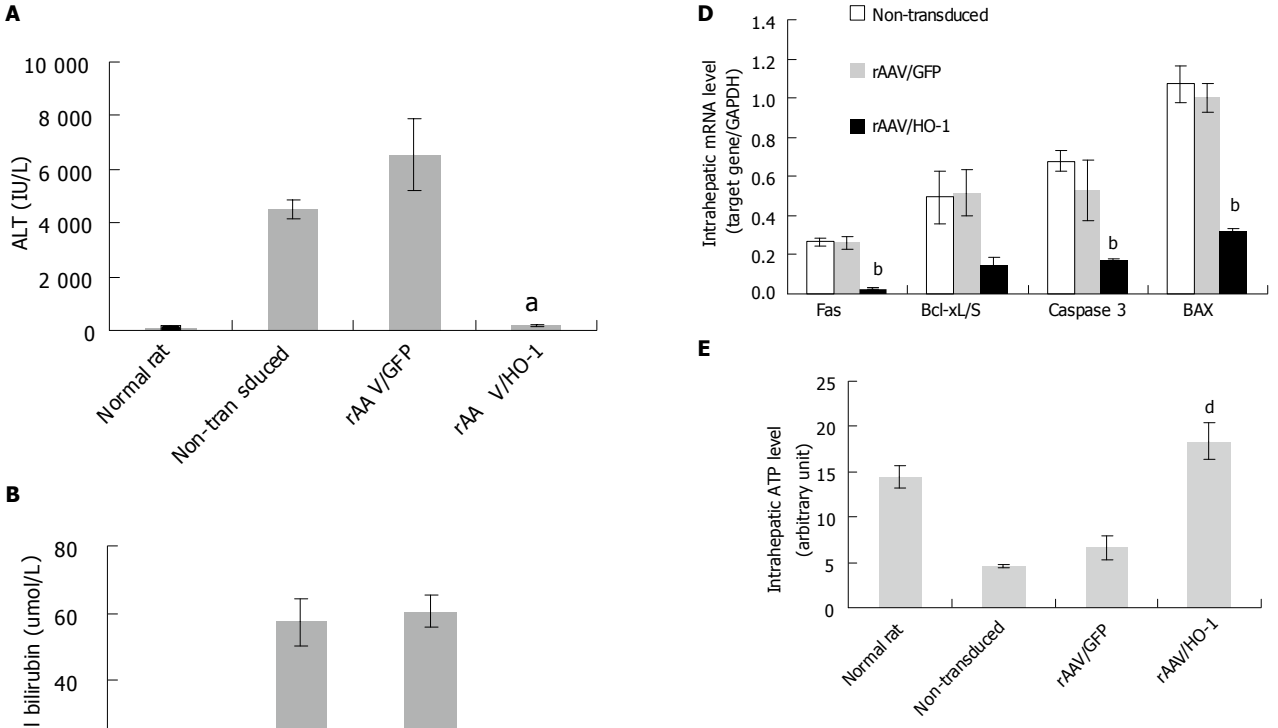
Data were shown as mean±SE, $n=5$, $^bP<0.001$; **D** and **E**: The systolic and portal pressure of rats after induction of liver cirrhosis with or without treatments. The data were shown as mean±SE, $n=10$, $^dP<0.001$.

staining, 4.4%±1.2% by fibronectin staining, $P<0.001$). In contrast, in the livers of non-treatment or rAAV/GFP treated groups, there was a higher level of fibrotic element deposition (22.2%±5.8% or 20.8%±3.8% by MT staining, 21.9%±5.7% or 24.5%±2.8% by collagen 1α staining, 24.1%±4.4% or 21.1%±3.6% by fibronectin staining, Figure 2C). In addition, the beneficial effects of HO-1 on the development of liver cirrhosis could be reflected by the reduction of portal hypertension (8.0±0.8 mmHg versus 13.3±0.4 mmHg in the non-treatment group and 13.8±0.6 mmHg in the rAAV/GFP treatment group, $P<0.001$), whereas there was no significant difference at the systolic blood pressure (81.7±0.3 mmHg) in comparison to non-treatment (81.8±0.6 mmHg) or vector controls (87.0±0.2 mmHg, $P>0.31$, Figures 2D and 2E).

Stable HO activity protected against CCl_4-mediated recurrent liver injury

Repeated administration of CCl_4 to adult rats led to chronic liver injury with elevated plasma level of total bilirubin (no treatment group: 57.25±6.95 μmol/L; rAAV/GFP group: 60.5±4.87 μmol/L) and ALT (non-treatment group: 4 522±334 IU/L; rAAV/GFP group: 6 552±1 363 IU/L, $n=5$). Increasing HO activity in the liver by rAAV/HO-1 significantly improved the liver function of rats under long-term CCl_4 toxicity, the amount of total bilirubin and ALT decreased dramatically in the rAAV/HO-1-treated rats in comparison to non-treatment or rAAV/GFP controls (total bilirubin: 6.20±3.49 μmol/L; ALT: 199.6±80.5 IU/L, $n=5$, $P<0.005$, Figures 3A and 3B). To further examine the protective effects of over-expressing HO-1 in the livers, we determined the transcript level of apoptotic genes and energy exchanges of livers under long-term CCl_4 toxicity. Rnase protection assay showed the transcript level of Fas, caspase 3, and BAX genes significantly diminished in the rAAV/HO-1-transduced livers ($n=3$, $P<0.05$,



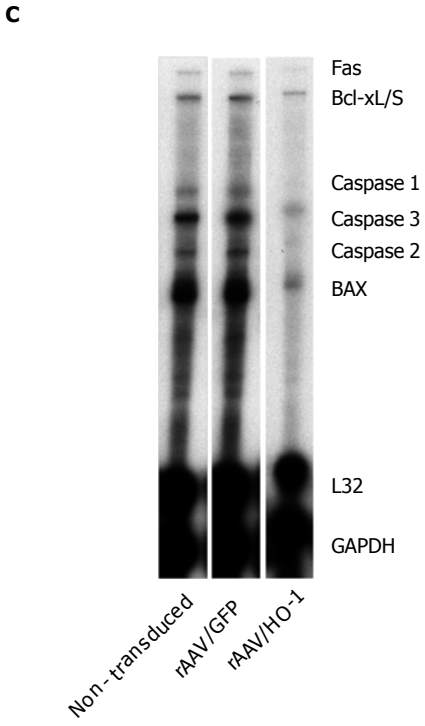


Figure 3 **A** and **B**: The liver function of rats with or with treatment under long-term CCl_4 toxicity was presented by the determination of plasma ALT and total bilirubin level. The data was shown as mean±SEM, n = 5-10, ^aP<0.001; **C** and **D**: The representative picture of the expression patterns of apoptotic genes in the livers at the 10th week. The mRNA level of genes was detected by RNase protection assay. The quantification of the expression level was measured by phosphoimager as described in Materials & Methods. The data were shown as mean ± SE, n = 3-5, ^bP<0.05; **E:** The ATP level of the livers of rats with or without treatments at the 10th wk, n = 5-10, ^dP<0.001.

Figures 3C and 3D), whereas these genes were strongly expressed in the non-transduced or rAAV/GFP-transduced livers. The beneficial effects of HO-1 on CCl_4-mediated chronic liver injury were also shown by the improvement of liver energy exchanges. Over-expression of HO-1 by rAAV significantly improved the intrahepatic ATP level in rAAV/HO-1transduced liver in comparison with non-treatment or rAAV/GFP-transduced livers of rats under long-term CCl_4 toxicity (n = 3-5, P < 0.05; Figure 3E).

Stable HO activity suppresses the pro-inflammatory and pro-fibrogenic responses in CCl_4-treated rats

To characterize the effects of HO-1 on the chronic inflammatory response followed by liver injury, we examined the histopathological parameters of liver tissues and transcript or protein level of pro-inflammatory cytokine-MIF. A large amount of ED1-positive (infiltrating) macrophages accumulated in the portal tract areas in the non-transduced or rAAV/GFP-transduced livers, whereas only a few ED1-positive macrophages were found in rAAV/HO-1-transduced livers (Figure 4A). In contrast, there was no significant change in the number of ED2-positive (tissue-residential) macrophages in the livers of CCl_4-treated rats. In consistent with the immunohistochemical stainings, detection of intrahepatic mRNA level by Rnase protection assay and serum levels of MIF by ELISA method showed significant reduction of the expression level of MIF in rAAV/HO-1-treated rats in comparison to non-treatment or rAAV/GFP controls (n = 3-5, P < 0.001, Figures 4B and 4C).

To examine the effects of rAAV/HO-1 on the fibrogenic process after liver injury, we next examined the

expression patterns of pro-fibrogenic cytokine-TGF-β1, which plays an important role in the activation and transition of HSCs to myofibroblast-like cells after liver injury. Immunohistochemistry showed that TGF-β1 was highly expressed in the portal tract areas in the livers of long-term CCl_4-treated rats. In contrast, only a minimal number of cells expressed TGF-β1 in rAAV/HO-1-transduced livers of rats under the same CCl_4 protocol (Figure 4A). Parallel to the immunohistochemical stainings, RNase protection assay also showed significant reduction in the transcript level of TGF-β1 in rAAV/HO-1-transduced livers (n = 3-5, P < 0.001, Figure 4B). This finding was associated with the decreased number of activated HSCs (desmin-positive) in rAAV/HO-1-transduced livers (Figure 4A).

DISCUSSION

There is a wide range of factors can result in hepatocellular injury. However, the primary response leading to subsequent pro-inflammatory and pro-fibrogenic responses in liver is extraordinary similar [14]. Analysis of clinical parameters based on the treatment of primary liver disease showed encouraging results in the decrease of the severity of liver fibrosis/cirrhosis [15,16]. However, none of anti-fibrotic treatment has been shown clinically effective. A number of therapeutic approaches targeting on anti-oxidant, anti-inflammatory response, suppression of HSC activation, induction of HSC apoptosis or increase of the degradation of extracellular matrix have been shown effective in the attenuation of the severity of liver fibrosis/cirrhosis in various animal models [14]. Most of them, however, cannot easily translate to the clinical setting, because the majority of approaches focus on the single step of disease progression and the clinical situation is far more complex than that in the experimental setting. Thus, it is still urged to find out a therapeutic target that has multiple effects on disease progression and can be applied potentially in the clinical setting.

HO-1-mediated anti-apoptotic and anti-inflammatory activities are among the most attractive mechanisms in cellular protection [17]. In fact, HO-1 only expresses in a subpopulation of Kupffer cells in normal liver, whereas a small amount of HO-2 is constitutively being expressed in hepatocyte [3,4]. None of them expresses in sinusoidal endothelial cells and hepatic stellate cells [3]. However, a significant increase in HO-1 expression was observed on the whole organ level under stress conditions [4]. In the liver with acute injury, HO-1 was expressed in the majority of Kupffer cells and infiltrating macrophages, which might function as a feedback loop to control the macrophage activation [18-20]. Although the whole HO activity increases dramatically, the need for the liver to overcome the insults of cellular injury seems to be relatively insufficient. Increasing HO activity by introduction of exogenous HO-1 by rAAV/HO-1 in our model that significantly improved the long-term outcomes of CCl_4-induced liver cirrhosis could be based on (1) the anti-apoptotic effects of HO-1 on hepatocyte; (2) the anti-inflammatory effects of HO-1 on the control of the cellular response of hepatocyte in the production of MIF under stress and/or injury condi-

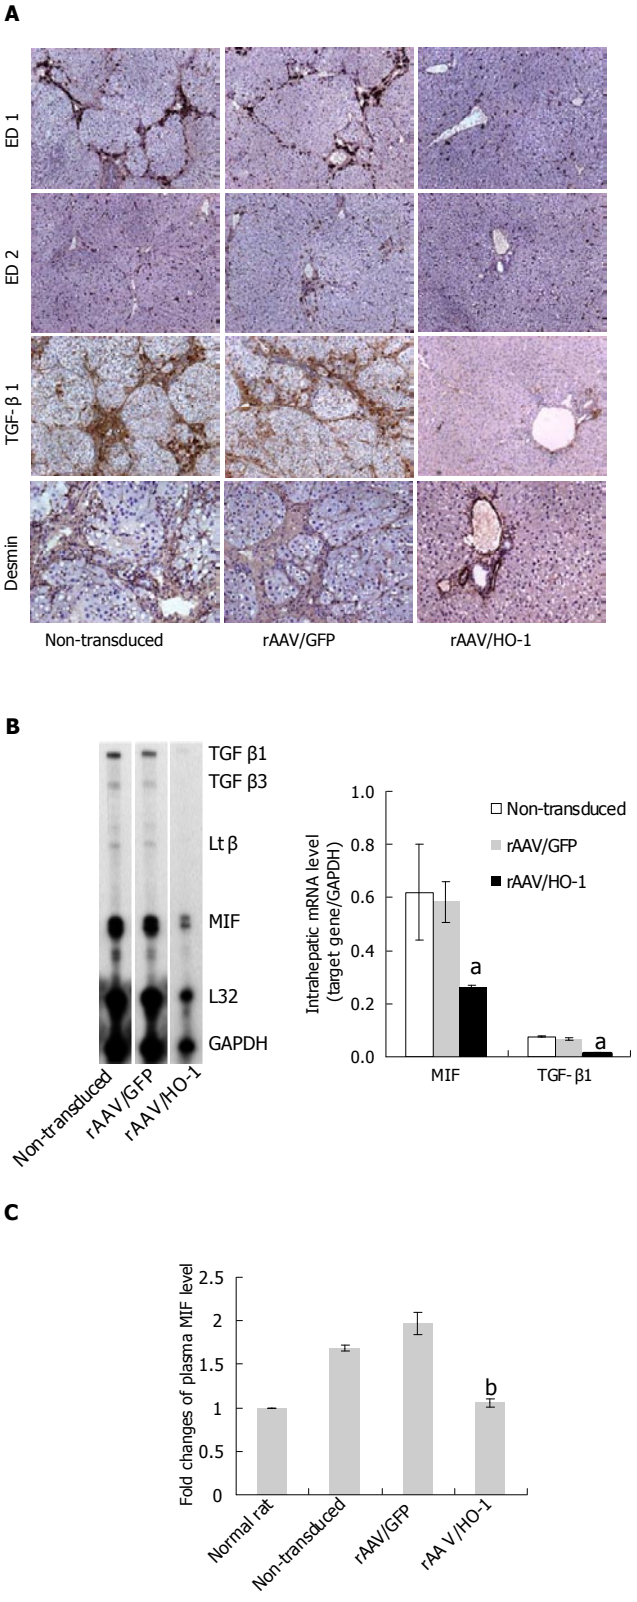

Figure 4 **A:** The representative pictures of pro-inflammatory and pro-fibrogenic responses in the livers of rats with or without treatment at the 10th week. Infiltrating macrophage (ED1), tissue residential macrophages (ED2), TGF-β1, and activated hepatic stellate cells (desmin) were detected by immunohistochemistry; original magnification, ×100; **B:** The profile of pro-inflammatory and profibrogenic cytokine expression. The level of mRNA was detected by RNase protection assay and was quantified by phosphoimager, n = 3-5, ^aP<0.05; **C**: The plasma level of macrophage migration inhibitory factor (MIF) was detected by ELISA. The data were shown as fold changes of over the level in normal rat, n = 3-5, ^bP < 0.001.

tions and the suppression of the macrophage activation; and (3) the anti-fibrogenic effects of HO-1 on the suppression of the collagen synthesis and/or proliferation of activated HSCs.

Improvement of liver function under long-term CCl_4 toxicity by rAAV/HO-1 may reflect the fact that the expression of HO-1 in the hepatocyte was able to prevent liver damage, which was supported by the down-regulation of pro-apoptotic genes and enhancement of liver ATP level in our model. In acute liver injury and ischemia/reperfusion injury of transplanted liver, recent data suggested that the resistance of HO-1 expressing cells to the pro-apoptotic stimuli might be directly through its enzymatic product CO and/or indirectly through the induction of the Fe^{2+}-sequestering protein ferritin. Exposure of CO to the primary hepatocyte could prevent the tumor necrosis factor-α-mediated and anti-CD95-mediated apoptotic events through the down-regulation of caspase-3 activity [21], whereas the induction of ferritin suppressed serum-deprived or oxidative stress-mediated hepatocyte apoptosis by modulation of intracellular Fe^{2+} level and inhibition of Fe^{2+}-mediated conversion of hydrogen peroxide into OH^- and OH through the Fenton reaction [7,22]. In addition to anti-apoptotic effects, HO-1 could also suppress the production of pro-inflammatory cytokine-MIF production in a human primary hepatocyte culture (Tsui TY, et al. unpublished data). This may suggest that HO-1 can function as homeostatic molecule in the prevention of apoptotic event and the control of cellular response.

HO-1 can be induced in various cell types including HSC through direct or indirect mechanisms. Our data are consistent with a recent finding in primary human HSC culture showing that the induction of HO-1 expression in HSC suppressed the transcript level of pro-collagen 1α and serum-mediated HSC proliferation [23]. This may suggest that HO-1 can serve as a negative regulator in the control of HSC activation and proliferation. Thus, less accumulation of fibrotic elements and prevention of the development of portal hypertension in rAAV/HO-1-transduced animals might reflect the outcomes of cellular protection, anti-inflammatory and anti-fibrogenic responses. Although further investigation is needed to clarify the mechanisms in more details, increased HO activity in liver and systemic effects of the products of HO enzymatic activity can be the key in the control of the development of cirrhosis and portal hypertension in our model.

In conclusion, our data demonstrated that enhancement the HO activity in a stable manner can suppresses the pathophysiological changes of cirrhosis. In addition, rAAV-mediated gene transfer may represent an attractive approach in controlling the development of cirrhosis. However, further studies should be carried out in order to answer the question of whether the rAAV approach is suitable for the hepatitis virus-mediated chronic liver injury and the subsequent outcome.

Abstract

AIM: To investigate the protective effect of rosuvastatin on ischemia-reperfusion (I-R)-induced small intestinal injury and inflammation in rats, and to determine the effect of this agent on the expression of endothelial nitric oxide synthase (eNOS) protein.

METHODS: Intestinal damage was induced in male Sprague-Dawley rats by clamping both the superior mesenteric artery and the celiac trunk for 30 min, followed by reperfusion for 60 min. Rosuvastatin dissolved in physiological saline was administered intraperitoneally 60 min before ischemia. The severity of the intestinal mucosal injury and inflammation were evaluated by several biochemical markers, as well as by histological findings. The protein levels of eNOS were determined by Western blot.

RESULTS: The levels of both intraluminal hemoglobin and protein, as indices of mucosal damage, were significantly increased in the I-R group compared with those in the sham-operated group. These increases, however, were significantly inhibited by treatment with rosuvastatin in a dose-dependent manner. The protective effects of rosuvastatin were also confirmed by histological findings. Exposure of the small intestine to I-R resulted in mucosal inflammation characterized by significant increases in thiobarbituric acid-reactive substances, tissue-associated myeloperoxidase activity, and the mucosal contents of rat cytokine-induced neutrophil chemoattractant-1 (CINC-1) and tumor necrosis factor-α (TNF-α). These increases in inflammatory parameters after I-R were significantly inhibited by pretreatment with rosuvastatin at a dose of 10 mg/kg. Furthermore, mRNA expression of CINC-1 and TNF-α was increased after I-R, and this increase was also inhibited by rosuvastatin. The mucosal protein levels of eNOS decreased during I-R, but were preserved in rats treated with rosuvastatin.

CONCLUSION: Rosuvastatin inhibits rat intestinal injury and inflammation induced by I-R, and its protection is associated with the preservation of eNOS protein.

INTRODUCTION

Intestinal ischemia-reperfusion (I-R) injury is a grave condition resulting from acute mesenteric ischemia, small bowel transplantation, abdominal aortic aneurysm, hemorrhagic, traumatic or septic shock, or severe burns[1,2]. Recent reports have demonstrated that neutrophil infiltration in the intestinal mucosa via neutrophil-endothelial cell interactions plays a significant role in the pathogenesis of I-R-induced intestinal injury because activated neutrophils generate tissue damaging products such as reactive oxygen species, protease, collagenase, and a ferrous iron-ferritin complex [3-5].

Leukocyte accumulation is a complex phenomenon that also involves endothelium-based adhesion molecules as well as leukocyte chemotaxis factors such as interleukin-8 (IL-8). Intercellular adhesion molecules (ICAMs) are normally expressed at a low basal level, but their expression can be enhanced by various inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α). A variety of cytokines, including TNF-α, interferon-γ and IL-1β, are released from post-ischemic tissues.

Statins, which are 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, are widely used in the treatment of hyperlipidemia and coronary artery disease [6]. Recently accumulating evidence suggests that statins have anti-inflammatory and endothelial cell protective actions that are independent of their cholesterol-lowering effect [7]. Statins can increase the expression of endothelial nitric oxide synthase (eNOS) by blocking Rho geranylgeranylation [8], and they can also block the lymphocyte function-associated antigen-1 (LFA-1)-ICAM-1 interaction by binding the L-site [9]. Rosuvastatin, a new HMG-CoA reductase inhibitor, has exhibited a more potent affinity for the active site of HMG-CoA reductase than other statins. In addition, the cytoprotective action of rosuvastatin against ischemic injury has been clearly documented [10-14]. Ikeda *et al* [10], for example, demonstrated that rosuvastatin reduces neutrophil-induced cardiac contractile dysfunction in the isolated ischemic reperfused rat heart. However, to date, the effects of rosuvastatin on intestinal I-R injury have not yet been investigated. In this study, we show that rosuvastatin dramatically attenuates I-R-induced intestinal injury and inflammation. Moreover, rosuvastatin was found to reverse the decrease in eNOS expression after I-R in intestinal mucosa.

MATERIALS AND METHODS

Chemicals

All chemicals were prepared immediately prior to use. Rosuvastatin was a gift from AstraZeneca UK, Ltd. (London, UK). Thiobarbituric acid (TBA) and 3,3',5,5'-tetramethylbenzidine were obtained from Wako Pure Chemical Indust. (Osaka, Japan), and 1,1,3,3-tetramethoxypropane was obtained from Tokyo Kasei (Tokyo, Japan). Enzyme-linked immunosorbent assay (ELISA) kits for rat TNF-α and cytokine-induced neutrophil chemoattractant-1 (CINC-1) were obtained from BioSource International (Camarillo, CA) and Immuno-Biological Laboratories Co., Ltd. (Gunma, Japan), respectively. All other chemicals used were of reagent grade.

Preparation of rats for intestinal I-R

Male Sprague-Dawley rats weighing 180-200 g were obtained from Keari Co., Ltd. (Osaka, Japan). The animals were housed at 22℃ in a controlled environment with 12 h of artificial light per day. They were allowed access to rat chow and water ad libitum. The rats were anesthetized with urethane (1 mg/kg, ip). After a midline laparotomy, the celiac and superior mesenteric arteries were isolated near their aortic origins. Intestinal ischemia was induced by clamping both the superior mesenteric artery and the celiac trunk for 30 min, resulting in a total occlusion of these arteries, following our previously reported method [15, 16]. After this period of occlusion, the clamps were removed. The animals were randomized into groups receiving different concentrations of rosuvastatin or physiological saline alone by intraperitoneal injection 1 h before ischemia. The maintenance of the animals and the experimental procedures performed on them were carried out in accordance with National Institutes of Health (NIH) guidelines for the use of experimental animals. All procedures were approved by the Animal Care Committee of Kyoto Prefectural University of Medicine (Kyoto, Japan).

Assessment of intestinal mucosal injury induced by I-R

The animals were killed after reperfusion, and the intestine was removed and submitted for examination. After making a 30-cm proximal intestinal loop, saline (10 mL) was injected into the loop. The contents were aliquoted after centrifugation. Intestinal injury after reperfusion was evaluated by examining the luminal contents of hemoglobin and protein, and by histological examination. Intestinal bleeding was quantified indirectly as the hemoglobin concentration in luminal lavage fluid using a kit and following the manufacturer's protocol (Wako). Luminal protein levels were also determined using a kit according to the manufacturer's protocol (Bio-Rad Laboratories, Hercules, CA, USA). For histological evaluation, formalin-fixed tissues were stained with hematoxylin and eosin and evaluated by light microscopy by a pathologist who was not informed of the experimental conditions for any given specimen.

Measurements of TBA-reactive substances and MPO activity

The concentrations of TBA-reactive substances were measured in the intestinal mucosa using the method described by Ohkawa *et al* [17] as an index of lipid peroxidation. The animals were killed by exsanguination from the abdominal aorta after the experiments, and their small intestines were removed. The intestinal mucosa was then scraped off using two glass slides, and homogenized with 1.5 mL of 10 mmol/L potassium phosphate buffer (pH 7.8) containing 30 mmol/L KCl in a Teflon Potter-Elvehjem homogenizer. The level of TBA-reactive substances in the mucosal homogenates was expressed as nanomoles of malondialdehyde per milligram of protein using 1,1,3,3-tetramethoxypropane as the standard. The total protein in the tissue homogenates was measured using a kit, according to the manufacturer's protocol (Bio-Rad).

Tissue-associated myeloperoxidase (MPO) activity was determined using a modification of the method described by Grisham *et al* [18] as an index of neutrophil accumulation. Briefly, two milliliters of mucosal homogenates were centrifuged at 20 000 g for 15 min at 4℃ to pellet the insoluble cellular debris. The pellet was then rehomogenized in an equivalent volume of 0.05-M potassium phosphate buffer (pH 5.4), containing 0.5% hexadecyltrimethylammonium bromide. The samples were centrifuged at 20 000 g for 15 min at 4℃ and the supernatants were saved. The MPO activity was assessed by measuring the H_2O_2-dependent oxidation of 3,3',5,5'-tetramethylbenzidine. One unit of enzyme activity was defined as the amount of MPO present that caused a change in absorbance of 1.0/min at

655 nm and 25 ℃.

Determination of mucosal content of CINC-1 and TNF-α

The concentrations of the inflammatory cytokines TNF-α and CINC-1 in the supernatant of mucosal homogenates were determined by rat TNF-α and CINC-1-specific ELISA kits according to the manufacturer's instructions.

RT-PCR

The mRNA expression of intestinal TNF-α and CINC-1 was determined by reverse transciprion-polymerase chain reaction the (RT-PCR). Samples of intestinal tissue for mRNA isolation were removed from the intestine. The total RNA was isolated by the acid guanidinium thiocyanate-phenol-chloroform (AGPC) method using Isogen (Nippon Gene, Tokyo, Japan) and the concentration of RNA was determined by absorbance at 260 nm in relation to that at 280 nm. RNA was stored at –70 ℃ until it was used for the RT-PCR. Amplification was carried out in a 50-μL mixture containing 2 μL of the RT product, 0.6 μmol/L of both the sense and antisense primers, 0.4 mmol/L dNTP mix, and 0.5 μL Taq DNA polymerase (Takara Shuzo Co., Shiga, Japan). The reaction was performed as follows: 35 cycles of amplication (denaturation at 94 ℃ for 30 s, annealing at 50 ℃ for 30 s, and extension at 72 ℃ for 60 s), followed by a final extension step of 7 min at 72 ℃. The primers had the following sequences: for TNF-α, sense 5'-ATGAGCACAGAAAGCATGATC-3', and antisense 5'-TACAGGCTTGTCACTCGAATT-3'; for CINC-1, sense 5'-CTGTGCTGGCCACCAGCCGC-3', and antisense 5'-ACAGTCCTTGGAACTTCTCTG-3'; and for ß-actin, sense 5'-ATCGTGGGCCGCCCTAGGCA-3', and antisense 5'-TGGCCTTAGGGTTCAGAGGGG-3'. The PCR products were separated electrophoretically in a 25 g/L agarose gel and stained by ethidium bromide.

Western blotting

Intestinal cells were thawed on ice and homogenized at 4 ℃ in a solution of 50 mmol/L Tris–HCl (pH 7.6), 300 mmol/L NaCl, 0.5 g/L Triton X-100, 10 g/L aprotinin, 10 g/L leptin, 1 mmol/L phenylmethysulfonyl fluoride (PMSF), 1.8 g/L iodoacetamide, 50 mmol/L NaF, and 1 mmol/L DTT in order to extract the total cell protein. Proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto nitrocellulose (Bio-Rad). Membranes were probed with specific antibodies against eNOS (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA) and immune complexes were visualized by Western blotting with a commercial kit (ECL, Amersham, Buckinghamshire, England), following the manufacturer's recommendations.

Statistics

All results are presented as mean ± SE. The data were compared by two-way analysis of variance (ANOVA), and differences were considered to be significant if the *P* value was less than 0.05 based on Scheffe's multiple comparison test. All analyses were performed using the Stat View 5.0-J program (Abacus Concepts, Inc., Berkeley, CA, USA) on a Macintosh computer.

RESULTS

Rosuvastatin inhibits intestinal reperfusion injury

We found that 60 min of reperfusion after 30 min of ischemia resulted in increases in luminal protein and hemoglobin concentrations (Figure 1). In contrast, pre-treatment with rosuvastatin 1 h before the ischemia was found to inhibit these increases in a dose-dependent manner (Figure 1). Neither vehicle alone nor rosuvastatin alone affected the luminal protein or hemoglobin concentrations (data not shown). Therefore, in the following experiments, we used rosuvastatin at a dose of 10 mg/kg and examined its pharmacological action. In rats treated with I-R, multiple erosions and bleeding developed in the small intestine; however, pretreatment with rosuvastatin at a dose of 10 mg/kg 1 h before the ischemia inhibited both the intestinal erosions and the bleeding. The protective effect of rosuvastatin was further confirmed histologically. Representative hematoxylin and eosin-stained sections of the ileum from sham, I-R, and I-R + rosuvastatin-treated animals are depicted in Figure 2. While the ileum of sham animals exhibited normal mucosal architecture with intact villi, I-R resulted in large areas of epithelial crypt loss, predominantly neutrophilic infiltrate throughout the mucosa, erosion, and mucosal bleeding. In contrast, pretreatment with rosuvastatin resulted in smaller erosions with few neutrophils. Rosuvastatin alone did not produce any macroscopic or microscopic lesions in the rat intestine.

Effect of rosuvastatin on TBA-reactive substances

The extent of lipid peroxidation was determined by measuring TBA-reactive substances in the small intestine. No significant differences were found in the intestinal TBA-reactive substance levels between vehicle- and rosuvastatin-treated rats in the sham-operated group. Sixty min of reperfusion caused a significant increase in TBA-reactive substances in the control rats. This increase in TBA-reactive substances in the intestinal mucosa was significantly inhibited by 10 mg/kg of rosuvastatin (Figure 3A).

Effect of rosuvastatin on MPO activity

A hallmark of intestinal reperfusion injury is the accumulation of neutrophils in the injured tissue. Therefore, we next evaluated neutrophil accumulation based on tissue-associated MPO activity. There were no differences in intestinal MPO activities between vehicle- and rosuvastatin-treated rats in the sham-operated group, while the MPO activity in the intestinal mucosa markedly increased from a basal activity of 0.23 ± 0.07 nkat/g protein to 5.20 ± 1.65 nkat/g protein after I-R in the control group. The increase in MPO activity in the intestinal mucosa after reperfusion was significantly inhibited by treatment with rosuvastatin (Figure 3B).

Effect of rosuvastatin on mRNA expression and mucosal protein contents of CINC-1

In order to determine whether or not treatment with rosuvastatin can modulate the inflammatory response through the regulation of cytokine production, we analyzed intestinal mucosal levels of CINC-1 and TNF-α. The intestinal concentrations of TNF-α and CINC-1 increased signifi-

cantly in rats treated with I-R, and these increases were significantly inhibited by treatment with rosuvastatin at a dose of 10 mg/kg (Figures 4A, 4B). To further confirm the inhibitory effect of rosuvastatin on CINC-1 and TNF-α production, we analyzed the intestinal expression of CINC-1 and TNF-α using RT-PCR yielding 495 and 225 base pair products to identify CINC-1 and TNF-α gene expression, respectively. As shown in Figure 5, we found the expression of these genes in rats treated with sham-operation to be negligible or faint. In contrast, transcription was readily enhanced in I-R-treated rats. Treatment with rosuvastatin suppressed the level of mRNA expression for each gene.

Effect of rosuvastatin on eNOS protein expression

Since previous studies have shown that statins exerts beneficial effects on the endothelium through an increase in NO production from eNOS [19, 20], we investigated whether eNOS expression could be affected by I-R with or without rosuvastatin pre-treatment. Figure 6 was a representative of at least 3 experiments performed on different experimental days. The expression levels of eNOS protein were decreased during the I-R. However, pretreatment with rosuvastatin significantly reversed the decrease in eNOS protein. Rosuvastatin alone did not affect intestinal eNOS protein levels in sham-operated rats.

DISCUSSION

The present study clearly demonstrates that rosuvastatin, a new HMG-CoA reductase inhibitor, has a protective effect against reperfusion-induced intestinal injury and inflammation in rats. In this study, intestinal injury was assessed by a variety of methods including luminal protein/hemoglobin concentrations and histological evaluation. The results of each assessment showed that rosuvastatin treatment significantly inhibited intestinal injury. In addition, we demonstrated that, in I-R-induced intestinal inflammation, the expression of pro-inflammatory cytokines (CINC-1 and TNF-α) was enhanced in association with neutrophil accumulation, as determined by MPO activity in the homog-

enate of the small intestine. Rosuvastatin treatment inhibited both the up-regulation of pro-inflammatory cytokine expression and the neutrophil infiltration, which prevents tissue injury. These results suggest that rosuvastatin has a protective action against I-R-induced intestinal mucosal injury as well as an anti-inflammatory action against reperfusion-induced inflammation.

Oxygen-derived free radicals produced during I-R are known to cause peroxidation of polyunsaturated fatty acids in cell membranes. The resulting increase in lipid peroxides can lead to changes in membrane fluidity and permeability, and finally to cell lysis. In the present study, TBA-reactive substances in intestinal mucosa, which are an index of lipid peroxidation, were significantly increased in I-R-treated rats compared to sham-operated rats, and rosuvastatin treatment significantly inhibited the increase in these substances. However, neither rosuvastatin nor other statins have been reported to have antioxidant activities *in vitro*, nor has the inhibition of lipid peroxidation been previously reported. Our recent study also showed that rosuvastatin had no effect on scavenging hydroxyl and superoxide radicals determined by electron spin resonance-spin trapping assay (data not shown). Therefore, the inhibitory effect of rosuvastatin on I-R-induced lipid peroxidation in rat intestinal mucosa may result from its anti-inflammatory activity, rather than from its direct antioxidant activity.

Recent reports hypothesize that neutrophil-mediated inflammation is involved in the pathogenesis of I-R-induced intestinal injury. This hypothesis has been supported by several studies; neutrophil depletion by intraperitoneal injection of anti-neutrophil serum has been found to significantly attenuate intestinal mucosal injury elicited by I-R [21, 22]; in addition, immunoneutralization of the CD11/CD18 adherence complex on neutrophils and CINC-1 is known to attenuate intestinal reperfusion injury [23, 24]. The present study showed that MPO activity, an index of tissue-associated neutrophil accumulation, increases in the intestinal mucosa after I-R, and that this increase is significantly inhibited by treatment with rosuvastatin. The inhibition of neutrophil-endothelial interaction by statins has been demonstrated in a number of previous reports. Honjo *et al* [25] have shown that both cerivastatin and pravastatin significantly reduce the number of rolling/accumulated leukocytes in the retinal veins after I-R. Naidu *et al* [26] have

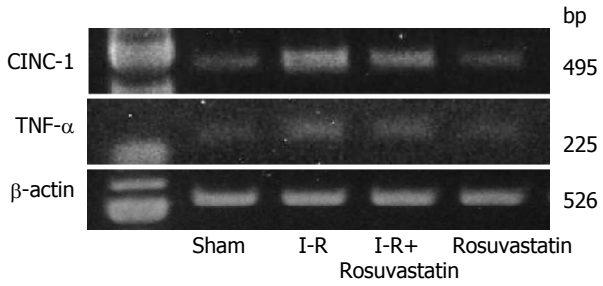

Figure 5 Effects of rosuvastatin on the expression of CINC-1 and TNF-α mRNA in the intestinal mucosa after I-R in rats.

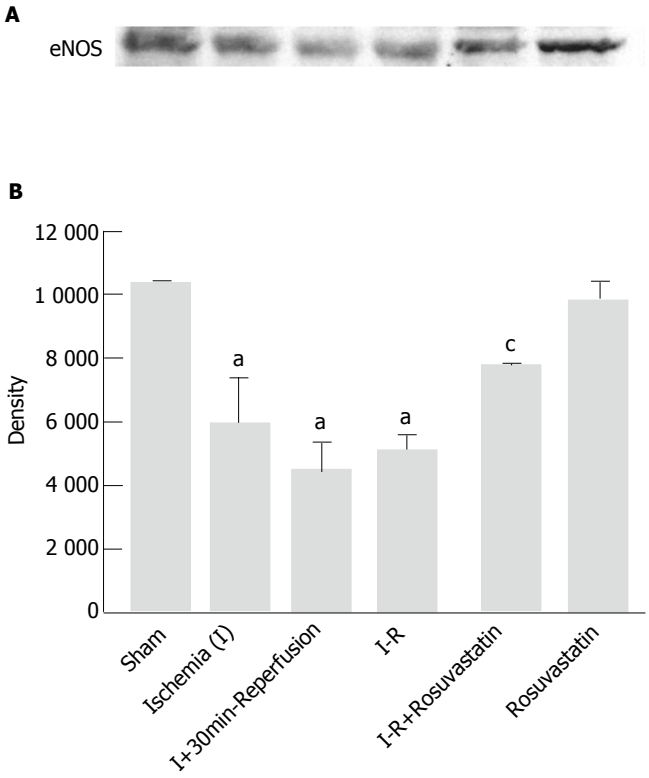

Figure 6 Effect of rosuvastatin on eNOS protein expression during I-R. $^{a}P<0.05$ *vs* Sham, $^{c}P<0.05$ *vs* Vehicle + I-R.

also demonstrated that pretreatment with simvastatin inhibits increases in tissue MPO content in lungs treated with I-R. In addition, the present study showed that the expression of the pro-inflammatory cytokines CINC-1 and TNF-α markedly enhanced in the intestine after I-R, and that these increases are also significantly inhibited by rosuvastatin. The inhibitory effect of statins against mRNA expression for inflammatory genes was also confirmed by a recent study using DNA microarray technology [27], in which it was demonstrated that the statins atorvastatin and pitavastatin directly affect the expression levels of genes involved in inflammation, including interleukin-8 (similar to rat CINC-1), in cultured human umbilical vein endothelial cell. These results, together with the present data, indicate that the inhibition of neutrophil accumulation as well as the inhibition of cytokine production by rosuvastatin may be one of the protective factors decreasing I-R-elicited intestinal mucosal injury.

The beneficial effects of statins on acute inflammation are abolished when it is administered together with an NOS inhibitor [20] or when it was administered to eNOS knockout mice [19], indicating that an enhanced release of NO from eNOS may be involved in the action of statins. Statins are known to up-regulate eNOS expression and activate this enzyme in the systemic vasculature by blocking Rho geranylgeranylation [8, 28] as well as by activating the PI-3 kinase/Akt pathway [20]. As shown in the present study, the intestinal levels of eNOS protein gradually decreased during 30-min ischemia and 60-min reperfusion, indicating that reperfusion may be associated with a posttranscriptional reduction in the expression of the eNOS enzyme. In addition, rosuvastatin-treated animals demonstrated preserved expression of eNOS protein compared to the I-R-treated group, although this agent did not affect the level of eNOS protein in normal rats. Therefore, the persistent expression of eNOS protein at 60 min of reperfusion in rosuvastatin-treated rats is likely to explain the reduction in tissue injury and neutrophil accumulation. In line with our observations, NO is reported to prevent leukocyte adhesion to the endothelium by repressing the up-regulation of cell adhesion molecules in the endothelial cells [29, 30].

Our results showed that I-R-induced intestinal inflammation is characterized by increased production of inflammatory mediators and decreased expression of eNOS. The blockade of these mediators and the preservation of eNOS expression by rosuvastatin were accompanied by significant suppression of intestinal inflammation *in vivo*. These data suggest that rosuvastatin may represent a novel therapeutic approach for the treatment of I-R-induced intestinal injury.

Abstract

AIM: To examine the histological and immunohistochemical findings of biopsy specimens taken from the major duodenal papilla of autoimmune pancreatitis (AIP) patients.

METHODS: The major duodenal papilla in the resected pancreas of 3 patients with AIP and of 5 control patients [pancreatic carcinoma (n = 3) and chronic alcoholic pancreatitis (n = 2)] was immunostained using anti-CD4-T cell, CD8-T cell and IgG4 antibodies. Forceps biopsy specimens taken from the major duodenal papilla of 2 patients with AIP and 5 control patients with suspected papillitis were prospectively taken during duodenoscopy and immunohistochemically examined.

RESULTS: Moderate or severe lymphoplasmacytic infiltration including many CD4-positive or CD8-positive T lymphocytes and IgG4-positive plasma cells ($\geqslant$10/HPF), was observed in the major duodenal papilla of all 3 patients with AIP. The same findings were also detected in the biopsy specimens taken from the major duodenal papilla of 2 patients with AIP, but in controls, there were only a few ($\leqslant$3/HPF) IgG4-positive plasma cells infiltrating the major duodenal papilla.

CONCLUSIONS: An abundant infiltration of IgG4-positive plasma cells is specifically detected in the major duodenal papilla of patients with AIP. Although this is a preliminary study, IgG4-immunostaining of biopsy specimens taken from the major duodenal papilla may support the diagnosis of AIP.

INTRODUCTION

Autoimmune pancreatitis (AIP) is a unique form of pancreatitis in which autoimmune mechanisms are involved in the pathogenesis. It is characterized by irregular narrowing of the main pancreatic duct, enlargement of the pancreas, increased levels of serum γ globulin or IgG, presence of autoantibodies, and responsiveness to steroid therapy[1,2]. Histological findings of the pancreas of AIP are also characteristic, and include dense lymphoplasmacytic infiltration with fibrosis[3]. Recently, it was reported that serum concentrations of IgG4 are significantly and specifically raised in patients with AIP[4]. However, the sensitivity of raised serum IgG4 concentrations is 67%[5]-68%[6] in some reports.

AIP occurs predominantly in elderly males and frequently presents as obstructive jaundice[7]. This presentation is also typical of pancreatic carcinoma. In typical cases of AIP that show diffuse change of the pancreas, the diagnosis can be easily made based on the combination of computed tomography (CT) and endoscopic retrograde cholangiopancreatography (ERCP) findings. However, in segmental mass-forming cases, the differentiation between AIP and pancreatic carcinoma remains difficult. The "double-duct sign", representing stricture in both the pancreatic and bile ducts, is often found in patients with pancreatic head carcinoma. This finding, however, is also frequently observed in AIP[7], because the inflammatory process compresses both the main pancreatic duct and the distal common bile duct[3]. As most patients with AIP respond to oral steroid therapy[2], an accurate diagnosis of AIP can avoid unnecessary

laparotomy or pancreatic resection. On the other hand, histopathological approach to the pancreas is sometimes difficult.

We previously reported that IgG4-positive plasma cells abundantly infiltrated various organs, as well as the pancreas of a patient with AIP, and that an abundant infiltration of IgG4-positve plasma cells was not observed in the organs of patients with pancreatic carcinoma or chronic alcoholic pancreatitis[3,8]. In order to find a useful new method to diagnose AIP on the basis of histological and immunohistochemical studies of the resected pancreas, we prospectively examined the histological and immunohistochemical findings of biopsy specimens obtained from the major duodenal papilla of AIP patients.

MATERIALS AND METHODS

The major duodenal papilla in the resected pancreas of 3 patients with AIP who underwent pancreatoduodenectomy due to suspected pancreatic carcinoma was histologically examined. The specimens were fixed in 10% formaldehyde. Serial sections were cut from paraffin-embedded tissue blocks, and immunostained using anti-CD4-T (Novocastra, Newcastle upon Tyne, UK), CD8-T (DakoCytomation, Glostrup, Denmark) cell subsets, as well as IgG4 (The Binding Site, Birmingham, UK) antibodies with avidin-biotin-peroxidase complex (ABC). The number of immunohistochemically identified cells per high power field (HPF) in each section was counted.

We recently treated 2 patients with AIP, a 73-year-old male and a 60-year-old female. Both patients had obstructive jaundice due to stenosis of the lower bile duct. Segmental narrowing of the main pancreatic duct was observed in the pancreatic head on ERCP, and focal enlargement of the pancreatic head was detected on CT. Serum IgG4 concentrations were elevated to 325 mg/dL in the male and 825 mg/dL in the female. The major duodenal papilla was normal on duodenoscopy during ERCP. Forceps biopsy specimens from the major duodenal papilla were taken during duodenoscopy. Histological and immunohistochemical studies were done on these biopsy specimens. After the biopsy was taken, steroid therapy was given to both patients, who showed marked responsiveness both morphologically and serologically. In 1 patient, rebiopsy from the major duodenal papilla was done after steroid therapy.

Histological and immunohistochemical studies were also done on control specimens. Controls consisted of the major duodenal papilla specimens of the pancreases resected by pancreatoduodenectomy for pancreatic head carcinoma ($n = 3$) and chronic alcoholic pancreatitis ($n = 2$), as well as endoscopically biopsied specimens taken from the major duodenal papilla of patients with suspected papillitis ($n = 5$).

RESULTS

Moderate or severe lymphoplasmacytic infiltration was observed in the major duodenal papilla of all 3 patients with AIP. Immunohistochemically an abundant infiltration of CD4- or CD8-positive T lymphocytes and IgG4-positive plasma cells (≥10/HPF) was observed in these 3 major duodenal papillae. Moderate or severe lymphoplasmacytic infiltration which included many CD4- or CD8-positive T lymphocytes and IgG4-positive plasma cells (≥10/HPF) was also observed in the biopsy specimens taken from the major duodenal papilla of 2 AIP patients (Figures 1 and 2). Although infiltration of CD4- or CD8-positive T lymphocytes was detected to some extent in the major duodenal papilla of controls, there were few IgG4-positive plasma cells infiltrating the major duodenal papilla of controls (≤3/HPF). The abundant infiltration of CD4- or CD8-positive T lymphocytes and IgG4-positive plasma cells disappeared in the biopsy specimen taken from the major duodenal papilla of 1 patient after steroid therapy.

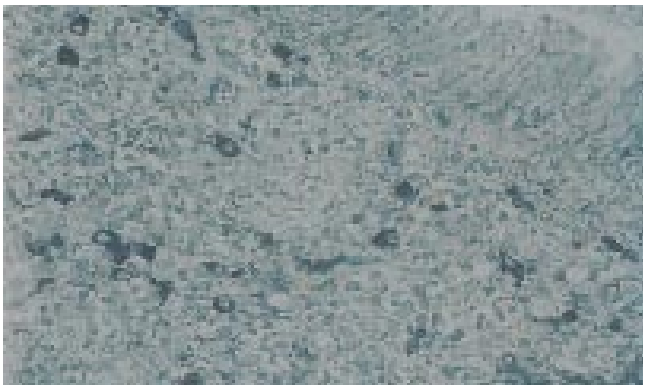

Figure 2 IgG4-immunostaining of biopsy specimen taken from the major duodenal papilla of a patient with autoimmune pancreatitis showing an abundant infiltration of IgG4-positive plasma cells (≥10/HPF).

DISCUSSION

Chronic pancreatitis and several other pancreaticobiliary diseases may be associated with inflammation of the major duodenal papilla, histologically showing infiltration of neutrophils or lymphocytes, or fibrosis[9]. In 2002, Unno *et al*[10] reported that a swollen major duodenal papilla was detected in 41% of 17 patients with AIP, and many infiltrating T lymphocytes were present in the biopsy specimens taken from the swollen papillary tissue. In 2004,

Sahin *et al*[11]reported that dense T-lymphocytic infiltration was present in the resected major duodenal papilla of 2 patients with AIP. In the present study, dense infiltration of CD4- or CD8-positive lymphocytes was also detected in the resected major duodenal papilla of 3 patients with AIP. Furthermore, an abundant infiltration of IgG4-positive plasma cells was detected in the major duodenal papilla of these patients and was not observed in the major duodenal papilla of controls.

Our previous immunohistochemical studies[3,8] of resected pancreases taken from AIP patients showed that the infiltrating inflammatory cells consisted of CD4- or CD8-positive T lymphocytes and IgG4-positive plasma cells, and that an abundant infiltration IgG4-positive plasma cells in the pancreas was not detected in other diseases. In addition, an abundant infiltration of IgG4-positive plasma cells was detected in various organs of patients with AIP, including peripancreatic retroperitoneal tissue, biliary tract, salivary glands, lymph nodes, and others. We therefore proposed the existence of a novel clinicopathological entity, an IgG4-related systemic disease characterized by extensive IgG4-positive plasma cell infiltration of organs together with CD4- or CD8-positive T lymphocytes[8]. Based on this concept, the dense infiltration of IgG4-positive plasma cells along with CD4- or CD8-positive lymphocytes that are detected in the major duodenal papilla of patients with AIP seems to be induced by the same mechanism as is operative in the pancreas.

These findings led us to do a prospective immunohistochemical study using an anti-IgG4 antibody to study the biopsy specimens taken from the major duodenal papilla of AIP patients. An abundant IgG4-positive plasma cell infiltration was detected in the biopsy specimens taken from the non-swollen major duodenal papilla of 2 AIP patients, and was not detected in the biopsy specimens taken from controls. Of note, the abundant infiltration of IgG4-positive plasma cells disappeared after steroid therapy. Although the number of examined cases is small, IgG4-immunostaining of biopsy specimens taken from the major duodenal papilla may be useful to support the diagnosis of AIP.

In conclusion, an abundant infiltration of IgG4-positive plasma cells was detected in the major duodenal papilla of patients with AIP. Although this is a preliminary study, IgG4-immunostaining of biopsy specimens taken from the major duodenal papilla may be useful to support the diagnosis of AIP.

Abstract

AIM: To compare the effects of *Aloe vera* and sucralfate on gastric microcirculatory changes, cytokine levels and gastric ulcer healing.

METHODS: Male Spraque-Dawley rats ($n=48$) were divided into four groups. Group1 served as control group, group 2 as gastric ulcer group without treatment, groups 3 and 4 as gastric ulcer treatment groups with sucralfate and *Aloe vera*. The rats from each group were divided into 2 subgroups for study of leukocyte adherence, TNF-α and IL-10 levels and gastric ulcer healing on days 1 and 8 after induction of gastric ulcer by 20% acetic acid.

RESULTS: On day 1 after induction of gastric ulcer, the leukocyte adherence in postcapillary venule was significantly ($P<0.05$) increased in the ulcer groups when compared to the control group. The level of TNF-α was elevated and the level of IL-10 was reduced. In the ulcer groups treated with sucralfate and *Aloe vera*, leukocyte adherence was reduced in postcapillary venule. The level of IL-10 was elevated, but the level of TNF-α had no significant difference. On day 8, the leukocyte adherence in postcapillary venule and the level of TNF-α were still increased and the level of IL-10 was reduced in the ulcer group without treatment. The ulcer treated with sucralfate and *Aloe vera* had lower leukocyte adherence in postcapillary venule and TNF-α level. The level of IL-10 was still elevated compared to the ulcer group without treatment. Furthermore, histopathological examination of stomach on days 1 and 8 after induction of gastric ulcer showed that gastric tissue was damaged with inflammation. In the ulcer groups treated with sucralfate and *Aloe vera* on days 1 and 8, gastric inflammation was reduced, epithelial cell proliferation was enhanced and gastric glands became elongated. The ulcer sizes were also reduced compared to the ulcer group without treatment.

CONCLUSION: Administration of 20% acetic acid can induce gastric inflammation, increase leukocyte adherence in postcapillary venule and TNF-α level and reduce IL-10 level. *Aloe vera* treatment can reduce leukocyte adherence and TNF-α level, elevate IL-10 level and promote gastric ulcer healing.

INTRODUCTION

Gastric ulcer is produced by the imbalance between gastroduodenal mucosal defense mechanism and damaging force. Impaired mucosal defense is invoked in ulcer patients with normal levels of gastric acid and pepsin. Patients chronically using non-steroid anti inflammatory drugs (NSAIDs), including aspirin, can be pointed with some assurance at suppression of mucosal prostaglandin synthesis. Cigarette smoking impairs healing and favors recurrence, possibly by suppressing mucosal prostaglandin synthesis. Alcohol is another agent causing gastric mucosal lesion. It rapidly penetrates the gastroduodenal mucosa causing membrane damage, exfoliation of cells and erosion[1]. Corticosteroids at a high dose and repeated use promote ulceration. Personality and psychologic stress are important contribution factors as well[2].

Gastric ulceration results from the imbalance between gastrotoxic agents and protective mechanisms result in acute inflammation. Interleukin-1 beta (IL-1β) and tumor necrosis factor alpha (TNFα) are the major proinflammatory cytokines, playing an important role in production of acute inflammation[3] accompanied with

neutrophil infiltration of gastric mucosa[4].

Aloe plants have been used medicinally for centuries. Among them, *Aloe barbadensis*, commonly called *Aloe vera*, is one of the most widely used healing plants in the history of mankind[5].

Two distinct preparations of Aloe plants are most used medicinally. The leaf exudate (aloe) is used as a laxative and the mucilaginous gel (*Aloe vera*) extracted from the leaf parenchyma is used as a remedy against a variety of skin disorders[6]. Aloe leaf exudate also possesses antidiabetic[7] and cardiac stimulatory activity[8].

Aloe vera is one of the few substances known to effectively decrease inflammation and promote wound healing[9,10]. *Aloe vera* gel could promote the healing of burns and other cutaneous injuries and ulcer[11, 12], thus improving wound healing in a dose-dependent manner and reducing edema and pain[9].

Aloe vera gel has been demonstrated to protect human beings[13-15] and rats[16-22] against gastric ulceration. This antiulcer activity is due to its anti-inflammatory[20], cytoprotective[16], healing[20, 23] and mucus stimulatory effects[24].

However, the effects of *Aloe vera* on gastric microcirculation, inflammatory cytokines in gastric ulcer patients have not yet been reported. Therefore, the aim of this study was to study the effects of *Aloe vera* and sucralfate on gastric microcirculatory changes, cytokine level and gastric ulcer healing.

MATERIALS AND METHODS

Animal preparation

Male Spraque Dawley rats weighing 200-280 g purchased from the International Animal Research Center, Salaya ($n = 48$), were used in this study. Group 1 served as control group, group 2 as gastric ulcer group without treatment, groups 3 and 4 as gastric ulcer treatment groups with sucralfate (200 mg/kg/dose, twice daily) and *Aloe vera* (200 mg/kg/dose, twice daily).

The animals were fasted but allowed only water 12 hours before experiment. On the day of experiment, the animals were weighed and anesthetised with intraperitoneal injection of sodium pentobarbital (50 mg/kg body weight). After tracheostomy, carotid artery and jugular vein were canulated for blood pressure measurement using polygraph and administration of fluorescent marker. The abdominal wall was incised and the stomach was extended and fixed. Then the leukocyte adherence in stomach was observed by *in vivo* microscopy.

Study of interaction between leukocytes and endothelial cells in postcapillary venule

For visualization of leukocytes, acridine orange was infused intravenously (0.5 mg/kg BW) as previously described[25]. The number of leukocyte adhesions was recorded using video recorder. Videotape of each experiment was played back and then leukocyte adherence was monitored. The leukocytes were markedly adhered to the postcapillary venule (about 15-35 μm in diameter). The location of leukocyte adherence in three areas was observed. Leukocytes were considered adherent to the vessel endothelium if they remained stationary for 30 or longer. Adherent leukocytes were expressed as the mean number of leukocyte adherences per field of view as previously described[26].

Mean number of leukocyte adherences = [the number of (area 1 + area 2 + area 3) cells/field]/3

Determination of serum cytokine levels

After the experiment, blood samples were taken by cardiac puncture, allowed to clot for 2 h at room temperature or overnight at 2-8 ℃ before centrifugation for 20 minutes at approximately 2000 r/min. Serum was separated and stored at about -80 ℃ for determining TNF α and IL-10 levels by ELISA kit (Quantikine, R&D systems).

Histological analysis

The stomach was fixed in 10% formalin and embedded in paraffin. Sections were cut at a thickness of 5 μm and stained with hematoxylin and eosin (H&E) as previously described[3]. Histopathological changes and maximum length of gastric ulcer were observed under light microscope with magnification × 20. Histopathological examination was performed by pathologists.

Statistical analysis

Data were expressed as mean ± SE. Statistical analysis was done using one-way analysis of variance and comparision of results between groups was made using post hoc test. $P < 0.05$ was considered statistically significant.

Ethical considerations

This study was approved by the Ethics Committee of the Faculty of Pharmaceutical Sciences, Chulalongkorn University, Bangkok, Thailand.

RESULTS

Interaction between leukocytes and endothelial cells

After gastric ulcer was induced by administration of 20% acetic acid, leukocyte adherence to endothelial cells of postcapillary venules (15-35 mm in diameter.) was observed under intravital fluorescence microscopy. The number of leukocytes adhered to postcapillary venules for 30 s or longer was counted per each field of observation. The mean number of leukocyte adherences in the ulcer group without treatment (d1: 13.13 ± 1.19 cells/field; d8: 13.61 ± 1.99 cells/field) was significantly increased compared to the control group (d1: 1.69 ± 0.17 cells/field; d8: 5.53 ± 0.65 cells/field).

On days 1 and 8 after induction of gastric ulcer, the number of leukocyte adherences was significantly decreased both in the ulcer group treated with sucralfate (d1: 3.22± 0.76 cells/field; d8: 3.80 ± 0.79 cells/field) and in the ulcer group treated with *Aloe vera* (d1: 4.29 ± 0.39 cells/field; d8: 4.46 ± 0.27 cells/field) ($P < 0.05$) compared to the ulcer group without treatment (d1: 13.13 ± 1.19 cells/field; d8: 13.61 ± 1.99 cells/field). The number of leukocyte adherences in the ulcer group treated with *Aloe vera* was reduced as the ulcer group treated with sucralfate. The mean ± SE of leukocyte adherences on days 1 and 8 is shown in Table 1 and Figure 1.

Table 1 Leukocyte adherence on postcapillary venules indifferent groups (mean ± SE, $n = 6$)

Group	Mean leukocyte adherence (cells/field)	
	Day 1	Day 8
Control	1.69 ± 0.17	5.53 ± 0.65
Ulcer	13.13 ± 1.19[a]	13.61 ± 1.99[a]
Ulcer+sucralfate	3.22 ± 0.76[c]	3.80 ± 0.79[c]
Ulcer+*Aloe vera*	4.29 ± 0.39[c]	4.46 ± 0.27[c]

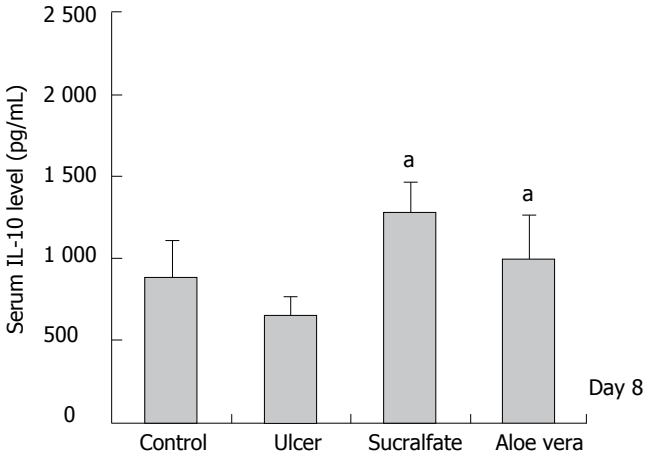

Figure 3 IL-10 level in different groups ($n = 6$) (mean±SD),[c]$P < 0.05$ *vs* ulcer groups.

Changes of TNF-α and IL-10 levels

After gastric ulcer was induced by administration of 20% acetic acid, the level of TNF-α (d_1: 151.40 ± 26.87 pg/mL; d_8: 280.44 ± 67.02 pg/mL) was significantly higher than that in the control group (d1: 12.51 ± 2.35 pg/mL; d8: 133.50 ± 20.95 pg/mL). However, the level of IL-10 after gastric ulcer was induced by administration of 20% acetic (d_1: 472.66 ± 167.75 pg/mL; d_8: 646.60 ± 118.92 pg/mL) was significantly lower than that in control group (d_1: 911.46 ± 230.81 pg/mL; d_8: 883.98 ± 227.62 pg/mL). The level of TNF-α in ulcer group treated with sucralfate (138.62 ± 47.45 pg/mL) and in ulcer group treated with *Aloe vera* (153.02 ± 26.90 pg/mL) was higher than that in control group (12.51 ± 2.35 pg/mL) on d 1. On d 8, the level of TNF-α in ulcer group treated with sucralfate (170.21 ± 23.82 pg/mL) and in ulcer group treated with *Aloe vera* (154.32 ± 43.55 pg/mL) was significantly ($P < 0.05$) lower than that in ulcer group without treatment (280.44 ± 67.02 pg/mL) and was different from that in control group (133.50 ± 20.95 pg/mL). TNF-α level was reduced in ulcer group treated with *Aloe vera* as in the ulcer group treated with sucralfate.

Furthermore, the level of IL-10 in ulcer group treated with sucralfate (d_1: 1 419.93 ± 359.81 pg/mL; d_8: 1 283.64 ± 179.72 pg/mL) and in ulcer group treated with *Aloe vera* (d_1: 1178.13 ± 159.87pg/mL; d_8: 984.02 ± 269.26 pg/mL) was higher than that in ulcer group (d_1: 472.66 ± 167.75 pg/mL; d_8: 646.60 ± 118.92 pg/mL) on days 1 and 8 after induction of gastric ulcer. The mean ± SE of TNF-α and IL-10 levels on d 1 and 8 is shown in Figures 2 and 3, respectively.

Histopathological changes

After administration of 20% acetic acid, histopathological examination revealed hemorrhage, congestion and edema in the gastric mucosa with mild to moderate leukocyte infiltration in gastric lesion. Gastric lesions were erosive and ulcerative. Congestion, edema and erosive lesion were found only in control group. Moreover, the mean maximum length of gastric ulcer in ulcer group without treatment (4.17 cm ± 0.11 cm) was significantly longer than that in control group (3.25 cm ± 0.11 cm) ($P < 0.05$). On day 8 after induction of gastric ulcer, control group and ulcer group without treatment had still mild congestion and edema, mild leukocyte infiltration and erosive lesion in gastric mucosa. The mean length of gastric ulcer in ulcer group without treatment (3.48 cm ± 0.10 cm) was larger than that in control group (3.20 cm ± 0.22 cm). On day 1, the mean maximum length of gastric ulcer in ulcer groups treated with sucralfate (3.73 cm ± 0.12 cm) and with *Aloe vera* (3.60 cm ± 0.18 cm) became shorter after treatment

Table 2 Maximum length of gastric ulcer (cm) in different groups ($n = 6$) (mean ± SE)

Group	Maximum length of gastric ulcer (cm)	
	Day 1	Day 8
Control	3.25 ± 0.11	3.20 ± 0.22
Ulcer	4.17 ± 0.11[a]	3.48 ± 0.10
Ulcer + sucralfate	3.73 ± 0.12[b]	3.33 ± 0.11
Ulcer + Aloe vera	3.60 ± 0.18[b]	3.43 ± 0.10

[a]P <0.05 *vs* control group, [b]P <0.05 *vs* ulcer groups

when compared to the ulcer group without treatment (4.17 cm ± 0.11 cm). On day 8, the mean maximum length of gastric ulcer in ulcer groups treated with sucralfate (3.33 cm ± 0.11 cm) and *Aloe vera* (3.43 cm ± 0.10 cm) was slightly reduced with no significant difference after treatment when compared to the ulcer group without treatment (3.48 cm ± 0.10 cm). The mean ± S.E of the maximum length of gastric ulcer is shown in Table 2.

DISCUSSION

In this study, after gastric ulcer was induced by administration of 20% acetic acid, gastric inflammation increased leukocyte adherence to the endothelial surface of postcapillary venules and was characterized by the migration of macrophages and PMNs in the ulcer area. The migrated macrophages then released proinflammatory cytokines such as TNF-α and interleukin-1β (IL-1β). Pro-inflammatory cytokines can up-regulate adhesion molecule expression on endothelial cells and leukocytes[27,28] and cause leukocyte recruitment[29]. Adhesion molecules on endothelial cells and leukocytes involve rolling, adhesion, and transmigration of leukocytes in gastric inflamed areas. It was reported that increment of PMNs may play an important role in the pathogenesis of NSAIDs-induced gastropathy[30]. On the other hand, NSAIDs may enhance the expression of cell adhesion molecules on the surface of endothelial cells[31]. Adhesion molecules play an important role in the recruitment of leukocytes to inflammation sites, leading to gastric mucosal injury[31, 32]. It was also reported that leukocyte adhesion and/or aggregation can occlude microcirculation, resulting in ischemic mucosal injury[31, 33]. Leukocyte infiltration in gastric mucosa can cause tissue damage leading the ulcerative lesion[34].

In this study, gastric ulcer induced by administration of 20% acetic acid had elevated TNF-α levels, demonstrating that elevated pro-inflammatory cytokine level induces interaction between leukocytes and endothelial cells. It was suggested that 20% acetic acid could stimulate macrophages to release proinflammatory cytokines. TNF-α can stimulate ICAM-1 expression on vascular endothelial cells. ICAM-1 is an adhesion molecule, which plays a pivotal role in inflammatory reaction by increasing leukocyte adhesion to endothelium and promoting transen-dothelial migration of leukocytes to inflammatory sites[3]. Moreover, it was reported that TNF-α can also stimulate expression of LFA-1 (CD11a/CD18)[35], an adhesion molecule on leukocytes. This might be the reason why of TNF-α and leukocytes-endothelium interaction is increased in the inflammatory area.

However, after gastric ulcer was induced by administration of 20% acetic acid IL-10 level was reduced on day 1, but elevated spontaneously on day 8 as compared to the control groups (Figure 3). This might be due to the fact that when the gastric mucosa was damaged by acetic acid, T and B lymphoctyes in submucosal beneath the damaged area that typically produce basal level of IL-10 were also damaged. The location of macrophages was actually beyond the damaged area, therefore, the macrophages were then survived. The survived macrophages are able to stim-ulate the release of TNF-α in response to acetic acid injury. Therefore, our findings suggest that TNF-α is synthesized more than IL-10. When inflammation occurs, IL-10 is synthesized. The increment of IL-10 level reduces gastric inflammation through its feedback inhibition of TNF-α production. Therefore, IL-10 is spontaneously elevated in chronic gastric inflammation. The elevation of IL-10 then reduces gastric tissue inflammation simultaneously.

Aloe vera and sucralfate could reduce leukocyte adherence after gastric ulcer was induced by 20% acetic acid. It has been reported that *Aloe vera* can decrease carrageenan- induced edema and neutrophil migration in rats[36]. In addition, *Aloe vera* has antiinflammatory effect on burn wounds by reducing leukocyte adhesion in rats[37, 38]. On the other hand, *Aloe vera* is able to inhibit prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and thromboxane B2 production in guinea pig with burn wounds[39]. Thromboxanes and prostaglandins (PGs) can elicit platelet aggregation, leukocyte adherence and vasoconstriction, thus enhancing ischemia. Moreover, *Aloe vera* possesses bradykininase activity and also decreases inflammation[9]. Bradykinin causes increase in vascular permeability and stimulates inflammation[40]. Therefore, these effects of Aloe vera might reduce the causes of inflammatory process, the effects and leukocyte adherence after gastric ulcer is induced by 20% acetic acid.

Aloe vera and sucralfate could reduce TNF-α level on days 1 and 8 after induction of gastric ulcer (Figure 2). *Aloe vera* has cytoprotective effect on gastric mucosa by stimulating endogenous prostaglandins production[20]. Sucralfate is a cytoprotective drug which also stimulates PG production. Prostaglandins (PGs), especially prostaglandin E2 (PGE2) can protect gastric mucosa from various irritants, promote mucus production and increase mucosal blood flow[41-43]. It was reported that PGE2 plays a role in modulating TNF-α production and is also a potent inhibitor of neutrophil adherence and chemotaxis[44]. Ding *et al*[45] reported that PGE2 inhibits TNF-α release in gastric mucosa and reduces in neutrophil activation and subsequently ischemia and mucosal damage. They also showed that inhibition of TNF-α by PGE2 could result in the reduction of neutrophil CD11b/CD18 and endothelial ICAM-1 expression directly or indirectly, thus subsequently reducing neutrophil adhesion on vascular wall.

In our study, *Aloe vera* and sucralfate could elevate IL-10 level on days 1 and 8 after induction of gastric ulcer. IL-10 is an anti-inflammatory cytokine produced by various cells including monocytes/macrophages and T lymphocyte. IL-10 can inhibit cytokine synthesis by macrophages[46]. In

addition, the mild anti-inflammatory effects of IL-10 may be due to the suppression of TNF-α production[47]. Bodger *et al*[48] showed that mucosal secretion of IL-10 and TNF-α is increased in *H pylori* gastritis. IL-10 may be protective and can limit tissue damage caused by inflammation. Therefore, elevation of IL-10 can down-regulate TNF-α production in macrophage.

Aloe vera and sucralfate could reduce inflammation and promote gastric ulcer healing, which has been confirmed by histopathological examinations. *Aloe vera* and sucralfate promote epithelial cell proliferation, elongation and dilatation of oxyntic grand. *Aloe vera* and sucralfate have a cytoprotective effect on gastric mucosa by stimulating PGE_2 production. PGE_2 plays an important role in the maintenance of mucosal integrity and mucus production. It was reported that *Aloe vera* could promote burn wound healing in rats[37, 38, 49]. In addition, *Aloe vera* could induce angiogenesis *in vivo*[5], which plays an important role in wound healing. *Aloe vera* can result in reduced vasoconstriction and improve perfusion of gastric mucosal capillaries, thus promoting ulcer healing[13, 50, 51]. Furthermore, gastric acid is considered as an important aggressive factor in the stomach and is known to produce gastric injury[52]. *Aloe vera* is able to decrease gastric acid secretion and increase mucus secretion[53].

The mechanism of *Aloe vera* could be explained by its action on inflammation and ulcer healing. The results of this study suggest that *Aloe vera* could decrease leukocyte adherence and TNF-α levels in inflammatory tissue. Our findings demonstrate that *Aloe vera* could act as an antiinflammatory agent on gastric ulcer. Our findings also indicate that ulcer healing effect of *Aloe vera* is mediated by increasing IL-10, an important cytokine for wound healing process.

In conclusion, *Aloe vera* acts on inflammation and promotes ulcer healing. *Aloe vera* might be used as a therapeutic agent for gastric ulcer patients.

Abstract

AIM: To construct two kinds of anti-gastrin immunogen based on P64K protein from *Neisseria meningitids* and to compare their immunogenic effect.

METHODS: G17P64K gene was cloned and ligated into pET28a plasmid, then transformed into BL21(DE3). After inoculation of LB medium and IPTG induction, the recombinant protein was solubly expressed at a high level. The purification of G17P64K fusion protein was similar to that of P64K. An initial step of purification consisting of 30% saturated ammonium sulfate precipitation was done. Additional fine optimizations included phenyl-sepharose, G200 Sephadex gel filtration and Q-sepharose anion exchanger chromatography. Highly purified protein was obtained and sequenced at the N-terminal amino acid residues. Polypeptide was synthesized by Fmoc solid phase chemical method and cross-linked to carrier protein P64K and DT mutant by MBS method and then the rabbit anti-gastrin 17 antibody was prepared by immunizing rabbit with cross-linked and fused protein. The titer and the activity *in vitro* of antibody were assessed.

RESULTS: G17P64K gene and the recombinant bacteria were obtained. After four steps purification, protein sample that has the purity above 90% was achieved. At the 84th day after the first immunization, the titer of antibody against cross-linked protein reached 51 200. Evaluation of the antibody *in vitro* manifested that it had a high inhibitory activity on the growth of tumor cell SW480.

CONCLUSION: The P64K-polypeptide cross-linked immunogen immunized rabbit and achieved a higher titer antibody against gastrin 17 than the G17P64K fusion protein immunogen, which could inhibit the growth of the tumor cell SW480.

Key words: Gastrin; P64K protein; therapeutic vaccine

INTRODUCTION

The peptide hormone gastrin, released from the G cells of the antrum and duodenum, is known to stimulate the secretion of gastric acid and act as a trophic factor within gastrointestinal tract[1-3]. In recent years evidence has accumulated that gastrin is a growth factor for gastrointestinal tumors, such as gastric cancer, colon cancer, and pancreatic cancer[3-6]. Therefore it has emerged as a potential anticancer target[7].

There are several forms of gastrin; the precursor molecule preprogastrin is cleaved by an endopeptidase to progastrin, which is further processed to glycine-extended gastrin 34 and to gastrin 34[8]. These 35- and 34-amino acid peptides can be cleaved to form glycine-extended gastrin 17 and gastrin 17 respectively. Cells with gastrin receptors can respond to mature amidated forms of gastrin, as well as precursor forms, particularly glycine-extended gastrin 17. It has become clear that in cancer cells originating in various parts of the gut, the gastrin gene and the genes that encode the gastrin receptors are switched on at a very early stage of oncogenesis. Scientists have demonstrated that the glycine-extended gastrin 17 and gastrin 17 can promote cancer cell division via an autocrine or endocrine pathway[9]. A unique B cell epitope to glycine-extended gastrin 17 and gastrin 17, which is not found on gastrin 34 and CCK, consisting of the 9-amino acid stretch at the amino-terminal end of the molecule, has been identified and mapped. The immunogens comprising this unique epitope result in high levels of anti-gastrin 17 antibodies

that do not cross-react with gastrin 34 and CCK, which share with gastrin 17 a common receptor to carry out their physiologic function.

P64K protein isolated from pathogenic bacterium *Neisseria* is found in the outer membrane of the cell and well recognised in sera from individuals convalescent from meningococcal disease or vaccinated with VA-MENGOC-BC®, a Cuban antimeningococcal vaccine based on outer membrane vesicles[10]. Its high molecular mass and strong immunogenicity have made it a suitable carrier protein for weak immunogens. Recent studies have manifested that P64K protein has a better immune enhancing effect than conventional carrier protein such as BSA, TT[11]. The B cell epitope of gastrin 17 was cross-linked or fused via a peptide spacer to P64K to comprise an immunogen against gastrin 17.

MATERIALS AND METHODS

Materials

P64K gene and protein were conserved in our laboratory. DH5α, BL21(DE3) were purchased from BioDev (Beijing China). Restriction endonucleases, polymerase, T4 DNA ligase and DL2000 were from Takara (Dalian,China). GENECLEAN II kit was ordered from Q.BIOgene (Morgan Irvine,USA). SV Minipreps DNA purification system was provided by Promega (Madison,USA). DT mutant (CRM197) was purchased from Sigma(Ronkonkoma, USA). Polypeptide was synthesized and cross-linked in Institute of Basic Medical Sciences (Academy of Military Medical Sciences, Beijing, China). Low molecular weight calibration kit for SDS electrophoresis was purchased from Amersham Biosciences(Beijing,China). Goat anti-rabbit IgG-HRP was from Bio-LAB(Beijing China). New Zealand white rabbits and BALB/C nude mice were supplied by Laboratory of Animal Center (Academy of Military Medical Sciences, Beijing, China).

SW480 is a human colonic epithelial tumor cell. It could be stimulated to proliferate by gastrin via an autocrine or endocrine pathway and inhibited by gastrin inhibitor[12,13]. It was obtained from The Cell Center of Basic Medical Sciences(Chinese Academy of Medical Sciences, Beijing, China). Cell lines were grown in DMEM (GIBCO-BRL) supplemented with 10% heat-activated fetal bovine serum(FBS) in a humidified incubator at 37 ℃ in an atmosphere of 5% CO_2.

Methods

Construction of recombinant expression plasmid: Cloning of gene, isolation of plasmid and all other molecular biology procedures were carried out according to the standard procedures published. P64K gene was cloned from *Neisseria meningitids* and gastrin17 B cell epitope was designed into 5' upperstream primer[14]. G17P64K gene was cloned by PCR amplification under the following conditions: 30 cycles of 94℃ for 1 min, 50 ℃ for 1 min and 72 ℃ for 2 min with one additional cycle for 10 min at 72 ℃. The reaction components were: 1μg of P64K DNA; 50 pmol of primer 1 (5'- CATGCCATGGAAGGCCCTTGGCTTGAAGAGGAAGAATCTTCACCCCCTCCGCCGCTTTAGTTGAATTGAAAGTG-3') and primer 2 (5'-GGGAATTCTTATTTTTTCTTTTGCGGAG-3'); 200 μmol/L of each deoxynucleotide triphosphates (dNTPs); PCR buffer (10 mmol/L KCl, 20 mmol/L Tris-HCl pH 8.8, 10 mmol/L $(NH_4)_2SO_4$, 2 mmol/L $MgSO_4$, 0.1%Triton X-100; double distilled water to a final volume of 50 μL and 1 unit per reaction of Pyrobest DNA polymerase. PCR product was purified by agarose gel electrophoresis, digested by *Nco*I and *Eco*RI, then ligated into the pET28a plasmid digested with the same enzymes. The ligation products were then transformed into *E.coli* DH5α. Positive clones were selected by PCR using the conditions described above and subjected to double-stranded DNA sequencing with T7 sequencing primer according to the manufacturer's specifications. Sequence processing was done with the DNAStar software.

Expression of recombinant protein in shake flask cultures: The strain *E.coli* BL21 (DE3) was transformed with G17P64K recombinant plasmid, which was also transformed with plasmid (negative control). A transformed colony from each construct was inoculated into 20 mL Luria Bertani (LB) cultures. Bacteria were grown in a shaker at 37℃. After measurement of the optical density at 600 nm (OD_{600}), IPTG was added to induce recombinant protein synthesis considering OD_{600} of 0.5. Cell culture was allowed to continue incubation for 4 h. Samples were collected and centrifuged at 10 000 g for 10 min at 4 ℃. The bacterial pellet was washed twice with 10 mmol/L Tris and 1mmol/L EDTA, pH8 (TE), and then resuspended in 1 mL TE. Cells were destructed by sonication for 15 min. After centrifugation of the lysate at 27 000 g for 30 min at 4℃, supernatants and pellets from destruction were collected. All protein samples were subjected to 15% SDS-PAGE according to the standard procedure of Laemmli. Protein bands were visualized by staining with Coomassie brilliant G-250. Gels were scanned and the purity was estimated by densitometry using the Molecular Analysis software.

Production of recombinant protein in bioreactors: The colony containing recombinant plasmid was inoculated into 5 mL cultures of LB containing kanamycin(30 μg/mL). Cells were grown in a shaker at 37 ℃ to an OD_{600} of 0.8. The sample was transferred into 200 mL LB culture and continued to grow for 12 h at 37 ℃ with shaking (200 rpm). This culture was used to inoculate 3 L of rich media supplemented with 30 μg/mL kanamycin. When OD_{600} reached 20, expression of G17P64K gene was induced by addition of IPTG to a final concentration of 1 mmol/L and allowed to take place at 37 ℃ for 7 h. One milliliter of the bacteria was taken out at 0, 1, 2, 3, 4, 5, 6 and 7 h after induction. Cells were harvested by centrifugation at 10 000 g for 20 min and stored at -20 ℃. Five microliters of bacteria were electrophoresed on a 15% SDS-PAGE for evaluation of protein expression.

Purification of the recombinant protein: The supenatant obtained after centrifugation of the lysate was precipitated by adding solid ammonium sulfate to 20%, 30%, 40%, 50% saturation respectively. And the condition of the most optimal purification effect was ascertained. The pellet was resuspended after centrifugation at 27 000

Table 1 The dosage of rabbit immunization

Polypeptide (mg/rabbit)	G17P64K protein (mg/rabbit)	G17(9) : P64K (mg/rabbit)	G17(9) : DT (mg/rabbit)	P64K protein (mg/rabbit)
0.25	2.0	0.5	0.5	0.25

g for 20 min at 4 ℃. The resuspended solution was applied to the following chromatography steps similar to P64K.

The first stage was a phenyl-sepharose hydrophobic interaction column. After the sample was loaded, the column was washed with loading buffer(2.0 M ammonium sulfate, 20 mmol/L Tris-HCl, 1 mmol/L EDTA, pH7.2) and eluted with a 1.5-0 mol/L ammonium sulfate gradient. G17P64K protein was eluted as a major peak in about 0.8M ammonium sulfate and G17P64K-containing fractions were pooled by adding solid ammonium sulfate to 100% saturation. The second step was a G200 Sephadex column. The concentrated sample was loaded on the column, re-equilibrated and eluted with PBS. G17P64K was eluted in the major peak and both sides contained only small amounts of contaminants. The last chromatography step was a Q-Sepharose anion exchange column. The sample from the previous G-200 sephadex column was diluted 10 times and loaded onto the anion exchange column. After washing the column with loading buffer (20 mmol/L KPB, 5mmol/L NaCl, 1mmol/L EDTA, pH6.0), G17P64K was eluted with 5-500 mmol/L NaCl gradient. In this step, the G17P64K-containing peak was the only major peak. The samples were subjected to 15% SDS-PAGE under denaturing conditions as previously described.

Chemical synthesis and crosslink of polypeptide: Polypeptide with the following amino acid sequences were synthesized: pyro-Glu-Gly-Pro-Trp-Leu-Glu-Glu-Glu-Glu-Gly-Gly-Gly-Gly-Ser-Cys. Synthetic polypeptide contained a B-cell epitope consisting of residues 1 to 9 of gastrin 17, a five amino acid peptide spacer, and an N-terminal cysteine. It was produced by Fmoc solid-phase synthetic chemical method and its purity was detected by high-performance liquid chromatography(HPLC) analysis method. The polypeptide was conjugated to amino group present on a carrier protein such as P64K and CRM-197(DT mutant) via the terminal peptide cysteine residue utilizing heterobifunctional linking agent-m-maleimidobenzoyl-N-hydroxysuccinimide ester(MBS). After desalting? and concentrating over a PM 10 ultrafiltration membrane, the conjugate was lyophilized and stored desiccatedly at -20℃ until use.

Preparation of rabbit anti-gastrin 17 antibody: New Zealand rabbits were immunized with the immunogens including synthetic polypeptide, G17P64K recombinant protein, polypeptide-DT conjugate and polypeptide-P64K conjugate. Four groups of 2 rabbits were immunized with one of the immunogens. Each animal was injected subcutaneously with 1.5 mL of immunogen. An additional group of 2 rabbits was immunized with P64K protein as a blank immunization control. Each group of rabbit was immunized as shown in Table 1. Rabbits were vaccinated by subcutaneous injection of immunogens emulsified with CFA/PBS for the first immunization and IFA/PBS for the subsequent 2 booster injections at 3-wk intervals. Blood samples were collected from rabbits at wk 0, 2, 5, 8 and 12.

Detection of antibody titer*:* Antibodies levels in sera were determined by enzyme linked immunosorbent assay (ELISA). To detect anti-gastrin 17 antibodies titer, 96-well plates were coated with 200 μL/well of corresponding peptide(10 μg/mL) in carbonate buffer(0.05 mol/L $NaCO_3$, pH 9.6) for 2 h at 37 ℃. Bovine serum albumin (2%) was used as a blocking reagent. After three washes in /0.05% PBS Tween 20 (PBST), 100 μL of serial dilution of each serum (starting dilution 1:100) was added to the plates, which were incubated for 2 h at 37 ℃. All sera were analyzed in four replicates. Serum anti-gastrin 17 antibody levels were expressed as their absorbance (492 nm) values in ELISA and used for statistical analysis.

Evaluation of the antibody in vitro: SW480 cells were seeded into 96 flat bottomed well plates(Costar) at a concentration of 5×10^4 per well in a 100 μL volume in the serum free medium. Affinity-purified immunoglobulins(IgG) raised against gastrin 17 and normal rabbit control IgG were normalized to standard protein concentration of 0.5 mg/mL. IgG dilutions from 1/2 to 1/256 were prepared in serum free medium and added to the cells in 100 μL volume per well. Each condition was performed with four replicates. Cell proliferation was assessed after 72 h by the methylthiazoyl tetrazolium(MTT) assay.

Statistical analysis

Statistics evaluation of *in vitro* data was performed by a one way analysis of variance on the SPSS package.

RESULTS

Construction of recombinant expression plasmid

After amplification of G17P64K gene by PCR, there was a band of about 1.8kb by agarose gel electrophoresis(Figure 1). The fragment was purified, digested by *Nco*I and *Eco*RI

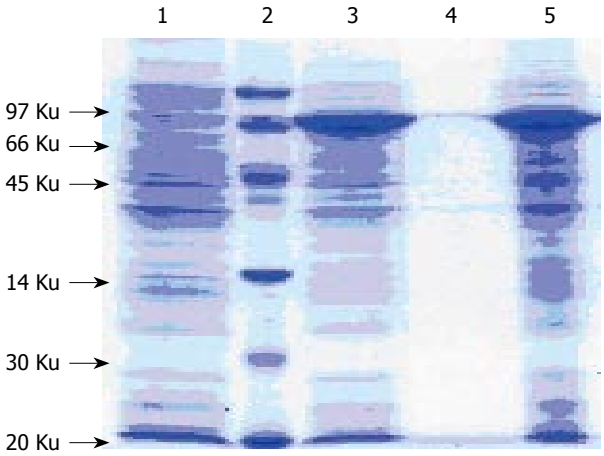

Figure 2 15% SDS-PAGE analysis of expression products. Lane 1: Non-recombinant bacteria; Lane 2: Low molecular protein marker; Lane 3: Recombinant bacteria; Lane 4: Deposition after sonication; Lane 5: Supernatant after sonication.

and cloned into the pET28a. The resulting plasmid was designated as pET28a-G17P64K. Sequencing revealed that the G17P64K gene was fused to the correct reading frame with the coding sequence.

Expression of recombinant protein in shake flask cultures

SDS-PAGE was carried out with the sample from BL21(DE3), which transformed with pET28a- G17P 64K (Figure 2). An approximate 70KD protein was solubly expressed in BL21(DE3) and accounted for about 30% of the total cellular protein.

Production of recombinant protein in bioreactors

Recombinant bacteria were grown in 5-L fermentors to investigate whether the G17P64K protein could be expressed and the yields could be amplified using a scale-up cultivation. The 5-L fermentors strategy allowed cultures to grow to final OD_{600} of 33. At 5-L fermentors culture of 5 h, induction of the T7 promotor and production of G17-P64K protein was initiated. The G17P64K protein was gradually increased per OD_{600} until the end of fermentation (Figure 3).

Purification of the recombinant protein

The G17P64K production system described in this work may permit the protein to be purified using commercially available, conventional method. SDS-PAGE manifested that 30% saturation of ammonium sulfate could most efficiently remove the contaminants (Figure 4). The first step consisted of a phenyl-sepharose hydrophobic interaction column chromatography and used a high con-centration to enhance G17P64K capture. A G200 Sep-hadex column chromatography was used next to further minimize host cell protein contaminants, followed by a Q-Sepharose anion exchanger column chromatography to help eliminate the residual contaminants. The results of this purification scheme are shown in Figure 5. After four steps of purification, the final product was judged to be more than 90% of purity. And the result of N-terminal amino acid sequencing (MEGPW) was in accordance to

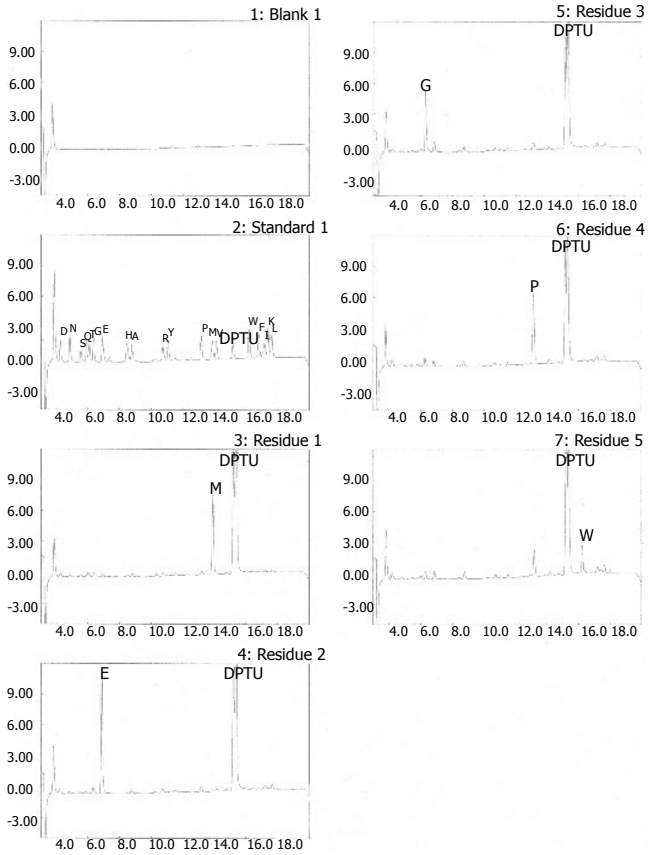

Figure 6 N-terminal amino acid sequence of G17P64K protein.

the anticipated sequence (Figure 6).

Chemical synthesis and crosslink of polypeptide

Polypeptide was synthesized by Fmoc solid-phase synthetic chemical methods. The total weight of synthetic polypeptide was determined to be 60mg and the purity was detected to be 66.84% by HPLC (Figure 7). The synthetic peptide was conjugated to carrier protein via MBS cross-linking reagent. The conjugate was lyophilized and stored desiccatedly at -20 ℃ until use.

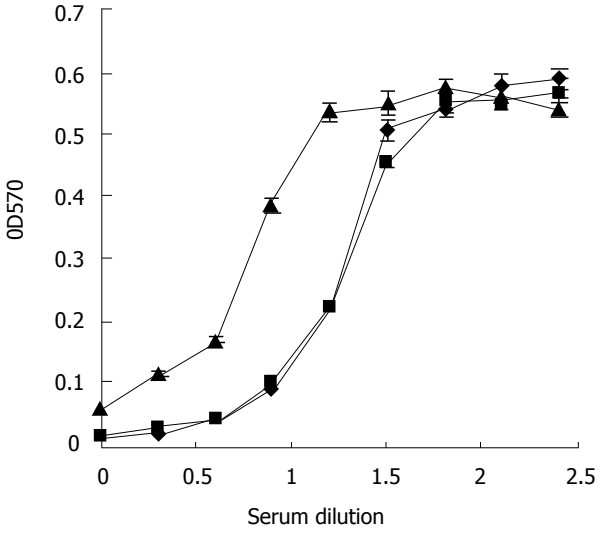

Figure 8 Effects of rabbit anti-gastrin 17 antibody on the *in vitro* growth of SW480 ◆: anti-gastrin 17(9): P64; ■Red: rabbit anti-gastrin 17(9): DT; ▲ : rabbit control IgG

Detection of antibody titer

Anti-gastrin 17 antibody levels in rabbit sera were determined by ELISA (Table 2). High levels of antibody were obtained against synthetic polypeptide conjugated to protein carriers DT and P64K. The result also revealed that the immunogenicity of G17P64K fusion protein was as weak as the single synthetic peptide.

Assessment of the activity of antibody in vitro

MTT uptake was used to measure *in vitro* proliferation which assesses the oxidative ability of the cell to convert a soluble tetrazolium compound into an insoluble colored crystalline product which can be dissolved and assessed colorimetrically. This has previously been shown to correlate with direct cell counts in many cases. The characterization of SW480 has revealed that endocrine/autocrine gastrin–mediate pathways may be operational in the growth of the cells. Figure 8 shows the MTT uptake of SW480 in the presence of increasing dilutions of rabbit ani-gastrin 17 IgG. In experiment, the growth of SW480 was significantly reduced by treatment with rabbit anti-gastrin 17(9) : DT and anti-gastrin 17(9) : P64K from 1/1 to 1/16 dilution, and modestly inhibited at dilutions of 1/32 and 1/64 ($P < 0.05$, one way analysis of variance). The effect of rabbit anti-G17(9) : P64K treatment on the *in vitro* growth of SW480 was not significantly different from rabbit anti-G17(9) : DT from 1/1 to 1/64.

DISCUSSION

Immunization against specific cancer promoting hormones may be useful in the treatment and prevention of cancer. Gastrin has been identified as the central trophic factor for gastrointestinal cancers and has therefore emerged as a potential anticancer target. There are many optional inhibitors of gastrin production[15]. Gastrin-receptors antagonists have been evaluated, but failed to produce any survival benefit in clinical trials[16-18]. Anti-gastrin antibody was demonstrated to be able to bind to gastrin peptides and prevent their interaction with gastrin receptors in preclinical research. And *in vivo* animal studies showed that infusion of anti-gastrin antibodies could inhibit the growth of human colorectal xenografts[19-22]. However, passive infusions of antibodies have serious drawbacks for the patient. Antibodies given passively to patients are not long-lasting and 1 or 2-h infusion would be required every week. In addition, antibody titer would have to be in excess of those required to neutralize normal gastrin secretion so that tumor-associated gastrin would be targeted. Active immunization was likely to work better. A novel immunotherapy has now completed phase III clinical trials of "Gastrimmune" as monotherapy in patients with pancreatic cancer and reported positive results[23-25]. Aphton Corp. has filed for marketing approval in Australia, Canada and New Zealand in 2004. Therefore targeting gastrin as an active-immunotherapeutic approach is appropriate.

There are several forms of gastrin. The glycine-extended gastrin 17 and gastrin 17 are the central trophic factor of cancer cell, while gastrin 34 and CCK are necessary for human body to maintain normal operation. A unique B cell epitope to glycine-extended gastrin 17 and gastrin 17 that is not found on gastrin 34 and CCK, consisting of the 9-amino acid stretch at the amino-terminal end of the molecule, has been identified and mapped. The immunogens comprising this unique epitope result in high levels of anti-gastrin 17 antibodies that do not crossreact with gastrin 34 and CCK, and could effectively decrease the side-effect of vaccine.

An important drawback for the use of the conventional carrier protein in different conjugate vaccines is carrierinduced hapten-specific suppression. It has been demonstrated when mice, presensitized with keyhole limpet hemocyanin (KLH) and subsequently vaccinated with KLH-dinitrophenol(DNP) conjugates, elicited a reduced anti-DNP IgG response[26]. Being a novel carrier protein, P64K protein has its superiority to BSA, TT and DT. This study evaluated the effect of P64K presensitization on its ability as a carrier, by comparing the hapten-specific humoral immune response elicited in rabbit. It proved that P64K protein can help to activate humoral immune system and enhance immune reaction against gastrin 17 B cell epitope as DT.

There are two problems for the immunogen comprising G17 recombinant protein associated with the low level of anti-gastrin 17 antibody because the immunogen is made up of single synthetic polypeptide. First, the excess methionine at the N-terminal of the G17P64K recombinant protein remodels the conformation of the B cell epitope of gastrin 17, and thereof disturbs the recognition of the B cell. Second, polypeptide could provide more B-cell epitope than the G17P64K recombinant protein in the experiment of preparation of anti-gastrin 17 antibody.

A series of tests should be done to assess the inhibitory effect and specificity of the P64K-gastrin immunogen, including the *in vivo* experiment and the adjustment between the inhibitory effect and the gastrin 17 levels. Furthermore, if there were a suitable cell line, an *in vivo* experiment could be done directly, but not human-rabbit-mice? conversion. Another test is the quality control of the crosslink immunogen of P64K and synthetic peptide. Other kinds of cancer cell line should be considered.

Abstract

AIM: To investigate the effect of Qinggan Huoxuefang (QGHXF) on improvement of liver function and pathology in rats, and to analyze the mechanism.

METHODS: Wistar rats were divided into three groups at random: normal control group (12), micro-amount carbon tetrachloride group (CCl_4)(12) and model group A (60). The model group A was ingested with the mixture (500 mL/L alcohol, 8 mL/kg per day; corn oil, 2 mL/kg per day; pyrazole, 24 mg/kg per day) once a day and intraperitoneal injections of 0.25 mL/kg of a 250 mL/L solution of CCl_4 in olive oil twice a week for 12 wk. The CCl_4 group received intraperitoneal injections only. At the end of 8 wk the model group A (60) was divided into 5 subgroups: model group, Xiaochaihu Chongji (XCH) group, QGHXF high dose group, moderate dose group and low dose group, and were given the drugs respectively. At the end of 12 wk, all the rats were killed and blood samples collected, as well as liver tissue. Blood samples were used for evaluation of alanine transaminase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), gamma-glutamyltransferase (γ–GT). Liver specimens were obtained for routine HE, apoptosis gene array and flow cytometry analysis.

RESULTS: A liver fibrosis animal model was successfully established. Fibrosis was obviously reduced in QGHXF high dose group, and no fibrosis formed in CCl_4 group. Compared with model group the QGHXF group and XCH group could obviously decrease the level of ALT, AST, ALP, and GGT ($P<0.05$). QGHXF high dose group was better than XCH group in ALT (615±190 *vs* 867±115), and AST(1972±366 *vs* 2777±608). Moreover, QGHXF could reduce liver inflammation, fibrosis-induced hepatic stellate cell (HSC) apoptosis and regulate apoptosis gene expression. The HSC apoptosis rates of QGHXF groups were 22.4±3.13, 13.79±2.26 and 10.07±1.14, higher than model group, 6.58±1.04 ($P<0.05$). Compared to model group, 39 genes were up-regulated, 11 solely expressed and 17 down-regulated in high dose group.

CONCLUSION: QGHXF can improve liver fibrosis and induce HSC apoptosis.

INTRODUCTION

Alcohol abuse and dependence have been a public problem all over the world. In the United States, 45 billion dollars were spent on alcoholic intemperance and its related problems[1,2]. In recent years morbidity rate of alcoholic liver diseases (ALD) has risen rapidly. It has become the second liver disease after viral hepatitis in China[3,4]. Liver disease in the alcoholics is due not only to malnutrition but also to ethanol's hepatotoxicity linked to its metabolism by means of the alcohol dehydrogenase and cytochrome P450 2E1 (CYP2E1) pathways and the resulting production of toxic acetaldehyde[5-8]. Alcoholic liver disease is a major source of alcohol-related morbidity and mortality. Heavy drinkers and alcoholics may progress from fatty liver to alcoholic hepatitis to cirrhosis, and it is estimated that 10 to 15 percent of alcoholics will develop cirrhosis[9]. Alcoholic liver fibrosis (AF) is one of the alcoholic liver diseases. It is the excessive accumulation of extracellular matrix (ECM) proteins including collagen that occurs in chronic liver diseases. Advanced liver fibrosis results in cirrhosis, liver failure, and portal hypertension and often requires liver transplantation[10]. However, recent evidence indicates that even ad-

focus of researches. Fibrogenesis in human ethanol injury is due to the activity of stellate cells, Kupffer cells, and to a lesser extent, to endothelial cells[14]. Above all of the factors, hepatic stellate cell (HSC) is the key to fibrosis. Activated HSCs are the source of collagen deposition in the liver[15]. This study aimed to explore the mechanism of QGHXF (a traditional Chinese herb) on AF through examination of liver function, and histopathology, detection of HSC apoptosis and gene array, in an effort to search for the experimental basis for traditional Chinese medicine in AF therapy.

MATERIALS AND METHODS

Materials

Jianzhuang Alcohol (52°) and corn oil were purchased from Lianhua Supermarket. Formaldehyde, 400 g/L, olive oil, carbon tetrachloride, hematoxylin and eosin were supplied by Shanghai Chemicals Company. The test kit of alanine aminotransferase (ALT), aspartate aminotransferase (AST), gamma-glutamyltransferase (γ-GT), and alkaline phosphatase (ALP) were purchased from Shanghai Rongsheng Biotech Co. Ltd. QGHXF (bupleurum root 9 g, scutellaria root 9 g, red sage root 15 g, carapax trionycis 9 g, *Radix puerariae* 15 g), concentrated to 2.6 kg/L were processed by Department of Pharmacy, Longhua Hospital, Shanghai University of Traditional Chinese Medicine. XCH was from Shanghai Shikang Technology Co. Ltd (ZZ-3484 No.081006). In situ cell death detection kit (Cat. No. 1684817) and DAB substrate (Cat. No.1718096) were purchased from Roche Diagnostics Ltd.

Animal preparation[16-20]

Eighty-four specific pathogen free (SPF) male Wistar rats weighing 150 ± 20g were purchased from Shanghai Experimental Animal Co. Ltd. All the rats were randomly assigned into three groups: normal group (12), micro-amount CCl_4 group (12) and model group A (60). The model group A was ingested the mixture (500 mL/L alcohol, 8 mL/kg per day; corn oil, 2 mL/kg per day; pyrazole, 24 mg/kg per day) once a day and intraperitoneal injections of 0.25 mL/kg of a 25% solution of CCl_4 in olive oil twice a week for 12 wk. The CCl_4 group received intraperitoneal injections only. Normal group was ingested saline (10 mL/kg per day). At the end of 8 wk the model group A (60) was divided into 5 subgroups: model group, XCH group, QGHXF high dose group, moderate dose group and low dose group, and drugs were given respectively. Model group was given saline (5 mL/kg per day); QGHXF high dose group was given QGHXF 2.6 g/kg, 5 mL/kg; moderate dose group was given 1.3 g/kg, 5 mL/kg; low dose group was given 0.65 g/kg, 5 mL/kg; XCH group was given XCH (3 g/kg per day,); and model group and CCl_4 group were given saline. At the end of 12 wk all the rats were anaesthetized and killed. Blood sample and liver tissue specimens were collected. A portion of liver was fixed for histopathology. Another portion was for flow cytometry assay and the remaining tissue stored at -80°C until assayed.

Serum ALT, AST, ALP and GGT determination

ALT, AST, ALP and GGT were evaluated in samples of serum obtained at the end of the experiment. The activity was evaluated by using a commercial clinical test kit (Shanghai Rongsheng Biotech Co. Ltd.) according to instructions of the kit.

Histopathology and estimation criterion

Liver tissue was instantly fixed in 40 g/L phosphate buffered formaldehyde, processed by routine histology procedures, embedded in paraffin, cut into 5 μm section and mounted on the slide. The samples were stained with hematoxylin and eosin (HE) for histopathological examination[21]. Histopathological criteria refer to the report[22].

Flow cytometry assay[23,24]

Six liver specimens were obtained randomly from each group. The liver tissue was rapidly removed, weighed, and placed into 10 mL of ice-cold PBS containing 2 g/L bovine serum albumin (BSA) (Sigma), 0.01 mol/L EDTA, and 10 g/L deoxyribonuclease I (Sigma), and then the tissue was broken in a glass homogenizer and passed through a 40 μm nylon cell stainer (Becton Dickinson). The suspension was centrifuged at 500 g for 10 min at room temperature. The pellet was resuspended in 500 μL of PBS with BSA and transferred into a fresh tube. The cells obtained by the above method were fixed with ice-cold 700 mL/L ethanol in PBS at 4°C for 8 h, then incubated with RNase (20 mg/L) for 30 min at 37°C and labeled with propidium iodide (50 mg/L). DNA contents were measured by an FACSCalibur cytometer (Becton Dickinson). Multicycle software (CellQuest software, Becton Dickinson) was used to produce histograms of DNA content frequency. Sub-diploid DNA peaks were quantified from the DNA content data.

The tests were completed in Flow Cytometry Laboratory of Shanghai Institute for Biological Sciences, Chinese Academy of Sciences.

Terminal deoxynucleotidyl transferase-mediated nick end labeling (TUNEL) assay

Tissue sections were dewaxed and rehydrated according to standard protocols. They were incubated for 15-30 min at 21-37 ℃ with proteinase K working solution (10-20 mg/L in 10 mmol/L Tris/HCl, 7.4-8). Slides were rinsed twice with PBS. Fifty microliter TUNEL reaction mixture was added to the sample tissue and incubated for 60 min at 37 ℃ in a humidified atmosphere in the dark. Slides were rinsed 3 times with PBS. Fifty microliter Converter-POD was added to the sample. Slides were incubated in a humidified chamber for 30 min at 37 ℃, rinsed 3 times with PBS, then DAB substrate was added and counterstained with hematoxylin, mounted under glass coverslip and analyzed under light microscope.

Apoptosis gene array[25-29]

Three liver specimens were taken from each group of QGHXF high dose group, model group and normal group, then homogenized and mixed for apoptosis gene array, including RNA isolation, RNA yield and quality assessment, probe synthesis, hybridization, chemiluminescent detection, image and data acquisition and analysis. The

Table 1 Impact of QGHXF on ALT, AST, ALP, and -GT in AF rats (mean ± SD)

Group	*n*	ALT (nkat/L)	AST (nkat/L)	ALP (nkat/L)	GGT (nkat/L)
Normal	12	464 ± 90 [b]	1156 ± 250[b]	1065 ± 315[b]	360 ± 98[b]
CCl_4	12	674 ± 172	1678 ± 293[a]	1695 ± 406[a]	748 ± 242[a]
Model	10	926 ± 154	3344 ± 330	2806 ± 639	1376 ± 215
Low dose	11	747 ± 113	2552 ± 388[b]	1748 ± 462[a]	982 ± 236[a]

High dose	10	615 ± 190[bc]	1972 ± 366[bc]	1570 ± 497[a]	770 ± 240[b]
XCH	10	867	2777 ± 608[a]	2413 ± 609[a]	768 ± 292[b]

[a]$P < 0.05$, [b]$P < 0.01$ *vs* model group; [c]$P < 0.05$ *vs* XCH.

data were analyzed and calculated by Gearray Analyzer software.

Statistical analysis

Data were expressed as mean ± SD and analyzed by the ANOVA and post-hoc test. $P < 0.05$ was regarded as statistically significant.

RESULTS

Rat condition

When the rats were given alcohol they became excited and ran around the cage. After that they could not walk, and at last fell into a profound sleep. As the time prolonged spoor time changed from 1~2 h to about 5 h. The weight of rats fell obviously and rats maintained cachexia. Conditions of the rats of QGHXF groups and XCH group were better than those of model group and CCl_4 group.

Liver function

Serum levels of ALT, AST, ALP, and γ-GT in model group were higher than those in normal group. All the indexes were improved in each medicine control group ($P < 0.05$ or 0.01), especially in QGHXF high dose group each index was better than that in XCH group. Details of the data are shown in Table 1.

Effects of QGHXF on liver pathology

The normal group showed normal lobular architecture with central veins and radiating hepatic cords (Figure 1A). The establishment of the model group was successful with marked fatty degeneration, slight confluence, inflammatory infiltrates of monocytes, portal inflammation and necrosis, obvious collagen deposition, and decreased density of hepatocytes (Figure 1B). The CCl_4 group only developed micro- and moderate steatosis. Inflammation and fibrosis could not be found (Figure 1C). The treatment group (QGHXF high dose group) could markedly improve those pathological parameters. Inflammation and collagen deposition decreased obviously, and steatosis could nearly not be found (Figure 1D).

Apoptosis of HSC

Apoptosis was measured in the liver tissue with FC-AS (Figure 2). All QGHXF groups had increased apoptosis rate of HSC, and decreased proliferation compared with the model group. The differences were significant (Table 2).

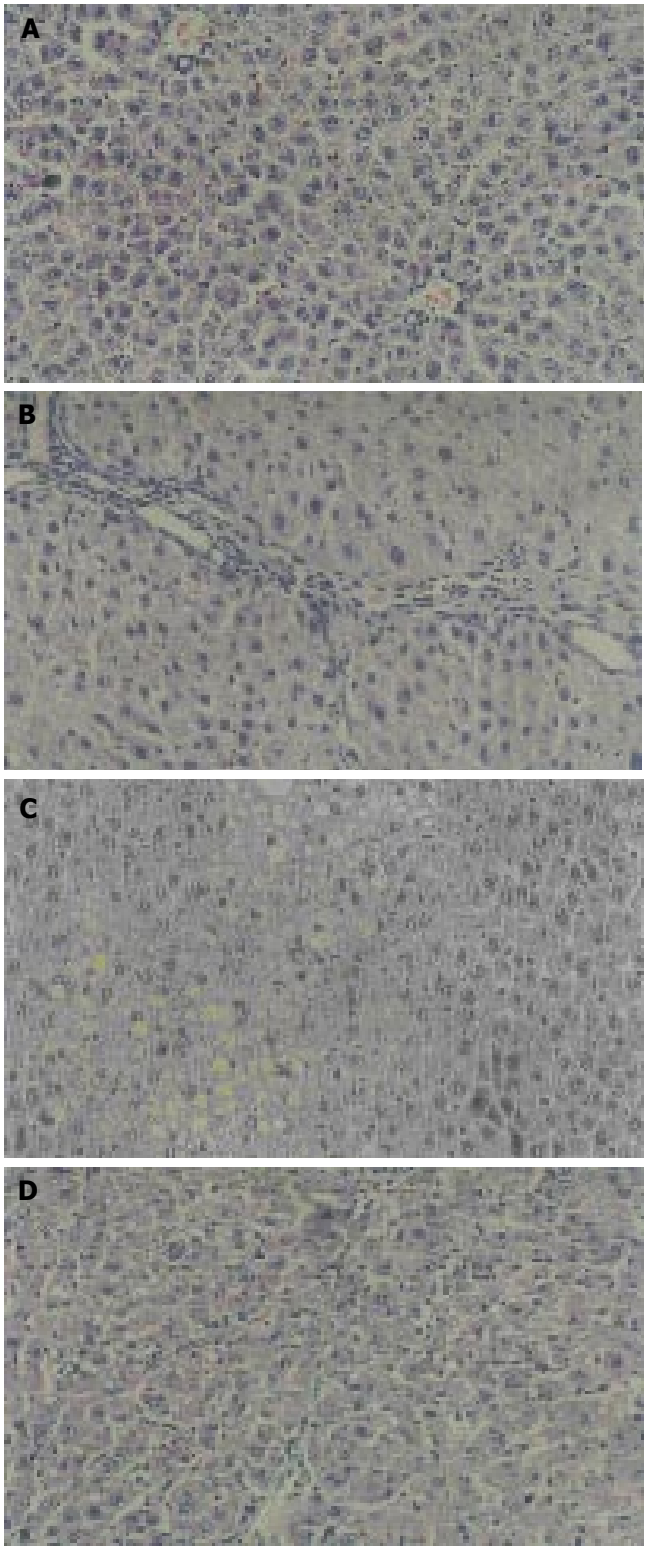

Figure 1 Analysis of liver pathology of each group (HE × 200). **A**: normal group; **B**: model group; **C**: CCl_4 group; **D**: high dose group.

TUNEL assay

TUNEL assay demonstrated standard apoptotic HSC in space of Disse and collagenous fibers in high dose group (Figure 3A), and in model group apoptotic hepatocytes

High dose	22.4 ± 3.13[b]	71.25 ± 1.05[b]	2.70 ± 0.46	26.06 ± 1.47[b]	28.75 ± 1.05[b]
Model	6.58 ± 1.04	64.55 ± 1.53	3.69 ± 0.66	31.76 ± 0.87	35.45 ± 1.53

Proliferative index = 100 % × (S+G_2/M)/(G_0/G_1+S+G_2/M). [a]$P < 0.05$, [b]$P < 0.01$ *vs* model group.

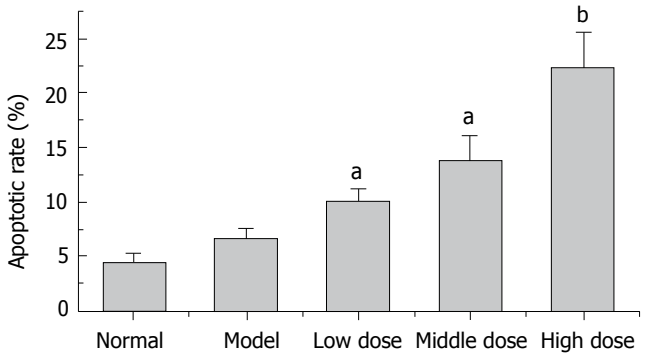

Figure 2 QGHXF induced apoptotic rate of HSC ($n = 6$, mean ± SD). There were significant differences between model group and QGHXF groups. [a]$P < 0.05$ *vs* model group. [b]$P < 0.01$ *vs* model group.

could be seen (Figure 3B). There were no obvious apoptotic cells in normal group (Figure 3C).

Gene array analysis

There were 112 genes in the apoptosis chip, and difference was defined when the same gene ratio was more than 2 or less than 0.5 between different groups. Compared to model group 39 genes were up-regulated (ratio > 2) in high dose group, 11 solely expressed and 17 down-regulated (ratio < 0.5). Compared with normal group 16 genes were up-regulated (ratio > 2) in model group, 6 solely expressed and 35 down-regulated(ratio < 0.5). Compared with normal group 38 genes were up-regulated (ratio > 2) in high dose group , 9 solely expressed and 21 down-regulated (ratio < 0.5). These different expression genes were mainly of TNF receptor family, Bcl-2 family, caspase family, and p53 and ATM pathway. Moreover, in model/normal group chip, only a few genes were consistent with those of high/model group chip, and they were Bad, Bak, Bik, NAIP1, 4-1BBL, TRIP (up-regulated) and TRAF2 (down-regulated). However, in high/model group compared with high/normal group, the up-regulated genes were nearly the same. The unique expressive genes in high/model group were Bar, Bcl-x, Bid, Casper, Caspase-7, chk1, DAPkinase, TNFb Mcl-1, OPG, FASL, and CD30L. In high/normal group they were Apaf-1, ATM, Bax, Bim, Bruce RAD53/chk2, TNFR1, TNFS, F11, and P53. Among down-regulated genes one fourth

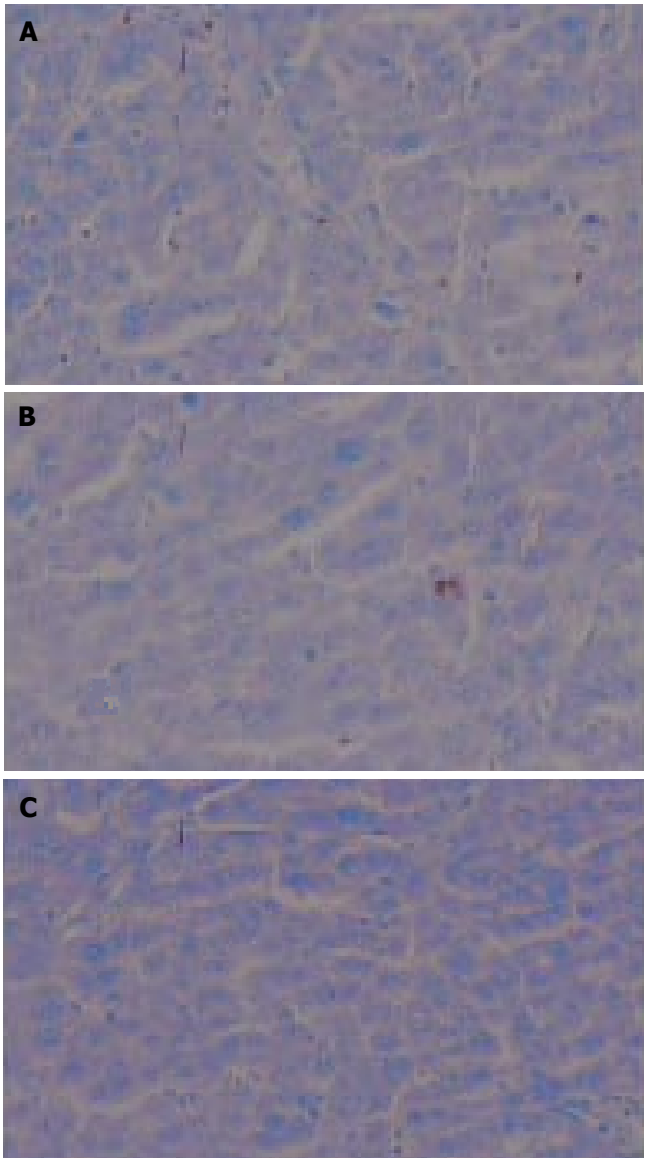

Figure 3 TUNEL assay of each group. **A**: High dose; **B**: Model; **C**: Normal; Counterstained with hematoxylin (original magnification, ×400).

were similar. They were Caspase-1, NOP30-like, RIP, TNFRF11A, and TRAF2. In comparison of model/normal group with high/normal group we found the up-regulated gene expression trend resembled the former result. The same genes were Bcl-2, hrk, IAP2, IAP3 Caspase-11, Caspase-14, and CD30. Down-regulated genes only expressed in high/normal group were CRAF1, CD27, TNFRF11A, RIP, NOP30-like, and Caspase-1 (Figure 4).

DISCUSSION

In contrast with the traditional view that cirrhosis is an irreversible disease, recent evidence indicates that even advanced fibrosis is reversible[11] . It has been demonstrated that apoptosis is the major mechanism by which activated HSCs are removed during recovery from fibrosis[30-32]. As a prophase of AC the reversibility of AF has been reported[33]. The toxicity of ethanol, acetaldehyde, reactive oxygen and other metabolic products are the main causes of AF. These factors lead to hepatocyte inflammation,

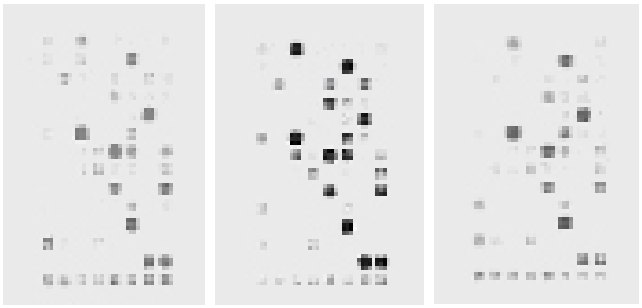

Figure 4 Gene expression profile of each group.

necrosis and apoptosis. AF was historically thought to be a passive and irreversible process due to the collapse of the hepatic parenchyma and its substitution with a collagen-rich tissue. Currently, it is considered a model of the wound-healing response to chronic liver injury. HSCs comprise 15% of the total number of resident liver cells, but they play a very important role in the course of AF[34]. They have been identified as the main collagen-producing cells in the liver. Following chronic injury, HSCs activate or transdifferentiate into myofibroblast-like cell, produce large amounts of extracellular matrix (ECM) and prevent ECM degradation[34,35]. So it is beneficial to induce HSC apoptosis in order to reduce its proliferation and ECM accumulation.

The aim of this study was to explore the mechanism of QGHXF on AF through induction of HSC apoptosis. According to TCM theory, "alcohol is pungent and hot". "Jingyue Quanshu" has already pointed out: if a man drinks too much he will be "Shuigu". Through our long-term clinical practice and epidemiological research we find dampness, heat and gore are the major pathogenesis of ALD, which is in consistent with TCM theory. Therefore, we used QGHXF to clear dampness and heat of the liver and eliminate the gore of the blood. There are five components in QGHXF: bupleurum root, scutellaria root, red sage root, *Carapax trionycis*, and *Radix puerariae*. Bupleurum root (bitter and pungent in flavor, slightly cold in property, acting on liver and gallbladder channel) can expel pathogenic factors from the exterior to reduce fever, sooth the depressed liver and invigorate the spleen-*yang*. Scutellaria root (bitter in flavor, cold in property, acting on the lung, gallbladder, stomach and large intestine channels) can clear away heat and dampness, purge fire, remove toxins from the body, stop bleeding, and prevent miscarriage. Red sage root (bitter in flavor, slightly cold in property, acting on the heart, pericardium and liver channel) can invigorate blood circulation, remove blood stasis, cool the blood, treat carbuncles and tranquilize the disturbed mind by nourishing the blood. *Radix puerariae* (sweet and pungent in flavor, cool in property, acting on the spleen and stomach channels) can dispel pathogenic factors from the superficial muscles to allay fever, promote the production of fluid to quench thirst, promote the eruption of measles and invigorate the spleen-yang to stop diarrhea. carapax trionycis (salty in flavor, slightly cold in property, acting on the liver and kidney channels) can nourish *yin* and suppress hyperactive *yang*, reducing fever and resolving hard lumps. So the QGHXF can clear dampness and heat of the liver and eliminate the gore of the blood.

In this experiment the levels of ALT, AST, GGT, and ALP were obviously decreased in XCH group and each of QGHXF groups($P < 0.05$) and QGHXF high dose group had the best effect. Moreover, QGHXF high dose group had better effect than XCH group on ALT and AST($P < 0.05$). In addition, histopathology proved the effect of the drug. In model group we could see marked fatty degeneration, slight confluence, inflammatory infiltrates of monocytes, portal inflammation and necrosis, obvious collagen deposition, fibrosis and hepatocyte loosening. The treatment group (QGHXF groups) could markedly improve those pathological changes. Inflammation and collagen deposition decreased obviously, and steatosis could nearly not be seen. To clarify that the fibrosis was caused by alcohol but not CCl_4, we established the CCl_4 group in which only micro- and moderate steatosis were found, while inflammation and collagen deposition were not found. It suggested that alcohol was the real reason for fibrosis. To analyse mechanism of the effect we used FCAS and TUNEL assay. The results showed QGHXF groups could not only increase apoptosis rate of HSC but also inhibit it from proliferation. It partly proved our hypothesis that QGHXF could induce HSC apoptosis to reverse liver fibrosis. However, the HSC proliferation rate of low dose group was higher than model group, the reason for which needs to be further studied.

What excited us was, from the FCM analysis, the double regulating function of Chinese medicine. Considering the multi- target effect of Chinese medicine we selected a gene chip for further investigation. According to gene chip result, the gene expression of *p53* and ATM pathway, Caspase family, Bcl-2 family, TNF receptor family, death effector domain family all changed in each group. It meant either alcohol or drug could affect the apoptosis gene expression of liver. As a mixed cell tissue of liver, the types and apoptosis pathway of apoptotic cells were so different that both up-regulated and down-regulated genes in model/normal groups were quite different from that of high/model groups. As we all know, alcohol can induce hepatocytic apoptosis so many apoptotic genes expressed in model/normal group, but these genes were not expressed in high/model group. Thus we deduced the types of apoptotic cells were not the same, and the result of TUNEL also supported this point.

By combination of the TUNEL results with that of FCM analysis (apoptotic rate of HSC was the lowest in model group, while it was the highest in high dose group), we could conclude that QGHXF can induce HSC apoptosis, prevent hepatocytic apoptosis and necrosis. As regards which pathway plays the key role in HSC apoptosis more profound studies are needed. QGHXF has been proven effective on AF from this experiment.

ACKNOWLEDGEMENTS

Abstract

AIM: To study the effects of obstructive jaundice on liver regeneration after partial hepatectomy.

METHODS: Hepatocyte growth factor (HGF), its receptor, c-Met, vascular endothelial growth factor (VEGF) and transforming growth factor-β1 (TGF-β1) mRNA expression in both liver tissue and isolated liver cells were investigated after biliary obstruction (BO) by quantitative reverse-transcription polymerase chain reaction (RT-PCR) using a LightCycler. Immunohistochemical staining for desmin and α-smooth muscle actin (α-SMA) was also studied. Regenerating liver weight and proliferating cell nuclear antigen (PCNA) labeling index, and growth factor expression were then evaluated after 70% hepatectomy with concomitant internal biliary drainage in BO rats or sham-operated rats.

RESULTS: Hepatic TGF-β1 mRNA levels increased significantly 14 days after BO, and further increased with duration of cholestasis. Meanwhile, HGF and VEGF tended to increase, but was not significant. In cell isolates, TGF-β1 mRNA was found mainly in the hepatic stellate cell (HSC) fraction. Immunohistochemical studies revealed an increased number of HSCs (desmin-positive cells) and activated HSCs (α-SMA-positive cells) in portal areas after BO. In a hepatectomy model, liver regeneration was delayed in BO rats, as compared to sham-operated rats. TGF-β1 mRNA was significantly up-regulated up to 48 h after hepatectomy, and the earlier HGF mRNA peak was lost in BO rats.

CONCLUSION: BO induces HSCs proliferation and activation, leading to up-regulation of TGF-β1 mRNA and suppression of HGF mRNA in livers. These altered expression patterns may be strongly involved in delayed liver regeneration after hepatectomy with obstructive jaundice.

INTRODUCTION

Recently, major hepatectomy has been performed for treatment of advanced hepatic and biliary carcinomas [1]. However, major hepatectomy associated with obstructive jaundice is often complicated by hepatic failure [2, 3], suggesting that biliary obstruction (BO) may influence liver regeneration and cause hepatic failure after major hepatectomy. Although several previous studies regarding liver regeneration after hepatectomy with obstructive jaundice have been reported [4-6], it is not clear how BO affects liver regeneration. Aronson *et al* [4] reported that extrahepatic cholestasis inhibits liver regeneration after hepatectomy, whereas Mizuno *et al* [5], demonstrated that it has no effects on liver regeneration. Thus, the effect of BO on liver regeneration after hepatectomy is still open to discussion even in an experimental model. In clinical cases, whether preoperative biliary drainage before surgery is beneficial or not is also a matter of debate.

In the liver regeneration process, several growth factors are reported to play a crucial role in regulation of regeneration by providing either stimulatory or inhibitory signals for hepatocytes [7]. Epidermal growth factor (EGF),

transforming growth factor-α (TGF-α), and hepatocyte growth factor (HGF) stimulate DNA synthesis in hepatocytes *in vivo* and in culture, but HGF is known to be the most powerful mitogen of hepatocytes [8, 9]. In liver, HGF is produced by nonparenchymal cells, mainly hepatic stellate cells (HSCs), and acts on hepatocytes in a paracrine manner via its receptor, c-Met [10-12]. Vascular endothelial growth factor (VEGF) is also reported to be the only angiogenic factor that stimulates proliferation of sinusoidal endothelial cells (SECs) [13-15]. On the other hand, transforming growth factor-β1 (TGF-β1) is a potent growth inhibitor of hepatocytes [16-19]. TGF-β1 mRNA levels are very low or undetectable in normal liver, but increase significantly after partial hepatectomy [20-22]. In cell isolates from regenerating normal liver, the TGF-β1 mRNA was relatively abundant in SECs, Kupffer cells, and HSCs [23]. Meanwhile, in a liver injury model, induced by carbon tetrachloride or D-galactosamine administration, TGF-β1 mRNA expression was up-regulated mainly in HSCs [23-25].

HSCs are known to be located in the space of Disse, below the SECs lining, in close contact to and partially intercalated between hepatocytes, with their long processes extending along sinusoids [26]. HSCs express desmin, a cytokeletal intermediate filament characteristic of muscle cells [27], but once HSCs are activated, they transform into myofibroblast-like cells, and express α-smooth muscle actin (α-SMA). Furthermore, myofibroblast-like cells derived from HSCs produce large amounts of TGF-β1, which stimulates activated HSCs to produce more TGF-β1 in an autocrine manner [28, 29]. On the other hand, activated HSCs lose HGF productivity, although HGF is primarily produced from non-activated HSCs [10].

At present, the influence of BO on HSCs phenotype, especially their TGF-β1 expression during cholestasis and their influence after hepatectomy, is not yet determined. In this study, HGF, c-Met, VEGF and TGF-β1 mRNA expression were investigated after BO in both liver tissue and isolated liver cells, by means of *in situ* collagenase perfusion and counterflow elutriation, to determine potential cellular sources of these growth/inhibitory factors. Immunohistochemical staining with desmin and α-SMA antibody was also studied to evaluate the number of HSCs and their activation status. To determine the effect of BO on liver regeneration, we also investigated changes in hepatic HGF, c-Met, VEGF and TGF-β1 mRNA expression after 70% hepatectomy with concomitant internal biliary drainage in BO rats, and compared them to those in sham-operated rats. Regenerating liver weight and PCNA labeling index were also studied to evaluate the relationship between growth factor expression and liver regeneration after hepatectomy.

MATERIALS AND METHODS

Animals

Male Wister rats (SLC, Inc. Shizuoka, Japan), weighing 200 to 300 g were used in this study. All animals were housed in a temperature- and humidity-controlled environment with a 12-h light dark cycle, and allowed to drink water and eat *ad libitum*. All surgical procedures were performed under light diethyl ether anesthesia. The operative procedure was carried out using clean, but not sterile technique. Experiments with the animals followed our institution's criteria for the care and use of laboratory animals in research, which conform to National Institutes of Health guidelines.

Experiment 1

The rats were subjected to BO or sham surgery (sham-operated control). In the BO rats, the extrahepatic bile duct was isolated and a polyethylene tube with an outer diameter of 0.8 mm (Natsume, Tokyo, Japan) was inserted into the extrahepatic bile duct, according to the cut-down technique. The other end of the tube was then ligated to induce BO. In the sham-operated rats, the extrahepatic bile duct was isolated but was not occluded. The liver was carefully excised before surgery, and 14 and 21 d ($n = 10$ at each time point) after surgery. HGF, c-Met, VEGF and TGF-β1 mRNA levels in liver tissue were investigated by quantitative reverse-transcription polymerase chain reaction (RT-PCR), using a LightCycler (Roche Diagnostics, Mannheim, Germany). Furthermore, to determine potential cellular sources of these growth factors, liver cells (hepatocytes, SECs, Kupffer cells and HSCs) were isolated from liver tissue 14 d after BO, by means of *in situ* collagenase perfusion and counterflow elutriation. The levels of HGF, c-Met, VEGF and TGF-β1 mRNA in each cell fraction were then investigated by quantitative RT-PCR. Immunohistochemical staining with anti-desmin and anti-α-SMA antibody was also performed, to evaluate the number and activation status of HSCs.

Experiment 2

Fourteen days after BO, rats were subjected to 70% hepatectomy with concurrent internal biliary drainage. The tied end of the polyethylene tube was released and embedded in the duodenum. 70% of the liver was then resected according to the method of Higgins and Anderson [30]. In the sham-operated group, rats underwent internal biliary drainage with concurrent 70% hepatectomy 14 d after sham operation. For the assessment of the HGF, c-Met, VEGF and TGF-β1 expressions, the right inferior lobe of the liver was carefully excised before and 6, 12, 24, 48, 72, 120, 168, and 240 h ($n = 10$ at each time point) after hepatectomy. The levels of HGF, c-Met, VEGF and TGF-β1 mRNA in liver tissue were investigated by quantitative RT-PCR. In addition, remnant liver weight ratio and PCNA labeling index were also evaluated and compared between BO and sham-operated rats.

Quantitative RT-PCR analysis of HGF, c-Met, VEGF, and TGF-β1 mRNA expression

Total RNA was extracted from liver tissues or freshly isolated liver cells by the acid guanidium-thiocyanate/phenol /chloroform method, and 1 mg of extracted total RNA was subjected to a reverse transcription reaction, using Ready To Go™ T-primed 1st strand cDNA synthesis kit (Amersham Pharmacia Biotech, Buckinghamshire, England). The cDNA from 33 ng of total RNA was used as a template. HGF, c-Met, VEGF, and TGF-β1 mRNA levels were quantified by means of a LightCycler (Roche Diagnostics, Mannheim, Germany), using the double-strand-specific dye SYBE Green I. Details of the primers used in this study are summarized in Table 1. The PCR condition was as fol-

lows: initial denaturation at 95 ℃ for 10 min, followed by 45 cycles of denaturation at 95 ℃ for 15 s, annealing for 10 s, and extension at 72 ℃ for 20 s. The expression level of each angiogenic factor was adjusted using the level of glyceraldehydes-3-phosphate dehydrogenase (GAPDH) mRNA, and expressed as ratio to GAPDH mRNA.

Isolated liver cells from liver tissue

Liver cells 14 d after BO were isolated, to determine potential cellular sources of TGF-β1 and HGF mRNA. Rat hepatocytes were isolated according to the methods of Gumucio *et al* [31]. The SECs, Kupffer cells and HSCs were also isolated by means of in situ collagenase perfusion and counterflow elutriation, as described by Knook *et al* [32], with minor modification. A JE-5.0 elutriator rotor (Beckman Instruments, Palo Alto, CA) was used in a J6-MI Beckman centrifuge. The separation process was started by adding the nonparenchymal cell suspension to a sample-mixing chamber. The HSCs were eluted at flow rates of 16 to 18 mL/min, and at a speed of 3 200 r/min. The SECs were then eluted at flow rates of 23 to 26 mL/min, and Kupffer cells at flow rates of 36 to 39 mL/min, at a speed of 2500 r/min. The purity of HSCs was > 90%, as assessed by their positive staining for desmin [33]. The purity of SECs and Kupffer cells was > 90% and > 92%, respectively, as assessed by typical cobblestone morphology and positive staining for ED-1 [34], respectively. To evaluate expression of HGF and TGF-β1 mRNA in each cell fraction, freshly isolated cells were used for total RNA extraction.

Immunohistochemical staining

Resected liver tissue specimens from rats were fixed in 4% paraformaldehyde (Wako Chemical Co. Osaka, Japan) in phosphate-buffered saline, washed with phosphate-buffered saline, dehydrated with 30%, 70%, 95%, and 100% ethanol and xylene, and then embedded in paraffin. Four-micrometer sections were cut and mounted onto superfrosted slide glass (Matsunami Glass Ind., Ltd., Osaka, Japan). Sections were incubated with methanol-1% hydrogen peroxide to destroy endogenous peroxidase, and blocked with nonspecific staining blocking reagent (Dako, Glostrup, Denmark). After overnight incubation at 4 ℃ with mouse monoclonal anti-desmin antibody (diluted 1 ∶ 100; Dako), or mouse monoclonal anti-α-SMA antibody (diluted 1 ∶ 100; DAKO) sections were processed according to the standard immunoperoxidase method, using a streptavidin biotin peroxidase complex kit (Dako LSAB + Kit/HRP; Dako). The peroxidase reaction was then developed with diaminobenzidine (Dako).

PCNA labeling index

Immunohistochemical staining for PCNA was performed on formalin-fixed and paraffin-embedded liver tissue with anti-PCNA antibody as previously described [35, 36]. A three-step immunoperoxidase method using strept-avidin biotin complex (Dako, Copenhagen, Denmark) was performed, according to the procedure described by Hall *et al* [36]. PC-10 monoclonal antibody (Dako, Copenhagen, Denmark) was used at a dilution of 1 ∶ 100, with overnight incubation at 4 ℃. Evaluation of PC-10 immunostaining was performed based on the percentage of positive nuclei of 500 hepatocytes at high power (400 ×), and was expressed as a PCNA labeling index.

Statistical analysis

The results were expressed as mean ± SD. The Mann Whitney test was used for statistical analysis of unpaired data, and differences were considered significant at $P < 0.05$.

RESULTS

HGF, c-Met, VEGF and TGF-β1 mRNA expression after biliary obstruction

The expression of TGF-β1 mRNA (Figure 1D) was at low levels before BO, but increased significantly at 14 d ($P < 0.05$ *vs* sham) and further increased at 21 d ($P < 0.03$ *vs* sham) after BO. Meanwhile, the expression of HGF (Figure 1A) and VEGF (Figure 1C) mRNA tended to increase at 14 and 21 d after BO, but no significant differences were found, as compared to the sham-operated control. The expression of c-Met mRNA (Figure1B) was lower at 14 and 21 d after BO, but was not significantly different from the sham-operated control.

HGF and TGF-β1 mRNA expression in isolated specific cell populations

To determine cellular sources of TGF-β1 mRNA during extrahepatic cholestasis, liver cells were isolated at 14 d after BO, because the expression of TGF-β1 mRNA was strongly induced by that time. In cell isolates, the mRNA for TGF-β1 was found mainly in the HSC fraction (Figure 2). On the other hand, the HGF mRNA expression was found in the nonparenchymal cell fraction, especially in the SEC fraction.

Immunohistochemical staining for desmin and α-smooth muscle actin

In the sham-operated control, several desmin-positive cells, presumed to be HSCs, were seen around the portal area (Figure 3A). But 14 d after BO (Figure 3B), the number

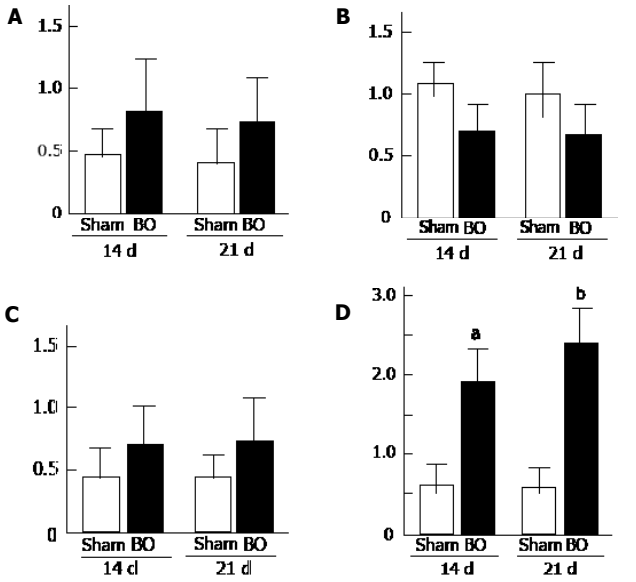

Figure 1 **A:** Hepatocyte growth factor (HGF); **B:** c-Met; **C:** vascular endothelial growth factor (VEGF); **D:** transforming growth factor-β1 (TGF-β1) mRNA expression in rat liver at 14 and 21 d after biliary obstruction (BO) and sham-operation (sham). ($^aP < 0.05$ *vs* sham-operated control, $^bP < 0.03$ *vs* sham-operated control). Results are expressed as mean ± SD of $n = 10$ for each period in each group.

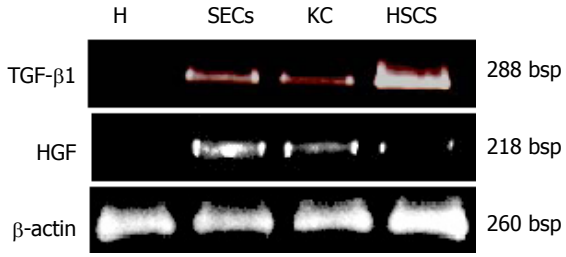

Figure 2 Hepatocyte growth factor (HGF) and transforming growth factor-β1 (TGF-β1) mRNA expression in isolated rat liver cells (H: hepatocytes; SECs: sinusoidal endothelial sells; KC: Kupffer cells; HSCs: Hepatic stellate cells) 14 d after biliary obstruction (BO).

of positive cells increased, and further increased at 21 d (Figure 3C). On the other hand, α-SMA-positive cells were hardly seen in the sham-operated controls (Figure 3D), whereas α-SMA-positive cells, presumed to be activated HSCs, were prominent in the surrounding portal areas 14 d after BO (Figure 3E).

Remnant liver weight and PCNA labeling index

The ratio of remnant liver to whole liver weight after 70% partial hepatectomy (PH) was approximately 30%. In the sham + PH group, the remnant liver weight ratio started to increase 24 h after hepatectomy (Figure 4A). A significant increase was found from 48 h to 120 h after surgery, as compared with the BO+ PH group. Thereafter, no significant differences were found between the two groups. The remnant liver weight in the BO+ PH group reached the same levels as that ~~in~~ attained by the sham + PH group 240 h after hepatectomy, but required a longer period.

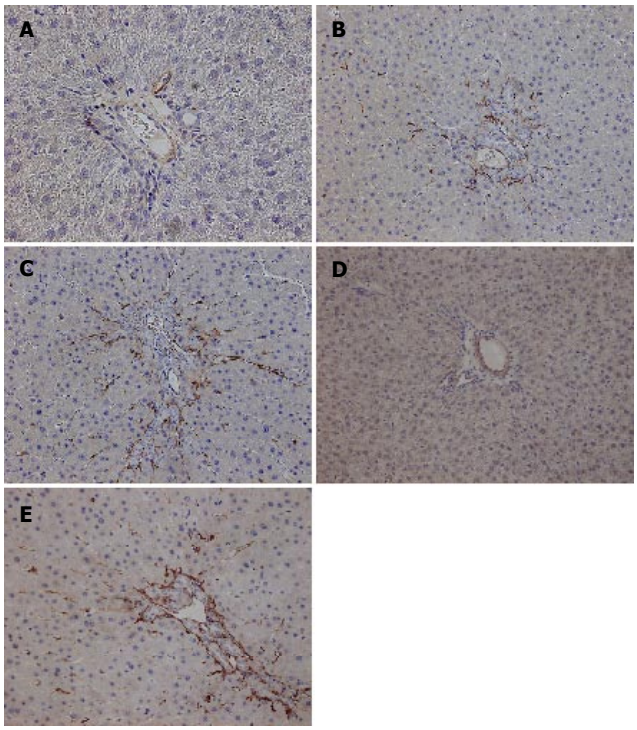

Figure 3 Immunohistochemical staining for desmin **A:** 14 d after sham operation; **B:** 14 d after biliary obstruction (BO); **C:** 21 d after biliary obstruction. Immunohistochemical staining for α-smooth muscle actin (α-SMA); **D:** 14 d after sham operation; E: 14 d after biliary obstruction.

Figure 4B shows changes in PCNA labeling index after hepatectomy. In the sham+ PH group, the PCNA labeling index was less than 5% in hepatocytes before hepatectomy. However, a dramatic increase in the PCNA labeling index of hepatocytes was observed 12 h after hepatectomy, reaching a peak 24-48 h after surgery ($P < 0.03$ *vs* BO+ PH group). In the BO + PH group, the PCNA labeling index was higher than in the sham+ PH before hepatectomy, and was then increased gradually, with a peak 120 h after hepatectomy. Thereafter, the PCNA labeling index decreased to the baseline value 240 h after surgery.

HGF, TGF-β1, VEGF, and c-Met mRNA expression after 70% hepatectomy

The expression of HGF mRNA in the sham + PH group started to increase 6 h after hepatectomy, with a peak at 12 h and 24 h (Figure 5A). Meanwhile, in the BO+ PH group, a small increase of HGF mRNA was observed up to 72 h after surgery, but no earlier peak was observed. The expression of c-Met mRNA in the BO+ PH group was lower, when compared with the sham+ PH control between 0 and 72 h after hepatectomy, but there was no significant difference between the groups (Figure 5B). The expression of VEGF mRNA in the BO+ PH group was somewhat higher up to 24 h after surgery, as compared to the sham+ PH (Figure 5C), but no significant differences were found at any point in this experiment. Meanwhile, the expression of TGF-β1 mRNA (Figure 5D) in the BO+ PH group was significantly up-regulated up to 48 h after hepatectomy, as compared to the sham+ PH group ($P < 0.05$). Thereafter, TGF-β1 mRNA expression was not significantly different between the groups.

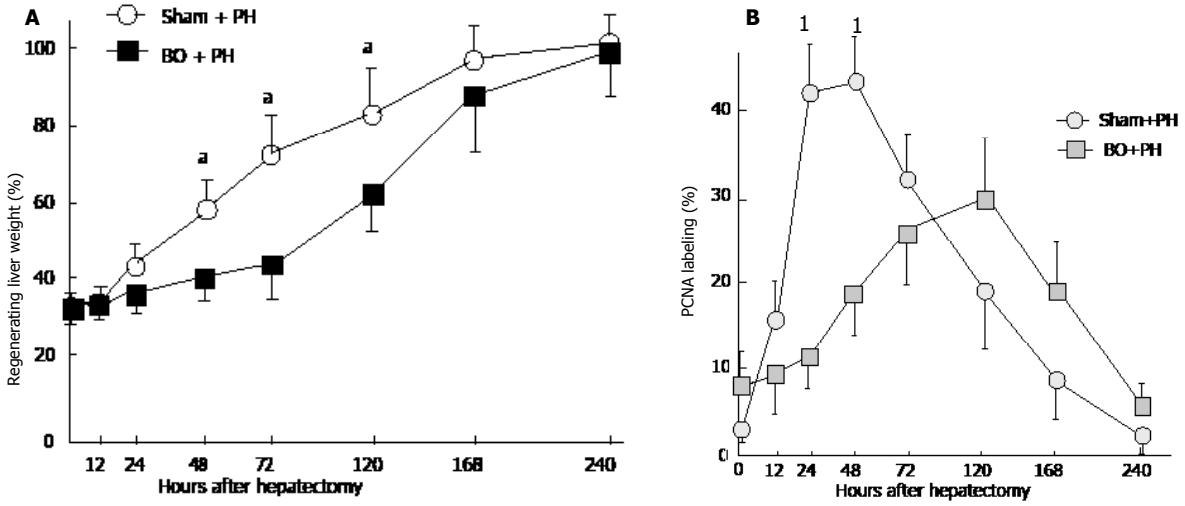

Figure 4 A: Changes in regenerating liver weight ratio after 70% partial patectomy (PH) in the sham-operated (sham) rats and the biliary obstructed (BO) rats (^aP <0.05 between the BO + PH group and the sham + PH group). Results are expressed as mean ± SD of n = 10 for each period in each group. B: Changes in the hepatocyte PCNA labeling index after 70% hepatectomy (PH) in the sham-operated (sham) rats and the biliary obstructed (BO) rats (^1P < 0.03 between the BO + PH group and the sham + PH group). Results are expressed as mean ± SD of n = 10 for each period in each group.

DISCUSSION

In the present study, we have clearly shown that hepatic TGF-β1 mRNA levels increased with length of cholestasis. Moreover, in cell isolates from BO liver tissue, TGF-β1 mRNA expression was found mainly in the HSC fraction. Immunohistochemical study also revealed an increased number of HSCs (desmin-positive cells) and activated HSCs (α-SMA-positive cells) in portal areas in proportion to the length of cholestasis. In the hepatectomy model, liver regeneration rate in the BO rats was delayed, as compared to sham-operated rats. TGF-β1 mRNA was also significantly up-regulated up to 48 h after hepatectomy in the BO rats, and no earlier peak of HGF mRNA expression was observed, despite a small increase in HGF mRNA during extrahepatic cholestasis. These findings suggest that increased TGF-β1 secreted from activated HSCs, and earlier suppression of HGF production, may greatly contribute to delayed liver regeneration in a paracrine manner. Earlier suppression of HGF after hepatectomy may be also related to HSCs activation, because activated HSCs reportedly lose their ability to express HGF mRNA [37].

Although several previous studies regarding liver regeneration after hepatectomy with obstructive jaundice have been reported, it is not clear how BO affects liver regeneration. Aronson *et al* [4] reported that extrahepatic cholestasis inhibits liver regeneration after hepatectomy, but they studied liver regeneration in the presence of postoperative BO. In this study, restoration of bile flow was performed simultaneously with hepatectomy, as in clinical cases. According to our results, the PCNA labeling index of hepatocytes, HGF and VEGF mRNA were somewhat higher in BO livers than in sham-operated livers. These results are consistent with previous studies [4, 6, 38, 39] indicating that BO induces DNA replication of hepatocytes. Furthermore, we clearly demonstrated that TGF-β1 mRNA was significantly up-regulated after BO. This phenomenon might be related to the hepatic repair process that compensates for hepatocyte injury caused by BO. This is also suggested by the fact that serum AST levels increased shortly after BO (data not shown). In cell isolates from BO liver, TGF-β1 producing cells were found to be mainly HSCs. Furthermore, an increased number of desmin-positive cells (HSCs) were found in portal areas, and α-SMA-positive cells, presumably activated HSCs, were progressively extended around portal areas in proportion to the length of BO. Activated HSCs reportedly lose their ability to express HGF mRNA, but produce a large amount of TGF-β1. These findings suggest that HSCs in portal areas were gradually activated into myofibroblast-like cells during BO. Activated HSCs produce TGF-β1, and TGF-β1 stimulates activated HSCs to produce more TGF-β1 in an autocrine manner, whereas activated HSCs hardly produce any HGF in the BO liver. HGF mRNA increased, to some extent, after BO, but HGF producing cells were mainly SECs, rather than HSCs. This may be related to the proliferative response of hepatocytes and bile duct cells during cholestatic liver injuries.

We clearly demonstrated that liver regeneration was significantly delayed after hepatectomy in the BO rats, as compared to the sham-operated rats. Moreover, TGF-β1 mRNA was significantly up-regulated up to 48 h after hepatectomy in the BO rats, and high levels of HGF mRNA were not induced in the earlier phase of hepatectomy. Meanwhile, c-Met expression in the BO liver was not significantly different from the sham-operated rats. These results suggest that delayed regeneration may be associated with the initial high expression of TGF-β1, and the suppression of HGF induction after hepatectomy. It is obvious that initial up-regulation of TGF-β1 has a non-beneficial effect on liver regeneration, because TGF-β1 is the most important cytokine controlling the inhibition of hepatocyte proliferation. Furthermore, although HGF mRNA increased to some extent in BO rats after hepatectomy, the amount may be insufficient to induce the initial stimulus for DNA synthesis of in hepatocytes for adequate

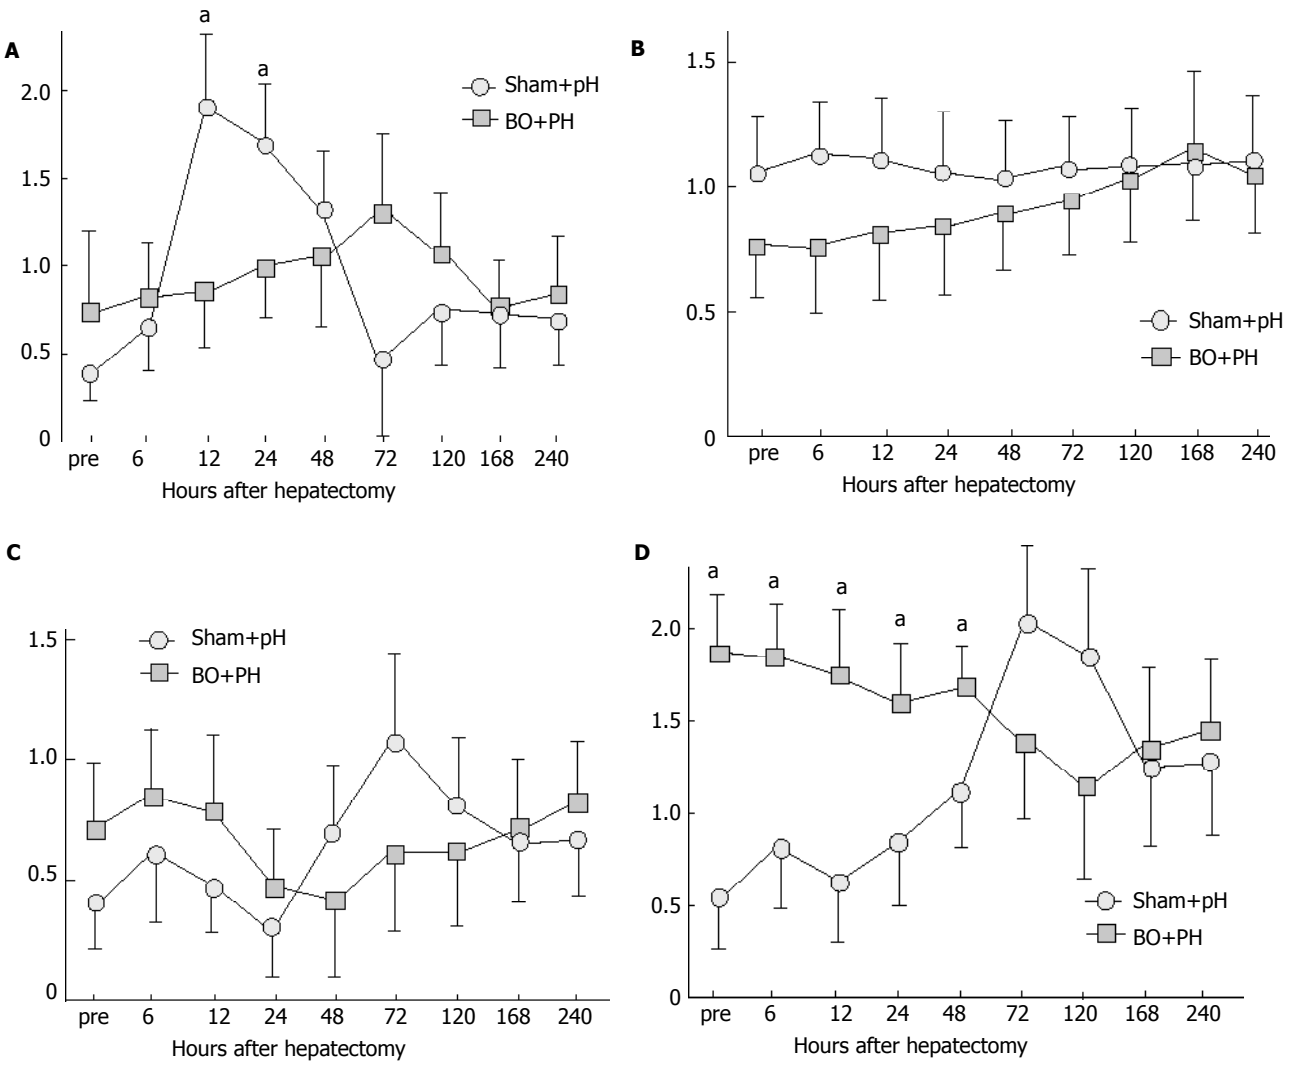

Figure 5 Changes in **A:** hepatocyte growth factor (HGF); **B:** c-Met; **C:** vascular endothelial growth factor (VEGF); **D:** transforming growth factor-β1 (TGF-β1) mRNA expression after partial hepatectomy (PH) in the sham-operated (sham) rats and the biliary obstructed (BO) rats (^aP <0.05 between the BO + PH group and the sham + PH group). Results are expressed as mean ± SD of n = 10 for each period in each group.

liver regeneration.

In conclusion, BO induces proliferation and activation of HSCs, resulting in up-regulation of TGF-β1 and negative regulation of HGF expression. The altered expression patterns may be involved to a considerable degree in delayed liver regeneration after hepatectomy in rats with obstructive jaundice. These findings may provide clues for the treatment of impaired hepatic regeneration after major hepatectomy with obstructive jaundice. That is, regulation of HSCs activation or restoration of an altered growth/inhibitory expression pattern might have beneficial effects on liver regeneration following major hepatectomy with obstructive jaundice.

Abstract

AIM: Most gastrointestinal stromal tumors (GISTs) express constitutively activated mutant isoforms of kit kinase or platelet-derived growth factor receptor alpha (PDGFRA), which are potential therapeutic targets for imatinib mesylate (Glivec). Partial response occurred in almost two thirds of GIST patients treated with Glivec. However, complete response (CR) after Glivec therapy was sporadically reported. Here we illustrated advanced GIST patients with CR after Glivec treatment.

METHODS: Between January 2001 and June 2005, 42 advanced GIST patients were treated with Glivec. Patients were administered 400 mg of Glivec in 100-mg capsules, taken orally daily with food. The response of the tumor to Glivec was evaluated after one month, three months, and every three months thereafter or whenever medical need was indicated. Each tumor of patients was investigated for mutations of kit or PDGFRA.

RESULTS: The median follow-up time of the 42 ad-vanced GIST patients treated with Glivec was 16.9 months (range, 1.0 - 47.0 months). Overall, 3 patients had complete response CR (7.1%), 26 partial response (67.8%), 5 stationary disease (11.9%), and 3 progressive disease (11.9%). The median duration of Glivec administration for the three patients was 36 months (range, 23-36 months). The median time to CR after Glivec treatment was 20 months (range, 9-26 months). Deletion and insertion mutations of c-kit exon 11 and insertion mutation of c-kit exon 9 were found in two cases and one case, respectively.

CONCLUSION: Complete response (CR) can be achieved in selected advanced GIST patients treated with Glivec. The median time to CR after Glivec treatment was 20 months. Deletion and insertion mutations of kit exon 11 and insertion mutation of kit exon 9 contribute to the genetic features in these selected cases.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are soft-tissue sarcomas primarily arising from mesenchymal tissue in the gastrointestinal (GI) tract and abdomen. They are rare neoplasms, estimated to represent 0.1 to 3% of all GI tract tumors[1]. However, GISTs are the most common mesenchymal malignancy of the GI tract with precise incidence unknown[2]. GISTs appear to be related to the interstitial cells of Cajal of the mesenteric plexus[3]. These cells are considered GI pacemaker cells, from the interface between the automatic innervation of the bowel wall and its smooth muscle[4,5]. GISTs express the cell-surface transmembrane receptor kit with a tyrosin kinase activity and is the protein product of the kit proto-oncogene. There are frequent gain-of-function mutations of kit in GISTs. These mutations result in constitutive activation of kit signaling, which leads to uncontrolled cell proliferation and resistance to apoptosis. It has been recently reported that kit activation occurs in all cases of GISTs, regardless of the mutation status of kit.

Surgical resection remains the mainstay of therapy for GIST. However, recurrence is common; the 5-year survival rates after complete resection range from 40 to 65%[6-10]. Unresectable or metastatic GIST is a fatal disease that resists conventional chemotherapy. In a recently reported series, the response rate to doxorubicin therapy was less than 5%[11]. The effectiveness of radiation therapy for unresectable or metastatic GIST has not been proved. The median length of survival for patients with a metastatic GIST is approximately 20 months, and 9 to 12 months for patients with local recurrence[3]. Before the development of Glivec, the outlook for patients with advanced GIST was extremely poor. A significantly large number of patients with initial resection of GIST eventually experience

Imatinib mesylate (formerly STI571, now referred to as Gleevec in the United States and Glivec in Europe [Novartis]) selectively inhibits certain protein tyrosin kinases: intracellular ABL kinase, chimeric BCR-ABL fusion oncoprotein of chronic myeloid leukemia, transmembrane receptor kit, and platelet-derived growth factor (PDRGF) receptors[12-15]. Glivec induced a sustained objective response in more than half of patients with advanced GISTs[16]. However, complete response (CR) induced by Glivec on GIST patients has been sporadically reported. We report herein our experience on three GIST patient treated with Glivec achieving complete response.

MATERIALS AND METHODS

Patients

During January 2001 to May 2005, 42 histologically confirmed, unresectable or metastatic GIST patients ex-pressing CD117 (a marker of kit-receptor tyrosine kinase) and CD34 treated at Department of Surgery, Chang Gung Memorial Hospital, Taiwan were enrolled in this study. Metastatic disease was defined as that occurring at structures noncontiguous with the primary tumor site. Criteria for inclusion were as follows: at least one measurable tumor; adequate hepatic, renal, and cardiac function; an adequate platelet count; and an Eastern Coo-perative Oncology Group (ECOG) performance status of 3 or less. Patients could have previously received che-motherapeutic regimens (the last chemotherapy treatment must have been at least four weeks before the study entry) and undergone radiotherapy, or surgery, or both. R0 resection means curative resection without microscopic evidence of tu-mor. R2 resection means resection with macroscopic evidence of tumor. The study was approved by the Local Institutional Review Board of Chang Gung Memorial Hospital and written informed consent for drug administration and the analysis of tumor-associated genetic alteration was obtained from each patient.

Study design

A prospective, non-randomized, and single center trial was conducted to evaluate the role of Glivec in inducing objective response in GIST patients. Patients were administered 400 mg of Glivec in 100-mg capsules, taken orally daily with food. Patients had regular physical examinations and evaluations of performance status, body weight, complete blood count, and serum chemistry. The administration of each dose and any adverse events were recorded for each patient. Standard computed tomography (CT) was performed on each patient every three months to assess patient response. Standard [18F] fluoro-2-deoxy-D-glucose positron-emission tomography (PET) scanning was performed on selected patients to complement standard CT and assess changes in the metabolic profiles of the tumors.

Efficacy and safety evaluation

The response of the tumor to Glivec was evaluated after one month, three months, and every three months thereafter or whenever medical need was indicated. Assessments were performed according to the standard Southwest Oncology Group (SWOG) criteria and based solely on CT or PET[17]. Responses were classified as follows: complete response (CR) (disappearance of all disease that could be measured and evaluated); partial response (PR) (> 50% decrease in the sum of the products of the perpendicular diameters of all measurable lesions, the absence of progression, and the absence of new lesions); stationary disease (SD) (a response that did not qualify as a complete response, a partial response, or disease progression); and disease progression (DP) [> 50% increase or an increase of 10 cm (whichever was smaller) in the sum of the products of the perpendicular diameter of all measurable lesions, worsening of a lesion that could be evaluated, the reappearance of any lesion or the presence of a new lesion, or failure of the patients to return for evaluation because of disease progression]. Toxic effects were recorded in accordance with the National Cancer Institute Common Toxicity Criteria[18].

Analysis of KIT and PDGFRA mutations

Sections were prepared from formalin-fixed, paraffin-embedded pretreatment specimens trimmed to enrich tumor cells. Polymerase chain reaction amplification of genomic DNA for KIT and PDGFRA was performed and amplification was analyzed for mutations as previously described[19].

RESULTS

Age and sex

The investigation comprised one male patient and two female patients with ages ranging from 45 to 56 years (median: 51 years) (Table 1). All three patients had grade 0 ECOG status.

Tumor location, size, and treatment

Table 1 summarizes the size and location of each tumor. One patient underwent laparotomy with excisional biopsy and the other two had curative segmental resection of jejunal GIST previously. Tumors of all three patients di-splayed strong positive kit staining with the tumor size ranging from 10 cm to 20 cm (median: 10 cm). The inter-val between diagnosis of GIST and tumor recurrence ranged from 0 to 15 months (median 7 months). All three patients displayed peritoneal carcinomatosis and two had liver metastasis.

Treatment

All three patients were administered 400 mg Glivec after diagnosis of metastasis was made. The duration of Glivec administration ranged from 24 to 36 months (median: 36 months). The side effect of Givec treatment was grade II to III edema.

Genetic investigations of tumors from GIST

The sequencing analysis of the tumor from the three patients exhibited mutation in c-kit gene. Two displayed deletion and insertion mutation in exon 11 and one insertion mutation in exon 9 (Figures 1, 2, and 3).

Time to response and follow-up outcome

Since 2000, Glivec has been administered to advanced GIST patients. Forty-two patients with advanced stages

of the disease were given 400 mg Glivec per day. The median follow-up duration was 16.9 months (range, 1.0-47.0 months). Overall, 3 (7.1%) patients had complete response (CR), 26 (67.8%) partial response, 5 (11.9%) stationary disease, 3 progressive disease, and 3 (7.2%) patients were unavailable to evaluate. The time to CR after Glivec treatment ranged from 9 to 26 months (median, 20 months) as illustrated by CT first and confirmed by PET without any metabolic activity (Figures 1, 2 and 3). The median follow-up period of the three advanced GIST patients treated with Glivec with CR was 40 months (range, 24 - 54 months).

DISCUSSION

Before the introduction of Glivec, poor responses to radiation and chemotherapy made surgery the only realistic treatment to cure the primary lesion[5,10,20-22]. A substantial number of patients with initial resection of GISTs eventually experience recurrence. There has been no effective treatment for advanced GISTs and the outlook for patients is extremely poor.

Therapeutic responses to targeted inhibition of activated tyrosine kinases have been demonstrated for certain types of leukemia, sarcoma, and breast cancer[19]. The mechanisms of kinase activation vary considerably among these cancers, but there is little information available in literature about the influence of these mechanisms on drug response[19]. The GISTs, in particular, present a variety of genomic mutations across two different receptor tyrosine kinase genes. The KIT or PDGFRA mutation in Asian clinically advanced small bowel GIST patients was examined in this study. The kit kinase oncoproteins were intrinsically sensitive to Glivec, accounting for the excellent overall clinical response to Glivec, and coincident with results obtained by Heinrich *et al*[19]. Similar to the report by Demetri's *et al*[16], the CR and PR rates for Glivec in this

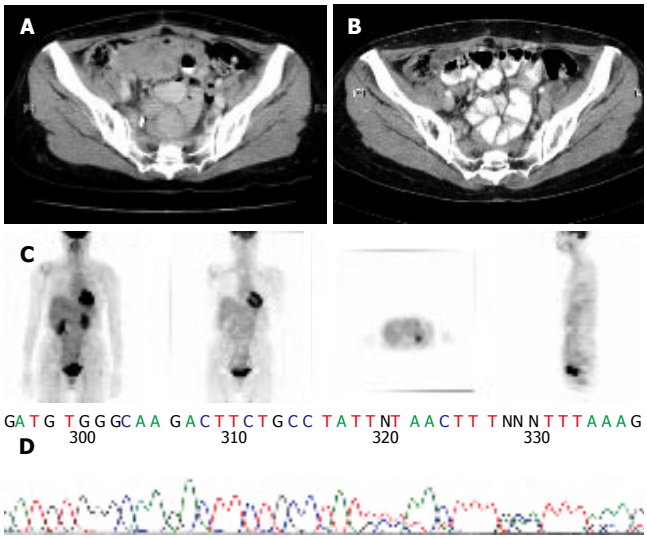

Figure 3 (**A**) Abdominal CT showing a tumor located near the ileum (arrow); (**B**) abdominal CT revealing complete response without tumor at the same level as Figure 3A; (**C**) PET showing no tumor with metabolic activity in the whole body; (**D**) direct sequencing analysis of DNA from patient 3 showed insertion AY at codons 502-503 in exon 9 (arrow).

study was 68.0%. Glivec induced a sustained objective response in more than half of the patients with advanced GISTs[16]. However, CR induced by Glivec on GIST patients was sporadically reported. In US Intergroup S0033 phase III study on 751 metastatic or unresectable GIST patients receiving 400 or 800 mg Glive per day[23], CR rate was 3%. Moreover, in the EORTC 62005 phase III study, the CR rate was 4.76% for 923 metastatic or unresectable receiving 400 or 800 mg Glive per day. Contrast to the aforementioned two studies, the CR rate in this study was 7%. The experience on CR after Glivec treatment for advanced or metastatic GIST patients in this study may justify the use of Glivec as neoadjuvant or adjuvant treatment in the future. FDG PET has been proven to be highly sensitive in detecting early response[24]. Stroobants *et al*[24] demonstrated that the CR rate increased to 52.3% (11/21), however, discrepancy was noted between the CT and PET results. In this study, CR was diagnosed according to SWOG criteria by CT scan first. PET scan was used to confirm its metabolic activity by FDG uptake on PET scan thereafter.

Regarding further use of Glivec for GIST patients with CR after Glivec treatment, no consensus was made. A recently reported randomized trial has shown that Glivec interruption after 1 year is associated with a high risk of relapse, even for patients with CR[25]. So, Glivec might be administered in the three patients until intolerance or patient refusal. The further use of Glivec for GIST patients with CR after Glivec treatment needs investigation.

In conclusion, CR can be achieved in selected patients with advanced GIST treated with Glivec. Deletion and insertion mutations of kit exon 11 and insertion mutation of kit exon 9 contribute to the genetic features in these selected cases.

ACKNOLWEDGEMENTS

We thank Novartis (Taiwan) Co., Ltd for financial support of genetic analysis and PET scan.

Abstract

AIM: To assess whether a correlation exists between oxidative DNA damage occurring in chronic HCV-related hepatitis and expression levels of pro-inflammatory cytokines, TGF-α and c-myc.

METHODS: The series included 37 patients with chronic active HCV-related hepatitis and 11 with HCV-related compensated cirrhosis. Eight-hydroxydeoxyguanosine in liver biopsies was quantified using an electrochemical detector. The mRNA expression of TNF-α, IL-1β, TGF-α and c-myc in liver specimens was detected by semi-quantitative comparative RT-PCR.

RESULTS: TNF-α levels were significantly higher in hepatitis patients than in cirrhosis patients ($P = 0.05$). IL-1β was higher in cirrhosis patients ($P = 0.05$). A significant correlation was found between TNF-α and staging ($P = 0.05$) and between IL-1β levels and grading ($P = 0.04$). c-myc showed a significantly higher expression in cirrhosis patients ($P = 0.001$). Eight-hydroxydeoxyguanosine levels were significantly higher in cirrhosis patients ($P = 0.05$) and in HCV genotype 1 ($P = 0.03$). Considering all patients, 8-hydroxydeoxyguanosine levels were found to be correlated with genotype ($P = 0.04$) and grading ($P = 0.007$). Also multiple logistic regression analysis demonstrated a significant correlation among the number of DNA adducts, TNF-α expression and HCV genotype ($P = 0.02$).

CONCLUSION: In chronic HCV-related liver damage, oxidative DNA damage correlates with HCV genotype, grading and TNF-α levels. As HCV-related liver damage progresses, TNF-α levels drop while IL-1β and c-myc levels increase, which may be relevant to liver carcinogenesis.

Key words: Oxidative DNA damage; Chronic HCV-related hepatitis; Inflammatory mediators

INTRODUCTION

Oxidative damage may affect a number of cell targets, including DNA[1-2]. Eight-hydroxydeoxyguanosine (8OHdG), a modified DNA base generated by genomic material interacting with reactive oxygen species, is a mutation that causes G-C to T-A transversion at DNA replication[3]. This adduct is a marker of oxidative DNA damage and one of the most widely-investigated lesions, since its consequences may well be linked to carcinogenic mechanisms[4-6].

Oxidative damage in general and 8OHdG accumulation in particular, have been described in experimental and clinical HCV infection, with HCV-related oxidative damage playing a major part in the induction of liver diseases[7-9]. Although it is well known that reactive oxygen species induction lies at the center of a complex network of tissue and inflammatory responses involving the expression of cytokines, growth factors and oncogenes, this network has not been thoroughly investigated in HCV-related liver diseases.

Liver injury is reportedly associated with a chronic inflammatory response involving tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β), etc. The former plays a central role in liver injury, triggering the production of other cytokines that in turn recruit inflammatory cells, promote fibrogenesis and further activate oxidative burst[10]. The initiation of a number of intracellular signal pathways involving apoptotic and/or anti-apoptotic signals should also be included amongst the effects of TNF-α[11] and HCV infection is indeed associated with an increase in TNF-α production, and the expression of viral proteins apparently results in more severe liver injury and hepatocyte death[12-14].

On the other hand, IL-1β gives rise to the cascade of

the inflammatory response and recent reports have shown that its levels are higher in HCV-related liver diseases than in other forms of liver damage[15]. Its polymorphisms behind are related to the risk of progression to HCC[16-17].

Our hypothesis is that oxidative DNA damage prompted by pro-inflammatory cytokines and/or by a specific effect of HCV core protein[18-19], and associated with an imbalance between apoptosis and cytoproliferation[20], is a fundamental event in HCV-related liver carcinogenesis.

Since a number of additional mediators are involved in liver carcinogenesis, including oncogenes such as c-myc that controls hepatocyte proliferation[21] and growth factors such as TGF-α involved in controlling liver regeneration and tumoral progression[22], particularly when they are co-expressed[23], the present study was to seek any correlations between oxidative DNA damage and the levels of pro-inflammatory cytokines like TGF-α and of c-myc in chronic HCV-related liver damage.

MATERIALS AND METHODS

Patients

Forty-eight patients consecutively recruited (34 M / 14 F, mean age 42 ± 12 years) with liver disease characterized by abnormal serum transaminase levels for more than 6 months, were admitted to the Division of Gastroenterology for diagnostic liver biopsy. Informed consent was obtained from all patients. Patients taking medication or vitamins capable of interfering with oxidative balance or liver damage were excluded from the study. The study was approved by the Human Research Committee of the University of Padova. Thirty-seven patients (24 M / 13 F, mean age 40.5 ± 11 years) were assigned to chronic active HCV-related hepatitis (CAH) group and 11 patients (7 M / 4 F, mean age 50.5 ± 14 years) were assigned to HCV-related compensated (Child class A) cirrhosis (CIRR) group. Before biopsy, each patient was tested to measure HCV antibodies using a second-generation ELISA and all positive sera were confirmed by RIBA II assay. In all patients, anti-HCV seropositivity was confirmed by positive HCV-RNA levels using the Amplicor HCV test (Amplicor PCR Diagnostic, Hoffman-La Roche, Basel Switzerland). A standardized genotyping assay (Inno-Lipa HCV III, Innogenetics, Gent, Belgium) was used. HCV genotypes were classified as genotype 1, subtypes 1a and 1b, genotypes 2, 3 and 4 and their subtypes. All the following studies were performed prior to any treatment.

Morphological evaluation

Biopsies (one per patient) were taken using a 16-17 gauge modified Menghini needle under ultrasound guidance and local anesthesia. Only patients whose biopsy material was adequate (i.e. about 4 cm long) were included in the study to avoid taking a second biopsy. At least 2 cm of biopsy material was cut, fixed in 10% buffered formaldehyde and handed over to the pathologists. The tissue was embedded in paraffin, cut and routinely stained with H&E and PAS for routine evaluation. Together with the overall diagnosis, the pathologist (who was unaware of the clinical diagnosis) also gave a semi-quantitative score (0-3) for the presence and extent of macro- and micro-vesicular steatosis and the Knodell index[24], as modified by Ishak *et al*[25], including both a grading and a staging of hepatic disease.

Biochemical findings

Serum levels of ferritin, transaminases and γ-glutamyl transpeptidase (γGT) were determined as part of the routine clinical procedure. The tissue for biochemical determination was around 15 mg wet weight. Samples were processed immediately and stored at -80℃.

Quantification of 8OHdG from hepatic biopsies

Liver biopsy specimens obtained at endoscopy were stored at -80℃ for no longer than 3 wk. Preliminary experiments indicated that storage under these conditions could not affect the results of the assessment obtainable with unfrozen samples and the samples might remain stable for as long as 1 month (data not shown).

After thawing, the specimens were homogenized in separation buffer (75 mM NaCl, 10 mM Tris/Cl pH 7.5, 5 mM EDTA pH 6, 0.5% sodium dodecyl sulfate) and proteinase K at 55℃ overnight. After treatment with ribonuclease A, the DNA was purified according to Fraga *et al*[26]. Following nuclease P1 and alkaline phosphatase hydrolysis, samples were filtered through 0.22 μm nylon filter units (Scientific Resources, Inc., Alfatech, Genova - Italy), and approximately 20 μg of DNA per sample was injected into the HPLC (Shimadzu, Kyoto, Japan). 8OHdG and normal deoxynucleosides were separated in a 3 μm Supelcosil LC-18-DB analytical column (7.5 cm × 4.6 mm, Supelco, Bellefonte, PA) equipped with a 5 μm SupelguardTM LC-18-DB guard column cartridge. The solvent system consisted of an isocratic mixture of 90% 50 mmol/L potassium phosphate (pH 5.5) and 10% methanol at the 1 mL/min flow rate. 8OHdG was detected using an electrochemical detector (ECD; ESA Coulochem II 5200A, Bedford, MA) equipped with a high-sensitivity analytical cell model 5011 with the oxidation potentials of electrodes 1 and 2 adjusted to 0.15 V and 0.35 V, respectively. 8OHdG levels were referred to the amount of deoxyguanosine (dG) detected in the same sample by UV absorbency at 254 nm. The amount of DNA was determined according to a calibration curve versus known amounts of calf thymus DNA. 8OHdG levels were expressed as the number of 8OHdG adducts per 10^5 dG bases. An 8OHdG standard (Sigma) prepared immediately before determination, was injected before any set of samples. The coefficient of variation was <10% and the amount of DNA required for the assay (expressed in μg of DNA) was 100 μg. Samples with lower amounts of DNA were rejected, since the risk of methodological error was only acceptable above this cut-off.

TNF-α, IL-1β, TGF-α and c-myc determination

The mRNA expression of TNF-α, IL-1β, TGF-α and c-myc in liver specimens was detected by semi-quantitative comparative RT-PCR. Total RNA extracted from frozen liver tissue (stored at -80℃) by acid guanidium thiocyanate-phenol-chloroform according to the Chomczynski and Sacchi method[27], was quantified spectrophotometrically. Integrity of the RNA sample was assessed by electrophoresis on 2% agarose gel (FMC Bio Product, Rockland,

Table 1 Eight-hydroxydeoxyguanosine levels in chronic HCV-mediated liver damage (mean ± SD)

	n° 8OHdG/10^5 dG		*n*° 8OHdG/10^5 dG
CAH	42.3±25.3	**HCV genotype 1**	74±36
CIRR	73.64±28.2	**Other genotypes**	46.9±23
P	0.05		0.03

Table 2 TNF-α, IL-1β, TGF-α and c-myc expression in chronic HCV-mediated liver damage (mean ± SD)

	TNF-α/β-actin	IL-1β/β-actin	TGF-α/β-actin	c-myc/β-actin
CAH	0.7 ± 0.2	1.1 ± 0.3	0.41 ± 0.1	0.09 ± 0.05
CIRR	0.5 ± 0.2	1.4 ± 0.6	0.43 ± 0.2	0.46 ± 0.2
P	0.05	0.05	N.S.	0.001

MC, USA). One μg of RNA was reverse transcribed in cDNA in the presence of 1× PCR buffer, 1 mM each of dNTPs, 1 U RNase inhibitor, 2.5 μM random exomers and 2.5 U of murine leukemia virus. cDNA was amplified in a final volume of 50 μL of PCR buffer, 2 U Amplitaq DNA polymerase, 0.056 μmol/L of Taq Start antibody, 0.2 mM of each of the dNTPs, 0.4 μmol/L of each primers for TNF-α, IL-1β, TGF-α, c-myc and β-actin. PCR products underwent a vertical electrophoresis on polyacrilamide gel. Electrophoretic bands were stained with silver nitrate and scanned on a densitometer image analyzer system (Quantity-one Biorad, Hercules, CA, USA). The results were expressed as the optical density ratio of TNF-α, IL-1β, TGF-α and c-myc to control β-actin.

Statistical analysis

The data were examined statistically by one-way ANOVA and Student's *t* - test, Kruskal-Wallis and linear regression. Multiple logistic regression analysis was also used by including the following variables: 8OHdG levels, diagnosis, age, expression of TNF-α, IL- 1β, TGF-α and c-myc, genotype.

RESULTS

Patient characteristics

No difference in the patients' age or gender distribution was observed between the CAH and CIRR groups. ALT levels were significantly higher in patients with chronic hepatitis than in patients with cirrhosis (87.9 ± 49 *vs* 50.5 ± 14, $P = 0.002$ by *t*), while AST levels were significantly higher in CIRR group than in CAH group (178 ± 95 *vs* 52 ± 23, $P = 0.002$ by *t*) . Serum ferritin and γGT levels did not differ significantly between the two groups of patients.

According to the classification Ishak *et al*[25], the stages of disease were, by definition, significantly higher in CIRR than in CAH patients (5.25 ± 0.4 *vs* 2.5 ± 0.8, $P = 0.0001$ by *t*), while grading was similar in the two groups. All patients were HCV-RNA positive. Type 1 (1a/1b) infection was the most prevalent (45%), followed by subtype 3a (29%), type 2 (17%) and finally type 4 (3%).

Oxidative DNA damage, TNF-α, IL-1β, TGF-α and c-myc expression

8OHdG levels were significantly higher in CIRR patients ($P = 0.05$ by *t*) and when oxidative damage was correlated with different HCV genotypes, 8OHdG levels were higher in HCV genotype 1 hepatitis than in the other genotypes ($P = 0.03$ by *t*). The results of 8OHdG are shown in Table 1. Considering all patients, 8OHdG levels correlated significantly with genotypes ($P = 0.04$ Spearman's rank correlation) and grading ($P = 0.007$ Spearman's rank correlation). The results for pro-inflammatory cytokines, TGF-α and c-myc are shown in Table 2. TNF-α expression was significantly higher in CAH group than in CIRR group (0.7 ± 0.2 *vs* 0.5 ± 0.2, $P = 0.05$ by *t*), whereas IL-1β expression was significantly higher in CIRR group than in CAH group (1.4 ± 0.6 *vs* 1.1 ± 0.3, $P = 0.05$ by *t*). The previously mentioned higher oxidative DNA levels in genotype 1 HCV infection correlated with TNF-α ($P = 0.04$). A significant correlation was also found between IL-1β levels and grading ($P = 0.04$), and between TNF-α and staging ($P = 0.05$). No significant correlations were found between pro-inflammatory cytokine levels, steatosis score or genotype. TGF-α levels were similar in the two groups of patients (0.41 ± 0.18 *vs* 0.43 ± 0.21, $P =$ NS by *t*), while c-myc expression was significantly higher in patients with cirrhosis (0.46 ± 0.2 *vs* 0.09 ± 0.05, $P = 0.001$ by *t*). No significant correlations were found between c-myc, steatosis score or genotype. Finally, multiple logistic regression analysis confirmed the previously reported significant correlation among the number of DNA adducts, TNF-α expression and genotype ($P = 0.02$).

DISCUSSION

We have previously reported that oxidative DNA damage in the liver is, at least to some degree, a specific feature of HCV infection, in which it reaches its maximal levels[7]. Even though it occurs in the early stages too, 8OHdG accumulation parallels the progression of the disease and is more striking in subjects with HCV genotype 1b infection[28].

This paper provides data on patients with HCV-related liver damage, partly describing the complex network of relationships between DNA oxidative damage, cytokine synthesis and release, c-myc and TGF-α expression that may both be strongly involved in liver cancerogenesis[29-31]. Numerous data link oxidative damage (and the parameters considered here) with the progression of liver disease and the onset of liver cancer. In primary murine hepatocyte cultures, TNF-α expression causes 8OHdG formation and an increase in cell cycle progression indicates a possible role of TNF-α in early malignant transformation of hepatocytes[32].

The first set of our results was related to TNF-α and IL-1β which plays a direct role in causing growth arrest and a chronic role in inducing TNF-α expression[10-11]. This effect was not confirmed in our series, since a correlation between IL-1β and TNF-α was not detected. On the other hand, IL-1β expression was higher in the later stages of HCV-related liver disease, as previously dem-

onstrated by Gramantieri *et al*[33], while the opposite was true of TNF-α, whose levels of expression were higher in CAH patients. We have previously reported that the balance between cytoproliferation and apoptosis is disrupted in HCV infection[20]. It is worth stressing that both TNF-α and IL-1β are involved in controlling the above described balance, thus taking part in determining the liver cell's fate and progression to liver cancer. In fact, the binding of TNF-α and IL-1β to their receptors leads to the activation of transcriptional factors, such as NFkB and AP-1, again involved in controlling cell proliferation[10]. What role does persistent oxidative stress play in this scenario? The overproduction of oxidative species, linked to over-expression of inflammatory cytokines (as shown by the positive correlation between TNF-α and 8OHdG levels in the liver), might be responsible for inhibiting the apoptotic process, most likely by activating the NFkB-dependent pathway[34].

Last but not the least, oxidative damage may be related to the expression of proto-oncogenes, such as c-myc[35]. In our study, c-myc transcript levels were significantly higher in cirrhotic than in non-cirrhotic tissues, indicating that tissue damage progression from hepatitis to cirrhosis, with the related cell growth changes, may be mediated to some degree by c-myc, which indeed is considered one of the activators of cell proliferation[36]. In this series, we could detect no relationship between 8OHdG and c-myc, suggesting that they have different and independent proto-oncogene activation mechanisms.

It was reported that TGF-α /c-myc double transgenic mice exhibit enhanced cell proliferation and build up extensive oxidative DNA damage which possibly accounts for massive DNA damage and accelerated neoplastic development in the liver[37]. In the present study, all liver samples with or without cirrhosis, expressed low levels of TGF-α mRNA and revealed no correlation with any of the other parameters investigated. This may not be totally surprising, since a strong and prominent localization of TGF-α in ground-glass hepatocytes of HBV-related liver disease in association with HBV pre-S1 antigen has been reported and this may mean that TGF-α is more involved in HBV than in HCV liver disease[38].

In our study DNA oxidative damage correlated with TNF-α over-expression in chronic HCV-mediated liver damage. Evolution to cirrhosis was characterized by an increased oxidative DNA damage, c-myc expression and IL-1β release. When disease activity was severe, it was paralleled by an increased expression of IL-1β and c-myc associated with genotype 1b infection and accumulation of 8OHdG. The above findings suggest that chronic HCV-mediated oxidative DNA damage in the liver may have an impact not only on hepatocyte proliferation rate through c-myc activation but also on cell proliferation and apoptosis through TNF-α activation.

In conclusion, HCV infection is associated with increasing cell proliferation unaccompanied with any substantial increase in apoptosis[20], while TNF-α activation in this scenario has more to do with cell proliferation rather than with cell apoptosis.

Abstract

AIM: To analyze whether the presence of anti-HBs in liver transplant recipients is effective in preventing HBV infection.

METHODS: Twenty-three patients receiving anti-HBc positive liver were studied. Nine recipients were anti-HBc positive as a result of previous HBV infection. Of them, one also received HBV vaccine during the pre-liver transplantation period. Fourteen recipients were anti-HBs positive due to HBV vaccine administered during the pre-transplant period. Liver biopsy was obtained in 10/14 anti-HBc negative/anti-HBs positive recipients and in 4/9 anti-HBc positive recipients.

RESULTS: After a mean follow-up period of 46 months, 1 recipient with protective serum anti-HBs levels developed *de novo* HBV infection as a consequence of immune escape HBV mutants. Among the 14 vaccinated anti-HBc negative/anti-HBs positive recipients, 1/10 patients with available liver biopsy (10%) had liver HBV-DNA at 13 mo post-liver transplantation without serum viral markers and did not develop *de novo* HBV infection. The vaccinated anti-HBc positive recipient without HBV vaccine response was HBV-DNA positive in serum and liver, viral DNA was continuously negative in the following tests, so a spontaneous seroconversion was diagnosed.

CONCLUSION: The presence of anti-HBs as a result of HBV vaccine or past HBV infection seems to be effective at protecting patients receiving livers from anti-HBc positive donors. However, the emergence of immune escape HBV mutants, which can evade the anti-HBs protection, should be considered as a risk of HBV infection.

Key words: HBV vaccine; Liver transplantation; De novo HBV infection; Hepatitis B core antibody

INTRODUCTION

It has been reported that the incidence of hepatitis B virus (HBV) infection is high in recipients after liver transplantation (LT) from hepatitis B surface antigen (HBsAg) negative but anti-core antibody (anti-HBc) positive donors[1,2]. The frequency of HBV transmission depends on the HBV serological recipient status, while the presence of anti-HBc and anti-HBs in organ recipients may confer resistance to HBV infection. Their absence results in *de novo* HBV infection[3-5]. To avoid the occurrence of *de novo* HBV infection in recipients without serum HBV markers, use of passive immunization with hepatitis B immune globulin (HBIG) in combination with lamivudine is necessary[6,7]. Another possibility to make use of these anti-HBc positive organs is to direct liver grafts to patients with anti-HBc and/or anti-HBs as a consequence of past HBV infection or HBV vaccination[8].

It is possible that HBV transmission from anti-HBc

Table 1 Features of donors and liver recipients

HCV: hepatitis C virus; HCC: hepatocellular carcinoma; HBV: hepatitis B virus; V: HBV vaccine; RC: partially double-stranded HBV DNA genome; ND: not determined.

donors to recipients via LT may be due to the persistence of HBV in tissue in a state of replication-competent that can be reactivated to form infectious particles. During initiation of HBV infection, the partially double-stranded HBV DNA genome (rcDNA) becomes a covalently closed circular DNA molecule (cccDNA) that serves as a template for viral transcription[9] and is regulated and amplified by an intracellular pathway[10]. This process establishes a pool of nuclear cccDNA, which persists in the nuclei of infected cells as long as hepatocytes survive, explaining the requirement for long-term antiviral therapies[11]. This fact could explain the reactivation of HBV under certain conditions such as administration of immunosuppressive drugs[12]. The genomic organization of the HBV direct repeat region (DR) provides a strategy to distinguish rcDNA from cccDNA using PCR primers flanking the DR region.

The purpose of this study was to analyze whether past HBV infection or positive response to HBV vaccine is effective in preventing *de novo* HBV infection in patients receiving a liver from anti-HBc positive donors.

MATERIALS AND METHODS

Patients

Anti-HBc screening is a general practice performed in organ donors at our hospital. Between February 1999 and February 2004, 31 HBsAg negative patients received anti-HBc positive liver. Thirty-one donors were anti-HBc positive and 16 of them were also anti-HBs positive (51.6%). Of the 31 recipients, 8 patients had a second LT or were under lamivudine treatment because they were anti-HBc and anti-HBs negative, so they were excluded from the study. The remaining 23 liver recipients were studied. Of them, 14 anti-HBc negative recipients developed protective anti-HBs levels after vaccination (40 mg/dose intramuscularly administered on days 0, 15 and 30; Engerix B, Smith-Kline Beechman, Belgium) and 9 were anti-HBc positive. Immunosuppression treatment included was of steroids and cyclosporin or tacrolimus. Characteristic and virological features of both donors and liver recipients are shown in Table 1.

Serum samples for detection of HBV markers anti-HBs and serum HBV-DNA were collected at the time of liver graft and during the post-transplant follow-up period. Liver tissues when possible were collected for analysis of HBV-DNA by PCR.

Hepatitis B virus markers

Serum samples were tested for HBsAg, anti-HBs and anti-HBc with commercially available radioimmunoassays kits (Abbott Laboratories, N Chicago, IL). Detection of viral DNA in serum was carried out by Abbott hybridization assay. Biopsy specimens were examined with immunohistochemical techniques for HBsAg and HBcAg

detection.

DNA extraction from paraffin-embedded liver tissues was performed using the MasterPure complete DNA purification kit (Epicentre, Madison, WI). Liver DNA was assayed for HBV DNA by 2 different sets of primers corresponding to the surface[13] and X genes. The sequences of the primers amplifying the X gene are as follows: HBVfe (TCTTGGACTCTCAGCAATGTCA nt 1438-1456), HBVre (GGTGAAAAAGTTGCATGGTGC nt 1583-1603), HBVfi (ACCGACCTTGAGGCATACTTCA nt 1463-1484), HBVri (CCAATTTATGCCTACAGCCTCC nt 1550-1571). PCR was started with the hot-start technique. The first round of PCR was performed with the outer primers for 30 cycles (at 95℃ for 15 s, at 55℃ for 10 s, and at 72℃ for 30 s) followed by an extension at 72 ℃ for 5 min. The second round was carried out with the inner primers for 30 cycles at 57℃ as the annealing temperature.

The selective detection of cccDNA was carried out by a nested PCR procedure as previously described with some modifications to distinguish between rcDNA genome present in virions and ccc HBV-DNA found in hepatocytes[14]. The rcDNA contains a single-stranded gap at the 5´end of the minus strand DNA. Since this region is sensitive to mung bean nuclease (MBN) leading to a disruption in the viral genome, no PCR product could be obtained using this rcDNA as a template. However, since cccDNA is a double-stranded covalently closed molecule and resistant to MBN, PCR could yield a fragment when this DNA was used as a template. MBN reaction was done as previously described[14]. The whole reaction was used as a template for the first round of nested PCR. The primers used to amplify cccDNA were HBVdr-s (TTACGCGGACTCCCCGT nt 1410-1424), 1900AS (GGTCAATGTCCATGCCCCAA nt 1769-1790), HBVfi (ACCGACCTTGAGGCATACTTCA nt 1463-1484), and HBVdr-as (GACATGAACAAGAGATGATTAGGCA nt 1706-1730). As a positive control, a PCR fragment containing the nick region of rcDNA was cloned into the pMosBlue vector (pMOSBlue blunt ended cloning kit, Amersham Pharmacia Biotech, UK). HBV DNA extracted from serum of HBsAg-positive individuals was used as a negative control. Both positive and negative controls were treated with MBN.

RESULTS

Only one patient developed *de novo* HBV infection after a follow-up of 45 ± 20.81 months (Table 1). This patient was vaccinated and developed a low anti-HBs response with anti-HBs title between 10 and 100 IU/mL. Seven months after LT, her routine biochemical tests showed abnormal level of liver enzymes (AST 97 U/L, ALT 151 U/L, GGT 136 U/L) but liver ultrasound was normal. Besides, virological analysis was found to be positive for HBsAg and serum HBV-DNA, even if her serum anti-HBs titer was 17 IU/mL. These virological tests did not reveal any other viral infections (CMV, CEV, HCV, HAV). Based on these results, *de novo* HBV infection was diagnosed and the patient was treated with lamivudine (100 mg/d). Serum HBV-DNA still remained positive, so a combined therapy of lamivudine and adefovir was administered 32 mo after LT. A second liver biopsy revealed marked steatosis with positive immunostaining for HBcAg (in nuclei and cytoplasm) and HBsAg (in cytoplasm and membrane). No tissue was obtained for the analysis of HBV-DNA.

It is known that the "a" determinant located within HBsAg is the target of immune response providing immunity against HBV infection[15]. The emergence of HBV with surface gene mutations is able to escape immune response against HBV vaccine, causing infection. In fact, HBV envelope mutants associated with the "a" determinant after HBV vaccination have been identified[16]. To know whether this might be the reason why *de novo* HBV infection occurred in this liver recipient, a serum sample taken 36 months after LT was used for HBV-DNA extraction, PCR amplification of the "a" determinant of the S gene and PCR fragment sequencing. Viral sequence revealed that this patient harbored a HBV variant with 2 point mutations at amino acid positions 127 and 145 of HBsAg. The first mutation resulted in a substitution of proline or lysine for threonine (Pro or Lys 127 Thr). The second mutation was a substitution of glycine for alanine (Gly 145 Ala). Several HBV mutants with amino acid changes in the "a" determinant have been reported in the post-transplant situation[16,17]. Among those mutations, the particular and almost invariably change is Gly 145 Arg, which can cause persistent infections[18]. Our patient also presented this change at position 145. However, the sequence analysis revealed the presence of an Ala instead of an Arg. This amino acid change has never been previously found in the literature. The change of Pro 127 Thr has been described in liver-transplanted patients [16].

A total of 18 biopsies taken at different post-LT time points from 14 recipients were obtained for the analysis of HBV-DNA in liver tissues. Open circular HBV-DNA (RC) was found in 2/14 patients (Table 1) and no cccDNA was detected in any of them. These results were reproducibly obtained in 3 repeated sets of PCR experiments. The anti-HBc negative patient with HBV-DNA in tissue (Table 1) had no detectable HBV-DNA and HBsAg in serum throughout a follow-up period of 66 mo. The anti-HBc positive recipient with viral DNA in liver (Table 1) was found to be serum HBV-DNA positive in one of his routine virological tests but this viral marker was continuously negative in the following tests. HBsAg was all negative during the whole follow-up period (66 months). No recurrent HBV infection could be considered in this patient.

DISCUSSION

Accumulating evidence suggests that HBV can be transmitted to the organ recipients from anti-HBc-positive donors through LT[19,20]. HBV transmission fluctuates among different studies between 50 % and 90 %. In our study only one patient receiving an anti-HBc positive liver developed *de novo* HBV infection as a consequence of an immune escape HBV mutant associated with the "a" determinant while in the absence of HBV mutants, none of the recipients developed HBV infection, suggesting that the presence of anti-HBs during LT, as a consequence of HBV vaccination or past HBV infection together with

anti-HBc, can protect against HBV infection transmitted by anti-HBc positive liver grafts.

Although less than 50% of the patients with cirrhosis due to HBV infection respond to HBV vaccine[21], a large number of patients can be considered as liver transplant recipients.

Anti-HBs levels >10 IU/mL due to HBV vaccine are considered protective in immunocompetent patients[22]. We consider this anti-HBs titer protective in those vaccinated patients[21].

We were aware of the short-term persistence of anti-HBs in these patients. Only 5 of them still maintained anti-HBs titers over the follow-up period while the rest of the patients lost this marker (Table 1). Since anti-HBs response is reduced in immunosuppressed patients[21,23], it is accepted that this rapid drop of anti-HBs levels is the consequence of their immunosuppressive therapy. Importantly, these results suggest that even with loss of anti-HBs during the post-LT period, HBV vaccination is effective as prophylaxis for the prevention of HBV infection in LT, which is in agreement with previous studies[24]. Another interesting finding that supports the efficacy of HBV vaccine against HBV infection is the continuous negativity for serum HBV DNA after LT during the follow-up period.

It is known that viral genome can persist in hepatocytes as a rcDNA molecule and as a cccDNA molecule, the later is required for viral replication[9]. Detection of intrahepatic cccDNA may indicate the possible ongoing viral replication[25]. Thus, its presence could explain the reactivation of HBV replication in patients receiving a liver from donors with anti-HBc. The only viral form detected in 2 recipients (1 anti-HBc negative, 1 anti-HBc positive) was rcDNA. The anti-HBc negative patient who had no history of previous HBV infection received HBV vaccine prior to LT with anti-HBs titers >10 IU/L. It is interesting to know that this patient, even maintaining HBV DNA in liver after one year of LT, did not show any virological evidence of *de novo* HBV infection during the follow-up period of 66 months (Table1). Moreover, he lost anti-HBs titers. The histopathological study at this time showed stage III fibrosis, confirming recurrence of HCV infection. The data may suggest that HBV graft infection may be infrequent. Likewise, in the anti-HBc positive recipient with viral DNA in liver tissue 23 months after LT (Table 1) and after 66 months of follow-up, no recurrent HBV infection occurred although he had positive serum HBV-DNA in one of his routine virological tests, suggesting that spontaneous seroconversion occurs in him.

However, even if the presence of anti-HBs in liver recipients seems to prevent recurrent or *de novo* HBV infection, the latest risk can still occur as seen in one of the recipients. Nevertheless, in this recipient HBV infection was not prevented by anti-HBs response because the cause was a circulating HBV mutant. The presence of circulating surface antigen-mutated HBV was proved when mutations in the "a" determinant region of the surface antigen were identified in this patient. In our study, the prevalence of HBV surface antibody escape mutants after liver transplantation was 6.6%, which is consistent with other studies[16, 26].

Our results are in agreement with an earlier study[27]. However, other reports have provided clear evidence that HBV genome is detectable in most anti-HBc positive donors[28]. The validity of our amplification method was confirmed by our control experiments using negative and positive controls. One possibility could be that DNA molecules isolated from preserved paraffin-embedded liver tissues are generally of poor quality because of the high degree of DNA degradation in these samples. However, HBV detection may be reduced beyond detectable levels but focal distribution of HBV infection cannot be excluded.

In conclusion, the presence of anti-HBs in liver recipients at the time of LT can prevent HBV recurrence or *de novo* HBV infection. Although we have described a new vaccine HBV mutant in a liver transplant recipient causing *de novo* HBV infection, the efficacy of HBV vaccine in organ recipients could not be considered as universal due to the development of immune escape HBV mutants associated with the "a" determinant which can evade the anti-HBs protection. Administration of HBV vaccine is mandatory in patients with chronic liver pathology potentially needing liver transplantation. Although these results are promising, the limited patient number may lead to an erroneous interpretation of the data. Most extensive studies including a large number of recipients need to be done.

Abstract

AIM: To retrospectively evaluate the prognosis of patients with hepatocellular carcinoma (HCC) with or without a history of therapy for HCC following transcatheter arterial embolization (TAE).

METHODS: One hundred and twenty-one patients with HCC treated with TAE from 1992 to 2004 in our hospital were enrolled in this study. Eighty-four patients had a history of treatment for HCC, while 37 did not. At the time of entry, patients with extra-hepatic metastasis, portal vein tumor thrombosis, or Child-Pugh class C were excluded. TAE was repeated when recurrence of HCC was diagnosed by elevated tumor markers, or ultrasonography or dynamic computed tomography findings.

RESULTS: Tumor size was larger and the number of tumors was fewer in patients without past treatment ($P < 0.01$). However, there were no differences in tumor node metastasis (TNM) stage or survival rate between the 2 groups. A bilobular tumor and high level of α-fetoprotein (AFP) (>100 ng/mL) were factors related to a poor prognosis in patients with a history of HCC.

CONCLUSION: The prognosis following TAE is similar between HCC patients with and without past treatment. Early diagnosis of HCC or recurrent HCC and obtaining good local control against HCC before entry to a repeated TAE course can improve prognosis.

Key words: Unresectable hepatocellular carcinoma; Prognosis; Repeated transcatheter arterial embolization

INTRODUCTION

Liver transplantation is recognized as an effective therapy for hepatocellular carcinoma (HCC)[1]. However, a shortage of donors in Japan has led to the general use of transcatheter arterial embolization and transcatheter arterial chemoembolization (TAE) in patients with unresectable HCC without an indication of surgery and percutaneous therapy. Although disappointing results are published[2-4], the usefulness of TAE has been reconfirmed recently as some studies found that the procedure reduces the overall 2-year mortality rate and improves the survival rate of patients with unresectable HCC[5-8]. Past reports regarding the prognosis of patients with HCC are usually limited to the initial therapy, including surgery[9], percutaneous ethanol injection therapy (PEIT)[10], radiofrequency ablation (RFA)[11,12], and TAE. In previous studies of TAE, the subjects had no history of treatment for HCC. However, most patients with HCC have no indication for therapy such as surgery, PEIT and RFA due to multiple recurrences finally. No reports have evaluated prognosis and its related factors of patients with a history of HCC following a repeated TAE course. In the present study, we retrospectively evaluated the prognosis of HCC patients with or without a history of therapy for HCC following TAE.

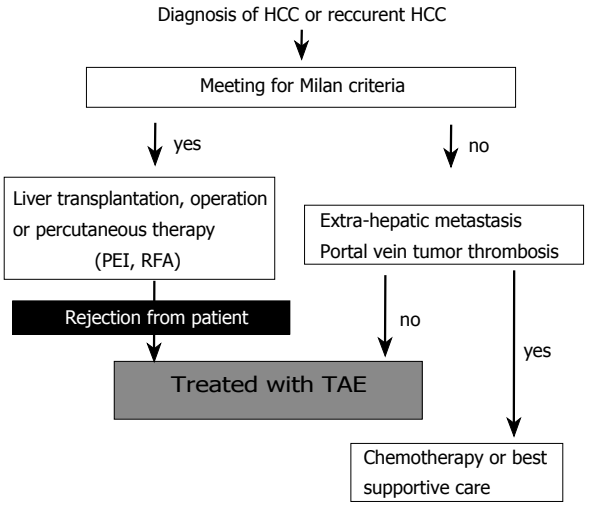

Figure 1 Strategy for treatment of HCC employed at our institution. Nearly all patients with HCC, which were outside of the Milan criteria, were recommended for a repeated TAE course.

MATERIALS AND METHODS

This was a single-center retrospective study conducted at Ehime University Hospital. One hundred and twenty-one patients with advanced HCC treated with TAE from 1992 to 2004 were enrolled in the study. After informed consent was obtained, the entry date was considered the day of the first TAE therapy after enrollment. The diagnosis of HCC was based on histological and cytologic findings or findings of dynamic computed tomography (CT). Tumor stage was established by dynamic CT, ultrasonography (US), angiography, chest CT, and bone scintigraphy examinations.

Patients with extra-hepatic metastasis, portal vein tumor thrombosis (PVTT), or Child-Pugh class C at entry were excluded from this study since the existence of PVTT and a high Child-Pugh score are poor prognostic markers and TAE can not improve these patients[5]. As a result, 37 patients with no history of treatment for HCC and 84 with such a history of surgery, PEIT, or RFA, were studied. During the 13-year study period, a total of 121 patients underwent 435 courses of TAE, with 99 (82%) outside of the Milan criteria[1]. In 37% of 121 patients, HCC was confirmed by histological examination. Others were diagnosed based on the increasing course of α-fetoprotein (AFP) and dynamic CT. All HCC nodules treated with TAE were hypervascular.

The patients treated with TAE were evaluated based on our strategy (Figure 1). TAE was repeated when HCC recurrence was diagnosed by the elevation of tumor markers, or US or dynamic CT examination findings. Experienced radiologists performed all the TAE procedures. A microcatheter was inserted into the artery feeding the tumor super-selectively after conventional hepatic angiography or angiography CT, and then a segmental or subsegmental TAE procedure[13] was performed. Before the procedure, antegrade flow in the portal vein and no obstruction of the main trunk of the portal vein were confirmed by US, dynamic CT, and portography findings via the superior mesenteric artery. Lipiodol and a gelatin sponge (Gelfoam, Upjohn, Kalamazoo, MI, USA) were used for embolization, and epirubicin hydrochloride was used together with Lipiodol in 25% of the cases. The goal of embolization was disappearance of tumor staining without complete obstruction of the hepatic artery. Patients that underwent additional chemotherapy via a subcutaneously implanted injection port, surgery, PEIT, or RFA for the purpose of reducing the size of the tumor after undergoing TAE were excluded from this study.

Table 1 Backgrounds of patients without or with history of treatment

	Patients without history of HCC ($n=37$)	Patients with history of HCC ($n=84$)	P value
Age (yr)	66.4 ± 9.9	67.0 ± 8.1	NS
Sex (male ： female)	32 ： 5	64 ： 20	NS
Frequency of positive for anti-HCV	72%	81%	NS
TNM stage (II ： III)	12 ： 25	35 ： 49	NS
Tumor size (mm)	46.4 ± 23.5	27.7 ± 16.1	$P<0.01$
Number of tumors (≤3 ： >3)	21 ： 16	23 ： 61	$P<0.01$
Monolobular ： bilobular	17 ： 20	27 ： 57	NS
Child-Pugh class (A ： B)	27 ： 10	48 ： 36	NS
Alanine transferase (IU/L)	63.8 ± 45.1	82.1 ± 64.3	$P=0.07$
AFP (≤100 ： >100 ng/mL)	23 ： 14	53 ： 31	NS
TAE with or without anti-cancer medication	13 ： 24	17 ： 67	NS
Average number of past treatments	-	2.9 ± 2.2	-
History of hepatectomy	-	18%	-
Average observation period (d)	557.6 ± 377.0	493.6 ± 390.6	NS

Anti-HCV: hepatitis C virus antibody; AFP: α-fetoprotein; TNM stage: tumor node metastasis stage.

The backgrounds of both groups at study entry are shown in Table 1. The group of patients without past treatment consisted of 32 males and 5 females, of whom 12 and 25 patients were in tumor node metastasis (TNM) stage[14,15] II and III, respectively. Furthermore, 27 were Child-Pugh class A and 10 were class B, of whom 72% were positive for the hepatitis C virus antibody (anti-HCV) and 14% for the hepatitis B surface antigen (HBs Ag).

As for the group of patients with treatment history, 64 were male and 20 female, of whom 35 and 49 were TNM stages II and III, respectively. Forty-eight patients in this group were Child-Pugh class A and 36 class B, of whom 81% were positive for anti-HCV and 16% for HBs Ag.

Determination of markers of hepatitis viruses

The presence of anti-HCV and HBs Ag was determined precisely using enzyme immunoassay kits (Imcheck-FHCV, Kokusai-Shiyaku, Kobe, Japan; AxSYM HBs Ag, Dainabot, Tokyo, Japan), according to the manufacturer's instructions.

Statistical analysis

All statistical analyses were carried out using a personal computer with StatView version 5.0 (SAS Institute, Inc., Berkeley, CA, USA). Analyses were conducted using Student's t-test, Mann-Whitney U test, Cox's proportional hazards regression model, logrank test, and the Kaplan-Meier method. $P < 0.05$ was considered statistically significant.

Table 2 Univariate analysis of patients with past treatment for HCC ($n=84$)

Factors	Number	Hazard ratio	95% CI	*P* value
Age (= and <65 ： >65)	38：46	0.99	0.95-1.02	NS
Sex (male ： female)	64：20	1.02	0.54-1.93	NS
Anti-HCV (positive ： negative)	67：17	1.31	0.64-2.67	NS
TNM stage (II ： III)	35：49	1.57	0.83-3.00	NS

RESULTS

There were no significant differences in the background findings between patients with or without past treatments for HCC, except for tumor size and the number of tumors ($P<0.01$) (Table 1). There was also no significant difference in patient distribution for TNM staging between the groups. None of the patients died due to the TAE procedure. For patients with treatment history, the average number of past treatments for HCC was 2.9±2.2 (range 1-10) and a hepatectomy was performed before entry to the repeated TAE course in 18% of these patients.

The survival rate was not significantly different between the 2 groups (Figure 2). The 1-, 2-, and 3-year survival rates were 90%, 57%, and 20% respectively in patients without past treatment, and 75%, 43%, and 25% respectively in those with past treatment. The factors related to poor prognosis in the 84 patients with past treatment for HCC were evaluated. Seventy-four of them (88%) were outside of the Milan criteria. According to univariate analysis, variables significantly associated with survival were tumor location (bilobular) and a high concentration of AFP (>100 ng/mL) ($P<0.05$). There were no relationships between the prognosis of patients with a history of treatment for HCC and other factors, including history of past hepatectomy and the number of past treatments for HCC (Table 2). Multivariate analysis showed that the existence of bilobular HCC and high concentrations of AFP (>100 ng/mL) were the factors for poor prognosis ($P<0.05$, Table 3). The survival rate of patients without both risk factors was better than that of those with both risk factors ($P<0.01$, Figure 3). In all 121 patients, the existence of bilobular HCC was related to poor prognosis ($P<0.01$), while a high concentration of AFP ($P=0.059$) and other factors including past treatments, were not related to poor prognosis.

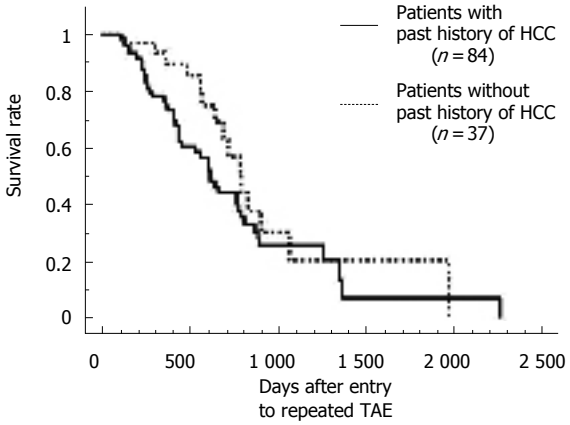

Figure 2 Survival rates of HCC patients with or without past treatment for HCC. There was no significant difference between the 2 groups. Survival rates after 1, 2, and 3 years were 90%, 57%, and 20% respectively for patients without past treatment, and 75%, 43%, and 25% respectively for patients with past treatment.

DISCUSSION

The prognosis of a patient with HCC is dependent on the hepatic reserve function and HCC staging[16,17]. A repeated TAE course is widely used for patients with unresectable HCC[18,19], though it was reported that TAE is not effective for improving the prognosis of such patients[2,3,4]. The reason for the disappointing results is that TAE is repeated within a fixed period of time although the liver reserves function and the patients have or have no recurrence of HCC. When TAE is repeated after a fixed period of time, embolization from the main trunk of the hepatic artery can lead to liver atrophy and deterioration of hepatic reserve function. Recently, the efficacy of TAE for patients with HCC has been reported, with good improvement of survival results[5-8]. Caturelli *et al*[20] reported that repeated TAE does not induce long-term deterioration of hepatic reserve function in HCC patients with Child-Pugh A and B but without PVTT.

Since repeated TAE for a fixed period without recurrence can lead to a reduction in hepatic reserve function, we think that it is important to perform TAE at the time

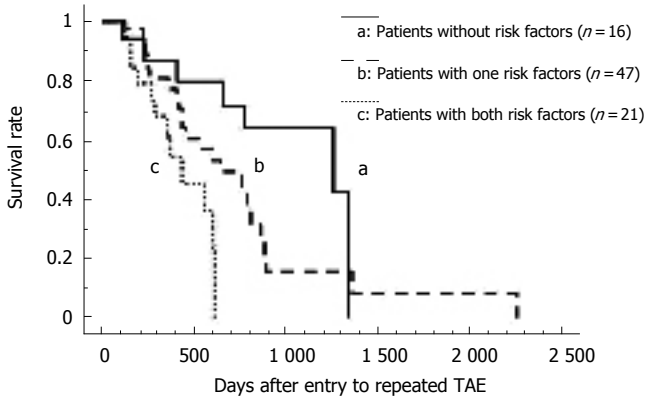

Figure 3 Survival rates of HCC patients with past treatment and with or without the 2 risk factors found in the present study. Significant differences were shown between "**a**" and "**b**" and between "**b**" and "**c**" ($P<0.01$ and $P=0.01$), while there were no significant differences between "**a**" and "**b**" ($P=0.08$). **a**: Patients without either factor [existence of bilobular tumors and high concentration of AFP (greater than 100 ng/mL; $n=16$)]; **b**: Patients with one of the factors ($n=47$); **c**: Patients with both factors ($n=21$).

when HCC recurrence is diagnosed by the elevation of tumor markers, or based on US or dynamic CT findings [21,22]. Recently, diagnostic progress of US and CT has made it easier to accurately diagnose new and recurrent HCC with low levels of AFP. Dynamic CT can offer detailed information about tumor vascularity and dynamic CT is useful to distinguish cholangiocarcinoma from HCC[23,24]. In our study metastatic liver tumor was denied from clinical course in all cases. In a large number of patients, HCC develops to an unresectable condition during the course of therapy and becomes outside of the Milan criteria. To our knowledge, the prognosis of patients with a history of HCC and factors for poor prognosis have not been reported after a repeated TAE course. In the present study, though the tumor maximum size and the number of tumors were different between the patients with or without past treatment, the survival rates of both groups after undergoing TAE did not show a significant difference, which might be due to no significant difference in TNM staging distribution between the groups.

As for the patients with past treatment, a past hepatectomy and the number of past percutaneous therapies (e.g. PEIT and RFA) did not influence the prognosis after repeated TAE in regard to maintaining liver reserve function. A high concentration of AFP and tumor location (bilobular) each had a significant influence. The elevation of AFP and existence of bilobular HCC are dependent on the malignant potential of HCC [25] and intra-hepatic metastasis, respectively.

Prognosis was not significantly different between HCC patients with or without a history of HCC following TAE. Our results show that diagnosis of HCC or recurrent HCC in the early stage and obtaining good local control against HCC before a repeated TAE course can reduce the time bias and improve prognosis.

Abstract

AIM: Recent studies have demonstrated that obesity is the common feature of cryptogenic cirrhosis (CC) and non-alcoholic steatohepatitis. However, there is little information on CC in the region where obesity is not prevalent.

METHODS: The clinical features, and the liver-related morbidity and mortality of CC were analyzed in Japan where the prevalence of obesity is low. Among 652 cirrhotic patients, we identified 29 patients (4.4%) with CC. Of these, 24 CC patients who were followed up for more than 6 months were compared in a case-control study with age-, sex-, and Child-Pugh score-matched controls having cirrhosis of viral etiology.

RESULTS: Obesity (BMI$\geqslant$25 kg/m^2), diabetes mellitus, and hypertriglyceridemia were more frequent, and the visceral fat area was larger in the CC patients than in the controls. The indices of insulin resistance were higher and the serum aminotransferase levels were lower in the CC patients than in the controls. Logistic regression analysis identified the elevated hemoglobin A1c, BMI $\geqslant$ 25 kg/m^2, and normal aminotransferase levels as independent predictors of CC. Kaplan-Meier analysis demonstrated lower occurrence of hepatocellular carcinoma and higher survival rate in the CC than in the controls in contrast to the similar cumulative probability of liver-related morbidity between those groups.

CONCLUSION: CC more frequently presents with the clinical features suggestive of non-alcoholic steatohepatitis compared with controls even in the region where obesity is not prevalent. The lower occurrence of hepatocellular carcinoma and higher survival rate may indicate an indolent clinical course in CC as compared with viral cirrhosis.

INTRODUCTION

Liver cirrhosis is the terminal condition of liver diseases resulting from various etiologies. Despite the recent development of diagnostic tools, no recognizable etiology can be detected in approximately 5% to 31% of cirrhotic patients who are therefore diagnosed as having cryptogenic cirrhosis (CC)[1-3]. Although several explanations such as unknown viral infections, occult alcohol abuse, or burnt out autoimmune hepatitis had been proposed as possible causes of CC, they actually induce CC only in some cases[3,4].

Obesity is an independent risk factor for chronic liver diseases, and liver fibrosis can develop in the obese patients without any known causes of liver diseases [5, 6]. Due to the recent increase of the obese population, great attentions have been paid to non-alcoholic steatohepatitis (NASH), which is characterized by obesity and insulin resistance. It has been widely recognized that NASH can progress to liver cirrhosis and hepatocellular carcinoma (HCC)[7]. Several studies have suggested that NASH may be an under-recognized cause of CC, because the prevalence of risk factors for NASH such as obesity and diabetes mellitus is definitely increased in the patients with CC[8-10]. However, these studies have been conducted

in the West where obesity is common, and there is little information on CC in the region where the dietary habits are different from those in the West and the prevalence of obesity is low. Because the key component of the association between NASH and CC is obesity[8-10], whether this association is true even in the non-obese population is an important issue.

In Japan where obesity is not prevalent, the clinical characteristics, and the liver-related morbidity and mortality of CC were investigated with a special reference to the association with NASH in this study. The aim was to clarify the clinical features of CC in the region where the prevalence of obesity is low.

MATERIALS AND METHODS

Patients

We identified 652 cirrhotic patients in whom sufficient data were available to establish the etiology of liver disease from the inpatients' registry of Nara Medical University since 1990. Liver cirrhosis was diagnosed on the basis of compatible clinical and imaging findings, and/or liver histology. The diagnosis of CC was made only after an exhaustive evaluation of the clinical history and laboratory data, from which no specific etiologies were defined. Patients with histological evidence of other defined causes of liver diseases were also excluded from the diagnosis of CC. Of 29 patients with CC, 24 patients who had been followed up for more than 6 months were classified as the CC group in our case-control study. For patients in CC group, 3 patients with cirrhosis of viral etiology [2 hepatitis C virus (HCV)-related and 1 hepatitis B virus (HBV)-related], age- (within 3 years), sex-, and Child-Pugh score-matched, were identified from the corresponding inpatients' registry in a consecutive manner. Finally, 24 patients with CC, 48 with HCV-related cirrhosis, and 24 with HBV-related cirrhosis were enrolled in the present case-control study. This study was approved by the Ethical Committee of Nara Medical University and was performed in accordance with the Declaration of Helsinki.

Methods

All patients underwent an exhaustive re-evaluation of the following clinical information: past or present evidences of diseases including diabetes mellitus, dyslipidemia, and hypertension; personal history of alcohol intake, intravenous drug use, or blood transfusion, and family history of liver diseases. The height and weight were measured, and the body mass index (BMI) was calculated as weight (kg) divided by squared height (m). The cases with ascites were evaluated after the resolution of ascites. HBV markers (surface antigen/antibody and core antibody) and HCV antibody were negative in all patients with CC. The following laboratory data were also collected at enrollment: total bilirubin, aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase, albumin, γ-globulin, cholinesterase, total cholesterol, triglyceride, prothrombin activity (International normalized ratio: INR), hemoglobin A1c, α1-antitrypsin, iron storage parameters (transferrin saturation and ferritin), copper and ceruloplasmin levels, anti-nuclear antibody, anti-mitochondrial antibody, and anti-liver kidney microsomal antibody. When immune mediated liver disease could not be ruled out, liver histology was evaluated. The fasting blood levels of glucose and insulin were determined, and the homeostasis model assessment parameter of insulin resistance (HOMA-IR) and the quantitative insulin check index (QUICKI) were calculated as the indices of insulin resistance[11,12]. Liver biopsy was performed in 12 of the 24 patients with CC and was used to investigate the histological features suggestive of NASH.

Abdominal fat distribution

Computed tomograms were recorded at the umbilical level, and the visceral fat areas were measured as described previously [13]. Other tomograms were taken at the level where the liver and spleen were observed in the same slice. The Hounsfield unit of the liver and spleen was determined, and the liver/spleen ratio was calculated as an index of the hepatic fat content [14].

Assessment of the outcomes

Clinical information including the tumor markers and the imaging studies was monitored every 6 months until data analysis. In cases which lost to follow-up, up-to-date clinical information was investigated by telephone interview and/or contact with the primary care physician. The following outcomes were evaluated; (1) liver-related morbidity including variceal bleeding, ascites, jaundice, and hepatic encephalopathy, (2) occurrence of HCC, (3) mortality and cause of the death. HCC was histologically confirmed or diagnosed by elevation of α-fetoprotein and/or compatible ultrasonographic or computed tomographic findings. Death was considered to be liver-related when it happened in consequence to hepatic failure, variceal bleeding, and/or HCC.

Statistical analysis

All analyses were performed with StatView 5.0 program (SAS Institute, Cray, NC, USA). Comparisons were made using the two-tailed Student's *t* test for quantitative variables and the Chi-square test for qualitative variables. Kaplan-Meier's method and the log-rank test were used to compare the cumulative probability to liver-related morbidity and mortality. The factors associated with CC were identified using a multivariate logistic regression model. All data are expressed as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

Etiology of liver cirrhosis

Among the 652 patients, cirrhosis was attributed to viral etiology in about 80% (HCV-related cirrhosis: 62.9%, HBV-related cirrhosis: 16.6%) and to alcohol in 9.5%. The prevalence of CC was 4.4%. The other cases resulted from various causes such as autoimmune liver diseases, hemochromatosis, Wilson's disease, Budd-Chiari syndrome, and congestion. The males were predominant in viral and alcoholic cirrhosis, whereas there was no gender difference

in CC (male/female ratio; HCV: 255/155, HBV: 82/26, alcohol: 52/10, CC: 15/14).

Characteristics of patients

The follow-up period was not significantly different between groups. Whereas one-third of the patients with viral cirrhosis were transfused, no patient with CC was transfused. BMI was significantly higher in the CC patients than in the controls of viral etiology. AST and ALT levels were lower in the CC patients than in the controls, although AST was higher than ALT in all groups. Cholinesterase, total cholesterol, and triglyceride were higher in the CC patients than in the controls. The fasting levels of blood glucose, hemoglobin A1c, insulin, and the indices of insulin resistance such as HOMA-IR and QUICKI were also higher in the CC patients than in the controls. Iron storage parameters such as transferrin saturation and ferritin were similar in all groups (Table 1). The visceral fat area was larger in the CC patients than in the controls, whereas the liver/spleen ratio was similar between groups. Obesity was more prevalent in CC patients than in controls (BMI ⩾ 30 kg/m^2: CC 16.7% *vs* controls 1.4%, $P<0.05$) (Table 2). The patients whose visceral fat area was larger than 100 cm^2 constituted 40% of the CC as compared with 5.3% of the controls ($P<0.05$). Type 2 diabetes mellitus and hypertriglyceridemia were more frequent in the CC patients than in the controls. No patient suffered from type 1 diabetes mellitus. The prevalence of hypertension was similar in all groups.

Although liver biopsy was performed in 12 of 24 patients with CC, there was no specific finding to define the etiology of liver disease. Ten of 12 biopsies, however, revealed one or more histological components suggestive of NASH such as macrovesicular steatosis,

ballooning hepatocyte degeneration, neutrophilic lobular inflammation, and Mallory hyaline. Eight cases had macrovesicular steatosis in less than 30% of the hepatocytes. Ballooning hepatocyte degeneration, neutrophilic lobular inflammation, and Mallory hyaline were present in 7, 2, and 2 cases, respectively. Two cases had no inflammatory activity, 7 cases demonstrated minimal activity, and 3 cases had mild-to-moderate activity. The inflammatory infiltrates consisted predominantly of lymphocytes in fibrous bands.

Factors associated with CC

In the univariate analysis, BMI≥25 kg/m^2, visceral fat area ≥ 100cm^2, and the coincidence of diabetes mellitus and dyslipidemia, were significantly associated with CC (Table 3). Moreover, normal ALT levels (<667nkat/L), elevated levels of cholinesterase, triglyceride, and hemoglobin A1c ≥ 6.0%, and HOMA-IR ≥ 4% were significantly associated with CC. The multivariate analysis identified the elevated levels of hemoglobin A1c (OR: 7.8, 95% CI: 1.62-37.55, $P<0.05$) and BMI (OR: 6.8, 95% CI: 1.41-32.87, $P<0.05$), and normal ALT levels (OR: 5.0, 95% CI: 1.12-22.43, $P<0.05$) as independent predictors of CC.

Clinical course of CC as compared with the viral cirrhosis

During a mean follow-up of 5.7 years for the CC group ($n=24$), 2 patients experienced variceal bleeding, and 6 patients developed ascites (Figure 1). Jaundice and hepatic encephalopathy occurred in 5 patients and 6 patients, respectively. The viral group ($n=72$) was followed-up for a mean of 5.9 years, during which variceal bleeding, ascites, jaundice, and hepatic encephalopathy occurred in 12, 27, 20, and 10 cases, respectively. The cumulative probabilities of the liver-related morbidity were not significantly different between the groups. HCC occurred in 9 patients of the CC group in contrast to 53 patients of the controls (HCV: 36 patients, HBV: 17 patients) (Figure 2A). Although the cumulative probability of HCC occurrence was lower in

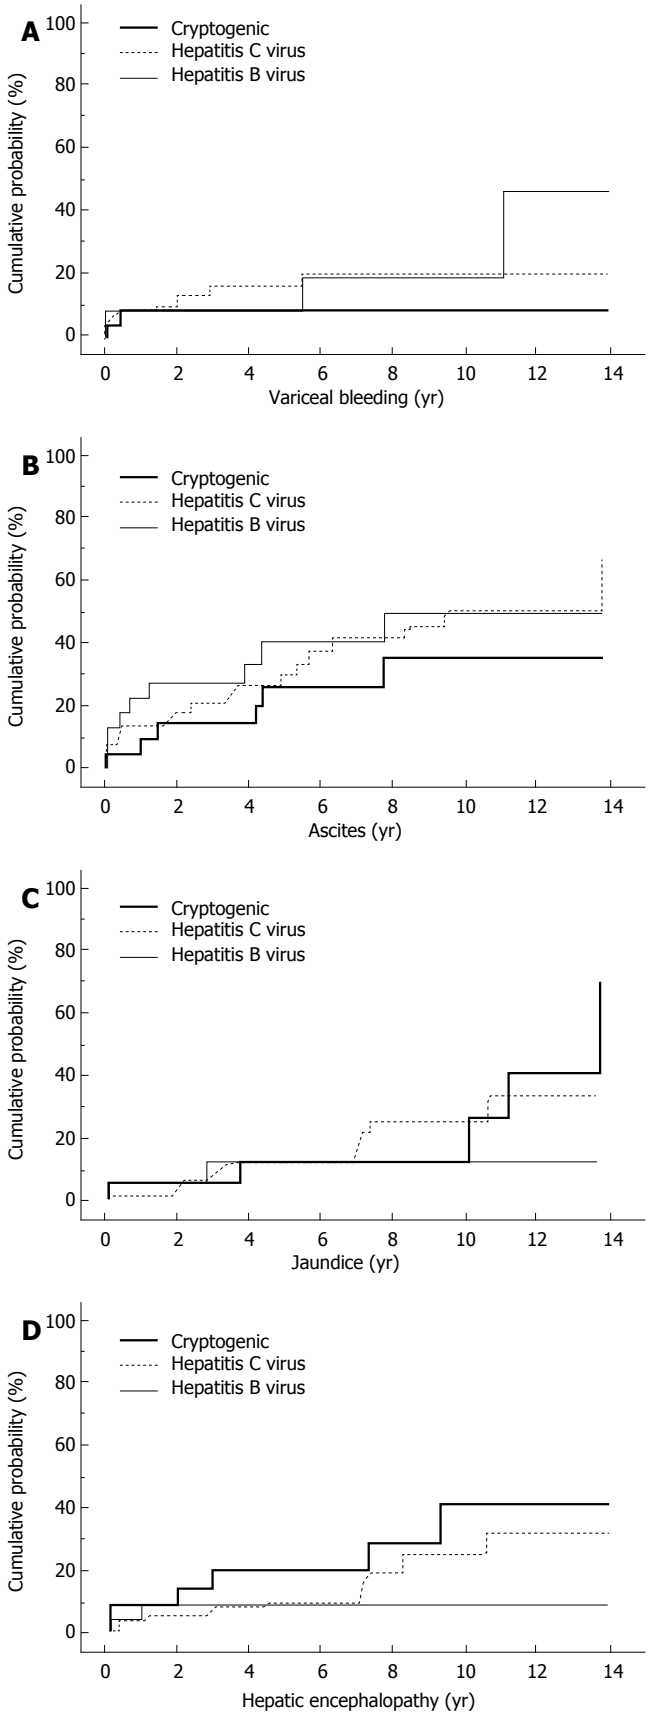

Figure 1 The cumulative probability of the liver-related symptoms for cryptogenic cirrhosis and viral cirrhosis using Kaplan-Meier's method and log-rank test.

the CC group than in the controls of viral etiology ($P<0.01$, CC *vs* HCV and CC *vs* HBV), HCC occurrence in the CC group rapidly increased 8 years after the observation. Of

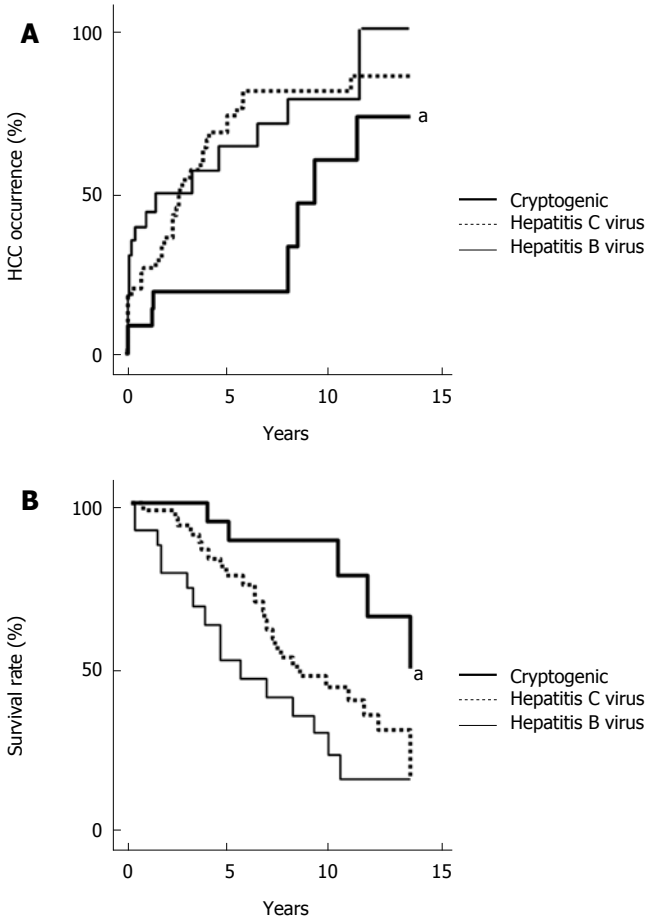

Figure 2 The cumulative probabilities of hepatocellular carcinoma and survival censoring non-liver related deaths for cryptogenic cirrhosis and viral cirrhosis. a: $P<0.01$, *vs* viral origin.

24 patients with CC, 3 died of liver failure and 2 of HCC (Figure 2B). No patient was associated with non-liver-related death. In the controls, 39 patients (24 HCV-related and 15 HBV-related) were associated with liver-related death (liver failure in 10 cases and HCC in 29 cases). The cumulative probability of survival censoring non-liver related deaths were higher in the CC group than in the controls ($P<0.05$, CC *vs* HCV, $P<0.01$, CC *vs* HBV).

DISCUSSION

Recent studies in the West have proposed that NASH may be an under-recognized cause of CC[8-10]. Although obesity is the key component of the association between CC and NASH, whether this association can be true even in the region with the low prevalence of obesity is unknown. The World Health Organization defined obesity as BMI $\geqslant$ 30[15], but in Japan, the prevalence of the population with such BMI is no more than 2%-3% in contrast to the 20%-30% in the West[16-18]. Moreover, the medical examination in 2002 ($n=6360$) in the local district where this study was performed showed that the prevalence of BMI $\geqslant$ 30 was 2.5% (data not published). We, therefore, investigated the clinical features of CC focusing on the association with NASH in Japan. This study demonstrated that in Japan, obesity, diabetes mellitus, and hypertriglyceridemia were more frequent, and insulin resistance, which is closely associated with the pathogenesis of NASH was greater in the CC group than in the controls of viral etiology. These findings are similar to those in the West, indicating that CC has the similar clinical features to NASH regardless of the prevalence of obesity.

The Japanese people as a race are known to suffer from obesity-related disorders even with a mild excess of adiposity[16,19-21]. The definition of obesity is proposed as BMI $\geqslant$ 25 in Japan, because the obesity-related disorders increase with a BMI $\geqslant$ 25[16,19]. This study demonstrated that the prevalence of BMI $\geqslant$ 30 in the CC group was 16.7% in Japan in contrast to 47% in the West. The prevalence of BMI $\geqslant$ 25 in the CC group was 54.2%, which is similar to that of BMI $\geqslant$ 30 in the West[9]. Moreover, our patients with CC, despite of the low prevalence of obesity, were accompanied with diabetes mellitus in 54.2% and hypertriglyceridemia in 20.8%, which is also similar to the reports in the West[8,9]. Although the BMI in viral cirrhosis was also lower in Japan than in the West (22.4 ± 3.0 *vs* 25.1 ± 4.2), the prevalence of diabetes mellitus was similar in these regions (26.4% *vs* 32.0%)[9]. Considering that the NASH patients in Japan are not as obese as those in the West [21], Japanese people, even with mild obesity, may suffer from NASH which may progress to CC.

Many researchers have shown that excess visceral fat is more closely related to the risk of health problems than the BMI itself[22-23]. The contribution of visceral fat area is greater in Japanese in whom the degree of whole fat accumulation is not as severe as in the West. Our present study demonstrated an increased visceral fat deposit in the CC group as compared with viral cirrhosis group. Because the increased visceral fat deposit plays a role in the pathogenesis of NASH via a production of various adipocytokines from the visceral fat tissue[23,24], the larger visceral fat area in CC further supports the association between CC and NASH. On the other hand, the hepatic fat deposit reflected by the liver/spleen ratio was similar in CC and viral cirrhosis groups. The hepatic fat deposit may decrease in the cirrhotic stage because the sinusoidal capillarization impairs the movement of gut-derived lipoproteins into the hepatocytes and the porto-systemic shunt diverts blood-borne lipids away from the liver. In fact, loss of the hepatic fat deposit has been observed in serial biopsies of NASH patients with progression to cirrhosis[7]. Because the excessive steatosis of the hepatocytes induces oxidative stress leading to the death of hepatocytes, loss of the hepatic fat deposit may be associated with lower ALT levels in CC.

This study demonstrated the lower occurrence of HCC and the higher survival rate in the CC than in viral cirrhosis, indicating that CC may take an indolent clinical course. There is a wide variation in the carcinogenic risk of CC among previously studies. Caldwell *et al*[8] showed that HCC developed in one of 71 patients with CC (1.4%). Another group reported higher prevalence of HCC in the CC group than in HCV-related cirrhosis[10]. The reason for these controversial data is unclear, but it may be attributed to the difference of the observation period. Bugianesi *et al*[25] suggested a later onset of HCC in the CC, because the patients with the CC-associated HCC were older as compared with the other cirrhosis-associated HCCs. Interestingly, this study demonstrated that although the

cumulative probability of HCC occurrence was lower in the CC than in the viral cirrhosis, HCC occurrence in the CC rapidly increased 8 years after the observation, indicating the later increase of HCC in CC. The later occurrence of HCC in CC can not be attributed to age and sex difference or degree of liver damage, because of a case-control study with age-, sex-, and Child-Pugh score matched viral cirrhosis. Therefore, HCC occurrence may be a late complication of CC.

In conclusion, the features suggestive of NASH were more frequently observed in the CC patients than in the controls of viral etiology even in Japan where obesity is not prevalent. It indicates that NASH may be a possible cause of CC regardless of the prevalence of obesity. Moreover, HCC developed less frequently and its prognosis was less severe in the CC group, indicating that CC may take an indolent clinical course. Further larger studies are necessary to understand the clinical features of CC.

Abstract

AIM: To evaluate whether an automatically controlled cut system (endocut mode) could reduce the complication rate of endoscopic sphincterotomy (EST) and serum hyperamylasemia after EST compared to the conventional blended cut mode.

METHODS: From January 2001 to October 2003, 134 patients with choledocholithiasis were assigned to either endocut mode group or conventional blended cut mode group at the time of sphincterotomy. The two groups were retrospectively compared for the complications after EST and serum amylase level before and 24 h after the procedure.

RESULTS: Of the 134 patients treated, 79 were assigned to conventional blended cut mode group and 55 to endocut mode group. There was no significant difference in age, sex, and serum amylase level before EST between the two groups. Complications were found in 5 patients of the endocut mode group (9%): hyperamylasemia (5 times higher than normal) in 4 and moderate pancreatitis in 1. Complications were found in 13 patients of the conventional blended cut mode group (16%): hyperamylasemia in 12 and moderate pancreatitis in 1. Serum amylase levels were elevated in both groups 24 h after EST ($P < 0.02$). The average serum amylase level 24 h after EST in the conventional blended cut mode group was significantly higher than that in the endocut mode group ($P < 0.05$).

CONCLUSION: Endocut mode offers a safety advantage over conventional blended cut mode for pancreatitis after EST by reducing hyperamylasemia.

Key words: Endocut mode; Endoscopic sphincterotomy; Choledocholithiasis

INTRODUCTION

The main complications of endoscopic sphincterotomy (EST) are pancreatitis, hemorrhage, perforation and sepsis[1-4]. Acute pancreatitis is still the most common complication associated with the procedures. Testoni *et al*[5] have shown that pancreatitis is associated with the elevation of serum amylase level 24 h after ERCP/EST.

An automatically controlled cut system, endocut mode (ICC 200 ERBE), can reduce the danger of papillary hemorrhage but may lead to pancreatitis[6]. This study was to evaluate whether the endocut mode could reduce the complication rate of EST and serum hyperamylasemia after EST compared to the conventional blended cut mode.

MATERIALS AND METHODS

From January 2001 to October 2003, 134 patients admitted to Aso Iizuka Hospital due to choledocholithiasis were assigned to either endocut mode group or conventional blended cut mode group at the time of EST. Three gastroenterologists performed the procedure. An Olympus UES-10 electrosurgical generator (Olympus, Japan) was used for conventional cut with the blended current set at output limit 30W and the coagulation current set at output limit 15W. An Erbe ICC200 (Erbe, Germany) was used for endocut with the effect 3 current set at output limit 120W and forced coagulation current set at output limit 30W.

The two groups were retrospectively compared for the complications, pancreatitis, hemorrhage after EST and

Table 1 Age, sex, and serum amylase level before EST

	Number of patients	Yr	Male (%)	Female (%)	Amylase (IU/L)
Conventional cut group	79	73.5±1.3	54	46	102±8
Endocut group	55	70.8±1.8	56	44	101±18

Table 2 EST complications

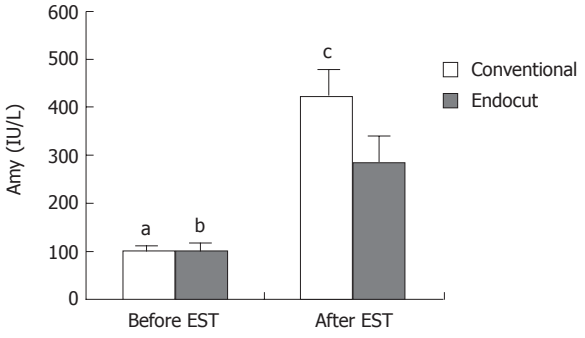

Figure 1 Average serum amylase level before and after EST. Data are expressed as mean ± SE. $^{a}P < 0.02$ *vs* conventional cut group after EST; $^{b}P < 0.02$ *vs* endocut group; after EST; $^{c}P < 0.05$ *vs* endocut group after EST.

serum amylase level before and 24 h after the procedure. Pancreatitis was defined when CT grade was higher than grade II (local pancreas swelling). A bleeding complication was defined when the patient required blood transfusion or had a drop in hematocrit level greater than 5%.

Results were presented as mean ± SE. Complications in the two groups were evaluated using χ^2 test and Fisher's exact test. Differences in serum amylase levels between the two groups were evaluated by Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

One hundred and thirty-four patients were evaluated in this study. Seventy-nine patients underwent conventional blended cut and 55 patients underwent endocut. There were no significant differences in age and sex distribution as well as serum amylase level before EST (Table 1).

Complications were found in 5 patients of the endocut mode group (9%): hyperamylasemia in 4 (serum amylase level was 5 times higher than normal) and moderate pancreatitis in 1 patient. On the other hand, complications were found in 13 patients of the conventional blended cut mode group (16%): hyperamylasemia in 12 patients and moderate pancreatitis in 1 patient (Table 2). One patient in each group had mild bleeding not showing hematocrit decrease. No major complications such as perforation were found in both groups. There were no significant differences in the incidence of complications such as pancreatitis, hemorrhage, and hyperamylasemia between the two groups.

Serum amylase levels were elevated in both groups 24 h after EST ($P < 0.02$). The average serum amylase level 24 h after EST in the conventional blended cut mode group was significantly higher than that in the endocut mode group ($P < 0.05$, Figure 1).

DISCUSSION

Since the introduction of EST, the indications for the procedure have grown steadily. The complications of EST are similar to those of diagnostic ERCP but occur more frequently. Freeman *et al*[3] have shown that the incidence of pancreatitis after EST is 5.4% and significant risk factors for pancreatitis are sphincter of Oddi dysfunction, younger age, the number of pancreatic contrast injections, precut sphincterotomy, and difficulty of cannulation. Elta *et al*[7] reported that the type of electrocautery current affects this risk and found that the use of pure cut current is associated with a lower incidence of pancreatitis rather than blended current.

A new high-frequency current generator equipped with an automatically controlled system (endocut mode) has been currently used in EST. With endocut mode, each interval of cutting is automatically triggered by the initial electric arc sensor within the ICC 200 and is thus reproducible in duration. The automatically-fractionated cut and controlled cutting speed can prevent perforation of the major papilla[6].

In this study, we observed the most common complications such as moderate pancreatitis and mild hemorrhage in both groups, which are consistent with the other reports[3,4,6,7]. The endocut mode could reduce hemorrhage after EST[6,9-10], but leads to pancreatitis[6]. On the other hand, Ellahi *et al*[11] reported that the endocut mode does not offer a safety advantage over the conventional blended cut mode. In this study, there were no significant differences in the incidence of complications such as pancreatitis and hemorrhage between the two groups. The rate of hyperamylasemia (serum amylase level was 5 times higher than normal) was 7% in the endocut mode group and lower than 15% in the conventional blended cut mode group. But there was no significant difference in the incidence of hyperamylasemia between the two groups. In this study, the number of patients might be too small to have a statistical significance as for the incidence of complications.

A larger study is needed for the evaluation of usefulness about the endocut mode in EST, because the number of patients was less than 150 in this and other studies[6,9-11]. It was reported that the endocut mode reduces hemorrhage after EST[8]. Our results showed that the average serum amylase level 24 h after EST in the endocut mode group was significantly lower than that in the conventional blended cut mode group ($P < 0.05$), which is consistent with study of Shinozuka *et al*[9]. In this study, in comparison with a conventional blended cut mode

unit, all the examiners noted the smooth, easy EST by the endocut mode unit. Thus it might shorten the procedure time, lower the risk of major papilla's edema as well as the number of contrast injections and the serum amylase level after EST.

The endocut mode offers a safety advantage over conventional blended cut mode for pancreatitis after EST by reducing the hyperamylasemia.

Abstract

AIM: To examine the hepatitis C virus (HCV) levels and immunological markers in cirrhotic patients after splenectomy.

METHODS: HCV RNA titers as well as cellular and humoral immune markers were determined in 20 cirrhotic patients after splenectomy and in 32 cirrhotic controls with an intact spleen.

RESULTS: Serum HCV RNA titers were lower in the splenectomized patients than in the controls ($186 \pm 225 \times 10^3$ copies/mL *vs* $541 \pm 417 \times 10^3$ copies/mL, $P < 0.01$). HCV RNA was judged to have been spontaneously eradicated in 4 splenectomized patients, but in none of the controls. Natural killer cell activity was higher in the splenectomized patients than in the controls (41.2 ± 19.3% *vs* 24.7 ± 15.3%, $P < 0.01$), and natural killer cell activity was negatively correlated to HCV RNA titers in the splenectomized patients except in those with serotype 2-related infection. The CD4/CD8 ratio was significantly lower in the splenectomized patients than in the controls.

CONCLUSION: The findings suggest that splenectomy may diminish virus burden in cirrhotic patients with HCV infection at least in part, through augmentation of natural killer cell activity.

Key words: Hepatitis C virus; Liver cirrhosis; Natural killer cell; Splenectomy

Sekiguchi T, Nagamine T, Takagi H, Mori M. Reduction of virus burden-induced splenectomy in patients with liver cirrhosis related to hepatitis C virus infection. *World J Gastroenterol* 2006; 12(13): 2089-2094

INTRODUCTION

Persistent infection with hepatitis C virus (HCV), a parenterally transmitted RNA virus, occurs in 70%-80% of HCV-infected patients. Chronic hepatitis C progresses gradually to liver cirrhosis, a condition frequently associated with hepatocellular carcinoma (HCC)[1-3]. To prevent progression to chronic liver disease, continuous virus burden must be interrupted. However, spontaneous elimination of the virus load rarely occurs[4-8]. HCV-specific cytotoxic T cells are thought to play a principal effector role in host defense against HCV infection[9-11]. In addition, natural killer (NK) cells are believed to participate in the defense against hepatitis viruses, because the human liver contains a significantly higher number of NK cells than peripheral blood or any other organs[12]. NK cells exert various effector functions during the early phase of HCV infection, including induction of apoptosis and production of IFN-gamma and TNF-alpha[13-16]. In addition, NK cells are suggested to play a crucial role in the clearance of HCV in patients undergoing interferon therapy[17,18], but the significance of NK cells in the pathogenesis of chronic hepatitis C remains to be clarified. Although several studies have reported reduced activity of NK cells in cirrhotic patients with a history of alcohol abuse[19,20] and complication of HCC[21-23], little is known whether NK cells vary in patients with HCV-positive liver cirrhosis[24,25].

Splenectomy was a popular surgical procedure for esophageal varices associated with liver cirrhosis until endoscopic sclerotherapy has become the first line treatment[26,27]. Splenectomy may compromise the immune system because the spleen plays an important role in phagocytosis and antibody production[28,29]. On the other hand, there is some evidence that splenectomy can positively affect Kupffer cell functions in the liver, and protects against viral infection[30-33]. Ferrante *et al*[32] have insisted that a compensatory increase in the activity of NK cells in splenectomized patients might offer protection against infection and malignant disease. Pereira *et al*[31] reported that the HCV genome is detectable in spleen specimens obtained from HCV antibody seropositive patients associated with chronic schistosomiasis, suggesting that the spleen is an extrahepatic reservoir of the virus. Splenectomy may therefore influence the immune system and virus load of cirrhotic patients with HCV infection. Changes in immune

mediators and HCV burden in cirrhotic patients after splenectomy remain to be evaluated. In the present study, we retrospectively evaluated the effect of splenectomy on replication of HCV as well as cellular and humoral immunity including NK cell activity and lymphocyte subsets in cirrhotic patients with HCV infection.

MATERIALS AND METHODS

Patients

Twenty Japanese cirrhotic patients positive for anti-HCV antibody after splenectomy were enrolled in the present study (splenectomized). Splenectomy was performed in combination with surgical treatment of esophageal varices (14 cases), HCC (5 cases), or gastric cancer (1 case). The patients were referred for follow-up at our hospital. The mean duration of follow-up after splenectomy was 9.2 years. Thirty-two HCV-positive cirrhotic patients with an intact spleen served as controls and were followed up at our hospital. All controls had complications of esophageal varices, 17 of whom were treated for esophageal varices with endoscopic sclerotherapy and/or band ligation. Morphological diagnosis of post-hepatitic cirrhosis was performed in all splenectomies and 22 controls. The remaining 10 controls were diagnosed clinically based on typical clinical and laboratory findings of liver cirrhosis and characteristic liver findings at computed tomography and ultrasonography, because 6 patients showed complicated severe coagulopathy and 4 patients refused liver biopsy. No patients were diagnosed with chronic liver diseases, such as alcoholic hepatitis, autoimmune hepatitis, and chronic hepatitis B infection, or drug-induced liver disease. Patients with a history of alcohol abuse or diagnosed as HIV positive were excluded. None of our patients underwent anti-viral therapy using interferon during the period studied. Patient characteristics are shown in Table 1. Clinical features, severity of liver cirrhosis according to Child' s classification, association of HCC, HCV serotype, and liver function tests did not differ significantly between the two groups. Platelet counts were significantly higher in the splenectomized patients than in the controls. The study protocol was approved by the Ethics Committee of the Department of Internal Medicine, and informed consent was obtained from all patients.

Serum HCV RNA levels were measured to evaluate the effect of splenectomy on viral load. In addition, peripheral activity of NK cells, proportion of CD4 and CD8 subsets of T cells, and levels of serum β2-microglobulin and soluble interleukin 2 receptor (sIL2R) were examined.

Virology

The presence of HCV antibody was determined by the second and/or third generation of enzyme-linked immunosorbent assay (Ortho Diagnostic System Co., Ltd., Tokyo, Japan) and confirmed by recombinant immunoblot assay (Chiron RIBA-2 and/or RIBA-3). HCV serotype was examined by serotyping assay (SRL Laboratory Co., Tokyo, Japan) according to the method of Tsukiyama-Kohara *et al*[34]. Serotype 1 corresponded to types 1a and 1b, while serotype 2 corresponded to types 2a and 2b of the Simmonds classification[35]. Quantitative levels of HCV-RNA in serum samples were analyzed by combined reverse transcription PCR assay (Amplicor-HCV monitor; Nippon Roche, Tokyo, Japan) that could detect viral concentrations above 10^3 copies per mL[36]. If serum HCV-RNA was undetectable by this assay, we performed the Amplicor hepatitis C viral test twice, which is more sensitive and can detect as low as 10^2 copies per mL[37]. If HCV RNA was still undetectable, it was judged to indicate 'virus eradication'.

Table 1 Characteristics of cirrhotic patients with HCV infection

	Splenectomy (+)	Splenectomy (-)
Age (yr)	62.6±5.5	63.2±13.6
Gender (m:f)	8:12	13:19
HCV Serotype		
1	15	29
2	3	3
unknown[a]	2	0
Child's Classification		
A	11	18
B	6	8
C	3	6
Association of HCC	7/20	9/32
Total bilirubin (mg/dL)	1.2±0.5	1.2±0.7
Albumin (g/L)	35±6	37±4
γ-globulin (g/L)	23±0.8	20±5
AST (IU/L)	65.3±30.5	61.8±23.7
ALT (IU/L)	31.5±9.1	25.1±4.9
Platelets ($\times 10^4$ /μL)	15.2±4.5	8.1±2.7[b]
NK cell activity (%)	41.2±19.3	24.7±15.3[b]
CD4/CD8	1.2±0.4	1.6±0.6[c]
β2-MG (mg/L)	2.5±1.2	2.4±0.6[n.s]
sIL2R (U/mL)	917±445	842±190[n.s]

HCC: hepatocellular carcinoma; AST: aspartic aminotransferase; ALT: alanine aminotransferase; NK cells: natural killer cells; β2-MG: β2-microglobulin; sIL2R: soluble interleukin 2 receptor. a: undeterminable serotype; [b]$P<0.001$, [c]$P<0.05$ *vs* splenectomized patients; NS: no significant difference.

Immunological markers

NK cell activity was assessed against the k-562 cell line (Dainippon Pharmaceutical Co., Osaka, Japan) marked with ^{51}Cr using a cytotoxicity test for 3.5 h[38]. Blood samples taken from the cubital vein were collected into heparinized tubes. After centrifugation of the blood sample with a lymphocyte separation medium (Limphosepar I; Tokyo, Japan), the interface mononuclear cells were collected and suspended at a cell density of 1×10^6 /mL in RPMI-1640 medium (IBL; Gunma, Japan) and supplemented with 10% FBS (Cansera; Ontario, Canada). Peripheral blood monocytes (2×10^5 cells) were added to round-bottomed 96-well microplates containing ^{51}Cr-labeled target cells (1×10^4 cells) in 0.2 mL of RPMI-1640 medium supplemented with 10% FBS. The effector cell/target cell ratio was determined as 20. After centrifugation at 800 r/min for 5 min using an exclusive centrifuge for microplates, the cells were incubated for 3.5 h at 37℃ under 50 mL/L CO_2 in air. After incubation, the culture supernatant was harvested using PETΣ-96 (Sohken; Tokyo, Japan), and the radioactivity was determined using a gamma counter (1272 clini gamma, Wallac; Turuku, Finland). The percentage of cytotoxicity was calculated as follows: % cytotoxicity = (experimental ^{51}Cr release - spontaneous ^{51}Cr release) /(maximal ^{51}Cr release-spontaneous ^{51}Cr release) × 100.

The proportion of peripheral CD4 and CD8 subsets

Table 2 Characteristics of cirrhotic patients after splenectomy

	Age	Sex	Years After splenectomy	Serotype	HCV RNA (k copies/mL)	Child's classification	association of HCC[1]

[1] Hepatocellular carcinoma; [2] undeterminable serotype.

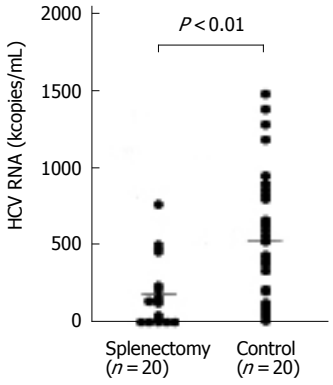

Figure 1 Serum HCV RNA titers in patients with liver cirrhosis. Splenectomized patients had significantly lower titers of HCV RNA than cirrhotic controls with an intact spleen.

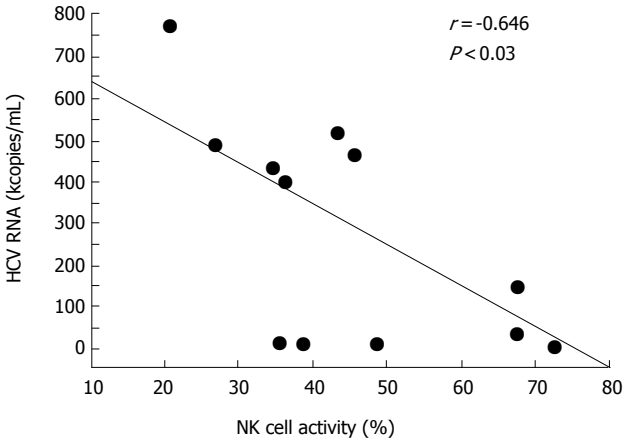

Figure 2 Relationship between HCV RNA titers and NK cell activity in non-serotype 2 splenectomized patients. There was a significantly negative correlation between HCV RNA titers and NK cell activity in non-serotype 2 splenectomized patients.

was assayed by flow cytometry. β2-microglobulin levels were measured by latex immunoaggregation assay (Eiken Co., Tokyo, Japan). sIL2R levels were determined using the cell-free IL-2R EIA kit.

Statistical analysis

Results were expressed as mean ± SD. Statistical analyses were carried out using the computer program StatView-J4.5 (Abacus Concepts, Inc. Berkeley, USA). Mean quantitative values were compared using Student's *t* test. Nonparametric data were compared using the Mann-Whitney U-test. All *p*-values were two-tailed. $P < 0.05$ was considered statistically significant.

RESULTS

HCV RNA titers (Figure 1)

Mean titers of HCV RNA were significantly lower in the splenectomized patients than in the cirrhotic controls ($186 \pm 225 \times 10^3$ copies/mL *vs* $541 \pm 417 \times 10^3$ copies/mL, $P < 0.01$). Among the serotype 1-related patients (15 splenectomized and 29 controls), the splenectomized patients showed a reduced viral load compared with the controls ($246 \pm 231 \times 10^3$ copies/mL *vs* $590 \pm 407 \times 10^3$ copies/mL, $P < 0.01$). Four (20.0%) of 20 splenectomized patients showed eradicated HCV in serum after 11 years of splenectomy in one patient, 12 years in two patients and 16 years in one patient. Two of the 4 patients had serotype 1-related HCV infection, while the serotype was undetermined in the other 2 patients (Table 2). No controls spontaneously eradicated HCV in their serum. Among the splenectomized patients with serotype 1, HCV RNA levels were lower, but not significantly lower in patients with a longer follow-up time (≥10 years) than in those with a shorter follow-up time (<9 years; $155 \pm 202 \times 10^3$ copies/mL *vs* $350 \pm 531 \times 10^3$ copies/mL, $P = 0.103$). No gender-related difference in virus load was observed in controls with serotype 1 (12 males: $649 \pm 469 \times 10^3$ copies/mL *vs* 17 females: $521 \pm 329 \times 10^3$ copies/ mL, $P = 0.43$).

Immunological markers (Table 1)

Peripheral activity of NK cells was significantly higher in the splenectomized patients than in the controls. In both splenectomized patients and controls, NK cell activity was lower in patients complicated by HCC than in those without HCC, although the difference was not significant [HCC (+): 33.6%±11.8%, HCC (-): 47.6%±18.1%, $P=0.16$]. NK cell activity in LC patients with an intact spleen was not significantly different from that in healthy subjects (data not shown).

The splenectomized patients showed a reduced proportion of CD4 cells, a similar proportion of CD8 cells and a significantly lower ratio of CD4/CD8 compared with those of the controls. Serum sIL2R and β2-microglobulin values were similar in both groups.

Relationship between HCV RNA levels and immunological markers

In the splenectomized patients without serotype 2-related infection, there was a significantly negative correlation between HCV RNA titers and NK cell activity (Figure 2). Such a relationship was not found in the controls. No relationships were found between HCV RNA levels and CD4/CD8 ratio, sIL2R, or β2-microglobulin.

DISCUSSION

This was the first retrospective study to examine the effect of splenectomy on the reduction of HCV in cirrhotic patients. We found that HCV RNA titers were significantly lower in cirrhotic patients after splenectomy than in cirrhotic controls with an intact spleen, indicating that splenectomy can reduce virus burden. The mechanisms through which splenectomy helps to reduce HCV remain to be determined, but a few possibilities have been suggested. One explanation for reduced viral load after splenectomy is that it might be immunologically based. The role of NK cells in controlling HCV replication remains obscure, but NK cells hold the potential to play a vital role in controlling HCV replication in hepatic cells using IFN-gamma-dependent mechanism[13]. Reports of the effect of splenectomy on the peripheral activity of NK cells are contradictory[27-31]. In the present study, HCV-positive cirrhotic patients splenectomy had the augmented activity of NK cells compared with those with an intact spleen. An inverse correlation between HCV RNA titers and NK cell activity was shown in the splenectomized patients, but not in the controls with an intact spleen. In addition, Ikuta *et al*[39] reported that liver mononuclear cells from splectomized mice produce a significantly larger amount of IFN-gamma than those from sham-operated mice. Taken together, increased NK cell activity post-splenectomy may reduce virus burden in HCV-positive cirrhotic patients.

The association of cirrhosis with HCC[21-23], cholestasis[40], and protein calorie malnutrition[20] is also important because these factors may influence the peripheral activity of NK cells in cirrhotic patients. Similar to previous reports, our data showed that cirrhotic patients complicated by HCC had a lower NK cell activity than those without HCC. The incidence of complication of HCC was slightly but not significantly higher in the splenectomized patients (35%) than in the controls (28%). Total bilirubin levels and severity of liver cirrhosis according to Child's classification were similar between the splenectomized patients and the controls. Accordingly, these biochemical and physiological factors did not cause increased activity of NK cells in patients after splenectomy.

Splenectomized patients with a longer follow-up time (≥10 years) had lower HCV RNA levels than those with a shorter follow-up time (9< years), although the difference was not significant. Further research should attempt to determine whether the lower HCV titers of patients with a longer follow-up time are due to the natural course of infection. To estimate the relevance of aging to virus load, we examined the changes in HCV levels over a mean period of 4.5 years in 20 patients with HCV-positive cirrhosis. The mean HCV RNA titers did not vary significantly during this period (baseline, 6.6±9.2 Meq/mL; after 4.5 years, 6.1±8.5 Meq/mL). Kato *et al*[41] reported that the amount of HCV RNA tends to increase as the duration of infection increases. These findings indicate that the virus load of splenectomized patients does not spontaneously reduce with age.

Interestingly, four splenectomized patients showed spontaneous eradication of HCV, whereas cirrhotic controls showed no such spontaneous clearance during the observation period. This is in contrast to the findings that spontaneous elimination of virus load rarely occurs in patients with persistent HCV infection and chronic liver disease[4-8]. To date, little attention has been focused on identifying the viral and host factors involved in the spontaneous disappearance of serum HCV RNA, because the time point of infection is unknown for many patients, which makes a prospective evaluation of long-term outcome of infection problematic. Evidence for factors related to the natural disappearance of HCV has been reported by Furuzaki *et al*[8]. HCV levels below 1.0 Meq/mL can contribute to natural clearance of the virus. Thus, reduced virus load caused by activated NK cells may have led to HCV eradication in four of the splenectomized patients.

The present findings suggest that splenectomy may diminish or remit virus burden in HCV-positive cirrhotic patients at least in part by increasing NK cell activity. However, simply because four HCV-eradicated patients underwent splenectomy before a method for HCV RNA assay was developed, it would be rash to conclude that splenectomy can lead to their clearance of HCV. Furthermore, influence of surgery for esophageal varices and HCC on virus load cannot be ruled out. A prospective study on the effect of splenectomy on HCV replication should be undertaken in order to clarify whether splenectomy may reduce virus burden and/or eradicate HCV in serum of HCV-positive cirrhosis.

Abstract

AIM: To present our experience with endoscopic placement of an esophageal endoprosthesis in 19 patients.

METHODS: A retrospective evaluation was made for the use of 19 stents positioned at the level of the cervical esophagus: 11 for malignant tumours (7 causing obstruction, 4 complicated by an esophago -tracheal or -cutaneous fistula), and 8 for an acquired benign tracheo-esophageal fistula due to prolonged intubation. The covered Ultraflex stent was used in all cases except two. These two patients had an esophagocutaneous fistula following laryngectomy and a Flamingo Wall stent was used.

RESULTS: Stent implantation was technically successful in all patients. Dysphagia score was improved from 3 to 2 in stenosis patients, while sealing of the fistula was achieved in all cases. The median hospital stay was 3 d for malignant tumour patients and 13.5 d for esophagocutaneous fistula patients. One Ultraflex stent and two Flamingo Wall stents were easily removed 33 d and 3 months respectively after implantation when the fistulas had totally occluded.

CONCLUSION: Endoprosthesis implantation for malignancy and/or fistula of malignant or benign origin at the level of the cervical esophagus is an easy, well tolerated, safe and effective procedure with no complications or mortality.

Key words: Cervical endoprosthesis; Pharyngo-esophageal stenosis; Dysphagia; Esophageal carcinoma; Esophagotracheal fistula

INTRODUCTION

The insertion of an endoprosthesis is one of the most acceptable means of palliative treatment of patients with obstructing esophageal lesions and/or an existing esophagorespiratory fistula. However, the proximity to the cricopharyngeal sphincter is traditionally regarded as a relative contraindication, because of the potential problems of persistent foreign body sensation, pain, odynophagia, compression of the trachea or proximal migration of the prosthesis[1-3].

Recently, this traditional view has begun to change, as witnessed by an augmented number of case reports or small series of data presentations[1,2,4-11]. In such patients, with the inability to swallow even their own saliva at times, palliative intubation aimed at relief of dysphagia, maintenance of nutrition and avoidance of respiratory complications is the primary treatment goal, while the close relationship between the cricopharynx and the cervical lesion continues to be a challenge for every endoscopist.

Herein, we present our experience with stent placement in the cervical esophagus at the level of hypopharynx and/or the upper esophageal sphincter.

MATERIALS AND METHODS

Patients

Over the last 10 years (1995-2004), 19 patients were referred to our department to be treated endoscopically for a lesion in the cervical esophagus. There were 11 patients with a malignancy and 8 patients who spontaneously developed tracheo-esophageal fistula [TEF] after prolonged tracheal intubation for mechanical ventilatory support in the ICU.

The eleven carcinoma patients (9 males and 2 females) with a median age of 70 years (range: 62 - 82 years) suffered from: laryngeal (3 cases), hypopharyngeal (2 cases) and esophageal inlet carcinoma (2 cases), all causing severe stenosis and obstruction, two cases of high esophagotracheal fistula, one due to radical thyroidectomy and concomitant radiotherapy and the other due to an inoperable hypopharyngeal carcinoma and two cases of esophagocutaneous fistula after total laryngectomy for carcinoma, performed postirradiation (Table 1).

The seven patients with obstructing-type cancer

Table 1 Data of carcinoma patients

	Age	Gender	Disease
1	64	Male	Laryngeal carcinoma causing obstruction
2	72	Male	Laryngeal carcinoma causing obstruction
3	75	Male	Laryngeal carcinoma causing obstruction
4	65	Male	Hypopharyngeal carcinoma causing obstruction
5	68	Male	Hypopharyngeal carcinoma causing obstruction
6	70	Female	Esophageal inlet carcinoma causing obstruction
7	80	Male	Esophageal inlet carcinoma causing obstruction
8	62	Female	Esophagotracheal fistula after thyroidectomy + radiotherapy
9	64	Male	Esophagotracheal fistula after hypopharyngeal carcinoma
10	82	Male	Esophagocutaneous fistulas after total laryngectomy + radiotherapy
11	72	Male	Esophagocutaneous fistulas after total laryngectomy + radiotherapy

Table 2 Data of benign disease patients

	Age	Gender	Underlined disease
1	21	Male	Multiple trauma
2	73	Female	Multiple trauma [in septic state]
3	76	Male	Cerebral hemorrhage
4	56	Male	Cerebral hemorrhage
5	47	Female	Post-operative complications [in septic state]
6	70	Female	Post-operative complications
7	72	Male	Post-operative complications [in septic state]
8	72	Male	Post-operative complications [in septic state]

presented with a median dysphagia score of 3 (unable to swallow liquids) ranging from 2 to 4. Under diazepam-induced conscious sedation they were subjected to a Savary bougie progressive dilatation of the stenosis for one to two sessions depending on the rigidity of the tumour. Dilatation was performed over a guide wire which was advanced into the stenosis through the endoscope up to the point of 12.8 mm in diameter, to facilitate the rapid expansion of the stent.

After dilatation the endoscope was advanced to the tumour site. The total length of the stenosis and the distance of the tumor upper orifice from the incisor teeth, were carefully recorded due to their great importance for the correct placement of the stent.

The remaining 4 patients had no need for dilatation, thus immediately following insertion of the endoscope and inspection of the tumourous fistulae, the exact distance of the most proximal end of the lesion from the incisors and the total length of the lesion were recorded as above.

Eight patients had benign TEF (5 males and 3 females with a median age of 71 years, range 21-76 years) due to multiple trauma (2 cases), extended cerebral hemorrhage (2 cases) and post-operative complications (4 cases) implicating cardio-respiratory insufficiency. All patients, previously subjected to a percutaneous endoscopic gastrostomy for feeding, had an overall median intubation time of 30 d (range 15 - 80 d) and had been subjected to percutaneous tracheostomy a median of 16 d (range, 5-62 d) before diagnosis of TEF. All were characterized by poor prognosis and 4 of them were in a septic state (Table 2).
