### Abstract

**AIM:** To investigate whether red wine and green tea could exert anti-*H pylori* or anti-VacA activity *in vivo* in a mouse model of experimental infection.

**METHODS:** Ethanol-free red wine and green tea concentrates were administered orally as a mixture of the two beverages to *H pylori* infected mice, or separately to VacA-treated mice. Gastric colonization and gastric inflammation were quantified by microbiological, histopathological, and immunohistochemical analyses.

**RESULTS:** In *H pylori*-infected mice, the red wine and green tea mixture significantly prevented gastritis and limited the localization of bacteria and VacA to the surface of the gastric epithelium. Similarly, both beverages significantly prevented gastric epithelium damage in VacA-treated mice; green tea, but not red wine, also altered the VacA localization in the gastric epithelium.

**CONCLUSION:** Red wine and green tea are able to prevent *H pylori*-induced gastric epithelium damage, possibly involving VacA inhibition. This observation supports the possible relevance of diet on the pathological outcome of *H pylori* infection.

### INTRODUCTION

*H pylori* chronically infects human stomach, causing atrophic gastritis. The majority of infections are asymptomatic; nevertheless, infected individuals can incur severe gastroduodenal diseases such as peptic ulcer<sup>[1]</sup> and gastric mucosa-associated lymphoid tissue (MALT) lymphoma<sup>[2]</sup>. *H pylori* infection plays a relevant role in gastric carcinogenesis, which was also shown in animals<sup>[3]</sup>. The current antibiotic-based therapies against *H pylori* are generally effective, but can fail due to antibiotic resistance or lack of patient compliance. To colonize the host stomach, *H pylori* expresses several factors that can play a role in pathogenesis. One that is most characterized is the vacuolating cytotoxin VacA, which induces cell vacuolation and rearrangements of late endosomes and lysosomes *in vitro*<sup>[4]</sup>. VacA forms anion-selective, urea-permeable channels in artificial and plasma membranes<sup>[5]</sup>. It promotes diffusion across the epithelium of urea<sup>[6]</sup>, which is hydrolysed by *H pylori* urease, leading neutralisation of acidic gastric juice and thus favouring bacterial survival. *In vitro*, VacA exhibits several properties that suggest its role in disturbing the host immune system, although *in vivo* experimental proof of similar activity remains to be provided<sup>[7]</sup>. The most evident *in vivo* activity of VacA is to cause damage of gastric epithelium, as shown in murine models<sup>[8,9]</sup>. Plant-derived substances have been reported to limit *H pylori* gastric colonization in Mongolian gerbils<sup>[10,11]</sup>. We have previously found that polyphenols and polyphenol-rich beverages, such as tea and wine, inhibit VacA activity *in vitro*<sup>[12]</sup>, and that some polyphenols can limit both *H pylori*- and VacA-induced gastric damage *in vivo*<sup>[13]</sup>. Also, it has been recently reported that hop bract extract exerts anti-VacA activity *in vitro* and *in vivo*<sup>[14]</sup>. In the present paper we investigated whether red wine and green tea concentrates could influence gastric colonization or gastric pathology in *H pylori*-infected or VacA-treated mice.

## MATERIALS AND METHODS

### Bacteria

SPM 326, a Type I *H. pylori* strain expressing s1/m1 VacA isoform, was used<sup>[15]</sup>. Bacteria were grown at 37°C in Columbia Agar (Oxoid, Basingstoke, UK) plates containing 5% fresh defibrinated horse serum and Dent's supplement (Oxoid), under microaerophylic conditions, using CampyGen (Oxoid), and harvested in saline immediately before challenge.

### Toxin

Native s1/m1-type VacA was produced and tested for vacuolating activity on HeLa cells as previously described<sup>[16,17]</sup>. Prior to use, it was activated at pH 2.0 for 10 min at R.T., then neutralized and diluted in saline.

### Red wine and green tea concentrates

Red wine (RW) was produced on a local (Sarmede, Italy) family vineyard by the traditional spontaneous fermentation process, without additives. Green tea (GT) infusion was obtained by boiling 2 g of lyophilised and otherwise untreated leaves from Morocco in 1 L of distilled water for 5 min. GT and alcohol-free RW concentrates were obtained by vacuum distillation at 30°C, then stored in aliquots at -20°C. Prior to administration concentrates were thawed, diluted in water to reach 3-fold (RW) or 1.5-fold (GT) concentration in comparison with the original volume, and filtered at 0.2 µm. RW + GT mixture was prepared at the same final concentrations.

### Mice and study design

Specific-pathogen-free mice (Charles River, Calco, Italy) were housed and treated in compliance with the current law. The schedule of the treatments is summarized in Table 1. Overnight starved 6-wk old CD1 mice (average body weight 22 g) were infected intragastrically by two administrations each other day of 10<sup>8</sup> CFU/mouse<sup>[15]</sup>. Alternatively, starved 6-wk old BALB/c mice (average body weight 18 g) received two intragastric administrations each other day of either 10 µg or 50 µg of VacA<sup>[8]</sup>. Controls received saline only. Starting 24 h before infection or VacA administration, the animals had free access to drinking water containing 1% glucose and RW + GT in the case of *H. pylori* infection, RW or GT in the case of VacA administration. Controls drank a 1% glucose solution. The beverages were changed daily; their intake was about 5 mL/d per mouse, without appreciable differences among the different groups. Two weeks after infection, or 4 d after the first VacA treatment, the animals were euthanized, and each stomach immediately removed and cut along the greater and lesser curvature, obtaining two equivalent parts. One part was formalin fixed and paraffin embedded for further histopathological analysis. Gastric mucosa was scraped from the remaining half stomach and cultured on selective plates, prepared as described above with the addition of 0.2 mg/mL bacitracin (Sigma-Aldrich), to quantify *H. pylori* colony forming units (CFU).

### Histopathology

From paraffin-embedded stomachs 4 µm-thick sections

Table 1 Schedule of treatments

Group	n	D -1 to the D of sacrifice	D 0	D 2	D 4	D 14
RW + GT	6	RW + GT	Infection	Infection	-	Sacrifice
Infected	6	1% glucose	Infection	Infection	-	Sacrifice
Non infected	6	1% glucose	Saline	Saline	-	Sacrifice
RW	5	RW	VacA 10 µg	VacA 10 µg	Sacrifice	-
	5	RW	VacA 50 µg	VacA 50 µg	Sacrifice	-
GT	5	GT	VacA 10 µg	VacA 10 µg	Sacrifice	-
	5	GT	VacA 50 µg	VacA 50 µg	Sacrifice	-
VacA control	5	1% glucose	VacA 10 µg	VacA 10 µg	Sacrifice	-
	5	1% glucose	VacA 50 µg	VacA 50 µg	Sacrifice	-
Saline	5	1% glucose	Saline	Saline	Sacrifice	-

were cut, dewaxed, and stained with haematoxylin-eosin (HE), then blindly examined. Gastritis was graded in antrum, corpus and fundus of each stomach according to the updated Sydney System<sup>[18]</sup>, and scored from 0 to 3 corresponding to normal, mild, moderate and severe, respectively. Gastric sections were also subjected to immunohistochemical (IHC) staining using either an anti-*H. pylori* polyclonal antibody (HistoLine) or an anti-VacA monoclonal antibody as already described<sup>[13,19]</sup>.

### Statistical analysis

Data were evaluated by one-tailed Mann-Whitney *U* test. Probability values less than 5% ( $P < 0.05$ ) were considered and referred to as statistically significant.

## RESULTS

### Red wine and green tea alter the *H. pylori* localization in gastric mucosa

*H. pylori* SPM 326 colonized stomachs of both control and RW + GT-treated mice, giving geometric means of  $1.6 \times 10^3$  and  $2.6 \times 10^3$  CFU/stomach respectively, lacking significant difference ( $P = 0.22$ ). While in RW + GT-treated animals *H. pylori* was detectable by IHC mainly on the surface of the gastric mucosa (Figure 1A), in the infected control both superficial and deep staining was observed (Figure 1C). In adjacent sections, VacA localization by IHC resulted very similar to that of *H. pylori*, with the difference that VacA staining appeared slightly weaker in RW + GT-treated animals (Figure 1B) and slightly stronger in the infected controls (Figure 1D) as compared with the corresponding *H. pylori* staining.

### Red wine and green tea prevent *H. pylori*-induced gastritis

The observation of HE-stained sections of gastric mucosa of *H. pylori*-infected controls revealed gastric inflammation of normal/mild grade in antrum, and mild/moderate in corpus and fundus. Gastritis scores were assigned to antrum, corpus and fundus of each mouse stomach and the mean of the three gastric sites was calculated. RW + GT-treated mice showed gastritis scores significantly lower than those of the corresponding infected, untreated controls ( $P < 0.05$ ) (Figure 2A).

**Figure 1** Representative images of IHC detection of *H pylori* (A and C) or VacA (B and D) in gastric mucosa sections from *H pylori*-infected mice in the presence (A and B) or in the absence (C and D) of RW + GT treatment. In the gastric epithelium of infected controls (C and D, adjacent sections) *H pylori* and VacA are detectable with a similar pattern, both superficially and deeply, while upon RW + GT treatment (A and B, adjacent sections) the immunostaining is mainly confined to the surface of the epithelium. Inserts at larger magnification show typical *H pylori* morphology (arrowheads).

### Red wine and green tea prevent VacA-induced gastritis

Administration of 10  $\mu$ g of VacA induced significant gastritis as compared with saline treatment ( $P < 0.05$ ), although epithelial damage was little or absent in the antrum, and very mild in corpus and fundus. With this dose of VacA, reduction of gastritis scores was significant upon administration of GT ( $P < 0.05$ ), but not of RW. Treatment with 50  $\mu$ g of VacA induced significant ( $P < 0.01$ ) and more evident gastritis (Figure 2B). The mucosal alterations were significantly milder in mice receiving RW or GT (Figures 2B, 3A and C) than those observed in VacA controls (Figures 2B and 3E). VacA controls presented mild epithelial damage in the antrum, and moderate/severe in corpus and fundus, where alteration of mucosal architecture was observed, with epithelial vacuolisation, diffuse mucosal erosion, and some ulcerations (Figure 3E). Gastric mucosa from saline controls did not show appreciable alterations as expected (Figures 2B and 3G).

### Green tea alters VacA localization in gastric mucosa

The presence and distribution of VacA was examined by IHC in RW- and GT-treated gastric mucosa (Figure 3B and D), in comparison with VacA and saline controls (Figure 3F and H). VacA was detected both superficially and deeply in the gastric mucosa of mice that received either 10  $\mu$ g (data not shown) or 50  $\mu$ g of VacA (Figure

**Figure 2** Gastritis score of *H pylori*-infected (A) or VacA-treated (B) mice in the presence or in the absence of RW and/or GT as indicated. Mean of antrum, corpus and fundus scores of each group. Bars = SE. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  comparison between the indicated groups.

3F), the higher VacA dose producing a qualitatively similar but more intense staining than the lower dose. RW-treated mice showed similar staining as compared with VacA-treated controls (Figure 3B and F, respectively). In contrast, gastric mucosa of GT-treated mice showed only superficial staining of VacA, which was undetectable in the gland crypts (Figure 3D). Saline controls were completely negative as expected (Figure 3H).

## DISCUSSION

Upon experimental infection, CD1 mice are stably colonized by *H pylori* and develop gastric inflammation reproducing several of the aspects of the gastric pathology observed in infected humans<sup>[15]</sup>. We chose to test in this model RW and GT on the basis of their previously demonstrated anti-VacA activity<sup>[12]</sup>, and also because they are very common beverages, whose activity against *H pylori* has been already proposed in other models<sup>[20,21]</sup>. In our model, upon *H pylori* infection, RW + GT did not induce significant variation of gastric colonization levels in terms of CFU count, although qualitatively altering the distribution of bacteria that were localized more superficially in the gastric epithelium. We cannot exclude that such a difference of bacterial localization could have affected the quantification of colonization. However, if on one hand the action of RW + GT on *H pylori* infection level was difficult to quantify, on the other hand we observed a measurable and significant reduction of gastric inflammation. This result could be due to the observed restriction of the infection to the surface of gastric epithelium, but also to the possible inhibition of VacA exerted by RW + GT *in vivo*. In fact, VacA-deficient strains are able to infect mice, even though VacA can confer an advantage at early stages of the infection<sup>[22]</sup>. Thus, *in vivo* inhibition of VacA could be reasonably expected to limit gastric damage, but not necessarily to produce a significant and stable decrease of *H pylori* colonization. Therefore, we evaluated the ability of GT and RW to prevent gastric epithelium damage induced by administration of purified native VacA to BALB/c mice. This mouse strain does not allow stable colonization by SPM326<sup>[23]</sup>, whereas it

**Figure 3** Representative images of sections of gastric corpus mucosa of mice treated with 50 µg of VacA in the presence (A-D) or in the absence (E and F) of RW or GT as indicated, in comparison with saline-treated control (G and H). HE staining (A, C, E and G): VacA control (E) shows a typical loss of mucosal architecture, with areas of cellular debris and inflammatory cells admixture (arrowhead), almost undetectable in the presence of RW (A) or GT (C). IHC detection of VacA (B, D, F and H): distribution of VacA upon RW treatment (B) is both superficial and deep, similarly to that of VacA-treated control (F), while upon GT treatment (D) VacA is detectable only on the surface of gastric epithelium.

is sensitive to VacA<sup>[8]</sup>. In this model both GT and RW were able to significantly prevent VacA-induced gastric inflammation. Moreover, GT treatment resulted in VacA to be localized only on the surface of the gastric epithelium, and not in the gland crypts, similarly to the results observed in *H. pylori*-infected mice subjected to RW + GT treatment, and also similarly to that reported for hop bracts extract administration to VacA-treated mice<sup>[14]</sup>. Thus, under our experimental conditions, different actions on VacA appear

to be exerted by RW and GT, the former preventing gastric epithelium damage without altering the toxin localization, the latter also limiting its penetration in the gastric epithelium. It must be remarked that VacA is not the only actor on the scene of the pathological outcome of *H. pylori* infection, whose mechanisms are only partially known, and that the identification of *H. pylori* virulence factors still requires investigation<sup>[24]</sup>. Both in humans and animals, the disease outcome depends on the virulence of the infecting

strain and on the host's genetic background and immune response<sup>[25-27]</sup>. Also, the development of gastric pathology in humans can be influenced by lifestyle<sup>[28,29]</sup>, and more generally by environmental factors. However, due to the evidence of the direct role of VacA in determining gastric damage<sup>[8,30,31]</sup>, its inhibition can be reasonably considered relevant to limit *H pylori*-induced gastric pathology. In conclusion, we have shown that green tea and red wine can prevent the deterioration of gastric mucosa induced by *H pylori* infection or VacA administration in mice, possibly involving inhibition of VacA toxin. The potential relevance in humans of this protective activity deserves further investigation.

## COMMENTS

### Background

*H pylori* infection of human stomach causes atrophic gastritis, peptic ulcer and gastric mucosa-associated lymphoid tissue (MALT) lymphoma, and plays a relevant role in gastric carcinogenesis. The current antibiotic-based therapy faces problems of antibiotic resistance or lack of patient compliance. No vaccines are presently licensed. Current research focuses on both antimicrobials and vaccines.

### Research frontiers

Several plant extracts or plant-derived substances, including polyphenols, have been reported to exert anti-*H pylori* activity *in vitro* and/or, more importantly, *in vivo*. This research field could lead not only to discover new antimicrobials, but also to clarify the possible relevance of diet in the complex mechanism of host-pathogen interaction and in the pathological outcome of *H pylori* infection.

### Innovations and breakthroughs

We report for the first time the ability of the mixture of red wine (RW) and green tea (GT) to restrict to the mucosal surface the *H pylori* gastric colonization, which otherwise was both superficial and deep. The altered colonization in RW + GT-treated mice was accompanied by the prevention of gastritis, similarly to that reported by Matsubara *et al* with GT extracts in Mongolian gerbils. In mice administered with VacA toxin, GT treatment both prevented gastric inflammation and limited VacA penetration into the gastric mucosa, while RW was able to prevent gastric inflammation only; the effect of both substances can be at least in part related to VacA inhibition, which we have previously observed *in vitro* with these substances. The results obtained with GT in VacA-treated mice are similar to those reported by Yahiro *et al* with hop bracts extract.

### Peer review

The authors described the effects of red wine and green tea against gastritis by infection of *H pylori* or VacA in mice. It was interesting that the combination red wine and green tea prevented induction of damage of gastric mucosa in the animal model. However, it is not clear whether red wine and green tea could prevent the damage, respectively.

Because the authors treated the animals before administration of the microorganism (or VacA), it was not clear if the combined treatment could inhibit the established gastritis either. Further work could better clarify this point.

## Abstract

**AIM:** To investigate the prevalence of hepatitis C virus (HCV) genotypes in Serbia and Montenegro and their influence on some clinical characteristics in patients with chronic HCV infection.

**METHODS:** A total of 164 patients was investigated. Complete history, route of infection, assessment of alcohol consumption, an abdominal ultrasound, standard biochemical tests and liver biopsy were done. Gene sequencing of 5' NTR type-specific PCR or commercial kits was performed for HCV genotyping and subtyping. The SPSS for Windows (version 10.0) was used for univariate regression analysis with further multivariate analysis.

**RESULTS:** The genotypes 1, 2, 3, 4, 1b3a and 1b4 were present in 57.9%, 3.7%, 23.2%, 6.7%, 6.7% and 1.8% of the patients, respectively. The genotype 1 (mainly the subtype 1b) was found to be independent of age in subjects older than 40 years, high viral load, more severe necro-inflammatory activity, advanced stage of fibrosis, and absence of intravenous drug abuse. The genotype 3a was associated with intravenous drug abuse and the age below 40. Multivariate analysis demonstrated age over 40 and intravenous drug abuse as the positive predictive factors for the genotypes 1b and 3a, respectively.

**CONCLUSION:** In Serbia and Montenegro, the genotypes 1b and 3a predominate in patients with chronic HCV infection. The subtype 1b is characteristic of older patients, while the genotype 3a is common in drug abusers. Association of the subtype 1b with advanced liver

## INTRODUCTION

Analysis of genome of hepatitis C virus (HCV) isolates from around the world has shown substantial heterogeneity of nucleotide sequences and has identified at least six genotypes<sup>[1,2]</sup>. The prevalence of HCV genotypes mostly depends on geographic location and for that reason, the genotype identification is crucially important in epidemiological investigation<sup>[3]</sup>. However, it is thought that HCV genotypes may influence some diversity in liver disease presentation, its outcome and response to antiviral treatment<sup>[4]</sup>.

The aim of our study was to determine the HCV genotype prevalence in this area of the Southeast part of the Balkan and to evaluate the genotype distribution and its association with some clinical characteristics in patients with chronic HCV infection.

## MATERIALS AND METHODS

### Subjects

We retrospectively studied 164 patients with chronic HCV infection that had been selected for antiviral treatment. Patients were hospitalized in the Institute for Infectious and Tropical Diseases, Department for Viral Hepatitis, from January 1, 2005 to March 31, 2006. Patients with decompensated liver cirrhosis, hepatocellular carcinoma (HCC), co-infection with hepatitis B virus (HBV) and human immunodeficiency virus (HIV) were excluded

**Table 1** Age of patients with chronic hepatitis C infection according to genotypes

Genotype	n	Mean $\pm$ SD (yr)	Range (yr)
1 <sup>1</sup>	95	44 $\pm$ 12	21-65
2	6	36 $\pm$ 13	22-51
3	38	37 $\pm$ 10	23-62
4	11	32 $\pm$ 13	16-55
1b3a	11	31 $\pm$ 9	18-48
1b4	3	42 $\pm$ 11	33-54
Total	164	41 $\pm$ 12	16-65

<sup>1</sup>Including 1b, 1a, 1ab and two non-determined subtypes.

from the study. Complete history with possible route of infection, physical examination, assessment of alcohol consumption, an abdominal ultrasound and standard biochemical liver functional tests were taken in investigated patients. Alanine aminotransferase (ALT) values were measured at presentation. Percutaneous liver biopsy was performed in all patients. The hepatic pathology expert assessed histological grades (activity) and stages (fibrosis) with Masson's trichrome stained tissue specimens, using the Ischak scoring system<sup>[5]</sup>. In the whole cohort of patients, there were 98 males and 66 females, aged from 16-65 years (mean, 41  $\pm$  12).

### Viral investigations

For detection of sera specific antibodies to HCV and HIV (anti-HCV, anti-HIV) and surface HBV antigen (HBsAg), commercial kits were used (Ortho EIA; BioRad, ELISA). Quantification of the viral genome (HCV RNA) in sera was done by the amplification method (Amplicor Roche Monitor) and expressed in copies/mL (dividing factor in IU/mL is 2.7). Gene sequencing of 5' NTR type-specific PCR or commercial kits (InnoLipa, Innogenetics, Genotyping Linear Array hepatitis C virus test, Roche Diagnostics) was performed for HCV genotyping and subtyping.

All tests of association between the genotypes and other parameters were based preferentially on data for the genotypes 1, 3 and 1b3a because only a few patients (less than 5%) had the genotypes 2 and 1b4. Histological scores of activity and fibrosis, viral load, and ALT values were separately divided into two categorical groups in order to evaluate the possible difference in pathogenicity of the genotypes. Activity scores combined necro-inflammatory lesions, periportal necrosis and lobular necrosis were graded as scores  $\leq 2$  (absent-mild) and scores  $\geq 3$  (moderate-severe). Fibrosis scores were divided into scores  $\leq 3$  (absent-moderate) and  $\geq 4-6$  (severe -cirrhosis). Viral load of HCV RNA was determined as high  $\geq 2 \times 10^6$  copies/mL. Values of ALT were determined high if they were  $2.5 \times$  and  $5 \times$  higher than normal values ( $\leq 41$  IU/mL).

### Statistical analysis

The electronic database organized in the Statistical Package for Social Science (SPSS) for Windows (version 10.0) was

**Figure 1** Distribution of HCV genotypes in patients with chronic HCV infection. 1<sup>1</sup>: 96.7% subtype 1b, 1.1% subtype 1a, 2.2% non-determined subtypes.

used. The results are expressed as means  $\pm$  SD or as percentages. Parametric (Mann-Whitney test, Kruskal-Wallis test) and non-parametric tests (chi-square test, Fisher's exact test) and the Spearman correlation test were performed to identify significantly different variables that entered into univariate logistical regression analysis with further multivariate analysis. The level of significance was set at  $P < 0.05$  and in the case of multiple testing at  $P < 0.01$ . Data is presented with 95% confidence levels.

## RESULTS

### Genotype distribution

The most commonly detected genotype in the whole cohort was genotype 1 (57.9%), with the predominant subtype 1b (54.9%). The subtype 1a was detected in one patient (0.6%) only. Genotype 3 was comprised exclusively of the subtype 3a, while genotype 2 comprised the subtypes a, b and c. Mixed inter-genotype infection, such as 1b3a and 1b4 were detected in 13 (8.54%) patients, while mixed intra-genotype infection (1ab) was detected in two (1.2%) patients (Figure 1).

### Association of the genotypes and demographic and behavioral data

Statistical analysis did not show a difference in the frequency distribution of genotypes according to gender of the patients. The age of the patients was analyzed as a continuous and a categorical variable ( $< 40$  and  $\geq 40$  years). Result of ages of the patients in detail is presented in Table 1. Significant statistical difference was found between ages of the patients depending on the genotypes ( $\chi^2 = 23.474$ ;  $r = 3$ ;  $P < 0.001$ ). Patients with genotype 1 (44.31  $\pm$  12) were older than patients with genotypes 3, 4 and 1b3a (37.18  $\pm$  10.02 versus 32  $\pm$  12.59 versus 31  $\pm$  8.73,  $P < 0.01$ ,  $P < 0.01$  and  $P < 0.001$ , respectively). In the whole cohort, approximately a half of the patients (52%) were aged  $\geq 40$  years. Analyzing the genotypes according to ages over  $\geq 40$ , differences in frequency distribution were found for genotypes 1, 3 and 1b3a (33 versus 25 versus 9,  $P < 0.01$ ,  $P < 0.05$  and  $P < 0.05$ , respectively).

**Table 2** Univariate logistic regression analysis of HCV genotypes according to age equal/older than 40 years

Genotype	Significance	Exp (B)	Lower-Upper <sup>1</sup>
1 <sup>2</sup>	0.000	3.757	1.952-7.232
3 <sup>3</sup>	0.015	0.390	0.183-0.832
1b3a	0.036	0.187	0.039-0.896

<sup>1</sup>95.0% CI for EXP (B); <sup>2</sup>Including subtypes 1b (94.74%), 1a (1.05%), intra-genotype variant 1ab (2.1%), and non-determined subtypes (2.1%); <sup>3</sup>3b subtype.

Result of univariate logistic analysis of all three genotypes according to age  $\geq 40$  years is presented in Table 2. Univariate analysis demonstrated independent association of age  $\geq 40$  years and all three genotypes: 1 (mainly subtype 1b), 3a and 1b3a. Further multivariate analysis revealed only the age  $\geq 40$  years as the positive predictive factor for the genotype 1 [ $P < 0.001$ , Exp (B) = 3.757; 1.952-7.232].

Data about alcohol consumption were available from 161 patients, 30 of them admitted moderate or heavy alcohol abuse (30 g/d or more). There was no statistically significant difference of the frequency distribution of the genotypes according to moderate and/or heavy alcohol consumption.

#### Genotypes and route of infection

The possible route of infection was recognized in 98 (59.7%) patients. Among these patients, patients who had a history of intravenous drug use (IVDU), received blood transfusion, had accidental inoculation and/or were undergoing chronic hemodialysis, and healthcare workers, were found in 45.9%, 32.6%, 15.3% and 6.1%, respectively. Statistical analysis showed significant differences in frequency of genotypes 1 and genotype 3 and IVDU (19/95 *vs* 17/38,  $P < 0.05$  and  $P < 0.05$ , respectively). Result of univariate logistic analysis of the genotypes 1 and genotype 3a and IVDU is presented in Table 3. Univariate analysis demonstrated independent association of the IVDU and the genotypes 1 (96.7% subtype 1b) and 3a. Further multivariate analysis revealed IVDU as the positive predictive factor for the genotype 3a [ $P < 0.01$ , Exp (B) = 2.833; 1.318-6.089].

#### Genotypes and histological findings

Fibrosis score was assessed in all patients. Score from  $\leq 3$  and  $\geq 4$  had 60% and 40% of the patients, respectively. Significant difference was found in the distribution of genotype 1 and fibrosis score  $\geq 4$  (45 *vs* 21,  $P < 0.05$ ). Further univariate logistic analysis showed a fibrosis score  $\geq 4$  being independent of genotype 1 [ $P < 0.05$ , Exp (B) = 2.056; 1.072-3.938]. Histological activity was assessed in 161 patients and scores of  $\leq 2$ , and  $\geq 3$  were established in 93.1% and 6.8% of patients, respectively. Statistical analysis of frequency in HCV genotype distribution according to activity score  $\geq 3$  showed a significant difference in frequency of genotype 1 and other genotypes and histological activity (92 *vs* 69,  $P < 0.05$ ), and also the positive correlation between these two variables ( $P <$

**Table 3** Univariate logistic regression analysis of HCV genotypes according to patients with a history of intravenous drug abuse

Genotype	Significance	Exp (B)	Lower-Upper <sup>1</sup>
1 <sup>2</sup>	0.013	0.413	0.205-0.833
3 <sup>3</sup>	0.008	2.833	1.318-6.089

<sup>1</sup>95.0% CI for EXP (B); <sup>2</sup>Including subtypes 1b (96.7%), 1a (1.1%), intra-genotype variant 1ab (1.2%), and non-determined subtypes (2.2%); <sup>3</sup>3b subtype.

**Table 4** Multivariate logistic analysis of HCV genotype 1 according to age, high HCV RNA, fibrosis score and intravenous drug use (IVDU)

Variable	Significance	EXP (B)	Lower-Upper <sup>1</sup>
$\geq 40$ yr	0.000	3.747	1.952-7.232
High RNA	0.012	3.819	1.339-10.89
Fibrosis score $\geq 4$	0.030	2.413	1.072-3.938
IVDU	0.013	0.413	0.205-0.833

<sup>1</sup>95.0% CI for EXP (B).

0.05). But further univariate logistic analysis did not show independent association of genotype 1 and histological activity score  $\geq 3$ .

#### Genotypes and biochemical activity

Values of ALT varied from 11 IU/L to 292 IU/L (mean,  $80 \pm 53$ ). ALT values  $2.5 \times$  and  $5 \times$  higher than normal value (102.5 IU/mL; 205 IU/mL) had 22.6% and 3.6% of the patients, respectively. No significant difference was found in the frequency of genotype distribution and the value of ALT  $2.5 \times$  higher than normal value.

#### Genotypes and viral load

Viral load was quantified in 126 sera samples. The level of HCV RNA varied from 2000 copies/mL to 31 333 575 copies/mL (mean,  $1 694 690 \pm 3 284 562$ ). Out of all patients, 27 (21%) had a high level of HCV RNA. Statistically significant difference in frequency of high HCV RNA was found for genotype 1 (96.7% subtype 1b) and other genotypes (23/57 *vs* 4/42,  $P < 0.05$ ). A positive correlation was found between genotype 1 and high viral load ( $P < 0.05$ ), as the univariate logistic analysis also revealed genotype 1 in independent association with high level of HCV RNA [ $P < 0.05$ , Exp (B) = 3.819, 1.339-10.89].

Finally, multivariate logistic regression analysis was calculated for genotypes 1 and 3a resulting in significance using univariate analysis. The result of multivariate logistic analysis for genotype 1 is presented in Table 4. The result of multivariate logistic analysis for genotype 3a is presented in Table 5. Accordingly, genotype 1 was demonstrated as significant for the age  $\geq 40$  years [ $P = 0.000$ , Exp (B) = 3.747, 1.952-7.232] whilst the genotype 3a was demonstrated as significant for IVDU [ $P = 0.008$ , Exp (B) = 2.833, 1.318-6.089].

## DISCUSSION

The predominating genotype in our study is the genotype 1 (57.9%), mostly the subtype 1b. The genotype 3a is the second most common genotype encountered in 23.2%. The prevalence of HCV genotypes in our investigation is mainly similar to reports of the HCV genotype distribution in other parts of Europe<sup>[6-10]</sup>. Our current results also confirm findings from Serbia previously published<sup>[11,12]</sup>. The difference between our result and results from some other European investigators suggests the lower prevalence of the subtype 1a in our cohort that we detected only in one patient. Also, the reported prevalence by other investigators of the genotype 2 particularly in advanced liver disease was more common than we found in our study<sup>[13,14]</sup>. However, comparison of the prevalence of genotypes between our results and results of other reports also depends on the time of these investigations. In the last decade, a shift in genotype distribution is obvious in many countries, mostly comprising an increase of the prevalence of the genotypes 3a, 1a and 4, and a decrease of the prevalence of genotypes 1b and 2<sup>[8,10,14]</sup>. The route of HCV transmission mainly causes this epidemiological change in genotype distribution whereas the intravenous drug abuse associated with genotype 3a and 1a has become nowadays the major risk factor of HCV infection<sup>[9,10,14-17]</sup>. In our investigation, only one patient with genotype 1a cannot confirm this epidemiological shift in IVDU patients of this genotype.

Evaluating the association of the genotypes and demographic data of the patients, we did not find differences in genotype distribution and gender of the patients or alcohol abuse. According to these results, we cannot point out female hormones or moderate to heavy alcohol abuse as participating factors in different disease presentation in association with the genotypes. Conversely, investigation of ages of the patients indicates that older age is strongly associated with the distribution of the genotypes. We found that the genotype 1 was the most common genotype in older patients, while the genotypes 3a, 4 and 1b3a characterized younger patients. Although all three genotypes are independent risk factors for ages over 40, genotype 1 for the age over 40 and genotypes 3a and 1b3a for the patients younger than 40, only the genotype 1 has the predictive importance. According to this finding, we can assume that infection with genotype 1 in this part of Balkan occurred earlier in the past than infection with other genotypes, subtypes and mixed inter-genotype infections, e.g., 4, 3a and 1b3a.

Early investigations from the USA did not find an association between HCV genotypes and mode of transmission<sup>[18]</sup>. However, the investigators from Europe reported that patients with a history of blood transfusion were mostly infected with genotype 1b while intravenous drug abusers were infected with genotype 3a<sup>[7,9,10,15-17,19,20]</sup>. Our results show that the genotype 3a is the most important predictive factor for IVDU that is in concordance with these reports. Although we did not confirm correlation of genotype 1b with a mode of HCV transmission, the presence of this genotype as the

**Table 5** Multivariate logistic regression analysis of HCV genotype 3 according to age and intravenous drug use (IVDU)

Variable	Significance	Exp (B)	Lower-Upper <sup>1</sup>
Age ≥ 40 yr	0.015	0.390	0.183-0.832
IVDU	0.008	2.833	1.318-6.089

<sup>1</sup>95.0% CI for EXP (B).

independent negative risk factor for IVDU may suggest other routes of infection. Additionally, it is possible that relatively high prevalence of mixed inter-genotype infection of 1b3a and 1b4 (8.5%) in our patients can suggest repeated infection in the same persons, although we did not find any association between these genotypes and mode of HCV transmission. Moreover, according to our study, genotype 1 (mostly subtype 1b) is the most common genotype in patients with advanced HCV-related liver disease (fibrosis score equal/higher than 4). We can assume that this association between subtype 1b and more progressive disease is paradigmatic for earlier infection with this subtype in comparison with the subtype 3a and mixed infection with 1b3a. Some previous reports also suggested that subtype 1b is associated with a more advanced stage of liver disease<sup>[19,21,22]</sup>. Concerning this problem, we must underscore that our cohort was a select group of patients preparing for antiviral treatment. Because of that, patients with end stage liver disease and HCC were excluded from the study. There is a probability that inclusion of these patients may give a more convincing association between the genotypes and the stage of the HCV-related disease.

However, our result of the association of the HCV genotype 1 with a high level of HCV RNA and higher histological activity suggests possible increased pathogenicity of this particular genotype. Although many authors did not confirm this association, some of them suggested similar findings as we did<sup>[13,18,19,23]</sup>. We must remember again that our study was a cross-sectional and retrospective investigation, and that the factor of time was not taken into account. In any case, our findings that genotype 1b is characterized with a higher level of RNA; in correlation with increased necro-inflammatory changes in the liver than other genotypes, although lack of an increase in biochemical activity could not be ignored as a possible indicator for increased pathogenicity of subtype 1b. Certainly, association between genotypes and the level of HCV RNA and necro-inflammatory activity may need to be investigated in future studies.

Finally, we can conclude that genotype 1, particularly the subtype 1b in older patients with chronic HCV infection, predominates in this geographic Southeast part of the Balkan. The second common prevalence of genotype 3, subtype 3a in younger patients, suggests the increased number of IVDU as the main mode of HCV transmission. The role of subtype 1b that correlates with high viral load and higher histological activity could indicate potentially more pathogenicity of this subtype with consequences such as longer persistence and more aggressive influence in disease outcome that requires careful analysis in prospective setting.

## COMMENTS

### Background

Hepatitis C virus (HCV) represents a cause of chronic liver disease that may progress to cirrhosis with serious consequences. Analysis of the HCV genome demonstrated its high heterogeneity and identified at least six different genotypes divided into several subtypes that have epidemiological and clinical importance.

### Research frontiers

Important areas in investigation of HCV-related chronic liver diseases are identifying infected persons, recognize the route of its transmission, evaluation of the stage of the disease, use of antiviral therapy and prevention measures.

### Innovations and breakthroughs

Prevalence of different HCV genotypes and subtypes and their influence on some clinical characteristics in the Southern part of the Balkan was investigated in 164 patients with chronic hepatitis C. The most common genotype is 1 (57.9%), mainly subtype 1b. Genotype 3 (3a) is the second most common genotype, whilst genotypes 1a and 2 are less common than in other European countries. Genotypes 1 and 3a were found as predicting factors for older age and IVDU, respectively.

### Application

Actual epidemiologic study of HCV genotypes in specific areas is present in the article. Additionally, different genotypes were related to age, gender, alcohol abuse, route of transmission, biochemical activity, histological findings and viral load. Eventual shifts in the correlation data will be recognized in the future.

### Terminology

HCV is a distinct member of the family *Flaviviridae* and placed into a separate genus, named *Hepacivirus*. Genotypes and subtypes of HCV represent its extensive genetic heterogeneity. Genotypes depend mainly on the geographic location and are classified into six main groups, designated as genotypes 1 to 6, with further subdivision within each genotype (a, b, c, etc.). It has been reported that genotypes differ in the severity of the liver disease they cause, baseline of serum RNA levels, response to antiviral treatment and route of transmission.

### Peer review

This article is an essentially confirmatory paper of the previously published observation on the genotype distribution in Serbia, particularly the confirmation of an unusual high prevalence of mixed genotype infection (about 8%-9% in the two papers). The finding of higher HCV RNA levels in genotype 1b is contradicted in most literature and the claim that genotype 1b had higher pathogenicity cannot be substantiated, unless in a prospective setting.

### Abstract

**AIM:** To evaluate the effects of different types of dietary fats on the hepatic lipid content and oxidative stress parameters in rat liver with experimental non-alcoholic fatty liver disease (NAFLD).

**METHODS:** A total of 32 Sprague-Dawley rats were randomly divided into five groups. The rats in the control group ( $n = 8$ ) were on chow diet (Group 1), rats ( $n = 6$ ) on methionine choline-deficient diet (MCDD) (Group 2), rats ( $n = 6$ ) on MCDD enriched with olive oil (Group 3), rats ( $n = 6$ ) on MCDD with fish oil (Group 4) and rats ( $n = 6$ ) on MCDD with butter fat (Group 5). After 2 mo, blood and liver sections were examined for lipids composition and oxidative stress parameters.

**RESULTS:** The liver weight/rat weight ratio increased in all treatment groups as compared with the control group. Severe fatty liver was seen in MCDD + fish oil and in MCDD + butter fat groups, but not in MCDD and MCDD + olive oil groups. The increase in hepatic triglycerides (TG) levels was blunted by 30% in MCDD + olive oil group ( $0.59 \pm 0.09$ ) compared with MCDD group ( $0.85 \pm 0.04$ ,  $P < 0.004$ ), by 37% compared with MCDD + fish oil group ( $0.95 \pm 0.07$ ,  $P < 0.001$ ), and by 33% compared with MCDD + butter group ( $0.09 \pm 0.1$ ,  $P < 0.01$ ). The increase in serum TG was lowered by 10% in MCDD + olive oil group ( $0.9 \pm 0.07$ ) compared with MCDD group ( $1.05 \pm 0.06$ ). Hepatic cholesterol increased by 15-fold in MCDD group [ $(0.08 \pm 0.02$ , this increment was blunted by 21% in MCDD + fish oil group ( $0.09 \pm 0.02$ )]. In comparison with the control group, ratio of long-chain polyunsaturated fatty acids omega-6/

omega-3 increased in MCDD + olive oil, MCDD + fish oil and MCDD + butter fat groups by 345-, 30- and 397-fold, respectively. In comparison to MCDD group ( $1.58 \pm 0.08$ ), hepatic MDA contents in MCDD + olive oil ( $3.3 \pm 0.6$ ), MCDD + fish oil ( $3.0 \pm 0.4$ ), and MCDD + butter group ( $2.9 \pm 0.36$ ) were increased by 108%, 91% and 87%, respectively ( $P < 0.004$ ). Hepatic paraoxonase activity decreased significantly in all treatment groups, mostly with MCDD + olive oil group (-68%).

**CONCLUSION:** Olive oil decreases the accumulation of triglyceride in the liver of rats with NAFLD, but does not provide the greatest antioxidant activity.

### INTRODUCTION

Non-alcoholic steatohepatitis (NASH) pathogenesis includes insulin resistance, increased exposure of the hepatocytes to  $\text{TNF-}\alpha$  and increased oxidative stress<sup>[1]</sup>. The development of hepatic steatosis results from an imbalance in the rate of entry, synthesis, or clearance of fat from the liver. More specifically, the increased influx of free fatty acids to the liver, reduced free fatty acid  $\beta$ -oxidation, a reduced hepatic secretion of triglyceride-rich lipoproteins and increased lipid peroxidation may be altered<sup>[1]</sup>.

Hepatic triglycerides are derived from different sources. First, from endogenous fatty acids which are synthesized in the liver. Second, from dietary triglycerides that enter the liver *via* the chylomicron remnant pathway and finally from free fatty acids that are released from adipose tissues during periods of fasting. An impaired postprandial triglyceride response has been reported in patients with NASH<sup>[2]</sup>. This may promote fatty liver in several ways, such as increasing

hepatic uptake of triglyceride-rich lipoproteins and their remnants in the postprandial period<sup>[2,3]</sup>. The contribution of hepatic lipogenesis to triglyceride secretion was 3 times higher in the patients as compared with the controls while that of non-esterified fatty acids (NEFA) re-esterification was reduced by 52%. Thus, enhanced lipogenesis appears as a prominent abnormality of hepatic fatty metabolism in the subjects with NASH<sup>[4]</sup>.

Several studies have emphasized the importance of dietary composition in the treatment of fatty liver. However, the optimal diet for prevention of NASH is unknown. NASH patients had significantly higher overnight fasting blood concentration of total and free fatty acids than controls, and higher total saturated and monounsaturated levels of lipid fractions, mainly due to increase of palmitate, palmitoleate and oleate acids<sup>[5,6]</sup>. Low-calorie diet for 2 wk in Sprague-Dawley rats exerted no significant effects on either serum lipid disorders or hepatic inflammatory changes<sup>[7]</sup>. Dietary omega-3 and omega-6 polyunsaturated fatty acids (PUFA), present in fish oil, can regulate hepatic lipogenesis by reducing sterol-regulatory element-binding protein-1 in the liver<sup>[8]</sup>. Moreover, PUFA administration decreased fatty acids, such as oleate (C18:1 n-9), palmitate (C16:0) and palmitoleate (C16:1 n-7)<sup>[9]</sup>. Diet of NASH patients who were free of hyperlipidemia, diabetes and obesity was richer in saturated fat and poorer in PUFA<sup>[10]</sup>. PUFA may act as “fuel partitioners”, directing fatty acids away from triglyceride storage and toward oxidation<sup>[11]</sup>. A recent clinical study that compared 19 patients who had non-alcoholic fatty liver disease (NAFLD) with 11 normal control subjects revealed that patients with NAFLD had a higher ratio of long-chain polyunsaturated fatty acids omega-6/omega-3 in their livers than did control subjects<sup>[6]</sup>. When dietary monounsaturated fatty acids, mainly oleic acid present in olive oil, replace high-carbohydrate diets, plasma triglycerides concentration decrease, both in patients without diabetes and in those with type 2 diabetes<sup>[12]</sup>. These findings provide the rational for undertaking the experiment to test the hypothesis that supplementation of different oils to methionine choline-deficient diet could attenuate fatty liver changes in a novel model of hepatic steatosis.

The aim of the current study was to evaluate the effects of different types of dietary fats (monosaturated fatty acids present in olive oil; polyunsaturated fatty acids present in fish oil, and saturated fatty acids present in butter) on the hepatic lipid content and oxidative stress in rat liver with experimental NAFLD.

## MATERIALS AND METHODS

### Animals and protocol

Methionine choline-deficient diet (MCDD) is the most widely used model for NASH in rats<sup>[13]</sup>. The development of steatosis is caused by impaired very low-density lipoprotein (VLDL) secretion. Unlike animals fed a choline-sufficient diet which developed only steatosis but not inflammation and fibrosis, animals fed an MCDD diet showed fibrosing steatohepatitis<sup>[13]</sup>. Thirty-two Sprague-Dawley rats were randomly divided into five groups. The animals in the control group ( $n = 8$ ) were on chow diet

Table 1 Lipid composition of dietary fats (g/100 g total lipids)

Lipid	Olive oil	Fish oil	Butter
Energy (kcal)	884	902	717
Fatty acid, total saturated	13.8	29.89	51.36
16:0 palmitic	11.29	16.64	21.69
Fatty acid, total monounsaturated	72.96	33.84	21.02
18:1 undifferentiated	71.26	14.75	19.96
Fatty acid, total polyunsaturated	10.52	31.86	3.04
18:2 undifferentiated	9.76	2.01	2.72

(Group 1). In group 2, there were six rats on methionine choline-deficient diet (MCDD). In group 3, there were six rats on MCDD supplemented with olive oil (0.45 mg/g rat weight). In group 4, six rats were on MCDD with fish oil (0.45 mg/g rat weight) and in group 5, 6 rats were on MCDD with butter-fat (0.45 mg/g rat weight). In all treatment groups, the MCDD diet was supplemented simply with the different oils and not as a semi-purified diet. The dietary fat was monitored daily and was supplied by the local pharmacy of the Sieff Hospital, Safed, Israel, and not by commercial sources. After two months, the rats were generally anesthetized and blood was sampled by heart puncture. Rats were sacrificed and the liver sections were examined. All animals were treated humanely and in accordance with the guidelines of the institution. The composition of the experimental diets and the levels of lipid fractions are shown in Table 1.

### Biochemistry

Determination of hepatic lipids composition: Rat liver lipid was extracted using the homogenate according to Folch *et al*<sup>[14]</sup>. Triglyceride concentration was determined according to the method of Gottfried and Rosenberg<sup>[15]</sup>. Total cholesterol concentration was determined as previously described<sup>[16]</sup>. Total lipid concentrations were determined using sulphophosphovaniline<sup>[17]</sup>. Phospholipids concentrations were determined by lipid phosphorus assay<sup>[18]</sup>. Phospholipids were separated into component species by thin layer chromatography (TLC) using silica gel G plates and chloroform: methanol: water (65:25:4, v/v) as the solvent system. The position of individual phospholipids was determined using the respective standards. The results were reported as percentage of total phospholipids content<sup>[19]</sup>.

Determination of hepatic pro-oxidant and anti-oxidants: Paraonase activity was measured according to the method described elsewhere<sup>[20]</sup> using 1.0 mmol/L phenyl acetate as substrate.  $\alpha$ -tocopherol was estimated spectrophotometrically<sup>[21]</sup>. Hepatic maleic dialdehyde (MDA) was estimated spectrophotometrically using thiobarbituric acid assay<sup>[22]</sup>.

Fatty acids composition: Rat liver cytosol was prepared by differential centrifugation. Approximately 0.5 g of the liver was homogenized in 5 mL of ice-cold 50 mmol/L phosphate buffer solution (pH 7.4). The liver homogenate was centrifuged for 10 min at 5000 r/min at 4°C, and the pellet was discarded. The supernatant was further centrifuged for 30 min at 8000 r/min at 4°C. Fatty acid methyl esters were analyzed by gas chromatography using

**Table 2** Effect of MCDD alone or enriched with different fats on rat body or liver weight (mean  $\pm$  SD,  $n = 6$ )

Group	Diet	Baseline rats weight (g)	Final rats weight (g)	Final liver weight (g)	Liver weight/rat weight ratio
1	Control	246 $\pm$ 6	367 $\pm$ 3	8.8 $\pm$ 0.3	0.023
2	MCDD	249 $\pm$ 6	184 $\pm$ 8	6.8 $\pm$ 0.6	0.037 <sup>a</sup>
3	MCDD + olive oil	247 $\pm$ 6	177 $\pm$ 7	6.6 $\pm$ 0.6	0.037 <sup>a</sup>
4	MCDD + fish oil	246 $\pm$ 7	176 $\pm$ 6	5.8 $\pm$ 0.6	0.033 <sup>a</sup>
5	MCDD + butter	242 $\pm$ 5	178 $\pm$ 6	6.6 $\pm$ 0.5	0.037 <sup>a</sup>

<sup>a</sup> $P < 0.05$  vs control group.

palmitic acid as the marker of fatty acids<sup>[23]</sup>.

### Histology

The specimens were fixed in buffered formalin and embedded in paraffin. Hematoxylin and eosin (H&E) sections, periodic acid Schiff with diastase stain for inflammatory grading as well as Mason's trichrome and reticulin stains were reviewed for fibrosis and architectural changes. The necroinflammatory grade and stage of fibrosis were assessed according to the method of Brunt *et al.*<sup>[24]</sup>. Steatosis was graded by semi-quantitative analysis as follows: mild = 5%-30%; moderate = 30%-60%; and severe = more than 60% of hepatocytes affected. Each biopsy was analyzed and graded by the same pathologist who was blinded to the rats group.

### Statistical analysis

Results were expressed as mean  $\pm$  SD. Analysis of variance was used to compare multiple group means, followed by the Newman-Keuls test to determine statistical significance between two groups. When the data were not normally distributed, the Kruskal-Wallis test was performed to compare multiple group means, followed by Mann-Whitney test. Correlation analysis was performed using Spearman rank correlation. The statistical comparisons were performed using the unit values rather than percentages.  $P < 0.05$  was considered statistically significant. The statistical analysis was performed using the Winstat program for windows (Kalmia, MA).

## RESULTS

### Liver weight/rat weight ratio

Rat weights significantly increased in the control group by 49% and decreased in MCDD, MCDD + olive oil, MCDD + fish oil, and MCDD + butter group by 35%, 40%, 40%, and 37%, respectively ( $P < 0.05$ ). Rat liver weights decreased relatively to the control group in MCDD, MCDD + olive oil, MCDD + fish oil, and MCDD + butter group by 22%, 25%, 34%, and 25%, respectively ( $P < 0.05$ , Table 2). Rat liver weight: rat weight ratios were markedly increased in MCDD, MCDD + olive oil, MCDD + fish oil, and MCDD + butter group by 54%, 54%, 38%, and 54%, respectively ( $P < 0.05$ ).

### Extent of fatty infiltration

There was a significant increase in the extent of fatty liver in MCDD, MCDD + olive oil, MCDD + fish oil, and

**Figure 1** Extent of hepatic fatty infiltration (A: severe; B: mild) in the different treatment groups. <sup>b</sup> $P < 0.01$ , comparison among olive oil, fish oil and butter fat groups; <sup>d</sup> $P < 0.01$ , comparison among fish oil, NASH and olive oil groups; <sup>f</sup> $P < 0.01$ , comparison among butter fat, NASH and olive oil groups.

MCDD + butter groups as compared to the control group ( $P < 0.001$ ). While no severe fatty (> 60%) infiltration was observed in MCDD + olive oil group, severe hepatic fatty infiltration was observed in 33% of rats in MCDD + fish oil group and in 83% of rats in MCDD + butter group ( $P < 0.01$ , Figure 1A). Mild to moderate fatty infiltration was similar in MCDD and MCDD + olive oil groups but significantly lower in MCDD + fish oil (67% of rats) and MCDD + butter group (17% of rats) ( $P < 0.01$ , Figure 1B). No inflammation was detected in the livers of the control group. Mild inflammatory changes were observed in all rats in MCDD, and MCDD + olive oil groups. While 66% of the rats in MCDD + butter group were without hepatic inflammatory changes, 50% of the rats in MCDD + fish oil group had moderate inflammatory changes (Table 3).

### Hepatic lipids

Hepatic triglyceride content (mol/g liver) increased by 43-, 30-, 48- and 45-fold in MCDD ( $0.85 \pm 0.04$ ), MCDD + olive oil ( $0.59 \pm 0.09$ ), MCDD + fish oil ( $0.95 \pm 0.07$ ), and MCDD + butter ( $0.09 \pm 0.1$ ) groups, respectively, as compared to the control group ( $0.024 \pm 0.007$ ,  $P < 0.001$ ). Most importantly, this increase was blunted by 30% in MCDD + olive oil group compared with MCDD group only ( $P < 0.004$ ), by 37% in MCDD + olive oil group compared with MCDD + fish oil group ( $P < 0.001$ ), and by 33% in MCDD + olive oil group compared with MCDD + butter group ( $P < 0.001$ , Figure 2). Hepatic

**Table 3** Effect of MCDD alone or enriched with different fats on hepatic fat infiltration and inflammation

3	MCDD + olive oil ( <i>n</i> = 6)	100 <sup>a</sup>	0	0	100 <sup>a</sup>	0
4	MCDD + fish oil ( <i>n</i> = 6)	67 <sup>a</sup>	33.3 <sup>a</sup>	17	33.3 <sup>a</sup>	50 <sup>ac</sup>
5	MCDD + butter ( <i>n</i> = 6)	17	83 <sup>a</sup>	66 <sup>ac</sup>	17	17

<sup>a</sup>*P* < 0.05 vs control group; <sup>c</sup>*P* < 0.05 vs group 3.

cholesterol content increased by 15-fold in MCDD group ( $0.08 \pm 0.02$ ) compared with the control group ( $0.03 \pm 0.01$ ). In MCDD + fish oil group, this increment was blunted by 21% compared with MCDD group. There was a significant increase in lipid content in the liver of MCDD ( $1.9 \pm 0.14$ ), MCDD + olive oil ( $2.06 \pm 0.4$ ), MCDD + fish oil ( $1.9 \pm 0.35$ ), and MCDD + butter ( $1.98 \pm 0.39$ ) groups by 6.8-, 7.1-, 6.6- and 6.8-fold, respectively, as compared to the control group ( $0.28 \pm 0.03$ , *P* < 0.01). Phospholipids content in the liver decreased in MCDD group ( $0.21 \pm 0.04$ ) by 2.6-fold compared with the control group ( $0.55 \pm 0.04$ , *P* < 0.05). All phospholipids fractions (lysolecithin, sphingomyelin, lecithin, phosphatidyl inositol and phosphatidyl ethanolamine) were reduced in the liver of all treatment groups.

### Plasma lipids

Serum triglyceride levels (mmol/L) increased significantly in MCDD ( $1.05 \pm 0.06$ ), MCDD + olive oil ( $0.9 \pm 0.07$ ), MCDD + fish oil ( $1.02 \pm 0.08$ ), and MCDD + butter ( $0.97 \pm 0.4$ ) groups by 98%, 79%, 94%, and 85%, respectively, as compared to the control group ( $0.53 \pm 0.09$ ), (*P* < 0.05). This increment was significantly lowered (by -10%) in MCDD + olive oil group as compared with MCDD group (*P* < 0.02). Serum cholesterol levels (mmol/L) were not significantly different among the control ( $1.2 \pm 0.37$ ), MCDD ( $1.0 \pm 0.1$ ), and MCDD + olive oil ( $0.87 \pm 0.2$ ) groups, but increased by 33% and 22% in MCDD + fish oil ( $1.4 \pm 0.2$ ), and MCDD + butter ( $1.27 \pm 0.2$ ) groups, respectively, when compared with MCDD group. Plasma lipid content ( $3.4 \pm 1.0$ ) did not change in any treatment group. Phospholipids levels in serum decreased in MCDD group ( $0.63 \pm 0.1$ ) by 5.4-fold compared with the control group ( $3.4 \pm 0.4$ ), but no significant difference in phospholipids level was observed between among the treatment groups. All phospholipids fractions (lysolecithin, sphingomyelin, lecithin, phosphatidyl inositol and phosphatidyl ethanolamine) were reduced in plasma.

### Hepatic pro-oxidant and anti-oxidants

MDA hepatic content (mol/g liver) increased significantly in MCDD ( $1.58 \pm 0.8$ ), MCDD + olive oil ( $3.3 \pm 0.6$ ), MCDD + fish oil ( $3.0 \pm 0.4$ ), and MCDD + butter ( $2.9 \pm 0.36$ ) groups in comparison to the control group ( $0.2$

**Figure 2** Hepatic triglycerides content (mol/g liver) in the different treatment groups. <sup>b</sup>*P* < 0.004, <sup>d</sup>*P* < 0.001, <sup>f</sup>*P* < 0.001 vs olive oil group.

**Figure 3** Hepatic paraoxonase contents (mol/L) in the different treatment groups. <sup>b</sup>*P* < 0.01, <sup>d</sup>*P* < 0.01, <sup>f</sup>*P* < 0.01 vs olive oil group.

$\pm 0.1$ ) by 7.4-, 15.3-, 14 and 13.7-fold, respectively (*P* < 0.05). Moreover, MDA hepatic contents in MCDD + olive oil, MCDD + fish oil, and MCDD + butter groups were higher in comparison to MCDD group by 108%, 91% and 87%, respectively (*P* < 0.004). Paraonase activity decreased significantly in the livers of all treatment groups. The most prominent decrease in paraonase activity was observed in MCDD + olive oil group ( $1.36 \pm 0.28$ , -68%, *P* < 0.01, Figure 3).  $\alpha$ -tocopherol content in the liver (mg/g liver) decreased in MCDD + olive oil group ( $0.26 \pm 0.09$ ) by 63% compared with the control group ( $0.7 \pm 0.05$ , *P* < 0.01), by 61% in comparison with MCDD + fish oil ( $0.66 \pm 0.1$ ) group (*P* < 0.003) and by 64% compared with MCDD + butter group ( $0.7 \pm 0.09$ , *P* < 0.002). However, no significant differences were found among the other groups.

### Plasma pro-oxidant and anti-oxidants

There was no obvious difference between the control group ( $8.8 \pm 1.6$ ) and MCDD group ( $7.5 \pm 1.5$ ) in plasma concentrations of MDA. MCDD + olive oil ( $11.9 \pm 3.2$ ), MCDD + fish oil ( $11.3 \pm 5.1$ ) and MCDD + butter ( $10.1 \pm 6.3$ ) groups had significantly higher plasma

<sup>1</sup>Comparison between MCDD and treatment groups; <sup>2</sup>comparison between the three treatment groups. <sup>a</sup>*P* < 0.02 *vs* MCDD + fish oil; <sup>c</sup>*P* < 0.02 *vs* MCDD + butter group.

concentration of MDA in comparison with MCDD group by 59%, 51% and 35%, respectively (*P* < 0.05). Plasma  $\alpha$ -tocopherol level decreased in MCDD group ( $2.5 \pm 0.87$ ) by 57% in comparison with the control group ( $5.7 \pm 0.78$ , *P* < 0.001). Plasma  $\alpha$ -tocopherol levels were increased by 70% in MCDD + olive oil group ( $4.2 \pm 0.5$ , *P* = 0.003), by 87.3% in MCDD + fish oil group ( $4.6 \pm 0.56$ ) and by 45% in MCDD + butter group ( $3.6 \pm 0.5$ ) as comparison to MCDD group (*P* < 0.05).

### Hepatic composition of fatty acids

MCDD diet did not increase palmitic acid percentage in the livers of the rats, but did increase significantly the oleic acid percentage by 4.2-fold. MCDD enrichment by olive oil further increased the oleic acid percentage by 25% (*P* < 0.05). Palmitoleic acid had small contribution to fatty acid liver content and increased in all other treated rat groups on MCDD by 4-7-fold. Fish oil did not alter either the palmitic or palmitoleic acid percentages in the livers of MCDD + fish oil group as compared with MCDD group (Table 4).

Long-chain polyunsaturated fatty acids (PUFA) n6:n3 ratio increased in MCDD + olive oil, MCDD + fish oil and MCDD + butter fat groups by 345-, 30- and 397-fold, respectively in comparison with the control group. MCDD enriched with olive or fish oil or butter fat increased arachidonic acid percentages in the rat livers. This increment was 29% less in MCDD + fish oil group when compared with MCDD + olive oil (*P* < 0.05). C20:4n6/C18:2n6 ratios increased in MCDD + olive fat, MCDD + fish oil and MCDD + butter fat groups by 56-, 41- and 57-fold, respectively, in comparison with the control group (Table 4). C22:6n3 percentage in the rat livers decreased by 3.5-fold in MCDD group in comparison with the control group. This decrease was also noted in the rat groups on MCDD enriched with olive oil or with butter fats. On the contrary, C22:6n3 percentage in the liver increased by 2-fold in MCDD + fish oil group in comparison with the control group (Table 4). Enrichment of MCDD by olive oil, fish oil and butter fat increased elaidic acid percentage by 15.2-, 11.9- and 14.2-fold, respectively, compared to

Table 5 Correlations between hepatic lipid fractions and parameters of oxidant-antioxidant status in the MCDD + olive oil group

Parameter	Malonyl dialdehyde (MDA)	Alpha-tocopherol	Paraoxonase
Triglycerides	<i>r</i> = -0.4	<i>r</i> = 0.45	<i>r</i> = -0.004
Cholesterol	<i>r</i> = -0.8	<i>r</i> = 0.05	<i>r</i> = 0.3
Phospholipids	<i>r</i> = -0.6	<i>r</i> = -0.4	<i>r</i> = -0.6
Lipids	<i>r</i> = -0.2	<i>r</i> = -0.4	<i>r</i> = -0.2
Palmitic	<i>r</i> = 0.6	<i>r</i> = 0.1	<i>r</i> = 0.1
Stearic	<i>r</i> = -0.5	<i>r</i> = -0.4	<i>r</i> = -0.9

MCDD group. Fish oil blunted elaidic acid percentage increase in the rat livers by 22% in comparison with olive oil. C18:1n9c/C18:0 ratios increased in MCDD, MCDD + olive oil, MCDD + fish oil and MCDD + butter fat groups by 16-, 20-, 1-, and 4-fold, respectively, when compared to the control group (Table 4). Correlations between the levels of various fats, triglycerides, cholesterol, phospholipids, saturated and unsaturated fatty acids in the MCDD + olive oil group and the oxidant-antioxidant status are shown in Table 5. A strong correlation was noted between hepatic MDA levels and hepatic cholesterol (*r* = -0.8), phospholipids (*r* = -0.6), and palmitic acid (*r* = 0.6), as well as between hepatic alpha-tocopherol and linolelaidic acid (*r* = 0.97), elaidic acid (*r* = 0.9), oleic acid (*r* = -0.7), and arachidonic acid (*r* = -0.7). Hepatic paraoxonase correlated well with tricosanoic acid (*r* = 0.9), stearic acid (*r* = -0.9), oleic acid (*r* = -0.8), and arachidonic acid (*r* = -0.7) (Table 5).

## DISCUSSION

The results of this study clearly indicate that rats on MCDD diet supplemented with olive oil, but not fish oil or butter fat, store less triglycerides in their liver and prevent the occurrence of dietary-induced severe

hepatic steatosis. Moreover, the results indicate also that olive oil diet provides the least antioxidant capability, whereas the fish oil and butter fat diets behave similarly with regard to antioxidant activities. As expected, these rats lost about 40% of body weight<sup>[25]</sup>. This weight loss is not in accordance with the clinical picture of NASH found in humans and may then results from the loss of subcutaneous fat<sup>[26]</sup>. Hepatic insulin resistance in the MCDD model of fatty liver is most likely caused by CYP2E1-induced oxidative stress and by elevated serum triglyceride levels<sup>[1]</sup>. In the current study, serum triglyceride levels were higher in all groups on MCDD (alone or enriched with fat) than in the control group, a finding which is also in accordance with the clinical NASH profile. Triglyceride content in the livers of the MCDD + olive oil group was lower than other groups on MCDD or MCDD enriched with saturated or polyunsaturated fatty acids. This may have been due to the inhibition of hepatic triacylglycerol synthesis<sup>[27]</sup>, and stimulation of hepatic peroxisomal beta-oxidation produced by the olive oil diet<sup>[28]</sup>. Decrease in lipoprotein lipase and triacylglycerol lipase in the liver after olive and fish oil consumption has also been described and this may be an adaptive response to the low concentration of substrates (triacylglycerol) for these enzymes. The low levels of triglycerides in the liver after olive oil consumption may also be related to the reduced levels of plasma triglycerides found in our study. Moreover, monounsaturated fatty acids, present in olive oil, may improve insulin resistance, and enhance the release of triglyceride from the liver. This also decreases leak of free fatty acids from peripheral adipose tissue back to the liver and may explain the difference between the olive oil and butter groups.

In animal studies, saturated fat, present in butter, significantly increased insulin resistance, whereas long- and short-chain omega-3 fatty acids improved it, and the effects of monounsaturated and omega-6 polyunsaturated fatty acids ranged somewhere in between the two. In humans, shifting from a diet rich in saturated to one rich in monounsaturated fatty acid improved insulin sensitivity in healthy people<sup>[28]</sup>. Saturated fat [(myristic acid (14:0) and di-homo- $\gamma$ -linolenic acid (18:3 n-6)] and the percentage of body fat had the strongest correlation with fasting insulin<sup>[29]</sup>. In normal subjects, consuming diet enriched with 10% elaidic (18:1 trans) acid induced insulin resistance acutely. In the present study, polyunsaturated fatty acids, present in fish oil failed to blunt the triglyceride accumulation in the liver. Fifty-nine percent of fatty acids stored in the liver of NASH patients arises from serum non-esterified fatty acids (NEFA), 26% from *de novo* lipogenesis and 15% from the diet<sup>[30]</sup>. Thus, the contribution of dietary olive oil to the fatty acid content in the liver appears small, suggesting the presence of other mechanisms preventing the accumulation of fatty acids in the liver under diet enrichment with olive oil. Eicosapentaenoic fatty acid administration decreased hepatic triglyceride content in ob/ob mice<sup>[31]</sup>. Polyunsaturated fatty acids can shift the energy balance from storage to consumption. Polyunsaturated fatty acids, particularly those of the n-3 family, play pivotal roles as "fuel partitioners" in that they direct fatty acids away

from triglyceride storage and toward oxidation and they enhance glucose flux to glycogen<sup>[31]</sup>. In the present study, the MCDD model of NASH did not show the protective effect of polyunsaturated fatty acids on triglyceride accumulation in the liver. Whether this is due to enhanced hepatic lipogenesis or decreased  $\beta$ -oxidation remains unclear.

The rates of oxidation for the same amount of fatty acids differed among healthy persons, e.g., more than 37% of the dose of lauric acid (12:0) was oxidized compared with less than 15% of the dose of stearic acid (18:0)<sup>[32]</sup>. In dietary fat-enriched diets, the increased free fatty acids influx into the hepatocytes exceeds the liver capacity to assemble or/and export triglyceride-rich VLDL particles, causing hepatic steatosis. This increases the substrate for lipid peroxidation in the liver<sup>[33-35]</sup>. Polyunsaturated fatty acids are prone to spontaneous peroxidation, thus forming lipid hydroperoxides and reactive aldehydes<sup>[33,34]</sup>. At the same time, free fatty acid content in the hepatocytes up-regulates PPAR- $\alpha$ . This enhances mitochondrial long-chain fatty acid  $\beta$ -oxidation, initiation of omega-oxidation of fatty acids in the microsomes<sup>[36,37]</sup> and peroxisomal  $\beta$ -oxidation<sup>[38]</sup> resulting in generation of reactive oxygen species accumulation<sup>[39]</sup>. MCDD diet increased oxidative stress in the liver, but not in the plasma. Fat enrichment with olive oil, fish oil or butter fat added more oxidative stress in the liver and in the plasma. This increased oxidative stress in the liver did not impoverish  $\alpha$ -tocopherol hepatic content in the rat groups fed diets enriched with fish oil or with butter. This, presumably, is due to the high content of  $\alpha$ -tocopherol in these two food resources. Hepatic paraoxonase activity decreased in all rat groups on MCDD. This decreased activity may be the result of hepatic injury secondary to fat accumulation and increased oxidative stress. Plasma paraoxonase 1 activity is decreased in chronic liver disease in correlation with the degree of hepatic dysfunction<sup>[40]</sup>. Paraoxonase gene expression has been observed only in the liver<sup>[41]</sup>. This decrease in paraoxonase activity was more pronounced in the rats fed MCDD enriched with olive oil. The oxidative stress in the liver of this group was also higher than other groups on MCDD. The reasons for that are unclear. It appears that changes in the liver fatty acid composition, due mainly to n-3 lipids, may increase the activity of some anti-oxidant enzymes. A potential mechanism for the induction of hepatic anti-oxidants following butter feeding might be an increase in the expression of their genes; induction of the expression of anti-oxidant enzymes has been reported in circumstances where an increase in free radicals is produced, such as ageing<sup>[42]</sup>.

Analysis of the fatty acid composition in the rat liver showed that MCDD increased palmitoleic and oleic acids percentage in the liver, but not palmitic acid. NASH patients showed increased overnight fasting serum levels of palmitic, palmitoleic and oleic acids<sup>[5]</sup>, suggesting that the source of these fatty acids in the liver is from blood circulation and not from gastrointestinal tract. Hepatic long-chain PUFA n6/n3 ratios increased in MCDD + olive oil, MCDD + fish oil and MCDD + butter fat groups in comparison with the control group. Increased long-chain PUFA n-6/n-3 ratio in the liver of NASH patients

may favor lipid synthesis over oxidation and secretion, thereby leading to steatosis<sup>[6]</sup>. This ratio increased less in MCDD + fish oil group, yet the MCDD + olive oil group had a lower fat content in the liver, making this ratio less effective in determining fatty acid content in the fatty liver in the MCDD rat model.

MCDD alone or enriched with olive, butter or fish fat increased arachidonic acid percentage in the rat livers, a possible marker of increased inflammatory state in the liver. Fish oil increased arachidonic acid less than olive or butter-supplemented groups, because PUFA can confer anti-inflammatory effect.

In the MCDD model, there was no reduction in C20:2n6/C18:2n6 ratio. In a previous study, NASH patients showed depletion of long-chain PUFA of the n-6 and n-3 series in the liver triacylglycerols<sup>[6]</sup>. In the present study, C22:6n3 was depleted in MCDD, MCDD + olive oil and MCDD + butter fat, but not in MCDD + fish oil due to dietary addition to the MCDD. MCDD enriched with olive oil, fish oil and butter fat increased hepatic elaidic acid percentage. Elaidic acid leads to defective PUFA desaturation by inhibiting desaturase and subsequently to depletion of hepatic long-chain PUFA<sup>[6]</sup>, but in the present study, C22:6n3 was depleted in MCDD group without a change in hepatic content percentage of elaidic acid. C22:6n3 depletion in MCDD, MCDD + olive oil and MCDD + butter fat may be due to inadequate intake of precursors, such as 18:3 n-3 and a higher peroxidation of long-chain PUFA due to oxidative stress<sup>[6]</sup>.

Although the MCDD model of fatty liver is the most commonly used in experimental studies, one limitation of our study is that MCDD model is not the ideal model for studying insulin resistance in humans and an extensive number of additional experiments would be required to be performed in order to derive definitive data in insulin-resistant models<sup>[26]</sup>. Another concern is that the rats fed MCDD for nine weeks did not develop the same phenotype as previous reports of MCDD-induced NASH in mice (as short as 10 d of MCDD). The phenotype described here largely consisted of marked steatosis with mild inflammation and mild fibrosis<sup>[43]</sup>.

Increased MDA level, and reduced serum paraoxonase 1 (PON1) activity reflect increased oxidative damage in rats with steatohepatitis. Reactive oxygen species, which are formed due to increased microsomal, peroxisomal and mitochondrial oxidation, trigger lipid peroxidation; this in turn causes cell death and release of MDA<sup>[1]</sup>. It also has been shown that TNF- $\alpha$  down-regulates mRNA expression of paraoxonase in Hep G2 cells<sup>[44]</sup>. This cytokine-mediated reduction of paraoxonase production by the liver might be responsible for the decreased paraoxonase activity in steatohepatitis. On the other hand, decreased paraoxonase activity could be accepted as another evidence of increased lipid peroxidation, since it was shown that a decrease in liver microsomal paraoxonase activity is an early biochemical change related to lipid peroxidation and liver injury observed in the rats with CCl<sub>4</sub>-induced cirrhosis<sup>[45]</sup>.

In conclusion, olive oil decreases the accumulation of triglycerides in the liver of rats with NASH, thereby

suggesting that olive oil should be included in the diet of patients with NASH and NAFLD.

## Abstract

**AIM:** To study the relationship between inflammatory response and liver regeneration (LR) at transcriptional level.

**METHODS:** After partial hepatectomy (PH) of rats, the genes associated with inflammatory response were obtained according to the databases, and the gene expression changes during LR were checked by the Rat Genome 230 2.0 array.

**RESULTS:** Two hundred and thirty-nine genes were associated with liver regeneration. The initial and total expressing gene numbers found in initiation phase (0.5-4 h after PH), G<sub>0</sub>/G<sub>1</sub> transition (4-6 h after PH), cell proliferation (6-66 h after PH), cell differentiation and structure-function reconstruction (66-168 h after PH) of liver regeneration were 107, 34, 126, 6 and 107, 92, 233, 145 respectively, showing that the associated genes were mainly triggered at the beginning of liver regeneration, and worked at different phases. According to their expression similarity, these genes were classified into 5 groups: only up-regulated, predominantly up-, only down-, predominantly down-, up- and down-, involving 92, 25, 77, 14 and 31 genes, respectively. The total times of their up- and down-regulated expression were 975 and 494, respectively, demonstrating that the expressions of the majority of genes were increased, and that of a few genes were decreased. Their time relevance was classified into 13 groups, showing that the cellular physiological and biochemical activities were staggered during liver regeneration. According to gene expression patterns, they were classified into 33 types, suggesting that the activities were diverse and complex during liver regeneration.

**CONCLUSION:** Inflammatory response is closely

## INTRODUCTION

Partial hepatectomy (PH)<sup>[1]</sup>, being severely harmful to the body, can cause inflammatory response<sup>[2]</sup>. Furthermore, it also activates the remaining liver cells to enter into cell cycle to replenish the lost livers, which is called liver regeneration (LR)<sup>[3,4]</sup>. Generally, an inflammatory response goes through the following processes: the change of vascular permeability<sup>[5]</sup> as a result of the tissue injury<sup>[6]</sup>, leukocytes' escape from blood vessel, activation and proliferation of target cells induced by released cytokines, elimination of foreign materials, wound repair and so on<sup>[6]</sup>. It is a defense mechanism developed during the long-term evolutionary process, being closely linked to survival of living organisms<sup>[7]</sup>.

Usually, the process of LR is classified based on the cellular physiological activities into 4 phases consisting of the initiation (0.5-4 h after PH), the G<sub>0</sub>/G<sub>1</sub> transition (4-6 h after PH), the cell proliferation (6-66 h after PH), the cell differentiation and structure-function reorganization (66-168 h after PH)<sup>[8]</sup>, or divided according to time course into 4 phases including forepart (0.5-4 h after PH), prophase (6-12 h after PH), metaphase (16-66 h after PH), and anaphase (72-168 h after PH)<sup>[9]</sup>, in which a variety of physiological and biochemical events including cell activation, de-differentiation, proliferation and its regulation, re-differentiation, reorganization of structure-function<sup>[10]</sup> are involved. The process is regulated by many factors including inflammation<sup>[11]</sup>. Studying the relationship between inflammatory response and liver regeneration at transcriptional level is helpful to clarify the molecular mechanism of liver regeneration<sup>[9,12]</sup>. In the current study,

the expression changes of genes in regenerating liver were detected by Rat Genome 230 2.0 array<sup>[13,14]</sup> containing 409 genes associated with inflammatory response. Two hundred and thirty-nine genes were found associated with liver regeneration<sup>[15]</sup>, and their expression changes, patterns and roles in LR were preliminarily analyzed.

## MATERIALS AND METHODS

### *Regenerating liver preparation*

Healthy SD rats weighing 200-250 g were obtained from the Animal Center of Henan Normal University. The rats were separated into groups at random and each group included 6 rats (Male:Female = 1:1). PH was performed according to Higgins and Anderson<sup>[3]</sup>: the left and middle lobes of the liver were removed. Rats were killed by cervical vertebra dislocation at 0.5, 1, 2, 4, 6, 8, 12, 24, 36, 54, 66, 72, 120, 144 and 168 h after partial hepatectomy and the regenerating livers were examined at corresponding time points. The livers were rinsed three times in PBS at 4°C. Then 100-200 mg liver tissues from middle parts of the right lobe, six samples of each group were gathered and mixed together to a total of 1-2 g (0.1-0.2 g × 6) of liver tissue, and stored at -80°C. The sham-operation (SO) groups were treated the same way with partial hepatectomy ones except that the liver lobes were unremoved. The laws of animal protection of China were followed strictly.

### *RNA isolation and purification*

Total RNA was isolated from frozen livers according to the manual of Trizol kit (Invitrogen)<sup>[16]</sup> and then purified based on the guide of RNeasy mini kit (Qiagen)<sup>[17]</sup>. Total RNA samples were examined and exhibited a 2:1 ratio of 28S to 18S rRNA intensities by agarose electrophoresis (180 V, 0.5 h). Total RNA concentration and purity were estimated by optical density measurements at 260/280 nm<sup>[18]</sup>.

### *cDNA, cRNA synthesis and purification*

As template, 1-8 µg total RNA was used for cDNA synthesis. cDNA and cRNA synthesis were proceeded according to the methods established by Affymetrix<sup>[13]</sup>. cRNA labeled with biotin was synthesized using 12 µL of the above synthesized cDNA as the template, and cDNA and cRNA were purified<sup>[13]</sup>. Measurement of concentration, purity and quality of cDNA and cRNA was the same as above.

### *cRNA fragmentation and microarray detection*

Fifteen microliters (1 µg/µL) cRNA incubated with 5 × fragmentation buffer at 94°C for 35 min was digested into 35-200 bp fragments. Rat Genome 230 2.0 microarray produced by Affymetrix was prehybridized, then the hybridization buffer was added at 45°C, and spun at 60 rotations per min for 16 h. The microarray was washed and stained by GeneChip fluidics station 450 (Affymetrix Inc., USA). The chips were scanned by GeneChip Scan 3000 (Affymetrix Inc., USA), and the signal values of gene expression were observed<sup>[14]</sup>.

### *Microarray data analysis*

The normalized signal values, signal detections (P, A, M)

and experiment/control (R<sub>i</sub>) were obtained by quantifying and normalizing the signal values using GCOS1.2<sup>[14]</sup>.

### *Normalization of microarray data*

To minimize error in the microarray analysis, each analysis was performed three times by Rat Genome 230 2.0 microarray. Result with a total ratio was maximal (R<sup>m</sup>) and that of which the average of three housekeeping genes (β-actin, hexokinase and glyseraldehyde-3-phosphate dehydrogenase) approached 1.0 (R<sup>h</sup>) were taken as a reference. The modified data were generated using a correction factor (R<sup>m</sup>/R<sup>h</sup>) multiplying the ratio of every gene in R<sup>h</sup> at each time point. To remove spurious gene expression changes resulting from errors in the microarray analysis, the gene expression profiles at 0-4 h, 6-12 h and 12-24 h after PH were reorganized by NAP software (normalization analysis program) according to the cell cycle progression of the regenerating hepatocytes. Data statistics and cluster analysis were done using GeneMath, GeneSpring, and Microsoft Excel software<sup>[14,19,20]</sup>.

### *Identification of genes associated with liver regeneration*

Firstly, the nomenclature of inflammatory response was adopted from the GENEONTOLOGY database (www.geneontology.org), and then input into NCBI (www.ncbi.nlm.nih.gov) and RGD (rgd.mcw.edu) to identify the rat, mouse and human genes associated with the inflammatory response. According to maps of biological pathways embodied by GENMAPP (www.genmapp.org), KEGG (www.genome.jp/kegg/pathway.html#amino) and BIOCARTA (www.biocarta.com/genes/index.asp), the genes associated with inflammatory response were collated. The results of this analysis were coded, and compared with the results from human and mouse studies in order to identify human and mouse genes which are different from those of rat. In comparison of these genes with the analysis output of the Rat Genome 230 2.0 array, those genes that showed a greater than twofold change in expression level, regarded as meaningful expression changes<sup>[15]</sup>, were referred to as rat homologous genes or rat specific genes associated with inflammatory response. Genes that displayed reproducible results with three independent analyses with the chip and showed a greater than twofold change in expression level at least at one time point during liver regeneration with significant difference (0.01 ≤ P < 0.05) or extremely significant difference (P ≤ 0.01) between PH and sham operation (SO), were referred to as associated with liver regeneration.

## RESULTS

### *Expression changes of genes associated with inflammatory response during liver regeneration*

According to the databases at NCBI, GENMAPP, KEGG, BIOCARTA and RGD, 661 genes were involved in inflammatory response, in which, 405 genes were contained in the Rat Genome 230 2.0 array. Among them, the expression of 239 genes displayed meaningful changes at least at one time point after PH, showed significant or extremely significant differences in expression when compared between PH and SO, and displayed reproducible

**Figure 1** Expression frequency, abundance and changes of 239 inflammatory response-associated genes during rat liver regeneration. Detection data of Rat Genome 230 2.0 array were analyzed and graphed by Microsoft Excel. **A:** Gene expression frequency. The dots above bias represent the genes up-regulated more than two fold, and total times of up-regulation were 975; those below bias down-regulated more than two fold, and times of down-regulation were 494; and the ones between biases no-sense alteration; **B:** Gene expression abundance and changes. One hundred and sixty-two genes were 2-257 fold up-regulated, and 147 genes 2-25 fold down-regulated.

**Figure 2** The initial and total expression profiles of 239 inflammatory response-associated genes at each time point of liver regeneration. Grey bars: Up-regulated gene; White bars: Down-regulated. Blank bars represent initial expressing genes, in which up-regulated genes were predominant in the forepart, and the down-regulated in the prophase and metaphase, whereas very few in the anaphase. Dotted bars represent the total expressing genes, in which some genes were up-regulated, and the others down-regulated during the whole LR.

results by three detections with Rat Genome 230 2.0 array, suggesting that the genes were associated with LR. Change in up-regulation ranged from 2 to 257 times higher than control, and down-regulation ranged from 2 to 25 times lower than control (Table 1). The data indicated that 92 genes were up-regulated, 77 genes down-, and 70 genes up/down-during liver regeneration. The total up- and down-regulated times were 975 and 494, respectively (Figure 1A). At the initiation phase (0.5-4 h after PH), 77 genes displayed up-regulation, 27 genes down, 3 genes up/down; at the G0/G1 transition (4-6 h after PH), 70 genes up-regulated, 20 genes down-, and 2 genes up/down-; at the cell proliferation phase (6-66 h after PH), 102 genes up-regulated, 84 genes down-, and 47 genes up/down-; at cell differentiation and structure-function reorganization phase (66-168 h after PH), 82 genes up-regulated, 44 genes down-, and 19 genes up/down- (Figure 1B).

#### Initial expression time of genes associated with inflammatory response during liver regeneration

At each time point of liver regeneration, the numbers of initial up-, down-regulated and total up-, down-regulated genes are as followings: both 34 and 10 at 0.5 h; 17, 12 and 47, 15 at 1 h; 15, 0 and 55, 2 at 2 h; 11, 8 and 64, 10 at 4 h;

7, 8 and 54, 18 at 6 h; 1, 2 and 49, 16 at 8 h; 2, 2 and 52, 15 at 12 h; 15, 13 and 51, 22 at 16 h; 14, 19 and 56, 41 at 18 h; 2, 1 and 49, 28 at 24 h; 7, 6 and 33, 29 at 30 h; 2, 8 and 41, 38 at 36 h; 0, 3 and 31, 15 at 42 h; 7, 3 and 66, 46 at 48 h; 0, 3 and 40, 38 at 54 h; 0, 1 and 37, 27 at 60 h; 0, 0 and 37, 18 at 66 h; 1, 2 and 31, 21 at 72 h; 1, 0 and 42, 20 at 96 h; 1, 0 and 40, 26 at 120 h; 0, 0 and 35, 18 at 144 h; 0, 1 and 31, 21 at 168 h (Figure 2). Generally, gene expression changes occurred during the whole liver regeneration, and the up- and down-regulations were 975 and 494 times, respectively. There were predominantly initial up-regulated genes in the forepart, and the down-regulated genes in the prophase and metaphase, whereas only a few in the anaphase.

#### Expression similarity and time relevance of genes associated with inflammatory response during liver regeneration

Two hundred and thirty-nine genes could be characterized based on their similarity in expression as following: only up-, predominantly up-, only down-, predominantly down-, up/down-regulated, involving 92, 25, 77, 14 and 31 genes, respectively (Figure 3). According to time relevance, they were classified into 13 groups, including 0.5 and 1 h, 2 h, 4 and 6 h, 8 and 12, 16 and 96 h, 18 and 24 h, 30 and 42 h, 36 h, 48 h, 54 and 60 h, 66 and 72 h, 120 and 144 h,

<sup>1</sup>Indicates the reported genes associated with liver regeneration; the letters "a" and "b" at the top right corner of the number "2" respectively indicate "Process of release" and "Cytokine" during the process of release cytokine, the letters "a", "b" and "c" at the top right corner of the number "3" respectively refer to "Cell activation", "Cell proliferation" and "Cell differentiation" in the process of cell activation, proliferation and differentiation.

**Figure 3** Expression similarity and time relevance clusters of 239 inflammatory response-associated genes during liver regeneration. Detection data of Rat Genome 230 2.0 array were analyzed by H-clustering. Red represents up-regulated genes chiefly associated with promotion of inflammatory response; Green represents down-regulation ones mainly associated with suppression of inflammatory response; Black: No-sense in expression change. The upper and right trees respectively show expression similarity and time series clusters, by which the above genes were classified into 5 and 13 groups separately.

168 h and the up- and down-regulated times were 81 and 25, 55 and 2, 118 and 28, 101 and 31, 93 and 42, 105 and 69, 64 and 44, 41 and 38, 66 and 46, 77 and 65, 68 and 39, 75 and 44, 31 and 21 respectively (Figure 3). The up-regulated genes were chiefly ones promoting inflammatory response, and the down-regulated genes were mostly ones suppressing inflammatory response.

### Expression patterns of genes associated with inflammatory response during liver regeneration

Two hundred and thirty-nine genes were categorized into 33 patterns, according to the changes in their expression. (1) up-regulation at one time point, i.e. 4, 6, 16, 18, 30, 48, 96, 120 h after partial hepatectomy (Figure 4A), 11 genes involved; (2) up at two time points, i.e. 6 and 66 h, 12 and 60 h, 16 and 42 h, 16 and 96 h, 24 and 48 h, 30 and 42 h, 36 and 66 h, 48 and 120 h, 72 and 120 h (Figure 4B), 13 genes involved; (3) up at three time points (Figure 4C), 5 genes involved; (4) up at multiple time points (Figure 4D), 6 genes involved; (5) up at one time phase, i.e. 0.5-6 h, 0.5-8 h, 1-48 h, 6-12 h (Figure 4E), 4 genes involved; (6) up at two time phases, i.e. 16-24 h and 42-48 h (Figure 4E), 1 gene involved; (7) up at three time phases (Figure 4E), 1 gene involved; (8) up at multiple time phases (Figure 4E), 1 gene involved; (9) up at one time point/phase, i.e. 0.5 and 4-12 h, 18 and 48-60 h, 48 and 2-24 h, 54 and 6-24 h, 66 and 6-24 h, 96 and 1-24 h, 120 and 2-72 h, 120 and 0.5-8 h (Figure 4F), 8 genes involved; (10) up at one time point/two phases (Figure 4G), 5 genes involved; (11) up at one time point/three phases (Figure 4G), 3 genes involved; (12) up at two time points/one phase (Figure 4H), 7 genes involved; (13) up at two time points/phases (Figure 4I), 6 genes involved; (14) up at two time points/three phases (Figure 4J), 8 genes involved; (15) up at three time points/one phase (Figure 4K), 1 gene involved; (16) up at three time points/two phases (Figure 4K), 6 genes involved; (17) up at multiple time points/phases (Figure 4L), 6 genes involved; (18) down at one time point, i.e. 4, 6, 16, 18, 30, 36, 42, 48, 54, 60, 72, 168 h (Figure 4M, 4N), 28 genes involved; (19) down at two time points, i.e. 0.5 and 48 h, 1 and 72 h, 16 and 42 h, 16 and 30 h, 18 and 54 h, 18 and

168 h, 30 and 42 h, 30 and 96 h, 42 and 66 h (Figure 4O), 11 genes involved; (20) down at three time points (Figure 4O), 2 genes involved; (21) down at multiple time points (Figure 4O), 1 gene involved; (22) down at one phase i.e. 4-8 h, 4-6 h, 4-12 h, 6-12 h (Figure 4P), 4 genes involved; (23) down at two phases, i.e. 18-24 and 48-54 h (Figure 4P), 1 gene involved; (24) down at one time point/phase, i.e. 36 and 48-60 h, 48 and 12-30 h, 48 and 18-24 h, 54 and 18-24 h, 72 and 120-144 h (Figure 4Q), 5 genes involved; (25) down at one time point/two phases (Figure 4Q), 4 genes involved; (26) down at one time point/three phases (Figure 4Q), 2 genes involved; (27) down at two time points/one phase (Figure 4R), 6 genes involved; (28) down at two time points/phases (Figure 4R), 6 genes involved; (29) down at three time points/one phase (Figure 4S), 2 genes involved; (30) down at multiple time points/phases (Figure 4S), 5 genes involved; (31) predominantly up (Figure 4T and U), 25 genes involved; (32) predominantly down (Figure 4V), 14 genes involved; (33) similarly up/down (Figure 4W and X), 31 genes involved.

## DISCUSSION

Inflammatory response is a self-protection mechanism formed during the long evolution, closely bound up with higher animal survival. In the process, six proteins including leukotriene B4 receptor (LTB4R), are associated with vascular reactions, through enhancing vascular permeability<sup>[21]</sup>. In addition, seven other proteins including platelet-activating factor receptor (PTAFR) have a role in increasing vasodilatation and permeability<sup>[22]</sup>. Four proteins including oxidized low density lipoprotein receptor 1 (LDLR1) promote leukocytes and proteins to exude from vessels<sup>[23]</sup>. Four proteins including regenerating islet derived 3 gamma (REG3G) accelerate vasodilatation<sup>[24]</sup>. Four proteins including amine oxidase copper containing 3 (AOC3) restrain leucocytes to migrate to sites of inflammation<sup>[25]</sup>. The meaningful expression profiles of the genes encoding the above proteins were the same or similar at some points while different at others, indicating that they may co-regulate vascular reaction. Among them,

**Figure 4** Thirty-three gene expression patterns of 239 inflammatory response-associated genes during liver regeneration. Expression patterns were obtained by the analysis of detection results of Rat Genome 230 2.0 array with Microsoft Excel. **A-L**: 92 up-regulated genes; **M-S**: 77 down-regulated genes; **T-X**: 70 up/down-regulated genes. X-axis represents recovery time after partial hepatectomy (h); Y-axis shows logarithm ratio of the signal values of genes at each time point to control.

*aoc3* was up-regulated at 36, 54 and 168 h after PH, and reached a peak at 36 h, which was 6.1 fold of control. *lib4r* was up- at 6, 18, 36, 48 and 60 h after PH, and reached a peak at 60 h, which was 6 fold of control. *oldlr1* was up- at 2-6, 18-24 and 48-66 h after PH, and reached a peak at 6 h, which was 6.5 fold of control. *ptaf1r* was up- at 16, 30, 42 and 96 h after PH, and reached a peak at 96 h, which was 7.1 fold of control. *reg3g* was up- at 12 and 36 h after PH, and reached a peak at 36 h, which was 7.5 fold of control. It is assumed that the above genes play a key role in vascular reaction during liver regeneration.

Ten proteins including lipocalin 2 (LCN2), associated with cytokine release, are activated by interleukins to promote inflammation<sup>[26]</sup>. Integrin beta 2 (ITGB2) stimulates leucocytes to secrete IL-12<sup>[27]</sup>. Nine proteins including regenerating islet-derived 3 alpha (REG3A) accelerate cytokines synthesis<sup>[28]</sup>. Fourteen proteins

including toll-like receptor 2 (TLR2) increase activation of macrophages<sup>[29]</sup>. Nine proteins including vacuolar protein sorting 45 (VPS45) stimulate the release of inflammatory factors, such as histamine, bradykinin<sup>[30]</sup>. The meaningful expression profiles of the genes encoding these proteins, being the same or similar at some points while different at others, indicate that they may co-regulate cytokine release. Among them, *len2* was up-regulated at 0.5-24, 36, 48-72 and 120-168 h after partial hepatectomy, and reached a peak at 24 h, which was 257 fold of control. *reg3a* was up- at 12, 36 and 96 h after PH, and reached a peak at 36 h, which was 64 fold of control. *tlr2* was up- at 0.5-8, 18-66 and 120-168 h after PH, and reached a peak at 168 h, which was 10.6 fold of control. *nps45* was up- at 16, 30, 42 and 96 h after PH, and reached a peak at 42 h, which was 12.6 fold of control. It is suggested that the above genes play a key role in cytokine release during liver regeneration.

Twelve proteins including chemokine C-C motif ligand 7 (CCL7), associated with inflammatory response, accelerate T cell migration to sites of inflammation<sup>[31]</sup>. Nine proteins including plasminogen activator urokinase receptor (PLAUR) promote leukocyte adhesion<sup>[32]</sup>. Eight proteins including serine or cysteine peptidase inhibitor clade E member 1 (SERPINE1) promote inflammatory cell migration<sup>[33]</sup>. Ten proteins including mitogen-activated protein kinase 8 (MAPK8) promote neutrophils, macrophages and T cells to ooze from blood vessel<sup>[34]</sup>. ATP-binding cassette sub-family B member 1 (ABCB1) enhances the transduction of inflammatory signaling<sup>[35]</sup>. Three proteins including alpha-2-macroglobulin (A2M) restrain the activities of various proteases including trypsin, thrombin and collagenase<sup>[36]</sup>. Twelve proteins including chemokine C-C motif receptor 1 (CCR1) inhibit the activities of leukocyte and inflammatory protein (MIP)-1 by enhancing the chemotaxis of neutrophils, monocytes, lymphocytes and eosinophils<sup>[37]</sup>. The meaningful expression profiles of these genes showed the sameness or similarity at some points while exhibited difference at others, suggesting that they may regulate the cytokine-mediated inflammation together. Among them, *a2m* was up- at 0.5-24, 36 and 48-54 h, and reached a peak at 8 h, which was 46.2 fold of control. This is generally consistent with the result reported by Scotte *et al.*<sup>[38]</sup>. *serpine1* was up- at 1-48 h, and reached a peak at 6 h, which was 16.7 fold of control. This is in conformity with the result reported by Mueller *et al.*<sup>[39]</sup>. *cl7* was up- at 1-4, 12, 24, 48, 66 and 144-168 h, and reached a peak at 48 h, which was 22.6 fold of control. *cr1* was up- at 8-36, 48 and 120 h, and reached a peak at 48 h, which was 27.9 fold of control. *mapk8* was up- at 0.5-24, 48-60, 72 and 144 h, having a peak at 4 h, which was 12 fold of control. *plaur* was up- at 1, 6, 18-24, 48, 72 and 120 h, and had the highest abundance of 13.9 fold at 6 h. It indicates that these genes play a key role in inflammation during liver regeneration.

Among the proteins associated with the inflammatory cell activation, connective tissue growth factor (CTGF) enhances macrophage activity via M-CSF (macrophage colony-stimulating factor)<sup>[40]</sup>. Eight proteins including cysteine aspartate-specific protease 8 (CASP8) lead inflammatory response by accelerating neutrophil apoptosis<sup>[41]</sup>. Ten proteins including v-fos FBJ murine osteosarcoma viral oncogene homolog (FOS) accelerate inflammatory response by activating MAPK<sup>[42]</sup>. Six proteins including forkhead box M1 (FOXM1) induce inflammatory response when they are over expressed<sup>[43]</sup>. Seven proteins including pancreatitis-associated protein (PAP) inhibit inflammatory response by suppressing the activity of NFκB<sup>[44]</sup>. Six proteins including fatty acid binding protein 4 (FABP4) inhibit inflammatory response by reducing the activities of NFκB and IκB of macrophages<sup>[45]</sup>. Eight proteins including interleukin 1 receptor antagonist (IL1RN) decrease inflammatory response by inhibiting the activities of IL1A and IL1B<sup>[46]</sup>. Four proteins including galanin (GAL) suppress inflammatory response by inhibiting proliferation of thymus cells and macrophages<sup>[47]</sup>. The meaningful expression profiles of the genes encoding the proteins mentioned above showed the sameness or similarity at some point while exhibited

difference at others, implying that they may co-regulate the activity of inflammatory cell. Among them, *ctgf* was up- at 0.5-8, 18-24, 36, 54 and 72 h after PH, and reached a peak at 6 h, which was 13.9 fold of control. This is consistent with the results reported by Pi *et al.*<sup>[48]</sup>. *foxm1* was up- at 1, 18-24, 36, 48-72 and 120 h after PH, and reached a peak at 66 h, which was 13.9 fold of control. This is in line with the results reported by Wang *et al.*<sup>[43]</sup>. *casp8* was up- at 1, 18-24, 36, 48-72 and 120-168 h, and reached a peak at 48 h, which was 10.6 fold of control. *fabp4* was up- at 4, 12-24, 36, 48-72 and 120-168 h, and reached a peak at 120 h, which was 29.9 fold of control. *fos* was up- at 0.5-30, 42-48 and 120 h after PH, and reached a peak at 0.5 h, which was 28.4 fold of control. *gal* was up- at 1-16, 30, 42 and 96-120 h after PH, and reached a peak at 96 h, which was 11.3 fold of control. *il1rn* was up- at 2-24 and 48 h after PH, and reached a peak at 8 h, which was 16.3 fold of control. *pap* was up- at 1-24, 36, 48-54, 66 and 120-144 h after PH, and reached a peak at 12 h, which was 68.6 fold of control. It is assumed that these genes play vital roles in inflammatory cell activation during LR.

Nine proteins including B-cell CLL/lymphoma 6 (BCL6), associated with inflammatory cell proliferation, promote the proliferation of T cells and B cells<sup>[49]</sup>. Five proteins including selectin E (SELE) promote recruitment of white blood cells to inflammation sites by activating neutrophils<sup>[50]</sup>. Three proteins including cluster of differentiation 276 (CD276) induced by LPS inhibit T cell proliferation<sup>[51]</sup>. The meaningful expression profiles of the genes encoding these proteins showed the sameness or similarity at some points while difference at others, indicating that they may modulate inflammatory cell proliferation together. Remarkably, *sele* showed up-regulation at 0.5-2, 16-24, 36, 54-66 and 96-120 h with the highest abundance of 12.9 fold of control at 66 h after PH. *bcl6* was up- at 0.5-12, 24, 48-54, 72 and 120-168 h, and reached a peak at 0.5 h, which was 8.6 times higher than the control. It is supposed that they are important in inflammatory cell proliferation during liver regeneration.

Interleukin 12 receptor beta 2 (IL12RB2), associated with inflammatory cells differentiation, promotes Th1 cells differentiation<sup>[52]</sup>. Three proteins including thymic stromal lymphopoietin (TSLP) facilitate the differentiation of CD4(+)T cells to Th2 cells<sup>[53]</sup>. The meaningful expression profiles of the genes encoding these proteins exhibited the sameness or similarity at some points while difference at others, indicating that they may co-regulate inflammatory cell differentiation. Remarkably, *tslp* displayed up-regulation at 18-24, 36, 48-60, 72 and 120-144 h with the highest abundance of 6.1 fold at 18 h after PH, indicating that it is essential to inflammatory cell differentiation during liver regeneration.

Five proteins including complement component 1 q subcomponent receptor 1 (C1QR1), associated with inflammation elimination, can clear dead cells by promoting monocytes, neutrophils and epithelial cells to secrete inflammatory factors<sup>[54]</sup>. Lysozyme (LYZ) promotes bacteriaeocyte dissolution<sup>[55]</sup>. NADPH oxidase 1, 4 (NOX1, NOX4) accelerate cell aging by catalyzing production of active oxygen<sup>[56]</sup>. The meaningful expression changes of these genes displaying sameness or similarity at some

points while difference at others indicate that they may co-regulate subsidence of inflammation. Especially, *h3* was up-regulated at 1-4, 48 and 96 h, and reached a peak at 48 h, which was 3.7 times higher than the control. *nax1* was up- at 0.5-8, 18 and 120 h, and had a peak expression at 2 h, which was 8.6 times higher than the control. *clqr1* was up- at 0.5-12, 24, 36, 60-72 and 120-168 h, reaching a peak at 8 h, which was 5.5-fold of control. It is supposed that the three genes are of importance in eliminating inflammation during liver regeneration.

In conclusion, the expression changes of the inflammatory response-associated genes after partial hepatectomy in rats have been investigated with high-throughput gene expression analysis. It is preliminarily confirmed that inflammatory response is enhanced during liver regeneration; that Rat Genome 230 2.0 array is a useful tool for analysis of the inflammatory response at the transcriptional level. However, the process of DNA→mRNA→protein→function is influenced by many factors including protein interaction. Therefore, further analyses of our results using techniques, such as Northern blotting, protein chip, RNA interference, protein-interaction are needed.

### Abstract

**AIM:** To establish the rats model of chronic fibrosing pancreatitis and to prove the anti-fibrotic effect of emodin in chronic pancreatitis with fibrosis.

**METHODS:** Fifty rats were randomly divided into five groups, 10 rats in each group. Trinitrobenzene sulfonic acid (TNBS) was infused into the pancreatic duct to induce chronic pancreatitis in rats (except for normal group). Emodin-treated rats were fed with different doses of emodin (20, 40 and 80 mg/kg body weight) for 28 d, while normal group and control group received 0.9% sodium chloride solution. Serum levels of hyaluronic acid (HA) and laminin (LN) were determined by radioimmunoassay. Histopathological alterations were studied by optical microscopy. Expression of collagen was also examined while transforming growth factor-beta-1 (TGF- $\beta_1$ ) was localized by immunochemistry.

**RESULTS:** In emodin-treated rats, the serum levels of HA and LN were decreased significantly (HA,  $62.2 \pm 19.3 \mu\text{g/L}$  vs  $112.7 \pm 26.5 \mu\text{g/L}$ ,  $P < 0.05$ ; LN  $44.3 \pm 10.4 \mu\text{g/L}$  vs  $86.2 \pm 16.5 \mu\text{g/L}$ ,  $P < 0.05$ ); the degree of fibrosis was ameliorated observably; the expression of collagen in pancreatic tissue was reduced especially in high-dose emodin-treated group ( $36\% \pm 5\%$  vs  $42\% \pm 6\%$ ,  $P < 0.05$ ); with the increased doses of emodin, the expression of TGF- $\beta_1$  was declined, compared with those in control group.

**CONCLUSION:** Emodin has an anti-fibrotic effect on pancreatic fibrosis in rats. Because of its anti-fibrotic effect, it could be a potential herb for the treatment of chronic pancreatitis.

**Key words:** Emodin; Fibrosis; Chronic pancreatitis; Animal model

### INTRODUCTION

Chronic pancreatitis is characterized morphologically by a progressive pancreatic fibrotic process<sup>[1]</sup>. Extracellular matrix (ECM) components are distributed in both healthy and diseased pancreas, and there is an increased deposition of disorganized ECM components in chronic pancreatitis<sup>[2]</sup>. However, the mechanism of the fibrotic process is not fully understood. Progressive fibrosis is a characteristic feature of chronic pancreatitis of various etiologies, thus anti-fibrosis is the key to the therapy of chronic pancreatitis. However, no ideal treatment is available yet. Could traditional Chinese herbs be effective? Emodin (1, 3, 8-trihydroxy-6-methylanthraquinone) isolated from a great deal of herbs is an effective constituent with many effects. Lots of pharmaceutical studies have demonstrated that emodin has many biological effects<sup>[3-5]</sup>, such as anticancer, antimicrobial, and anti-inflammatory effects, etc. Moreover, several studies<sup>[6,7]</sup> have revealed that emodin is efficacious in the management of acute pancreatitis and hepato-cirrhosis, but studies on chronic pancreatitis are rare. We designed this experiment to investigate the effect of emodin on pancreatic fibrosis in rats, and elucidate its potential therapeutic mechanisms.

### MATERIALS AND METHODS

#### Materials

Male Sprague-Dawley rats weighing 200-250 g were provided by the Animal Center of Zhejiang University. Trinitrobenzene sulfonic acid (TNBS) was obtained from Sigma Chemical Company. Radioimmunoassay kits of rat hyaluronic acid (HA) and laminin (LN) were purchased from Shanghai Tiancheng Science and Technology Ltd. Emodin was offered by Hunan Huaguang Chemical Company. TGF- $\beta_1$  polyclonal antibody was provided by Santa Cruz Company. Immunochemistry kits (Envision TM) were offered by DAKO, Denmark.

#### Grouping and animal model

Fifty male Sprague-Dawley rats were randomly divided into five groups, 10 rats in each group. A chronic pancreatitis model was induced in rats by infusion of TNBS into the pancreatic duct with a modification of the method

Table 1 Grading of pancreatic fibrosis

Grade	Duct dilation	Periductal fibrosis	Intralobular fibrosis	Glandular atrophy
F0	-	-	-	-
F1	+	-	-	-
F2	+	+	-	-
F3	+	+	+	-
F4	+	+	+	+

described by Puig-Divi *et al.*<sup>[8]</sup> (except for normal group). After fasted for 3 d, the rats in group 1 (normal group, nonoperation) and group 2 (control group, nontreating) received oral 0.9% sodium chloride solution. Emodin-treated rats in groups 3-5 were fed with different doses of emodin (20, 40 and 80 mg/kg body mass). Twenty-eight days after treatment, all rats were killed. Pancreatic tissues and blood samples were collected and kept for further study.

#### Measurement of serum HA and LN

Blood samples were obtained 28 d after treatment, and serum levels of HA and LN were determined by radioimmunoassay.

#### Histological examination

Paraffin sections of rat pancreatic tissue were stained with hematoxylin and eosin. We evaluated the morphologic changes by light-microscopy. Grading of pancreatic fibrosis was carried out as previously described<sup>[9]</sup> (Table 1).

#### Mesurement of collagen expression

Pancreatic fibrosis was observed by the Van Gieson staining, semi-quantitative analysis of collagen fibres was carried out by the KS400 imaging analysis system (KS400 ver. 2.0).

#### Immunohistochemistry

Paraffin-embedded tissue sections were subjected to immunostaining using the DAKO EnVisin two-step procedure. Tissue sections were submerged for 10 min in Tris buffered saline (TBS) (10 mmol/L Tris-HCl, 0.85% NaCl, pH 7.4) containing 3% hydrogen peroxide in order to quench the endogenous peroxidase activity. Following washing with distilled water, the sections were incubated in TBS with polyclonal antibodies against TGF- $\beta_1$  diluted at 1:200 for 30 min. After 10-min washing with TBS, the sections were incubated with Envision TM for another 30 min. After washing with TBS for 10 min, the sections were incubated with diaminobenzidine (DAB) as a substrate and counterstained. The results were evaluated by microscopy. All samples were classified according to the percentage of TGF- $\beta_1$  positive cells (brown colour reaction). We defined 0 as no, + as 0%-25%, +2 as 25%-50%, +3 as 50%-75%, +4 as > 75%.

#### Statistical analysis

Serum levels of HA and LN and pancreatic collagen content were expressed as mean  $\pm$  SE. Student's *t* test was

Table 2 Effect of emodin on serum hyaluronic acid (HA) and laminin (LN) (mean  $\pm$  SE)

Group	<i>n</i>	HA ( $\mu$ g/L)	LN ( $\mu$ g/L)
1 (Normal)	10	55.2 $\pm$ 23.7	40.5 $\pm$ 12.2
2 (Control)	8	112.7 $\pm$ 26.5 <sup>b</sup>	86.2 $\pm$ 16.5 <sup>b</sup>
3 (emodin, 20 mg/kg)	8	86.6 $\pm$ 22.1 <sup>a</sup>	66.8 $\pm$ 14.4 <sup>a</sup>
4 (emodin, 40 mg/kg)	8	78.0 $\pm$ 24.5 <sup>d</sup>	56.7 $\pm$ 12.3 <sup>a</sup>
5 (emodin, 80 mg/kg)	9	62.2 $\pm$ 19.3 <sup>d</sup>	44.3 $\pm$ 10.4 <sup>d</sup>

<sup>b</sup>*P* < 0.01 vs group 1; <sup>a</sup>*P* < 0.05, <sup>d</sup>*P* < 0.01 vs group 2.

used for statistical analysis. Chi square test was used for the ranked data statistical analysis. If the expected cell count was less than or equal to 5, Fisher's exact test was used. SPSS 11.0 was used for statistical analysis, and *P* < 0.05 was considered statistically significant.

## RESULTS

#### Survival rate of rats

The survival rate was 83.3% in emodin-treated groups (25/30) and 80.0% (8/10) in control group. However, no significant difference was found between these groups.

#### Serum HA and LN

The mean serum level of HA and LN was the lowest in normal group (group 1, *P* < 0.05), and the levels of HA and LN were significantly lower in emodin-treated groups (groups 3-5) than in control group (group 2, *P* < 0.05). With the increased doses of emodin, the serum levels of HA and LN were decreased in emodin-treated groups, but there was no statistically significant difference between them (Table 2).

#### Histopathological examination

Pancreatic fibrosis was evaluated according to the criteria described above (Table 1), and the results are shown in Figure 1. The extent of fibrosis was much milder in emodin-treated groups than in control group. Structural changes such as periductal fibrosis, intralobular fibrosis and glandular atrophy were ameliorated. With the increased doses of emodin, the changes were significantly improved.

#### Pancreatic collagen content

Pancreatic collagen was detected by Van Gieson staining. An extensive accumulation of collagen and glandular atrophy were found in control group, while the accumulation of collagen was decreased and no glandular atrophy was found in emodin-treated groups. We obtained the positive proportions of Van Gieson staining by the imaging analysis system. The positive proportions in each group are shown in Table 3. With the increased doses of emodin, the changes were improved obviously. Only a significant difference was found between group 5 and group 2 (*P* < 0.05).

#### Immunohistochemistry

Four groups (except for normal group) showed TGF- $\beta_1$  expression (brown colour reaction) (Figure 2). The

**Figure 1** Effect of emodin on histopathological alterations in rats. Grading: 1 = F0, 2 = F1, 3 = F2, 4 = F3, 5 = F4, 6 = F5.

results are shown in Table 4. With the increased doses of emodin, the changes were improved obviously, similar to the above results. For the sake of statistical analysis, we divided all samples into two large groups: low expression of TGF- $\beta_1$  (0, +1, +2) and high expression of TGF- $\beta_1$  (+3, +4). Fisher's exact test was used for statistical analysis. Compared with group 2 (0 rat in low expression group and 8 rats in high expression group), a significant difference was found between group 4 (7 rats in low expression group and 1 rat in high expression group) and group 5 (9 rats in low expression group and 0 rat in high expression group) ( $P < 0.05$ ). Compared with group 3 (4 rats in low expression group and 4 rats in high expression group), only group 5 had a significant difference ( $P < 0.05$ ). There was no statistically significant difference between any other two groups.

## DISCUSSION

The incidence of chronic pancreatitis is increasing, and the most important etiological factor is alcohol. The pathogenesis of chronic pancreatitis has not been completely understood. Nevertheless, it was reported that various factors such as TGF- $\beta_1$ , ECM, oxidative stress *etc.*, are involved in the progression of pancreatic fibrosis<sup>[10,11]</sup>. Since pancreatic fibrosis is the characteristic feature of chronic pancreatitis, preventing and inverting pancreatic fibrosis is the key to therapy of chronic pancreatitis and amelioration of its prognosis.

Drugs which could prevent or invert pancreatic fibrosis might be developed and interventioned for the treatment of chronic pancreatitis with fibrosis. Emodin isolated from a great deal of herbs is an effective constituent with many effects<sup>[3-5]</sup>. It was reported that emodin could inhibit the expression of  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA) and reduce the transformation and synthesis of TGF- $\beta_1$ <sup>[6]</sup>. Some researchers observed that emodin could inhibit transformation of hepatic stellate cells (HSCs) from G<sub>1</sub> phase to S phase and S phase to G<sub>2</sub> phase that could prevent HSC proliferation. It also has been reported that emodin could inhibit lipid peroxidation<sup>[12]</sup>. However, previous studies of emodin mainly focused on how to inhibit liver fibrosis, while studies on pancreatic fibrosis are rare. The aim of this research was to study the effect

**Table 3** Pancreatic collagen content in different groups (mean  $\pm$  SE, %)

of emodin on pancreatic fibrosis, and the results of our study indicate that emodin has an anti-fibrotic effect on pancreatic fibrosis in rats.

Cells similar to HSCs have been identified and isolated from the pancreas, known as pancreatic stellate cells (PSCs)<sup>[13,14]</sup>. It was reported that PSCs are activated in both experimental and human pancreatic fibrosis and these activated PSCs are the main cellular source of collagen in chronic pancreatitis<sup>[15]</sup>, suggesting that pathological alteration of pancreatic fibrosis is similar to liver fibrosis, and may share the same mechanism of fibrosis and anti-fibrosis.

The potential mechanisms of emodin include the following aspects. The first is cell protection. As we know, tissue injury is the first step of fibrosis. Apte *et al*<sup>[16]</sup> showed that activated PSCs around the pancreatic micrangium express  $\alpha$ -SMA, which could aggravate fibrosis of the pancreas, because of vasoconstriction and pancreatic ischemia caused by  $\alpha$ -SMA. Emodin could protect pancreatic cells and organs from impairment. In our study, the extent of fibrosis was much milder in emodin-treated groups than in control group. This may be the first mechanism of emodin's anti-fibrotic effect. The second is the effect of emodin on cytokines. PSCs produce ECM after stimulation with TGF- $\beta_1$ , platelet-derived growth factor (PDGF), *etc*<sup>[17]</sup>. It was reported that TGF is the key regulating factor of fibrosis. Modulation of TGF- $\beta$  signaling may be the therapeutic target for the prevention of chronic pancreatitis<sup>[18]</sup>. It was reported that emodin could inhibit the expression of TGF- $\beta_1$  in liver fibrosis model of rats<sup>[6]</sup>. Imanishi *et al*<sup>[19]</sup> found that emodin could modulate the effect of PDGF, which could slow down the progression of fibrosis. In our study, emodin-treated groups showed low expression of TGF- $\beta_1$ , especially in high-dose emodin-treated group. Emodin could counteract cytokines and their receptors, which are

**Figure 2** Pancreatic immunochemistry changes in normal group (A), control group (B) and 20 mg/kg (C), 40 mg/kg (D) and 80 mg/kg (E) emodin-treated groups ( $\times 100$ ). Normal group had no TGF- $\beta_1$  expression (brown color reaction), control group had the highest expression of TGF- $\beta_1$  while 20, 40 and 80 mg/kg emodin-treated groups had different levels of TGF- $\beta_1$  expression.

relevant to the progression of fibrosis, and then brings its anti-fibrotic effect into play. The third is the regulatory effect of emodin on ECM metabolism. Disbalance in ECM metabolism is the common way of fibrosis. Chronic pancreatitis is due to the cumulative intrapancreatic ECM deposition. ECM is consisted of collagens and noncollagenous glycoproteins (fibronectin, laminin). It was reported that serum HA and LN are two important markers responsible for the degrees of fibrosis<sup>[20]</sup>. Our study revealed that the serum levels of HA and LN were significantly lower in emodin-treated groups than in control group, suggesting that emodin can affect the metabolism of ECM. However, the exact mechanism by which emodin regulates the content of ECM still needs further investigation. The fourth is the effect of emodin on ECM-producing cells. PSCs rapidly proliferate following injury and are the major source of pancreatic ECM component during pancreatic fibrogenesis, and accumulating evidence has placed PSCs at the center of pancreatic fibrosis<sup>[15]</sup>. Emodin not only inhibits proliferation and activation of PSCs, but also induces their apoptosis. This is another mechanism underlying the anti-fibrotic effect of emodin. The fifth is the antioxidizing effect of emodin. Yoo and co-workers<sup>[11]</sup> reported that oxidative stress is principally involved in the pathogenesis of chronic pancreatitis with fibrosis and antioxidants could prevent and ameliorate the extent of pancreatic fibrosis, suggesting that antioxidants can be considered in preventing and treating chronic pancreatitis. Emodin could inhibit lipid peroxidation<sup>[12]</sup>, and antioxidization maybe another mechanism underlying the anti-fibrotic effect of emodin.

Chronic pancreatitis is a progressive pancreatic fibrotic process, and anti-fibrosis is the key therapy for liver fibrosis. However, previous studies on the effect of emodin on chronic pancreatitis in rats are not available. Our study showed that emodin had an effect on pancreatic fibrosis in rats.

The results of this study indicate that emodin can

significantly affect the development of pancreatic fibrosis by reducing the serum levels of HA and LN, ameliorating the degrees of fibrosis, diminishing the content of collagen, inhibiting TGF- $\beta_1$  expression. Therefore emodin has an excellent prospect in the development of some new praeparatum for the management of chronic pancreatitis. However, there are still some questions we need to answer, such as whether emodin can be used in patients with chronic pancreatitis, whether it is safe, since few previous data are available so far. Further detailed experiments and clinical trails are required to prove the potential clinical application. As a traditional herb, emodin also has a long long way to go.

## COMMENTS

### Background

Chronic pancreatitis is characterized by a progressive pancreatic fibrotic process. However, the mechanism of fibrotic process is not fully understood. Thus anti-fibrosis is the key to the therapy of chronic pancreatitis.

### Research frontiers

Emodin has many biological effects, but studies about its application in chronic pancreatitis are rare.

### Innovations and breakthroughs

There are few studies on the application of emodin in chronic pancreatitis. We designed this experiment to investigate the effect of emodin on pancreatic fibrosis.

### Applications

No ideal therapy is available so far for the treatment of chronic pancreatitis. Emodin may be efficacious in the management of chronic pancreatitis in rats.

### Terminology

Emodin (1, 3, 8-trihydroxy-6-methylanthraquinone), isolated from a great deal of herbs, is an effective constituent with many effects, such as anticancer, antimicrobial, and anti-inflammatory effects, etc.

### Peer review

The topic is of interest because up to now no antifibrotic treatment option is

available in patients with chronic pancreatitis. The positive effect of emodin on development of pancreatic fibrosis described in this paper shows that emodin may be a potential treatment option.

expression and the severity of liver fibrosis. Many of the identified genes were involved in immune responses and cell signaling. To quantify the extent of liver fibrosis, we developed a new genetic fibrosis index (GFI) based on gene-expression profiling of 4 clones using a linear support vector regression analysis. This technique, based on a supervised learning analysis, correctly quantified the various degrees of fibrosis in both 74 training samples ( $r = 0.76$ , 2.2% vs 2.8%,  $P < 0.0001$ ) and 12 independent additional test samples ( $r = 0.75$ , 9.8% vs 8.6%,  $P < 0.005$ ). It was far better in assessing liver fibrosis than blood markers such as prothrombin time ( $r = -0.53$ ), type IV collagen 7s ( $r = 0.48$ ), hyaluronic acid ( $r = 0.41$ ), and aspartate aminotransferase to platelets ratio index (APRI) ( $r = 0.38$ ).

**CONCLUSION:** Our cDNA microarray-based strategy may help clinicians to precisely and objectively monitor the severity of liver fibrosis.

## Abstract

**AIM:** To study a more accurate quantification of hepatic fibrosis which would provide clinically useful information for monitoring the progression of chronic liver disease.

**METHODS:** Using a cDNA microarray containing over 22 000 clones, we analyzed the gene-expression profiles of non-cancerous liver in 74 patients who underwent hepatic resection. We calculated the ratio of azan-stained: total area, and determined the morphologic fibrosis index (MFI), as a mean of 9 section-images. We used the MFI as a reference standard to evaluate our method for assessing liver fibrosis.

**RESULTS:** We identified 39 genes that collectively showed a good correlation ( $r > 0.50$ ) between gene-

## INTRODUCTION

The prognosis and management of chronic liver diseases often depends heavily on the degree of liver fibrosis. This is particularly true of viral hepatitis, where chronic hepatitis B and C infections affect as many as 370 and 130 million persons respectively worldwide<sup>[1,2]</sup>. Liver histology has been the gold standard for monitoring hepatic fibrosis. In response to a need for critical evaluation of fibrosis in controlled therapeutic trials, a variety of staging systems have been developed<sup>[3,4]</sup>. However, intra- and inter-observer variability has resulted in discrepant staging, even in studies involving expert hepatopathologists<sup>[5]</sup>. Alternatively, several serum markers, such as alpha2 macroglobulin

and hyaluronic acid, have substantial predictive value for the diagnosis of cirrhosis, but not the important earlier stages of liver fibrosis<sup>[6]</sup>. Therefore development of a new comprehensive and objective evaluation system to quantify the extent of liver fibrosis is important. More recently, the value of noninvasive assessments of liver fibrosis, such as liver stiffness (Fibroscan) and METAVIR fibrosis score have been studied<sup>[7-10]</sup>. However, no standard diagnostic modality is currently established for assessing liver fibrosis.

To date, there are a few DNA microarray studies investigating gene-expression patterns of non-cancerous liver from patients with chronic liver disease<sup>[11-15]</sup>. These studies successfully identified differentially regulated genes in liver fibrosis, but none investigated any correlation between gene-expression profiles and the extent of liver fibrosis. In our recent report<sup>[16]</sup>, we demonstrated that a specific gene-expression signature can objectively and accurately quantify the variable degrees of hepatic fibrosis in a rat model. Here, we focused on identifying whether our molecular based strategy precisely quantifies the severities of liver fibrosis in humans as well.

## MATERIALS AND METHODS

### Liver samples

Seventy-four patients, including 67 with hepatocellular carcinoma (HCC) and 7 with colorectal liver metastasis who had undergone an initial hepatectomy at our institute and affiliated hospitals were entered in this study. The 67 included 11 positive for hepatitis B surface antigen (HBsAg), 47 positive for hepatitis C virus (HCV) antibody, and 9 negative for either HBsAg or HCV antibody. The 7 metastatic patients were seronegative for either HBsAg or HCV antibody, and they all had liver function values within the normal limits and histologically normal liver was analyzed. The resected non-cancerous liver specimens were meticulously taken as far from the tumor as possible, and were immediately frozen in liquid nitrogen and kept at -80°C until subsequent RNA preparation. Remaining liver was soaked in 10% formaldehyde then embedded in paraffin for azan staining. Written informed consent was obtained from all patients according to the guidelines approved by the Institutional Research Board at each hospital.

### Preparation of sections and measurement of the area of liver fibrosis

Five thick fixed sections were stained with azan for collagen fibers as described previously<sup>[16]</sup>. The section images ( $\times 40$ ) were randomly selected and captured using the Sony DXC S500/OL digital camera. These captured images were entered into a personal computer as PICT files (Adobe Photoshop version 7.0). To determine the morphologic fibrosis index (MFI), the ratio of azan-stained:total area was calculated as described<sup>[16]</sup>. We examined how many or few section-images would be sufficient to determine the MFI as a reference for the degree of liver fibrosis (Figure 1). The fluctuation rate of the MFI in each liver specimen was calculated as follows:

$$\text{Fluctuation rate (\%)} = (n - n-1) / n-1 \times 100$$

**Figure 1** The number of section-images used to calculate the morphological fibrosis index (MFI) and the fluctuation rates of the MFI in the 12 randomly selected liver samples (mean  $\pm$  SD).

where,  $n$  represents the mean MFI value for  $n$  section-images. We calculated the fluctuation rates in 12 randomly selected liver tissue specimens and plotted the mean of these 12 samples according to the number of section-images. As expected, when the number of images was small, the mean MFI value fluctuated markedly. As the number of section-images increased, the fluctuation attenuated and a plateau was subsequently reached at 9 images. In this study, we thus determined the MFI value as a mean of 9 section-images. The mean MFI value (1.13%) of the 7 patients with colorectal liver metastasis but normal liver histology was considered as background and subtracted to determine the MFI values for the 67 patients with HCC.

All non-cancerous liver specimens were independently examined by 2 experienced hepatopathologists (A.S. and Y.Y.) blinded to the results of the DNA microarray analysis, MFI values, and clinical data. The severity of liver fibrosis (0-4) was evaluated semi-quantitatively according to the METAVIR scoring system<sup>[5]</sup>: F0, no fibrosis; F1, portal fibrosis without septa; F2, portal fibrosis and few septa; F3, numerous septa without cirrhosis; and F4, cirrhosis. Quadratic weighted kappa was calculated to estimate the reproducibility of the staging between the 2 pathologists.

### Liver function tests

We calculated the Pearson correlation coefficient between MFI values and 10 preoperative clinical parameters that have been associated with liver function or disease: indocyanine green dye retention at 15 min, prothrombin time (as a% of normal time), hepaplastin, platelet count, albumin, total bilirubin, aspartate aminotransferase, alanine aminotransferase, type IV collagen 7 s and hyaluronic acid. The correlation coefficient between the MFI and aspartate aminotransferase to platelets ratio index (APRI)<sup>[17]</sup> was also calculated.

### RNA preparation

Total liver RNA was isolated from frozen tissue by a guanidium/cesium trifluoroacetate extraction method

using a Quick Prep total RNA extraction kit (Amersham Pharmacia Biotech, Little Chalfont, England)<sup>[18]</sup>. To ensure the use of only high quality RNA, the concentration and purity were determined by an Agilent 2100 bioanalyzer (Agilent Technologies, Palo Alto, CA)<sup>[19]</sup>.

### **Oligonucleotide microarray**

We used the commercially available Human 1A Oligo Microarray (Agilent) containing over 22000 unique 60-mer oligonucleotides representing over 17000 unique human genes, listed <http://www.chem.agilent.com/scripts/generic.asp?page=5175&indcol=Y&prodcol=Y>. Cyanine-labeled cRNA was prepared using a T7 linear amplification as described in the Agilent Low RNA Input Fluorescent Linear Amplification Kit Manual (Agilent). Briefly, 50 ng of purified total RNA was reverse transcribed to generate double-stranded cDNA using an oligo dT T7 promoter primer and MMLV reverse transcriptase. Next, cRNA was synthesized using T7 RNA polymerase, which simultaneously incorporated Cy3 or Cy5 labeled CTP. During this process, experimental samples from potentially fibrotic liver specimens were labeled with Cy5 whereas a control sample from a mixture of the 7 normal liver specimens was labeled with Cy3. The quality of the cRNA was again checked using the Agilent 2100 Bioanalyzer. One microgram aliquots each of Cy3 and Cy5 labeled cRNA were combined, and fragmented in a hybridization cocktail (Agilent). The labeled cRNAs were then hybridized to 60-mer probe oligonucleotide microarrays and incubated for 17 h at 60°C. The fluorescent intensities were determined by an Agilent DNA Microarray Scanner and were analyzed using G2567AA Feature Extraction Software Version A.7.5.1 (Agilent), which used the LOWESS (locally weighted linear regression curve fit) normalization method. The gene-expression values were calculated as the log ratio of the Cy5 to Cy3 channel signals. All calculated data were imported into the Rosetta Luminator system v2.0. (Rosetta Biosoftware, Kirkland, WA) and all intensity data were plotted as log ratios. The original data will be available at URL supplemental website at [http://www.mib-beppu.kyushu-u.ac.jp/MIB\\_res/clin\\_surg/MA/MA\\_data.html](http://www.mib-beppu.kyushu-u.ac.jp/MIB_res/clin_surg/MA/MA_data.html). This microarray study followed MIAME guidelines issued by the Microarray Gene Expression Data group<sup>[20]</sup>.

### **Identification of genes associated with liver fibrosis**

We first excluded genes which had missing values in > 20% of samples. We thus analyzed 16990 genes, missing values in each sample were estimated using the 10-nearest neighbors' method based on the Euclid distance<sup>[21]</sup>. The 67 samples whose MFI values were measured, and the 7 normal liver samples (MFI = 0%), were used for this analysis. The correlation coefficient between MFI values and the expression of each gene in the 74 samples was calculated.

### **Development of quantification scores for liver fibrosis: Genetic fibrosis index**

Next, we determined the parameters in the estimation equation using a linear support vector regression (L-

SVR) analysis<sup>[22]</sup>. The estimation equation based on the L-SVR was expressed in linear equation form, namely "the estimated MFI value = parameter 1 × the expression value of gene a1 + parameter 2 × the expression value of gene a2 + ... + constant b". These parameters and the constant were determined according to Cherkassky's method<sup>[23]</sup>. Here, we define the estimated MFI value based on the gene-expression values as the genetic fibrosis index (GFI)<sup>[16]</sup>. To select the optimal set of marker genes that best correlate GFI to MFI, we used a forward-backward stepwise selection method. In this method, the correlation coefficient between the expression value of each gene listed in Table 1 and the MFI value for the 74 samples was calculated and genes with the highest correlation coefficients were selected. Using these selected genes, the estimation equation parameters and constant were determined, and the correlation coefficient between the GFI and MFI values was calculated one at a time by the L-SVR based system. We repeated these steps with the addition or elimination of genes to improve the correlation coefficient, and we subsequently determined the 4 optimized marker clones. For independent validation, the GFI of 12 additional test samples (one normal and 11 chronically damaged livers) was calculated using these 4 marker clones.

## **RESULTS**

### **MFI and the histological stage of liver fibrosis**

The MFI of the 67 patients with HCC ranged from 0.2% to 18.8% ( $6.8\% \pm 3.5\%$ ). To understand the distribution of MFI values in a clinical setting, we first examined the correlation between the MFI and the stage of liver fibrosis in the METAVIR scoring system (Figure 2). The correlation coefficients between the MFI and the stages of liver fibrosis by Pathologists A and B were  $r = 0.62$  and  $r = 0.61$ , respectively. The reproducibility of the METAVIR scoring between the 2 pathologists was good (quadratic weighted kappa = 0.86). The mean MFI value for liver cirrhosis, stage F4, was approximately 10%.

### **MFI and liver function tests**

We next determined the correlation between the MFI and the results of so-called liver function tests in the 74 samples. The best correlation coefficient ( $r = -0.53$ ) was observed between the MFI and the prothrombin time. The platelet count ( $r = -0.52$ ), indocyanine green dye retention test at 15 min ( $r = 0.49$ ), and type IV collagen 7s ( $r = 0.48$ ) also had good correlation coefficients (Figure 3). Conversely, APRI did not correlate well with the MFI ( $r = 0.38$ ).

### **Identification of differentially regulated genes during liver fibrogenesis**

We identified differentially regulated genes associated with the degree of liver fibrosis in the 74 samples. Thirty-nine genes showed a good correlation ( $r > 0.50$ ) between gene-expression and MFI (Table 1). There were no genes with a correlation coefficient more negative than -0.5. The 39 genes included 24 named genes 18 of which (75%) were associated with immune functions. Specifically, 9 genes

<sup>1</sup>For each clone, the correlation coefficient (CC) between the gene expression level and the morphological fibrosis index (MFI) was determined;

<sup>2</sup>These 4 clones were used to calculate the genetic fibrosis index (GFI).

### Development of a genetic fibrotic index to quantify the degree of liver fibrosis

We selected 4 clones, namely *PIK3C2B*, *NM\_152270*, *BC036926*, and *S65186*, as the optimal marker set using the supervised learning method, L-SVR analysis. Based on the expression profiles of only these 4 clones, the GFI of each sample was then calculated, and the correlation between the GFI and the MFI was determined (Figure 4A). Our method correctly quantified the degree of liver fibrosis in the 74 training samples (Figure 4A,  $r = 0.76$ ,  $P < 0.0001$ ). Furthermore, an almost identical quantification was successfully achieved in the 12 additional independent test samples (one normal and 11 chronically damaged livers) (Figure 4B,  $r = 0.75$ ,  $P < 0.005$ ), supporting the usefulness of our quantifying system for liver fibrosis. Two representative azan-stained images of test samples with

a good correlation between GFI and MFI are shown in Figure 4C. In addition, we showed that good correlations were obtained both in livers positive for HBsAg and those positive for HCV antibody (Figure 5).

## DISCUSSION

To assess the severity of hepatic fibrosis using newer methods, such as Fibroscan and Fibrotest<sup>[7-10]</sup>, most recent studies use the liver biopsy as a reference standard. However, studies using the Fibrotest have suggested that most errors are due to the histological staging itself<sup>[24]</sup>, particularly, the difficulty in distinguishing F2 from F1 or F3 seems to be the main cause of misclassification. Histological scoring system, such as the METAVIR fibrosis score, is a categorical assessment and not a numerical

**Figure 4** Correlation between the morphologic MFI values and the genetic GFI values in the 74 training samples (A) and the 12 test samples (B). (C) Two representative sections after azan staining ( $\times 40$ ) and their corresponding MFI and the GFI values.

measurement along a continuum in a mathematical sense<sup>[25]</sup>. In the current study, we therefore used as our reference the MFI, which is a mean of 9 surgical section-images, and subsequently investigated the value of our cDNA microarray-based strategy for the assessment of liver fibrosis. Although the MFI correlates well with the METAVIR scoring system (Figure 2), there was overlap among the different stages, indicating a limitation of such a histological staging system. The MFI can represent a linear score from mild fibrosis to overt cirrhotic livers. It has been reported that the area of fibrosis determined by image analysis is a reliable morphological method and was superior to histological staging, even if only small pieces of liver biopsy specimens were examined<sup>[26,27]</sup>. To the best of our knowledge, this is the first study to use the area of fibrosis (MFI) of human surgical specimens, which provide relatively large amounts of liver tissue, as a reference standard to evaluate new strategies for assessing hepatic fibrosis.

Using a cDNA microarray containing over 22000 clones, we analyzed the gene-expression profiles of liver tissue specimens and correlated them to the MFI values. We identified 39 differentially regulated genes, including 24 named genes, associated with the degree of liver fibrosis in 74 liver samples. Both the number of genes and the number of patients examined in this study were larger than those of previous reports investigating gene expression profiles of human livers with fibrosis<sup>[11-15]</sup>. Many of the genes we identified are involved in immune responses and cell signaling, which is consistent with a previous report investigating HCV-infected livers<sup>[14,15]</sup>. Among these, genes encoding MHC class II molecules were correlated most predominantly to the severity of liver fibrosis. Because MHC gene products are critical in regulating antiviral

**Figure 5** Correlation between the morphologic MFI values and the genetic GFI values in livers infected with hepatitis B virus (HBV) and hepatitis C virus (HCV).

immune reactions against both HBV and HCV, genetic factors controlling the host's immune response might also play an important role in determining the disease severity in patients with viral hepatitis<sup>[28-30]</sup>. In addition, we identified several genes, such as *PIK3C2B* and *ARHGDI*, which regulate the activation of hepatic stellate cells<sup>[31,32]</sup>, which might contribute to the molecular pathogenesis of liver fibrosis.

To examine possible advantages of our method over the use of blood markers of liver damage, we calculated the correlation coefficient between the MFI and 10 clinical parameters of so-called "liver function tests" (Figure 3) to include some of the large number of promising serum markers of hepatic fibrosis, e.g. collagen IV and hyaluronic acid. Prothrombin time correlated best with the MFI ( $r = 0.53$ ). The correlation

**Figure 6** Gene-expression correlation between surgical resection and 22-gauge needle liver biopsy specimens from the same patient. Intensity data were plotted and the correlation coefficient calculated by the Rosetta Luminator system v2.0 (A). The GFI values of resected and biopsy specimens were determined using the same formula based on the 4 marker clones (B). RS: Resected specimen.

coefficient ( $r = 0.38$ ) between the MFI and the APRI<sup>[17]</sup> was inferior to that of the prothrombin time alone. It may well be that a panel of serum markers may prove more accurate than any individual marker. We next developed quantified scores for human liver fibrosis based on a specific gene-expression signature or index (GFI), which was validated by a supervised learning analysis. Our data showed that the GFI in the 74 training samples correlated with the MFI markedly better ( $r = 0.76$ ) than any biochemical or hematological markers examined in this study. Furthermore, a similar correlation ( $r = 0.75$ ) was confirmed in the 12 test samples as well. Therefore, our current study demonstrates for the first time that a single test based on gene-expression profiling accurately quantifies the variable extent of liver fibrosis in a clinical setting.

Marker genes involved in the pathogenesis of liver fibrosis might differ depending upon the etiology of the chronic liver damage. We therefore examined whether a different correlation with the MFI was observed between different etiologies (Figure 5). The correlation between MFI and GFI did not apparently differ markedly between HBV and HCV infected livers. This is reasonable because we selected our marker genes that were correlated to the degree of liver fibrosis regardless of etiology. One might expect a better performance if we analyzed samples with a single cause of liver fibrosis. However, we did not obtain better results even when we examined only livers infected with HCV ( $n = 54$ ) using the same statistical method (data not shown).

Although the MFI may reliably determine the extent of fibrosis, a distinct advantage of the GFI is the potential for measuring a fibrosis index using very small liver biopsies. For example, in preliminary studies there was a very high correlation ( $r = 0.98$ ,  $P < 0.01$ ) between the levels of gene expression comparing genetic profiles of resected liver

tissue and very small 22-gauge liver biopsy specimens from the same patient (Figure 6A). Regardless of the sample size, the GFI values were quite reproducible from the same patient (Figure 6B). We extracted on average  $3.4 \pm 0.5$  g of high quality total RNA using the 23-gauge Surecut needle (TSK Laboratories), while only 0.2 g total RNA is sufficient for microarray analysis in our system. This will need to be validated with a larger number of patients, and might even include sampling more than two liver areas to reduce sampling error with minimal risk using the 23-gauge needle.

Finally, we successfully created a scoring system to accurately and objectively quantify the degree of liver fibrosis in humans, based on the gene-expression signatures. This genome-wide information contributes to an improved understanding of molecular alterations during the development of liver cirrhosis, and could potentially become a powerful tool for monitoring the stage of liver fibrosis before and after treatment, such as with interferon/ribavirin therapy. This may be particularly important given recent exciting evidence on the potential reversibility of hepatic fibrosis in some patients<sup>[33]</sup>. Although our method still relies on invasively obtained liver tissue, however small, our data does draw attention to potentially helpful novel diagnostic and therapeutic targets, some of which may even have serum-measurable correlates based on future research.

## Abstract

**AIM:** To determine the effectiveness of yoga on improving the quality of life in patients of chronic pancreatitis.

**METHODS:** The patients were randomized to two groups. The control group continued their usual care as directed by their physicians. Patients in the yoga group, in addition, received biweekly yoga sessions for 12 wk. The patients' demographic and health behaviour variables were assessed before and after the yoga programme using Medical Outcomes Short Form (SF-36) for quality of life, Profile of Mood States for assessing mood and Symptoms of Stress Inventory for measuring stress.

**RESULTS:** A total of 60 patients were enrolled, with 8 drop-outs. Thirty patients were randomized to the yoga group and 30 to the control group. Significant improvements were seen in overall quality of life, symptoms of stress, mood changes, alcohol dependence and appetite after the 12 wk period apart from the general feeling of well-being and desire to continue with the programme in future in the yoga group, while there was no difference in the control group.

**CONCLUSION:** Yoga is effective on improving the quality of life in patients of chronic pancreatitis.

## INTRODUCTION

The pain that develops in chronic pancreatitis is often severe, chronic, aggravated by meals and may be present continuously including at night. In some patients the pain is so severe that they develop a fear for eating and, as a consequence, they lose significant amounts of weight. The pain may begin gradually; however, in many patients over time they develop into continuous pain. The pain is usually worse in the back rather than in the front of the abdomen. The severity of the pain makes many patients into pain cripples. The worsening of the pain with meals may lead to avoidance of foods, causing severe weight loss and malnutrition of the patient.

Treatment of the pain requires familiarity with the patient's disease, an understanding of wide variations in presentation and manifestations of chronic pancreatitis and knowledge of the different treatment options available, their advantages and disadvantages. Treatment is best provided in a centre where experienced physicians from different specialties provide comprehensive approaches to the care of the patient and there is coordination of care between the different specialties.

At our center, we offer a comprehensive approach to pain from pancreatic diseases with clinical evaluation by a pain management specialist, pancreatic surgeon, gastroenterologist and psychologist as indicated. Many patients may also require treatment in a rehabilitation program prior to or after the surgery for drug dependency. The drug dependency develops on narcotic drugs due to years of over usage prior to a surgical consultation in many patients. Yoga was introduced as a tool for rehabilitation programme and to supplement the other pain relief measures being taken by the patients.

Therapy of chronic pancreatitis rests on five arms: Avoidance of alcohol, treatment of pain, replacement therapy for exocrine and endocrine insufficiency and adequate nutrition. Alcohol withdrawal improves pain and the patient's compliance. It also seems to retard the chronic inflammatory process. Therapy of pain depends on the pathomechanism of pain. There is a lack of prospective, controlled studies comparing various treatment regimens. Thus, treatment options are partly dependent on the experience of the physician taking care of the patient. Thanks to improved substitution with acid resistant porcine pancreatic extracts with high lipase activity, fat restriction is no longer of paramount importance. However, supply with sufficient calories is still difficult due

to pain and inadequate compliance<sup>[1]</sup>.

It was reported that the use of alternative therapies in the United States increased from 33.8% in 1990 to 42.1% in 1997<sup>[2]</sup>. Therapeutic recreation (TR) has traditionally provided many of approaches in their work with clients. Typically embedded in the rubric of stress management, TR professionals teach and provide complementary alimentary medicine (CAM) techniques such as aromatherapy, massage, yoga, and tai chi to clients<sup>[3]</sup>. Yoga as a clinical intervention has been associated with a variety of physical and psychological health outcomes such as improved mood and reduced symptoms of anxiety and depression<sup>[4]</sup>.

Stress reduction and anxiety management programs could be useful for any disease because they help to create a supportive environment, in which the individual may have reduced anxiety. Caroleo identified several programs that reduce stress and anxiety among AIDS patients, including "yoga, massage, acupuncture, acupressure, chiropractic services, meditation, reiki, physical and breathing exercises and visualization"<sup>[5]</sup>.

Despite yoga's wide popularity, there are limited numbers of randomized, controlled yoga studies using objective quantitative outcome measures, and these studies often have small numbers of subjects<sup>[6-9]</sup>.

## MATERIALS AND METHODS

A computer-generated random allocation sequence was prepared. The assignments were placed in serially numbered, sealed, opaque envelopes. Patients were randomized after enrolment. The study enroller screened the patient and, if the patient was qualified, obtained informed consent and completed the baseline measurement. Then the next envelope was opened and the treatment allocation discussed. No assignment was reused with another patient once the envelope had been opened. Patients completed their own assessments, and blinding was not possible.

Both treatment groups continued the standard therapy as directed by their primary physician during the 12 wk intervention period. Patients were asked to remain on the same medications and not to start new ones. A medication diary was provided to document medications for pain, and their dosages, frequencies and side effects.

### Data collection

Demographic data and patients' history were obtained using a checklist and short answer questionnaire. Demographic variables included age, ethnic background, marital status, education, employment status, and occupation.

The SF-36 questionnaire was used to assess the quality of life. SF-36 is a generic health outcome measure that is designed for use across varied populations<sup>[10]</sup>. It is comprised of 36 items across eight scales: physical functioning, role function-physical, bodily pain, general health, vitality, social functioning, role function-emotional, and mental health. Each scale is scored from 0 to 100, with higher values indicating more favourable health status. The SF-36 has been used in numerous studies of cancer

patients and has evidence of validity in both cancer and pain patient groups<sup>[11,12]</sup>.

The Profile of Mood States (POMS)<sup>[13]</sup> is a 65-item scale, which assesses six affective dimensions. It has been widely used in the assessment of mood changes resulting from a variety of interventions due to its responsiveness and has been used extensively in various populations<sup>[14]</sup>.

The Symptoms of Stress Inventory (SOSI) is designed to measure physical, psychological, and behavioural responses to stressful situations. Respondents are instructed to rate the frequency with which they experience various stress-related symptoms on a five-point scale, ranging from "never" to "frequently," during a designated time frame selected by the investigator (in this case, the past week). The SOSI overcomes the limitations of checklist measures, which assume universally valid weightings of stressful events based on normative data, by focusing on manifest symptoms of stress and obviates the need for patients to identify and rate all relevant stressful events occurring in their lives. Both predictive and concurrent validities have been demonstrated, and, in a mixed chronic-illness sample of patients with malignant melanoma and myocardial infarction, manifest symptom distress as measured by the SOSI was directly related to functional alterations due to disease and inversely related to cognitive adaptation and perceived quality of life<sup>[15]</sup>.

The yoga program was designed to complement the management of pain and anxiety based on a sequence of yoga poses by B.K.S. Iyengar<sup>[16]</sup>. Iyengar is one of the world's foremost exponents of yoga and is recognized by the medical community in India as an expert in treating medical problems with yoga. Iyengar has evolved the therapeutic application of yoga postures. Iyengar's yoga is particularly beneficial for people with chronic pain because he has researched and understood the therapeutic benefits of the poses<sup>[17]</sup>. In consultation with a certified yoga instructor, the psychiatrist, members of the interdisciplinary team and the literature on Iyengar's sequence of poses, a yoga program was designed for participants.

The yoga program was implemented, directed and evaluated by the authors. Yoga sessions were planned for thrice a week over a 12 wk period. Each session lasted approximately one hour. The sessions were held in early morning in an open park. This area provided ample space for participants to practice yoga without feeling confined.

Prior to the start of the yoga intervention, the authors consulted with the nurse manager, attending physician and psychiatrist, and reviewed the medical records to authenticate the diagnosis of chronic pancreatitis for each participant. Prior to the start of the yoga program, each participant was interviewed to determine his or her willingness to participate in the study and signed informed consent for involvement in the study.

At this time, each participant was given a brief definition of yoga and particularly a description of the sequence of poses that were to be used. Preparation and guidelines for the yoga classes were reviewed, such as to come empty stomach, not to eat anything for one hour before the session, and wearing loose and comfortable clothing. Finally, participants were told of the duration and frequency of the yoga program and that if they wish, they

Table 1 Demographic profile of the participants, (mean  $\pm$  SD)

Variable	Yoga group	Control group	P
Age (yr)	50 $\pm$ 5.2	50 $\pm$ 6.3	0.712
Body mass (kg)	55.4 $\pm$ 17.6	56.1 $\pm$ 16.4	0.801
Education (yr)	16.0 $\pm$ 2.4	15.8 $\pm$ 3.2	0.72
Marital status (% married)	73	74	0.865
Employment (% employed)	56	57	0.928

could discontinue participation at any time.

As the participants entered the session, initial evaluation data were collected including the recording of each participant's pain levels, weight, average diet, pain relief medications.

As in many classical yoga classes, the class started with 15 min of meditation. During the meditation, the participants were instructed to breathe diaphragmatically. This breathing technique 'pranayama' allowed the participants to slow down their breathing and at the same time begin to slow down their body and mind. Further instructions were given to clear the mind of any unwanted thoughts and as the thoughts came into their mind, to allow them to flow freely out. During the meditation, the participants were instructed to concentrate on their breathing and follow each breath. After meditation, the participants completed a 10-min warm-up of various yoga arm stretches and movements to relax their muscles and circulate their blood and oxygen throughout their body. Once warm-ups were completed, each participant attempted to remain in each pose for 1 to 3 min or as tolerated. Modifications were necessary for several of the participants when the poses became too uncomfortable.

At the end of the last pose, the relaxation pose (Savasana), participants were instructed to slowly awaken the body by opening their eyes and begin to gently stretch various parts of the body such as neck, hands, and feet. Participants then completed a seated cross-leg pose with their palms together at the heart.

Suitable alterations were made in yoga programme for the participants finding some difficulty in doing the various poses (asanas).

### Analysis and observations

Out of 30 patients randomised to yoga group, 26 completed the full 12 weeks course. They ranged in age from 41 to 69 years (mean, 50). All participants were diagnosed with chronic pancreatitis and were taking pain and anxiety medications. 86% of the patients were males and 90% of them were alcoholic at some stage of their life.

### Statistical analysis

All data were analysed using the SPSS version 12 statistical software package. Descriptive statistics (frequencies, means, standard deviations, and percentages) were used to characterize the sample. An alpha level for a significant difference was set at 0.01 because of the number of variables.

Table 2 Comparison of SF-36 score in yoga and control groups, (mean  $\pm$  SD)

SF-36 subscale	Yoga group			Control group		
	0 wk	12 wk	P	0 wk	12 wk	P
Physical functioning	62.9 $\pm$ 0.6	74.1 $\pm$ 0.5	0.0001	63.8 $\pm$ 0.8	63.6 $\pm$ 0.6	0.08
General health	66.8 $\pm$ 0.4	74.8 $\pm$ 0.3	0.001	67.7 $\pm$ 11.3	69.6 $\pm$ 12.4	0.10
Role-physical	57.9 $\pm$ 21.4	63.1 $\pm$ 19.3	< 0.01	56.3 $\pm$ 18.6	54.6 $\pm$ 16.7	0.12
Bodily pain	41.4 $\pm$ 14.1	60.4 $\pm$ 14.4	< 0.01	45.5 $\pm$ 17.4	48.0 $\pm$ 15.9	0.05
Vitality	32.1 $\pm$ 14.2	45.2 $\pm$ 16.3	< 0.01	33.2 $\pm$ 13.9	33.0 $\pm$ 12.6	0.61
Social functioning	61.4 $\pm$ 22.3	78.4 $\pm$ 20.2	< 0.01	63.8 $\pm$ 18.1	70.5 $\pm$ 15.7	0.22
Role-emotional	47.2 $\pm$ 38.8	77.7 $\pm$ 30.1	< 0.01	47.8 $\pm$ 29.7	48.6 $\pm$ 31.1	0.55
Mental health	41.3 $\pm$ 14.3	61.3 $\pm$ 13.9	< 0.01	45.9 $\pm$ 12.6	46.3 $\pm$ 15.9	0.33

Data were analysed using the intention-to-treat approach. The last-observation-carried-forward procedure was used for participants who did not complete the trial. No transformations were required for statistical analyses. Baseline comparisons between the two groups were made using independent-sample *t*-tests for continuous data and Pearson's  $\chi^2$  tests for categorical data. This adjusted statistical analysis was performed to reduce the impact of baseline differences on study outcomes (given the relatively small sample size of the trial). A two-sided *P* value of < 0.05 indicated statistical significance. No adjustments were made for multiple comparisons. Data are presented as the means  $\pm$  SD with 95% confidence intervals. As a check for the validity of the parametric test, we also made a nonparametric analysis for 2 independent groups (Mann Whitney U) and found the same variables to be significant as by the *t*-test. Formal directional hypotheses were not made a priori. However, we expected to find improvement in quality of life in participants in the yoga programme.

## RESULTS

There was no statistical difference between the demographic profile of the patients in yoga group and control group (Table 1), indicating that the participants were properly randomised and matched.

### Quality of life scores

The SF-36 results shown in Table 2 revealed a statistically significant improvement in all components of the scoring system in the participants of the yoga group, while there was no marked difference after 12 wk in the control group. Only scores of those who completed the program (*n* = 52) were included because 12 wk scores were not available for dropouts. Dropouts were eliminated from all subsequent analyses. The scores before the start of yoga programme in both groups were comparable, indicating the appropriate matching of the participants.

### Mood scores

POMS change scores for all patients (yoga and control)

**Table 3** Comparison of POMS score between yoga and control groups, (mean  $\pm$  SD)

Variable	Yoga group		Control group	
	0 wk	12 wk	0 wk	12 wk
Anxiety	11.7 $\pm$ 6.5	9.1 $\pm$ 5.4 <sup>a</sup>	11.5 $\pm$ 4.6	11.7 $\pm$ 5.3
Depression	9.7 $\pm$ 6.6	5.4 $\pm$ 5.8 <sup>d</sup>	9.6 $\pm$ 4.7	9.4 $\pm$ 6.3
Anger	9.8 $\pm$ 5.6	5.9 $\pm$ 6.6 <sup>b</sup>	9.6 $\pm$ 6.1	9.2 $\pm$ 2.6
Vigour	12.8 $\pm$ 3.8	17.1 $\pm$ 5.2 <sup>b</sup>	12.9 $\pm$ 2.6	13.6 $\pm$ 6.0
Fatigue	14.1 $\pm$ 3.4	8.6 $\pm$ 3.8 <sup>b</sup>	13.9 $\pm$ 4.1	14.2 $\pm$ 4.3
Confusion	5.5 $\pm$ 4.9	3.2 $\pm$ 2.8 <sup>b</sup>	5.7 $\pm$ 1.8	5.6 $\pm$ 2.3

<sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.01$ ; <sup>d</sup> $P < 0.001$ .

who completed the study are presented in Table 3. At 12 wk (after the yoga group had completed the program), POMS scores were significantly higher in the yoga group, indicating less mood disturbance. When change scores were calculated and assessed with independent-samples *t* tests, the difference between the two groups was even clearer, with significantly more change in the direction of reduced mood disturbance in the yoga group. The treatment program resulted in a 40% reduction in Total Mood Disturbance as measured by the POMS; while the reduction in the control group was only 2%.

### Stress scores

SOSI scores for the yoga and control groups before and after the yoga programme are presented in Table 4. There were no differences between the two groups before the start of yoga programme, again indicating that the groups were initially matched in stress symptoms. There was a statistically significant decline in stress scores in the patients of yoga group after 12 wk, while there was no difference in the scores in control group. Using independent-samples *t* test, there was a greater decrease in yoga group in the subscales of depression, gastrointestinal, habitual patterns and anxiety scores.

### General well being

Interviews were conducted with participants at the end of the 12-wk yoga intervention to help determine its effectiveness. Each participant's thoughts regarding the yoga intervention were noted and all candidates claimed some benefits from the yoga programme. While each individual reported gains as a result of the yoga intervention, perhaps the best indicator of its effectiveness was found in the participant's request to continue the program. After the conclusion of the 12-wk yoga intervention, all participants expressed an interest in continuing the yoga.

## DISCUSSION

These results provided evidence that a relatively brief mindfulness meditation and exercise based stress reduction programme could effectively improve the quality of life, mood disturbance and stress related symptoms in patients with chronic pancreatitis, consistent with other investigations of similar interventions in different

**Table 4** Comparison of SOSI score between yoga and control groups, (mean  $\pm$  SD)

<sup>a</sup> $P < 0.05$ ; <sup>b</sup> $P < 0.01$  vs control.

populations<sup>[18-20]</sup>. It is reasonable to conclude that even greater benefits may be obtained by participants who continue to practice over time and adopt yoga as part of their daily life. The current study was a pragmatic one, intending to study yoga as it is commonly practiced, i.e. as an adjunctive therapy to the standard therapy. The clinical question the study sought to answer was: does yoga add any benefit to patients with chronic pancreatitis in addition to the standard therapy? Our data indicate that yoga plus the standard therapy does increase quality of life in these patients compared with the standard therapy alone, in a clinically and statistically significant manner. Our protocol does not require a standardized regimen for the standard therapy, which makes it possible for baseline differences between the two treatment groups to occur. In addition, every patient followed the standard therapy protocol within defined parameters. The data from this pragmatic study also more closely resembles the clinical setting in which yoga is actually used, i.e. an adjunctive therapy to a variety of standard therapies.

It is commonly held that patients choose to use CAM because they are dissatisfied with conventional treatments that are perceived to be ineffective or have unpleasant side effects, or to be impersonal or too costly<sup>[21]</sup>. It has, however, been pointed out that disenchantment with conventional medicine is not necessarily the reason why patients turn to CAM<sup>[22]</sup>. This appears to be supported by a US study that reported users of alternative health care are no more dissatisfied with or distrustful of conventional care than non-users are<sup>[23]</sup>.

In addition, an extensive review of meta-analyses and recently published studies of mind-body therapies concluded that there is strong evidence for the efficacy of mind-body therapies for coronary artery disease, headaches, insomnia, incontinence, chronic low back pain, disease and treatment-related symptoms of cancer, and improving post-surgical outcomes<sup>[24]</sup>.

Most standard therapies for chronic pancreatitis frequently carry adverse effects, particularly in older patients, further compromising their quality of

life. NSAIDs carry a 2- to 5-fold increased risk of gastrointestinal bleeding, which increases with age<sup>[25]</sup>. NSAID-induced renal, cardiovascular, central nervous system (CNS) and hematological side effects are also more common in older individuals. Use of narcotic analgesic agents results in an increased risk of falls in patients aged 60 yr and over (odds ratio of 1.54)<sup>[26]</sup>, as does polypharmacy with CNS active medications (odds ratio of 2.37)<sup>[27]</sup>. Bed rest leads to de-conditioning and osteoporosis, especially in the elderly, who often are already at risk for these conditions<sup>[28]</sup>. The literature has shown yoga to be a safe treatment. Our study, likewise, documents its safety. When yoga was added to the standard therapy, patients tended to take fewer medications.

There has been little research on the mechanisms by which yoga practice might relieve back pain. Although Westerners often think of yoga as a form of exercise, the practice of yoga places as much emphasis on mental focus as on physical movement<sup>[29]</sup>, and considers the breath, which links the mind and the body, as the key to achieving both physical and psychological benefits<sup>[17]</sup>.

Several large follow-up studies in the past decade suggest that recurrent acute exacerbations dominate the clinical picture in the first few years after onset of symptoms, and progressive pancreatic insufficiency is the predominant feature in the late stages of the disease<sup>[30]</sup>.

Chronic pain is complex physiologically and there are many influencing factors on the pain experience. The approach to treatment therefore needs to be multimodal, often with a number of different interventions, both physical and psychological, delivered in parallel. Chronic pain differs from acute pain in that management follows a rehabilitative rather than a treatment model, though these are not mutually exclusive. Full assessment of the patient, preferably multi-disciplinarily, will improve his or her outlook. Management should be holistic, rigorous in the application of conventional therapies (including analgesics and physical therapy) and ready to admit an improved understanding of psychological and social techniques<sup>[31-33]</sup>.

Patients appreciate their surgeon's continued interest and involvement in their disease and management, and the surgeon can overcome a sense of abandonment that may accompany the discharge of a patient who is not fully healed. Patients who have chronic pain often understand that their pain will not disappear. That their surgeon will not disappear can help them to accept and live with their pain<sup>[34,35]</sup>.

Chronic pain can trigger a cycle of disabilities. Those who suffer from it often retreat into themselves, becoming inactive and minimizing contact with other people. This lack of social interaction often contributes to feelings of depression and isolation. These individuals traditionally rely on pain medications to get through the day and then to sleep, and those medications may cause side effects including dizziness, nausea, and drowsiness that immobilize them further. In addition, the severe pain commonly leads to inactivity that weakens or de-conditions muscles to make them feel even more infirm. Over time, despair may set in, and pain may seem even worse. Chronic pain is pervasive and often limits participation in desired activities.

Because pain is such a complicated problem, managing

it requires a multidimensional approach. Some patients seek alternative solutions such as yoga to relieve their pain. Because yoga is multifaceted physical exercise, breathing, relaxation and meditation is integrated into one's being when it is practiced. Such integration has a strengthening effect on the whole self, and fortifies resistance to pain. Yoga offers a very distinct approach to pain. It brings awareness to the body, especially to the parts that are in pain. Yoga helps individuals become more accepting of their body and less judgmental and reactive to pain. With time, an individual with pain will know what makes them feel worse and how to coax their body into balance. Additionally, as individuals practice various yoga poses, their attention is gently directed to other parts of the body at any given moment. In other words, attention is diverted from pain areas and focused on yoga poses. Finally, the poses themselves can ease pain. They can increase muscle strength and flexibility, improve circulation in the joints and muscles, and stimulate the brain to produce painkilling chemicals.

Studies indicate that yoga was beneficial in reducing anxiety and depression in older adults who attended a geriatric clinic and presented with a wide range of affective symptoms related to anxiety and depression<sup>[36]</sup>.

Yoga lowers heart rate, promotes deeper breathing, and induces brain wave patterns that are associated with relaxation and optimism. These effects are much like those of meditation, and it is appropriate to think of yoga as a kind of meditation to the body. A study of 22 medical patients with a defined anxiety disorder showed clinical and statistically significant improvements in objective symptoms of anxiety and panic following an eight-week outpatient physician-referred group stress reduction intervention based on mindfulness meditation and yoga stretches<sup>[37]</sup>.

Regular practice of the classical yoga postures can be quite helpful in producing a healthy immune system and proper environment for its functioning. Many of the Iyengar yoga poses are extremely effective in producing the "relaxation response" and in counteracting the negative effects of the "stress response" on the immune system<sup>[38]</sup>. These poses are useful for calming and nurturing and are especially valuable when one is too sick or too weak to perform the more vigorous, classical poses<sup>[39]</sup>.

Yoga helps lower stress hormones that compromise the immune system, while also conditioning the lungs and respiratory tract, stimulating the lymphatic system to oust toxins from the body, and bringing oxygenated blood to various organs to ensure their optimal function. The practice of specific asanas can help balance the immune system and help support the thymus and blood to the sinus.

This brief review of the literature provides preliminary support for considering yoga as a CAM intervention in patients who are experiencing pain and anxiety. The literature, while limited, indicates that yoga has been shown to be effective in minimizing pain and anxiety in some populations, specifically the elderly and individuals with behavioural health diagnoses, and that it is effective in minimizing stress in cancer patients. The literature also indicates that pain and anxiety are frequent and distressing

co-occurring disorders in patients of chronic pancreatitis that significantly detract from their health and well-being. Based on this review, yoga may be a beneficial intervention for managing patients with chronic pancreatitis.

Future yoga intervention studies will be needed to carefully control for the class aspect that may be beneficial to everyone, especially seniors. There is also likely some placebo effect related to the yoga intervention. One group has already shown that psychological benefits of an aerobic exercise intervention in a group of healthy young adults could be increased simply by telling subjects that the exercise program was specifically designed to improve psychological well being<sup>[40]</sup>.

Further studies should be emphasized to examine the long-term effects of yoga in terms of management for patients of chronic pancreatitis. In our study, the participants self-reported a decrease in pain and anxiety frequently after each yoga session; however, this study did not examine how long these reductions were maintained. Besides, we did not compare the biochemical data of the patients before and after the yoga programme, which can be researched in future studies. While findings from the current study provide preliminary results, indicating that yoga can be used as an intervention to reduce stress and anxiety in patients of chronic pancreatitis, proper training and knowledge of the principles that guide the practice of yoga must be thoroughly understood and demonstrated by any recreation therapist who would like to use this intervention with clients.

As the use of CAM techniques continues to become more common in many health care facilities, it will only benefit recreation therapists to take advantage of a modality such as yoga to assist in the self-management of illness and disease. Nonetheless, there is room for more education of patients and professionals, and for more research in order to establish the effectiveness of the wide range of management options available.

### Abstract

**AIM:** To evaluate the role of leptin levels in the differential diagnosis of ascites.

**METHODS:** Ascitic leptin,  $\text{TNF}\alpha$  and serum leptin levels were measured in 77 patients with ascites (35 with malignancies, 30 cirrhosis and 12 tuberculosis). Control serum samples were obtained from 20 healthy subjects. Leptin and  $\text{TNF}\alpha$  levels were measured by ELISA. Body mass index (BMI) and percentage of body fat (BFM) by skin fold measurement were calculated for all patients and control groups. Peritoneal biopsy, ascites cytology and cultures or biochemical values were used for the diagnosis of patients.

**RESULTS:** In patients with malignancies, the mean serum and ascites leptin levels and their ratios were significantly decreased compared to the other patient groups and controls. In tuberculosis peritonitis, ascitic fluid  $\text{TNF}\alpha$  levels were significantly higher than malignant ascites and cirrhotic sterile ascites. BMI and BFM values did not distinguish between patients and controls.

**CONCLUSION:** In patients with malignant ascites, levels of leptin and  $\text{TNF}\alpha$  were significantly lower than in patients with tuberculous ascites.

### INTRODUCTION

Leptin, a product of the obese gene, is a multifunctional hormone secreted predominantly by adipocytes. It was discovered in 1994 by Friedman *et al*<sup>[1]</sup>. The importance of leptin in the regulation of energy balance, food intake and body composition through a central feedback mechanism has been demonstrated in both animal and human studies<sup>[2-5]</sup>. In humans, circulating leptin levels exhibit a particularly strong positive correlation with the body fat mass (BFM), body mass index (BMI) and sex. Serum leptin concentration is higher in obese than in lean subjects and in females than in males<sup>[6]</sup>. On the other hand, leptin serum levels can be altered in various diseases<sup>[7]</sup>.

Liver cirrhosis is associated with hypercatabolism and malnutrition that leads to increased energy expenditure<sup>[8]</sup>. Previous studies have shown that circulating leptin levels are modestly elevated in patients with alcoholic and posthepatic cirrhosis<sup>[9-12]</sup>. Another study reported that the ascitic fluid leptin levels of cirrhotic patients with sterile ascites are on average two times higher than circulating levels of this hormone<sup>[13]</sup>. Serum leptin levels have been reported to be reduced in cancer patients<sup>[14,15]</sup>. Abramov *et al*<sup>[16]</sup> found low leptin levels in serum, pleural, peritoneal fluids and in Meigs' syndrome as well. In the literature, there is no study about leptin levels in malignant ascites. In patients with active pulmonary tuberculosis, a previous study found increased leptin concentrations and a correlation with increased concentrations of tumor necrosis factor than control groups. After antituberculosis therapy, leptin levels of these patients were elevated, but this increase was not statistically significant<sup>[17]</sup>. However, in a recent study in patients with active pulmonary tuberculosis, leptin levels were determined to be decreased. Reduced body fat content secondary to anorexia and cachexia during the active disease period was claimed as a reason for this<sup>[18]</sup>. To our knowledge, there is no study

about this subject in either ascites or serum of patients with tuberculosis peritonitis.

There are problems in the differential diagnosis of ascites. Especially diagnosis of exudative ascites (including lymphoma, various forms of peritonitis, peritoneal carcinomatosis, and peritoneal tuberculosis) is a dilemma. Non-invasive tests such as laboratory tests, acid-fast stain and culture of the ascitic fluid, ADA levels are usually insufficient for the differential diagnosis of ascites<sup>[19,20]</sup>. Therefore laparoscopy with directed biopsy is necessary for the diagnosis of ascites. In the light of these findings of our prospective study, leptin may be accepted as a new criterion for the differential diagnosis of malignant and benign ascites.

## MATERIALS AND METHODS

### Materials

The study population consisted of 77 patients with ascites and 20 healthy people who were recruited from the Department of Gastroenterology, Gaziantep University Hospital, Gaziantep, Turkey. The patients were divided into three groups. Group I consisted of 35 patients with various types of malignant diseases (seven ovarian adenocarcinoma, ten adenocarcinoma of the colon, five lymphoma, seven pancreatic adenocarcinoma, six gastric adenocarcinoma). Mean age was  $56.2 \pm 17.4$  years (20 men and 15 women). Group II included 30 cirrhotic patients (mean age  $55.05 \pm 13.26$  years, 15 men and 15 women). The diagnosis of cirrhosis was based on the typical findings of hepatic cirrhotic appearance, splenomegaly, esophageal varices and ascites (by ultrasonography and upper gastrointestinal endoscopic examinations), with biochemical data. Etiology of cirrhosis was hepatitis C virus in fifteen patients, hepatitis B virus in thirteen patients and cryptogenic in two patients. The severity of cirrhosis was graded according to the Child-Pugh classification<sup>[21]</sup>. All of the patients were Child C. Group III consisted of 12 patients with tuberculous peritonitis (these patients were diagnosed with laparoscopic peritoneal biopsy, mean age  $51.9 \pm 15.3$  years, 5 men and 7 women). The control groups included 20 healthy volunteers (mean age  $52.9 \pm 13.3$  years, 10 men and 10 women). Exclusion criteria were diabetes mellitus, existence of pleural effusion, gastrointestinal bleeding, spontaneous bacterial peritonitis and renal failure, treatment with corticosteroids, immunosuppressive agents and oral contraceptive agents within the last 6 mo. Control group consisted of healthy individuals with normal medical history, physical examination and blood biochemistry. None of them have had a restriction of diet for losing weight during the last three months. The local ethics committee approved the study and written consents were received from all participants.

### Methods

Blood samples were obtained in the early morning after an overnight fasting (12 h). The blood was centrifuged at 3000 rpm for 20 min at 4°C and serums were stored at -80°C until analysis of leptin concentrations. Biochemical

analyses were done during the same day. After paracentesis of peritoneal fluid, ascitic fluid was collected under sterile conditions and seeded in both aerobic and anaerobic cultures. It was immediately centrifuged at 3000 rpm for 20 min at 4°C and stored at -80°C in tubes for assessment of leptin levels. Ascitic fluid was also obtained for routine biochemical analysis, cytologic exam and white blood cell counts.

Body composition such as BMI, skin fold thickness, body fat percentage (BFP), and BFM analysis was performed in patients and controls. BMI was defined for study populations as weight divided by height squared ( $\text{kg}/\text{m}^2$ ). Skinfold thickness was measured at four different sites on the left side of the body (triceps, biceps, subscapular and supra-iliac) using a Holtain skinfold caliper. Percent body fat (%BF) was calculated using the Jackson's formula<sup>[22]</sup>, BFM was calculated using BFP and body weight as in kilograms, and triceps skinfold thickness less than a 10<sup>th</sup> of a percentile<sup>[23]</sup> was excluded. Serum and ascitic fluid leptin and serum TNF $\alpha$  levels were measured by a commercially available ELISA kit (Quantikine Human Leptin Immunoassay; RD Systems). The lower limit of detection was 0.05  $\mu\text{g}/\text{L}$ . The intra-assay and interassay coefficients of variation was below 12%.

### Statistical analysis

Results were given as mean  $\pm$  SE. Comparisons between and among the groups were made using a non-parametric test (Mann-Whitney *U* test) and one way ANOVA variant analyses. Statistical analysis for the comparison of serum and ascitic fluid analyses was carried out by means of Wilcoxon matched pairs signed rank test. The correlation among numerical data was analyzed by the Pearson correlation coefficient (*r*). Spearman's rank correlation test was used for estimation of the level of the association between two variables. Data were statistically evaluated using the SPSS v10.0 (Statistical Program for Social Science, version 10.0, Chicago, IL, USA) software packages.  $P < 0.05$  was taken as significant.

## RESULTS

### Patients' demographic data

The demographic, anthropometrical characteristics of all patients and control groups are showed in Table 1. There were no statistically significant differences between three patients groups and the controls regarding BMI, BFP and BFM ( $P > 0.05$ ).

### Serum and ascitic fluid leptin and TNF $\alpha$ levels

The main biochemical analyses, leptin, and TNF $\alpha$  levels of the ascitic fluid of the patients and serum leptin levels are shown in Table 2. None of the patients had spontaneous bacterial peritonitis. Serum concentrations of leptin were significantly elevated in tuberculosis and cirrhotic patients compared with serum levels in control and malignant patients groups ( $P = 0.0001$ ). There were no statistically significant differences in serum leptin levels between cirrhosis and tuberculosis patient groups ( $P > 0.05$ ). In addition serum leptin levels of malignant patients were

Table 1 Demographic and anthropometrical characteristics of all subjects

Characteristic	Mean age $\pm$ SD (yr)	BMI (kg/m <sup>2</sup> )	BFP (%)	BFM (kg)
Cirrhotic patients (n = 30)	55.05 $\pm$ 13.26	22.1	26.4	17.3
Male (n = 15)	57.2 $\pm$ 12.3	21.5	23.8	16.6
Female (n = 15)	53.3 $\pm$ 13.05	22.6	28.8	17.9
Malignant ascites (n = 35)	56.2 $\pm$ 17.4	22.4	26.8	17.4
Male (n = 20)	58.2 $\pm$ 15.3	22.1	24.2	17.1
Female (n = 15)	54.1 $\pm$ 14.2	22.8	29.4	17.9
Tuberculous peritonitis (n = 12)	51.9 $\pm$ 15.3	22.6	26.9	17.6
Male (n = 5)	53.8 $\pm$ 13.2	22.2	24.6	17.2
Female (n = 7)	50.1 $\pm$ 12.4	23	29.4	18.1
Control (n = 20)	52.9 $\pm$ 13.3	22.7	27	17.7
Male (n = 10)	54.6 $\pm$ 11.8	22.5	24.8	17.3
Female (n = 10)	51.6 $\pm$ 10.9	22.9	29.2	18.2

significantly lower than control groups ( $P < 0.001$ , Table 2).

On the other hand, the levels of leptin in ascitic fluid were significantly higher in tuberculosis and cirrhotic patients than in patients with malignant effusions ( $P < 0.001$ ). In cirrhotic patients, ascitic fluid levels of leptin were higher than in patients with tuberculosis peritonitis, but the difference was not statistically significant ( $P > 0.05$ , Table 2). Leptin levels were significantly higher in ascitic fluid than in serum ( $P < 0.01$  Wilcoxon test), with a mean ascites/serum ratio of approximately 2.0 in all patient groups (Table 2). Serum and ascitic fluid leptin levels showed significant positive correlation in all patient groups (Malignant group:  $r = 0.979$ ,  $P = 0.0001$ ; Cirrhotic group:  $r = 0.999$ ,  $P = 0.0001$ ; Tuberculosis group:  $r = 0.995$ ,  $P = 0.0001$ ).

Ascites TNF $\alpha$  levels were significantly increased in patients with tuberculosis peritonitis, when compared to the other patient groups. Ascites TNF $\alpha$  levels were not statistically significant between cirrhosis and malignant ascites groups ( $P < 0.001$ , Table 2). We observed that ascitic fluid TNF $\alpha$  levels were significantly positively correlated with ascitic leptin levels in the tuberculosis peritonitis group ( $r = 0.979$ ,  $P = 0.0001$ ). However, this correlation was not observed in the other patient groups.

## DISCUSSION

Recently, several studies have suggested that serum levels of leptin are significantly elevated in patients with chronic liver disease. The relation between serum levels of leptin, TNF $\alpha$ , and associated liver fibrosis have been investigated in patients with chronic hepatitis C by Piche *et al*<sup>[24]</sup>. Serum fasting levels of leptin were significantly more elevated than the control group and a significant correlation has been demonstrated between serum levels of leptin, TNF $\alpha$  and severity of liver fibrosis in those patients<sup>[24]</sup>. Several studies found higher leptin levels among female alcoholic cirrhotic patients than the control group<sup>[10,11]</sup> and Henriksen *et al*<sup>[11]</sup> suggested that the elevated circulating leptin in patients with alcoholic cirrhosis was most likely caused by a combination of decreased renal extraction and increased release from fat tissue areas. However, in an

Table 2 Ascitic leptin, TNF $\alpha$  and serum leptin levels in study population (mean  $\pm$  SD)

	Control subjects	Cirrhotic patients	Malignant ascites	Tuberculous peritonitis
Leptin (ascites) ( $\mu$ g/L)	-	7.19 $\pm$ 3.43	2.45 $\pm$ 1.25	5.59 $\pm$ 1.08
Leptin (serum) ( $\mu$ g/L)	2.93 $\pm$ 0.32	3.77 $\pm$ 2.04	1.30 $\pm$ 0.63	3.72 $\pm$ 0.64
TNF $\alpha$ (ascites) (ng/L)	-	30.36 $\pm$ 6.37	29.65 $\pm$ 7.08	65.5 $\pm$ 18.4
Total proteins (ascites) (g/L)	-	15.4 $\pm$ 6.3	26.1 $\pm$ 11.5	28.2 $\pm$ 21.9
Albumin (ascites) (g/L)	-	7.1 $\pm$ 4.0	14.3 $\pm$ 7.2	13 $\pm$ 11.6
LDH (ascites) (U/L)	-	142.97 $\pm$ 93.99	546.5 $\pm$ 473.8	351.40 $\pm$ 378.82
Glucose (ascites) (mg/L)	-	1253.6 $\pm$ 348.1	1057.2 $\pm$ 443.8	1176 $\pm$ 482.3
Total leukocyte (ascites) ( $\times 10^6$ /L)	-	0.43 $\pm$ 0.46	976 $\pm$ 608.4	1.16 $\pm$ 1.17

Lymphocytes (ascites) ( $\times 10^6$ /L)	-	0.12 $\pm$ 0.01	223.34 $\pm$ 102.3	0.75 $\pm$ 0.32

animal study with chronic ethanol consumption rats, it has been shown that serum concentrations of tumor necrosis factor were increased and leptin was induced in the liver and peripheral adipose tissues by TNF $\alpha$ <sup>[25]</sup>. In addition, experimental and animal studies have shown that TNF $\alpha$  is one of the major leptin producer and regulators in anorexia and inflammation<sup>[26-28]</sup>. It has also been suggested that leptin mediates anorexia in chronic inflammatory states<sup>[29]</sup>. Anorexia and increased energy expenditure usually accompanies cirrhosis<sup>[30]</sup>. In previous studies, association between the severity of posthepatitis cirrhosis and serum leptin levels is controversial<sup>[12,30,31]</sup>. In cirrhotic patients, a significant negative correlation was found between serum levels of leptin and Child-Pugh score<sup>[31]</sup>. On the contrary, a significant elevation in leptin levels was observed as the Child-Pugh score worsened independently of gender and BMI in cirrhotic patients. Anorexia and hypermetabolism in cirrhosis are held responsible for this<sup>[12]</sup>. In our study, we also observed that circulating leptin levels were increased in the non-alcoholic cirrhosis group caused by viral hepatitis and not in the control group.

Previous studies have demonstrated that TNF $\alpha$  levels are elevated in the ascitic fluid of cirrhotic patients with spontaneous bacterial peritonitis<sup>[32]</sup>. Nevertheless Giannini *et al*<sup>[13]</sup> found that serum and ascitic TNF $\alpha$  levels are significantly elevated but serum and ascites TNF $\alpha$  levels were not correlated and the ascitic fluid leptin levels were either twice as high as serum levels or positively correlated in cirrhotic patients with sterile ascites. High leptin levels in ascites were explained as a result of TNF $\alpha$  stimulation and production of intra-abdominal leptin. The results of our study support the hypothesis of Giannini *et al*<sup>[13]</sup>. In 30 patients with active pulmonary tuberculosis in Turkey, a recent study found increased leptin concentrations and a correlation with TNF $\alpha$ <sup>[17]</sup>. Similar results were reported in another study from Turkey involving 25 patients with tuberculosis<sup>[33]</sup>. After antituberculosis therapy in two studies, leptin levels were more elevated. One study from

Indonesia found lower leptin concentrations in 60 HIV-negative patients with active tuberculosis compared to 30 healthy control<sup>[18]</sup>. In another study performed in with patients with tuberculous pleural effusions, it has been demonstrated that serum and pleural fluid levels of tumor necrosis factor were significantly elevated compared with transudative pleural effusion<sup>[34]</sup>. For the time, no study dealing with leptin concentrations in tuberculosis peritonitis has been reported in the literature to our knowledge. In this study, we found that ascitic fluid TNF $\alpha$  levels in tuberculosis peritonitis are significantly elevated when compared to the other patients groups, serum and ascitic leptin levels were significantly higher than in malignant patients. In addition, we observed that ascitic fluid TNF $\alpha$  levels were significantly positively correlated with ascitic leptin levels in the tuberculosis peritonitis group. Our findings support that in tuberculosis peritonitis, TNF $\alpha$  may be a major stimulating factor of leptin secretion.

Low serum leptin levels have been observed in patients with malignancy<sup>[14,15]</sup>. It has been shown that serum leptin levels of prostate cancer are lower than benign prostatic hyperplasia<sup>[14]</sup>. On the other hand, it has recently been demonstrated that in patients with pre-menopausal carcinoma in situ of the breast cancer, serum leptin levels were decreased compared with the control group<sup>[15]</sup>. In a case report, while levels of leptin in the serum, peritoneal and pleural fluids were lower in patient Meigs' syndrome, serum levels were increased following surgical therapy of the tumor along with the resolution of ascites and pleural fluids. Abramov and coworkers suggested that mediators of the tumoral tissue inhibit leptin secretion and excision of the tumoral tissue increased leptin levels<sup>[16]</sup>. In patients with malignant pleural effusions, levels of TNF $\alpha$  were significantly lower than in patients with tuberculous effusions<sup>[34]</sup>. In a recent study, we investigated the importance of ascitic fluid LDH level and LDH isoenzyme activities in patients with malignant and nonmalignant ascites. LDH level, LDH-4 activity and LDH-5 activity were found to be significantly higher, and LDH-1 activity was found to be lower in malignant ascites when compared with nonmalignant ascites. We conclude that ascitic LDH and its isoenzyme pattern may be helpful for the differential diagnosis of ascites<sup>[35]</sup>.

According to our knowledge, there is no study about leptin levels in malignant ascites in the literature. In the present study, we observed that ascitic fluid TNF $\alpha$  levels, serum and ascitic fluid leptin levels of malignant patients are significantly lower than tuberculosis patients. Is the reason for low leptin levels that some mediators released by the tumor which inhibit leptin secretion? Or does decreased body fat, secondary to malnutrition and cachexia caused by tumor, results in decreased levels of leptin? More studies are necessary to explain these. In summary, our study has demonstrated that serum and ascitic fluid leptin levels of malignant patients are significantly lower than tuberculosis peritonitis and cirrhotic patients with sterile ascites. These findings suggest that leptin may be an important marker in the malignant ascitic fluid. Especially, leptin as a tumour marker may be useful in differential diagnosis of benign and malignant ascites.

## Abstract

**AIM:** To evaluate the effect of age and acoustic stress on gastric myoelectrical activity (GMA) and autonomic nervous system function.

**METHODS:** Twenty-one male subjects (age range 22-71 years, mean 44 years) were recruited and exposed, in random order, to three auditory stimuli (Hospital noise, conversation babble and traffic noise) after a 20-min baseline. All periods lasted 20 min and were interspersed with a 10 min of recovery. GMA was obtained using a Synectics Microdigitrapper. Autonomic nerve function was assessed by monitoring blood pressure and heart rate using an automatic recording device.

**RESULTS:** Dominant power tended to decrease with increase of age ( $P < 0.05$ ). The overall percentage of three cycle per minute (CPM) activity decreased during exposure to hospital noise (12.0%,  $P < 0.05$ ), traffic noise (13.9%,  $P < 0.05$ ), and conversation babble (7.1%). The subjects in the younger group ( $< 50$  years) showed a consistent reduction in the percentage of 3 CPM activity during hospital noise (22.9%,  $P < 0.05$ ), traffic noise (19.0%,  $P < 0.05$ ), and conversation babble (15.5%). These observations were accompanied by a significant increase in bradygastria: hospital noise ( $P < 0.05$ ) and traffic noise ( $P < 0.05$ ). In contrast, the subjects over 50 years of age did not exhibit a significant decrease in 3 CPM activity. Regardless of age, noise did not alter blood pressure or heart rate.

**CONCLUSION:** GMA changes with age. Loud noise can alter GMA, especially in younger individuals. Our data indicate that even short-term exposure to noise may alter the contractility of the stomach.

**Key words:** Noise; Acoustic stress; Gastric myoelectrical

## INTRODUCTION

Excessive noise has been linked to a variety of health issues, including hearing loss<sup>[1]</sup>, mental illness<sup>[2,3]</sup>, sleep disturbance<sup>[4]</sup>, hypertension<sup>[5,6]</sup> and cardiovascular diseases<sup>[7-9]</sup>. In terms of gastrointestinal tract, non-specific abdominal complaints<sup>[10,11]</sup>, gastritis and peptic ulcers<sup>[12,13]</sup> have been noted in populations, including workers, that are exposed to high levels of environmental noise. Despite this relationship with gastric disorders, little is known regarding the effects of loud sounds on gastrointestinal function. On theoretical grounds, however, an interaction between noise and gastrointestinal function would seem likely given the abundant neural connections between the human auditory system, the autonomic nervous system and the gastrointestinal tract<sup>[1]</sup>. To the extent that noise has an influence on the autonomic nervous system, an effect on many digestive functions, including peristalsis and acid secretion, would be expected. In this respect, Tomei *et al*<sup>[13]</sup> observed that noise increased gastric acid production in humans with normal baseline levels of gastric acid, and Gue *et al*<sup>[14]</sup> have shown that noises slows the emptying of food from canine stomach.

The motility of the stomach is controlled by gastric myoelectrical activity (GMA) that results in contractions of its muscular component. GMA is measured and recorded using surface electrodes. The information so obtained is termed an electrogastragram (EGG). The EGG is obtained using standard EKG electrodes placed on the skin of the upper abdominal wall. These signals are amplified and filtered prior to computer analysis. The validity of such cutaneous measurements has been validated by simultaneously obtaining direct measurements from the wall of the stomach<sup>[15,16]</sup>. In humans, the normal GMA is an approximately 3 cycles per minute (CPM) sinusoidal wave, and these waves may result in gastric contractions at a similar frequency. Additionally, under normal conditions, most of the voltage (termed "power") measured during EGG is concentrated around the 3 CPM activity.

From a clinical standpoint, EGG recordings have been employed to investigate patients with dyspepsia whose complaints cannot be defined by routine tests, such as barium X-rays and endoscopy. In this respect, a dominant frequency of GMA greater or less than 3 CPM or a shift in the relative distribution of power away from 3 CPM activity are associated with abnormalities of gastric motor activity<sup>[17]</sup>. These alterations are thought to be the basis of many stomach complaints collectively referred to as "indigestion" or "dyspepsia".

In light of above observations, the hypothesis evolved that loud noise might alter the EGG, perhaps by a mechanism involving the autonomic nervous system. To test this possibility, we exposed healthy volunteers to a variety of noises while recording the myoelectrical activity of their stomachs and monitoring their blood pressure and heart rate. A secondary hypothesis of this study was that advancing age would attenuate the effects of noise inasmuch as the reactivity of the autonomic nervous system declines with age.

Under the conditions employed in our study, we found that noise was capable of decreasing the percentage of normal 3 CPM activity and these changes were less pronounced in older individuals.

## MATERIALS AND METHODS

### Subjects

This investigation was approved by the Human Studies Subcommittee (IRB) of the James J. Peters VA Medical Center and informed consent was obtained prior to initiating the studies herein described. A screening hearing test was performed several days prior to the study which assessed the ability to identify sounds at a volume equal or less than 25 dB hearing level at 500, 1000, and 2000 Hz in the both ears and a sound at a volume equal to or less than 45 dB at 4000 Hz in the both ears. If the subjects could not correctly identify each sound, they were excluded from the study and were referred for further workup to the audiology service. All subjects were considered healthy and had no underlying medical problems. Volunteers were excluded from the study if detailed questioning revealed a previous history of chronic gastrointestinal discomforts including heartburn, abdominal pain, constipation or diarrhea. In addition, entry into the study required a normal baseline EGG with a dominant frequency between 2.4-3.7 CPM. Of the 26 screened candidates, 21 male subjects (age range 22-71 years, mean 44 years) met the criteria for inclusion into the study.

### Experimental protocol

All subjects were requested not to eat or drink within 4 h prior to the start of the study. They were seated in a special sound room in a reclining chair and instructed not to move or talk for the remainder of the study. The sound room was double walled and approximately thirty-five square feet in area. The ambient noise levels were well within the standards of the American National Standards Institute. The subjects were observed through a one-way viewing window so as to discourage any movement during

the study. The subjects were fitted with both an automatic blood pressure recording device and three electrodes that measured GMA.

The duration of the study was 110 min. During this period, the subjects wore stereophonic headphones continuously and were exposed in a random pattern to three periods of different types of auditory stimuli. A twenty-minute baseline period of silence preceded the auditory stimuli. Each stimulus lasted 20 min and was interspersed with a 10 min of silence as a recovery period to minimize potential carry-over effect from previous period. The 10-min recovery time was assumed to be adequate as our preliminary study had shown the effect of noise on GMA did not go beyond this period of time. The three auditory stimuli were as follows: (1) unedited hospital noise recorded during the afternoon of a weekday in the Intensive Care Unit of the James J. Peters Veterans Affairs Medical Center and played back at a level of 87.4 dBA (SPL), a level comparable to that of actual ambient level meter; (2) conversation babble (Auditec, St. Louis, MO) played back at a sound level of 91.3 dBA (SPL); and (3) traffic noise in New York City played back at a sound level of 85.6 dBA. All sound pressure levels were measured with a Lason-Davis 800 B precision sound level meter.

Since GMA may change with age, and many responses to auditory stimuli are believed to decline with age, we further divided subjects into two groups, those under 50 years of age (age range 22-47 years, mean 34 years,  $n = 12$ ), and those over 50 years of age (age range 51-71 years, mean 56 years,  $n = 9$ ). The baseline characteristics of GMA of these two age groups were compared and the effect of noise on these two particular age groups was analyzed.

### Electrogastrogram

Gastric myoelectrical activity was recorded using a Microdigitrapper (Medtronic-Synectics, Shoreview, Minnesota). Three surface electrodes were placed on the anterior wall of the abdomen. The first electrode was placed midway between the xiphoid and the umbilicus. The second electrode was placed 5 cm to the right of the first electrode. The third electrode was placed five centimeters to the left and thirty degrees above the first electrode. Excess hair was shaved from the immediate area, the skin was gently abraded with an alcohol swab, and conducting gel was applied. All recordings were made at a sampling frequency of 4 Hz, with a cutoff frequency of 15 Hz. The recorded data were uploaded into a computer, transformed (fast-Fourier) and analyzed using a dedicated software (Multigram Version 6.31, Medtronic's-Synectics, Shoreview, Minnesota). Visual inspection of the raw data was performed to detect motion artifacts prior to analysis. Several quantitative parameters were derived including the percentage of 3 CPM activity (defined as normal myoelectrical activity in the range of 2.4-3.7 CPM), bradygastria (< 2.4 CPM) and tachygastria (> 3.7 CPM), dominant frequency (DF) and dominant power (DP). DF refers to the frequency at which the EGG power spectrum has a peak power in the range of 0.5-9.0 CPM, which equals to the frequency of the gastric slow wave measured

**Table 1** Characteristics of baseline gastric myoelectrical activity over age

	Dominant frequency	Dominant power	3 CPM activity (%)
Age < 50 yr ( <i>n</i> = 12)	3.0 ± 0.1	401.4 ± 103.8	87.9 ± 5.1
Age > 50 yr ( <i>n</i> = 9)	3.1 ± 0.3	115.1 ± 45.7	77.7 ± 7.6
<i>P</i> value	<i>P</i> = 0.724	<i>P</i> < 0.05	<i>P</i> = 0.259

from the implanted serosal electrodes<sup>[15,16]</sup>. The power at the DF in the power spectrum of the EGG was defined as the DP. The relative change of the EGG dominant power may reflect gastric contractility<sup>[16,18]</sup>.

### Blood pressure and heart rate monitoring

An automatic blood pressure recording device was applied *via* an arm cuff placed around the upper arm of each participant. Recordings were made automatically every 5 min during the whole course of study. Systolic pressure, diastolic pressure and heart rate were analyzed to see whether noise affected autonomic nerve activity.

### Statistical analysis

Data were presented either as percent change relative to baseline (percentage of 3 CPM activity, bradygastria and tachygastria) or means ± SE (DF and DP). Student's *t* test or one way RM ANOVA was used for comparison wherever appropriate. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

### Effect of age on GMA

We subjectively divided participants into two age groups, using age 50 as a cutoff line. Percentage of 3 CPM activity, DF and DP were derived from the twenty-minute baseline period and comparisons were made between these two age groups. Detailed data are presented in Table 1. In brief, though no significant difference was observed in DF and percentage of 3 CPM activity during the baseline, younger people tended to have obviously higher dominant power (401.4 ± 103.8) than those above age 50 (115.1 ± 45.7, *P* < 0.05).

### Effect of noise on percentage of 3 CPM activity

During exposure to hospital noise and traffic noise, the percentage of 3 CPM activity (range 2.4–3.7 CPM) was decreased by 12.0% (*P* < 0.05) and 13.9% (*P* < 0.05), respectively, in our overall population (*n* = 21). Reduction in percentage of 3 CPM activity was also observed during exposure to conversation babble (7.1%), but was not statistically significant.

In the younger group (*n* = 12; age range 22–47 years, mean 34 years), the percentage of 3 CPM activity decreased to a greater degree during exposure to hospital noise (22.9%, *P* < 0.05) and traffic noise (19.0%, *P* < 0.05). A non-significant decrease was also seen during conversation noise (15.5%). In the older group (*n* = 9; age range 51–71 years, mean 56 years) showed no such a trend. In fact, during exposure to hospital noise and conversation

**Table 2** Effect of various types of noise on blood pressure and heart rate

		Baseline	ICU	Babble	Traffic
Age < 50 yr ( <i>n</i> = 12)	Systolic	122.2 ± 11.3	122.1 ± 19.3	119.3 ± 13.2	122.2 ± 12.6
	Diastolic	78.1 ± 11.5	76.1 ± 14.8	74.3 ± 12.9	79.2 ± 12.6
	Pulse	73.6 ± 9.5	75.6 ± 10.2	76.4 ± 14.8	75.5 ± 9.8
Age > 50 yr ( <i>n</i> = 9)	Systolic	132.9 ± 18.8	136.5 ± 15.6	135.1 ± 19.3	136.0 ± 14.8
	Diastolic	85.4 ± 11.4	85.7 ± 11.3	86.3 ± 13.1	83.6 ± 12.3
	Pulse	70.7 ± 16.5	75.4 ± 14.8	72.9 ± 15.1	71.7 ± 15.0

No significant change was observed in these parameters during exposure to auditory stimuli.

babble, their percent activity of 3 CPM actually increased by 2.5% and 4%, respectively. During exposure to traffic noise, the percent activity of 3 CPM fell in this group by 7.1%.

Decreases in 3 CPM activity were accompanied mainly by rises in bradygastria activity. In the younger group, bradygastria activity rose during hospital and traffic noise by 16.3% (*P* < 0.05) and 13.4% (*P* < 0.05), respectively.

### Effect of noise on dominant frequency and dominant power

Trends toward a decrease in DF (Figure 1) and an elevation in DP (Figure 2) were consistently observed in the both age groups (> 50 years and < 50 years), but none of them reached statistical significance.

### Effect of noise on autonomic nerve activity

No effect of noise was seen either on diastolic, systolic pressure or on heart rate (Table 2). For the total population in the study, systolic pressure changed by 1.6 mmHg, -0.5 mmHg, and 1.4 mmHg for hospital, conversation, and traffic noise, respectively. Diastolic pressure changed by -0.9 mmHg, -1.6 mmHg, and -0.2 mmHg, respectively (Table 1). Finally, heart rate changed by 3.2 beats per minute (bpm), 2.5 bpm, and 1.5 bpm, respectively.

## DISCUSSION

Our results indicate that GMA may change with advancing age, manifested mainly by a decline in dominant power. In addition, the average percentage of 3 CPM activity declined during exposure to noise in the younger subjects. Together with these decreases in 3 CPM activity, bradygastria became more prominent. A trend toward a decrease in DF and an elevation in DP was consistently observed during exposure to noises in both age groups. None of the noises employed in this study had a significant effect on autonomic nerve function reflected by blood pressure and heart rate.

Many non-auditory effects of noise have been described and have been reviewed in detail elsewhere<sup>[1]</sup>. In general terms, these non-auditory responses can be considered reflexive in nature and tend to increase the level of alertness and arousal. These reflexes included a focused posture directed to the source of noise, a shunting blood away from vegetative regions like the stomach, a rise in adrenalin, noradrenalin, and 17-hydroxycorticosteroids,

**Figure 1** Effect of various types of noises on dominant frequency in the subjects of age below 50 ( $n = 12$ ) and above 50 ( $n = 9$ ). Base-, baseline; Conv-, conversation babble; Hosp-, hospital noise; Traf-, traffic noise. One-way RM ANOVA vs individual baseline, no statistical significance was observed.

a release of glucose into the blood stream, and an increase in blood pressure<sup>[19,20]</sup>.

Many non-auditory responses to noise have been linked to activation of the autonomic nervous system. However, in the present study, noise did not alter blood pressure or heart rate. These are parameters that one would have expected to reflect enhancement of the autonomic nervous system and which have previously been shown to be affected by loud noise<sup>[5,6,11]</sup>. Our negative results in this regard suggest that, under the present conditions, alterations in GMA may occur at levels of autonomic stimulation less intense than that required to alter the circulatory system.

Our findings that exposure to noise decreases the percentage of normal 3 CPM activity is consistent with a recent report<sup>[21]</sup> in which the authors found that loud music and household noise all tended to alter the rhythmicity of gastric slow waves by an increase in bradygastria and a concurrent reduction in the normal 2-4 CPM activity. As in the present study, there were no signs of autonomic activation.

Workers in noisy jobs commonly report nausea and are known to have an increased incidence of digestive disorders including gastritis and ulcers<sup>[10,13]</sup>. As noted before, acoustic stress has been linked to increased gastric acid secretion<sup>[13]</sup>. An additional mechanism is suggested by the present study. Our finding that the percentage of normal 3 CPM activity decreased in younger subjects after exposure to noises raised the possibility that digestive problems, at least in part, might reflect alterations in contractile activity of the stomach. In this respect, it has been demonstrated that reduction in the normal GMA, the presence of bradygastria or arrhythmias is associated with reduced or absent gastric contractions<sup>[22]</sup>. Decreased movement of gastrointestinal tract has long been considered a *sine qua non* of the "fight or flight" response and, as noted above, probably arises from autonomic (specifically, sympathetic) stimulation. Our findings are consistent with studies by Gue *et al*<sup>[14]</sup>, showing that the noise slowed the emptying of food by the canine stomach.

The relationship between age and characteristics of

**Figure 2** Effect of various types of noises on dominant power (DP) in the subjects of age below 50 ( $n = 12$ ) and above 50 ( $n = 9$ ). Base-, baseline; Conv-, conversation babble; Hosp-, hospital noise; Traf-, traffic noise. One-way RM ANOVA vs individual baseline, no significance was observed. The baseline DP of the older group (age > 50 yr) was significantly lower than that of the younger group (age < 50 yr): <sup>a</sup> $P < 0.05$ , Student's *t* test.

GMA has been investigated. It is clear that gastric slow waves are absent at birth and go through periods of maturation after birth<sup>[23]</sup>. Whether GMA changes with the advancement of age at adulthood is still inconclusive but studies have reported that aging increases the instability of electrical frequency<sup>[24]</sup>, or the frequencies of the rhythm of surface EGG<sup>[25]</sup>. In our study, it is interesting to note that the dominant power was significantly lower in the older subjects than those of younger group. Although the significance of this phenomenon is unclear, it is possible that the aging stomach might be less active in motility and strength.

Advancing age is accompanied by a deterioration of autonomic nervous function<sup>[26]</sup>. This may, in part, explain why GMA of older individuals is diminished during exposure to stimuli such as meal<sup>[27]</sup>, or head out of water immersion<sup>[28]</sup>. Finally, in an animal study by Pharm and Willott<sup>[29]</sup>, it was determined that the "threshold" auditory stimulus required to initiate an acoustic startle response grew with age. These studies may clarify why older subjects in our study showed a diminished gastric electrical response to noise that did the younger subjects.

In previous studies, noise has been observed to both increase<sup>[5,19,30]</sup> and have no effect<sup>[31,32]</sup> on blood pressure and heart rate. Our own negative results in this respect are consistent with the latter findings. However, the duration, intensity and quality of the noise undoubtedly determine whether and to what extent an effect on blood pressure and heart rate will be observed.

## COMMENTS

### Background

To understand the influence of environmental noises on GI physiological functions.

### Research frontiers

Environmental noises have been linked to cardiovascular and neurological disorders. However, the effect of noise on the GI system has been minimally explored.

### Innovations and breakthroughs

This is the first study that to show that noise can affect physiological gastric electrical activity in healthy subjects and that the degree of this effect seems to be age-related.

### Applications

Prevention of over-exposure to environmental noises may prevent some negative health issues.

### Terminology

Electrogastrogram: Gastric myoelectrical activity is recorded using a portable device via surface electrodes placed on the anterior wall of the abdomen.

### Peer review

It is a well-written study. Electrogastrography is an evolving field, and worth of further investigation.

### Abstract

**AIM:** To evaluate the effects of extrahepatic collaterals to the liver on liver damage and patient outcome after embolotherapy for the ruptured hepatic artery pseudoaneurysm following hepatobiliary pancreatic surgery.

**METHODS:** We reviewed 9 patients who underwent transcatheter arterial embolization (TAE) for the ruptured hepatic artery pseudoaneurysm following major hepatobiliary pancreatic surgery between June 1992 and April 2006. We paid special attention to the extrahepatic arterial collaterals to the liver which may affect post-TAE liver damage and patient outcome.

**RESULTS:** The underlying diseases were all malignancies, and the surgical procedures included hepatopancreatoduodenectomy in 2 patients, hepatic resection with removal of the bile duct in 5, and pancreaticoduodenectomy in 2. A total of 11 pseudoaneurysm developed: 4 in the common hepatic artery, 4 in the proper hepatic artery, and 3 in the right hepatic artery. Successful hemostasis was accomplished with the initial TAE in all patients, except for 1. Extrahepatic arterial pathways to the liver, including the right inferior phrenic artery, the jejunal branches, and the aberrant left hepatic artery, were identified in 8 of the 9 patients after the completion of TAE. The development of collaterals depended on the extent of liver mobilization during the hepatic resection, the postoperative period, the presence or absence of an aberrant left hepatic artery, and the concomitant arterial stenosis adjacent to the pseudoaneurysm. The liver tolerated TAE without significant consequences when at least one of the collaterals from the inferior phrenic ar-

tery or the aberrant left hepatic artery was present. One patient, however, with no extrahepatic collaterals died of liver failure due to total liver necrosis 9 d after TAE.

**CONCLUSION:** When TAE is performed on ruptured hepatic artery pseudoaneurysm, reduced collateral pathways to the liver created by the primary surgical procedure and a short postoperative interval may lead to an unfavorable outcome.

### INTRODUCTION

Delayed massive arterial bleeding in the postoperative period is a rare complication for patients with hepatobiliary pancreatic diseases, but often results in a lethal outcome due to the abrupt onset of massive hemorrhage. Bleeding occurs mainly from erosion or pseudoaneurysm of major visceral arteries as a result of an adjacent septic condition or an intraoperative arterial injury<sup>[1-3]</sup>.

Transcatheter arterial embolization (TAE) has been proposed as the first-line treatment to control massive bleeding associated with a ruptured hepatic artery pseudoaneurysm after hepatobiliary pancreatic surgery because of its advantages over surgery. Such advantages include an easier approach, precise localization of the pseudoaneurysm, assessment of collateral pathways to the liver, less chance of re-bleeding, and low mortality rates<sup>[1-7]</sup>. Meanwhile, TAE on the hepatic artery may lead to liver abscesses, gallbladder necrosis, biliary stricture, intrahepatic biloma, and embolization of normal vessels<sup>[8-10]</sup>. Furthermore, hepatic TAE may cause a total interruption of the arterial blood supply to the liver, thus

presenting a risk for liver infarction, especially in patients after right or left hepatic lobectomy<sup>[11-14]</sup>.

In this study, we retrospectively reviewed the patients who underwent TAE for a ruptured hepatic artery pseudoaneurysm following major hepatobiliary pancreatic surgery, paying special attention to the extrahepatic collateral pathways which may be associated with post-TAE liver damage and a negative patient outcome.

## MATERIALS AND METHODS

Between June 1992 and April 2006, 10 patients developed a rupture of the hepatic artery pseudoaneurysm following major hepatobiliary pancreatic surgery in our department. This included 1 patient who suddenly died due to abrupt massive hemorrhaging. The remaining 9 patients who underwent a diagnostic angiography and subsequent transcatheter hemostasis treatment were reviewed in this study. The clinical characteristics of these 9 patients are summarized in Table 1. These patients included 6 men and 3 women with a mean age of 70 years (range 63-75). A total of 11 pseudoaneurysms developed: 4 in the common hepatic artery, 4 in the proper hepatic artery, and 3 in the right hepatic artery. Subsequent ruptures of the portal vein were seen in 2 patients. The underlying diseases included hilar bile duct carcinoma, ampullary carcinoma, gallbladder carcinoma, intrahepatic cholangiocarcinoma, and metastatic liver cancer from colon cancer.

The surgical procedures performed were hepatopancreatoduodenectomy in 2 patients, left hepatic lobectomy with a resection of the caudate lobe and bile duct in 4, a segmental resection of the liver with removal of the bile duct in 1, and pylorus-preserving or conventional pancreaticoduodenectomy in 2. All patients received lymphadenectomy around the hepatic artery. During the hepatic resection, the whole liver was mobilized from the diaphragm for the surgical procedure in 2 patients, and a unilateral mobilization of the liver was done in 4 patients. The postoperative complications included hepaticojejunal or pancreaticojejunal anastomotic leakage in 6 patients. The bleeding from ruptured pseudoaneurysm occurred 12-256 d following the primary operation. During the follow-up, 2 patients (cases no.1 and 2) had melena or hematemesis. Of the remaining 7 patients, 6 presented bleeding from the drain in the abdominal cavity, which was preceded by an intermittent minor hemorrhage or "sentinel bleed" in 5 of the cases. A contrast-enhanced abdominal CT scan was carried out immediately after the initial "sentinel bleed" in 2 patients, and both depicted pseudoaneurysm in the hepatic artery (Figure 1). In addition, hemorrhagic shock (systolic blood pressure < 90 mmHg, pulse rate > 100/min) was presented in 6 of the patients.

The diagnostic angiography was performed using a 4-Fr or 5-Fr angiographic catheter (Clinical Supply, Tokyo, Japan) through a transfemoral approach. In all cases, celiac, common hepatic, and superior mesenteric angiographies and arterial portographies, were routinely taken to detect the bleeding points. Immediately after identifying pseudoaneurysms, with or without extravasation of the contrast media, TAE was performed with distal and proximal placement of embolic coils to

**Figure 1** A 66-year-old female with pylorus-preserving pancreaticoduodenectomy (12 d after surgery). A contrast-enhanced CT scan presents a pseudoaneurysm on the distal side of the common hepatic artery (arrow).

the pseudoaneurysm for the hemostasis. The embolic coils used were 0.035-inch stainless-steel coils, 3-8 mm in diameter, or 0.018-inch platinum coils, and 3-6 mm in diameter (Cook, Bloomington, IN).

The procedural success of TAE and the presence of collateral arterial blood flow to the liver were confirmed at the end of the procedure by performing angiographies of the celiac, superior mesenteric, and inferior phrenic arteries. The hepatic function tests evaluated before and after TAE included total bilirubin (T-Bil), aspartate aminotransferase (AST), and alanine aminotransferase (ALT). We retrospectively reviewed the 9 patients with special attention paid to the impact of collateral pathways to the liver on post-TAE complications and patient outcome.

## RESULTS

Embolization of the hepatic artery was done in the extrahepatic level in all patients (Table 2). However, the embolic coils migrated to the intrahepatic level of the left hepatic artery in 2 patients. An immediate successful hemostasis was accomplished during the initial TAE in all cases, except for 1 patient (case no. 3) who required a second TAE because of re-bleeding 1 hour after the first procedure. The first TAE was performed at the proximal side of the right hepatic artery where pseudoaneurysm and extravasation were observed. The second TAE was performed by adding the coils distally and proximally.

Angiographies after the completion of the TAE showed extrahepatic collateral pathways to the liver in 8 of 9 patients. This consisted of the right inferior phrenic artery in 6 cases (Figure 2), the jejunal branches in 2 (Figure 3), and the aberrant left hepatic artery branched from the left gastric artery in the other 2. These collateral pathways supply the arterial flow throughout the hepatic lobes via intrahepatic communicating branches (Figure 4). Among these extrahepatic collaterals, the main collateral pathways to the liver were either the right inferior phrenic artery or the aberrant left hepatic artery. In 5 patients who underwent a hepatic resection without whole liver mobilization, the collateral pathways from the right inferior phrenic artery were well developed. In 2

HTX: hepatectomy; BDR: bile duct resection; S7 + 8: hepatic posterior inferior and superior segments; S1 + 2 + 3 + 4: caudate lobe and hepatic lateral and medial segments; S4a + 5: hepatic medial inferior and anterior inferior segments; PD: pancreaticoduodenectomy; PPPD: pylorus-preserving pancreaticoduodenectomy; R: right; L: left; HJ: hepaticojunal anastomosis; PJ: pancreaticojunal anastomosis; BFD: bleeding from drain; PHA: proper hepatic artery; RHA: right hepatic artery; CHA: common hepatic artery.

**Figure 2** A 74-year-old male with left hepatic lobectomy (105 d after surgery). The right inferior phrenic artery (arrows) is presented as a collateral pathway to the liver on an angiography after TAE for the proper hepatic and gastroduodenal arteries.

**Figure 3** The jejunal branches (arrow) are seen as a collateral pathway to the liver in the same patient as in Figure 2.

patients who received whole liver mobilization from the diaphragm during the hepatic resection, 1 patient (case no. 2) presented a well-developed collateral pathway from the right inferior phrenic artery, but the other (case no. 3) demonstrated no collateral pathways. The postoperative interval was 105 d and 28 d, respectively. Collateral pathways from the jejunal branches were seen in 2 patients who had a long postoperative course (cases no. 1 and 2), meanwhile, arterial stenosis or spasm adjacent to the pseudoaneurysm were identified in 6 patients. The extra- and intrahepatic arterial pathways to the liver developed in accordance with the degree of arterial stenosis (Figure 5).

One patient with no extrahepatic collateral pathways to the liver died of liver failure due to total liver necrosis 9 d after TAE. However, 8 patients with extrahepatic collateral pathways tolerated TAE. Six of these 8 patients showed mild to moderate elevations of T-Bil, AST, and ALT after TAE, and liver functions returned to normal within 10

d without any complication. The remaining 2 patients (cases no. 7 and 8) showed a considerable liver dysfunction likely due to a chance migration of embolic coils to the left hepatic artery during TAE. They were subsequently cured with a conservative treatment, although 1 patient developed a liver abscess in the left hepatic lobe.

Two patients who developed a rupture of the portal vein after TAE were managed with re-laparotomy (case no. 2) and interventional radiologic technique (case no. 6), respectively. In the former, the rupture of the portal vein occurred 37 d after TAE, in which the embolic coils in the proper hepatic artery migrated to the adjacent portal vein, resulting in disruption of the vein. Although this patient underwent re-laparotomy, the ruptured portal vein could not be repaired due to huge adhesions around the portal system and the fragility of the portal vein. He died of multiple organ failure (MOF) 14 d after re-laparotomy. In the latter patient, the bleeding from the portal vein

**Figure 4** A 71-year-old male with left hepatic lobectomy (41 d after surgery). The intrahepatic communicating branches (arrows) are visualized via the branches of the right inferior phrenic artery on an angiography after TAE for the right hepatic artery.

**Figure 5** A diagnostic celiac angiography showing a stenosis of the right hepatic artery (black arrow) distal to the ruptured hepatic artery pseudoaneurysm in the same patient as in Figure 1. The aberrant left hepatic artery (white arrow) originating from the left gastric artery was dilated and supplied arterial blood flow to the right hepatic artery through the intrahepatic communicating branches before TAE.

occurred 3 d after TAE. A Gianturco expandable metallic stent (Z-stent; Cook, Bloomington, IN) was placed in the portal vein to bridge the site of venous disruption via a peripheral branch of the ileocecal vein under a small laparotomy in the right lower quadrant of the abdomen. The extra-portal cavity was then packed with 30 microcoils through a slit in the Z-stent. This patient died of MOF induced by sepsis originating from the abscess around the microcoils packed in the extra-portal cavity 51 d after placement of the stent.

## DISCUSSION

Massive arterial bleeding can occur early or late in the postoperative course of patients undergoing hepatobiliary pancreatic surgery. Early bleeding within 24 h after operation usually originates from vessels at the anastomotic suture-line or in the intra-abdominal cavity due to

inadequate hemostasis<sup>[15,16]</sup>. On the other hand, delayed bleeding occurs mainly due to erosion or pseudoaneurysm of major visceral arteries and has a higher mortality rate than those with suture-line bleeding<sup>[16]</sup>.

Three major predisposing factors for delayed arterial bleeding after hepatobiliary pancreatic surgery have been suggested: (1) digestion of arterial walls due to activated pancreatic juice or infectious bile from anastomotic insufficiency, (2) arterial irritation by localized abscess in the intra-abdominal space, and (3) a mechanical injury of the artery during operation, particularly due to lymph node dissection for malignancy<sup>[1-3,14,17,18]</sup>. In the present study, lymphadenectomy around the hepatic artery was performed on all 9 patients. In addition, postoperative hepaticojejunal or pancreaticojejunal anastomotic leakage was identified in 6 cases. Although the rupture of visceral arteries after surgery may be a complex process and actual pathogenesis remains obscure, histopathology of autopsy

of our case no. 3 demonstrated that infectious bile invaded the hepatic arterial wall and completely destroyed the media consisting of elastic fibers<sup>[11]</sup>.

The compensatory arterial circulation to the liver after TAE for the treatment of ruptured hepatic artery pseudoaneurysm was recognized in 8 of the 9 patients who underwent major hepatobiliary pancreatic surgery in this study. Michels has described the details of extrahepatic arterial collaterals to the liver after ligation of the hepatic artery in a series of 200 cases of hepatic resection, in which at least 26 possible routes of collateral arterial blood supply to the liver from the common hepatic trunk were noted<sup>[19]</sup>. Among them, the following are clinically important: (1) the subphrenic branch of the phrenic artery or internal mammary artery, (2) the aberrant hepatic artery, (3) the periductal arterial plexus, (4) other collaterals into the hepatic hilum from the superior mesenteric artery, and (5) the intrahepatic branches<sup>[19,20]</sup>. Although the significance of extrahepatic collateral pathways in association with liver damage after hepatic TAE has been reported<sup>[2,21-23]</sup>, the relationship between the primary surgical procedure and the development of extrahepatic collaterals following hepatobiliary pancreatic surgery has not been described in detail.

In this study, the main collateral pathways to the liver after TAE in patients with major hepatobiliary pancreatic surgery included the right inferior phrenic artery, the aberrant left hepatic artery, and the intrahepatic communicating branches. The development of these collaterals depended on the primary operative procedure, postoperative duration, and concurrent arterial stenosis adjacent to the pseudoaneurysm. They subsequently affected post-TAE liver damage and patient outcome. Following TAE, total liver necrosis occurred in 1 patient who had no extrahepatic collateral pathways. This was probably due to whole liver mobilization during hepatopancreatoduodenectomy 28 d prior to TAE. Another patient received whole liver mobilization along with left hepatic lobectomy 105 d prior to TAE, and showed a well-developed collateral pathway from the right inferior phrenic artery. Conversely, the inferior phrenic artery was maintained in 5 patients who underwent a hepatic resection without whole liver mobilization. The hepatic arterial stenosis adjacent to the pseudoaneurysm was also associated with the development of extra- and intrahepatic collateral pathways. As a result, the liver tolerated TAE without significant consequences when one of the collaterals from the inferior phrenic artery or the aberrant left hepatic artery was present. Therefore, when performing hepatic TAE, all the information mentioned above should be considered in individual patients who have undergone hepatobiliary pancreatic surgery. TAE on the hepatic artery has generally been considered to be relatively safe if the portal blood flow is maintained<sup>[12,13,24]</sup>. However, it could result in an unfavorable outcome when the development of extrahepatic pathways to the liver is poor. In such cases, endovascular repair of hepatic artery pseudoaneurysms using a stent-graft with preservation of the arterial blood flow to the liver<sup>[25]</sup>, may be an alternative treatment to TAE.

Brodsky and Turnbull<sup>[26]</sup> emphasize a “sentinel

bleeding” as a precursor of vessel erosion after pancreatic surgery. In our series, episodes of sentinel bleeding from the drainage tube prior to massive hemorrhage were recognized in 5 patients. Interestingly, an urgent contrast-enhanced CT scan successfully depicted hepatic artery pseudoaneurysm in 2 patients when the abdominal CT scan was carried out immediately after the initial sentinel bleeding. The significance of a CT scan in the detection of visceral pseudoaneurysm following pancreaticoduodenectomy has previously been reported<sup>[1,27]</sup>. Moreover, a dilated right inferior phrenic artery representing an extrahepatic collateral after TAE for hepatocellular carcinoma has been demonstrated by using biphasic helical CT scans<sup>[28]</sup>. Early diagnosis and management of an arterial pseudoaneurysm before it ruptures is essential to improve the prognosis of this condition. Accordingly, early CT scan should be required in patients associated with postoperative leakage of enteric anastomosis or intra-abdominal abscess, as well as in cases with a sentinel bleeding after surgery.

Subsequent ruptures of the portal vein were seen in 2 patients. Although the Z-stent placement in the portal vein was effective in the hemostasis of 1 case, the patient finally died of MOF induced by sepsis originating from abscess around the microcoils packed in the extra-portal cavity. In such a case, a “second-look” operation for the abscess should be performed after the hemodynamic condition of the patient becomes stable.

In conclusion, TAE should be the first choice of treatment for ruptured hepatic artery pseudoaneurysms after hepatobiliary pancreatic surgery. In performing hepatic TAE, however, information on liver mobilization, the postoperative period, the presence or absence of an aberrant left hepatic artery, and concomitant arterial stenosis adjacent to the pseudoaneurysm is of prime importance due to these factors affecting the development of extrahepatic collateral pathways to the liver and the post-TAE patient outcome.

### Abstract

**AIM:** To assess the clinical features and prognosis of 151 patients with extrahepatic metastases from primary hepatocellular carcinoma (HCC), and describe the treatment strategy for such patients.

**METHODS:** After the diagnosis of HCC, all 995 consecutive HCC patients were followed up at regular intervals and 151 (15.2%) patients were found to have extrahepatic metastases at the initial diagnosis of primary HCC or developed such tumors during the follow-up period. We assessed their clinical features, prognosis, and treatment strategies.

**RESULTS:** The most frequent site of extrahepatic metastases was the lungs (47%), followed by lymph nodes (45%), bones (37%), and adrenal glands (12%). The cumulative survival rates after the initial diagnosis of extrahepatic metastases at 6, 12, 24, and 36 mo were 44.1%, 21.7%, 14.2%, 7.1%, respectively. The median survival time was 4.9 mo (range, 0-37 mo). Fourteen patients (11%) died of extrahepatic HCC, others died of primary HCC or liver failure.

**CONCLUSION:** The prognosis of HCC patients with extrahepatic metastases is poor. With regard to the cause of death, many patients would die of intrahepatic HCC and few of extrahepatic metastases. Although most of HCC patients with extrahepatic metastases should undergo treatment for the primary HCC mainly, treatment of extrahepatic metastases in selected HCC patients who have good hepatic reserve, intrahepatic

### INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly malignant tumor with frequent intrahepatic metastasis. The prognosis of HCC patients has improved because of progress in therapeutic procedures, such as surgical resection, radiofrequency ablation (RFA), percutaneous ethanol injection (PEI), and transcatheter arterial chemoembolization (TACE)<sup>[1-3]</sup>. Moreover, progress in diagnostic modalities, such as ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), and digital subtraction angiography (AG) has led to a better detection of patients with early and small HCC or asymptomatic extrahepatic metastases.

The above improvements in survival and diagnostic modalities have resulted in increased detection of extrahepatic metastases from primary HCC and further increases are anticipated in the future. Several groups have investigated extrahepatic metastases from HCC, but many of such cases were in autopsy cases, in a small number of cases or case reports<sup>[4-15]</sup>. At present, the prognosis of patients with extrahepatic metastases from primary HCC is poor<sup>[16,17]</sup>. In this regard, there is only little information about the causes of death of such patients<sup>[18]</sup>, and there is no consensus on the treatment strategy for extrahepatic metastases from HCC. For example, what treatment strategy should be used to treat intrahepatic HCC or extrahepatic metastases? Among patients with extrahepatic metastases from primary HCC, which patients should be treated? To our knowledge, there are no reports that

deal directly with these questions. In this relatively large study, we retrospectively assessed the clinical features and prognosis of 151 patients with extrahepatic metastases from primary HCCs, and described the treatment strategy for such patients.

## MATERIALS AND METHODS

### Patients

From June 1990 to December 2005, 995 consecutive patients with HCC were admitted to our hospital. Among these patients, 880 were initially diagnosed with HCC in our hospital while the others were treated previously for HCC in other hospitals. Extrahepatic metastases from primary HCC were detected in 151 (15.2%) of 995 patients. None of the patients was treated for extrahepatic metastases. All the 151 HCC patients with extrahepatic metastases (117 men and 34 women, median age: 64 years, range: 21-82 years) were enrolled in the present study.

Table 1 summarizes the clinical profile of the 151 patients at the initial diagnosis of extrahepatic metastases. These 151 patients were divided into groups A and B. Group A was consisted of 68 patients presented with extrahepatic metastases together with primary HCC at the initial diagnosis of HCC, group B was composed of 83 patients who received treatment for intrahepatic HCC, and developed extrahepatic metastases during the follow-up period. Among them, 37 (25%) patients were treated previously for primary HCC in other hospitals, 90 patients were of performance status (PS) of 0, 43 patients of 1, 9 patients of 2, 6 patients of 3, and 3 patients of 4<sup>[19]</sup>. The etiology of the background liver disease was hepatitis B virus (HBV) in 33 patients, hepatitis C virus (HCV) in 89 patients, HBV and HCV in 5 patients, and non-B non-C in 24 patients. The hepatic reserve was Child-Pugh grade A in 88 patients, grade B in 48 patients, and grade C in 15 patients. We evaluated the primary tumor stage according to the Liver Cancer Study Group of Japan criteria<sup>[20]</sup>, based on the following three conditions (T factor): solitary, < 2 cm in diameter, and no vessel invasion. T1 was defined as fulfilling the three conditions, T2 as fulfilling two of the three conditions, T3 as fulfilling one of the three conditions, T4 as fulfilling none of the three conditions. The primary HCC tumor stage at the first diagnosis of extrahepatic metastases was T0 (no intrahepatic HCC) in 11 (7%) patients, T1 in 4 (3%) patients, T2 in 13 (9%) patients, T3 in 43 (28%) patients, and T4 in 80 (53%) patients. Twenty seven of 28 patients with intrahepatic tumor stage T0-T2 were treated previously for intrahepatic HCC. The median size of the main intrahepatic primary tumor was 48 mm (range, 0-160 mm). Intrahepatic tumor morphology was nodular type in 83 (55%) patients, non-nodular type in 57 (38%) patients, and no intrahepatic HCC in 11 (7%) patients. Table 1 lists the sites of extrahepatic metastases at enrollment. Among the 151 patients with extrahepatic metastases, the sites of metastases were the lungs in 63 patients, lymph nodes in 60 patients, bones in 51 patients, adrenal glands in 16 patients and other locations (e.g., peritoneum, pancreas and nasal passages). In some patients, two or more distant metastatic tumors were found in one or more organs.

**Table 1 Clinical profile of 151 HCC patients with extrahepatic metastases at the initial diagnosis of extrahepatic metastases**

Age (yr)	64 (21-82)
Sex (male/female)	117/34
Etiology (HBV/HCV/HBV + HCV/others)	33/89/5/24
PS (0/1/2/3/4)	90/43/9/6/3
Intrahepatic tumor stage (T0/1/2/3/4)	11/4/13/43/80
Intrahepatic main tumor size (mm)	48 (0-160)
Intrahepatic tumor volume (< 50%/≥ 50%)	103/48
Intrahepatic tumor morphology (nodular type/non nodular type/no intrahepatic HCC)	83/57/11
Grade of portal vein invasion (Vp 0/1/2/3/4)	74/0/26/28/23
Child-Pugh grade (A/B/C)	88/48/15
AFP (ng/mL)	741.8 (< 5-861600)
DCP (mAU/mL)	1300 (< 10-391400)
Site of extrahepatic metastases, n (%)	
Lung	63 (42)
Lymph nodes	60 (40)
Bone	51 (34)
Adrenal	16 (11)
Peritoneum	1 (0.7)
Pancreas	1 (0.7)
Nasal passages	1 (0.7)

Data are expressed as medians and ranges unless indicated otherwise. HBV: hepatitis B virus; HCV: hepatitis C virus; PS: Eastern Cooperative Oncology Group performance status; T0: no intrahepatic HCC; Portal invasion assessed Vp1: tumor thrombus in a third or more of the peripheral branches; Vp2: in the second branch; Vp3: in the first branch; Vp4: in the trunk; AFP: alpha-fetoprotein; DCP: Des-γ-carboxy prothrombin.

### Hepatocellular carcinoma

A definitive diagnosis of HCC was based on the finding of typical hypervascular radiological features or histopathological examination of needle biopsy specimen. HCC was also assessed by US, CT, and/or AG. Furthermore, CT was obtained during arterial portography and computerized tomographic hepatic arteriography. Further assessment of HCC was conducted by measuring α-fetoprotein (AFP) and des-γ-carboxy prothrombin (DCP).

Extrahepatic metastases were diagnosed by CT, MRI, bone scintigraphy, X-ray, and/or positron emission tomography (PET) with <sup>18</sup>F-fluorodeoxyglucose (FDG), or diagnosed by histopathological examination of surgically resected specimen or biopsy. When we suspected extrahepatic metastases with HCC, we always ruled out other malignancies (such as gastric cancer, colon cancer and lung cancer) by several imaging modalities, serological tumor markers and/or pathological examination.

### Follow-up

All the 151 HCC patients with extrahepatic metastases were followed up during the observation period and no one was lost to follow-up. The median follow-up period was 4.9 mo (range, 1-37 mo). After the diagnosis of HCC, all patients were screened at regular intervals for the development of intra/extra hepatic metastases by clinical examination, AFP, DCP, and/or various imaging modalities. Serological tumor markers were measured once every month. US, CT or MRI was performed once every three to six months.

### Statistical analysis and ethical considerations

Differences between groups were examined for statistical significance using the Mann-Whitney test (*U*-test) and  $\chi^2$  test where appropriate. Cumulative survival rate was assessed by the Kaplan-Meier life-table method and the differences were evaluated by the log rank test. The following 15 potential predictors were assessed in this study: PS (0 *vs* 1-4), age ( $\leq 65$  *vs*  $> 65$  years), sex (M *vs* F), Child-Pugh stage (A *vs* B, C), intrahepatic tumor stage (T0-T2 *vs* T3, T4), main intrahepatic tumor size ( $\leq 50$  *vs*  $> 50$  mm), intrahepatic tumor volume ( $\leq 50\%$  *vs*  $> 50\%$ ), intrahepatic tumor morphology (nodular type *vs* non nodular type), portal venous invasion (Vp 0-2 *vs*  $> 3$ , 4), AFP ( $\leq 400$  ng/mL *vs*  $> 400$  ng/mL), DCP ( $\leq 1000$  mAU/mL *vs*  $> 1000$  mAU/mL), site of extrahepatic metastases (lung *vs* others, bone *vs* others, only lymph node *vs* others), and treatment for extrahepatic metastases (performed *vs* not performed). All factors that were at least marginally associated with the survival after diagnosis of extrahepatic metastases ( $P < 0.05$ ) were entered into a multivariate analysis. The hazard ratio and 95% confidence interval (95% CI) were calculated to assess the relative risk confidence. All analyses described above were performed using the SPSS program (version 11.0, SPSS Inc., Chicago, IL).

The study protocol was approved by the Human Ethics Review Committee of Graduate School of Biomedical Sciences, Hiroshima University and a signed consent form was obtained from each patient.

## RESULTS

### Site of extrahepatic metastases

Table 2 lists the sites of extrahepatic metastases identified throughout the follow-up period. The most frequent site of metastases that were identified throughout the follow-up period was the lung ( $n = 71$  patients, 47%), followed by lymph nodes ( $n = 68$  patients, 45%), bone ( $n = 56$  patients, 37%), and adrenal glands ( $n = 18$  patients, 12%). Brain metastases were identified in 2 (1%) patients. One (0.7%) patient each had metastases in the peritoneum, pancreas, nasal passages, muscle, skin, diaphragm, and colon. Autopsy was performed in 14 cases with metastases. Despite the detection of extrahepatic metastases in these 14 patients before autopsy, additional extrahepatic metastases were detected on postmortem examination (lymph nodes, diaphragm, and colon). At the first diagnosis of extrahepatic metastases, 109 (72%) patients had single-organ metastases, while the others had multiple organ metastases.

Among the 71 patients with lung metastases, 23 patients had bilateral lung metastases, 14 had additional extrapulmonary site of metastatic disease. The size of pulmonary nodules ranged from 9 to 30 mm at initial diagnosis of extrahepatic HCC. Few patients had symptoms (cough, dyspnea, and pleural effusion) related to lung metastases, and 8 patients who had severe symptoms died subsequently of respiratory failure. The median survival period of these 8 patients was 4.3 mo (range, 2.5-14.4 mo).

Table 2 Sites of extrahepatic HCC detected throughout the entire follow-up period

Site	Patients ( $n = 151$ ), $n$ (%)
Lung	71 (47)
Lymph nodes	68 (45)
Bone	56 (37)
Adrenal	18 (12)
Brain	2 (1)
Peritoneum	1 (0.7)
Pancreas	1 (0.7)
Nasal	1 (0.7)
Muscle	1 (0.7)
Skin	1 (0.7)
Diaphragm	1 (0.7)
Colon	1 (0.7)

Among the 68 patients with lymph node metastases, metastases were identified in 64 regional lymph nodes. The most common site was in the paraaortic nodes (31/64), followed by portohepatic nodes (21/64), periceliac nodes (6/64) and peripancreatic nodes (6/64). The majority of patients with regional lymph nodes metastases were asymptomatic, but few regional lymph nodes (portohepatic nodes) caused obstructive jaundice. Distant nodal metastases were found at 17 sites. The most common site was the mediastinum nodes (10/17), followed by subclavicular nodes (3/17), iliac nodes (2/17), cardiophrenic node (1/17), and retrocrural node (1/17). All distant lymph node metastases were not associated with clinical symptoms in this study.

Fifteen of 56 patients with bone metastases had multiple bone metastases at the initial diagnosis of bone metastases. The total number of bone metastatic sites was 88. The most frequent site was the vertebra (63/88; cervical vertebrae = 9, thoracic vertebrae = 38, and lumbar vertebrae = 16), followed by the ribs (8/88). Bone metastases were diagnosed by CT, MRI, bone scintigraphy, and/or PET with FDG.

Of the 18 patients with adrenal gland metastases, 13 had right adrenal gland metastases, 4 had left adrenal gland metastases and only one patient had bilateral metastases. These metastases were not associated with symptoms.

### Treatments of extrahepatic metastases

All patients with Child-Pugh grade other than C or PS other than 2-4 were treated for intrahepatic HCC, and many of them were continuously treated after the diagnosis of extrahepatic metastases. On the other hand, HCC patients with Child-Pugh grade C or PS of 2-4 received supportive care. Forty-nine (32%) of 151 patients were treated for extrahepatic metastases by surgical resection, TACE, systemic chemotherapy, and/or radiotherapy. The 49 patients had extrahepatic metastases that were considered to worsen prognosis.

Surgical resection was performed in three (2%) patients (with regional lymph node, adrenal gland and lung metastases). The survival periods after surgical resection of extrahepatic metastases were 7 mo (in patients with lymph node metastases), 23 mo (in patients adrenal gland metastases), and 37 mo (in patients with lung metastases).

**Figure 1** Survival rate of 151 HCC patients with extrahepatic metastases (A), intrahepatic tumor stage (B) [solid line: T0-T2, dashed line: T3, T4 (log-rank test:  $P < 0.001$ )], and after treatment of extrahepatic metastases (C) [solid line: treatment group, dashed line: no treatment group (log-rank test:  $P < 0.001$ )].

These three were all alive without recurrence of extrahepatic metastases during the observation period. In each of these 3 patients, hepatic reserve was Child-Pugh stage A, no intrahepatic HCC was not detected, and PS was 0.

TACE was performed in 8 (5%) patients (7 patients with adrenal gland metastases, and one patient with paraaortic lymph node metastases). Systemic chemotherapy was used in 39 (26%) patients. Chemotherapy included 5-fluorouracil, carboplatin, cisplatin. Twenty-five of the 39 patients had lung metastases, 10 had lymph node metastases, 2 had bone metastases, one had lung and lymph node metastases, and one had lung, adrenal gland and lymph node metastases.

Radiotherapy was performed in 36 (24%) patients.

**Table 3** Univariate analysis of predictors of survival after initial diagnosis of extrahepatic metastases in 151 patients

Variable	Hazard Ratio	95% CI	P
PS (0 vs 1-4)	2.181	1.50-3.17	< 0.001
Age ( $\leq 65$ vs $> 65$ yr)	0.988	0.97-1.0	0.18
Sex (M vs F)	0.889	0.57-1.38	0.601
Child Pugh stage (A vs B, C)	2.323	1.73-3.12	< 0.001
Intrahepatic main tumor size ( $\leq 50$ vs $> 50$ mm)	2.321	1.52-3.54	< 0.001
Intrahepatic tumor volume ( $\leq 50$ vs $> 50\%$ )	2.523	1.71-3.72	< 0.001
Intrahepatic tumor morphology (nodular vs non nodular)	1.506	1.04-2.18	0.03
Vp (0-2 vs 3, 4)	2.247	1.53-3.29	< 0.001
AFP ( $\leq 400$ vs $> 400$ ng/mL)	1.158	0.80-1.68	0.439
DCP ( $\leq 1000$ vs $> 1000$ mAU/mL)	1.584	1.08-2.33	0.02
Treatment (performed vs not performed) <sup>1</sup>	2.385	1.51-3.77	< 0.001
Site (lung vs others) <sup>2</sup>	1.065	0.74-1.52	0.731
Site (bone vs others)	1.61	1.11-2.33	0.012
Site (only lymph node vs others)	1.133	0.74-1.74	0.567

<sup>1</sup>Treatments: various treatments for extrahepatic metastases (surgical resection, TACE, systemic chemotherapy and/or radiotherapy); <sup>2</sup>Site: site of extrahepatic metastases.

Curative therapy was performed in 10 patients (6 patients with lymph node metastases and 4 patients with adrenal gland metastases). Palliative therapy was performed in the remaining 26 patients who had severe pain due to bone metastases. Furthermore, 9 patients with painful bone metastases were treated with RFA therapy combined with cementoplasty<sup>[21]</sup>. Nonsteroidal anti-inflammatory drugs or opioids were used in patients with bone metastases due to severe pain.

### Survival data

The cumulative survival rates of the 151 HCC patients with extrahepatic metastases after initial diagnosis of extrahepatic metastases at 6, 12, 24, and 36 mo were 44.1%, 21.7%, 14.2%, and 7.1%, respectively (Figure 1A). The median survival period was 4.9 mo (range, 1-37 mo). Survival was compared among patients with intrahepatic tumor stage T0-T2 and T3, T4 (Figure 1B). The rate was significantly higher in the intrahepatic tumor stage T0-T2 groups than in the T3, T4 groups ( $P < 0.001$ ). We investigated the determinants of survival after initial diagnosis of extrahepatic metastases. Univariate analysis identified the following 9 factors significantly influencing survival: PS, 0 ( $P < 0.001$ ); Child-Pugh grade, A ( $P < 0.001$ ); intrahepatic main tumor size,  $< 50$  mm ( $P < 0.001$ ); intrahepatic tumor volume,  $< 50\%$  ( $P < 0.001$ ); portal venous invasion, Vp 0-2 ( $P < 0.001$ ); use of treatment for extrahepatic metastases ( $P < 0.001$ , Figure 1C); bone metastasis ( $P = 0.012$ ); DCP  $< 1000$  mAU/mL ( $P = 0.02$ ); and nodular type intrahepatic tumor ( $P = 0.03$ ) (Table 3). Since the variables could be mutually correlated, multivariate analysis was performed. The analysis identified the following four variables as significant and independent determinants of survival after initial diagnosis of extrahepatic metastases: PS ( $P < 0.001$ ), portal venous invasion ( $P < 0.001$ ), treatment of extrahepatic metastases ( $P = 0.003$ ), and Child-Pugh grade ( $P = 0.009$ ) (Table 4).

**Table 4** Multivariate analysis of predictors of survival after initial diagnosis of extrahepatic metastases among 151 patients

Variable	Hazard ratio	95% CI	P
PS (0 vs 1-4)	5.576	2.431-12.152	< 0.001
Vp (0-2 vs 3, 4)	4.792	2.137-10.712	< 0.001
Treatment (performed vs not performed)	4.134	1.539-11.011	0.003
Child pugh stage (A vs B, C)	2.372	1.247-4.914	0.008

### Causes of death

Twenty-five patients were still alive at the end of this study while 126 patients died. Of the latter group, intrahepatic tumor stages at the first diagnosis of extrahepatic metastases were T0-2 in 17 patients and T3-4 in 109 patients. One hundred and twelve (89%) patients died of intrahepatic HCC or liver failure. Fourteen (11%) patients died of extrahepatic HCC (Table 5). Eight patients died of respiratory failure due to lung metastases. Four patients died of bone metastases-related disease. Two patients died of obstructive jaundice due to portohepatic node metastasis.

Of the 4 patients who died of bone metastases-related disease, 3 died of intracranial hypertension due to skull metastasis. Another patient died of vertebra metastasis-related disease. He was 69-year old at first diagnosis of bone metastases. He suffered from complete spinal cord injury due to vertebral metastasis with gradual worsening of PS. Finally, PS changed to 4 and the patient died of aspiration-related pneumonia. The survival period after first diagnosis of extrahepatic metastases was 11.5 mo.

Among the 14 patients who died of extrahepatic HCC, 3 had chronic hepatitis, 7 had cirrhosis of Child-Pugh grade A, 3 had cirrhosis of Child-Pugh grade B, and 1 had cirrhosis of Child-Pugh grade C. All patients who died of extrahepatic HCC with the exception of that with Child-Pugh grade C had some hepatic reserve until death. Intrahepatic tumor stage at first diagnosis of extrahepatic metastases was T0 (3 patients), T1 (4 patients), T2 (1 patient), T3 (5 patients), and T4 (1 patient). All 8 patients with intrahepatic tumor stage T0-T2 were treated previously for intrahepatic HCC. Eight of 17 (47%) patients with intrahepatic tumor stage T0-T2 died of extrahepatic metastases. On the other hand, 6 of 109 (6%) patients with intrahepatic tumor stages T3 and T4 died of extrahepatic metastases. The mortality rate of patients with intrahepatic tumor stage T0-T2 was significantly higher than that of patients with intrahepatic tumor stages T3 and T4 ( $P = 0.001$ ) (Table 6).

## DISCUSSION

The prognosis of HCC patients with extrahepatic metastases is unsatisfactory<sup>[16,17]</sup> and often not well known<sup>[18]</sup>. In the present study, we assessed the clinical features and prognosis of 151 consecutive HCC patients with extrahepatic metastases. The incidence of extrahepatic metastases from HCC was 15.2%. The most frequent metastatic sites were the lung, lymph nodes, bone, and adrenal gland. The cumulative survival rates of

**Table 5** Clinical profile of 14 patients who died of extrahepatic metastases during the follow-up period

Case	Presentation	Site	Intrahepatic HCC stage	Sex	Age (yr)	Child-Pugh stage	Etiology
1	R	Lung	T3	M	65	A	HCV
2	R	Lung	T4	M	35	CH	HBV
3	R	Lung	T3	M	56	A	HBV
4	R	Lung, vertebra	T0	M	40	CH	HBV
5	R	Lung, vertebra	T1	M	69	A	HBV
6	R	Lung, LN	T0	M	63	B	HBV
7	R	Lung, vertebra, nasal	T0	M	50	A	HBV
8	R	Lung	T3	M	73	A	NBNC
9	I	Skull	T1	M	57	A	HCV
10	I	Skull	T2	F	72	C	HCV
11	I	Skull	T3	M	56	B	HCV
12	A	Vertebra	T3	M	69	A	HCV
13	O	Lung, rib, LN	T1	M	74	A	HCV
14	O	Vertebra, LN	T1	M	70	B	HCV

All patients with intrahepatic tumor stage T0-T2 were treated previously for intrahepatic HCC. R: respiratory failure; CH: chronic hepatitis; LN: lymph node; NBNC: no hepatitis B virus or hepatitis C virus; I: intracranial hypertension symptom; A: aspiration-related pneumonia; O: obstructive jaundice.

**Table 6** Causes of death of 126 HCC patients with extrahepatic metastases

Intrahepatic tumor stage	Intrahepatic HCC or liver failure	Extrahepatic HCC
T0-2 (n = 17)	53% (9/17)	47% (8/17)
T3-4 (n = 109)	94% (103/109)	6% (6/109)

the 151 patients after the initial diagnosis of extrahepatic metastases at 6, 12, 24, and 36 mo were 44.1%, 21.7%, 14.2%, 7.1%, respectively. The median survival period was 4.9 mo (range, 1-37 mo). The mortality rate due to extrahepatic metastases from HCC was 11% (14/126).

Extrahepatic metastases have been reported to occur in 13.5%-42% of HCC patients<sup>[22-24]</sup>. In this study, the prevalence of extrahepatic metastases was 15.2%. Though we screened all HCC patients at regular intervals for intra/extra hepatic metastases, not all patients received a full metastatic follow up based on the use of several diagnostic techniques. Since the majority of HCC patients with extrahepatic metastases were asymptomatic, it is possible to miss asymptomatic metastases such as those in the lungs, distant lymph nodes, muscles and rectum.

Based on the initial diagnosis of intrahepatic HCC, Natsuzaka *et al*<sup>[16]</sup> reported that patients with advanced HCC develop extrahepatic metastases significantly more frequently than those with less advanced HCC. At the initial diagnosis of extrahepatic metastases, many HCC patients with extrahepatic metastases have been reported

to have advanced intrahepatic stage<sup>[16,22]</sup>. In our study, 123 (81%) patients with extrahepatic metastases had intrahepatic tumor stages T3 (28%) and T4 (53%), at the initial diagnosis of extrahepatic metastases, suggesting that HCC patients with advanced intrahepatic tumor stage (T3, T4) are at risk of developing extrahepatic metastases, and that such patients should be followed up carefully.

On the other hand, our study identified 28 (19%) patients with early intrahepatic tumor stage (T0-T2) at the initial diagnosis of extrahepatic HCC. Eight of the 17 (47%) patients later died of extrahepatic metastases. With regard to previous treatment, 27 of 28 patients with early intrahepatic tumor stage were treated previously for intrahepatic HCC. Considering the possibility of extrahepatic metastases, HCC patients with early intrahepatic tumor stage should be followed up carefully, particularly those who have been treated previously for intrahepatic HCC. This also includes HCC patients who have received complete resection or ablation.

In this study, the most frequent metastatic sites were the lungs, lymph nodes, bones, and adrenal glands. Other studies have reported similar findings<sup>[16,22]</sup>. HCC is thought to spread mainly *via* the hematogenous route, thus causing intra/extra hepatic metastases. Most of HCCs are hypervascular tumors. Moreover, HCC tends to invade vessels, such as portal and hepatic veins. Therefore, HCC could spread through the lung and systemic circulation via the hepatic or portal vein. This could explain why the lung is the most frequent site of metastases in HCC. Most of HCC patients with lung metastases are asymptomatic. To detect lung metastases from HCC, chest CT should be performed at regular intervals during routine metastasis follow-up.

Though there is no standard treatment for extrahepatic metastases of primary HCC, several authors have reported the use of various treatment modalities for extrahepatic metastases<sup>[5,7,15,23,25-28]</sup>. Some reports have described successful treatment of extrahepatic metastases with no or few intrahepatic HCC<sup>[5,7,25,26]</sup>. However, only few HCC patients can undergo surgical resection of extrahepatic metastases because of hepatic reserve or intrahepatic tumor stage. In this study, the prognosis of 3 patients after surgical resection of extrahepatic metastases seemed good. These 3 patients had good hepatic reserve, no intrahepatic HCC (PS = 0) and no intra/extra hepatic HCC and are expected to have good prognosis. The clinical features of HCC patients with extrahepatic metastases varied widely. All patients were not symptomatic and thus not necessary to receive treatment of extrahepatic metastases. Thus, treatment of extrahepatic metastases from primary HCC must be performed carefully taking into consideration the clinical features.

Multivariate analysis in our study identified PS, portal venous invasion, treatment for extrahepatic metastases, and Child-Pugh grade as important determinants of survival after the initial diagnosis of extrahepatic metastases. Ishii *et al*<sup>[17]</sup> reported that brain metastases, number of metastatic tumors and primary tumor status are important factors for survival. In our study, only two patients had brain metastases. With regard to the number of metastatic tumors, we might miss asymptomatic metastases. Thus,

Figure 2 Initial sites to be treated.

we did not include brain metastasis and number of metastatic tumors in this multivariate analysis. Treatment of extrahepatic metastases was an important determinant of survival in our study. There might be selection bias of patients treated for extrahepatic metastases because many of them had good hepatic reserve. HCC patients with poor hepatic reserve did not receive treatment for extrahepatic metastases in this study. Regardless of such bias, treatment of extrahepatic metastases might be important for improvement of prognosis.

With regard to the cause of death, many HCC patients with extrahepatic metastases died of intrahepatic HCC or liver failure and few (11%) died of extrahepatic HCC. Of the 14 patients who died of extrahepatic metastases, 10 had good hepatic reserve and 8 had early intrahepatic tumor stage, at the initial diagnosis of extrahepatic metastases. Usually, HCC patients with good hepatic reserve, no or few intrahepatic HCCs, and those without portal venous invasion show relatively good prognosis. According to the univariate analysis of HCC patients with extrahepatic metastases, patients with early intrahepatic tumor stage have a significantly better prognosis than those with advanced intrahepatic tumor stage. In our study, the mortality rate due to extrahepatic metastases with early intrahepatic tumor stage was significantly higher than that due to those with advanced intrahepatic tumor stage. This might be explained by the differences in survival periods between these intrahepatic tumor stage groups. Extrahepatic metastases with early intrahepatic tumor stage can spread during the relatively long survival period, and few patients die of extrahepatic metastases. Extrahepatic metastasis with early intrahepatic tumor stage is a very important cause of death of HCC patients. Successful treatment of extrahepatic metastases in HCC patients with early intrahepatic tumor stage might improve the prognosis.

In conclusion, the majority of HCC patients with extrahepatic metastases should undergo treatment for intrahepatic HCC. Selected HCC patients with critical extrahepatic metastases could undergo treatment for extrahepatic metastases. However, these selected patients must have good hepatic reserve, intrahepatic tumor stage: T0-T2, and are free of portal venous invasion (Figure 2). The important sites of critical metastases from primary

HCC are the lungs, bones and the portohepatic node. Further studies are needed for the improvement of the prognosis of HCC patients with extrahepatic metastases.

## Abstract

**AIM:** To evaluate plasma levels of nitrite/nitrate (NOx), soluble Fas (sFas) antigen, tumor necrosis factor alpha (TNF- $\alpha$ ) and interleukin-6 (IL-6) in patients with compensated and acute decompensated cirrhosis and to evaluate mediators causing acute decompensation in liver cirrhosis.

**METHODS:** This prospective study was conducted in the medical intensive care unit of an academic tertiary center. Fifty-five patients with acute decompensation (gastrointestinal hemorrhage, encephalopathy, hydropic decompensation) and twenty-five patients with compensated liver cirrhosis were included. Blood samples were taken for analyses of sFas, NOx, IL-6, TNF- $\alpha$ . Liver enzymes and kidney functions were also tested.

**RESULTS:** In patients with acute decompensation, plasma sFas levels were higher than in non-decompensated patients ( $15305 \pm 4646$  vs  $12458 \pm 4322$  pg/mL,  $P < 0.05$ ). This was also true for the subgroup of patients with alcoholic liver cirrhosis ( $P < 0.05$ ). The other mediators were not different and none of the parameters predicted survival, except for ALT (alanine-aminotransferase). In patients with portal-hypertension-induced acute hemorrhage, NOx levels were significantly lower than in patients with other forms of decompensation ( $70.8 \pm 48.3$  vs  $112.9 \pm 74.9$  pg/mL,  $P < 0.05$ ). When NOx levels were normalized to creatinine levels, the difference disappeared. IL-6, TNF- $\alpha$  and sFas were not different between bleeders and non-bleeders. In decompensated patients sFas, IL-6 and NOx levels correlated positively with creatinine levels, while IL-6 levels were dependent on Child class.

**CONCLUSION:** In acute decompensated cirrhotic patients sFas is increased, suggesting a role of apoptosis in this process and patients with acute bleeding have lower NOx levels. However, in this acute complex clinical situa-

tion, kidney function seems to have a predominant influence on mediator levels.

## INTRODUCTION

Liver cirrhosis with portal hypertension is characterized by several systemic and splanchnic hemodynamic changes, such as splanchnic and systemic vasodilation, with increased cardiac output and a compensatory renal vasoconstriction<sup>[1]</sup>. A high level of nitric oxide (NOx), a short-lived soluble vasodilating molecule, has been proposed as one of the major endogenous vasodilators in portal hypertension<sup>[2,3]</sup>. Increased serum NOx levels in patients with cirrhosis have been reported repeatedly<sup>[4-10]</sup>. It is also thought to be the cause of some of the complications associated with end stage liver disease. Certain complications of cirrhosis such as the hepatopulmonary syndrome may be in part mediated by local overproduction of nitric oxide<sup>[11]</sup>. In contrast, exogenous application of nitrates is helpful in primary prophylaxis of variceal hemorrhage<sup>[12]</sup> and the endothelial dysfunction in cirrhosis results in impaired release of endothelial relaxing factors including NO<sup>[13]</sup>. Therefore, we speculated that changes in NOx levels could lead to acute decompensation of liver cirrhosis. In addition to NOx, other mediators such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6) have also been associated with the hemodynamic alterations in liver cirrhosis<sup>[14-18]</sup> and might therefore influence events of acute decompensation.

Experimental studies have also suggested that apoptosis *via* the soluble Fas (sFas)/Fas-ligand (FasL) signalling system may play an important role in the development of liver failure<sup>[19]</sup>. High levels of sFas have also been described in certain chronic liver diseases<sup>[20,21]</sup>. However, the effects on acute decompensation of chronic liver diseases are not yet known. The aim of our study was to evaluate serum

levels of NOx, cytokines and sFas in patients with portal-hypertension-associated gastrointestinal hemorrhage and to compare these with levels in patients with other forms of acute decompensation or compensated cirrhosis.

## MATERIALS AND METHODS

### Patients

A total of 80 consecutive patients with liver cirrhosis with ( $n = 55$ ) and without ( $n = 25$ ) decompensation entered this prospective study at the Department of Medicine, University Hospital Heidelberg between October 1999 and June 2000. Patients with decompensation had to be admitted immediately to the Intensive Care Unit of the medical department. Patients with additional signs of infection were excluded from this study to eliminate the influence of the infection *per se* on serum levels of NOx, cytokines and sFas<sup>[22]</sup>. The study was approved by the ethical committee of the University of Heidelberg. After signing informed consent patients were enrolled.

Criteria for decompensation in patients with histologically proven cirrhosis were: hydropic decompensation with ascites and peripheral edema (hydropic decompensation), encephalopathy or portal-hypertension-associated gastrointestinal hemorrhage. Patients were categorized according to their initial symptoms, and no patient was in more than one category. The severity of liver disease was evaluated according to Pugh's modification of Child's criteria.

Since cytokine levels are influenced by accompanying infections, patients with additional signs of infection were excluded. Spontaneous bacterial peritonitis (SBP) was defined as infection of the ascitic fluid, in the absence of any intra-abdominal source of infection, with a neutrophil count higher than 250 cells/mm<sup>3</sup> ascitic fluid and/or a positive culture. Urinary tract infection was considered when the polymorphonuclear cell count was higher than 10<sup>5</sup>/mm<sup>3</sup> and/or a positive culture of urine. Systemic infection was diagnosed when two positive blood cultures were found. A pneumonia was diagnosed based on a positive sputum culture and/or typical chest X-ray.

On admission blood samples for cytokines, NOx and soluble Fas were taken. These parameters were measured together with routine laboratory tests on admission so as to exclude influences of therapies and disease outcomes on cytokine levels. The clinical and biochemical features of the patients are shown in Table 1. Five ml blood was obtained on admission in S-monovettes (Sarstedt, Germany). Serum was immediately separated by centrifugation (3000 r/min), divided into aliquot portions and stored at -25°C until assayed (within 2 mo of sampling).

### Methods

IL-6 and TNF- $\alpha$  were measured in duplicates using commercially available EIA assays (CYTImmune Sciences Inc. College Park, MD USA). TNF- $\alpha$  assay sensitivity was 4.8 pg/mL, the intra-assay coefficient of variation was  $\pm 8.3\%$ , and the inter-assay coefficient of variation was  $\pm 10.8\%$ . For IL-6 the assay sensitivity was 3.4 pg/mL, the intra-assay coefficient of variation was  $\pm 8.1\%$ , and the

Table 1 Patient characteristics on admission

Characteristics	Decompensated cirrhosis ( $n = 55$ )	Compensated cirrhosis ( $n = 25$ )
Age (yr)	56.1 $\pm$ 14.2	55.6 $\pm$ 13.7
Gender (M/F)	34/21	15/10
Etiology of cirrhosis		
Alcoholic	31 (56%)	14 (56%)
Viral	8 (15%)	2 (8%)
Others	16 (29%)	9 (36%)
Child Pugh class		
A/B/C	7/24/24	19/6/0

inter-assay coefficient of variation was  $\pm 10.4\%$ .

SFas in serum was quantified by a colorimetric ELISA kit (Quantikine, R&D Systems GmbH Wiesbaden, Germany) according to the manufacturers' instructions. Serum samples (100  $\mu$ L) were poured into antibody-coated wells using multichannel pipettes, then incubated for 2 h at room temperatures. After washing four times 200  $\mu$ L peroxidase-conjugated-polyclonal antibody solution was added to each well and incubated for 2 h at a room temperature. After washing, the substrate solution (200  $\mu$ L) was added to each well and incubated for 30 min. The stop solution (50  $\mu$ L) was then added to the wells and the absorbance of each well was measured at a wavelength of 450 nm (Anthos AR 2001). SFas concentrations were calculated by comparison of the optical densities (mean of duplicate patient samples) to those of the standard run on the same plate. For sFas the assay sensitivity was 3.4 pg/mL, the intra-assay coefficient of variation was  $\pm 3.8\%$ , and the inter-assay coefficient of variation was  $\pm 4.5\%$ .

NOx was determined from total nitrite levels. Total nitrite measurements were performed on stored samples from all patients, using commercially available kits (Nitric Oxide Assay, R&D Systems GmbH Wiesbaden, Germany). The assay involved the conversion of nitrate to nitrite by nitrate reductase. The detection of nitrite is determined as a colored azo-dye product of the Griess reaction that absorbs visible light. The concentration of NO was indirectly measured by determining both nitrate and nitrite levels in the same sample. Before analyses samples were thawed at a room temperature and ultrafiltered through a 10000 Molecular Weight cutoff filter (Microcon YM-10, Millipore Corporation, USA) to eliminate proteins. Supernatants were placed in microtiter plates in duplicates. The steps used in the assay followed manufacturers' guidelines. After development, plates were read on a microtiter plate scanner (Anthos AR 2001 [550 nm]) and the endogenous nitrite and total nitrite concentrations were calculated by normalization of the optical densities (mean of duplicate samples) of patient samples to those of the standard on the same plate.

The nitrate concentration was determined by subtracting the endogenous nitrite concentration from the total nitrite concentration. The analytic sensitivity of the nitrite assay is typically less than 0.22  $\mu$ mol/L and of the nitrate reduction assay 0.54  $\mu$ mol/L. Liver enzymes and creatinine levels were measured using standard commercial

photometric assays. Because NOx levels correlate with kidney function (serum creatinine), they were divided by creatinine levels<sup>[16]</sup>.

### Statistical analysis

The data were evaluated using descriptive statistical methods (mean  $\pm$  SD, ranges). For comparison of two independent variables the non-parametric Mann-Whitney U-test was used.  $P < 0.05$  was considered significant. Correlations were assessed by Spearman's test. Statistical calculations were performed using SPSS Version 10.0 for Windows (SPSS Inc. Chicago, USA).

## RESULTS

A total of 80 patients were consecutively analyzed. There were more men than women (Table 1). Alcohol was the predominant reason for cirrhosis in both groups (56%). Liver cirrhosis, as assessed by the Child-Pugh score, showed higher stages in the decompensated group.

### Decompensated vs compensated cirrhosis

Serum levels of soluble Fas, NOx, TNF- $\alpha$  and IL-6 of patients with and without hepatic decompensation are summarized in Table 2. Among these only sFas was different ( $P < 0.05$ ) between the groups with greater values in patients with decompensation. Further differences between the groups were aspartate-aminotransferase (AST) and alanine-aminotransferase (ALT) levels. In decompensated patients the values averaged  $99.7 \pm 273.1$  U/L and  $46.3 \pm 153.8$  U/L, respectively. The corresponding values in compensated patients were  $25.2 \pm 15.6$  and  $20.5 \pm 13.9$  U/L ( $P < 0.05$ ). Kidney function, as determined by serum levels of creatinine, was impaired in patients with decompensation ( $1.3 \pm 0.9$  vs  $0.8 \pm 0.2$  mg/dL,  $P < 0.01$ ).

### Survival

Within the follow up period of two months, 7 patients with decompensated livers died, while none of the compensated patients died. In comparison to the decompensated survivors, neither sFas, NOx, and TNF- $\alpha$  nor IL-6 levels were different. Kidney function was also comparable. However, ALT levels were significantly higher in patients who died during the observation period ( $73.6 \pm 74.8$  vs  $42.0 \pm 162.8$  U/L,  $P < 0.01$ ).

### Comparison of decompensated patients with and without bleeding

Portal hypertension related gastrointestinal hemorrhage was the reason for admission in 21 patients. IL-6, TNF- $\alpha$  and sFas levels were not significantly different between patients with and without bleeding. However, NOx levels were significantly lower in patients with bleeding ( $70.8 \pm 48.3$  vs  $112.9 \pm 74.9$  pg/mL,  $P < 0.05$ ). At the beginning kidney function, as assessed by creatinine levels, was poorer in patients with bleeding compared to patients without bleeding ( $0.9 \pm 0.4$  vs  $1.5 \pm 1.0$  mg/dL,  $P < 0.05$ ). NOx levels are dependent on kidney function and were therefore normalized to creatinine levels. This eliminated

**Table 2** Serum levels of soluble Fas (sFas), nitrite/nitrate (NOx), tumor necrosis factor alpha (TNF- $\alpha$ ) and interleukin-6 (IL-6) in patients with acute decompensation (hemorrhage, encephalopathy, and hydropic decompensation) of liver cirrhosis (mean  $\pm$  SD)

	Decompensated cirrhosis (n = 55)	Compensated cirrhosis (n = 25)
SFas (pg/mL)	15305 $\pm$ 4646	12458 $\pm$ 4322 <sup>a</sup>
NOx ( $\mu$ mol/L)	96.9 $\pm$ 68.7	64.2 $\pm$ 40.2
TNF- $\alpha$ (pg/mL)	90.9 $\pm$ 65.2	73.5 $\pm$ 46.5
IL-6 (pg/mL)	84.8 $\pm$ 154.3	180.9 $\pm$ 662.2

<sup>a</sup> $P < 0.05$  vs decompensated cirrhosis.

the difference. In the bleeding group, the ratio was  $0.88 \pm 0.62$  vs  $1.13 \pm 0.95$  in decompensated patients without bleeding ( $P = \text{NS}$ ). In addition, transaminase levels were not different between the patient groups.

### Correlation between mediators, transaminases (ALT, AST) and creatinine levels in patients with decompensated cirrhosis

Serum sFas levels and NOx correlated positively with creatinine levels ( $P < 0.05$ ). Serum TNF- $\alpha$  and IL-6 levels showed no correlations and none of the mediators correlated with each other, whereas ALT correlated with AST ( $P < 0.001$ ).

### Etiology of cirrhosis

In patients with decompensated livers, alcohol was the reason for cirrhosis in 31 cases and viral infection was the cause in 8 patients. In alcoholic cirrhosis NOx levels were higher ( $104.2 \pm 57.5$   $\mu$ mol/L), while in viral hepatitis NOx levels were significantly lower ( $63.9 \pm 60.7$   $\mu$ mol/L,  $P < 0.05$ ). In patients with alcoholic decompensated cirrhosis sFas levels were higher ( $15711 \pm 4406$  pg/mL) than in patients with compensated alcoholic cirrhosis ( $14882 \pm 4588$  pg/mL,  $P < 0.05$ ). This again indicates a potential role of apoptosis in deteriorating liver function in these patients. The TNF- $\alpha$  and IL-6 levels were similar in both groups.

### Dependency on liver function

Several reports have found a correlation between liver function, as assessed by the Child-Pugh score, and cytokine levels. For sFas, TNF- $\alpha$  and NOx no dependency on liver function was observed. However, there was a clear dependency of IL-6 levels on liver function. With deteriorating liver function, IL-6 levels increased significantly ( $P < 0.05$ ) (Figure 1).

## DISCUSSION

Acute decompensation of liver cirrhosis is a life threatening complication of a chronic disease. The reasons why acute decompensation occurs are not well understood, but bacterial infections are thought to be involved in some patients<sup>[23]</sup>. To exclude this possibility and to evaluate the role of different mediators only patients without any signs

of infection were enrolled in this study. Our results showed that in a large cohort of decompensated cirrhotic patients decompensation was accompanied by increased sFas levels. This was independent of the kind of decompensation, i.e., bleeding or hydropic decompensation and was also independent of Child stage. SFas had no relation to outcomes or transaminase levels, but correlated with kidney function.

The data showed that clinical progression and decompensation of liver disease was accompanied by an increase in sFas levels. These results are consistent with other studies demonstrating that the clinical progression of HBV from acute to chronic to malignancy is reflected by a profile of steadily increasing sFas levels<sup>[21]</sup>. Similar results were reported in patients with chronic hepatitis C<sup>[24]</sup>. We first describe such a correlation in patients with acute decompensation of chronic liver disease, especially in patients with alcoholic cirrhosis. Evidence from *in vitro* studies suggests that sFas can interfere with immune cell-mediated Fas/FasL apoptosis induction<sup>[25,26]</sup>. The results therefore indicate that such interference plays a progressively enhanced role during the evolution of the disease and the occurrence of acute decompensation.

In accordance with other studies we also found a dependency of sFas levels on kidney function<sup>[27]</sup>. In patients with chronic renal failure and in patients undergoing dialysis elevated sFas levels have been described. Therefore, the elevation of sFas levels in our patients might also be mediated by the degree of kidney failure. This additional factor was not mentioned in several other studies where kidney function was not evaluated.

Among many potential mediators, NOx has emerged as the main candidate implicated in the pathogenesis of the hemodynamic alterations in liver cirrhosis. In chronic liver diseases NOx is either produced as a result of high systemic endotoxin levels or shares stress of endothelial cells. In our study, NOx levels tended to be greater in patients with decompensated liver cirrhosis, however, this did not reach statistical significance. Among the decompensated patients, those with portal hypertension associated bleeding (i.e., variceal bleeding, portal hypertensive gastropathy and colonopathy) had significantly lower NOx levels than patients with other forms of decompensation (i.e., encephalopathy, hydropic decompensation).

NOx levels are determined not only by NO production but also by the degree of kidney dysfunction, the fasting state and exogenous nitrate sources<sup>[28]</sup>. There is an inverse correlation of kidney function and NOx serum levels<sup>[16]</sup>. In our cirrhotic patients with bleeding, kidney function at entry was better, as assessed by measuring serum creatinine levels, than in patients with other forms of decompensation. We therefore normalized NOx levels to serum creatinine levels and found no difference in NOx levels in decompensated patients with and without bleeding<sup>[16]</sup>, thus changes in NOx levels were not responsible for the acute bleeding episode. Kidney function was evaluated by creatinine levels. This is sufficient, since alterations in kidney functions reflected by changes of creatinine concentrations are accompanied by changes in NOx levels<sup>[29]</sup>. NOx levels were determined

**Figure 1** Dependency of IL-6 on Child Pugh class in patients with acutely decompensated liver cirrhosis (mean ± SD). <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs class C.

within 24 h after admission of the patients. Since NOx serum levels have a half-life period of 5 h and serum samples from all patients were obtained in similar fashion, this should not have influenced our results<sup>[30]</sup>.

In our study NOx levels were determined regardless of the fasting state. However, it has to be kept in mind that a gastrointestinal bleeding leads to a high intestinal protein load and induces encephalopathy in severe cirrhotic patients. Thus, our bleeding patients had an endogenous protein load, which could have even higher plasma NOx levels.

NOx is not the only mediator involved in the hyperdynamic circulation in cirrhosis. IL-6 and TNF- $\alpha$  are also thought to be involved<sup>[14,31,32]</sup> and both are able to increase NOx levels. In our study there were no differences at all between the groups and also patients with bleeding had no difference in these cytokine levels compared to patients with other forms of decompensation. Moreover, we could not find a dependency of TNF- $\alpha$ , sFas and NOx levels on liver function as assessed by the Child classification. Only IL-6 levels showed a dependency on liver function. This is in contrast to some studies, where such a relation could be observed<sup>[10]</sup>. Other studies were inconsistent<sup>[16]</sup>. However, serum levels were not corrected for kidney function<sup>[10]</sup>. It has been suggested that some of the elevations seen in these mediators are a consequence of liver cirrhosis and its hemodynamic alterations, rather than the cause of them. In fact, IL-6 is cleared mainly in the liver<sup>[33]</sup>, and consequently the elevated IL-6 levels might be secondary to liver dysfunction.

In summary, we show that IL-6 and TNF- $\alpha$  are not altered in acute decompensated patients. SFas and NOx levels are different, but dependent of and correlated with kidney function. None of the mediators alone is able to induce acute decompensation. However, in this acute complex clinical situation, kidney function seems to have predominant influence on mediator levels.

### Abstract

**AIM:** To investigate the expression of Cyclooxygenase-2 (COX-2), proliferating cell nuclear antigen (PCNA), Ki-67 and p53 in gastrointestinal stromal tumors (GISTs) and its relationship with histopathological parameters.

**METHODS:** Twenty-five GISTs were examined by light microscopy and immunohistochemistry. c-kit, CD34, SMA, S-100 protein, COX-2, PCNA, Ki-67 and p53 were detected immunohistochemically and the relationship was evaluated among histopathologic parameters such as mitotic index (MI), tumor grade, tumor size, COX-2, PCNA, Ki-67 and p53.

**RESULTS:** COX-2 protein expression was found in 19 of 25 (76%) of the tumors, and expression was noted in the cytoplasm of the tumor cells. p53 was significantly related to MI and tumor grade but no relationship was found between COX-2, proliferation markers and MI, tumor grade and tumor size.

**CONCLUSION:** COX-2 is expressed in most GISTs and it may play an important role in the proliferation and progression of these tumors or a useful marker to identify GIST. Although immunohistochemical assessment of p53 can be used for distinguishing the risk groups of GISTs, tumor size and mitotic rate should be considered at the same time.

### INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are specific mesenchymal tumors of gastrointestinal tract (GI) that may occur in the entire length of GI tract from the esophagus to the anus<sup>[1]</sup>. Its histopathological origin has recently been suggested to be the interstitial cells of Cajal (ICC)<sup>[2]</sup>. For the majority of GISTs, it may be very difficult or impossible to determine the presence of any specific line of differentiation histologically. Tumors showing partial or incomplete myogenic, neural or myenteric ganglionic features may present virtually identical features under light microscopy<sup>[3]</sup>.

However, immunohistochemistry of GISTs yields a diverse and confusing array of data, the antibodies most commonly used to characterize GISTs are those directed against vimentin, desmin, muscle specific actin (MSA), smooth muscle actin (SMA), S-100 protein, neurofilament (NF), neurone specific enolase (NSE), PGP9.5, CD34 and CD117 (c-kit). The myogenic markers MSA and SMA are variably expressed, whereas desmin is almost never present. Furthermore, MSA and SMA are generally only focally present or completely absent, indicating that most smooth muscle differentiation is incomplete. A possible schwannian/neural differentiation (S-100 protein, PGP9.5 and NSE positivity) may be present in a proportion of SMA and MSA negative tumors, both myogenic and schwannian/neural differentiation in a small proportion of tumors, whereas a small number of GISTs were positive for vimentin only and exhibited no detectable

differentiation immunohistochemically<sup>[1-4]</sup>.

The results of recent molecular pathologic studies that most GISTs are immunoreactive for CD34, a hematopoietic progenitor cell antigen, and CD117, c-kit proto-oncogen protein, as well as the gain of function c-kit gene mutations cause pathologic activation of the tyrosine kinase of c-kit in GISTs, seem to support the concept of GISTs as a biologically distinct entity<sup>[5,6]</sup>.

The cyclooxygenase (COX) isoenzymes, COX-1 and COX-2 catalyze in the oxidation of arachidonic acid to prostaglandins, prostacyclin and thromboxanes and are inhibited by aspirin and non-steroidal anti-inflammatory drugs (NSAIDs)<sup>[7]</sup>. COX-1 is constitutively expressed in most normal tissues; COX-2 is induced by cytokines, mitogenic agents, and growth factors, and it produces inflammation and cell growth. Up-regulation of this enzyme *in vitro* has several tumorigenic effects such as induction of cell cycle arrest, resistance to apoptosis, increased cell growth, and stimulation of mitogenesis<sup>[7-8]</sup>. Recent studies have shown that COX-2 expression is elevated in gastrointestinal carcinomas but little is known about COX-2 expression in GISTs<sup>[9-11]</sup>.

Multiple histological parameters such as mitosis, tumor size, cellularity, necrosis and pleomorphism have been used to predict the biological behavior of GISTs with limited success<sup>[2,12]</sup>. The proliferation markers Ki-67 and PCNA and tumor suppressor gene p53 have been reported as prognostic markers in many tumors, but only a few such studies have been reported in GISTs<sup>[2]</sup>.

In this study, we used CD34, SMA and S-100 for differentiation of GISTs and investigated the expression of COX-2 in an attempt to correlate histopathologic parameters such as mitotic index (MI), tumor grade and tumor size and COX-2, proliferating cell nuclear antigen (PCNA), Ki-67 and p53.

## MATERIALS AND METHODS

Formalin-fixed, paraffin-embedded tissue sections from 25 primary GISTs were obtained from the files of the Faculty of Medicine, Cukurova University, and Department of Pathology, Baskent University Adana Research and Practice Hospital. The material consisted of 11 gastric, 11 small intestinal, and 3 large intestinal tumors. The GIST cases were re-evaluated to confirm the diagnosis, and choose appropriate blocks of paraffin-embedded tissue for immunohistochemical analysis. Clinical information, including tumor size, was obtained from the surgical and pathological records. The tumors were reclassified as very low risk, low risk, intermediate risk and high risk according to MI (mitotic figures per 50 high-power fields; HPF) and tumor size (Table 1)<sup>[13]</sup>.

### Immunohistochemical analysis

Immunohistochemistry was performed using a strept avidin-biotin-peroxidase technique with antibodies to c-kit (CD117, monoclonal mouse antibody, Novacastra-dilution 1:30), CD34 (monoclonal mouse antibody, Dako-dilution 1:40), vimentin (monoclonal mouse antibody, Biogenex-dilution 1:100), SMA (monoclonal mouse antibody, Novacastra-dilution 1:50), S-100 protein (polyclonal rabbit

Table 1 Risk categories in GISTs

	Size	Mitotic count
Very low risk	< 2 cm	< 5/50 HPF
Low risk	2-5 cm	< 5/50 HPF
Intermediate risk	< 5 cm	6-10/50 HPF
	5-10 cm	< 5/50 HPF
High risk	> 5 cm	> 5/50 HPF
	> 10 cm	Any mitotic rate
	Any size	> 10/50 HPF

antibody, Novacastra-dilution 1:200), COX-2 (polyclonal goat antibody, Santa Cruz-dilution 1:100), Ki-67 (polyclonal rabbit antibody, Dako-dilution 1:50), PCNA (monoclonal mouse antibody, Biogenex-dilution 1:25), p53 (monoclonal mouse antibody, Dako-dilution 1:60). A 5- $\mu$ m thick sections of formalin-fixed, paraffin-embedded tissue samples were deparaffinized and rehydrated through a series of graded alcohols. Endogenous peroxidase activity was blocked by a 30-min incubation in 3% hydrogen peroxide-methanol solution and washed in phosphate-buffered saline (PBS). The slides were kept in citrate buffer for 5-10 min in a microwave oven, rinsed in PBS at room temperature and incubated for 20-30 min with A2 blocking serum (citrate buffer incubation was not performed for vimentin, and the sections were incubated with 0.1% trypsin for 30 min). After washing, the sections were incubated for 60-120 min with primary antibodies and incubated for 30 min with biotinylated horse anti-mouse IgG immunoglobulin (Dako, K0675). The sections were incubated for 30 min with strept avidin peroxidase reagent and washed again. The immunoperoxidase was visualized with AEC (3 amino 9 ethyl carbazole), (Dako, AEC substrate K0696). The sections were counterstained with Mayer's hematoxylin and then coverslipped.

### Assessment of staining reactions

The cytoplasmic immunostaining for c-kit, vimentin, CD34, SMA, S-100 and COX-2, and nuclear staining for Ki-67, PCNA and p53 were considered as positive reaction. The following scoring system was used for Ki-67 and PCNA: score 0, not positive; score 1, positively stained nuclei in < 10% of the tumor cells; score 2, 10-50% positive; and score 3, > 50% positive. The following scoring system was used for p53 evaluation: 0, not positive; 1+, 1-25% positive; 2+, 25-50% positive; 3+, 50-75% positive and 4+, > 75% positive.

### Statistical analysis

Chi-square test was used to analyse the relation between MI, tumor grade, tumor size and COX-2, Ki-67, PCNA and p53. A *P* value of < 0.05 was considered significant in difference. Statistical analyses were performed with SPSS version 10.0 (Chicago, USA).

## RESULTS

Sixteen (64%) of 25 GIST cases were male and 9 (36%) were female. Their ages ranged from 38 to 81 with a mean age of  $62.30 \pm 11.18$  years (male:  $62.86 \pm 10.97$ , female:

**Figure 1** Diffuse cytoplasmic staining of COX-2 in the tumor cells of GIST.

**Figure 2** High PCNA immunoreactivity in GIST with more than 50% of nuclear positivity.

61.44 ± 12.12). Eleven (44%) of the tumors originated from stomach, 11 (44%) from small intestine and 3 (12%) from large intestine. The mean size of the tumor was 7.70 ± 3.62 cm, 10.0 ± 4.43 cm and 5.0 ± 1.73 cm and the mean mitotic index of the tumor was 5.60 ± 5.10, 11.0 ± 10.76 and 16.0 ± 7.21 in stomach, small intestine and large intestine, respectively. The tumors were classified as low risk ( $n = 3$ ), intermediate risk ( $n = 6$ ) and high risk ( $n = 16$ ). Two of the low risk tumors were gastric and one was small intestinal. Four of the intermediate risk tumors were gastric and two were small intestinal tumors. Five of the high risk tumors were gastric, eight were small intestinal and three were large intestinal tumors. The clinicopathological data of the 25 patients with GIST are summarized in Table 2. The immunostaining results are listed in Table 3.

All 25 cases of GIST were positive for vimentin. Twenty-three (92%) tumors were positive for c-kit. Only one small intestinal and one large intestinal tumors were negative for c-kit but these tumors showed positive reactivity with CD34. There was diffuse cytoplasmic staining for both c-kit and CD34. CD34 reactivity was found in 21 (84%) tumors. Two gastric and two small intestinal tumors were negative for CD34. Ten (40%) tumors were positive for SMA. There was focal cytoplasmic staining for SMA. The frequency of SMA reactivity was higher in the nonstomach tumors (6 in small

**Table 3** Immunostaining results of 25 cases of GISTs

Site of origin	c-kit +	COX-2 +	CD34 +	SMA + S-100 +	SMA + S-100 -	SMA - S-100 +	SMA - S-100 -
Stomach ( <i>n</i> = 11)							
Low risk	2	1	2	-	-	1	1
Intermediate risk	4	4	3	-	-	2	2
High risk	5	3	4	2	-	1	2
Small intestine ( <i>n</i> = 11)							
Low risk	1	1	1	-	1	-	-
Intermediate risk	2	1	2	1	-	1	-
High risk	7	6	6	2	2	4	-
Large intestine ( <i>n</i> = 3)							
High risk	2	3	3	2	-	-	1
Total <i>n</i> (%)	23 (92)	19 (76)	21 (84)	7 (28)	3 (12)	9 (36)	6 (24)

intestine and 2 in large intestine). S-100 reactivity was found in 16 tumors (6 in stomach, 8 in small intestine and 2 in large intestine). There was focal staining for S-100. Both SMA and S-100 reactivity were found in 5 intestinal tumors while they were found only in 2 gastric tumors. In contrast, 5 gastric tumors were negative for SMA and S-100 while only one intestinal tumor was negative.

COX-2 immunostaining was found in 19 of 25 (76%) of the tumors (Figure 1). Three gastric and three small intestinal tumors were negative for COX-2. In the stomach, two high risk and only one low risk tumor were negative. In the small intestine, two high risk and one intermediate risk tumors showed negative staining with COX-2 (Table 3).

PCNA index was high in most cases; score 3 was found in 18 (72%) tumors; and score 2 in 5 (20%) (Figure 2). Only one case was negative for PCNA. Based on Ki-67 index, score 0 was assigned to 9 (36%) tumors; score 1, to

**Figure 3** Low Ki-67 immunoreactivity in GIST with less than 50% of nuclear positivity.

**Figure 4** High p53 immunoreactivity in GIST with more than 75% of nuclear positivity.

10 (40%); score 2, to 5 (20%); and score 3, to only one (4%) (Figure 3).

p53 was positive in 18 (72%) tumors whereas it was negative in 7 (28%) (Figure 4). Immunostaining results for p53 are shown in Table 4.

Follow-up information was available in 13 cases. Four patients died in early postoperative period (4-21 d). Two patients died 18-24 mo after diagnosis. Seven patients are alive 36-12 mo after diagnosis.

Statistically, p53 was related to MI and tumor risk groups ( $P < 0.05$ ). Although p53 score was markedly high in cases with tumor size  $> 5$  cm in diameter, it was statistically insignificant ( $P = 0.05$ ). There was no relationship between COX-2, proliferation markers (PCNA, Ki-67) and MI, tumor risk groups and tumor size ( $P > 0.05$ ).

## DISCUSSION

GISTs differ from true leiomyomas, leiomyosarcomas and schwannomas, and their histological origin has recently been suggested to be the ICC. These cells are located between the muscular layers of gastric and intestinal wall associated with the myenteric plexus which are thought to play a role in coordinating intestinal motility. Ultrastructurally, they show both incomplete myogenic and neural differentiation and characterized by dual immunopositivity for CD34 and CD117<sup>[4,13]</sup>. It is also accepted that the term "GIST" should apply only to neoplasms expressing CD117 with only very rare exceptions. The majority of studies have demonstrated that immunoreactivity for CD34 is seen in 60%-80% of cases<sup>[6,13,14]</sup>.

Beside consistent positivity for CD117 and CD34, 30%-40% of GISTs show immunopositivity for SMA and usually 5%-10% and rarely up to 40% show immunopositivity for S-100 protein<sup>[3,13,15]</sup>.

In our study, SMA positivity was seen most often in bowel tumors with a ratio of 40%. Some studies have showed a reciprocal relationship with CD34 expression and SMA positivity. Similarly, SMA negative tumors were often CD34 positive in our cases. Additionally, the percentage of S-100 protein reactivity was higher than most of the previous studies. Beside conflicting results in the literature this finding may represent autonomic nerve-

like differentiation in a proportion of GISTs so that the relationship between GAN and GISTs can not be ignored. Also, a significant number of gastric tumors were negative for SMA and S-100 protein while most of bowel tumors had showed S-100 protein and/or SMA positivity.

Overexpression of COX-2 has been reported in various types of gastrointestinal carcinomas<sup>[9-11]</sup>. COX-2 is located in tumor-derived epithelial cells of colonic adenocarcinomas, whereas it is found in stroma cells in tissues of colonic adenoma and colorectal carcinoma<sup>[9,16]</sup>. In addition, COX-2 is also located in interstitial cells of colonic adenomatous polyps<sup>[17-19]</sup>. These discrepant findings should be sorted out to determine the role of COX-2 in not only carcinogenesis but also tumor growth and progression of human carcinomas in terms of epithelial-stromal interactions<sup>[8]</sup>. Asano *et al*<sup>[8]</sup> showed that the expression of COX-2 in gallbladder carcinoma was increased in parallel to the depth of invasion. Sheehan *et al*<sup>[7]</sup> described for the first time the expression of COX-2 in GISTs, and demonstrated COX-2 protein expression in 12 of 15 (80%) of the tumors. Stewart *et al*<sup>[20]</sup> showed COX-2 protein expression in 35 of 38 (92%) GISTs and indicated that COX-2 may be useful as an additional molecular marker to aid in the identification of GIST, particularly in those cases with epithelioid histology or where KIT is only weakly or focally positive. Epidemiologic data suggest that the treatment with aspirin and NSAIDs prevents colorectal cancer and reduces the size and number of colorectal polyps<sup>[21,22]</sup>. There is no evidence of inhibitory effect of aspirin or NSAIDs in GISTs but treatment with COX inhibitors as adjuvant therapy may be beneficial.

There are many parameters for distinguishing benign from malignant GISTs such as MI, tumor size, cellularity, necrosis, mucosal invasion. MI and tumor size are the most reasonable and replicable parameters<sup>[13,23]</sup>.

Other parameters have been studied to evaluate GISTs behaviors, including immunohistochemical markers of cell proliferation (e.g., Ki-67, MIB-1, PCNA), flow cytometry, image analysis, telomerase activity and assessment of nucleolar organizer regions<sup>[13,24]</sup>.

There are controversies about prognostic impact of PCNA<sup>[25-28]</sup>. Ray and *et al*<sup>[25]</sup> demonstrated that PCNA index was correlated with necrosis, high grade atypia, cellularity and mitotic rate. In contrast, Sbasching *et al*<sup>[27]</sup> did not find a correlation of PCNA expression with survival in GIST. More recently, Ki-67 analogues have replaced PCNA because PCNA index is instable due to variations in antigen preservation and recovery<sup>[29]</sup>. Seidal *et al*<sup>[30]</sup> studied 31 cases of GIST and found a correlation with Ki-67 and outcome of patients. Wang *et al*<sup>[2]</sup> showed that expression of Ki-67 was more frequently seen in malignant GISTs than in benign GISTs. Regarding p53 expression in GIST, only a few studies have been carried out, with conflicting results. Al-Bozom<sup>[23]</sup> evaluated p53 expression in 15 cases and concluded that p53 is usefull in distinguishing between benign and malignant GIST. In contrast, Lopes *et al*<sup>[31]</sup> studied 33 cases and did not find any correlation between p53 and behavior.

In our study, p53 was found to be related to MI and tumor grade ( $P < 0.05$ ). Although p53 score was markedly high in the cases with tumor size  $> 5$  cm in diameter, it was statistically insignificant ( $P = 0.05$ ). We could not find any significant relationship between proliferation markers (PCNA, Ki-67), MI, tumor grade and tumor size ( $P > 0.05$ ).

In conclusion, COX-2 is expressed in most GISTs and may play an important role in the proliferation and progression of these tumors or a useful marker to help identify GIST. Immunohistochemical assessment of p53 can be used for distinguishing the risk groups of GISTs but the best way to distinguish the risk groups of these tumors is thought to be the tumor size and mitotic rate. We found out that PCNA and Ki-67 are independent factors from MI, tumor grade and tumor size. Further studies to find additional prognostic parameters will provide valuable insights into the behavior of GISTs.

causes of obstruction, as well as of bowel ischemia, necrosis, and perforation. Although an important proportion of these patients can be nonoperatively treated, a substantial portion requires immediate operation. Great caution should be taken for the treatment of these patients since the incidence of bowel ischemia, necrosis, and perforation is significantly high.

### Abstract

**AIM:** To identify and analyze the clinical presentation, management and outcome of patients with acute mechanical bowel obstruction along with the etiology of obstruction and the incidence and causes of bowel ischemia, necrosis, and perforation.

**METHODS:** This is a prospective observational study of all adult patients admitted with acute mechanical bowel obstruction between 2001 and 2002.

**RESULTS:** Of the 150 consecutive patients included in the study, 114 (76%) presented with small bowel and 36 (24%) with large bowel obstruction. Absence of passage of flatus (90%) and/or feces (80.6%) and abdominal distension (65.3%) were the most common symptoms and physical finding, respectively. Adhesions (64.8%), incarcerated hernias (14.8%), and large bowel cancer (13.4%) were the most frequent causes of obstruction. Eighty-eight patients (58.7%) were treated conservatively and 62 (41.3%) were operated (29 on the first day). Bowel ischemia was found in 21 cases (14%), necrosis in 14 (9.3%), and perforation in 8 (5.3%). Hernias, large bowel cancer, and adhesions were the most frequent causes of bowel ischemia (57.2%, 19.1%, 14.3%), necrosis (42.8%, 21.4%, 21.4%), and perforation (50%, 25%, 25%). A significantly higher risk of strangulation was noticed in incarcerated hernias than all the other obstruction causes.

**CONCLUSION:** Absence of passage of flatus and/or feces and abdominal distension are the most common symptoms and physical finding of patients with acute mechanical bowel obstruction, respectively. Adhesions, hernias, and large bowel cancer are the most common

### INTRODUCTION

Acute mechanical bowel obstruction is a common surgical emergency and a frequently encountered problem in abdominal surgery<sup>[1,2]</sup>. It constitutes a major cause of morbidity and financial expenditure in hospitals around the world<sup>[3]</sup> and a significant cause of admissions to emergency surgical departments<sup>[2,4]</sup>. Intestinal obstruction belongs to highly severe conditions, requiring a quick and correct diagnosis as well as immediate, rational and effective therapy<sup>[5,6]</sup>.

Surgeons are concerned about bowel obstruction cases because strangulation, causing bowel ischemia, necrosis and perforation might be involved, and it is often difficult to distinguish simple obstruction from strangulation. Accurate early recognition of intestinal strangulation in patients with mechanical bowel obstruction is important to decide on emergency surgery or to allow safe nonoperative management of carefully selected patients<sup>[1,2,7,8]</sup>. Although close and careful clinical evaluation, in conjunction with laboratory and radiologic studies, is essential for the decision of proper management of patients with acute mechanical bowel obstruction<sup>[1]</sup>, a preoperative diagnosis of bowel strangulation cannot be made or excluded reliably by any known parameter, combinations of parameters, or

by experienced clinical judgement<sup>[7-9]</sup>.

Mechanical bowel obstruction is an old and common surgical emergency<sup>[1,2]</sup>. Immediate and correct diagnosis of this condition and its etiology is essential<sup>[5,6,9-11]</sup>, and appropriate treatment is of utmost importance<sup>[5,6,9-11]</sup>. The clinical picture, however, of these patients<sup>[6,12,13]</sup> along with the etiology of obstruction<sup>[1,3,11,14-16]</sup> and strangulation prevalence are variable<sup>[8,17,18]</sup>, while appropriate management remains controversial<sup>[1-3,10,17,19]</sup>. We, therefore, conducted this prospective study to identify and analyze the clinical presentation of patients with acute mechanical bowel obstruction in our department, the etiology of obstruction as well as management and outcome of these patients. Moreover, we evaluated the incidence and causes of bowel ischemia, necrosis, and perforation.

## MATERIALS AND METHODS

This is a prospective observational study of all adult (over 14 years old) patients admitted to the 1<sup>st</sup> Department of Propaedeutic Surgery, Hippokration Hospital, Athens Medical School, University of Athens with a diagnosis of acute mechanical bowel obstruction between January 2001 and December 2002. The enrollment of the patients in the study was approved by the ethics committee of the University of Athens and written informed consent was obtained from all patients. Patients with paralytic ileus were excluded from our study while, since our hospital does not have a Pediatric Surgery Department, patients under 14 years of age are not referred to our hospital. Consequently, all adult patients with clinical and radiological evidence of acute mechanical bowel obstruction were included in the study.

Data collection (including pre-hospital, emergency department and in-hospital information) was started immediately after patients' arrival at the Surgical Emergency Department and continued on a daily basis. Recorded variables were: age, gender, time between the onset of symptoms and arrival at the emergency department, vital signs (systolic and diastolic arterial blood pressures, heart rate, breathing rate, and body temperature), symptoms and physical examination findings, white blood cell (WBC) counts, imaging features, types of management, time between arrival and operation, operative findings, etiology of obstruction, incidence and causes of bowel ischemia, necrosis, and perforation, complications, admission in the Intensive Care Unit (ICU), length of ICU and hospital stay, and the final outcome of the patients.

Vital signs were non-invasively measured every 3 h apart from the patients who were admitted to the ICU and had continuous invasive monitoring. Serial clinical examinations every 6 h by the same attending surgical team were performed in all patients to evaluate the patients' symptoms and signs. All patients underwent WBC count testing as well as plain abdominal X-ray every 24 h. Abdominal ultrasound (US) was performed in all patients on arrival at the Surgical Emergency Department while an abdominal computed tomography (CT) scan and colonoscopy were performed in a portion of the patients based on the clinical judgement of the attending surgical team.

**Table 1** Demographic, clinical, and laboratory data of the total study group on arrival at the Emergency Department (*n* = 150)

Value	Variable
Age (yr) <sup>1</sup>	63.8 ± 1.3 (65.0) (range: 16-98)
Sex (Male/Female) <sup>2</sup>	M: 60 (40%)/F: 90 (60%)
Time between onset of symptoms and arrival (h) <sup>1</sup>	33.5 ± 2.3 (24.0) (range: 2-120)
Systolic arterial blood pressure (mmHg) <sup>1</sup>	121.2 ± 1.7 (120.0) (range: 80-170)
Diastolic arterial blood pressure (mmHg) <sup>1</sup>	62.1 ± 0.9 (65.0) (range: 40-90)
Heart rate (/min) <sup>1</sup>	80.4 ± 0.8 (79.5) (range: 60-130)
Breathing rate (/min) <sup>1</sup>	15.4 ± 0.1 (15.0) (range: 11-22)
Body temperature (°C) <sup>1</sup>	36.4 ± 0.03 (36.4) (range: 35.5-37.4)
Fever (temperature > 38.0°C) <sup>2</sup>	0 (0%)
Absence of passage of flatus <sup>2</sup>	135 (90%)
Absence of passage of feces <sup>2</sup>	121 (80.6%)
Vomiting <sup>2</sup>	118 (78.6%)
Nausea <sup>2</sup>	89 (59.3%)
Abdominal discomfort <sup>2</sup>	99 (66%)
Abdominal distension <sup>2</sup>	98 (65.3%)
Colicky abdominal pain <sup>2</sup>	111 (74%)
Continuous abdominal pain <sup>2</sup>	22 (14.6%)
Abdominal muscle guarding <sup>2</sup>	56 (37.3%)
Rebound tenderness <sup>2</sup>	7 (4.6%)
Small bowel obstruction <sup>2</sup>	114 (76%)
Large bowel obstruction <sup>2</sup>	36 (24%)
White blood cell (WBC) count (10 <sup>9</sup> /L) <sup>1</sup>	9.93 ± 0.29 (8.90) [range: 3.58-24.4]
Leukocytosis <sup>2</sup>	55 (36.6%)
(WBC count > 10.8 × 10 <sup>9</sup> /L) <sup>2</sup>	

<sup>1</sup>Values are expressed as mean ± SE and median (parenthesis); <sup>2</sup>Values are expressed as number of patients and percentage (parenthesis).

Criteria for operative management of the patients were hemodynamic instability despite fluid resuscitation with crystalloid solution or recurrence of instability after initial stabilization, peritoneal signs on physical examination, identification by imaging studies (X-ray, US, or CT scan) of bowel ischemia, necrosis, and/or perforation, and failure of nonoperative management on the 4<sup>th</sup> post-admission day.

Intraoperative findings were also recorded with great emphasis on the etiology of obstruction as well as the incidence and causes of bowel ischemia, necrosis, and perforation.

## RESULTS

During the two years study period, 150 consecutive adult patients with acute mechanical bowel obstruction were admitted and composed our study group. Mean age of the patients was 63.8 ± 1.3 years while women comprised 60% of the group. The majority of the patients (76%) presented with small bowel obstruction. Demographic, clinical, and laboratory data of the study group on arrival at the Emergency Department are presented in Table 1. Regarding clinical presentation of the patients, absence of passage of flatus (90%) and/or feces (80.6%) were the most common presenting symptoms and abdominal distension (65.3%) was the most frequent physical finding on clinical examination.

Table 2 Etiology of acute mechanical bowel obstruction *n* (%)

Cause	Small bowel obstruction group ( <i>n</i> = 114)	Large bowel obstruction group ( <i>n</i> = 36)	Total study group ( <i>n</i> = 150)
Adhesions	84 (73.8%)	13 (36.3%)	97 (64.8%)
Hernia	21 (18.5%)	1 (2.7%)	22 (14.8%)
Large bowel cancer	3 (2.6%)	17 (47.4%)	20 (13.4%)

Table 4 Incidence of bowel ischemia, necrosis, and perforation *n* (%)

Value	Small bowel obstruction group ( <i>n</i> = 114)	Large bowel obstruction group ( <i>n</i> = 36)	Total study group ( <i>n</i> = 150)
Ischemia	15 (13.2%)	6 (16.6%)	21 (14%)
Necrosis	8 (7%)	6 (16.6%)	14 (9.3%)
Perforation	4 (3.5%)	4 (11.1%)	8 (5.3%)

The etiology of obstruction is shown in Table 2. Regarding patients with small bowel obstruction, adhesions, incarcerated hernias, large bowel cancer, and small bowel tumors were the most frequent causes of obstruction (73.8%, 18.5%, 2.6%, and 2.6%, respectively). Large bowel cancer, adhesions, retroperitoneal tumors, and hernias were the most common causes in large intestinal obstruction group (47.4%, 36.3%, 5.5%, and 2.7%, respectively). Finally, in the total study group of patients with small or large bowel obstruction, adhesions, incarcerated hernias, and large bowel cancer constituted the most frequent causes (64.8%, 14.8%, and 13.4%, respectively). Moreover, all patients with adhesive obstruction had previously undergone abdominal operations; the vast majority of these cases had undergone one operation (*n* = 70, 72.1%), 18 (18.6%) had two, and 9 (9.3%) had three operations. In terms of the types of previous operations, 34 patients (25.6%) had undergone an appendectomy, 31 (23.3%) gynecological procedures, 21 (15.8%) had a cholecystectomy, 15 (11.2%) had large bowel cancer resection, 13 (9.8%) had adhesiolysis in previous mechanical bowel obstruction episodes, 8 (6.0%) had abdominal wall hernia repair surgical procedures, and 11 (8.3%) had other surgical procedures. It is of note that, except for 3 patients with a laparoscopic cholecystectomy in the group of two previous abdominal operations, all patients had undergone open surgical procedures. Furthermore, regarding the types of incarcerated hernias, 9 patients (40.9%) presented with an inguinal hernia, 4 (18.2%) with an umbilical hernia, 3 (13.6%) with an incisional hernia, and 2 (9.1%) with a femoral hernia, while in 4 patients (18.2%) an internal hernia was intraoperatively identified. Sigmoid cancer was overrepresented accounting for 15 (75%) of the 20 patients with obstruction due to

Table 3 Management and outcome of the patients

a large bowel cancer, whereas two (10%) patients had an ascending colon cancer, one (5%) had a transverse colon cancer, one (5%) had a descending colon cancer, and one (5%) had a rectum cancer.

Data regarding management and outcome of the patients are described in Table 3. Eighty-eight patients (58.7%) of the total study group were safely and effectively treated conservatively. Nonoperatively treated patients composed the highest proportion (69.3%) of the patients with acute mechanical small bowel obstruction, while they only accounted for the minority (25%) in the large intestinal obstruction group. Of the 62 patients (41.3% of the total study group) who were operatively treated, a substantial portion (19.3%) required surgical intervention on the first day. Six cases (4%) sustained complications; two suffered from septic shock along with acute respiratory and renal failure, one suffered from pneumonia, one suffered from myocardial infarction, one had urinary tract infection, and one was reoperated because of an anastomotic leakage. Two patients died, resulting in a mortality rate of 1.3%; one died due to multiple organ failure attributable to sepsis and one died owing to myocardial infarction.

As it is shown in Table 4, the rate of bowel ischemia, necrosis, and perforation in the total study group were significantly high (14%, 9.3%, and 5.3%, respectively). In the small bowel obstruction group, ischemia was intraoperatively reversible in 7 out of 15 patients, whereas the remaining 8 patients had bowel necrosis. In contrast, no reversible ischemia was observed in the large bowel obstruction group. Therefore, although patients with small bowel obstruction and those with large bowel obstruction presented similar ischemia rate, the incidence of necrosis

**Table 5** Etiology of small bowel ischemia, necrosis, and perforation (small bowel obstruction group, *n* = 114) *n* (%)

Cause	Ischemia ( <i>n</i> = 15)	Necrosis ( <i>n</i> = 8)	Perforation ( <i>n</i> = 4)
Hernia	11 (73.3%)	5 (62.5%)	3 (75%)
Adhesions	2 (13.3%)	2 (25%)	1 (25%)
Small bowel volvulus	1 (6.7%)	1 (12.5%)	0 (0%)
Large bowel cancer	1 (6.7%)	0 (0%)	0 (0%)
Small bowel tumor	0 (0%)	0 (0%)	0 (0%)

**Table 6** Etiology of large bowel ischemia, necrosis, and perforation (large bowel obstruction group, *n* = 36) *n* (%)

Cause	Ischemia ( <i>n</i> = 6)	Necrosis ( <i>n</i> = 6)	Perforation ( <i>n</i> = 4)
Large bowel cancer	3 (50%)	3 (50%)	2 (50%)
Adhesions	1 (16.6%)	1 (16.6%)	1 (25%)
Hernia	1 (16.6%)	1 (16.6%)	1 (25%)
Sigmoid volvulus	1 (16.6%)	1 (16.6%)	0 (0%)
Retroperitoneal tumor	0 (0%)	0 (0%)	0 (0%)
Ovarian cystadenocarcinoma	0 (0%)	0 (0%)	0 (0%)

and perforation was much higher in the large intestine group.

Etiology of bowel ischemia, necrosis, and perforation in the small bowel obstruction group, the large bowel obstruction group, and the total study group is presented in Table 5, Table 6 and Table 7, respectively. Incarcerated hernias were the cause in the vast majority of the small bowel obstruction group, that presented ischemia, necrosis, and perforation, while adhesions were the second most frequent cause. Regarding the large bowel obstruction group, large bowel cancer, adhesions, and hernias constituted the most common causes. Finally, in the total group, hernias, large bowel cancer, and adhesions were the most frequent causes of bowel ischemia, necrosis, and perforation. It was notable that bowel ischemia was reversible in half of the cases with obstruction due to incarcerated hernias justifying, thus, immediate operative intervention in these patients.

With regard to the risk of strangulation, a significantly much higher risk was noticed in incarcerated hernias than all the other obstruction causes. Of the 22 patients with acute mechanical bowel obstruction caused by incarcerated hernias, 12 (54.6%) had bowel ischemia, 6 (27.3%) had necrosis, and 4 (18.2%) had sustained perforation. On the contrary, only 3 (3.1%) of the 97 cases with adhesive obstruction presented ischemia and necrosis, and 2 (2.1%) had perforation. Additionally, out of 20 patients with obstruction due to large bowel cancer, 4 (20%) had ischemia, 3 (15%) had necrosis, and 2 (10%) had perforation.

## DISCUSSION

Acute mechanical bowel obstruction remains a frequently encountered problem in abdominal surgery and a common surgical emergency<sup>[1,2]</sup>, which is a frequent cause of admissions to hospital emergency surgical departments<sup>[2,4]</sup>.

The majority of our study group presented with acute mechanical small bowel obstruction. This has also been found in other studies with small bowel obstruction accounting for about 80% of total obstruction cases<sup>[9,20,21]</sup>. Regarding clinical presentation of our patients, absence of passage of flatus and/or feces were the most frequent presenting symptoms and abdominal distension was the most common physical finding on clinical examination. Additionally, vomiting, nausea, colicky abdominal pain, and abdominal discomfort were frequent symptoms on arrival. Our results, even though some differences are noticed, are in accordance with the literature<sup>[6,12,13,22,23]</sup>.

**Table 7** Etiology of bowel ischemia, necrosis, and perforation (total study group, *n* = 150) *n* (%)

Cause	Ischemia ( <i>n</i> = 21)	Necrosis ( <i>n</i> = 14)	Perforation ( <i>n</i> = 8)
Hernia	12 (57.2%)	6 (42.8%)	4 (50%)
Large bowel cancer	4 (19.1%)	3 (21.4%)	2 (25%)
Adhesions	3 (14.3%)	3 (21.4%)	2 (25%)
Small bowel volvulus	1 (4.7%)	1 (7.2%)	0 (0%)
Sigmoid volvulus	1 (4.7%)	1 (7.2%)	0 (0%)
Small bowel tumor	0 (0%)	0 (0%)	0 (0%)
Retroperitoneal tumor	0 (0%)	0 (0%)	0 (0%)
Ovarian cystadenocarcinoma	0 (0%)	0 (0%)	0 (0%)

Particularly, Cheadle *et al*<sup>[6]</sup> reported abdominal pain (92%), vomiting (82%), abdominal tenderness (64%), and distention (59%) as the most frequent symptoms and signs, whereas abdominal distension, bilious vomiting, absolute constipation and abdominal pain were the main signs and symptoms in another series<sup>[12]</sup>. Perea *et al*<sup>[13]</sup> prospectively studied 100 patients with adhesive small bowel obstruction and found that the presenting symptoms were vomiting (77%), colicky abdominal pain (68%), absence of passage of flatus and/or feces (52%), and constant pain (12%), whereas abdominal distension constituted the most frequent clinical sign with a prevalence of 56%. In a study of patients with bowel obstruction due to large bowel volvulus, the most common sign of sigmoid volvulus was distension (79%) and the most frequent symptoms were pain (58%) and obstipation (55%), whereas most patients with cecal volvulus presented with pain (89%)<sup>[22]</sup>. Furthermore, in a review of cases with obstruction because of small and large bowel intussusception, abdominal pain, nausea, vomiting, and abdominal distension were the commonest symptoms and signs, respectively<sup>[23]</sup>.

Adhesions, incarcerated hernias, and large bowel cancer constitute the most frequent causes of obstruction<sup>[3,4,9,11,14,16,17,20,21,24-30]</sup>. This finding was also noticed in our study. Moreover, adhesions were the most prevalent etiology of obstruction in the small bowel obstruction group and the total study group and the second most common etiology in the large bowel group. Several studies postulate that adhesions are responsible for 32%-74% of bowel obstruction and are the leading cause of small intestinal obstruction representing 45%-80% of it<sup>[1-4,7,9,14,17,20,24-26,28-30]</sup>. The vast majority (65%-90%) of the patients with adhesive obstruction have undergone previous abdominal operations<sup>[6,13,14,18,19,26,28,29]</sup>. In the present study,

this was observed in all such patients. As for the types of previous operations in our study patients, appendectomies, gynecological operations, cholecystectomies, and large bowel cancer resections were more prevalent. This is also in accordance with the literature<sup>[2,18,19,28,29]</sup>. Even though the appropriate management of adhesive obstruction is still controversial, a substantial share of these patients, ranging from 35% to 75% in several studies, can safely and effectively be treated with nonoperative management as it was also shown in our patients<sup>[2,3,9,12,16-19,24,28-30]</sup>. The increasing role of adhesions as a cause of acute intestinal obstruction demands greater need for routine preventive measures against adhesion formation<sup>[14]</sup>. A number of intraoperative measures are now encouraged during elective abdominal surgery to reduce the incidence of adhesions that might subsequently produce intestinal obstruction<sup>[1]</sup>.

As it was also observed in our study, large bowel cancer, particularly sigmoid cancer, is the most common etiology of obstruction in patients with large intestinal obstruction with a prevalence of 40%-90%<sup>[9,10,14,21]</sup>. The majority of such patients in our study were operatively treated. Moreover, incarcerated hernias were the second most common etiology of obstruction as well as the predominant cause of bowel ischemia, necrosis, and perforation. It should also be emphasized that bowel ischemia was reversible in half of our cases with obstruction due to incarcerated hernias justifying, thus, immediate surgery in these patients. Since abdominal hernias continue to account for 8%-25% of all cases of intestinal obstruction<sup>[1,4,14,17,20,24,26,30]</sup>, while in a few series represent the most common cause of intestinal obstruction accounting for 30%-55%<sup>[11,16,21,27]</sup>, and, moreover, they still remain the most common cause of strangulation<sup>[1,4,11,17,21,24,27]</sup>, surgeons should continue their aggressive attitude towards elective repair of all abdominal hernias as well as towards immediate operative intervention in patients with acute mechanical bowel obstruction secondary to incarcerated hernias.

Other less common causes of obstruction reported in the literature are Crohn's disease<sup>[3,17,20]</sup> and gallstones<sup>[21]</sup>, accounting for 3%-7% and 2% of small bowel obstruction cases, respectively, and bowel volvulus<sup>[14,15,20,24]</sup> and intussusception<sup>[14,20,25]</sup>, accounting for 4%-15% and 4%-8% of total obstruction cases, respectively. In our series, the prevalence of Crohn's disease and bowel volvulus was much lower, whereas no case of obstruction due to gallstone or intussusception was observed.

An important share of our patients was successfully nonoperatively treated. This was more prevalent regarding adhesive small bowel obstruction. This has also been noticed in other studies<sup>[2,3,9,12,16-19,24,28-30]</sup>. Similar to other studies<sup>[12,24]</sup>, of those patients that were operated, a substantial proportion required immediate operation.

Much attention should be paid to the treatment of these patients since the incidence of bowel ischemia, necrosis, and perforation is significantly high. Strangulation rate in the literature ranges from 7% to 42%<sup>[4,8,12,17,24,26,28]</sup>. In addition, Kossi *et al*<sup>[18]</sup> reported an incidence of ischemia of 20%, of necrosis of 8%, and of perforation of 2%. In regard to the risk of strangulation in the present study, a

significantly much higher risk was noticed in incarcerated hernias in comparison to all the other obstruction causes. Moreover, the incidence of bowel ischemia, necrosis, and perforation in adhesive obstruction was very low. These results have been also described in other studies<sup>[1,4,11,17,21,24,27]</sup>.

In our study, complication and mortality rate were relatively low. In the literature, complication rate ranges from 6% to 47%<sup>[6,20,25,27,31,32]</sup> whereas mortality ranges from 2% to 19%<sup>[4,6,11,14,17-20,24-27,31,32]</sup>.

In general, appropriate treatment of acute mechanical bowel obstruction as well as timing of surgery for patients selected to undergo operative intervention still remain controversial<sup>[1-3,10,17,19]</sup>. Management of this condition requires careful assessment and awareness while the appropriate treatment needs to be tailored to the individual situation<sup>[10,19]</sup>. Furthermore, no specific factors that may predict success of conservative or surgical management have been identified<sup>[19]</sup>. Although modern surgical management continues to focus appropriately on avoiding operative delay whenever surgery is indicated, not every patient is always best served by immediate operation. As it was also proved in the present study, certain entities, such as bowel obstruction secondary to incarcerated abdominal wall hernia, and patients with clinical signs and symptoms suggestive of strangulation do require prompt operative intervention<sup>[1,3,16,17]</sup>. Other conditions, however, such as postoperative adhesions, particularly in patients with numerous previous abdominal procedures or concomitant medical problems, often justifiably benefit from a trial of nonoperative management<sup>[1-3,9,16-18,28-30]</sup>. A substantial portion of these patients was successfully conservatively treated in our study. As it was also shown in this study, the risk of strangulation with adhesive bowel obstruction is significantly lower as compared to incarcerated hernia<sup>[1,4,17,24]</sup>.

Strangulated obstruction requires emergency surgery, and early recognition is often life-saving since delay in treatment is an independent predictive factor of mortality and, in addition, bowel strangulation is an independent predictor of complication and, even more, of mortality while the mortality rates of patients with strangulated obstruction are two to 10 times higher than those of patients with non-strangulated obstruction<sup>[4,6,10,11,12,14,16,17,31]</sup>. Moreover, accurate early recognition of intestinal strangulation in patients with mechanical bowel obstruction is important to allow safe nonoperative management of carefully selected patients<sup>[1,2,7,8]</sup>. Traditionally, such recognition is based on the presence of one or more of the classical signs: vascular compromise, continuous abdominal pain, fever, tachycardia, peritoneal signs on physical examination, leukocytosis, and metabolic acidosis<sup>[7,8]</sup>. Close and careful clinical evaluation, in conjunction with laboratory and radiologic studies, is essential for the decision of proper management of patients with acute mechanical bowel obstruction; if any uncertainty exists, prompt operative intervention is indicated<sup>[1]</sup>. It should be emphasized, though, that great caution should be taken for the management of these patients since studies have shown that preoperative diagnosis of bowel strangulation cannot be made or excluded reliably by any known clinical, laboratory, or

radiologic parameter, combinations of parameters, or by experienced clinical judgement<sup>[7-9]</sup>.

In conclusion, absence of passage of flatus and/or feces and abdominal distension are the most common symptoms and physical finding of patients with acute mechanical bowel obstruction, respectively. Adhesions, hernias, and large bowel cancer are the most common causes of obstruction as well as of bowel ischemia, necrosis, and perforation. Although an important share of these patients can be safely and effectively nonoperatively treated, particularly those with adhesive obstruction, a substantial portion requires immediate operation. Moreover, the risk of strangulation is significantly higher in incarcerated hernias than other obstruction causes. Great caution should be taken for the treatment of patients with acute mechanical bowel obstruction since the incidence of bowel ischemia, necrosis, and perforation is significantly high. Further studies are necessary in order to determine appropriate management for treatment of these patients as well as to identify accurate early predictors of success of conservative or operative treatment and, particularly, of intestinal strangulation giving the greatest attention to reversible ischemia.

### Abstract

**AIM:** To assess whether depression and anxiety are more expressed in patients with the first episode of inflammatory bowel disease (IBD) than in individuals with newly discovered cancer of the colon (CCa).

**METHODS:** A total of 32 patients with IBD including 13 males and 19 females, aged 27 to 74, and 30 patients with CCa including 20 males and 10 females, aged 39-78, underwent a structured interview, which comprised Hamilton's Depression Rating Inventory, Hamilton's Anxiety Rating Inventory and Paykel's Stressful Events Rating Scale.

**RESULTS:** Patients of the IBD group expressed both depression and anxiety. Depressive mood, sense of guilt, psychomotor retardation and somatic anxiety were also more pronounced in IBD patients. The discriminant function analysis revealed the total depressive score was of high importance for the classification of a newly diagnosed patient into one of the groups.

**CONCLUSION:** Newly diagnosed patients with IBD have higher levels of depression and anxiety. Moreover, a psychiatrist in the treatment team is advisable from the beginning.

### INTRODUCTION

Patients with inflammatory bowel disease (IBD-the common term which comprises Crohn's disease and ulcerative colitis) and cancer of the colon often report serious psychological and emotional morbidities<sup>[1,2]</sup>. Though specific pathophysiological links between psychiatric disorders such as depression or anxiety and inflammatory bowel disease have largely been discredited<sup>[3,4]</sup>, little is known about the influences of depression and anxiety on the ongoing adaptation that these patients make to the aversive symptoms of their chronic disease<sup>[5]</sup>. It is almost impossible to tell whether the psychiatric discomfort influences the severity of the gastrointestinal symptoms or, conversely, could gastrointestinal symptoms aggravate the psychiatric status. Stressful life events and psychological distress have been shown in patients without IBD to be associated with common bowel symptoms such as irregularity, gas and bloating, and abdominal pain, often labeled as irritable bowel syndrome or functional bowel diseases<sup>[6,7]</sup>.

This study presents pilot data in which we sought to investigate the effects of common psychiatric illnesses (i.e., anxiety and depression episodes) on the appearance and functional disability in 32 first episode, therapy-naïve patients with IBD, and 30 patients with newly diagnosed cancer of the colon. We hypothesized that the presence and intensiveness of one or both current psychiatric disorders (depression and anxiety) have a higher impact on the appearance of one of the diseases of interest. Also, we attempted to estimate the eventual difference of the initial levels of the psychological suffers, and which one, if not both, of the two groups of patients requires the routine preliminary psychiatric evaluation prior to the beginning of gastroenterological treatment.

### MATERIALS AND METHODS

#### Setting

This study is a subset of a larger investigation of 71 patients with the first episode of IBD and 40 patients with newly diagnosed cancer of the colon (CCa), out of which

32 patients with IBD (21 with ulcerative colitis [UC] and 11 with Crohn's disease [CD]), 13 (8 with UC and 5 with CD) males and 19 females (13 with UC and 6 with CD), aged 27 to 74 years ( $49.16 \pm 16.58$ ) and 30 patients with CCa, 20 males and 10 females, aged 39-78 years ( $63.47 \pm 9.14$ ) met with the recruiting criteria and were included in the study. The study was conducted at the Department of Gastrointestinal Surgery, Clinical Center of Serbia, and Department of Gastroenterohepatology, Clinical and Hospital Center "Bezanijska Kosa". All patients of 18 years old or over attending the Gastroenterology Clinics and Gastrointestinal Surgery Department from March to October 2003 who presented symptoms common for IBD and CCa: blunt abdominal pain, rectorrhagia and diarrhea syndrome on the first visit, were eligible for the study. The participating gastroenterologist or gastrointestinal surgeon (M.K. T.R., and B.F.F.) screened the clinic appointment schedule each morning and directly communicated with the other staff gastroenterologists or surgeons on a daily basis to recruit their patients into the study. Patients were interviewed at the end of their medical appointments or at a more convenient time, no later than 2 d from their medical visits or admission to hospitals. Only patients who satisfied all the recruiting criteria were selected for the study. The results of the interviews were matched with the final diagnosis, but no matched pair procedure between groups was used. The entire testing was designed and supervised by the psychiatrist (BRF). The study was approved by the Ethical Committee of the School of Medicine, Belgrade.

### Recruiting criteria

The patients included in the study met the following criteria: No previous treatment for one of the diseases of interest; a negative family history of IBD and CCa; no previous treatment for any psychiatric illness or disorder; no self-medications for any kind of gastrointestinal or psychiatric illnesses; weight loss not surpassing 5 kg in the last month and they were not under weight loss regimes; radiographs of the lungs and ultrasonographic examination (N.M. M.K. and B.F.F.) of the abdominal and pelvic cavities free of metastasis and anatomical abnormalities; no surgical intervention in past three years; no abdominal or any kind of mutilating surgical intervention; not treated for any kind of malignancy; not suffering from an immunodeficiency disease, especially human immunodeficiency virus infection or systemic lupus; a negative history of bowel inflammation caused by infectious agents in last one year; and hepatitis B (HBs) or hepatitis C negativity. The definitive diagnosis was confirmed after immediate endoscopy-guided biopsy and subsequent histopathological examination. During the interview, 39 IBD patients were found to be unsuitable while 10 patients with colorectal cancer were omitted from further investigation. The difference was caused by more pronounced sincerity in answers during the admittance and higher motivation to be part of the study among patients with CCa.

### Structured interview

All the patients, after being informed in detail about

the study and signing a written consent, underwent the structured psychiatric interview, which involved Hamilton's depression inventory consisting of 21 items<sup>[8]</sup> and Hamilton's anxiety inventory consisting of 14 items<sup>[9]</sup>. Results were interpreted using Hamilton's depression and anxiety rating scales. All the items were rated in 5 grades: 0, absent; 1, mild; 2, moderate; 3, severe; 4, incapacitating (some items, like insomnia, hypochondriasis, diurnal mood variations, insight into the illness and obsessive-compulsive symptomatology are only graded in three levels: 0, absent; 1, doubtful or trivial; 2, present). Usually, Hamilton depression and anxiety inventories contain items related to gastrointestinal symptoms and weight loss. This time they were omitted because the mentioned symptomatology is part of the illness. Interpretation of the total score of Hamilton's depression rating scale is: less than 8, without depression; 9-17, mild depression; 18-24, moderate depression; higher than 24, severe depression requiring hospitalization. According to the Hamilton's anxiety rating scale, persons with generalized anxiety disorder and panic disorder tended to have a total anxiety score of above 20. The 61 item-Paykel's scale for stressful events<sup>[10]</sup> was used to evaluate the possible influence of different life events in the past one-year period on the appearance of the diseases of interest. The interview was performed by three previously trained interns in psychiatry as part of their professional educations in liaison psychiatry. All the testing was conducted in Serbian language, and prior to the final diagnosis was reported to the patient. To the moment, the definitive diagnosis was available only to the relevant intern and surgery specialists (B.F.F., M.K., N.M. T.R.).

### Clinical evaluation

Index of the activity for patients of the IBD group was computed according to the standard procedures for patients with newly diagnosed CD and UC. For patients with CD, a routine Crohn's disease activity index (CDAI)<sup>[11]</sup> comprising eight items was categorized as follows: (1) Number of liquid or very soft stools in one week  $\times 2$ ; (2) Sum of seven daily abdominal pain ratings (0: none; 1: mild; 2: moderate; 3: severe)  $\times 5$ ; (3) Sum of seven daily ratings of general well-being (0: well; 1: slightly below par; 2: poor; 3: very poor; 4: terrible)  $\times 7$ ; (3) Symptoms or findings probably related to CA (arthritis or arthralgia, iritis or uveitis, erythema nodosum, pyoderma gangrenosum, aphthous stomatitis, anal fissure, fistula or perirectal abscess, other bowel-related fistula, febrile episodes over  $37.8^{\circ}\text{C}$  during the past week)  $\times 20$ ; (4) Taking Lomotil<sup>®</sup> or opiates for diarrhea (yes or no)  $\times 30$ ; (5) Abnormal mass (0: none; 0.4: questionable; 1: present)  $\times 10$ ; (6) Hematocrit (normal average: male, 47, female, 42), obtained values should be subtracted from the average. Score is multiplied with 6; (7) Body weight:  $100 \times [1 - \text{actual body weight} / \text{standard weight}]$ , where standard weight is computed from the tables using the body height and age of the patients; (8) Active phase of CD takes values between 220 and 450. Average index in our group was  $289.84 \pm 45.37$  (221-375). For UD activity index, a modified Ulcerative Disease Scoring System<sup>[12]</sup> was used: (1) Stool frequency (0: normal number; 1: 1-2 stools more than normal; 2: 3-4 stools

Table 1 Expression of the depression symptoms according to the results from Hamilton's Depression Inventory (IBD/CCa)

Symptom	0	1	2	3	4	Statistical analysis
Depressive mood	2/9	3/8	7/8	6/3	14/2	$\chi^2 = 16.75$ , DF = 4, $P = 0.002$

Anxiety-psychological	5/14	5/8	1/4	12/4	9/0	$\chi^2 = 19.71$ , DF = 4, $P = 0.01$
Anxiety-somatic	14/10	7/8	2/10	6/2	3/0	$\chi^2 = 11.04$ , DF = 4, $P < 0.05$
Hypochondriasis	28/28	4/1	0/1			$\chi^2 = 2.738$ , DF = 2, $P > 0.05$
Insight into the presence of the illness	13/8	17/6	2/16			$\chi^2 = 17.29$ , DF = 4, $P < 0.001$
Diurnal variations of the mood	13/15	9/13	10/2			$\chi^2 = 2.738$ , DF = 2, $P > 0.05$
Depersonalization and derealization, presence of the nihilistic ideas	24/29	5/1	1/0	2/0	-	$\chi^2 = 6.08$ , DF = 3, $P > 0.05$
Paranoid ideas	30/29	0/1	2/0	-	-	$\chi^2 = 2.96$ , DF = 2, $P > 0.05$
Obsessive-compulsive symptomatology	29/29	1/1	2/0			$\chi^2 = 1.94$ , DF = 2, $P > 0.05$
Mean score $\pm$ SD						$18.56 \pm 8.77/10.83 \pm 5.26$ ; $t = 4.17$ , DF = 60, $P < 0.001$
Centroids: IBD = 0.513, CCa = - 0.547						Equation for the selection: $-2.033 + 0.137 \times \text{total depressive score}$
Section point (average of the centroids) = -0017						

more than normal; 3: 5 or more stools than normal). Each subject reported his/her degree of abnormality of the stool frequency. (2) Rectal bleeding (0: no blood; 1: streaks of blood with stools less than half the time; 2: obvious blood with stools most of the time; 3: blood alone passed). The daily bleeding score represents the most severe bleeding of the day. (3) Modified Baron Score for findings of endoscopy (0: normal or non-inflamed mucosa; 1: mild disease-erythema, decrease vascular pattern, mild friability; 2: moderate-marked erythema, absent vascular pattern, friability, erosions; 3: Severe-spontaneous bleeding, ulcerations). (4) Physician's global assessment: 0: normal; 1: mild disease; 2: moderate; 3: severe. The physicians' global assessment acknowledges three other criteria, the subject's daily record of abdominal discomfort and general sense of well-being, and other observations, such as physical findings and subject's performance status. Rating of the severity: 1-5, mild; 6-10, moderate; 11, severe. Average UC activity index in our study group was  $8 \pm 2$  (range, 5-12). Clinical evaluation of cancers was performed by TNM classification as follows: Stage I (T2 N0 M0), 18 cases; Stage II (T3 N0 M0), 10 cases; Stage III (T3 N1 M0), 1 case and T3 N2 M0, 1 case. Indices were compared to the total scores of depression and anxiety rating scales in order to investigate the eventual correlation between them.

### Statistical analysis

After coding, all the answers were systematized in the common database, and the following statistical analyses were performed: The Kolmogorov-Smirnoff Z test was used to evaluate distribution of the data. The results were satisfactory: all the values belonged to normal distribution, which made them adequate for the subsequent statistical testing. Besides usual parameters of central tendency (descriptive statistics: mean, standard deviation [SD], extreme values); Pearson's Chi-square test and Fisher's exact probability test were used to reveal the differences in

attributive values. Student's *t* test for independent samples was applied to evaluate possible differences in parametric data. The Pearson's bivariate correlation was used to investigate the interconnection between the depression and anxiety scores and in-group's life span. This test was enforced by the difference in average life span between groups, mostly dependent on the nature of the very illness:  $49.16 \pm 16.58$  for persons in IBD groups and  $63.47 \pm 9.14$  for persons with CCa (*t*-test = -5.094, degrees of freedom [DF] = 30,  $P < 0.01$ ). No correlation was obtained whatsoever  $r = -0.225$ ,  $N = 62$ ,  $P > 0.05$ , for the depression score, and  $r = -0.149$ ,  $N = 62$ ,  $P > 0.05$ , for the anxiety score. The same test was used to correlate the IBD activity indices with total scores of depression and anxiety questionnaires. Discriminant function analysis (DFA) was used to determine which variable(s) discriminate between two groups: IBD and CCa. Centroids are mathematically derived grouping values whereas the section point between groups used the average of the centroids. The entire testing was performed at 95% level of confidence.

## RESULTS

### Depression levels

Differences in the levels of the depression symptoms are shown in Table 1. The main difference was found in the intense of the depressive mood and in the sense of guilt, which were significantly higher in the group with IBD. Also, IBD patients expressed problems with early and transitory insomnia and had a poorer ability to focus their attention on various activities and manual or intellectual work, which resulted in slow down in everyday activities. Agitation, anxiousness, early and transitory insomnia and somatic symptoms were more pronounced in the IBD group, likewise. On the other hand, awareness that something is going wrong with them was expressed in CCa patients. Twenty-two out of 32 patients with IBD and

Table 2 Expression of the anxiousness symptoms according to the Hamilton's Anxiety Rating Inventory (IBD/CCa)

Symptom	0	1	2	3	4	Statistical analysis
Anxious mood-greed, hopelessness	4/9	1/8	6/5	10/5	11/3	$\chi^2 = 13.55$ , DF = 4, $P = 0.009$
Tension	4/7	1/8	6/5	10/9	11/1	$\chi^2 = 14.69$ , DF = 4, $P = 0.005$
Fears: dark, loneliness, animals	19/26	2/1	4/2	7/0	0/1	$\chi^2 = 10.03$ , DF = 4, $P = 0.04$
Intellectual impairments-memory problems, difficulties in communication	18/22	6/4	5/4	3/0	-	$\chi^2 = 3.85$ , DF = 3, $P > 0.05$
Depressive aspect	5/15	3/4	4/8	6/1	2/14	$\chi^2 = 19.003$ , DF = 4, $P = 0.002$
Somatic symptoms: muscular symptoms, sensory symptoms-tinnitus, blurred vision, attacks of heath, itching, etc., cardiovascular symptoms-tachycardia, palpitations, sense of pulsing, irregularities in heart actions, respiratory symptoms, urogenital symptoms	16/9	3/3	7/10	2/7	4/1	$\chi^2 = 7.01$ , DF = 4, $P > 0.05$
Neurovegetative symptoms-face blushing, mouth dryness, vertigo, sweating	20/18	1/6	7/6	4/0	-	$\chi^2 = 7.7$ , DF = 4, $P > 0.05$
Behavior during the interview-restlessness, agitation, walking around, frowned face, tense, sobbing, accelerated breathing, pallor, gulping and belching, vivid muscular reflexes, jerks, dilated pupillae, exophthalmus	4/10	0/5	8/13	10/0	10/0	$\chi^2 = 24.06$ , DF = 4, $P < 0.001$
Mean score $\pm$ SD	16.22 $\pm$ 7.42/9.73 $\pm$ 6.03; $t = 3.76$ , DF = 60, $P < 0.01$					

5 CCa patients could be considered seriously depressive because their total score surpassed the accepted limit of 16 points ( $F$ -test:  $P = 4.02 \times 10^{-5}$ ). A correlation between IBD activity indices and the depression total score was not revealed: For CD,  $r = 0.39$ ,  $df = 17$ ,  $P > 0.05$ ; for UC,  $r = 0.004$ ,  $df = 10$ ,  $P > 0.05$ . The TNM system for cancer staging was not adequate for any kind of correlation testing.

### Anxiousness levels

The trend disclosed in the depression evaluation remained when the anxiousness level was analyzed (Table 2): Patients with IBD expressed higher levels of anxiousness, nervous tension and susceptibilities to different kinds of fears. Despite the absence of significant differences in neurovegetative symptom intensity, the behavior of IBD patients exhibited more pronounced neurotic components: vivid facial mimics and gesticulation, gulping and belching during the conversation, with occasional staring into the examiner, associated with intermittent jerks of facial muscles and musculature of the extremities (not the ticks). The total anxiousness score did not correlate with IBD activity indices: for CD,  $F = 0.06$ ,  $df = 17$ ,  $P > 0.05$ ; for UC,  $F = 0.013$ ,  $df = 10$ ,  $P > 0.05$ .

### Paykel's scale for stressful events

Evaluation of the impacts of events, mostly stressful ones, on the appearance of either IBD or CCa showed no significant differences between the groups (Table 3). Financial difficulties, major or minor, dominated among stressors. The necessities for hospitalization of one of the family members seemed to bother more people who had cancer than those with IBD, while separation from a close person seemed to influence more IBD patients. On the other hand, only three patients of the IBD group and six from CCa group had no stress events at all in the past one year.

### Discriminant function analysis (DFA)

This analysis was used to investigate whether one of the obtained parametric values (total scores of depression

Table 3 Major stressful events (revealed in five or more persons in at least one of the groups) in IBD and CCa suffering patients according to the Paykel's scale

Event	IBD group (n)	CCa group (n)
Death of family members	8	7
Major financial difficulties	12	10
Business failure	5	2
Hospitalization of the family member due to serious illnesses	4	8
Frequent argues with parents	5	0
Separation from close person	7	2
Death of close friend	3	5
Minor financial difficulties	9	8
Mild organic illness	4	7
No stressful events at all	3	6

$\chi^2 = 12.83$ , DF = 9,  $P > 0.05$ .

and/or anxiety) possessed a predictive potential, i.e. could it be used for classification of a newly discovered case into one of the groups of interest. This analysis delineated total depressive score as such a parameter that an equation for an a priori selection was computed (Table 1). Application of this equation to our samples showed 79.04% of accuracy (13 out of 62 cases were inadequately classified). The main problem was represented by the patients with IBD and low depressive scores and, *vice versa*, CCa patients with high depressive scores. Nonetheless, almost 80% of correctly classified patients were quite satisfactory for the accuracy of the DFA equation.

Finally, no gender-based and in-group differences between patients with UC and CD were obtained.

## DISCUSSION

In this interview-based case-control study we intended to investigate how great the impact of anxiety and depression was on patients with IBD and cancer of the colon. The results suggested that psychological conditions influenced the pathogenesis of IBD. The uncontrolled trial, relatively

restrictive criteria and not very large sample limited the interpretation of the results. Nevertheless, proclaimed criteria were necessary to eliminate the influence of the genetic factors, major surgery consequences and other impacts on the appearance of IBD or CCA. The difference in life span and gender between our groups could be interpreted by the nature of the illnesses: IBD has already been reported as an illness with slight female predominance<sup>[13]</sup>, while, according to epidemiological studies, males have higher mortality rate of cancer of the colon (8.4: 6.0/100 000 inhabitants)<sup>[14]</sup>. Surprisingly, women smokers have milder forms of IBD and less need for hemicolectomy<sup>[15]</sup>. Moreover, ethnic-based differences in the prevalence of IBD exist as well, and it is higher in Caucasians than in the Hispanic population of North America<sup>[16]</sup>.

Still, there are some dilemmas about emotional status in IBD and CCA: one of the most frequent is: Could the depression be of the reactive type and could the symptoms of the gastrointestinal disease influence the presence of emotional instability? Moreover, patients are required to observe his/her own blood in the stool, in addition to suffering the abdominal pain and tenderness. Results of several studies have suggested that IBD patients more frequently suffer from psychiatric illnesses, particularly depression and anxiety at a triple higher rate than either the general population or patients with other kinds of chronic illnesses<sup>[17-19]</sup>. Individuals with IBD and similar bowel disorders experience a frequency of depression that is triple those of the general population. It is important for clinicians to assess depression and suicidal ideation among their patients with active IBD symptoms, particularly among those reporting moderate to severe pain<sup>[20]</sup>. The results of some studies suggested that psychoimmunological components might be involved in the etiology of IBD<sup>[21,22]</sup>, but such a possibility is relatively uncertain due to the small relative risk for persons with depression affected by IBD<sup>[21]</sup>. Some authors tried to link the IBD occurrence with some personality traits<sup>[19,23]</sup>, such as neuroticism or introversion, but we did not examine personality traits or disorders, thus we remained limited to depression and anxiety as ICD-10 recognized diagnoses. Nonetheless, emotional abuse, depression, self-accusing and the sense of guilt, have already been reported to be more common in women with irritable bowel syndrome<sup>[24]</sup>, and, according to our results, sense of guilt, which involves self-blame as well, were emphasized in persons with IBD<sup>[21]</sup>. On the other hand, judging from the data obtained in this study, CCA patients had better insight into the illness and this could be the reason why patients with IBD, to our highly empiric observation, more frequently abandon the therapy as soon as they get better, without the permit of their gastroenterologists.

Recent studies showed that depression occurring with the recurrence of IBD in chronic patients and with anxiety and poor quality of health condition may exert a negative influence on the course of IBD<sup>[25]</sup>. Furthermore, some investigators reported simultaneous rise of CDAI and depression rate, estimated by Beck's depression self rating scale during disease progression, an evaluation independently confirms the lack of correlation between the

clinical activity of the illness and the level of anxiety and depression revealed by Hamilton's rating scale, considering the high correlation between two mentioned scales in sensitivity for mood changes<sup>[26]</sup>. Also, antidepressants in the therapy of IBD is suggested for two reasons: first, the reduction of the depression and anxiety and, second, but not less important, the pain relief<sup>[20,27]</sup>. Recent studies, however, warn that the treatment with Selective serotonin reuptake inhibitors (SSRIs) could increase the bleeding risk in patients with IBD<sup>[28]</sup>.

No difference in the impact of stressful events was found in our study. According to the investigation using Paykel's scale published elsewhere, stressful events are correlated with the major depression and generalized anxiety disorder, but no specificities in life events could be delineated<sup>[29]</sup>. We can speculate that stressful events could indirectly influence the IBD occurrence, worsening the depressive and anxiety symptoms that are undeniably related to the presence of IBD. For CCA, genetic, nutritional or environmental factors seem to be decisive, while circumstances play an ambiguous and, probably, less relevant role in its pathogenesis<sup>[30-32]</sup>.

In conclusion, patients with newly obtained inflammatory bowel disease have higher levels of depression and anxiety, compared with individuals with newly diagnosed colon cancer. The discriminant function analysis reveals the total depression score as a parameter of importance for the classification of a newly diagnosed patient into one of the groups of interest. Our analysis indicates that the psychiatrist should take part in the treatment of IBD, although, according to our results, the initial IBD activity indices show no correlation with the depression or anxiety scores. On the other hand, events in the past one year do not have a particular influence on the occurrence of either inflammatory bowel disease or colon cancer.

## COMMENTS

### Background

It has already been reported that the level of depression and anxiety is augmented in patients with inflammatory bowel disease (IBD) and cancer of the colon (CCA). The present study compares the level of anxiety and depression in therapy-naïve, first episode IBD patients to those suffering from newly discovered CCA, using Hamilton's Depression Scale and Hamilton's Anxiety Scale.

### Research frontiers

Both IBD and CCA should be recognized as complex illnesses, especially IBD and it is advisable that psychiatrists should be included in the team for the treatment.

### Innovations and breakthroughs

No comparison has been made between emotional states in IBD and CCA suffering patients so far. The current study emphasizes the impact of depression and anxiety on the appearance of IBD, rather than the formation of CCA.

### Applications

Continual psychiatric evaluation is recommended in IBD suffering patients and psychiatric treatment is necessary, parallel to the IBD medication in order to restrict the depression and to improve the pain in IBD suffering individuals.

### Peer review

This study compares anxiety and depression levels in patients with IBD and patients with CCA. It is understandably written and discriminates certain reasons of

depression and anxiety in patients with IBD. The study is well designed and results are convincing. The presentation and readability of the manuscript is satisfactory.

### Abstract

**AIM:** To assess the efficacy of premedication with pronase or N-acetylcysteine (NAC) at 20 min before upper gastrointestinal (UGI) endoscopy and to determine whether pronase or NAC pretreatment influences the reliability of the rapid urease test.

**METHODS:** A total of 146 patients were prospectively and randomly assigned into the study groups according to different premedications before endoscopy. One endoscopist assessed mucosal visibility (MV) with scores ranged from 1 to 4 at four sites in the stomach. The sum of the MV scores from these four locations was defined as the total mucosal visibility (TMV) score. Identification of *H pylori* was performed using CLO test, histology, and serology.

**RESULTS:** The Group with pronase premedication had a significantly lower TMV score than did the groups with gascon and gascon water ( $P < 0.001$  and  $P < 0.01$ , respectively). The group with NAC had a significantly lower TMV score than the group with gascon ( $P < 0.01$ ) and a trend of a lower MV score than the group with gascon water ( $P = 0.06$ ). The TMV score did not significantly differ between the group with pronase and the group with NAC ( $P = 0.39$  and  $P = 0.14$ , respectively). The sensitivity and specificity of the CLO test were 92.5% and 93.9%, respectively, in groups premedicated with pronase and NAC together.

### INTRODUCTION

The 5-year survival rate for early gastric cancer exceeds 90%<sup>[1,2]</sup>. Western endoscopists are less successful than Japanese endoscopists in the detection of gastric cancers at an early stage. This is not because the Japanese endoscopists detect the cancers by screening the asymptomatic population. Even in Japan, most cases are incidental findings of opportunistic screening at endoscopy, and only 10% of gastric cancers are picked up by screening program<sup>[3,4]</sup>. More than 50% of all gastric cancers in Japan were found in an early stage but probably fewer than 5% are in the West<sup>[5,6]</sup>. A single-center study in the UK reported that 13.5% patients (11 of 81 patients presenting with advanced gastric cancer) supposed to be missed of early gastric cancer those who had undergone endoscopy within the previous 2 years<sup>[7]</sup>. A diagnosis of early gastric cancer can be improved by effective premedication with a defoaming agent during upper gastrointestinal endoscopy. Dimethylpolysiloxane (DMPS) is commonly used at most endoscopic centers to eliminate bubbles and foam<sup>[8-10]</sup>. However, a lot of mucus and bubbles can still be encountered with premedication of DMPS during gastroendoscopy. Pronase is a proteolytic enzyme isolated in 1962 from the culture filtrate of *Septomyces griseus* which has already been used as a

raw material to prepare anti-inflammatory and digestive enzymes. In 1964, Koga and Arakawa used this enzyme as a premedication for roentgenographic examinations to remove gastric mucus<sup>[11]</sup>. Since then, Ida *et al*<sup>[12]</sup> applied this enzyme to gastroendoscopy. Fujii *et al*<sup>[13]</sup> also concluded that premedication with pronase improved endoscopic visualization during conventional endoscopy and chromoendoscopy. They recommended routinely use of pronase for endoscopy is helpful. N-acetylcysteine (NAC) is both a mucolytic agent and a thiol-containing antioxidant. NAC, unlike some other bronchial mucolytics such as carbocysteine and bromhexine, has been shown in *in vitro* studies to change the viscoelastic properties of gastric mucin<sup>[14]</sup>. In this study, we investigated the effectiveness of premedications with DMPS only, DMPS with water, DMPS with pronase, and DMPS with NAC on the visibility during UGI endoscopy.

Pronase and NAC are both mycolytic agents. There are two studies discussing about *H pylori* detection after treatment with pronase and NAC<sup>[15,16]</sup>. Rapid urease testing is most commonly used to identify *H pylori* during the examination of UGI endoscopy. Therefore, we also attempted to determine whether pronase or NAC pretreatment influences the reliability of identifying *H pylori* infection by the rapid urease test.

## MATERIALS AND METHODS

### Patients

From January to July 2005, 146 consecutive patients were referred to our department for upper gastrointestinal (UGI) endoscopy. We excluded those patients with previous gastric surgery, gastric malignancy, corrosive gastric injury, or gastrointestinal bleeding.

UGI endoscopic procedures were performed by a single experienced endoscopist (Chang CC) between 9:00 am and 1:00 pm in the endoscopic room of Taipei Medical University Hospital. Patients who consented to participate in the study were randomly assigned to four different oral liquid solutions for premedication before endoscopy. All oral solutions were given around 20 min before UGI endoscopy. The endoscope used was a GIF-Q240X video endoscope (Olympus, Tokyo, Japan).

The patients were randomly divided into four groups according to the treatment with oral liquid solutions. Group A: 100 mg, 5 mL of DMPS (Gascon, Kisssi Corp., Matsumoto, Japan); Group B: 100 mg, 5 mL of DMPS plus water up to 100 mL; Group C: 20000 U pronase (Pronase MS, Kaken Corp., Tokyo, Japan), 1.2 g sodium bicarbonate, 100 mg, 5 mL of DMPS plus water up 100 mL water; and Group D: 400 mg N-acetylcysteine (Acetin, Synmosa Corp., Taipei, Taiwan), 5 mL of DMPS plus water up 100 mL.

The endoscopist was unaware of the kind of oral liquid solution used for premedication for each patient before UGI endoscopy. UGI endoscopy was performed to check the mucosal visibility of the gastric antrum, the greater curvature of the gastric lower body, the greater curvature of the gastric upper body, and the gastric fundus. The scores of mucosal visibility were classified from 1 to 4 and this score was modified from Kuo *et al*<sup>[15]</sup> (Figure 1A-D).

**Figure 1** Mucosal visibility scores evaluated during UGI endoscopy. (A) Score 1: No adherent mucus on the gastric mucosa; (B) Score 2: a small amount of mucus on the gastric mucosa without obscuring the vision; (C) Score 3: a large amount of mucus on the gastric mucosa, which took less than 50 mL of water to clear; and (D) Score 4: a large amount of mucus on the gastric mucosa, which took more than 50 mL of water to clear.

Score 1: No adherent mucus on the gastric mucosa; Score 2: little amount of mucus on the gastric mucosa but no obscuring vision; Score 3: large amount of mucus on the gastric mucosa, with less than 50 mL of water to clear; Score 4: large amount of mucus on the gastric mucosa, with more than 50 mL of water to clear. The sum of the scores from the four locations was defined as the total mucosal visibility score (TMVS).

The rapid urease test using the Campylobacter-like organism test (CLO test; Delta West, Perth, Australia), the

Table 1 Demographic characteristics of patients

Category	Group A	Group B	Group C	Group D
Number (n)	39	35	34	39
Age (yr)	44.4 ± 14.2	44.1 ± 14.4	47.8 ± 13.9	48.7 ± 16.5
Gender (M:F)	18:21	18:17	16:18	18:21
Indication				
Cancer screening	9	9	7	10
Dyspepsia	20	17	18	22
Acid regurgitation	10	9	9	7

No significant difference between each two groups. Group A received dimethylpolysiloxane, group B received dimethylpolysiloxane plus water, group C received pronase, sodium bicarbonate, and dimethylpolysiloxane plus water, and group D received N-acetylcysteine and dimethylpolysiloxane plus water.

Table 3 CLO test for *H pylori* detection in groups C and D

Category	<i>H pylori</i> -positive	<i>H pylori</i> -negative
Positive CLO test	37	2
Negative CLO test	3	31

$P < 0.05$  by Chi-square test.

histologic examination for *H pylori* using hematoxylin-eosin staining during the UGI endoscopy and serum anti-*H pylori* IgG were carried out to determine the presence of infection by *H pylori*. *H pylori* infection was considered when two of the three tests were positive.

### Statistical analysis

The demographic characteristics were assessed using a chi-square test or one-way analysis of variance. The visibility scores for the four groups were assessed using one-way analysis of variance with Tukey's multiple comparisons. The correlation of the results of the CLO test was analyzed using a chi-square test. The results were expressed as mean ± SD.  $P < 0.05$  was considered statistically significant.

## RESULTS

Of 147 patients (70 men and 77 women), 39, 35, 34, and 39 patients were randomly placed in groups A, B, C, and D, respectively. The demographic data of patients are shown in Table 1. The mean (± SD) ages of groups A, B, C, and D were 44.4 ± 14.2, 44.1 ± 14.4, 47.8 ± 13.9, and 48.7 ± 16.5 years, respectively. The ratios of males to females among groups A, B, C, and D were 1:1.1, 1:0.9, 0.9:1 and 1:1.1, respectively. There was no significant statistical difference between any pair of groups for age or the gender ratio.

The means of the TMV score among groups A, B, C, and D were 8.2 ± 3.1, 7.6 ± 2.6, 5.8 ± 2.3, and 6.5 ± 2.2, respectively. Group C had a significantly lower TMV score than groups A and B ( $P < 0.001$  and  $P < 0.01$ , respectively). Group D also had a significantly lower TMV score than group A ( $P < 0.01$ ) and a trend of a lower TMV score than group B ( $P = 0.06$ ) (Figure 2). The TMV

Table 2 Mucosal visibility scores at different locations of the stomach (mean ± SD)

	Antrum	Greater curvature of the lower gastric body	Greater curvature of the upper gastric body	Fundus
Group A	1.74 ± 0.91 <sup>e,g</sup>	2.18 ± 1.14 <sup>e,g</sup>	2.92 ± 1.06 <sup>c,e,g</sup>	1.38 ± 0.67 <sup>c,e,g</sup>
Group B	1.49 ± 0.82 <sup>e,g</sup>	1.89 ± 0.87 <sup>e,g</sup>	2.49 ± 0.82 <sup>a,e</sup>	1.80 ± 0.80 <sup>a,e</sup>
Group C	1.18 ± 0.63 <sup>a,c</sup>	1.38 ± 0.78 <sup>a,c</sup>	2.06 ± 0.89 <sup>a,c</sup>	1.21 ± 0.41 <sup>a,c</sup>
Group D	1.21 ± 0.52 <sup>a,c</sup>	1.77 ± 0.90 <sup>a,c</sup>	2.33 ± 0.79 <sup>a</sup>	1.28 ± 0.67 <sup>a,c</sup>
Total	1.41 ± 0.77	1.82 ± 0.95	2.46 ± 0.94	1.41 ± 0.69

There were significant differences in mucosal visibility scores in the upper gastric body when compared to the antrum, lower gastric body, and fundus. <sup>a</sup> $P < 0.05$  vs group A; <sup>c</sup> $P < 0.05$  vs group B; <sup>e</sup> $P < 0.05$  vs group C; <sup>g</sup> $P < 0.05$  vs group D. (a, c, e, g: one-way analysis of variance and Tukey's multiple comparison).

Figure 2 Total mucosal visibility score of each group. <sup>b</sup> $P < 0.01$  vs groups A and B; <sup>a</sup> $P < 0.01$  vs group A, <sup>d</sup> $P = 0.06$  vs group B.

score did not significantly differ between groups A and B or between groups C and D ( $P = 0.39$  and  $P = 0.14$ , respectively). The visibility score of each location of the stomach and TMV score for each group are shown in Table 2.

The scores of mucosal visibility at different locations in all patients were 1.4 ± 0.7 at the gastric fundus, 2.5 ± 0.9 at the greater curvature of the upper gastric body, 1.8 ± 0.9 at the greater curvature of the lower gastric body, and 1.4 ± 0.7 at the gastric antrum. A significantly poorer visibility score of the greater curvature of the upper gastric body compared to that of the gastric fundus, the greater curvature of the lower gastric body, and the gastric antrum was noted (all  $P < 0.05$ ). In addition, the greater curvature of the lower gastric body had a significantly poor visibility score than did the gastric fundus and the gastric antrum (both  $P < 0.05$ ). There was no significant difference of mucosal visibility score between the gastric antrum and the gastric fundus.

According to the effect of pronase and NAC on the reliability of the CLO test for identifying *H pylori* infection (Table 3), 68 of 73 patients had matching results between the CLO test and *H pylori* infection ( $P < 0.05$ ). The sensitivity and specificity were 92.5 % and 93.9%, respectively.

## DISCUSSION

For better visualization of the gastric mucosa, decreasing the amount of mucus and bubbles is very important during UGI endoscopy. Adequate premedication can eliminate

the need to carry out flushing during the procedure. In Japan, pronase is widely used as a mucolytic agent before gastrointestinal endoscopy. A randomized study by Fujii *et al*<sup>[13]</sup> showed that premedication with pronase significantly improved visibility before and after methylene blue spraying and also significantly shortened the time for the chromoendoscopic examination. Kuo *et al*<sup>[15]</sup> also concluded that premedication with 2000 U pronase, 1.2 g of sodium bicarbonate, 100 mg of DMPS plus up to 100 mL of warm water provided the clearest endoscopic visibility. Without the application of DMPS, pronase alone could not improve endoscopic visibility<sup>[15]</sup>. Similarly, in our study, we found that group C (premedication with 20000 U pronase, 1.2 g of sodium bicarbonate, 100 mg of DMPS plus up to 100 mL of warm water) had better TMV scores than those in groups A and B. In comparison to the study by Kuo *et al*<sup>[15]</sup>, we used 20000 U pronase rather than 2000 U pronase. In addition to the different doses of pronase, we gave all premedications around 20 min before UGI endoscopy, and we did not ask patients to change position before UGI endoscopy. Because the fluid ingested by those patients flowed into the gastric fundus, then gradually into the gastric antrum by the way of the gastric body, we thought it was not necessary to change the position before UGI endoscopy. Moreover, there can still be a lot of bubbles in the stomach 10 min after administering DMPS prior to UGI endoscopy in our previous experience.

NAC is a mucolytic agent which is commonly used for digestion of the esophageal mucus for the detection of Barrett's esophageal cancer prior to chromoendoscopy with methylene blue<sup>[17,18]</sup>. Its effectiveness in improving the mucosal visibility of the stomach during UGI endoscopy is not known. In our study, NAC also provided better TMV scores in the stomach as did pronase. Premedication with NAC can achieve good mucosal visibility during gastrointestinal endoscopy if pronase is not available.

In our study, we found the greater curvature of the upper gastric body had the poorest mucosal visibility among all locations evaluated, suggesting that this area needs to be observed with caution during UGI endoscopy.

Pronase and NAC can disrupt the gastric mucus by a mucolytic effect. It is not well known whether pronase or NAC interferes with the accuracy of the CLO test for identifying *H pylori* infection. Our study showed greater than 90% sensitivity and specificity for the CLO test with premedication with pronase or NAC, which is consistent with the study by Kuo *et al*<sup>[15]</sup> based on the urea breath test. In conclusion, in order to improve the mucosal visibility of the stomach, premedication with pronase or NAC at 20 min before UGI endoscopy is feasible. It is not necessary to change the position of the patient from supine, left or right lateral to prone before UGI endoscopy. The greater curvature of the upper gastric body needs to be cautiously observed, for it had the poorest mucosal visibility among

all locations evaluated. Neither pronase nor NAC produce any obvious interference with the CLO test for identifying *H pylori* infection.

Changchien CS, Wang JH, Lu SN, Hung CH, Chen CH, Lee CM. Liu-stain quick cytodiagnosis of ultrasound-guided fine needle aspiration in diagnosis of liver tumors. *World J Gastroenterol* 2007; 13(3): 448-451

<http://www.wjgnet.com/1007-9327/13/448.asp>

### Abstract

**AIM:** To combine ultrasound-guided fine-needle aspiration (US-FNA) and Liu (Riu) stain to make a quick study on liver tumor lesions.

**METHODS:** Two hundred and twenty-eight aspirations from 232 patients were completely studied. The operator himself made the quick cytodiagnosis of US-FNA smear stained by Liu method within thirty minutes. The US-FNA specimen was also sent to the pathological department for cytological study and cellblock histology. The result of our Liu-stain quick cytodiagnosis in each patient was confirmed by the final cytopathological diagnosis from pathological report.

**RESULTS:** Among 228 samples, the quick cytodiagnosis revealed 146 malignancies, 81 benign lesions and one inadequate specimen. Cytopathological diagnosis from the pathological department revealed 150 malignancies, and 78 benign lesions. Four well-differentiated hepatocellular carcinomas (HCCs) were under-diagnosed by quick cytodiagnosis as benign and 3 benign lesions were over-diagnosed as well-differentiated HCCs. Compared with cytopathological diagnosis, quick cytodiagnosis correctly diagnosed 143 malignancies and 77 benign lesions. Except for the one inadequate specimen in quick cytodiagnosis, the accuracy of quick cytodiagnosis was 96.9% (220/227), and its sensitivity, specificity and positive and negative predictive values were 97.9%, 95.1%, 97.3% and 96.3%, respectively.

**CONCLUSION:** Liu-stain quick cytodiagnosis is a fast, convenient, safe and effective method for hepatologists in clinic practice to diagnose liver tumor. In few cases of well-differentiated HCC, Liu-stain quick cytodiagnosis has its limitation.

### INTRODUCTION

Abdominal ultrasonography now is the first line to find liver tumor. Fine needle aspiration (FNA) is able to get tumor specimens for cytological interpretation<sup>[1]</sup>. Ultrasound-guided FNA (US-FNA) can get a correct specimen and provide a good diagnosis of liver tumor<sup>[2-4]</sup>. US-FNA is a safe and effective method for cytodiagnosis of liver tumor<sup>[2-4]</sup>. Tsou *et al*<sup>[5]</sup> reported that fine needle aspiration cytodiagnosis with Riu's stain has its value in diagnosing liver tumors. The procedure of Liu (Riu) stain takes about two minutes. So, Liu stain for FNA smear is a quick method in cytological study. We tried to combine the ultrasound-guided FNA and Liu stain to shorten the time of cytodiagnosis of liver tumors.

### MATERIALS AND METHODS

#### Case selection

From June 2004 to May 2005, 232 patients (128 males, 104 females) underwent US-FNA for liver nodular lesions with a diameter > 1 cm detected by abdominal sonography. US-FNA was done from one lesion in each patient who signed the informed consent. The diameter of lesions ranged 1-16 cm. The mean age of 232 patients was 56.9 (range 25-96) years. A total of 232 aspirations were done. The patients who had positive malignant result from the pathological department underwent tumor treatment modalities (such as pure ethanol injection or radiofrequency ablation for small tumors, or surgical resection of operable tumors, or transhepatic arterial embolization of larger tumors). The patients who had benign result from the pathological report were followed up for six to twelve months with no change in alpha-fetal protein level, ultrasound examination, and clinic course.

**Figure 1** Needle aspiration under real-time ultrasound guidance. The needle (larger arrow) is advanced into the liver nodular lesion (small arrows) through the abdominal wall and liver parenchyma under the direct guidance of US.

### Specimen preparation

All US-FNAs were performed with Aloka SSD-680 or 2000 machine (Aloka Corp. Tokyo, Japan) using a 3.75-MHz lineal puncture probe or convex probe with a puncture adaptor. Needle aspiration was done under real-time US guidance with a 15-cm long 22-gauge Chiba needle (Hakko-Shoji, Tokyo) attached to a 20-mL syringe. The needle was advanced into the liver nodular lesion through the abdominal wall and liver parenchyma under the direct guidance of US (Figure 1). The piston of the syringe was pulled back and maintained in a maximal aspiration position to obtain the maximal negative pressure. The needle was quickly moved back and forth several times (about 3-5 passes) in the lesion under US observation. After this, the piston of the syringe was released and the pressure returned to normal, and the needle was withdrawn. The aspiration material was ejected and smeared onto glass slides (average 3-5 slides). One to two slides were stained by Liu stain solution and cytological reading was immediately done by the operator himself and Dr. Wang, and had cytological training at the Department of Pathology, Kurume University School of Medicine. The Liu stain solution for blood smear containing 2 kinds of solution, Liu A and B was used. The cytological smear for quick cytodiagnosis was directly (without dry-up) stained with Liu A for 30 s and then with Liu B for 1 min. After the stain solution was washed softly with water and the slide was dried by tissue paper, cytological reading was done, it took about 10 min. The cytological reader had the clinical data as assistant information. The total time of quick cytodiagnosis of US-FNA with Liu stain was within thirty minutes (including US-FNA procedure).

The remaining 2-3 slides were fixed in 95% ethanol and sent to the pathological department for hematoxylin and eosin (H & E) and/or papanicolaou staining. The remaining small, cohesive tissue fragments were also collected into a tube containing 10% neutral buffered formalin and processed for cell block histology study. The tissue was held using 2% agarose and paraffin-embedded. The pathologists studied the ethanol-fixed cytology and cellblock histology. The smear for quick cytodiagnosis was not sent for pathological study.

The quick cytodiagnosis was made depending on the findings on any slides. The cytological results were categorized into four groups: benign, suspicious for malignancy, positive for malignancy, and inadequate specimen. The positive malignancy encompassed both

**Figure 2** Cytodiagnosis of hepatocellular carcinoma by quick Liu stain showing scattered distribution of malignant cells bearing atypical naked (A) and large nuclei (B) with scanty cytoplasm but without trabecular structure and sinusoids (A: 100 x, B: 400 x) and bile pigmentation (arrows) in cytoplasm (C) (400 x).

**Figure 3** Cytodiagnosis of well-differentiated hepatocellular carcinoma by quick Liu stain showing cytological features of well-differentiated HCC with thickened trabecular structure (A) and polygonal tumor cells bearing centrally placed nuclei with a mild degree of pleomorphism and enlargement (B) (A: 100 x, B: 400 x) and cellular monomorphism and mildly increased nuclear/cytoplasmic ratio (C). Glandular structure was present, but the reticular pattern was not shown in Liu stain.

primary (hepatocellular carcinoma and cholangiocarcinoma) and metastatic malignancies. The diagnosis of hepatocellular carcinoma (HCC) by quick cytology depended on the high cellularity with high nuclear/cytoplasmic ratios, polygonal outlines, dense granular cytoplasm, central nuclei and obvious morphologic kinship of tumor cells similar to ordinary hepatocytes. The characteristic findings in trabecular pattern and/or bile production (Figures 2 and 3) were also a clue to HCCs. The result of our Liu-stain quick cytodiagnosis in each patient was confirmed by the final cytopathological diagnosis from the pathological report. The diagnostic accuracy of quick cytodiagnosis was compared with that of cytopathological diagnosis. Sensitivity and specificity were calculated using conventional methods. Diagnostic accuracy was calculated as follows:  $(TP+TN)/(TP + TN+FP + FN)$ , where TP = true positive, TN = true negative, FP = false positive and FN = false negative.

## RESULTS

Four patients were excluded due to inadequate specimens

for both quick Liu-stain cytodiagnosis and cytopathological diagnosis. Among the 228 patients enrolled, the quick cytodiagnosis revealed 142 malignancies (Figure 2), 4 suspicious malignancies, 81 benign lesions and one inadequate specimen. Cytopathological diagnosis from the pathological department revealed 150 malignancies, and 78 benign lesions. Four suspicious malignancies by quick cytodiagnosis were 2 suspicious HCCs and 2 necrotic tissues with ghost cells. The former two were finally diagnosed as HCC and the latter two as metastatic adenocarcinoma and lymphoma respectively. One inadequate specimen by quick cytodiagnosis was proved to be adenocarcinoma by cytopathological diagnosis.

A total of 146 cases were diagnosed as malignancy by quick cytodiagnosis. Among them, 115 cases were diagnosed as HCC (1.2 cm-over 10 cm in diameter). For the 115 HCCs by quick cytodiagnosis, 14 were initially diagnosed as well-differentiated HCCs (Figure 3). Among them, 5 were well-differentiated, 6 moderately-differentiated and 3 non-malignancies by cytopathological diagnosis. The diameter of these three non-malignancies ranged 1.2 cm-1.6 cm. Of the 81 benign lesions by quick cytodiagnosis, four were proved to be well-differentiated HCCs and one to be adenomyolipoma with fat by cytopathological diagnosis. The overall quick cytodiagnosis rate was 96.5% (143 + 77/228). Except for one inadequate specimen in quick cytodiagnosis, the accuracy of quick cytodiagnosis was 96.9% (220/227), and the sensitivity, specificity, positive and negative predictive values were 97.9%, 95.1%, 97.3% and 96.3%, respectively.

Among the 143 malignancies, 13 cases of malignancy by quick cytodiagnosis did not match the final cytopathological diagnosis. Four HCCs became adenocarcinoma, 3 adenocarcinomas became HCC, and 6 malignancies without identification of cell nature became three adenocarcinomas, two HCCs and one transitional cell carcinoma.

The final diagnosis of 150 cytopathological malignancies revealed 126 HCCs, 18 adenocarcinomas (including 3 cholangiocarcinomas), 2 lymphomas, 2 unidentified malignancies, one squamous cell carcinoma, and one transitional cell carcinoma. The 78 benign lesions included fibroconnective tissue (regeneration nodule), focal nodular hyperplasia (6 cases), abscess (8 cases), hemangioma (2 cases), and others (leiomyoma, adenomyolipoma). No complication in relation with quick cytodiagnosis was found in the study.

## DISCUSSION

The specimen was sent to our pathological department, and cytopathological diagnosis was made by hematoxylin and eosin (H & E) and/or Papanicolaou staining and cell block histology. Special staining (in some cases) was also done to identify the nature of malignancy. It was reported that cytodiagnosis of liver tumors has good sensitivity and specificity<sup>[4]</sup>, suggesting that our final results based on the cytopathological diagnosis from our pathological department are reliable.

In this study, the overall quick cytodiagnosis rate was 96.5% (143+77/228). The accuracy of quick cytodiagnosis

in 227 cases of liver tumor was 96.9% (220/227), and its sensitivity, specificity, positive and negative predictive values were 97.9%, 95.1%, 97.3% and 96.3%, respectively. The results of Liu-stain quick cytodiagnosis were acceptable, compared with the reported sensitivity of 67%-100% and specificity of 80%-100%<sup>[1]</sup>, and 93.3 % sensitivity and 100% specificity by Riu's stain study<sup>[5]</sup>. The process of Liu stain on smears takes about 2 min. Including FNA aspiration procedure and cytological reading, the quick cytodiagnosis in this study took about thirty minutes to make a diagnosis. The procedure of cytodiagnosis was fast and effective in diagnosing liver tumors. It is very convenient for a hepatologist to diagnose liver tumors.

In most of our cases, Liu stain provided sufficient diagnostic elements, such as nuclear/cytoplasmic ratio, nuclear pattern, hyperchromatin, *etc*, to make a correct diagnosis of malignant or benign tumors. However, the nature of malignancy in quick cytodiagnosis was hard to identify in 13 cases, because special staining and cellblock histology were not available. This is the limitation of quick Liu stain cytodiagnosis. Although some limitations in diagnosing the nature of malignancies, quick cytodiagnosis can identify malignant from benign tumors except in some conditions such as well-differentiated HCCs.

In this series, incorrect diagnosis was made in 7 cases by quick cytodiagnosis. Four well-differentiated HCCs were under-diagnosed as benign tumors and 3 benign lesions were over-diagnosed as well-differentiated HCC. The mistake always occurs in the cases of well-differentiated HCC. Through the under-diagnosed cases of well-differentiated HCC in this study, we have got experience and increased our ability to diagnose well-differentiated HCC. Although the improvement in diagnosing well-differentiated HCC, we are still not able to make a perfect diagnosis of well-differentiated HCC, because the Liu stain alone cannot provide the complete information on the diagnosis of well-differentiated HCC. Boer *et al*<sup>[6]</sup> suggested that FNA cytodiagnosis of well-differentiated HCC should pay close attention to the architectural features and reticulin stain in both smears and cell blocks. The reticular pattern is an important criterion in diagnosing malignancy<sup>[7,8]</sup>. Without cell block and reticulin stain, the reticular pattern in aspiration cytological smear is hard to identify. Since the architecture features in Liu stain cytology show a poor reticular pattern, it was difficult to make a differentiation between the well-differentiated HCC and benign lesion in our 7 cases. In this study, although we made a correct diagnosis of 11 well-differentiated HCCs by quick cytodiagnosis, Liu-stain quick cytodiagnosis is not sufficient in diagnosing well-differentiated HCC.

Under ultrasound-guidance, FNA may correctly get specimens from small lesions less than 1 cm in diameter (Figure 1). FNA is also safer than core biopsy in getting specimens from liver to which it is difficult to approach. The Liu stain is a very simple and quick method in cytological study. In practice, we usually achieve one-shot aspiration to get specimens<sup>[5]</sup>. The quick Liu-stain is done immediately and the operator reads the cytological findings. If the specimen is inadequate or not informative, a second or third shot of aspiration should be done. The

conventional cytopathology preparation cannot provide the opportunity to do a second aspiration. Liu-stain quick cytodiagnosis can minimize the failure of FNA aspiration. In this study, it was as low as 2.2% (5/232). Therefore, Liu-stain quick cytodiagnosis may avoid inadequate specimens and improve cytodiagnosis. The process of Liu stain needs no air-drying of smears, the biosafety is stable, even in infective cases.

In conclusion, Liu-stain quick cytodiagnosis is a fast, safe, convenient and effective method for hepatologists to diagnose liver tumors and may provide a quick decision in HCC treatment. However, Liu-stain quick cytodiagnosis had its limitation in diagnosing well-differentiated HCC.

## APPENDIX

Liu stain solution (Figure 4).

## COMMENTS

### Innovations and breakthroughs

US-FNA cytodiagnosis of liver tumors has been confirmed, US-FNA Liu-stain

cytodiagnosis makes a correct and quick cytodiagnosis of liver tumors.

### Applications

Diagnosis of liver malignancy by quick cytodiagnosis should be performed as early as possible. When the specimen is inadequate or not informative, subsequent US-FNA aspiration should be performed to avoid the failure of cytodiagnosis.

### Peer review

The manuscript is interesting and could help obtain more informative histological data without losing time and significant impact in clinical hepatology.

### Abstract

**AIM:** To investigate the effectiveness and safety of recombinant human growth hormone (rhGH) in postoperative patients.

**METHODS:** A total of 48 consecutive patients undergoing abdominal operations were randomized to receive either subcutaneous rhGH (0.15 IU/kg) or placebo (menstruum) injections daily for 7 d after surgery. The two groups had similar nutritional intake. Blood samples for serum fibronectin, albumin, prealbumin, transferrin and the total lymphocyte count, as well as glucose levels were collected to study the rhGH effect. Basal laboratory evaluation, and nutritional status were estimated on d 1 before as baseline and d 3 and 10 after operation using standard laboratory techniques. Nitrogen balance was measured from d 3 to 9 after operation.

**RESULTS:** The cumulative nitrogen balance was significantly improved in rhGH group compared with the placebo group ( $11.37 \pm 16.82$  vs  $-9.11 \pm 17.52$ ,  $P = 0.0003$ ). Serum fibronectin was also significantly higher in the rhGH group than in the placebo group ( $104.77 \pm 19.94$  vs  $93.03 \pm 16.03$ ,  $P < 0.05$ ), whereas changes in serum albumin, prealbumin, transferrin and total lymphocyte counts were not statistically significant. Mean blood glucose levels were significantly higher in the rhGH group from d 3 to 6 after operation.

**CONCLUSION:** If blood glucose can be controlled, low-dose growth hormone together with hypocaloric nutrition is effective on improving positive nitrogen balance and protein conservation and safe is in postoperative patients.

### INTRODUCTION

Patients undergoing abdominal surgery often suffer severe trauma or infections associated with the catabolic responses<sup>[1]</sup>, which cannot be prevented with conventional parenteral or enteral nutritional formulas<sup>[2,3]</sup>. Administration of recombinant human growth hormone (rhGH) has been shown to significantly maintain the nitrogen balance in surgery patients receiving either parenteral or enteral nutrition<sup>[4-7]</sup>. However, it is still uncertain whether short-term treatment with low-dose rhGH is effective as well and whether its effect on blood glucose will lead to more severe outcomes. Furthermore, there is a lack of well-controlled prospective clinical studies investigating the clinical value of serum proteins as nutritional assessment indexes in GH-treated patients. The objective of the present study was to evaluate the relative nitrogen and protein conservation effects associated with administration of rhGH together with hypocaloric nutritional support after elective abdominal surgery. In addition, we measured the changes in blood glucose levels, the effects of hyperglycemia caused by rhGH administration on postoperative convalescence and other adverse events during GH treatment period.

### MATERIALS AND METHODS

#### Patients

The study was conducted in accordance with the guidelines for Good Clinical Practice and the provisions of the Declaration of Helsinki in 1995 as revised in Edinburgh 2000, and approved by the Ethical Review Committee of West China Hospital. Only those who consented to participate after explanation of the objectives and the protocol were included in the study. Signed, informed consent was obtained from all patients and their close relatives.

Forty-eight adult patients were enrolled in the study, and all met the following criteria: undergoing an elective

abdominal operation; aged 18-75 years; willing and able to comprehend the protocol and give written informed consent. Exclusion criteria were as follows: severe bacterial infection, liver and renal dysfunction, previous or current treatment with corticosteroids, diabetic mellitus or fasting glucose levels greater than or equal to 7.0 mmol/L, metabolic diseases, gestation, severe malnutrition (serum albumin < 21 g/L), tumor recrudescence or metastasis.

### Study design

The study was a randomized, prospective, double-blind, placebo-controlled clinical trial. Eligible patients were arranged randomly as follows: rhGH or placebo group with each group including 24 patients. The randomization codes were prepared with the random number table according to the design of a computer. Patients, surgeons and nursing staff members remained blind to the allocation status of the study drugs throughout the experimentation.

After the operation, all patients received continuous combined intravenous or/and enteral nutrition. The daily total caloric requirement was 20 kcal/kg and total nitrogen requirement was 140 mg of nitrogen/kg. Parenteral nutrition (PN) solution was prepared aseptically using commercially available products, including vitamins, trace elements and electrolytes (Addamel, Vitalipid, Soluvit and Glycophos; Fresenius Kabi Deutschland GmbH, Bad Homburg, Germany). Amino acid injections were provided as Novamin 8.5% and 11.4% (Fresenius Kabi Deutschland GmbH). Energy calories were provided with glucose and fat emulsion injections (glucose 50% and Lipovenos® MCT 20%; Fresenius Kabi Deutschland GmbH). All the nutrients were given in an all-in-one bag. Enteral nutrition (EN) emulsion (Fresubin®, Fresenius Kabi Deutschland GmbH) was provided orally or *via* a nasogastric tube with a continuous perfusion pump.

Postoperatively, patients received general intravenous infusions with only glucose on d 1; PN provided only half of total caloric and nitrogen requirement on d 2 and all of total requirement on d 3; on d 4, PN provided 2/3 of total requirement and EN provided another 1/3; on d 5, PN provided 1/3 of total requirement and EN provided 2/3; only EN emulsion was given from d 6 to 9.

From d 3 to 10 post operation, patients were randomly assigned to receive identical-looking treatments consisting of either rhGH (JINTROPIN®, 0.15 IU/kg) or menstuum injections (1 mL, consisting of glycin, mannitol, lactose and sodium bicarbonate) subcutaneously once daily. rhGH and placebo were provided by GeneScience Pharmaceuticals Co. Ltd, Changchun, China.

### Laboratory and nutritional condition measurements

Blood samples were drawn from each patient before operation to measure baseline values and on d 3 and 10 after operation to study the rhGH effect. Complete blood counts were estimated by the XE-2100 (Sysmex, Kobe, Japan). Plasma glucose, serum urea nitrogen, creatinine, bilirubin, alanine aminotransferase, alkaline phosphatase, total protein, albumin and electrolytes were estimated by an Olympus AU5400 Autoanalyser (Olympus, Tokyo, Japan). Serum fibronectin, prealbumin and transferrin were estimated by immunoturbidimetry and radioimmunoassay

Table 1 Baseline characteristics of patients (mean ± SD)

Variable	Placebo (n = 24)	rhGH (n = 24)	P
Age (yr)	58.50 ± 9.35	59.08 ± 10.93	0.789
Range	39-75	35-74	
Sex (female/male)	11/13	9/15	0.558
Weight (kg)	57.90 ± 8.42	56.19 ± 11.83	0.567
Height (cm)	162.42 ± 6.92	162.88 ± 7.16	0.823
Sepsis score	0.79 ± 0.98	0.67 ± 0.87	0.742
Operation position, n (%)			
Resection of stomach	6 (25)	5 (20.8)	0.297
Resection of colon	5 (20.8)	7 (29.2)	
Resection of rectum	12 (50)	9 (37.5)	
Others	1 (4.2)	3 (12.5)	

methods, respectively. Body weight were confirmed using qualified body weight scales before operation and on postoperative d 3 and 10.

### Nitrogen balance

Daily nitrogen input was assumed to be the nitrogen contents of PN and/or EN solution given. Daily nitrogen loss was assessed by collecting 24-h output and measuring the nitrogen content in feces, urine and gastric juice. Nitrogen loss through the surgical drains was also included. Daily nitrogen balance was calculated by subtracting daily nitrogen output from daily nitrogen input. Accumulated nitrogen balance was calculated by subtracting 7 d nitrogen output from 7 d nitrogen input. Nitrogen contents of samples were determined by the micro-Kjeldahl procedure<sup>[8]</sup>.

### Monitoring of adverse effects

All outcome and adverse effect parameters were monitored, especially GH-related adverse effects such as hyperglycemia, hypertension, edema, tetter, arthritis, and hand stiffness. Routine clinical evaluation included breath rate, pulse rate, temperatures and blood pressures. All infection, sepsis and deaths and their causes were recorded.

### Statistical analysis

All data were assessed for normality of distribution and equality of variance. Student's *t* test and ANOVA were used to compare normally distributed data. Data are presented throughout as means and standard deviations (SD). Categorical data were compared using the Pearson  $\chi^2$  test or Fisher exact test. All data analysis was performed using the program SPSS 11.5 for Windows. *P* < 0.05 was considered statistically significant.

## RESULTS

### Patient characteristics

There were no differences between the two groups in baseline characteristics (Table 1).

### Daily and accumulated nitrogen balance

Changes in daily nitrogen balance are shown in Table 2. Patients given rhGH showed decreased nitrogen excretion and increased nitrogen retention compared with patients

**Table 2** Daily and accumulated nitrogen balance after operation (g)

Time after operation	rhGH ( <i>n</i> = 24)	Placebo ( <i>n</i> = 24)	<i>P</i>
D 3	0.29 ± 3.31	-0.86 ± 5.81	0.405
D 4	0.87 ± 3.23	-2.43 ± 5.60	0.016
D 5	0.87 ± 3.85	-0.94 ± 5.93	0.217

D 9	2.18 ± 4.27	-1.36 ± 6.16	0.025
Accumulated NB (7 d)	11.37 ± 16.82	-9.11 ± 17.52	0.0003

Data presented as mean ± SD. NB: Nitrogen balance.

given the placebo during the study period. Postoperatively, daily nitrogen balance in the rhGH group was increased significantly compared with the placebo group on d 4 and from d 6 to 9 ( $P < 0.05$ ). On d 9, the accumulated nitrogen balance in the rhGH group was significantly improved compared with the placebo group.

### Nutritional condition measurement

On d 1 before and d 3 after operation, there were no significant differences between the two groups in serum albumin, transferrin, prealbumin, fibronectin and total lymphocyte counts. On postoperative d 10, mean serum fibronectin levels were significantly higher in the rhGH group than in the placebo group. While mean serum albumin, transferrin, prealbumin levels and total lymphocyte counts were not significantly different between the two groups (Table 3). The weight change was also not significantly different between the two groups.

### Adverse events

The main adverse effects seen during the study are summarized in Tables 4 and 5. Mean blood glucose levels were significantly higher in the rhGH group from d 3 to d 6 after operation (Table 4). Twenty-three patients in the rhGH group experienced hyperglycemia and 5 of these required insulin treatment (Table 5). Furthermore, 3 patients had other mild adverse events including 1 patient with edema, 1 with tetter and 1 with a fever. In the placebo group, 3 of 4 patients presenting hyperglycemia required insulin treatment. Concerning adverse events not related to the trial drug, 5 placebo-treated patients experienced mild electrolytes imbalance. There were no significant differences between the two groups in complete blood counts, liver and renal functions, body weights and the daily clinical parameters such as temperatures, blood pressures, and pulses.

## DISCUSSION

Many attempts have been made to reverse the catabolic changes that occur in postoperative patients. Conventional nutrition support is unable to provide adequate nutritional supplements to increase or even maintain body proteins in hypercatabolic response conditions<sup>[9-11]</sup>. Recent studies

indicated that rhGH had beneficial effects on stimulating body protein syntheses and producing nitrogen-spacing effects<sup>[6,12-14]</sup>.

However, the impact of rhGH on body proteins and the change in blood glucose levels have not been previously investigated in patients receiving PN or EN following elective gastrointestinal surgeries<sup>[15-17]</sup>. In the present experiment, we observed the effect of rhGH on nitrogen balance, plasma proteins and blood glucose levels. The number of patients enrolled in the study is based on previous publications and the dosage of rhGH used is small considering its efficacy and safety<sup>[7,18,19]</sup>. rhGH treatment significantly increased the nitrogen retention of postoperative patients compared with the placebo group. Nitrogen balance began to improve from postoperative d 3 in the rhGH group, and 15 of 24 patients showed positive nitrogen balance on d 4. On d 9, 21 of 24 patients showed positive nitrogen balance in the rhGH group and the accumulated nitrogen balance was positive nitrogen balance, which was significantly different compared with the placebo group. Patients receiving only standard nutrition support were in a state of negative nitrogen balance during the whole period of the study. Our results demonstrated that administration of rhGH could result in significant anabolic effects on nitrogen balance and improve the efficiency of nutrition support.

In fact, changes of nitrogen balance may be associated with protein synthesis and breakdown<sup>[12,13,16]</sup>. The alteration in concentrations of plasma proteins reflects the metabolic responses to surgical traumas<sup>[20]</sup>. We found that serum fibronectin levels were higher in the rhGH group than in the control group after termination of treatment. This reflects a beneficial effect of rhGH on protein synthesis. However, serum transferrin, albumin, and prealbumin levels were not significantly different between the two groups. The potential reason might be that these protein levels are markedly affected by the acute-phase responses, thus they are not sufficiently sensitive and reliable in

nutritional assessment<sup>[21-23]</sup>.

GH given during sepsis has been thought to impair immune function and result in hyperglycemia, which may explain why acute critically ill patients do not benefit from GH treatment<sup>[24,25]</sup>. However, GH can be administrated safely after acute inflammatory response stage for elective surgery patients, especially with a low dose and temporary duration of treatment. rhGH treatment was generally well tolerated with no serious adverse events in our trial. The mortality rate in the GH-treated group was zero, confirming its safety. These results are contrary to the increase in mortality among critically ill patients treated with GH reported in two large clinical trials by Takala *et al*<sup>[24]</sup>. We hypothesize that this discrepancy might be due to the difference in study patients. In our study, the patient populations were elective surgery subjects. Moreover, rhGH given during the response to stress leads to uncontrolled systemic inflammation in Takala's study. The main adverse events of the rhGH treatment were hyperglycemia. Insulin resistance caused by rhGH plays an important role in the rise of blood glucose. Other reasons may include nutritional support and systemic inflammation syndrome<sup>[26,27]</sup>. In our test, the hyperglycemia caused by rhGH administration was mild, for which low-dose rhGH and hypocaloric nutrition may be the reason. Furthermore, the hyperglycemia could be controlled easily by insulin. Considering the difference between critically ill patients and elective surgery patients, rhGH seems to be well tolerated after operation.

Our study included 14 cancer patients in the rhGH group, so the potential tumor-promoting effect of GH must be addressed. In animal models, whether rhGH administration promotes tumor recurrence is controversial<sup>[28-30]</sup>. Several authors even concluded that GH could promote host growth selectively and inhibit tumor metastasis<sup>[31,32]</sup>. Only two trials assessed the impact of GH on tumor recurrence in humans. Based on 2632 adverse events reports, the National Cooperative Growth Study analyzed the recurrence of brain tumors in patients receiving long-term GH replacement. It was

concluded that there was no evidence of increased tumor recurrence<sup>[33]</sup>. Only one study investigated the impact of short-term treatment with three different doses of GH on long-term tumor recurrence in postoperative cancer patients<sup>[34]</sup>. Thirty-five percent of rhGH-treated patients showed tumor recurrences in comparison to 44% of patients given placebo. Based on the above two studies, we believe that when complete resection and appropriate antineoplastic treatment is administered, short-term GH treatment can be given safely to cancer patients.

In conclusion, our results indicate that postoperative rhGH treatment for 7 d improves nitrogen retention and protein conservation, enhances the efficiency of nutrition support in adult patients undergoing major abdominal surgeries. rhGH also is well tolerated without clinically significant adverse effects and the blood glucose level can be well controlled. A larger trial is required to measure clinical endpoints such as infection, morbidities, mortalities and tumor recurrences.

## COMMENTS

### Background

Administration of recombinant human growth hormone has been shown to significantly maintain the nitrogen balance in surgery patients receiving nutritional support. However, it is still uncertain whether short-term treatment of low-dose recombinant human growth hormone (rhGH) is effective as well and whether its effect on blood glucose will lead to higher risk.

### Research frontiers

Conventional nutrition support is unable to provide adequate nutritional supplements to increase or even maintain body protein under hypercatabolic response conditions. Recent studies indicated that rhGH had beneficial effects on stimulating body protein and producing nitrogen-spacing effects.

### Innovations and breakthroughs

The present study confirmed that administration of rhGH together with hypocaloric nutrition support produced nitrogen conservation and protein synthesis effects after elective abdominal surgery. In addition, the changes in blood glucose levels, especially the hyperglycemia caused by rhGH administration was slight and could be controlled in GH treatment period.

### Applications

Our results indicate that postoperative rhGH treatment improves nitrogen retention and protein conservation, enhances the efficiency of nutrition support in adult patients undergoing major abdominal surgery. rhGH also is well tolerated without clinically significant adverse effects and the blood glucose level can be well controlled.

### Peer review

The authors assess the role of a low dose of growth hormone in postoperative nitrogen balance in patients undergoing gastrointestinal operations who also received a "hypocaloric" feeding. They also discuss the adverse effects and potential disadvantage of rhGH administration and monitor the change of blood

glucose levels. The study demonstrates that the appropriate application of rhGH is well tolerated and of great benefit to postoperative patients.

## Abstract

**AIM:** To investigate the effect of N-desulfated heparin on tumor metastasis and angiogenesis, and expression of vascular endothelial growth factor (VEGF) of orthotopic implantation of human gastric carcinoma in male severe combined immune deficiency (SCID) mice.

**METHODS:** Human gastric cancer SGC-7901 cells were orthotopically implanted into the stomach of SCID mice. The mice were randomly divided into normal saline group and N-desulfated heparin group. One week after operation, the mice in N-desulfated heparin group received i.v. injections of N-desulfated heparin (Shanghai Institute of Cell Biology, Chinese Academy of Sciences, 10 mg/kg.d) twice weekly for 3 wk. The mice in normal saline group received i.v. injections of normal saline (100  $\mu$ L) twice weekly for 3 wk. The mice were sacrificed six weeks after implantation. Tumor metastasis was evaluated histologically for metastasis under microscope. Intratumoral microvessel density (MVD) and VEGF expression were evaluated immunohistochemically. VEGF mRNA expression in gastric tissue of SCID mice was detected by real time PCR.

**RESULTS:** The tumor metastasis rate was 80% in normal saline group and 20% in N-desulfated heparin group ( $P < 0.05$ ). MVD was  $8.0 \pm 3.1$  in normal saline group and  $4.3 \pm 1.8$  in N-desulfated heparin group ( $P < 0.05$ ). VEGF positive immunostaining was found in cytoplasm

of cancer cells. The rate of VEGF positive expression was higher in normal saline group than in N-desulfated heparin treated group (90% vs 20%,  $P < 0.05$ ). VEGF mRNA expression was significantly inhibited by N-desulfated heparin and was higher in normal saline group than in N-desulfated heparin group (Ct value  $19.51 \pm 1.01$  vs  $22.55 \pm 1.36$ ,  $P < 0.05$ ). N-desulfated heparin significantly inhibited the expression of VEGF mRNA in cancer cells. No bleeding occurred in N-desulfated heparin group.

**CONCLUSION:** N-desulfated heparin can inhibit metastasis of gastric cancer by suppressing tumor VEGF expression and tumor angiogenesis, but has no obvious anticoagulant activity.

## INTRODUCTION

Gastric carcinoma is one of the most frequent malignancies and is the leading cause of cancer deaths in China. Up to now, there is no effective treatment for metastasis of tumor. Recent studies showed that angiogenesis plays a crucial role in tumor growth and metastasis. The regulation of angiogenesis is balanced by proangiogenic and antiangiogenic factors and is associated with prognosis of patients with tumors. Inhibition of angiogenesis can control tumor metastasis and improve the prognosis<sup>[1-4]</sup>. Vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2) are the main

factors promoting angiogenesis, and anti-VEGF therapy is effective in inhibiting angiogenesis and metastasis of tumor<sup>[5-7]</sup>.

Heparin, a highly sulfated proteoglycan, has been extensively used as an anticoagulant drug for a long time. Aside from its anticoagulant action, heparin binds to various growth factors, cytokines, and extracellular proteins and consequently is able to affect migration of cancer cells and angiogenesis in tumors. *In vitro* study<sup>[8]</sup> indicates that heparin can inhibit VEGF and FGF-2-induced proliferation of vascular endothelial cells and vascular formation, while *in vivo* study<sup>[9]</sup> has demonstrated that heparin has antimetastatic activity. However, clinical use of heparin in treatment of tumor is limited by its strong anticoagulant activity, which may cause severe bleeding complications. Chemically modified heparin shows a significantly reduced anticoagulant activity and enhanced ability to interact with FGF, VEGF and hepatocyte growth factor, which are known to stimulate angiogenesis<sup>[10]</sup>. In this study, we investigated the effect of N-desulfated heparin on tumor metastasis in mouse models of human gastric cancer constructed by orthotopic implantation of histologically intact tumor tissue.

## MATERIALS AND METHODS

### Materials

Goat anti-human CD34 antibody and goat anti-human VEGF antibody were obtained from Santa Cruz Biotechnical Company. VEGF probe for real time PCR was provided by Daan Gene Company of Zhongshan University.

### Animal model

Male severe combined immune deficiency (SCID) mice were obtained from Shanghai Experimental Animal Center of Chinese Academy of Sciences. Animals used were 6 wk old and weighed 20-25 g. Human gastric cancer SGC-7901 (Shanghai Cancer Institute), a poorly-differentiated adenocarcinoma line, was originally derived from a primary tumor and maintained by passage in the subcutis of nude mice. Animal models were made using orthotopic implantation of histologically intact tissue of human gastric carcinoma<sup>[11]</sup>. Tumors were resected aseptically. Necrotic tissues were cut and the remaining healthy tumor tissues were scissor minced into pieces (about 5 mm × 7 mm in diameter) in Hank's balanced salt solution. Each tumor piece was weighed and adjusted to be 150 mg. Mice were anesthetized with 4.3% trichloraldehyde hydrate. An incision was made through the left upper abdominal pararectal line. Then peritoneal cavity was carefully exposed and a part of serosal membrane in the middle of the greater curvature of stomach was mechanically injured using scissors. A tumor piece of 150 mg was fixed on each injured site of the serosal surface. The stomach was returned to the peritoneal cavity, and the abdominal wall and skin were closed.

After metastatic models were made, the mice were randomly divided into N-desulfated heparin group ( $n = 10$ ) and normal saline group ( $n = 10$ ). One week after opera-

tion, the mice in N-desulfated heparin group received i.v. injections of N-desulfated heparin (Shanghai Institute of Cell Biology, Chinese Academy of Sciences, 10 mg/kg.d) twice weekly for 3 wk. The mice in normal saline group received i.v. injections of normal saline (100  $\mu$ L) twice weekly for 3 wk. The mice were weighed twice weekly.

### Sample collection and pathological examination

All animals were sacrificed 6 wk after implantation. An incision was made through the abdominal wall, and then peritoneal cavity was carefully exposed. Tumors growing on the stomach wall were removed and fixed in 10% formalin, and processed for routine paraffin embedding. Tissues from all organs and lymph nodes were collected and fixed in 10% formalin, and processed for routine paraffin embedding after careful macroscopic examination. Four-micron-thick sections were stained with hematoxylin and eosin, and evaluated histologically for liver metastasis or lymph node metastasis or other organ metastasis under microscope.

### Mean microvascular density of tumor (MVD)

Immunostaining was performed using a labeled streptavidin biotin method. Four-micron-thick sections were deparaffined in xylene and rehydrated with graded alcohol. Immunohistochemical staining was carried out to detect CD34 expression following the manufacturer's protocol. The concentration of anti-CD34 antibody was 1:300. MVD (CD34-positive microvessels) was calculated under 200 fold microscope. The modified Weidner's method was used for the evaluation of MVD according to CD34 endothelial cell immunostaining. For the microvessel counting, positive stainings for MVD in 5 most highly vascularized areas in each section were counted in 200 × fields. MVD was expressed as average of the microvessel count in the areas.

### Detection of VEGF protein expression

Immunostaining was performed using a labeled streptavidin biotin method. Four-micron-thick sections were deparaffined in xylene and rehydrated with graded alcohol. Immunohistochemical staining was carried out to detect VEGF expression following the manufacturer's protocol. The concentration of anti-VEGF antibody was 1:60. Positive cells under 10% were defined as positive +, over 10% as positive ++. Positive expression was defined as positive + or positive ++. VEGF primers and probe used are VEGF f: GTTCGAGGAAAGGGAAAGGGTC, VEGF r: GCGAGTCTGTGTTTTTGCAGGA, VEGF probe: AGCGCAAGAAATCCCGGTTTAAATC.

### Detection of VEGF mRNA expression

VEGF RNA was isolated by method of Trizol. Synthesis of the first strand cDNA was performed according to the instructions delivered with reverse transcription kit, using human VEGF antisense strand primers and reverse transcriptase. After 1 h incubation at 37°C, samples were heat inactivated for 3 min at 95°C and kept at -80°C until use.

Aliquots of 5  $\mu$ L of cDNA were amplified in a final

**Figure 1** CD34 expression in intratumoral endothelium of gastric cancer  $\times 200$ .

**Figure 2** VEGF positive immunostaining in cytoplasm of gastric cancer cells  $\times 200$ .

**Table 1** Effect of N-desulfated heparin on VEGF expression in gastric cancer (mean  $\pm$  SD)

Groups	<i>n</i>	-	+	++	Positive rate (%)

N-desulfated heparin group	10	8	1	1	20 <sup>a</sup>

<sup>a</sup> $P < 0.05$  vs normal salt group.

volume of 50  $\mu$ L using PCR buffer at the presence of 1  $\mu$ L of Taq DNA polymerase and 0.5  $\mu$ L of VEGF probe. Samples were amplified at 93°C for 2 min, at 93°C for 0.5 min and at 55°C for 1min followed by 40 cycles. Real time PCR was carried out in an automated real time PCR cycler (American ABI 7000).

### Statistical analysis

All data were expressed as mean  $\pm$  SD. Student's *t* test and  $\chi^2$  precise method were used to determine changes in different groups.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Inhibition of N-desulfated heparin on metastasis of human gastric cancer

All mice developed localized tumors at the implanted site which were poorly-differentiated adenocarcinomas under microscope. Tumor growth did not differ significantly between the animals treated with normal saline or with N-desulfated heparin. Of the 10 animals treated with normal saline, 8 developed metastatic tumors in regional lymph nodes, 6 in liver, and 6 in other organs. However, after the mice were treated with N-desulfated heparin for 3 wk, metastasis of tumor was inhibited significantly. Of the 10 animals treated with N-desulfated heparin, 2 developed metastatic tumors in liver. The metastatic rate was higher in mice treated with normal saline than in those treated with N-desulfated heparin (80% *vs* 20%,  $P < 0.05$ ).

N-desulfated heparin had no significant effect on body changes in SCID mice. No bleeding complications were found in N-desulfated heparin group.

**Figure 3** VEGF mRNA expression in normal saline and N-desulfated heparin treated mice.

### Effect of N-desulfated heparin on MVD

In normal saline-treated mice, many CD34 positively stained vessels were diffusely located and formed tube-like structures in tumor (Figure 1). However, they were almost absent in N-desulfated heparin-treated mice. The MVD was significantly lower in N-desulfated heparin-treated mice than in normal saline-treated mice ( $4.3 \pm 1.8$  *vs*  $8.0 \pm 3.1$ ,  $P < 0.05$ ).

### Effect of N-desulfated heparin on VEGF protein expression

Under microscope, VEGF positive immunostaining was found in cytoplasm of cancer cells (Figure 2). The rate of VEGF positive expression was higher in normal saline group than in N-desulfated heparin group ( $P < 0.05$ , Table 1).

### Effect of N-desulfated heparin on VEGF mRNA expression

VEGF mRNA expression in gastric tissue of SCID mice detected by real time PCR was higher in normal saline group than in N-desulfated heparin group (Ct value  $19.51 \pm 1.01$  *vs*  $22.55 \pm 1.36$ ,  $P < 0.05$ ) (Figure 3).

## DISCUSSION

Recent studies showed that angiogenesis is a critical determinant of solid tumor metastasis, and antiangiogenic therapy plays an important role in improving prognosis of patients with gastric carcinoma<sup>[12-14]</sup>. It was reported that low molecular weight heparin has significantly-

reduced anticoagulant activity and enhanced ability to bind to FGF-2 and VEGF, thus inhibiting angiogenesis of tumor<sup>[15]</sup>.

N-desulfated heparin, a modified heparin, is known to have more significantly-reduced anticoagulant activity (1/76 of heparin) than O-desulfated heparin (5%-30% of heparin) or N-acetylated heparin (10% of heparin)<sup>[16]</sup>. There is no report so far on the effect of N-desulfated heparin on tumor metastasis. Therefore, the effect of N-desulfated heparin on tumor metastasis, angiogenesis and VEGF expression was observed in mouse model of orthotopic implantation of human gastric carcinoma tissue.

In the present study, tumor metastasis was inhibited significantly by N-desulfated heparin. Szende *et al*<sup>[17]</sup> found that fraxiparine has a significant effect on lung metastases, while heparin does not influence metastasis. These data suggest that low molecular heparin may be of antimetastatic activity<sup>[18]</sup>. Kragh *et al*<sup>[19]</sup> reported that non-anticoagulant heparin can inhibit tumor metastasis.

To evaluate the effect of N-desulfated heparin on angiogenesis, immunohistochemical staining of CD34 in tumors was carried out. The results showed that N-desulfated heparin significantly inhibited angiogenesis in these tumors. Mousa *et al*<sup>[20]</sup> have demonstrated anti-angiogenic activity of the low molecular weight heparin, tinzaparin. Naggi *et al*<sup>[10]</sup> reported that N-acetylated and glycol-split heparins are potential antiangiogenic and antimetastatic agents which are more effective than unmodified heparin, suggesting that N-desulfated heparin can inhibit tumor metastasis by inhibiting angiogenesis.

In the present study, the rate of VEGF positive expression was higher in normal saline group than in N-desulfated heparin group and VEGF mRNA expression was higher in normal saline group than in N-desulfated heparin group, demonstrating that N-desulfated heparin can significantly inhibit the expression of VEGF in cancer cells. Kakeji *et al*<sup>[21]</sup> showed that VEGF is expressed in early and advanced gastric cancer. Multivariate analysis has revealed that VEGF is an independent prognostic factor and an independent risk factor for liver metastasis. Fondevila *et al*<sup>[22]</sup> demonstrated that VEGF expression is an independent predictor of tumor recurrence and survival following curative resection of gastric cancer. Pisano *et al*<sup>[23]</sup> showed that undersulfated, low-molecular-weight glycol-split heparin may be an antiangiogenic VEGF antagonist. In the present study, hemorrhage was never observed in N-desulfated heparin treated mice, suggesting that N-desulfated heparin has no obvious anticoagulant activity.

In conclusion, VEGF produced by cancer cells is an angiogenic factor in human cancer tissue and plays an important role in tumor metastasis. N-desulfated heparin inhibits tumor metastasis by inhibiting expression of VEGF and angiogenesis and can be used in the treatment of tumor metastasis.

### Abstract

**AIM:** To investigate the protective effect of stronger neo-minophagen C (SNMC) on fulminant hepatic failure (FHF) and its underlying mechanism.

**METHODS:** A mouse model of FHF was established by intraperitoneal injection of galactosamine (D-Gal N) and lipopolysaccharide (LPS). The survival rate, liver function, inflammatory factor and liver pathological change were obtained with and without SNMC treatment. Hepatocyte survival was estimated by observing the stained mitochondria structure with terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) method and antibodies against cytochrome C (Cyt-C) and caspase-3.

**RESULTS:** The levels of plasma tumor necrosis factor alpha (TNF- $\alpha$ ), nitric oxide (NO), ET-1, interleukin-6 (IL-6), and the degree of hepatic tissue injury were decreased in the SNMC-treated groups compared with those in the model group ( $P < 0.01$ ). However, there were no differences after different dosages administered at different time points. There was a significant difference in survival rates between the SNMC-treated groups and the model group ( $P < 0.01$ ). The apoptosis index was 32.3% at 6 h after a low dose of SNMC, which was considerably decreased from 32.3%  $\pm$  4.7% vs 5%  $\pm$  2.83% ( $P < 0.05$ ) to 5% on d 7. The expression of Cyt-C and caspase-3 decreased with the prolongation of therapeutic time. Typical hepatocyte apoptosis was obviously ameliorated under electron microscope with the prolongation of therapeutic time.

**CONCLUSION:** SNMC can effectively protect liver against FHF induced by LPS/D-Gal N. SNMC can prevent hepatocyte apoptosis by inhibiting inflammatory reaction

### INTRODUCTION

Fulminant hepatic failure (FHF) is clinically characterized by prolonged prothrombin time and hepatic encephalopathy. It has been known that the onset of acute and chronic hepatitis is related to the inflammatory necrosis resulting from cell immunity and abnormal hepatocyte apoptosis caused by injury in mitochondria<sup>[1,2]</sup>. Stronger neo-minophagen C (SNMC), a compound mainly composed of glycyrrhizic acid, has anti-inflammatory and anti-allergic effects. However, it is not clear whether this compound protects liver against FHF<sup>[3]</sup>. The present study was to clarify the effect of SNMC on immune-mediated injury and hepatic cell apoptosis and its mechanism underlying liver failure induced by endotoxin.

### MATERIALS AND METHODS

Kunming mice weighing 18-20 g at the age of 6-7 wk were provided by the Center of Experimental Animals of Harbin Medical University. Female mice were never impregnated and reproduced. SNMC was obtained from Minofayan Pharmaceutical Co, Ltd, Japan. Galactosamine (D-Gal N) and lipopolysaccharide (LPS) were purchased from Sigma. Nitric oxide (NO) fluorescein reagent kit was obtained from Jian Cheng Bio-Engineering Research Institute (Nanjing, China). Tumor necrosis factor alpha (TNF- $\alpha$ ), ET-1, interleukin-6 (IL-6) radioimmunoassay reagent kits were bought from Radioimmunoassay Institute, General Hospital of Chinese PLA. Caspase-3 monoclonal antibody was from Sigma. Anti cytochrome C (Cyt-C) antibody immunohistochemistry staining reagent kit and terminal deoxynucleotidyl transferase-mediated

**Figure 1** Optical microscopy showing liver cell apoptosis and necrosis (A) and liver cell necrosis (B) 24 h (C), 36 h (D), 72 h (E) after given SNMC (HE,  $\times 20$ ).

deoxyuridine triphosphate fluorescence nick end labeling (TUNEL) reagent kit were purchased from Zhongshan Biotechnology Co, Ltd (Beijing, China).

### Preparation

D-Gal N (1000 mg/kg) and LPS (100  $\mu$ g/kg) were injected into the abdominal cavity of mice to induce FHF. Pathological changes in liver tissues corresponded to the FHF pathological features (Figure 1A and B). One hundred and ten mice were randomly divided into control group, model group and treatment group. Mice in the control group were administered SNMC for a week before LPS/D-Gal N treatment. Mice in the model group were given SNMC and LPS/D-Gal N at the same time. Mice in the treatment group were injected with LPS/D-Gal N 8 h after SNMC was given. The results showed that 280 mL, 200 mL and 140 mL SNMC had the most significant protective effect. The survival rate of mice in the model group after injected 140 mL SNMC was the highest. Then 60 mice were given 140 mL SNMC and 5 mice in each group were sacrificed 6 h, 1 d, 3 d and 7 d after LPS/D-Gal N injection. Liver tissue was collected for immunohistochemical analysis. Pyrogen free blood sample was obtained from eyeball and centrifuged for 10 min at 3000 r/min to get serum/plasma. Serum and plasma were stored at  $-20^{\circ}\text{C}$ .

### Experiment

TNF- $\alpha$ , ET-1, IL-6 were determined by radioimmunoassay (RIA). The nitrate reductase method was employed to analyze NO. Alanine aminotransferase (ALT), total bilirubin (TBIL) and albumin (ALB) were analyzed with fully automatic biochemical instruments.

Four pieces of the left lobe of liver were taken. One was fixed in 2.5% glutaraldehyde for electron microscopy (EM), 2 were fixed in 4% paraformaldehyde and embedded in paraffin for immunohistochemical analysis, and 1 was fixed in 10% formalin and embedded in paraffin for

histological examination.

Routinely deparaffinized and rehydrated sections were stained with cell apoptosis detection kit according to the manufacturer's instructions. The sections were visualized with diaminobenzidine (DAB). The apoptosis index was calculated and the degree of hepatocyte apoptosis was determined. The cells with brown nuclei and cytoplasm were regarded as apoptotic cells, whereas the cells with blue nuclei were considered normal cells. The sections were incubated with monoclonal antibodies against caspase-3 (1:100) and Cyt-C antibody (1:100) after routine deparaffinization and rehydration, and stained with DAB and counterstained with hematoxylin.

### Statistical analysis

The data were expressed as mean  $\pm$  SD. All statistical analyses were performed using the Statistical Program for Social Sciences (SPSS 10.0 for Windows). F test was used for comparing variables. The 95% confidence interval for all estimates was provided when appropriate.  $P < 0.05$  was considered statistically.

## RESULTS

### Survival rate within 24 h

All the mice of the control group were alive at the end of experiments. Death occurred in the model group at 6 h after LPS/D-Gal N treatment and all mice died within 21 h. Death occurred in the SNMC-treated group at 8 h and all the survivors lived for more than 24 h. The survival rate for the model group was 60% after 140 mL SNMC was given.

### Liver tissue histophysiological response

In the control group, the structure of hepatic lobules was intact, and the hepatocytes were radially arranged around the central vein. In the model group, histological hepatocyte damage with slight hydropic degeneration

$F_{(4,29)} = 2.70$ .

could be seen 3-5 h after the administration of D-Gal N and LPS. Furthermore, pronounced hydropic degeneration, slight spotty necrosis and apoptotic bodies (Figure 1A) could be observed 6 after administration of D-Gal N and LPS. Widespread necrosis (exceeding 2/3 of the whole slide), dissociated hepatocytes with loss of the normal structure of liver, hemorrhage and neutrophil and lymphocyte infiltration were seen mainly in necrosis area and periportal zone 12 h after administration of D-Gal N and LPS (Figure 1B). However, various degrees of hydropic and vacuolar degeneration were found in the model group 24 h after administration of 140 mL SNMC (Figure 1C). In the model group, marked cytoplasm rarefaction was found 36-48 h after administration of D-Gal N and LPS (Figure 1D), while sporadic and focal necrosis (Figure 1E) as well as inflammatory cell infiltration were found 72 h after administration of D-Gal N and LPS.

#### Levels of TNF- $\alpha$ , ET-1, IL-6, ALT, ALB, and TBIL in control, model and treatment groups

The F values were determined in the control, model and treatment groups. The results were as follows: F (NO) = 58.328, F (TNF- $\alpha$ ) = 69.489, F (ET-1) = 57.328, F (IL-6) = 46.914, F (ALT) = 3.257, F (TBIL) = 7.477, [ $F_{(4,25)0.05} = 2.76$ ,  $P < 0.05$ ]. F (ALB) = 1.204, NS. The F values in the treatment group were as follows: F (NO) = 2.676, F (TNF- $\alpha$ ) = 2.043, F (ET-1) = 3.347, F (IL-6) = 2.676, F (ALT) = 0.452, F (ALB) = 1.535, F (TBIL) = 0.020, [ $F_{(2,12)0.05} = 3.68$ , NS]. The F values in different groups injected with different dosages of SNMC were as follows: F (NO) = 84.907, F (TNF- $\alpha$ ) = 44.519, F (ET-1) = 13.236, F (IL-6) = 37.760, F (ALT) = 2.904, F (TBIL) = 7.681, [ $F_{(4,25)0.05} = 2.76$ ,  $P < 0.05$ ], F (ALB) = 1.004, NS. The results of

different dosages were: F (NO) = 3.351, F (TBIL) = 2.756, [ $F_{(2,12)0.05} = 3.68$ , NS], with no significant differences (Table 1).

#### Results of electron microscopy (EM)

In the control group, the hepatocytes with prominent nuclei were well arranged in plates and abundant in structure of intracellular membrane. However, the model group showed condensed nuclei, chromatin margination, enlarged mitochondria, and derangement of plasmalemma and inner cytomembrane (Figure 2A). Condensed nuclei, chromatin margination, and enlarged rough endoplasmic reticulum (RER) showing degranulation were present in the 140 mL SNMC group. Normal bilayer nuclear membrane, abundant crista mitochondria, moderate density of matrix, tight cholangiole junctions and intact endothelium of the hepatic sinusoid were observed 3 d after administration of SNMC (Figure 2B). After 7 d, the structure of liver cell membranes was intact, the cell organs were rich, the crista mitochondria were dense, the matrix density was moderate, and the structure of hepatic sinusoid endothelia was intact. We could see the penetration of liver cell microvilli inside the Disse interspace (Figure 2C).

#### Detection of hepatocyte apoptosis

Two sections from each group were observed at each indicated time. Five visual fields of each section were analyzed, and 100 cell nuclei were counted in each visual field. The average percentage of hepatocyte apoptosis was considered the index of apoptosis<sup>[4]</sup> (Table 2). The apoptotic cells were characterized by intact bilayered cytomembrane and condensed nuclei. Nuclei and/or cytoplasm with brown staining (leakage of nuclear DNA) were assessed as positive staining. Besides, the apoptotic bodies were also positively stained. No apoptotic cells were

found in the control group. More apoptotic liver cells were found mainly in the necrosis area of the model group with the prolongation of time.

### Detection of cytosol cytochrome C (Cyt-C) and caspase-3

Cytoplasm with brown staining was assessed as positive. Three fields randomly selected from each section were chosen to detect Cyt-C and caspase-3 positive cells under optical microscope at a magnification of 400. The mean value was considered the positive cell number of each group (Table 2). In the control group, hepatocytes were normal in size and shape and well arranged. Cyt-C and caspase-3 were expressed only in a few scattered cells. In the model group, liver cells were mainly expressed in the inflammation necrosis area and portal area, and showed positive Cyt-C and caspase-3 staining. In the treatment group, the expression of Cyt-C and caspase-3 was gradually decreased and the structure of liver cells was gradually recovered with the prolongation of time.

## DISCUSSION

It is well-known that virus infection results in primary liver injury and endotoxin, by which inflammatory mediator-induced secondary liver injury is caused, leading to hepatocyte apoptosis and necrosis<sup>[5]</sup>. TNF- $\alpha$ , one of the most important inflammatory mediators, induces hepatocyte apoptosis and necrosis through the activation of caspase-3, leading to liver cell DNA shift<sup>[6]</sup>. In the present study, SNMC reduced serum level of ALT, ALB and total bilirubin, and attenuated hepatocyte apoptosis, leading to the secondary liver injury induced by LPS. Its related mechanisms such as reducing the release of NO and ET-1, restraining the formation of hepatic sinusoid microthrombi and microcirculation dysfunction, inhibiting immunologic injury caused by cytokines especially TNF- $\alpha$ , and suppressing the formation of endotoxin, may contribute to the protective effect against FHF<sup>[7]</sup>. However, in the present study, SNMC failed to raise the albumin levels during FHF, probably due to the longer half life of albumin.

Most researchers believe that abnormal hepatocyte apoptosis contributes significantly to the occurrence of FHF<sup>[8]</sup>. The crucial role of mitochondria and Cyt-C in hepatocyte survival and death has caused more and more attention. Some mediators in the mitochondria are closely associated with cell apoptosis, including Cyt-C, apoptosis inducing factor (AIF) and reactive oxygen species (ROS). Under the stimulation of apoptosis signals, augmented mitochondrial membrane permeability initiates a series of key changes including release of Cyt-C, decrease in mitochondrial transmembrane potential, alteration of the oxidation-reduction system inside the cells and intervention with the Bcl gene family, thus finally leading to hepatocyte apoptosis<sup>[9]</sup>.

TUNEL staining results indicated that the apoptosis index in the treatment group decreased from 32.3% at 6 h to 5% on d 7 after LPS/D-Gal N injection ( $P < 0.05$ ). Typical morphological changes during apoptosis, including nucleus shrinkage and chromatin margination *etc*, were

**Table 2** Hepatocyte apoptosis index and number of cells expressing Cyt-C and caspase-3 (mean  $\pm$  SD, number/HP)

<sup>b</sup> $P < 0.01$  vs the model group. Apoptosis index:  $t_{6h} = 0.56$ ,  $t_{1d} = 4.10$ ,  $t_{3d} = 8.26$ ,  $t_{5d} = 13.73$ ,  $t_{7d} = 17.52$ . Cyt-C:  $t_{6h} = 0.72$ ,  $t_{1d} = 9.45$ ,  $t_{3d} = 20.1$ ,  $t_{5d} = 24.46$ ,  $t_{7d} = 31.99$ . Caspase-3:  $t_{6h} = 1.09$ ,  $t_{1d} = 12.2$ ,  $t_{3d} = 26.9$ ,  $t_{5d} = 47.2$ ,  $t_{7d} = 62.9$ .

observed under electron microscope (EM) in the model group. The treatment group improved proportionately with the prolongation of therapeutic time. The results suggest that SNMC can effectively attenuate hepatocyte apoptosis.

The release of Cyt-C is a key event in the apoptosis process<sup>[10]</sup>. Cyt-C has a duplex function as an initiator to activate cell apoptosis and participate in electron transfer. Cyt-C shifting to the cytoplasm could bring about a cascade of reactions of caspases, finally activate caspase-3 and result in hepatocyte apoptosis. Immunohistochemistry staining demonstrated that Cyt-C and caspase-3 expression was significantly reduced in treatment group with the prolongation of therapeutic time when compared with the model group ( $P < 0.01$ ), suggesting that the expression of caspase-3 is closely related with Cyt-C and possibly regulated by releasing Cyt-C. Meanwhile, we speculated that SNMC inhibited the progression of hepatocyte apoptosis mainly by stabilizing the mitochondrial membrane and inhibiting the release of Cyt-C and subsequent caspase-3 activations.

The present study demonstrated that SNMC not only reduced serum aminotransferase and bilirubin, but also attenuated the hepatocyte apoptosis. SNMC reduced the necrotic area and increased the survival rate of mice by promoting hepatocyte regeneration and recovery of denatured cells, and protecting the undamaged cells. However, the dosages of SNMC in the treatment of FHF and the therapeutic time have not yet been firmly established. The low dose administered in this experiment corresponds to ordinary clinical dosages. Whether high dose would bring about toxic effects or other side effects awaits future study.

In summary, the results of the present study support SNMC treatment for FHF, but the precise mechanism should be further studied.

## COMMENTS

### Background

It is well-known that virus infection results in primary liver injury and endotoxin, by which inflammatory mediator-induced secondary liver injury is caused, thus finally leading to hepatocyte apoptosis and necrosis. Most researchers believe that abnormal hepatocyte apoptosis contributes significantly to the occurrence of FHF.

### Research frontiers

SNMC, a compound mainly composed of glycyrrhizic acid, has anti-inflammatory and anti-allergic effects. However, it is not clear whether this compound protects liver against FHF. The present study was to clarify the effects of SNMC on immune-mediated injury and hepatic cell apoptosis and its related mechanisms underlying liver failure induced by endotoxin.

### Innovations and breakthroughs

SNMC can effectively protect liver against FHF induced by LPS/D-Gal N. SNMC prevents hepatocyte apoptosis by inhibiting inflammatory reaction and stabilizing mitochondria membrane to suppress the release of Cyt-C and sequent activation of caspase-3.

### Applications

SNMC can not only reduce serum aminotransferase and bilirubin, but also the mortality of patients with FHF.

### Terminology

SNMC, a compound mainly composed of glycyrrhizic acid, has anti-inflammatory and anti-allergic effects.

### Abstract

Angiolipoma is a common benign tumor with a characteristic vascular component that usually occurs in subcutaneous tissue. Although lipomas are frequently encountered at colonoscopy as submucosal tumors, angiolipomas are rarely found in the gastrointestinal tract including the large intestine. Here we report a 77-year old Japanese man who underwent transanal resection of a tumor that was diagnosed tentatively as a leiomyoma. Histologically, the tumor consisted of mature fat cells and blood vessels. Immunohistochemically, the tumor cells were negative for c-kit and HMB-45, which are consistently expressed in tumors such as gastrointestinal stromal tumor and angiomyolipoma. The tumor was therefore diagnosed as an angiolipoma. This is thought to be the first case report of a surgically resected angiolipoma of the rectum.

### INTRODUCTION

Angiolipomas are subcutaneous tumors made up of mature fat and prominent blood vessels, and usually occur in young adults and older teenagers. They are rarely larger than 2 cm in diameter, frequently multiple, and characteristically tender or painful<sup>[1]</sup>. The most common

locations are the forearm, trunk, and upper arm, and they rarely occur in the gastrointestinal tract. Grossly, angiolipomas are well circumscribed and yellow with varying amounts of red surface. A characteristic feature is fibrin thrombi within the vessels. The proportion of adipose and vascular tissue varies from predominantly lipomatous to predominantly angiomatous. Here we describe the first case of rectal angiolipoma diagnosed postoperatively.

### CASE REPORT

A 77-year old Japanese man was admitted to our hospital with a 1-year history of anal bleeding. The patient lacked any findings suggestive of tuberous sclerosis. He had no cutaneous or retinal lesions, neurologic symptoms, or evidence of mental retardation. The family history and past medical history were unremarkable. All routine laboratory parameters, including carcinoembryonic antigen, were within normal limits. A double-contrast barium enema revealed a sessile lesion in the periproct area measuring 20 mm × 15 mm (Figure 1). A subsequent colonofiberscopy disclosed a sessile-type submucosal tumor with internal hemorrhoids, and the tumor had no reddish depression or ulceration at its top (Figure 2). The other parts of the colon and rectum appeared normal. A biopsy specimen revealed proliferation of the muscle component with no atypical cells. A tentative diagnosis of leiomyoma was therefore made. Enhanced CT of the abdomen demonstrated a partially enhanced mass lesion with fat component which was not suspected of having infiltrated the proper muscle layer, on the right wall of the lower rectum (Figure 3). Trans-anal endoscopic ultrasonography revealed that the tumor was located in the submucosal layer. Because the tumor was considered to be benign, and difficult to resect by endoscopic surgery, we elected to perform trans-anal tumor resection with an ultrasonically activated device (Harmonic Scalpel<sup>®</sup>) to prevent bleeding from the internal hemorrhoids. Under general anesthesia, with the patient in the lithotomy position, we were able to approach the anal side of the tumor easily and resect it without massive oozing. Complete resection was performed with a sufficient surgical margin from the submucosal tumor. The total operation time was 42 min and bleeding was only slight. The postoperative course was uncomplicated, and the patient was discharged five days later. He was followed up for 12 mo at the outpatient clinic and no tumor recurrence was observed during that time. Macroscopic observation revealed that the sessile tumor, measuring 2

**Figure 1** Double-contrast barium enema revealing a 20 mm × 15 mm sessile lesion in the periproct area (arrows).

**Figure 2** Colonoscopy disclosing a sessile lesion with a smooth surface.

**Figure 3** Enhanced CT of the lower abdomen demonstrating a fat-containing and slightly enhanced mass at a slice level corresponding to the right side of the lower rectum (arrow).

**Figure 4** The tumor composed of a mixture of fat cells, proliferated blood vessels, spindle cells and immature mesenchymal cells (A), smooth muscle of a blood vessel demonstrating staining for alpha-smooth muscle actin but not for spindle cells (B), no tumor cells but only a few histiocytes displaying staining for c-kit (C), and no cells showing positive staining for HMB-45 (D).

cm × 1.5 cm × 1 cm, was yellowish in color, located in the submucosal layer and covered with normal mucosa. A cross-section of the formalin-fixed tumor revealed massive growth without a capsule. The proper muscle layer was not infiltrated by the tumor. The tumor consisted of mature fat cells and blood vessels of various sizes. No mitoses or cytological atypia were found in the cells. Immunohistochemical staining for alpha-smooth muscle actin, S-100 protein, HMB-45 and c-kit was performed. Only the blood vessels were positive for alpha-smooth muscle actin, and the tumor cells were negative for HMB-45, c-kit and S-100 (Figure 4).

## DISCUSSION

Angiolipoma was first described in 1912 by Bowen<sup>[2]</sup>. In 1960, Howard and Helwig<sup>[3]</sup> demonstrated that the clinicopathologic features of angiolipomas differ from those of lipomas, thereby delineating angiolipoma as a new entity.

Angiolipomas usually develop as encapsulated subcutaneous tumors, most commonly on the arms and trunk in young adults. Only 15 cases of angiolipoma occurring in the gastrointestinal tract were found in a MEDLINE search. These angiolipomas were located in the esophagus in one case<sup>[4]</sup>, the stomach in 4 cases<sup>[5-8]</sup>, the small intestine in 5 cases<sup>[9-13]</sup> and the colon in 5 cases<sup>[14-18]</sup>. The search revealed no reported cases of rectal angiolipoma. There are clinical differences between angiolipomas located in the gastrointestinal tract and those commonly occurring in subcutaneous tissue. The 15 reported gastrointestinal lesions were all solitary, and 4 showed bleeding from the tumor<sup>[5,8,9,13]</sup>, all except one<sup>[7]</sup> occurring in elderly patients. In the bleeding cases, the tumor was over 2 cm in diameter and the bleeding point was located on the top of the tumor<sup>[14,16]</sup>, which had a pumpkin-like shape<sup>[16]</sup>. In the present case, the tumor was less than 2 cm in diameter and its surface was covered with smooth and normal mucosa. It was thought that the tumor was too small to show a bleed-

ing tendency. The differential diagnosis of angiolipoma includes angiomylipoma<sup>[19]</sup>, which is composed of smooth muscle, fatty tissue and blood vessels. Because a minor smooth muscle component was recognized in this case, the initial pathological diagnosis was angiomylipoma. However, examination in detail showed that proliferation of the lamina muscularis mucosae might have caused physical irritation, especially during defecation, and that the smooth muscle component was not a dominant component of the tumor. Additionally, immunohistochemical staining for HMB-45 was effective for differential diagnosis between angiolipoma and angiomylipoma. In this case, HMB45 staining was negative. However, there is a case report of angiomylipoma that was immunohistochemically negative for HMB45<sup>[15]</sup>. In addition, pathologically, angiomylipoma is common in the kidney and is often associated with dermatomyositis.

Angiomylipoma is difficult to diagnose preoperatively and is usually diagnosed as lipoma.

Surgical excision is the treatment of choice. The recurrence rate is high in cases that are inadequately resected, but when the tumor can be removed completely, the prognosis is excellent. In this case, we selected transanal tumor resection because of the difficulty to obtain a good field for performing endoscopic resection<sup>[20]</sup> or transanal endoscopic microsurgery for this periproctoc tumor with internal hemorrhoids that would bleed easily. Transanal tumor resection allowed us to obtain a good field and we were able to minimize bleeding from the internal hemorrhoids by removing the tumor with a Harmonic Scalpel<sup>®</sup> with a sufficient surgical margin.

devastating disease, especially when it is complicated with peritonitis carcinomatosa, which has no effective treatment at all up to date. On the other hand, the introduction of novel antineoplastic agents and protocols has led to certain improvement in the treatment of gastric cancer, including distant metastasis and/or malignant ascites. Here we report a case of scirrhous gastric cancer with peritonitis carcinomatosa, treated with repetitive courses of TS-1<sup>®</sup> (Tegafur-Gimeracil-Oteracil potassium) plus paclitaxel, which resulted in partial remission with disappearance of malignant ascites for over 28 mo, and survival of the patient for 36 mo after diagnosis.

## Abstract

A 34-year-old female complaining of abdominal fullness was diagnosed as scirrhous gastric cancer (type 4') with peritonitis carcinomatosa in July 2002. A combined chemotherapy regimen was selected to control massive ascites; TS-1<sup>®</sup> 80 mg/m<sup>2</sup> was given orally on d 1-14, 22-35, and paclitaxel 50 mg/m<sup>2</sup> was administered intravenously on d 1, 8, 22 and 29. After 2 courses of this regimen, the primary tumor was markedly reduced, and ascites completely vanished. Alopecia (grade 1, since d 30), leukocytopenia (grade 2, on d 34) and anemia (grade 2, on d 34) were the only adverse events throughout the following courses. The chemotherapy was effective for 28 mo, and then it was discontinued upon the patient's own request, and she survived for 36 mo after diagnosis.

## INTRODUCTION

Scirrhous gastric cancer has long been, and still is a

## CASE REPORT

A 34-year-old female, complaining of abdominal fullness, visited our hospital on 15th July, 2002. She has been disturbed by epigastric discomfort, increasing abdominal fullness and severe constipation for about a month. And she gained weight by 5-6 kg within 2 mo. Physical examinations showed obvious abdominal distension with an abdominal circumference of 80.0 cm, and body weight of 60 kg for a height of 167.5 cm. A low grade fever (37.2°C) was the only abnormal finding in vital signs. Laboratory data revealed no major abnormalities other than hypercholesterolemia. CEA and CA19-9 were within normal range, while CA125 was slightly elevated (Table 1). A paracentesis was performed to examine the ascites, and the findings were as follows: turbid and yellow colored, specific gradient = 1.034, with 1070 cells/mm<sup>3</sup> including many clusters of adenocarcinoma cells. A gastroscopy revealed conspicuous swelling of gastric fold with multiple erosions, and poor wall expansion exclusively at the body. The antral mucosa seemed almost intact except one submucosal tumor (SMT) like lesion at the greater curvature. Expandability at the antrum was fair (Figure 1A-C). A biopsy examination confirmed poorly differentiated adenocarcinoma and signet ring cell carcinoma. In upper GI series, the wall expansion was poor at the body (Figure 2A). Local and distant lymph node metastases were unlikely on CT scan images; yet massive ascites were detected, extending from the liver surface to the pelvic cavity (Figure 3A and B). A barium enema revealed severe stenosis of the rectosigmoid colon, probably caused by the extrinsic compression due to peritonitis carcinomatosa (Figure 4A). We therefore diagnosed this case as "scirrhous gastric cancer (type 4') with peritonitis carcinomatosa".

We selected TS-1<sup>®</sup> and paclitaxel as a combined

**Figure 1** Gastroscopic findings at diagnosis (upper lane, A-C) and after 4 courses of chemotherapy (lower lane, D-F). **A:** Lower body: Wall thickening and erosions can be observed; **B:** Mid body: Wall expandability is extremely poor in this part; **C:** Antrum: An SMT like lesion at the greater curvature suggests submucosal invasion of the cancer; **D:** Lower body: Wall thickening is less prominent; **E:** Mid body: Wall expandability has drastically improved; **F:** Antrum: the SMT like lesion has disappeared.

chemotherapy regimen. TS-1® 80 mg/m<sup>2</sup> was given orally on d 1-14 and 22-35, and paclitaxel 50 mg/m<sup>2</sup> was administered intravenously on d 1, 8, 22 and 29. One course consisted of 35 d, and the following 2 wk were spent as a drug-free period. After 2 courses, the primary tumor was markedly reduced, and the gastric wall expandability improved (Figure 1D-F) (Figure 2C). Ascites have completely vanished (Figure 3C and D), and wall expandability of the sigmoid colon was also improved (Figure 4B).

Adverse effects were carefully monitored and evaluated according to the NCI-CTC criteria. Transient leukocytopenia (grade 2, WBC 2700/μL) and anemia (grade 2, Hb 93 g/L) were observed on d 34, however, both improved during the late courses. Alopecia (grade 1, since d 30) was the only adverse event throughout the following courses.

Since the 1st of August 2002, this regimen was performed predominantly at home, except during the days of paclitaxel infusion (2 days' admission for each), and 27 courses have been completed with the patient in partial remission state, with neither ascites progression nor impairment of activity of daily living. In November 2004, the patient requested to stop further treatment, and the chemotherapy was disrupted in the 28th month since the initial diagnosis. After a 2 mo interval, the patient was, again, hospitalized for the recurrence of massive ascites in January 2005. TS-1® + paclitaxel regimen was resumed immediately; yet the control of ascites was difficult. Despite following several months of treatment, the patient died of peritonitis carcinomatosa in July 2005, 36 mo

**Table 1** Laboratory findings on admission

WBC	5.3 × 10 <sup>9</sup> /L	ALP	142 IU/L
Neutrophil	75.4%	Total bilirubin	5 mg/L
Eosinophil	1.9%	Glucose	830 mg/L

Platelet	2.6 × 10 <sup>11</sup> /L	CA19-9	9.7 kU/L
Total protein	67 g/L	CA125	44 kU/L
Albumin	37 g/L	PT	10.6 s (99%)
GOT	23 IU/L	APTT	29 s
GPT	21 IU/L	Fbg	2600 mg/L
LDH	275 IU/L		

Hypercholesterolemia and mild elevation of CA125 were the only abnormal findings. WBC: White blood cells; RBC: Red blood cells; MCV: Mean corpuscular volume; MCH: Mean corpuscular hemoglobin; MCHC: Mean corpuscular hemoglobin concentration; GOT: Glutamic oxaloacetic transaminase; GPT: Glutamic pyruvic transaminase; LDH: Lactate dehydrogenase; ALP: Alkaline phosphatase; BUN: Blood urea nitrogen; CRP: C-reactive protein; CEA: Carcinoembryonic antigen; CA19-9: Carbohydrate antigen 19-9; CA125: Carbohydrate antigen 125; PT: Prothrombin time; APTT: Activated partial thromboplastin time; Fbg: Fibrinogen.

after the diagnosis. The primary tumor in the stomach has been reduced in size, and no metastases other than in peritoneum were detected.

**Figure 2** Upper gastrointestinal series before (A) and after treatment (B). A: At diagnosis, wall thickening and loss of expandability is prominent at the body, while normal mucosa is relatively spared at the antrum; B: After 6 courses of chemotherapy, the expandability at the body has restored.

**Figure 3** CT scan findings before (Left, A and C) and after 6 courses of chemotherapy (Right, B and D). A: Antral level: Wall thickening at the body and massive ascites are detected; B: Antral level: Wall thickening at the body is less prominent and no ascites can be observed; C: Pelvic level: Massive ascites extend to pelvic level; D: Pelvic level: Ascites have completely vanished.

## DISCUSSION

The prognosis of scirrhous gastric cancer (type 4<sup>a</sup>) is extremely poor, and the 5-year survival rate is reported to be 8.7%-11.3%<sup>[1,2]</sup>. According to Green *et al*<sup>[3]</sup>, the median survival time (MST) is estimated to be 5.4 mo with chemotherapy, and 1.1 mo with best supportive care. Peritoneal invasion is found in many advanced cases, and even after treatment most of them recur with peritonitis carcinomatosa. Many attempts have been made to treat these cases, for example, systemic/intraperitoneal administration of antineoplastic agents, immunomodulative therapy or hyperthermia, yet none of them have proved prominent efficacy.

On the other hand, TS-1<sup>®</sup>, both in monotherapy and combined chemotherapy, has shown superior results in the treatment of gastric cancer. In a phase II trial in Japan, single administration of TS-1<sup>®</sup> yielded a higher efficacy (46.5%, 60/129 cases), longer MST (8.1 mo), with a lower incidence of adverse events than historical controls (5-FU, DXR, MTX + LV, CDDP). It proved to be one of the

most promising antineoplastic agents<sup>[4]</sup>. However, against poorly differentiated gastric cancer, the agents above are effective in only a certain proportion of patients. Peritonitis carcinomatosa is especially difficult to treat and is critical to the prognosis. There are several case reports demonstrating the effect of TS-1<sup>®</sup>, as a monotherapy, against malignant ascites, but evidences from clinical trials are yet to come. To achieve a higher response rate in treating peritonitis carcinomatosa, local concentrations of the agents in ascites are an important factor, and the agents should have different pharmacological effects from TS-1<sup>®</sup>. Taking these into consideration, we selected paclitaxel as the counterpart of TS-1<sup>®</sup>, based on the evidence that paclitaxel is highly infiltrative into ascites<sup>[5]</sup>.

Paclitaxel is a novel antimetabolic agent, which promotes tubulin polymerization and stabilizes microtubules, resulting in inhibition of mitosis. Besides, it is said to induce tumor apoptosis and inhibit tumor angiogenesis<sup>[6]</sup>. This agent has been selected as one of the second-line drugs against gastric cancer, especially for cases refractory to first-line drugs (i.e., CDDP, 5-FU) or recurrent cases

**Figure 4** Barium enema before (A) and after treatment (B). A: At diagnosis, poorly expandable segments within the rectosigmoid suggest severe malignant ascites; B: After 6 courses of chemotherapy, the rectosigmoidal colon can fully expand with air enema.

after surgery. As a monotherapy, the response rate was 26% in previously treated gastric cancer and 21% in those with prior chemotherapy. And it is remarkable that paclitaxel is the only drug, used in uncombined regimens, that increased over 300 d of MST against advanced and recurrent gastric cancer, regardless of prior treatment history<sup>[7]</sup>. The administration of paclitaxel against previously untreated gastric cancer has seldom been reported, and the evaluation of combined regimens with TS-1<sup>®</sup> is still ongoing in phase I / II studies. At present, the safety of the regimen has been reported in phase I study<sup>[8]</sup>, but the efficacy is yet to be proved.

In this aspect, our report suggested important findings; the combined regimen of paclitaxel + TS-1<sup>®</sup> was safely administered for previously untreated gastric cancer patient, and it was remarkably effective against massive invasion of the cancer, peritonitis carcinomatosa. With the development of many other combined regimens, the treatment against gastric cancer would have various choices. At least, TS-1<sup>®</sup> + paclitaxel could be one of the first-line regimens against far advanced gastric cancer, especially poorly differentiated adenocarcinoma complicated with peritonitis carcinomatosa.

## Abstract

Pancreatic tuberculosis is an extremely rare form of extrapulmonary disease. The diagnosis preoperatively is difficult because clinical, laboratory and radiologic findings are nonspecific. Published data indicate that these lesions mimic cystic neoplasms of the pancreas and the confirmation of clinical suspicion could only be obtained by an open surgical biopsy. Recently, fine needle aspiration cytology has been shown to be a safe, reliable and cost-effective alternative. We report a new case of a peripancreatic tuberculosis in a 52 year old woman and review the relevant literature, paying special attention to the usefulness of endoscopic ultrasound guided-fine needle aspiration in the diagnosis of abdominal tuberculosis.

<http://www.wjgnet.com/1007-9327/13/474.asp>

## INTRODUCTION

Tuberculosis is a potentially systemic disease that can affect any organ<sup>[1]</sup>. Extra-pulmonary organ involvement of tuberculosis is estimated to occur in 10% to 15% of

the patients noninfected by HIV. With the increasing use of immunosuppressants and the emergence of AIDS, there has been a resurgence of tuberculosis and the frequency is about 50% to 70% in patients infected by HIV<sup>[2]</sup>. Abdominal tuberculosis is one of the most prevalent forms of extra-pulmonary diseases. Abdominal infection with tuberculosis commonly affects the spleen, liver and ileo-cecal region. Pancreatic tuberculosis is an extremely rare disease, especially when it is isolated in the pancreas<sup>[3]</sup>. The abdominal form of tuberculosis has an insidious course without any specific clinical, laboratory or radiological findings<sup>[4]</sup>. As a result, the diagnosis of abdominal tuberculosis is correct in only 35%-50% of cases and a diagnostic delay is not unusual<sup>[5]</sup>. Most cases are not diagnosed preoperatively because special staining of biopsy specimens is necessary and cultures of the aspirate require prolonged incubation<sup>[6]</sup>.

A case is presented that highlights the benefit of endoscopic ultrasound (EUS) for evaluation of pancreatic and peri-pancreatic lymphadenopathy tuberculosis. In particular, this case demonstrates the value to obtain suitable tissue samples by EUS fine needle aspiration, thus avoiding unnecessary surgical explorations.

## CASE REPORT

A 52-year-old woman, native of a small city in Lebanon, was admitted to the hospital for abdominal pain and fever. She was a cigarette smoker (60 pq/year) without excessive alcohol consumption and had a history of pulmonary embolism. She had been well until one month earlier, when mild epigastric pain developed. Four days before admission, the abdominal pain became constant and severe and nausea developed. She had also chills without frank rigors and a weight loss of 8 kg. The temperature was 38.5°C, the pulse was 100 beats/min, and the respiratory rate was 20 breaths/min. The blood pressure was 130/85 mmHg. On physical examination, the patient did not appear to be severely suffered and there was no jaundice. The lungs and heart sounds were normal. The abdomen was flat, and bowel sounds were present. There was a diffuse abdominal tenderness without rebound tenderness. No mass or hernia was detected. The arms and legs were well perfused. No abnormalities were found on rectal examination. The WBC was normal. C reactive protein (CRP) was moderately elevated (40 UI, normal < 6). The plasma levels of urea nitrogen, creatinine, glucose, electrolytes,

**Figure 1** Abdominal computed tomograph revealed a heterogeneously enhanced, multicystic structure, 3 cm in diameter, cephalad to the pancreatic head.

**Figure 2** EUS with a radial echoendoscope revealed a large, 2-2.5 cm anechoic, homogenous, well-defined mass which lay adjacent to the neck of the pancreas.

**Figure 3** EUS-guided FNA of the peripancreatic lesion was performed using a linear-array echoendoscope.

**Figure 4** Staining with Ziel Nielsen within 30 min yielded a positive result for acid-fast bacilli.

bilirubin, amylase and lipase were normal. Activities of aspartate aminotransferase, alanine aminotransferase and alkaline phosphatase were normal. The total protein level was 75 g/L. A stool specimen was negative for occult blood. The urinalysis was normal. Serologic tests of wright and widal were normal. Radiographs of the abdomen in the supine and upright positions showed air-filled loops of the small bowel, without dilatation or air-fluid levels. No abnormal calcifications were identified. Abdominal and pelvic computed tomographic (CT) studies, performed after the oral and intravenous administration of contrast material, revealed a heterogeneously enhanced, multicystic structure, 3 cm in diameter, cephalad to the pancreatic head (Figure 1). The remainder of the pancreas was unremarkable. The liver, spleen, gallbladder, adrenal glands, kidneys, distal small bowel, colon, urinary bladder, and imaged bones were unremarkable, and no retroperitoneal lymphadenopathy was evident. EUS with a radial echoendoscope (GF-UM160; Olympus [key med], UK) revealed a large, 2-2.5 cm anechoic, homogenous, well-defined mass, which lay adjacent to the neck of the pancreas (Figure 2). Another homogeneous tumor, 1 to 1.3 cm in diameter, was detected between splenic vessels. EUS-guided FNA (EUS FNA) of the peripancreatic lesion was performed using a linear-array echoendoscope (GF-UC 160P, Olympus) (Figure 3). Blood-stained cellular aspirates

were obtained in a total of 2 passes with a 22-gauge needle (Echotip; Wilson Cook). An initial examination of the specimen was not diagnostic (squamous cells, macrophages, and inflammatory cells with no malignant tumor cells). Staining with Ziel Nielsen within 30 min yielded a positive result for acid-fast bacilli (Figure 4). Although the patient had no personal or familial history of tuberculosis, the tuberculin test result was positive. The diagnosis of tuberculosis was adopted, and we initiated a four-drug regimen. She was treated with that regimen for 2 months and tolerated it well.

## DISCUSSION

Tuberculosis of the pancreas and peripancreatic lymph nodes in immunocompetent patients is rare and could present a diagnostic challenge<sup>[1]</sup>. The main symptoms are non-specific: epigastric pain, fever, anorexia and weight loss. The duration of symptoms prior to presentation ranges from 5 d to 5 mo<sup>[7]</sup>. This rare infection usually starts in the peripancreatic lymph nodes and initially spares the pancreas<sup>[8]</sup>. Tuberculosis can affect the pancreas either by contiguous spread from the peripancreatic lymph nodes or by hematogenous spread<sup>[9]</sup>.

The diagnosis remains difficult and it is especially difficult to differentiate pancreatic tuberculosis from a

pancreatic tumor<sup>[1]</sup>. Lesions resulting from mycobacterial infection of the pancreas are often complex and cystic and they mimic cystic neoplasms of the pancreas<sup>[10-11]</sup>. Their cystic nature and the finding of rim enhancement on CT studies probably reflect the presence of central necrosis<sup>[12]</sup>. The diagnosis of abdominal tuberculosis classically requires microbiological and culture confirmation of mycobacterium tuberculosis<sup>[13]</sup>. In the past, histopathological and/or bacteriological confirmation of the clinical suspicion of abdominal tuberculosis could only be obtained by an open surgical biopsy<sup>[14]</sup>. During recent years, fine needle aspiration cytology (FNAC) has been shown to be a safe, quick, reliable and cost-effective alternative for obtaining tissue for cytopathological and bacteriological examination<sup>[15]</sup>. US guided FNAC is widely accepted as an accurate and safe technique for obtaining tissue from lesions located in virtually any region of the body<sup>[16]</sup>. In a study by Das *et al*<sup>[17]</sup>, US guidance helped in obtaining an adequate sample in a significantly higher percentage of cases (84.6%) compared with non-guided FNAC (61.5%). On the basis of cytomorphological analysis, results were classified into four groups as follows: (1) definite evidence of tuberculosis: epithelioid granulomas or necrotic material positive for acid-fast bacilli (AFB); (2) presumptive evidence of tuberculosis: epithelioid granulomas with or without necrosis but negative for AFB; (3) suggestive of tuberculosis, presence of necrotic material only with AFB negativity, but in an appropriate clinical setting and with characteristic radiological findings; (4) negative for tuberculosis, presence of atypical inflammation or inadequate material or non representative samples<sup>[14]</sup>.

EUS has been shown to have a high sensitivity for detecting pancreatic masses, although its ability to distinguish a malignancy from an inflammatory disease may be limited<sup>[18]</sup>. EUS guided-FNA may detect a variety of pathologic processes in the pancreas, including malignant or benign neoplasms, pseudocysts, and reactive changes. Pancreatic EUS guided-FNA allows an accurate and safe diagnosis without the risk, the cost, and the time expenditure of an open biopsy or laparotomy. A review of the literature about image-guided FNA biopsy of the pancreas reveals a relatively high overall sensitivity (64%-98%), specificity (80%-100%), and positive predictive value (98.4%-100%)<sup>[19]</sup>. Recent technologic advances have made EUS-guided FNA of pancreatic lesions practical. In a study by Volmar *et al*<sup>[20]</sup>, a logistic regression analysis showed that for lesions < 3 cm, the EUS-guided FNA method had higher accuracy than US or CT guided-FNA and no statistically significant difference was seen for larger lesions or for the number of FNA passes. Tumor seeding along a needle tract is an established complication of percutaneous sampling of pancreatic masses under CT or transcutaneous US guidance. The risk of peritoneal carcinomatosis appears to be lower with EUS-guided FNA compared with transcutaneous sampling methods<sup>[21]</sup>. This is a potential advantage often cited for EUS-FNA. For these reasons, EUS-guided FNA is the method of choice to obtain a tissue sample from the pancreas.

The present case illustrates the usefulness of EUS guided-FNA in the diagnosis of tuberculous lymphadenitis

involving peripancreatic lymph nodes.

In conclusion, EUS guided FNA offers a safe and accurate method of achieving a diagnosis in patients with suspected abdominal tuberculosis who present with radiologically demonstrable lesions, especially involving the lymph nodes. EUS guided-FNA should be used as a first step in the diagnosis of abdominal tuberculosis. A laparotomy should be performed only when complications develop or the diagnosis remains unclear in spite of these diagnostic modalities.

## Abstract

Isolated pancreatic tuberculosis is an extremely rare condition, more so in an immunocompetent individual. Its presentation as pancreatic abscesses with colonic perforation has not been reported so far. This condition poses difficulties in clinical diagnoses. Herein we report a case who was operated in another hospital for pancreatic abscesses, and referred to our institution later when he developed fecal peritonitis due to colonic perforation. Re-laparotomy, resection and exteriorisation of the colon were done. Acid fast bacilli was seen in the histopathological examination of the resected colon. The patient responded remarkably to anti-tuberculous therapy and two sittings of debridement. Post procedure the patient developed pancreatic fistula, which was managed successfully with stenting. Pancreatic tuberculosis should be considered as a differential diagnosis when pancreatitis is atypical.

## INTRODUCTION

Tuberculosis (TB) of the abdomen is seen in 12% of patients with miliary TB<sup>[1]</sup>. Isolated involvement of the pancreas without miliary TB or immunocompromised status is extremely rare. In view of the non-specific clinical presentation, the disease can elude a diagnosis, but once diagnosed it responds favourably to anti-tuberculous therapies (ATT).

## CASE REPORT

A 28-year-old male patient was admitted to the casualty department with suspected fecal peritonitis 10 d after having undergone a laparotomy and drainage for pancreatic abscesses at another hospital. He was put on continuous peritoneal lavage. The patient had a history of vague back pain for the past 6 mo. The diagnosis was based on a CT scan as he presented with an unexplained and non-responding fever. CT showed multiple hypodense well defined lesions behind the pancreas (Figure 1).

On admission to our institution, the patient was in a state of severe sepsis with ventilator and hemodynamic support. His abdomen was distended and there was feculent discharge from the main wound and drain. The patient underwent an exploratory laparotomy, which revealed 1 L of purulent fluid and two perforations in the transverse colon. The pancreas appeared edematous and collections of pus were found behind the head of the pancreas. Limited segmental excision of the colon, peritoneal lavage, proximal colostomy and end mucous fistula were done. The patient was managed in the intensive care unit (ICU) in the post-operative period. The patient continued to be in sepsis and was performed a re-exploration, lavage, and laparotomy.

Histopathological examinations (HPE) revealed acid fast bacilli (AFB) (Figure 2) in the specimen of the serosal side of the colon and hence the patient was started on streptomycin/isoniazid/rifampicin/ethambutol. The patient recovered well in the post operative period except for increased pancreatic fluid in the drain tube (71 318 IU/L). The ERCP showed pancreatic ductal disruption and a normal biliary tree. Pancreatic stenting was done. Two days later he was operated for the wound closure. The patient improved with ATT/antibiotics/octreotide/ionotropes and nutritional support and was discharged after two

**Figure 1** Low density area within lymph node.

**Figure 2** Acid fast bacilli.

weeks. He has improved and gained weight on follow up. A colostomy closure is planned as he has recovered completely.

## DISCUSSION

TB of the pancreas is a rare disease and the incidence has been reported to be around 0%-4.7%<sup>[2,3]</sup>. So far 38 cases of TB of the pancreas were reviewed in a report published in 2000<sup>[4]</sup> and many more case reports have been published. Various modes of presentation have been reported including pancreatic abscesses<sup>[5]</sup>, acute or chronic pancreatitis, gastrointestinal (GI) bleeding, obstructive jaundice, portal vein obstruction and pancreatic mass mimicking malignancy. Our case is an extremely rare presentation with pancreatic abscesses and colonic perforation. The patient did not have a personal or family history of TB and was immunocompetent with no evidence of any other foci of TB.

Infection is said to involve the pancreas by direct extension, lymphohematogenous dissemination or following reactivation of previous abdominal TB<sup>[5,6]</sup>. Contrast enhanced CT (CECT) scans may demonstrate a focal hypodense mass, diffuse enlargement of the pancreas, but none of the signs are pathognomonic. Ring enhancement or low-density areas within enlarged lymph nodes should make one suspect tuberculous lymph nodes<sup>[7]</sup>.

In the case we have reported the diagnosis of TB was a surprise and was revealed on HPE of the biopsy specimen obtained at a laparotomy<sup>[5]</sup>, the demonstration of AFB is even more rare as most of the abdominal tuberculosis are paucibacillary. Percutaneous image guided fine needle aspiration of suspicious lesions might suggest the diagnosis of tuberculosis, thereby obviating the need for a diagnostic laparotomy<sup>[5]</sup>.

The presence of caseating granulomatous inflammation

is the commonest finding on HPE. In almost half of the patients with extra pulmonary TB, Ziehl Neelson staining for AFB and prolonged culture for mycobacterium tuberculosis has been found negative<sup>[8]</sup>. Very few are diagnosed by FNA/BIOPSY<sup>[5-10]</sup>. Once the diagnosis has been established, the majority of patients with tuberculosis respond favourably to ATT<sup>[5]</sup>.

In view of the nonspecific clinical presentation and absence of pathognomonic features on imaging studies, the physician should be alert and have a high index of suspicion, particularly when dealing with young patients, coming from endemic areas with a short duration of symptoms of common pancreatic diseases.

## Abstract

A 54-year old man with a family history of hyperlipidemia was admitted with a 12 h history of severe generalized abdominal pain associated with nausea, vomiting and abdominal distension. Examination of the abdomen revealed tenderness in the periumbilical area with shifting dullness. Serum pancreatic amylase was 29 IU/L and lipase 44 IU/L, triglyceride 36.28 mmol/L. Ultrasound showed ascites. CT of the abdomen with contrast showed inflammatory changes surrounding the pancreas consistent with acute pancreatitis. Ultrasound (US) guided abdomen paracentesis yielded a milky fluid with high triglyceride content consistent with chylous ascites. The patient was kept fasting and intravenous fluid hydration was provided. Meperidine was administered for pain relief. On the following days the patient's condition improved and he was gradually restarted on a low-fat diet, and fat lowering agent (gemfibrozil) was begun, 600 mg twice a day. On d 14, abdomen US was repeated and showed fluid free peritoneal cavity. The patient was discharged after 18 d of hospitalization with 600 mg gemfibrozil twice a day. At the time of discharge, the fasting triglyceride was 4.2 mmol/L. After four weeks the patient was seen in the clinic, he was well.

## INTRODUCTION

There are many etiologic factors leading to pancreatitis.

Hypertriglyceridemia (HTG) is seldom diagnosed as one of these factors. Pancreatitis secondary to HTG, presents typically as an episode of acute pancreatitis (AP) or recurrent AP, rarely as chronic pancreatitis. Although AP often requires clinicians to rely on laboratory tests, such as serum amylase and lipase, as diagnostic aids, patients with acute pancreatitis secondary to HTG can have normal amylase<sup>[1]</sup> and lipase levels. Furthermore, acute pancreatitis is a recognized cause of chylous ascites<sup>[2]</sup>. Association of normal amylase and lipase acute pancreatitis secondary to HTG with chylous ascites is extremely rare. A PubMed search of the literature revealed no cases with such association. We report here an exceptionally rare case of a 54-year old man with chylous ascites secondary to hyperlipidemic pancreatitis with normal serum amylase and lipase.

## CASE REPORT

A 54-year old man was admitted with a 12 h history of severe generalized abdominal pain associated with nausea, vomiting and abdominal distension. His history was negative for weight loss, malignancy, recent abdominal surgery, travel abroad, abdominal trauma, and underlying liver or kidney diseases. He had a positive family history of hyperlipidemia. Initial examination was notable for a temperature of 37°C, pulse 113 beats/min, respiratory rate 16/min, and blood pressure 130/85 mmHg. The patient appeared ill and examination of the abdomen revealed tenderness in the periumbilical area with shifting dullness but without organomegaly. Rectal examination was normal. The remainder of the examination was unremarkable.

Initial investigations showed hemoglobin level of 150 g/L, total leucocyte count  $12 \times 10^9/L$  (60% neutrophils, 31% lymphocytes) and adequate number of platelets. Blood chemistry, liver function test and coagulation profile were normal. Serum pancreatic amylase was 29 IU/L (normal, 15-55 IU/L) and lipase 44 IU/L (normal, 13-60 IU/L), triglyceride 36.28 mmol/L, total cholesterol 5.2 mmol/L. On the next day serum pancreatic amylase was 45 IU/L, lipase 50.2 IU/L, and fasting triglyceride 25 mmol/L. An antibody to human immunodeficiency virus was negative.

Ultrasound showed fluid collection (ascites) but could not visualize the pancreas. CT of the abdomen and pelvis with contrast showed pelvic ascites (Figure 1A) and inflammatory changes surrounding the pancreas consistent with acute pancreatitis (Figure 1B). The pancreas was well demarcated and homogenous with no focal lesions. No

**Figure 1** CT of the abdomen with contrast showing pelvic ascites (A) and inflammatory changes surrounding the pancreas (B). The pancreas is well demarcated and homogenous with no focal lesions.

abnormal masses or enlarged lymph nodes were found.

Acute pancreatitis secondary to hypertriglyceridaemia was diagnosed despite normal plasma amylase and lipase concentrations. Ultrasound-guided abdomen paracentesis yielded a milky fluid with the following biochemical composition: 3.2 g/L triglycerides, 0.85 g/L cholesterol, 49 g/L total protein, 30 g/L albumin, 0.72 g/L glucose and 121 U/L LDH. Cell count of the fluid was  $230 \times 10^6$ /L and no acid-fast bacilli (AFB) were present in smear. This high triglyceride ascites was consistent with chylous ascites.

The patient was kept fasting from the first hospital day, and intravenous fluid hydration was provided. Meperidine was administered for pain relief. On the 5th hospital day the pain reduced and the serum pancreatic amylase was 48 IU/L, lipase 55 IU/L, and triglyceride 16.2 mmol/L. On the 6<sup>th</sup> d a low fat diet was resumed and fat lowering agent (gemfibrozil) was initiated, 600 mg, twice a day. On 14<sup>th</sup> d abdomen ultrasound (US) was repeated and showed fluid free peritoneal cavity. Workup for lymphoma and malignancy including chest CT, colonoscopy and upper endoscopy were negative. A culture of ascitic fluid for TB infection was negative. The patient was discharged after 18 d of hospitalization with gemfibrozil 600 mg twice a day. At the time of discharge, the serum pancreatic amylase was 15 IU/L, lipase 33 IU/L, and triglyceride 4.2 mmol/L.

On follow-up evaluation approximately 4 wk after the patient was discharged from the hospital, the patient was symptom free. Repeat physical examination was unremarkable. Laboratory evaluation yielded serum pancreatic amylase of 8 IU/L and lipase of 20 IU/L, triglyceride of 3.2 mmol/L. Abdomen ultrasound and CT showed fluid free peritoneal cavity with normal pancreas.

## DISCUSSION

Acute pancreatitis is an important cause of acute upper abdominal pain. Because its clinical features are similar to a number of other acute illnesses, it is difficult to make a diagnosis only on the basis of symptoms and signs. Acute pancreatitis can be suspected clinically, but requires biochemical and radiologic and sometimes histologic evidence to confirm the diagnosis.

The diagnosis is most often confirmed by evaluation of serum amylase and lipase levels. The diagnosis of acute pancreatitis is made by a serum amylase activity four times above normal (or by a lipase activity greater than twice the

upper limit of normal)<sup>[3]</sup>.

The sensitivity and specificity of amylase and lipase are reported to be considerably dependent on the detection method used, ranging from 70% to 100% and 33% to 89% for serum amylase, and from 74% to 100% and 34% to 100% for serum lipase, respectively<sup>[4]</sup>. Recognizing factors that reduce the sensitivity and specificity of serum amylase and lipase can help prevent misdiagnosis and allow for appropriate treatment. Factors that can lead to normal amylase and lipase values are hypertriglyceridemia (as in this patient) and extensive pancreatic necrosis (acute fulminant or acute chronic pancreatitis)<sup>[5]</sup>.

In such patients (as in this patient) CT scanning provides an accurate confirmation of clinical and laboratory findings and offers excellent anatomic and morphologic representation of the pancreas and peripancreatic tissue.

It was observed that plasma triglyceride levels higher than 500 mg/dL interfere with *in vitro* determination of the actual amylase level by preventing the calorimetric reading of the assay end point<sup>[4]</sup>. However, the reasons for normal serum amylase and lipase level in patients with hypertriglyceridemia-associated pancreatitis are still a dilemma. We reviewed the files of the patients admitted to our hospital with acute pancreatitis, from January 2004 to December 2005. The number of patients labeled as hypertriglyceridemia-associated pancreatitis was 18, of which only one patient (5.5%) had normal serum amylase and lipase level. Serial dilutions of the patient's sample with the assay buffer to reduce interference of light transmission by hyperlipidemic serum can reveal an abnormal amylase value that was previously masked by the lactescent plasma<sup>[1]</sup>.

Overall, although pancreatitis caused by hypertriglyceridemia has the same prognosis as other causes of the acute episode<sup>[6]</sup>, early recognition and treatment have been shown to hasten clinical recovery<sup>[7,8]</sup>.

True chylous ascites is defined as the presence of ascitic fluid with high fat (triglyceride) content, usually higher than 2 g/L, although some authors use a cutoff value of 1.1 g/L<sup>[9-12]</sup>. True chylous ascites must be distinguished from chyliform and pseudochylous effusions, in which the turbid, milky appearance is due to cellular degeneration caused by bacterial peritonitis or malignancy. A low triglyceride level is characteristic of these effusions.

There are multiple causes of chylous ascites. The

most common causes in Western countries are abdominal malignancy and cirrhosis, which account for over two-thirds of all cases. In contrast, infectious etiologies (i.e., tuberculosis and filariasis) are responsible for the majority of cases in developing countries. Other causes include congenital, inflammatory (e.g., acute and chronic pancreatitis), post-operative, traumatic, and miscellaneous disorders.

Kelley and Butt of the Mayo Clinic<sup>[13]</sup> reported that 62 (87%) of 71 cases of chylous ascites, were secondary to malignancy.

Chylous ascites might occur due to different mechanisms<sup>[14]</sup>: (1) obstruction of the lymph flow caused by external pressure (mass) causing leakage from dilated subserosal lymphatics into the peritoneal cavity; (2) exudation of lymph through the walls of dilated retroperitoneal vessels lacking valves, which leak fluid through a fistula into the peritoneal cavity as in congenital lymphangiectasia; and (3) traumatic thoracic duct obstruction causing direct leakage of chyle through a lymphoperitoneal fistula.

Basically, acute or chronic pancreatitis, can cause compression of adjacent lymphatic channels resulting in chylous ascites<sup>[15]</sup>.

Conservative medical treatment should be the first step in managing all patients with chylous ascites. The treatment should be directed at the underlying disorder. In this patient, cure of acute pancreatitis and reduction in triglyceride level led to resolution of chylous ascites. General measures include withholding oral feedings and starting total parenteral nutrition to minimize pancreatic exocrine secretion<sup>[16]</sup>. One-third of patients can improve on conservative management and do not require any further intervention<sup>[17]</sup>. Treatment with somatostatin or octreotide together with diuretics and repeated paracentesis may be beneficial for some patients<sup>[18,19]</sup>. Some patients fail medical therapy, ultimately requiring surgery<sup>[20]</sup>.

In conclusion, relying solely on high serum amylase and/or lipase level to establish the diagnosis of acute pancreatitis is unjustified and should be abandoned, because hypertriglyceridemia can cause spuriously normal amylase and lipase levels. Consequently, abdominal computer tomography scan might be useful in establishing the diagnosis of acute pancreatitis when hypertriglyceridemia interferes with the evaluation of pancreatic enzyme activities and ultrasound examination provides poor pancreatic visualization.

### INTRODUCTION

The inflammatory response to deeply penetrating peptic ulcer can lead to formation of a fistula between the stomach and duodenum or any structure nearby. Fistulae to the pancreatic duct, biliary tract, and colon have been described more commonly. Fistula arising between the stomach and duodenum called “double pylorus” is also a well-recognized complication of peptic ulcer disease<sup>[1,2]</sup>. Rarely, duodenal ulcer can penetrate to adjoin vascular structures and induce aorto-enteric or cavo-enteric fistula<sup>[3,4]</sup>. Such fistulae are usually characterized by less acute symptoms and in some instances represent a very challenging problem. In each case in which fistula is identified, cancer must be considered in differential diagnosis. In general, the small intestine is not found in proximity to the stomach or duodenum, protected as it is by the transverse colon and mesocolon. However, fistula to the small intestine has been reported to occur with typical ulcer symptoms<sup>[5]</sup>. We present a case of gastric ulcer disease complicated by gastrojejunal fistula.

### CASE REPORT

A 77-year old woman was admitted for diffuse abdominal pain, weight loss, malaise, nausea, and occasional dark stools. Physical examination revealed malnourished, pale skin and apparent mucosa. The abdomen was soft (no local or rebound tenderness), diffusely painful, mostly in epigastrium. Laboratory test showed extreme hyposideremic anemia (HGB = 39 g/L, RBC =  $2.38 \times 10^{12}$ /L, HCT = 13.4%, MCV =  $5.64 \times 10^{-14}$  L, and serum Fe = 5.6  $\mu$ mol/L) and inflammatory syndrome (ESR = 44 mm/h, fibrinogen = 7.4 g/L, C-reactive protein = 38.0 mg/L, and PLT =  $813 \times 10^9$ /L). In addition, biochemical parameters of malnourishment were presented (such as cholesterol level = 3.0 mmol/L, triglycerides = 0.6 mmol/L, total proteins = 55.5 g/L, and serum albumins = 29 g/L). Upper endoscopy revealed the patent esophagus along the full length without any pathological changes. Large and deep ulceration with perforation in the small intestine was detected in the posterior gastric wall (Figure 1). The small intestine loop was reached by endoscope through spontaneously developed gastrojejunal fistula (Figure 2). Antrum, pylorus, bulbous and postbulbar duodenum were

### Abstract

Spontaneous gastrojejunal fistula formation is an extremely rare complication of gastric ulcer disease. We report a 77-year old woman who presented with diffuse abdominal pain, weight loss, malaise, nausea, and occasional dark stools. Laboratory tests showed extreme hyposideremic anemia with inflammatory syndrome. In addition, biochemical parameters of malnourishment were presented. Upper endoscopy revealed the patent esophagus along the full length without any pathological changes. Large and deep ulceration with perforation in the small intestine was detected in the posterior gastric wall. The small intestine loop was reached by endoscope through spontaneously developed gastrojejunal fistula. Polytopic biopsies of described ulcerative change were carried out. Histopathologically reepithelialized ulcerous zone was seen in the gastric mucosa. Also, gastrojejunal fistula was visualized after wide opening of hepatogastric and gastrocolic ligament. Jejunal loop 25 cm from ligament of Treitz was attached to mesocolon and posterior gastric wall because of ulcer penetration. Postoperative course was uneventful. Per oral intake started on the 4<sup>th</sup> postoperative day, and the patient was discharged on the 8<sup>th</sup> postoperative day. In summary, this case indicates that persistent symptoms of peptic ulcer disease associated with nutritional disturbances may be caused by gastrojejunal fistula.

Ćulafić ĐM, Matejić OD, Đukić VS, Vukčević MD, Kerkez MD. Spontaneous gastrojejunal fistula is a complication of gastric ulcer. *World J Gastroenterol* 2007; 13(3): 483-485

**Figure 1** Upper endoscopy showing large and deep ulceration in the posterior gastric wall (A) and ulceration with perforation in the small intestine (B).

normal in appearance. Polytopic biopsies of described ulcerative change were carried out. A histopathologically reepithelialized ulcerous zone was seen in the gastric mucosa. The signs of chronic antral atrophic inflammation were noted around the ulcerous mucosal parts, with strong activity, and hypersecretory and partially regenerative foveolar hyperplasia. *H. pylori* test result was negative. The signs of non-specific active non-homogenous inflammatory infiltration with occasional sero-hemorrhagic superficial exudation were present in the mucosa of the small intestine. Real-time abdominal ultrasonography and computerized tomography findings were normal.

Upper central laparotomy was performed. A gastrojejunal fistula was visualized after wide opening of hepatogastric and gastrocolic ligament. The jejunal loop 25 cm from ligament of Treitz was attached to mesocolon and posterior gastric wall because of ulcer penetration (Figure 3A). After careful division of the jejunal loop from duodenojejunal reflection, the fistula was resected (Figure 3B). The jejunal loop defect was closed after wedge excision (histopathological verification ex tempore confirmed benign finding), with two-layer 4.0 vicryl (Ethicon) stitches. Subsequently, subtotal mastectomy was performed because of another giant gastric ulcer proximal to fistula. Gastrojejunostomy was created in the usual fashion (two layers of 4.0 vicryl) continuously with retro colic position of anatomists. After lavage and drainage of the right sub hepatic space, the abdominal wound was closed with Maxon-loop2 (Davis-Gecko). Postoperative course was uneventful. Per oral intake started on the 4<sup>th</sup> postoperative day, and the patient was discharged on the 8<sup>th</sup> postoperative day.

**Figure 2** Small intestine loop reached by endoscope through spontaneously eloped gastrojejunal fistula.

**Figure 3** Hole in mesocoline with gastrojejunal fistula (A) and defect in posterior gastric wall after resection of fistula and deep gastric ulcer (B).

## DISCUSSION

Spontaneous gastrojejunal fistula formation is rare and its differential diagnosis is multifactorial. Malignancy should be ruled out by careful endoscopic evaluation and appropriate imaging studies. Precise etiologic determination is necessary for proper management. In contrast to gastrocolic fistula, symptoms of the gastrojejunal fistula are those of the ulcer diathesis itself. However, if the target region of the fistula is very proximal, there is no short-circuiting of gastric contents; but if the target site is distal, the symptoms and nutritional disturbances may be similar to those observed with gastrocolic fistula<sup>[6]</sup>.

Our patient manifested the symptoms of nutritional disturbances other than symptoms of ulceration, abdominal pains and recurring hemorrhage. Matsuoka *et al*<sup>[7]</sup>

have described an 81-year old woman who had multiple recurrences of gastric ulcer after the left femoral head fracture, necessitating the mechanical bone head exchange operation. Gastro-endoscopic examination revealed a giant ulcer with long-axis diameter of more than 5 cm in the lesser curvature of stomach. Two weeks later, a fistula was formed between the stomach and jejunum. It was successfully managed by intravenous H<sub>2</sub>-antagonist and oral intake was restricted. Operative stress and application of ipriflavone appeared to have induced gastric ulcer recurrence. However, malnourishment of the patient contributed to the development of fistula between the stomach and jejunum which was very lean and had minimal mesenteric adipose tissue. Our patient was also lean with minimal mesenteric adipose tissue. However, risk factors, *H. pylori* infection, nonsteroidal anti-inflammatory drug ingestion, and operative stress were absent. Indications for surgery are other complications such as free perforation, obstruction, refractory bleeding, or failure to heal with maximum medical therapy and persistent symptoms, rather than the fistula *per se*.

In case of our patient, surgical intervention was definitely indicated due to recurrent bleeding and symptoms of nutritional disturbances. In addition, gastrojejunal fistula secondary to gastric cancer is extremely rare. Choi *et al*<sup>[8]</sup> have described a 56-year-old man who was diagnosed with advanced gastric cancer. Fluoroscopic examination visualized two abnormal passages of contrast medium from the stomach: one to the colon, and the other to the jejunum. Fiber gastroscopy revealed a tumor in the greater curvature of stomach which appeared to penetrate in the colon, and a tumor in the antrum directly which invaded the jejunum. Souma *et al*<sup>[9]</sup> have described a 55-year old man seen for epigastralgia and weight loss. Barium radiography and endoscopic study revealed a gastric cancer associated

with gastrojejunal fistula. At laparotomy, they found that the gastric tumor had extended to the transverse mesocolon, jejunum and pancreas, although no liver metastasis or peritoneal dissemination was seen. In addition, this patient, to their knowledge, is the fifth reported case in the world. In summary, this case indicates that persistent symptoms of peptic ulcer disease associated with nutritional disturbances may be caused by gastrojejunal fistula.

## TO THE EDITOR

In the UK, clear guidelines exist as to the expected level of competence an individual endoscopist should achieve. This is of utmost importance given the variance in practice among endoscopic departments as highlighted by the National Colonoscopy audit in 2002<sup>[1]</sup>. The audited variables included sedation practice, caecal completion and complication rates, but not the type of instrument used.

The type of instrument used has been shown by some groups to influence colonoscopy performance; for example paediatric colonoscopies are thought to aid intubation in patients with fixed angulation of the colon whilst variable stiffness colonoscopes are useful to negotiate tortuous recto-sigmoid junctions. Several studies have attempted to determine if different instruments have effects either on caecal intubation or time to caecal intubation. The findings however are conflicting, with some studies showing a benefit<sup>[2-3]</sup> and others none<sup>[4-6]</sup>. Most of these studies made comparisons between different types of Olympus colonoscopes, i.e. single manufacturer rather than an alternative (Fujinon/Pentax). Furthermore, only one study<sup>[2]</sup> assessed the dose and type of sedation used whilst in two studies<sup>[4,5]</sup>, assessments were by a single experienced endoscopist. Thus, it is difficult to conclude definitively if a different make of colonoscope in less experienced hands influences not only colonoscopic performance but also sedation practice. The aim of this study was to determine

Table 1 Subject characteristics and summary of results

Total (n = 199)	M:F	Age (SD) (yr)	Mean dose of Mdz/mg (SD)	No sedation	CIR	TIR
Olympus CF 240 (n = 105)	1:1.3	65 (± 14)	2.7 (± 1.4)	31 (30%)	102 (97%)	73 (70%)
Fujinon EC-450 (n = 94)	1:2.1	64 (± 11)	3.7 <sup>b</sup> (± 1.4)	0	84 <sup>d</sup> (89%)	46 (49%)

SD: Standard Deviation; Mdz: Midazolam; CIR: Caecal intubation rates; TIR: Terminal ileal intubation rate. <sup>b</sup> $P < 0.001$ , <sup>d</sup> $P < 0.001$  comparison between Fujinon EC-450 and Olympus CF 240 on mean dose of Mdz and CIR.

if the type of colonoscope used could influence not only caecal intubation rates but also sedation practice.

We studied 199 consecutive procedures on two sites performed by a single endoscopist prospectively. The first 105 procedures were performed using the Olympus EVIS CF 240 variable stiffness scope whilst the subsequent 94 were performed using a Fujinon EC-450 WL scope. Demographic data, dose and type of sedation used as well as caecal and terminal ileal intubation rates were recorded. Results are shown in Table 1.

Indications for colonoscopy were similar in both groups as were hysterectomy rates (5%). Mean list size was 5 (range 4-6) patients and the number of therapeutic procedures was 8 (8%) in the first 105 procedures and 20 (21%) in the subsequent 94. Adjusted completion rates were superior with the Olympus colonoscope (97% *vs* 89%;  $P < 0.001$ ) compared to the Fujinon colonoscope. Similarly, adjusted analgesic dose was also significant with patients endoscoped with the Olympus colonoscope requiring less Midazolam (2.7 mg *vs* 3.7 mg;  $P < 0.001$ ) whilst none required any opioid analgesics. Moreover, 30% endoscoped with the Olympus colonoscope required no sedation at all. Individual departmental caecal completion rates were similar to those of the endoscopist in this study, thereby precluding a learning curve phenomenon with the different make of colonoscopes. Although this study was not randomised and for obvious reasons cannot be blinded, operator bias was reduced as the operator had near equal experience with both types of scopes. This is the first study to our knowledge that has compared two different makes of instruments and shown that it influences not only caecal intubation rates but also sedation practice.

The optical performance of the Fujinon system is deemed superior than that of the Olympus system<sup>[7]</sup> with better resolution at target distances of less than 1 cm. A 'back to back' randomised study design, using the two

different systems to determine rates of early mucosal changes, would be required to determine if this was clinically significant. The implications of colonoscopic performance and sedation practice being influenced by different makes of instrument are far reaching. It has implications not only in training endoscopists but also in assessing individual performance, particularly those undertaking colon cancer screening.

## Meetings

### MAJOR MEETINGS COMING UP

Meeting Falk Research Workshop:  
Morphogenesis and Cancerogenesis  
of the Liver  
25-26 January 2007  
Goettingen  
symposia@falkfoundation.de

Meeting Canadian Digestive Diseases  
Week (CDDW)  
16-20 February 2007  
Banff-AB  
cagoffice@cag-acg.org  
www.cag-acg.org/cddw/cddw2007.  
htm

Meeting Falk Symposium 158:  
Intestinal Inflammation and  
Colorectal Cancer  
23-24 March 2007  
Sevilla  
symposia@falkfoundation.de

Meeting BSG Annual Meeting  
26-29 March 2007  
Glasgow  
www.bsg.org.uk/

### NEXT 6 MONTHS

Meeting 42nd Annual Meeting of the  
European Association for the Study  
of the Liver  
11-15 April 2007  
Barcelona  
easl2007@easl.ch  
www.easl.ch/liver-meeting/

Meeting Falk Symposium 159: IBD  
2007 - Achievements in Research and  
Clinical Practice  
4-5 May 2007  
Istanbul  
symposia@falkfoundation.de

Meeting European Society for  
Paediatric Gastroenterology,  
Hepatology and Nutrition Congress  
2007  
9-12 May 2007  
Barcelona  
espghan2007@colloquium.fr

Digestive Disease Week  
19-24 May 2007  
Washington Convention Center,  
Washington DC

Meeting Gastrointestinal Endoscopy  
Best Practices: Today and Tomorrow,  
ASGE Annual Postgraduate Course  
at DDW  
23-24 May 2007  
Washington-DC  
tkoral@asge.org

Meeting ESGAR 2007 18th Annual  
Meeting and Postgraduate Course  
12-15 June 2007  
Lisbon  
fca@netvisao.pt

Meeting Falk Symposium 160:  
Pathogenesis and Clinical Practice in

Gastroenterology  
15-16 June 2007  
Portoroz  
symposia@falkfoundation.de

Meeting ILTS 13th Annual  
International Congress  
20-23 June 2007  
Rio De Janeiro  
www.ils.org

Meeting 9th World Congress on  
Gastrointestinal Cancer  
27-30 June 2007  
Barcelona  
meetings@imedex.com

### EVENTS AND MEETINGS IN 2007

Meeting Falk Research Workshop:  
Morphogenesis and Cancerogenesis  
of the Liver  
25-26 January 2007  
Goettingen

troenterology and Endoscopy Lon-  
don, United Kingdom 2009*

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

#### Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

#### Published by

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

#### Editorial Office

##### *World Journal of Gastroenterology*

Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>  
Telephone: +86-10-85381892  
Fax: +86-10-85381893

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under

illustrations should be expressed as  $^1F$ ,  $^2F$ ,  $^3F$ ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

**Patent (list all authors)**

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

**Abbreviations**

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

**Italics**

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

**SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED**

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

**Language evaluation**

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

**Copyright assignment form**

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

**Ms:**

**Title:**

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

**Criteria for authorship:** The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

## Abstract

Gastric acid plays an important role in digesting food (especially protein), iron absorption, and destroying swallowed micro-organisms. H<sup>+</sup> is secreted by the oxyntic parietal cells and its secretion is regulated by endocrine, neurocrine and paracrine mechanisms. Gastrin released from the antral G cell is the principal physiological stimulus of gastric acid secretion. Activation of the enterochromaffin-like (ECL) cell is accepted as the main source of histamine participating in the regulation of acid secretion and is functionally and trophically controlled by gastrin, which is mediated by gastrin/CCK-2 receptors expressed on the ECL cell. However, long-term hypergastrinemia will induce ECL cell hyperplasia and probably carcinoids. Clinically, potent inhibitors of acid secretion have been prescribed widely to patients with acid-related disorders. Long-term potent acid inhibition evokes a marked increase in plasma gastrin levels, leading to enlargement of oxyntic mucosa with ECL cell hyperplasia. Accordingly, the induction of ECL cell hyperplasia and carcinoids remains a topic of considerable concern, especially in long-term use. In addition, the activation of ECL cells also induces another clinical concern, i.e., rebound acid hypersecretion after acid inhibition. Recent experimental and clinical findings indicate that the activation of ECL cells plays a critical role both physiologically and clinically in the regulation of gastric acid secretion.

## INTRODUCTION

One of the main functions of the stomach is to produce hydrochloric acid, which plays an important role in protein digestion, iron absorption and particularly in destroying swallowed micro-organisms<sup>[1,2]</sup>. The stomach is rich in neuroendocrine cells<sup>[3-5]</sup>. At present, at least six endocrine cells have been described in the stomach: G cells, D cells, enterochromaffin-like (ECL) cells, A-like cells, D1/P cells, and enterochromaffin (EC) cells. In the stomach, G cells are found only in the antral mucosa, while A-like and ECL cells are confined to the oxyntic mucosa<sup>[4]</sup>. D and D1/P cells are found in both the antral and oxyntic mucosa. These endocrine cells constitute approximately 2% of the oxyntic mucosal cells in rodents. The ECL cell was originally described by Hakanson *et al*<sup>[6]</sup> and Capella *et al*<sup>[7]</sup> respectively. However, its physiological function was also long disputed, except for in rat where it was initially recognised as the major histamine producing cell of the stomach<sup>[8]</sup>. It is now recognized that the ECL cell is the dominant endocrine cell in the oxyntic mucosa of all mammals studied so far. Localization within the glands differs from one species to another. In rodents, they are mainly located in the basal third of the oxyntic mucosa. Gastric acid is produced by the parietal cell in the oxyntic mucosa<sup>[9]</sup>, and the production of acid is regulated by neurons, hormones and paracrine substances<sup>[10,11]</sup>.

Gastrin released from the antral G cells, histamine from the oxyntic ECL cells and acetylcholine (ACh) from postganglionic cholinergic neurons are the main stimuli of acid secretion<sup>[9]</sup>. The ECL cell is under the control of gastrin. Gastrin-ECL cell axis activation has been found to be important physiologically and pathophysiologically. In this mini-review, we will summarize the physiological and clinical significance of ECL cell activation in regulating gastric acid secretion.

## THE PHYSIOLOGICAL SIGNIFICANCE OF ECL CELL ACTIVATION IN REGULATING GASTRIC ACID SECRETION

Gastrin is a potent stimulus of gastric acid secretion by stimulating the release of histamine from ECL cells<sup>[12-16]</sup>. The gastrin-ECL cell axis plays a critical role in regulating acid secretion from parietal cells. In the totally isolated vascularly perfused rat stomach model, gastrin induces an immediate and concentration-dependent histamine release from the ECL cell<sup>[12]</sup>. With concomitant administration of the histamine-2 (H2) receptor antagonist, ranitidine, together with gastrin, the acid secretion in the isolated stomach model is reduced to baseline level. Thus, the stimulation of acid secretion by gastrin occurs most likely *via* histamine release from the ECL cells *via* gastrin/CCK-2 receptors<sup>[17-20]</sup>. This finding was supported by studies using isolated ECL cells *in vivo*<sup>[21-23]</sup>. Not only histamine release but also the synthesis of histamine in the ECL cell is regulated by gastrin<sup>[24-26]</sup>. Administration of exogenous gastrin, at a dose giving concentration in the physiological range, can evoke a significant increase in histidine decarboxylase (HDC) activity<sup>[13]</sup>, as well as an increase in HDC mRNA abundance<sup>[24-26]</sup>. HDC catalyses the formation of histamine from histidine. Endogenous hypergastrinemia after potent acid inhibition can induce a similar increase in HDC activity<sup>[13,27]</sup>. Histamine release from ECL cells is considered to be a limiting step in gastrin-stimulated maximal gastric acid secretion<sup>[12,28]</sup>. Now it is generally accepted that the gastrin-histamine sequence is the main pathway for gastrin stimulation of gastric acid secretion. Recently, the role of gastrin precursors (glycine-extended gastrin and progastrin) in stimulating acid secretion was also postulated<sup>[29,30]</sup>. It was found that a high dose infusion of glycine-extended gastrin into isolated stomach can activate histamine release from ECL cells and acid secretion, which could be blocked by antagonists of H2 receptors and gastrin/CCK-2 receptors<sup>[31,32]</sup>. This supported the activation of ECL cells as mediating the main pathway of glycine-extended gastrin acid secretion stimulation. Moreover, the role of glycine-extended gastrin in preserving parietal cell density was found. Coexpression of glycine-extended gastrin with gastrin in transgenic mice reduced long-term hypergastrinemia induced parietal cell loss. Thus, an important physiological role of gastrin precursors was postulated<sup>[30]</sup>.

Furthermore, the stomach is innervated by different nerves<sup>[33]</sup> and peptides produced by intrinsic neurons influence stomach functions, including acid secretion<sup>[34]</sup>. The vagal efferent fibers are preganglionic, and do not directly innervate stomach endocrine or exocrine cells<sup>[33]</sup>. The targets of these vagal preganglionic neurons are the intrinsic neurons that are located in the myenteric ganglion cells. The intrinsic neurons contain Ach and different peptides<sup>[33]</sup>, such as GRP, VIP, galanin, and PACAP. They innervate the G, D, ECL and parietal cells. The effect of vagal nerves on gastric acid secretion is complex. Ach mainly has a direct effect on acid secretion by acting on a M3 receptor on the parietal cell. *In vivo*, galanin and PYY, for example, have been shown to inhibit histamine

release from ECL cells *via* their own receptors<sup>[35-39]</sup>. VIP induces somatostatin release from D cells, but stimulates histamine release from ECL cells probably *via* a PACAP receptor<sup>[35,36,39,40]</sup>. PACAP is a potent stimulus of histamine release from ECL cells *via* PACAP-1 receptors<sup>[36,39,41,42]</sup>. Gastric acid secretion, besides being regulated by the hormonal and neural routes, is also regulated by paracrine factors<sup>[11]</sup>. Somatostatin, which is a principal paracrine inhibitory factor, can exert its inhibitory effect on gastric acid secretion<sup>[17]</sup>. The reciprocal paracrine pathway between D and G cells is well known<sup>[43]</sup>, and ECL cells are also in close contact with oxyntic D cells<sup>[4]</sup>. The antral somatostatin acts on the antral G cells, while the oxyntic somatostatin affects both ECL cells and parietal cells. Thus, somatostatin inhibits acid secretion *via* actions on different cells of the gastrin-ECL cell axis.

## THE CLINICAL SIGNIFICANCE OF ECL CELL ACTIVATION IN LONG-TERM GASTRIC ACID INHIBITION

Potent acid inhibitors, such as proton pump inhibitors (PPIs), are highly effective gastric antisecretory agents with long duration<sup>[44]</sup>. They are intensively used to treat acid related disorders, and are nowadays prescribed even for children<sup>[45]</sup>. ECL cells are activated during the use of potent acid inhibitors. From a clinical viewpoint, safety concerns for such long-term activation by acid inhibitors have to be considered.

Rebound acid hypersecretion was first described in rats more than 20 years ago after treatment with omeprazole<sup>[46]</sup>. In humans, rebound acid hypersecretion was found in patients who received long-term acid inhibitors, such as H2 receptor antagonists and PPIs<sup>[47-51]</sup>. It has been observed that a 3-mo omeprazole treatment, at a dose of 40 mg daily in patients with reflux esophagitis, resulted in a significant (over 50%) increased maximal acid secretion accompanied by remarkable elevated gastrin and histamine levels<sup>[48]</sup>. This finding was confirmed in our subsequent studies<sup>[52,53]</sup> and others<sup>[50,51]</sup>, and is due to the fact that gastrin is the most important trophic factor for ECL cell self-replication and that histamine released from ECLs is the main stimulator for gastric acid secretion. Long-term acid inhibition induces hypergastrinemia and ECL cell hyperplasia in patients treated with PPIs for various diseases with dyspepsia. The mechanism of rebound acid hypersecretion is likely related to the activation of the gastrin-ECL cell axis caused by drug-induced hypoacidity.

Apart from a stimulatory action on gastric acid secretion, gastrin also has a trophic effect on the oxyntic mucosa<sup>[54-56]</sup>, particularly on ECL cells, which are stimulated to replicate *via* gastrin/CCK-2 receptors expressed in ECL cells<sup>[13,19,20]</sup>. It has become apparent that rat ECL cells, in response to hypergastrinemia, whether endogenous or exogenous, show hypertrophy within days, hyperplasia within weeks and carcinoids after months through a sequence of diffuse-linear-micronodular hyperplasia to ECL carcinoids<sup>[13]</sup>. Therefore, there is a causal connection between hypergastrinemia and ECL cell carcinogenesis<sup>[13,57-59]</sup>. Thus, in patients received long-term

acid inhibition treatment, another concern is the increased gastric carcinoid risk. In fact, sporadic gastric carcinoid cases have been reported in patients exposed to long-term PPI treatments<sup>[60,61]</sup>. Long-term safety is still of high concern.

Finally, gastrin was also connected with other types of human cancers; i.e. gastric and colonic adenocarcinoma, and more recently, studying the important role of precursors for gastrin progastrin and glycine-extended gastrin in the carcinogenesis of gastrointestinal mucosa has been one of the developing research fields. Several outstanding reviews have summarised this topic<sup>[62-65]</sup>. Thus, whether long-term activation of ECL cells by potent acid inhibition can contribute to increased risk of gastrointestinal adenocarcinoma in humans is still unknown and needs to be studied in the future. In addition, one of the growth factors that regenerates gene proteins, i.e., (Reg)-1, that is mainly released from ECL cells has been found to be a unique growth factor of gastric mucosal cells<sup>[66]</sup> and may play an important trophic role in the development of gastric cancer<sup>[67]</sup>.

## CONCLUSION

It is now generally accepted that ECL cell activation is the most important physiological pathway in the regulation of gastric acid secretion, which is being influenced by both activating and inhibiting stimuli. Furthermore, it has become apparent that the gastrin-ECL cell axis also plays a role in gastric acid disorder, such as rebound acid hypersecretion, and increased risk for gastric tumorigenesis, especially in chronic hypergastrinemic conditions. Therefore, clinicians should be aware that there are important clinical safety issues related to the dose and duration of potent inhibitors of acid secretion.

## Abstract

miRNAs are a class of small, ~22nt, non-coding RNAs that negatively regulate gene expression at the post-transcriptional level. They play profound and pervasive roles in manipulating gene expression involved in cell development, proliferation and apoptosis in various eukaryotes, which, in theory, could provide an access to many human diseases in theory. Recent evidence demonstrates that aberrant miRNA expression is a hallmark of tumor development, revealing that miRNA genes could function as potential oncogenes and repressors in the human body. miRNAs can affect tumorigenesis mainly by interrupting the cell cycle at the cellular level and by interacting with signaling, oncogenes and with the response to environmental factors at the molecular level. The established miRNA expression signature could be a potent tool to diagnose and treat human cancers in the future.

## INTRODUCTION

miRNAs (microRNAs) are a subset of small, typically 21-23 nt in length, non-coding RNAs evolutionarily conserved in many organisms as disparate as yeast, fruit

flies, human and plants<sup>[1]</sup>. This growing family of small RNAs was first discovered in *Caenorhabditis elegans* in 1993<sup>[2]</sup> and newly honored as a milestone in the process of the gene concept<sup>[3]</sup>. Until now hundreds of miRNAs have been identified in many organisms by using experimental and bioinformatic prediction approaches. It is well known that, unlike its cousin signal interfering RNAs (siRNAs), miRNAs have the unique ability to negatively regulate gene expression involved in cell development, proliferation, apoptosis and the stress response<sup>[4]</sup>. Consequently, it is proposed that these biological properties of miRNAs could offer an access to many human diseases including cancers<sup>[5]</sup>. Recent findings have demonstrated that miRNAs play critical roles in human cancer, revealing that miRNAs could act as potential oncogenes and repressors<sup>[6,7]</sup>. Thus, this class of miRNAs are now dubbed 'oncomirs'-miRNAs which is closely related to tumor<sup>[8]</sup>.

Cancer is characterized by uncontrolled proliferation and the inappropriate survival of damaged cells. Although cells have evolutionarily developed several safeguards to prevent malignant transformation during development and adulthood, this normal process can be disrupted in cancer cells. Cancer cells can take advantage of their unique strategy to escape scrutiny during cell division. The oncogenesis conventionally refers to tumor suppressors and oncogenes, such as APC,  $\kappa$ -RAS, Myc, P53 and P21. Although these regulatory molecules do play critical roles in tumor development, recent intense interest is being attached to miRNAs.

We are just beginning to appreciate the novel involvement of miRNAs in human cancers but much more remain obscure. Few investigations to date have converged to support the concrete links between miRNAs and each cancer species. However, most cancer species share the same mechanisms that give rise to tumorigenesis even in different tissues, so the general mechanism may be applied extensively to each cancer species. The potential link between miRNAs and tumors discussed in this review will be limited to only a few of the elucidated cancers.

## miRNA BIOGENESIS AND MECHANISMS OF GENE EXPRESSION CONTROL

The biogenesis of miRNAs has recently been elucidated (Figure 1)<sup>[1]</sup>. RNA Pol II generally transcribes miRNA genes in the nucleus and gives rise to large primary miRNA (pri-miRNA) transcripts that, like mRNA, are capped at 5' terminus and polyadenylated at 3' terminus. The initial pri-miRNAs are then processed by RNase III,

**Figure 1** miRNAs biogenesis and two mechanisms involved in gene expression. MiRNAs genes often cluster on the chromosome and are transcribed by RNA Pol II to form pri-miRNAs in the nucleus. The pri-miRNAs then undergo processing by RNase III, Drosha, and are exported to cytoplasm by Exportin 5. Another RNase III, Dicer, further processes the pre-miRNA to generate a ~22nt miRNA:miRNA\* duplex, where miRNA\* is complementary to miRNA. Helicase can divide the duplex into two separate ones. Whereas miRNA\* is degraded, mature miRNA can enter the miRNA-induced silence complex (miRISC). The miRISC complex block protein synthesis by imperfectly binding to the 3'UTR of the mRNA (upper right), the other one is to endonucleolytically cleave the target mRNA by perfect or nearly perfect base pairing (lower right).

Drosha, to form 70-bp pre-miRNAs in the nucleus. The pre-miRNAs are exported into the cytoplasm by the RNA GTP-dependent transporter Exportin 5 and undergo an additional processing step to produce a miRNA:miRNA\* duplex with the aid of another RNase III, Dicer. The RNA duplex is subsequently unwound by Helicase and the mature miRNA finally enter the RNA-induced silence complex (RISC)<sup>[9,10]</sup>.

Two mechanisms of miRNA repression have been suggested depending on the degree of complementarities between the miRNAs and the target mRNAs (Figure 1)<sup>[4]</sup>. First, is interference with protein synthesis by binding to imperfect complementary sites within the 3' untranslated region of the target mRNA. The 3'UTR of target mRNA usually contains multiple complementary sites for distinct miRNAs, but the precise mechanism is still poorly understood. Second, is endonucleolytic cleavage of the target mRNA by perfect base pairing. The latter was previously thought to function solely in flowering plants, but the paradigm that animal miRNAs do not affect the stability of imperfectly base-paired miRNA has been challenged recently. Lim *et al*<sup>[11]</sup> used microarray analysis to investigate changes in global mRNA level in HeLa cells in response to miRNAs that are normally undetectable in those malignant cells and observed the reduction of 100-200 genes at the mRNA level. This observed reduction in mRNA level was attributed to AU-rich elements (AREs) that induced mRNA turnover by degrading mRNAs in exosome<sup>[12]</sup>. AREs are often found in transcripts that encode cell proliferation factors (e.g., TNF- $\alpha$ , GM-CSF, c-Fos, IL-6 and IL-8), and therefore stability of these transcripts in the absence of specific miRNAs contributes to the cell proliferation that accelerate tumor formation and development<sup>[13]</sup>. Nevertheless, one recent finding indicated that the reverse step also exists in the latter mechanism, where the mRNA can be relieved from the miRNA-induced inhibition in cells subject to different stress conditions<sup>[14]</sup>. This repression and derepression of mRNA expression cooperatively contribute to the dynamic

balance of mRNA in cells, but the detailed mechanism is still not clear.

miRNAs could provide a convenient and efficient pathway to manipulate gene expression at posttranscriptional level. Natural miRNAs exert their effects by base pairing with the target mRNAs in a much more compact and energy-efficient manner than protein encoding regulatory molecules like enzymes and hormones, which show a necessary adaptation to regulate gene expression in eukaryotes<sup>[15]</sup>.

## miRNA GENE CLUSTERS AND LOCI

The human genome contains up to 1000 miRNA genes, which constitute approximately 1-5% of the expressed genes<sup>[16]</sup>. miRNAs are endogenetically conserved with evolutionary plasticity in eukaryotic genomes and are often organized in tandem and closely clustered on the chromosome<sup>[17]</sup>. This arrangement can have particular significance in the control of gene expression. When clustered miRNAs have a similar sequence, miRNAs gene products may synchronize to regulate a set of mRNA targets. However, clusters can also contain miRNAs with different sequences that extensively deploy toward their specific targets. These closely related characteristics may allow miRNAs to function as pleiotropic regulators at the cellular level in many organisms.

Over half of miRNA genes (52.5%) are located in or near fragile sites or cancer-associated genomic regions<sup>[18]</sup>. These sites are preferential sites of sister chromatid exchange, translocation, deletion, amplification or integration of plasmid DNA and tumor-associated virus, which frequently cause the aberrant miRNA expression during pathogenesis. For instance, *miR-15a* and *miR-16a* genes, frequently deleted and/or underexpressed in patients with B cell chronic lymphocytic leukemia, map to 13q14 that is deleted in many cases<sup>[19]</sup>. This result highlights that aberrant miRNA expression is possibly geared towards the intrinsic defect that gives rise to tumors.

## miRNA IN CANCER STEM CELLS

Most tissues contain rare cells that follow the norm of stem cell biology to tissue self-renewal and repair<sup>[20]</sup>. The unprecedented self-renewal rate of robust tissues (like intestine, skin, blood and breast) often parallels a high susceptibility to malignant transformation, because the molecular mechanisms that control homeostatic self-renewal and those underlie tumors are evidently symmetric<sup>[21]</sup>. Currently the emerging notion is that tumor might contain stem cell-like 'cancer stem cells'-rare cells with indefinite proliferative potential that trigger tumor formation and growth, and with the presumed ability to transport new tumor seeds to distant sites<sup>[22]</sup>. Despite this controversial notion, one cancer (leukaemias) of the haematopoietic system provides the strong evidence that cancer cell proliferation is driven by cancer stem cells<sup>[23]</sup>. Given that cancer cells and normal stem cells share the similar potential to indefinite self-renew, it seems reasonable to propose that newly arising cancer cells appropriate the machinery for self-renewing cell division which is normally used in stem cells<sup>[24]</sup>.

It is well known that miRNAs function as critical regulators of gene expression in the control of stem cells during development<sup>[5]</sup>. If miRNAs play a similar role in cancer stem cells then, in theory, it is possible support the hypothesis that several miRNAs appropriate the miRNA-mediated machinery for self-renewal in stem cells to develop tumors. Indeed, it has been validated that tumor tissues are constantly characterized with altered miRNA expressions.

## A HALLMARK OF TUMOR

Currently the potential connection between miRNAs and cancers is just beginning to be appreciated. Cancer cells tend to undergo the distinct expression of miRNA, distinguishing them from the normal ones. Calin *et al.*<sup>[25]</sup> first found that specific miRNA expression is abnormal in B-leukemia, suggesting that altered miRNA expression correlate with specific tumor development. In accordance with this, Michael *et al.*<sup>[26]</sup> investigated possible changes at the miRNA level during tumorigenesis and showed the reduced accumulation of two specific miRNAs: miR-143 and miR-145, but consistent levels of the 70-bp precursor pre-miRNA in colorectal neoplasia as well as breast carcinoma, prostate carcinoma, chronic myelogenous leukemia and cervical carcinoma, implying that many tumors share aberrant specific miRNA expression. Recently Lu *et al.*<sup>[27]</sup> found that cancer cell lines showed low miRNA expression profile when they used a new, bead-based flow cytometric miRNA expression profiling method to analyze a large-scale expression of 217 mammalian miRNA from 334 samples including multiple human cancers. Their study further demonstrated that tumors originating from tissue with a common embryonic source share the similar miRNA, but not mRNA, expression signature, and that distinct patterns of miRNA expression are consistent with the developmental history of human cancer, revealing that miRNAs could be used to classify different cancers and validate the developmental history of cancer. Volinia *et al.*<sup>[7]</sup> further found that global

miRNA expression signatures from solid tumors show a good separation between the different tissues, but not all miRNA expressions are underexpressed compared with their respective normal tissues. The studies support the hypothesis that the global change in miRNA expression is a hallmark of all human cancers, providing a hint that miRNAs correlate with various tumor development.

Moreover, impaired components of machinery mediating miRNA processing and miRNA-mediated gene repression give rise to tumorigenesis<sup>[28,29]</sup>, demonstrating that altered specific miRNAs expression might play a causal role in the generation or/and maintenance of tumors. This description of cancers in molecular terms is likely to improve the way in which human cancers are diagnosed, classified, monitored, and (specially) treated, which will promise the emergency of the new era in cancer research in the future<sup>[30]</sup>.

## miRNA AND CELL CYCLE

Normal cells can tightly control cell proliferation and death by means of the cell cycle, thereby preventing malignant transformation during development and adulthood. The 3'UTR of mRNAs encoding many cell cycle-associated cytokines often contain binding sites to miRNAs, indicating that normal miRNAs are essential for cell cycle control. Hatfield *et al.*<sup>[31]</sup> reported that *Drosophila melanogaster* germline stem cells subject to constitutively eliminated miRNA expression exhibited normal identity but were defective in cell cycle control, showing that miRNAs are essential in the control of cell cycle. Thus constitutive miRNAs are necessary to control cell cycle and maintain the balance of cell proliferation, differentiation and apoptosis, which play essential roles in preventing normal tissues from malignancy<sup>[32,33]</sup>.

However, cancer cells are insensitive to cell division stop signals in an environment where most of the cells are quiescent. It is tempting to speculate that miRNAs could have a similar role in cancer cells and particularly rare cancer stem cells, where the disrupted miRNAs expression makes cells insensitive to environmental signals that normally stop the cell cycle. Brennecke *et al.*<sup>[34]</sup> assigned a novel role to miRNA encoded by the *bantam* gene in control of cell proliferation and apoptosis during *Drosophila* development. *Bantam* miRNA could stimulate cell proliferation and simultaneously suppress apoptosis by manipulating the proapoptosis gene *hid* expression. It controls both cell growth and cycle progression in a coordinated manner, revealing that the putative vertebrate homologs of *bantam* miRNA genes may be oncogenes, whereas there are no homologues of *bantam* in human, other oncogenic miRNAs could play a similar role in control of cell proliferation and apoptosis. When the miRNA expression is impaired, normal tissues could have a high risk to develop tumor.

## miRNA AND CANCER-ASSOCIATED SIGNALING PATHWAYS

The signaling transductions (Wnt, Notch, SHH and BMP) play essential roles in the processes of cell life at the

molecular level, but these pathways controlling cell growth and differentiation in normal cell are almost invariably changed in cancer. Consistent with the altered miRNA expression in cancer cells, it is reasonable that the two can work together to control cell fate.

Several cancer-associated signaling pathways directly regulate expression of specific miRNA genes. Yoo *et al*<sup>[35]</sup> found that LIN-12/Notch signaling pathway directly binds to one miRNA gene, *mir-61*, and promote its expression in vulval precursor cells during *C. elegans* development. Stimulated expression of *mir-61* gene subsequently represses the translation of Vav-1, the ortholog of the vav oncogene, who negatively regulates the *lin-2* gene activity. These cyclic regulations form a positive feedback loop that helps maximize *lin-12* activity and continually stimulate Notch signaling pathway (Figure 2). It has been known that Notch signaling pathway plays an important role in many cancer species. If the similar mechanisms exist in cancer cell, this positive loop could trigger and accelerate tumorigenesis.

miRNAs can influence the signaling pathway by repressing several secreted signaling proteins. RAS is a signaling protein in many significant signaling pathways and its overexpression usually results in oncogenic transformation. The 3'UTL of the human RAS genes contains multiple *let-7* complementary sites, allowing *let-7* to regulate RAS expression. Johnson *et al*<sup>[36]</sup> found that *let-7* expression is lower in lung tumors than in the normal lung tissue, providing a possible strategy to treat lung cancer by repairing mutated *let-7* gene. It was reported that miR-143 and miR-145, lower in colorectal cancer than in normal tissues, are predicted to regulate several target mRNAs encoding components of signal transduction pathway (Raf, Rho, GTPase activating protein, G-protein  $\gamma$ , NF- $\kappa$ B and HGK)<sup>[20]</sup>. Hence, the direct and indirect interaction between miRNAs and secreted signaling protein can influence tumorigenesis.

Thus, it is supposed that miRNAs and signal as well as other regulatory molecules constitute a network where normal cells follow a rule to divide, differentiate, and die. When the regulatory network is impaired, cell cycle will be out of control, giving rise to tumor development. However, the networks of miRNAs and signals are largely elusive to date.

## INTERACTION BETWEEN miRNA AND ONCOGENES

Due to mutation, many human proto-oncogenes can convert to oncogenes. These oncogenes often encode common regulatory molecules that can stimulate the tumor development in the body. For example, the proto-oncogene *C-MYC* encodes a helix-loop-helix leucine zipper transcriptional factor that regulates cell proliferation, growth and apoptosis. Recent findings revealed that c-Myc directly binds to the locus of a cluster of six miRNAs and stimulates their expression<sup>[37]</sup>. Overexpression of *miR-17-5p* and *miR-20a*, two miRNAs in this cluster, reduced the expression of E2F1 (one transcriptional factor). c-Myc

**Figure 2** The positive loop between *mir-16* and LIN-12. Exogenous signal activates LIN-12/Notch signaling pathway, which promotes the transcription of *mir-61*. Overexpression of *mir-61* inhibits the activity of VAV-1 (purple) that reduces the activity of LIN-12 (pink), where LIN-12, *mir-61*, and VAV-1 form a feedback loop that helps maximize LIN-12 activity.

and E2F1 are reciprocally induced in normal cell to form a putative positive feedback loop, like the one between *mir-16* and LIN-12. So these two miRNAs provide a potent tool to dampen this reciprocal activation and tightly regulate c-Myc-mediated cellular proliferation in normal cells. When this cluster of miRNA genes is deleted or underexpressed, the cell cycle would be out of control and have a risk of tumorigenesis.

Notably, not all miRNAs function as tumor repressors in the body. For example, enforced expression of the *mir-17-92* cluster positively cooperates with c-Myc expression to accelerate tumor development in a mouse B-cell lymphoma model, implicating that the *mir-17-92* cluster as a potential oncogene<sup>[2]</sup>. The oncogenic miRNAs can be upregulated in cancer cells, which are consistent with the conclusion drawn by Volinia that not all miRNAs are underexpressed in cancer cells<sup>[7]</sup>. In fact, specific miRNA expression influencing cell fate is dependant on the milieu of miRNAs and their target mRNAs expressed in individual cell.

## RULERS OF miRNA

As the pleiotropic regulators in cells, who regulate the expression of miRNA genes? As LIN-12/Notch signaling pathway directly regulates the expression of *mir-16* gene discussed above<sup>[35]</sup>, it seems that the regulation of miRNA expression follows the classic model widely used to control the mRNA expression. Taganov *et al*<sup>[38]</sup> recently reported that three putative NF- $\kappa$ B consensus binding sites locate upstream of the predicted *miRNA-146* gene, so *miRNA-146* is a NF- $\kappa$ B-dependent gene. Is this general model the common one or just an exceptional one with respect to diverse miRNAs and cytokines in cells? Our understanding of this knowledge awaits further investigations.

## NOT THE END OF STORY

We have discussed the potential roles of miRNAs in cancers by means of cell cycle, signaling and oncogene, but they are just the tip of emerging iceberg, because exploding data show that miRNAs have a potentially much more widely influence over diverse developmental and physiological pathways than imagined. Recent evidence revealed that miRNAs could participate in genomic stability and epigenetic modification<sup>[2,39]</sup>, in metabolic changes compatible with tumor formation, growth and metastasis<sup>[40]</sup>, and in the immune response to virus-mediated infection<sup>[41-45]</sup>. Many more aspects of miRNAs are available for exploration, so this is not the whole story.

More intriguingly, the other cousin of miRNAs, piwi-interacting RNAs (piRNAs), have just been discovered in rat germline cells and are also shown to control gene expression involved in sperm development at posttranscriptional level<sup>[46]</sup>. The world of three small RNAs (siRNAs, miRNAs, and piRNAs) is undoubtedly yielding newly provocative insights and revolutionizing our thinking about genome control<sup>[47]</sup>. Although transcriptional control is the most prevalent form of gene expression control, it is by no means the only way in complex eukaryotes. For example, it is important for mature blood red cells to control the stability of expressed mRNAs accounting for no extra mRNA transcription any more or is for immune cells to make a rapid response to stress without mRNAs transcription initiation. Posttranscriptional control has been ignored, but many novel small RNAs are changing our thinking.

## PROSPEROUS OUTLOOK IN miRNA

Evaluating the novel roles of miRNAs as repressors and oncogenes enriches our knowledge, which addresses the precise mechanism leading to tumorigenesis. The investigation will certainly bring about a potent tool to diagnose and treat human cancers, but a detailed, mechanistic understanding of miRNAs functions as oncogenes and tumor repressors is now retarded by lacking a valid and efficient biochemical technique to precisely identify miRNAs and their corresponding targets. It is estimated that many more miRNAs are still waiting to be discovered in the human genome and functions of most known miRNAs have not been elucidated. The other challenge is to accurately identify targets that are manipulated by miRNAs, because miRNAs can bind to their imperfect targets, even with no canonical complementarities that allow short stretch of mismatched base-pairs and G-U base pair. Other outstanding questions about miRNAs remain unresolved. What regulates the expression of miRNAs? Do distinct miRNAs have a direct function in cancer progression, or just simply differentially modulate in tumor? Who determines the opposite roles of miRNAs as both oncogenes and repressors? Do miRNAs act mainly to 'fine-tune' gene expression or more often as binary on/off switch? What factors affect the accessibility and efficacy of a miRNA at a 3'UTR? Another key one is how to apply this novel technique to cancer therapy. However, more sophisticated experimental approaches, in combination with

computational prediction strategies, will shed light on these challenges.

It has been shown that miRNA expression profile is a more accurate signature than protein expression one, and several patients got better prognosis after repairing the abrogated miRNAs. We enthusiastically expect that traditional and bioinformatics technique will generate a tremendous amount of excitement and inspiration about miRNAs in future.

## Abstract

**AIM:** To detect aneusomic changes with respect to chromosome 11 copy number in esophageal precancers and cancers wherein the generation of cancer-specific phenotypes is believed to be associated with specific chromosomal aneuploidies.

**METHODS:** We performed fluorescence *in situ* hybridization (FISH) on esophageal tissue paraffin sections to analyze changes in chromosome 11 copy number using apotome-generated images by optical sectioning microscopy. Sections were prepared from esophageal tumor tissue, tissues showing preneoplastic changes and histologically normal tissues (control) obtained from patients referred to the clinic for endoscopic evaluation.

**RESULTS:** Our results demonstrated that aneusomy was seen in all the cancers and preneoplastic tissues, while none of the controls showed aneusomic cells. There was no increase in aneusomy from precancers to cancers.

**CONCLUSION:** Our results suggest that evaluation of chromosome 11 aneusomy in esophageal tissue using FISH with an appropriate signal capture-analysis system, can be used as an ancillary molecular marker predictive of early neoplastic changes. Future studies can be directed towards the genes on chromosome 11,

## INTRODUCTION

More than 30% of the adult population exhibits upper gastrointestinal tract disorders associated with symptoms such as regurgitation, heartburn and dysphagia, warranting an endoscopic evaluation. Some of these esophageal pathologies require medication while others can be managed by altering life-style and dietary habits. A certain percentage of these, however, progress into esophageal malignancies. In India, esophageal cancer is the second leading cancer in men and fourth leading cancer in women<sup>[1]</sup>.

Epithelial tumors of the esophagus [squamous cell carcinoma (SCC) and adenocarcinoma (ADC)] are responsible for more than 95% of all esophageal carcinomas. This malignancy presents generally as a locally advanced disease, hence leading to poor prognosis with an average 5-year survival of < 12% in India<sup>[2]</sup>. Abnormal proliferation of the esophageal epithelial cells with hyperplasia and dysplasia in the normal squamous lining are regarded as premalignant lesions<sup>[3,4]</sup>. Another common premalignant condition is Barrett's esophagus (BE), where patients have a forty-fold increased risk for developing adenocarcinoma as compared to normal individuals. Although significant advances have been made in the diagnosis and treatment of esophageal carcinomas, not many studies have evaluated markers in the target tissue, in association with increased risk for malignant

transformation. Hence, there is a need to identify the genetic and molecular factors responsible for the progression of these esophageal lesions into malignancy.

Neoplastic progression is a complex multistep process associated with gross chromosomal alterations and mutations in regulatory genes, culminating in tumorigenesis. Genomic instability is a prominent feature of most cancers, wherein aneuploidy, a change in chromosomal number caused by unequal partitioning of chromosomes during cell division, occurs frequently in many solid tumors<sup>[5,6]</sup>. Aneuploidy then generates specific aneusomies autocatalytically, due to errors in chromosome segregation and repair processes<sup>[7]</sup>. Aneusomies have been reported in non-cancerous conditions such as Down's syndrome, wherein the extra chromosome 21 is considered to be associated with an increased risk for leukemias. The study of human cancers shows evidence for cancer-specific aneusomies, despite a plethora of unspecific aneuploidies<sup>[8,9]</sup>. Recently, it has been demonstrated cytogenetically that chromosome 11 may be important in the etiology of SCC of the esophagus<sup>[10,11]</sup>.

The present study was a hospital-based, unmatched, case-control study in 25 cases referred to our clinic from different hospitals in Hyderabad, South India. Chromosome 11 aneusomy was investigated in esophageal biopsies taken from controls, premalignant and malignant lesions, using fluorescence *in situ* hybridisation (FISH). Our results demonstrated that aneusomy was seen in all the cancers and preneoplastic tissues, while none of the controls showed aneusomic cells. There was no increase in aneusomy from precancers to cancers. Evaluation of chromosome 11 aneusomy in esophageal tissue can be used as an ancillary molecular marker predictive of early neoplastic changes.

## MATERIALS AND METHODS

### Tissue specimens

Esophageal biopsy specimens were endoscopically resected from patients referred for histopathological evaluation by a qualified gastroenterologist. The control samples were taken from those patients undergoing an endoscopy, which showed normal tissue histology. All samples were included in the study after informed consent was obtained from the patients. The study was approved by our Institutional Ethical Committee. Formalin-fixed, paraffin-embedded tissue sections from 25 selected cases were subjected to FISH analysis subsequent to confirmation by histology.

### Histopathological analysis

Paraffin-embedded tissue sections (4  $\mu$ m thick) were first subject to deparaffinization. Slides were placed in xylene (3 min  $\times$  3 min), 100% alcohol (3 min  $\times$  3 min), rinsed in running water and stained with haematoxylin (Harries, Merck) for 5-10 min. They were then placed in running water, dipped in 1% hydrochloric acid and subsequently transferred to Eosin yellow staining (Merck) for 30 s. After that the slides were passed through graded alcohol series for dehydration, placed in xylene and mounted in DPX (Ref: Histopathology Laboratory, Armed Forces Institute of Pathology, Washington DC, 20 305, USA). Suitable images

**Figure 1** Representative HE stained sections at  $\times 400$  magnification selected for FISH analysis. **A:** Neoplastic streaks with eosin stained keratin pearls indicating a well-differentiated squamous cell carcinoma; **B:** Adenocarcinomatous tissue showing columnar epithelial replacement of the normal squamous lining.

of the required areas from representative tissue sections were taken using a CCD camera (Figure 1).

Based on the endoscopic and histopathological evaluation, 25 tissue biopsies were selected for FISH analysis using a Spectrum Green labeled, centromere enumeration probe (CEP) for chromosome 11 [Vysis India Ltd] (This was used instead of the LSI probes that would help evaluate gene amplification).

### FISH on esophageal tissue sections

Paraffin sections of 4  $\mu$ m thick were deparaffinized in an oven at 95°C for 20 min, then immediately placed in xylene (3 min  $\times$  3 min) and transferred into 100% ethanol (3 min  $\times$  5 min). Dried slides were incubated in 2  $\times$  SSC solution at 75°C for 10 min followed by treatment with proteinase K solution (2 mg/mL) at 37°C for 15 min. The slides were rinsed in 2  $\times$  SSC solution at room temperature. They were then immersed in a 75°C denaturant bath (70% formamide/2  $\times$  SSC) for 5 min and dehydrated in gradient ethanol. Dry slides were placed on a 45-50°C slide warmer. Probe mixture was simultaneously prepared at room temperature (7  $\mu$ L of hybridization buffer + 1  $\mu$ L Spectrum Green labeled CEP 11 DNA probe + 2  $\mu$ L purified double distilled H<sub>2</sub>O) and then denatured at 95°C. Ten microliters of the probe mix were applied to the slide, and a coverslip was placed on it immediately. The slides were hybridized in a pre-warmed humidified chamber overnight (12-16 h) at 37°C. Post-hybridization washes were done with freshly prepared 0.4  $\times$  SSC/0.3% NP-40 solution at 55°C followed by 2  $\times$  SSC/0.1% NP-40 at room temperature. The slides were then air-dried in the dark. Ten microliter DAPI counterstain was applied to the target area and a coverslip was placed on it carefully to avoid formation of air bubbles.

The slides were viewed under a fluorescence microscope (Olympus, Optical sectioning microscope attached to an Axioplan imaging Apotome apparatus, Zeiss, Germany) using a suitable filter set (DAPI Exc: 367nm; Emi: 452 nm and Spectrum Green Exc: 509 nm; Emi: 538 nm). The optical sectioning microscope provided a high-quality image enhancement required for proper signal visualization. The sections were visualized through Optical sectioning mode using the Apotome for the best probe signals in a 3D mode. Ten to fifteen areas per slide were taken for analysis based on the density of the nuclei. Each area allowed optical sectioning of about

Table 1 Details of cases analyzed for chromosome 11 aneusomy using FISH in different esophageal pathologies and controls

Case, No.	Case type	Details	Chromosome 11 % aneusomy		
			Trisomy (%)	Tetrasomy (%)	Pentasomy (%)

Percentage of aneusomy in different cases from the first 250 cells scored. (Monosomies and normal disomies are not shown in the table). ADC: Adenocarcinoma; WDSCC: Well differentiated SCC; MDSCC: Moderately differentiated SCC; PDSCC: Poorly differentiated SCC; Sq.: Squamous.

**Figure 2** Images showing aneusomy with regard to chromosome 11 in esophageal cancer cells. **A:** Trisomy and tetrasomy chromosome 11 in the same area; **B:** Pentasomy chromosome 11 with normal disomy.

8-10 consecutive sections using the apotome. The images were captured at 1500 × magnification with oil immersion. Analysis was done using the 3D analysis of the Axiovision Apotome 1 imaging and Adobe Photoshop 7.0 version softwares.

### Criteria for evaluating FISH signals

Data were scored from areas showing uniform fluorescence intensity. We screened a large number of nuclei per sample in order that we did not miss any aneusomic cells, especially with respect to precancer tissues. In each case, clear, distinct FISH signals were evaluated by counting 250 non-overlapping nuclei. Only those samples in which the artifactual nullisomy (negative nuclei) did not exceed the prescribed 25% were chosen for evaluation. A baseline frequency of monosomic population was established to control 'truncation' artifacts resulting from cut nuclei during microtomy.

## RESULTS

From the patients with upper GI tract disorders referred for endoscopic evaluation, 25 cases were selected into the FISH study based on endoscopic and histopathological categorization. Of these 25 cases, 20 gave analyzable results; they included five normal tissues, four precancers (two squamous dysplasias and two BE with high-grade dysplasia) and eleven esophageal cancers as shown in Table 1.

FISH was performed on a few metaphase cells and, in conjunction with G-banded chromosome analysis, we confirmed the probe hybridization. Subsequently the method was applied to esophageal tissue sections obtained from paraffin blocks. Optical sectioning generated 3D images were evaluated and screened for chromosome 11 probe signals (Figure 2).

The results in each sample were tabulated as nullisomy (absence of signals), monosomy (single signal), normal disomic condition (two signals), trisomy (three signals), tetrasomy (four signals) and pentasomy (five signals). Esophageal tumor cells with trisomic, tetrasomic and pentasomic signals indicating the presence of extra chromosome 11 are shown in Figure 3.

Artifactual nullisomy was found to be less than 15% in all 20 cases studied. Monosomy was seen in < 35% of the cells in all three groups of controls, precancers and cancers; this was not included in the analysis as it was considered as a technical artifact. The controls showed normal disomy in all the remaining cells analyzed. Premalignant tissues showed an increase in the copy number of chromosome 11; all the four precancer cases showed trisomy of chromosome 11 (4%, 10%, 15.2%, 5.6%); of these, one case with severe squamous dysplasia exhibited tetrasomy (0.4%), and a case of BE with high

**Figure 3** Axiovision Apotome software generated 3D-image from overlay of 10 consecutive images captured by the Optical sectioning microscopy. **A:** A portion of the esophageal tissue section from the control showing normal disomy of chromosome 11 (indicated by an arrow); **B:** Tissues from patients with well-differentiated squamous cell carcinoma (arrow indicating cell with trisomy for chromosome 11).

grade dysplasia showed tetrasomy and pentasomy of chromosome 11 (2.4% and 0.8%), respectively (Table 1).

All eleven cancer cases showed varying degrees of aneusomy of chromosome 11 in the affected tissues. Both cases of adenocarcinoma showed trisomy and tetrasomy. Of the remaining SCC cases, 4/9 showed only trisomy, 5/9 also showed tetrasomy and 1/9 also exhibited pentasomy of chromosome 11 (Table 1).

## DISCUSSION

Chromosomal instability leading to aneuploidy and subsequently, specific aneusomies is characteristic of cancers<sup>[7,12]</sup>. In spite of the somatic gene-mutation hypothesis supporting the role of oncogenes and tumor suppressor genes in carcinogenesis, it has not been possible to disprove the century-old aneuploidy hypothesis even today. Cancer independent evidence suggests that specific aneusomies encode the phenotypes of irreversible precancerous lesions and are sufficient to alter the phenotype of eukaryotic cells to trigger cellular transformation<sup>[13-16]</sup>. Given this, it follows that chromosome number mutation, not gene mutation alone, is a probable cause of many dominant cancer cell phenotypes. Aneusomy can alter the dosage and thus the relevant activities of thousands of genes on the chromosome involved. Dividing aneuploid cells become increasingly unstable and most of these cells die eventually; rarely, these generate a specific aneusomy which then promotes the cell toward neoplastic transformation.

Specific chromosomal aneuploidies are characteristic of solid tumors unlike the random aneuploidies exhibited in hematological malignancies<sup>[9,17]</sup>. Chromosome 11 has a number of oncogenes and tumor suppressors including Cyclin D1, which is overexpressed in a wide variety of human neoplasms<sup>[18,19]</sup>. Reports suggest that overexpression of cyclin D1 is not due to gene amplification but due to chromosome number changes<sup>[5]</sup>. Other studies show the partial segmental aneusomy involving chromosome 11 in esophageal cancers, indicating its probable role in the disease etiology<sup>[10,11]</sup>. In the present work, FISH was used to assess change in chromosome 11 copy number in esophageal tumors using centromeric DNA probes.

Interestingly, our results showed that 100% of the cancerous lesions of the esophagus were aneusomic

for chromosome 11. These ranged from trisomies to pentasomies in the same sample, indicating heterogeneity in the tumor tissue (Table 1). The baseline monosomy established (due to experimental artifacts) was similar in all controls, precancers and cancers. This is the first study to report that chromosome 11 copy number is altered in both esophageal SCC and ADC tumors. Because the number of ADC cases was small, there was no significant difference in the levels of aneusomy between SCC and ADC tumors. None of the controls showed any aneusomy suggesting that this chromosomal alteration is associated only with the neoplastic changes.

In addition, we also made a detailed investigation regarding the esophageal pathologies in each sub-group (though small in number) and the aneusomy in them.

There have been very few reports of specific aneusomies in esophageal premalignant lesions; using FISH, some studies showed hyperdiploidy involving chromosomes 4 and 8 in BE, aneuploidy in chromosome 11 in esophageal tumors and Barrett's dysplasias<sup>[20-23]</sup>. In the present work, all the precancerous lesions including BE with high-grade dysplasia exhibited aneusomy of chromosome 11. Our data indicate that levels of aneusomy of chromosome 11 seemed to occur increasingly in preneoplastic tissues suggesting that there may be genes on chromosome 11 that have a role in the initiation and neoplastic transformation of esophageal lesions.

Cytogenetic analysis by conventional chromosomal banding is labor-intensive and time-consuming. Besides, it is difficult to analyze some of the complex karyotypes characteristic of many human tumors. On the other hand, FISH is a relatively more convenient and quick method for evaluating tissue cell chromosomal changes<sup>[24,25]</sup>. Moreover, we have observed that by using adequate fluorescent signal capture (optical sectioning microscopic method) and analysis systems, an accurate estimate of the changes in chromosome copy number could be obtained from tumor tissues, based on which we could make satisfactory interpretations. Our study supports the finding that solid tumor cancers are often aneuploid for specific chromosomes and this may be used as an ancillary marker for detecting early changes associated with cancer.

Epigenetic changes like DNA methylation may lead to chromosomal instability, activation of endogenous parasitic sequences and mutations<sup>[26]</sup>. Cancer cells undergo methylation changes resulting in overexpression/silencing of several genes that are responsible for maintaining chromosomal integrity. Our study also revealed that 4/11 cancers and 2/5 precancers with increased copies of chromosome 11 had a hypermethylated hMLH1 repair gene promoter known to be responsible for altered repair efficiency (data not shown).

We did not perform any studies to assess whether this aneusomy correlates with the DNA content aneuploidy (i.e. gross chromosomal instability) of the tissues. The sample number (with a mix of ADCs and SCCs, which might have different etiologies), though, was not sufficient to make conclusions about predictive values, the results showed the differences in the frequencies of aneusomy in the two types of tumor. The present work clearly indicates that aneusomy is observed in early esophageal

lesions and may be involved in neoplastic transformation. Aneusomy of other chromosomes cannot be ruled out, however here, chromosome 11 is clearly demonstrated in all the esophageal pathologies studied. This marker merits investigation in a larger number of cases to determine its potential as a predictive molecular marker for an increased risk for malignant transformation.

## ACKNOWLEDGMENTS

We acknowledge help from Gastroenterology Units of Bhagwan Mahavir Medical Research Center, AC Guards, Hyderabad, Osmania General Hospital, Afzalgunj, Hyderabad and Kamineni Hospitals, LB Nagar, Hyderabad. We thank Mr. Srinivas and Mr. Mallesh, technicians of the Department of Pathology for their assistance with histopathology.

## COMMENTS

### Background

More than 30% of the adult population exhibits esophageal tract disorders, where a certain proportion of chronic cases even develop malignancy. Markers for early detection, which will help improve survival and treatment response are still lacking. This study investigates specific aneusomies which are believed to be associated with solid cancer phenotypes.

### Research frontiers

Current biopsy surveillance programs are based on histopathological assessment of the tissue. However, molecular changes precede visible histopathological changes in cancer. FISH-based assay using brush cytology specimens (more easily accessible than biopsy) are increasingly used for investigation of chromosomal alterations and after validation these molecular markers can be used for routine surveillance in order to aid in early detection.

### Innovations and breakthroughs

FISH, when compared to conventional cytogenetic analysis, is a more convenient and quick method for evaluating tissue cell chromosomal changes. An apotome-attached optical sectioning microscope to capture fluorescent probe signals has shown maximum efficiency for signal analysis in tissue FISH. This will aid in satisfactory data collection and interpretation.

### Applications

Chromosome 11 aneusomy has been demonstrated in all the cases of cancer and precancer studied by us indicating its potential as an early marker for neoplastic transformation. Our results call for evaluating this marker in a larger cohort of patients.

### Terminology

Regurgitation: bringing back undigested food from the stomach; Dysphagia: difficulty in swallowing; Dysplasia: Nuclear atypia, loss of normal cell polarity, and abnormal tissue maturation.

### Abstract

**AIM:** To investigate the effects of 2-(8-hydroxy-6-methoxy-1-oxo-1H-2-benzopyran-3-yl) propionic acid (NM-3) alone and in combination with carboplatin on tumor growth and apoptosis in mouse models of human gastric cancer constructed by subcutaneous implantation of histologically intact tumor tissue.

**METHODS:** Human gastric cancer SGC-7901 tissues were implanted into the dorsal subcutis of nude mice. One week after tumors reached to a volume of 50-100 mm<sup>3</sup> for around 1 wk, these mice were randomly divided into 8 groups ( $n = 10$ ). NM-3 was injected peritoneally at the dose of 10 mg/kg, 20 mg/kg or 40 mg/kg every other day for 5 wk, combined with carboplatin (5 mg/kg) every third day for 4 wk. As controls of combined treatment, another 4 groups of mice were injected with either NM-3 at 10 mg/kg, 20 mg/kg or 40 mg/kg, or with carboplatin alone (5 mg/kg). The control mice received normal saline. Tumor weight, tumor growth inhibition (TGI), and intratumoral microvessel density (MVD) were evaluated. Apoptosis of human gastric cancer was detected by TUNEL method and flow cytometry analysis, respectively.

**RESULTS:** The mean tumor volume ( $692.40 \pm 58.43$  mm<sup>3</sup>,  $548.30 \pm 66.02$  mm<sup>3</sup>,  $382.13 \pm 43.52$  mm<sup>3</sup>) after treatment with carboplatin combined NM-3 at the dose of 10 mg/kg, 20 mg/kg or 40 mg/kg was lower than that after treatment with either NM-3 at the dose of 10 mg/kg, 20 mg/kg or 40 mg/kg or with carboplatin alone. Compared with the normal saline group, NM-3 administered at 10 mg/kg, 20 mg/kg or 40 mg/kg significantly reduced the tumor weight in these groups ( $P < 0.05$ ). Carboplatin used alone at 5 mg/kg

showed minimal effects. But NM-3 in combination with carboplatin had greater effects of tumor weight than either NM-3 or carboplatin alone. NM-3 alone at the dose 10 mg/kg or in combination with carboplatin had no obvious effects on body changes. Two mice died of diarrhea in each of the two groups treated with 40 mg/kg NM-3 or with 40 mg/kg NM-3 in combination with carboplatin. A significant increase in apoptosis was observed in the NM-3 treated groups, and the effect was more significant in the groups treated with carboplatin in combination with NM-3 at 10 mg/kg, 20 mg/kg and 40 mg/kg, than in the control group. The induction of apoptosis was positively associated with the dose of NM-3. NM-3 significantly reduced the neo-microvascular formation of gastric cancer. The MVD was lower in the groups treated with NM-3 or with NM-3 in combination with carboplatin than in the group treated with carboplatin or in the normal saline group ( $P < 0.05$ ).

**CONCLUSION:** The results suggest that the inhibitory effect of NM-3 on gastric cancer growth is mediated through decreased angiogenesis and the increased induction of apoptosis. Furthermore, NM-3 alone at the dose of 10 mg/kg or in combination with carboplatin has no obvious effects on body changes, indicating that NM-3 in combination with carboplatin may be effective in the treatment of gastric cancer. The toxicity of NM-3 needs further studies.

### INTRODUCTION

Gastric carcinoma is one of the most frequent malignancies and one of the major causes of cancer deaths

in China<sup>[1]</sup>. Up to now, the prognosis of patients with gastric cancer is very poor because gastric cancer is usually diagnosed at its advanced stage throughout the world. Even after curative resection, it remains at a high risk of relapse. Chemotherapy is one of the most important treatment modalities for gastric cancer. However, its effect is limited due to its adverse reactions and resistance of tumor cells to chemotherapeutic agents<sup>[2]</sup>.

Apoptosis plays an important role in the growth of malignant tumor cells. It has been shown that apoptosis can be induced in gastric cancer by some chemotherapeutic drugs, such as 5-fluorouracil, cisplatin and paclitaxel<sup>[3]</sup>. Recent studies have demonstrated that angiogenesis plays a crucial role in tumor growth and metastasis. Vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2) are the main factors promoting angiogenesis<sup>[4-6]</sup>. It has been shown that radiation-induced tumor regression is enhanced by angiogenesis inhibitors. Angiostatin or antibody to VEGF in combination with chemotherapy produces greater antitumor effects than either treatment alone<sup>[7,8]</sup>.

Recently, induction of apoptosis by antiangiogenic therapy has been suggested as a new anticancer strategy<sup>[9]</sup>. 2- (8-hydroxy-6-methoxy-1-oxo-1H-2-benzopyran-3-yl) propionic acid (NM-3), is a synthetic derivative of cytochrome c. *In vitro* studies have demonstrated that the inhibitory effects of NM-3 at lower concentrations are stronger on the growth of human umbilical vein endothelial cells than on the growth of normal fibroblasts or tumor cells<sup>[10]</sup>. NM-3 alone inhibits endothelial sprouting and tube formation *in vitro*. It has been shown that NM-3 can enhance 5-fluorouracil-induced tumor growth inhibition in breast carcinoma xenografts with no effects on body changes<sup>[11]</sup>. In this study, we investigated the effects of NM-3 alone or in combination with carboplatin on tumor growth and apoptosis in mouse models of human gastric cancer constructed by subcutaneous implantation of histologically intact tumor tissue.

## MATERIALS AND METHODS

### Materials

Male BALB/c/nu/nu nude mice were obtained from Shanghai Experimental Animal Center of the Chinese Academy of Sciences. Animals used were 6-wk old and weighed 20-25 g. Human gastric cancer SGC-7901 was obtained from Shanghai Cancer Institute. NM-3 was provided by professor Robert (National Cancer Research Center of America), concentration of NM-3 was 20 mg/mL.

### Animal experimental method

Animal models were made using subcutaneous implantation of histologically intact tissue of human gastric carcinoma. Tumors were resected aseptically. Necrotic tissue was removed and the remaining tumor tissues were minced into pieces about 2 mm in diameter and implanted into the dorsal subcutis of mice.

One week after tumors reached a volume of 50-100 mm<sup>3</sup> for around 1 wk, these mice were randomly divided into 8 groups ( $n = 10$ ). NM-3 was injected peritoneally

at the dose of 10 mg/kg, 20 mg/kg or 40 mg/kg every other day for 5 wk, in combination with carboplatin (5 mg/kg) every third day for 4 wk. As controls of combined treatment, another four groups of mice were injected NM-3 or carboplatin alone. The control mice received normal saline as indicated. The mice were weighed twice weekly, and tumor measurements were taken by calipers twice weekly. Tumor volume was measured using the formula ( $V = ab^2/2$ ), where  $a$  is the largest diameter and  $b$  the smallest diameter. Tumor growth inhibition (TGI) in each group was (mean control tumor weight - mean treated tumor weight)/mean control tumor weight  $\times 100\%$ .

### Sample collection and pathological examination

All animals were sacrificed 7 wk after the implantation. Tumors were biopsied, fixed in 10% formalin, and processed for routine paraffin embedding. Tumors were evaluated histologically under microscope.

### Mean microvascular density (MVD of tumor)

Four-micron-thick sections were deparaffined in xylene and rehydrated in graded alcohol. Immunostaining was performed using a labeled streptavidin biotin method. Immunohistochemical staining was carried out to detect CD34 expression following the manufacturer's protocol (Santa Cruz Biotech Company). The modified Weidner's method was used for the evaluation of MVD according to CD34 endothelial cell immunostaining. For microvessel counting, positive staining for MVD in five most highly vascularized areas in each section was counted in 200  $\times$  fields. MVD was expressed as the average of the microvessel count in the 5 areas. Any endothelial cell or endothelial cluster positive for CD34 (brown-yellow staining) was a single countable microvessel.

### Detection of cell apoptosis index (AI)

Apoptosis of human gastric cancer was detected by terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate-fluorescence nick end labeling (TUNEL) method and flow cytometry analysis, respectively. TUNEL method was performed as indicated. Flow cytometry analysis was conducted as follows. In brief, propidium iodide (PI) staining was used for flow cytometric detection of apoptosis,  $1 \times 10^6$  cells from each of the samples were treated with RNase and stained with PI. DNA strand-labeled apoptotic cells were calculated with a flow cytometer (FACS Calibur, Becton Dickinson, USA.). Data were collected from  $1 \times 10^6$  cells/sample, stored and analyzed using CELLQUEST and MODFITLT for macV 1.01 software.

### Statistical analysis

All data were expressed as mean  $\pm$  SD. Student's  $t$  test was used to determine changes in different groups.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Inhibitory effect of NM-3 on growth of xenografted human gastric cancer in nude mice

The mean tumor volume (MTV) in the groups treated

Table 1 Inhibitory effect of NM-3 on gastric cancer growth (mean  $\pm$  SD)

Groups	n	MTV (mm <sup>3</sup> )	Body weight (g)	Tumor weight (mg)	TGI (%)
Normal saline	10	81.24 $\pm$ 12.63	25.8 $\pm$ 1.04	1754.0 $\pm$ 144.2	
NM-3 (10 mg/kg)	10	79.68 $\pm$ 13.72	24.4 $\pm$ 0.76	1351.0 $\pm$ 116.9	23.0 <sup>a</sup>
NM-3 (20 mg/kg)	10	81.08 $\pm$ 12.90	23.1 $\pm$ 0.82	1041.1 $\pm$ 143.5	40.6 <sup>a</sup>
NM-3 (40 mg/kg)	8	81.36 $\pm$ 11.20	22.9 $\pm$ 1.06	765.5 $\pm$ 140.1	56.2 <sup>a,c</sup>
NM-3 (10 mg/kg) + carboplatin	10	80.29 $\pm$ 14.26	24.2 $\pm$ 0.88	1002.0 $\pm$ 101.4	42.7 <sup>a,c</sup>
NM-3 (20 mg/kg) + carboplatin	10	82.30 $\pm$ 14.53	24.4 $\pm$ 0.78	919.0 $\pm$ 149.8	47.6 <sup>a,c</sup>
NM-3 (40 mg/kg) + carboplatin	8	81.97 $\pm$ 12.77	22.5 $\pm$ 1.13	645.7 $\pm$ 135.1	63.2 <sup>a,c</sup>
Carboplatin	10	80.01 $\pm$ 13.67	23.0 $\pm$ 1.03	1655.0 $\pm$ 157.4	5.6

<sup>a</sup>*P* < 0.05 vs normal saline control group and carboplatin group, <sup>c</sup>*P* < 0.05 vs NM-3 (10 mg/kg) group.

Figure 1 Propidium iodide (PI) staining for flow cytometric detection of apoptosis in control group (A) and NM-3-treated group (B).

with 10 mg/kg, 20 mg/kg or 40 mg/kg NM-3 was 989.50  $\pm$  102.17 mm<sup>3</sup>, 826.20  $\pm$  76.52 mm<sup>3</sup>, and 709.75  $\pm$  89.30 mm<sup>3</sup>, respectively, which was significantly smaller than that in the control group receiving normal saline (1609.60  $\pm$  122.11 mm<sup>3</sup>, *P* < 0.05). Carboplatin at the dose of 5 mg/kg had no significant inhibitory action on gastric carcinoma with MTV being 1532.14  $\pm$  110.12 mm<sup>3</sup>. However, the mean tumor volume in groups treated with carboplatin in combination with NM-3 was 692.40  $\pm$  58.43 mm<sup>3</sup>, 548.30  $\pm$  66.02 mm<sup>3</sup>, and 382.13  $\pm$  43.52 mm<sup>3</sup>, respectively, which was lower than that in the groups treated either with NM-3 or with carboplatin alone. Compared with the normal saline group, NM-3 administered at 10 mg/kg, 20 mg/kg or 40 mg/kg significantly reduced the tumor weight in these groups, and the effect was more significant when NM-3 was given at a dose of 40 mg/kg (*P* < 0.05). Carboplatin used alone at the dose of 5 mg/kg showed minimal effects. But NM-3 in combination with carboplatin, however, had a more significant effect on tumor weight than NM-3 or carboplatin alone (Table 1). The mean tumor volume did not differ among groups before treatment (Table 1).

During the experiment, diarrhea occurred in some mice when NM-3 was given at the dose of 20 mg/kg or 40 mg/kg. Two mice died of diarrhea in each of the two groups treated with 40 mg/kg NM-3 or with 40 mg/kg NM-3 in combination with carboplatin. The remaining mice recovered at the latter stage of the experiment. NM-3 alone at the dose of 10 mg/kg or in combination with carboplatin had no obvious effects on body changes.

Table 2 Effect of NM-3 on cell apoptosis of gastric cancer (mean  $\pm$  SD, %)

Groups	n	AI (TUNEL)	AI (FAScan)
Normal saline	10	2.12 $\pm$ 2.19	1.59 $\pm$ 0.24
NM-3 (10 mg/kg)	10	6.02 $\pm$ 1.63 <sup>a</sup>	3.84 $\pm$ 0.68 <sup>a</sup>
NM-3 (20 mg/kg)	10	10.43 $\pm$ 3.15 <sup>a,c</sup>	8.21 $\pm$ 1.01 <sup>a,c</sup>
NM-3 (40 mg/kg)	8	22.06 $\pm$ 5.68 <sup>a,c</sup>	18.26 $\pm$ 4.46 <sup>a,c</sup>

### Effect of NM-3 on cell apoptosis of human gastric cancer cells

Apoptosis of gastric cancer cells was observed microscopically. Manifestations of apoptosis could be found more frequently in NM-3-treated groups, such as cell shrinkage, nuclear condensation, DNA fragmentation and formation of apoptotic bodies. Apoptosis was detected with flow cytometry (Figure 1).

The apoptosis index of tumors treated with carboplatin alone was not significantly different from that of the control group (*P* > 0.05). However, a significant increase in apoptosis was observed in the NM-3-treated groups, and the effect was more significant in the groups treated with carboplatin in combination with NM-3 at 10 mg/kg, 20 mg/kg and 40 mg/kg than in the control group (Table 2). The induction of apoptosis was positively associated with the dose of NM-3.

### Effect of NM-3 on MVD

NM-3 significantly reduced the neo-microvascular formation of gastric cancer implanted into nude mice. The MVD was lower in groups treated with NM-3 or with NM-3 in combination with carboplatin than in carboplatin group or normal saline group (*P* < 0.05). More significant inhibitory effects on MVD of tumor were observed in NM-3-treated groups at the dose of 40 mg/kg or in combination with carboplatin than in control group (*P* < 0.05, Table 3, Figure 2A-H).

## DISCUSSION

Recent studies have shown that angiogenesis plays a

critical role in solid tumor growth and its development<sup>[8]</sup>. Antiangiogenic agents inhibit tumor growth by preventing proliferation, migration and sprouting of tumor endothelial cells and formation of new blood vessels. Antiangiogenic therapy plays an important role in improving prognosis of patients with gastric carcinoma<sup>[12-15]</sup>. NM-3, a small molecule isocoumarin, is a recently discovered angiogenesis inhibitor. It has been shown that NM-3 enhances the antitumor effects of some chemotherapeutic drugs in breast and prostate tumor models<sup>[11]</sup>. The increased antitumor effects of chemotherapy in combination with NM-3 can be achieved without any apparent increase in toxicity. To date, the effect of antitumor and induction of cell apoptosis of NM-3 on human gastric cancer have not been reported. It is worthwhile, therefore, to further research its antitumor mechanisms underlying gastric cancer.

In the present study, NM-3 significantly inhibited the growth of human gastric cancer in mice. Compared with the controls, growth of the tumor implanted subcutaneously was remarkably reduced in size and weight in the mice treated with NM-3 at the doses of 10 mg/kg, 20 mg/kg, 40 mg/kg. These doses of NM-3 in combination with carboplatin delayed the growth of SGC-7901 human gastric cancer in mice, compared with NM-3 or carboplatin alone. NM-3 alone at the dose of 10 mg/kg or in combination with carboplatin had no obvious effects on body changes. However, two mice died of diarrhea in each of the two groups treated with 40 mg/kg NM-3 or with 40 mg/kg NM-3 in combination with carboplatin, suggesting that the toxicity and doses of NM-3 used in patients need further studies. Although tumor growth was inhibited by NM-3 in combination with carboplatin as compared with normal saline group, tumor weight increased. This may be due to the lower dose of carboplatin used. In our study, carboplatin at the dose of 5 mg/kg showed minimal effects on tumor growth. Previous studies have demonstrated that chemotherapy in combination with an angiogenesis inhibitor can enhance tumor growth inhibition. Reimer *et al*<sup>[11]</sup> demonstrated that NM-3 can significantly enhance tumor growth inhibition in breast and prostate carcinoma xenografts at nontoxic doses in combination with 5-fluorouracil, paclitaxel or cyclophosphamide given at subtherapeutic doses. These effects were particularly marked when NM-3 was combined with cyclophosphamide. Vinblastine in combination with

VEGF receptor-2 antibody could cause sustained tumor regression. Salloum *et al*<sup>[10]</sup> studied the antitumor effects of NM-3 in combination with radiotherapy, and found that the tumor is significantly regressed after combined treatment compared with radiotherapy alone with no increase in systemic or local tissue toxicity, suggesting that NM-3 in combination with chemotherapy or radiotherapy can increase the efficacy of cancer treatment.

Cell apoptosis is an active death process of cells, its imbalance or changes are related to the occurrence of many diseases. Gastric cancer is not only a disease with abnormal cell proliferation and differentiation, but also a disease with abnormal apoptosis<sup>[16,17]</sup>. Increased apoptosis in human gastric cancer cells could be observed after treatment with 5-fluorouracil, cisplatin, *etc.* The results suggest that these drugs can be used in the treatment of patients with gastric cancer by inducing apoptosis of cancer cells. The results obtained by TUNEL method and cytometry analysis indicate that apoptosis is induced by NM-3. Matsushashi *et al*<sup>[18]</sup> investigated the relationship between p53 expression and apoptosis induction of 5-fluorouracil and cisplatin on gastric cancer cells, and found that combined administration of 5-fluorouracil and cisplatin does not induce apoptosis of MKN-28 (mutant-type p53), while apoptotic cells can be observed in the case

of MKN-45 (wild-type p53). Browder *et al*<sup>[19]</sup> demonstrated that TNP-470 at a low dose in combination with cyclophosphamide can eradicate drug-resistant Lewis lung carcinoma. Agata *et al*<sup>[20]</sup> revealed that NM-3 potentiates dexamethasone-induced apoptosis of human multiple myeloma cells. Moreover, NM-3 is effective against dexamethasone-resistant RPMI8226 and U266 multiple myeloma cells. NM-3 enhances dexamethasone-induced release of mitochondrial apoptogenic factors (cytochrome c and smac/DIABLO) and dexamethasone-induced activation of intrinsic caspase-9→caspase-3 apoptotic pathway. These results suggest that NM-3 inhibits the growth of gastric cancer by enhancing apoptosis of cancer cells.

Angiogenesis has been implicated in the growth and metastasis of gastric cancer. MaCarty *et al*<sup>[21]</sup> reported that ZD6474, a vascular endothelial growth factor receptor (tyrosine kinase inhibitor) inhibits orthotopic growth and angiogenesis of gastric cancer and increases tumor cell apoptosis. Stoeltzing *et al*<sup>[22]</sup> demonstrated that inhibition of hypoxia-inducible factor 1 activity can inhibit gastric cancer growth and angiogenesis. Kamiya *et al*<sup>[23]</sup> showed that the antitumor effect of VEGF Ab on gastric cancer is exerted by inducing mild hypoxia and apoptosis. Reimer *et al*<sup>[11]</sup> reported that the antitumor effects of NM-3 in combination with chemotherapeutic agents are mediated through decreased proliferation of endothelial cells. The present study indicated that NM-3 significantly inhibited angiogenesis in gastric cancer, suggesting that apoptosis of gastric cancer is mediated by NM-3 through decreased angiogenesis and that the inhibitory effect of NM-3 on gastric cancer growth is related to the induction of apoptosis.

In conclusion, NM-3 in combination with carboplatin is effective against gastric cancer. The toxicity and mechanism of NM-3 underlying apoptosis of gastric cancer need further studies.

## COMMENTS

### Background

Gastric carcinoma is one of the most frequent malignancies in China. Angiogenesis plays a crucial role in tumor growth and metastasis. Recently, induction of apoptosis by antiangiogenic therapy has been suggested as a new anticancer strategy.

### Research frontiers

2-(8-hydroxy-6-methoxy-1-oxo-1H-2-benzopyran-3-yl) propionic acid (NM-3) is a synthetic derivative of cytogenin. In vitro studies have demonstrated that the inhibitory effects of NM-3 at lower concentrations are stronger on human umbilical vein endothelial cells than on normal fibroblasts or tumor cells. NM-3 alone inhibits endothelial sprouting and tube formation *in vitro*.

### Innovations and breakthroughs

There is some experience of NM-3 as an apoptotic and antiangiogenic inducer in other types of tumors such as lung and prostatic cancers, but not in gastric cancer which is associated with high chemotherapy resistance. Inhibitory effects of NM-3 on gastric cancer growth are mediated through decreased angiogenesis and the increased induction of apoptosis. NM-3 at the dose of 10 mg/kg alone or in combination with carboplatin has no obvious effects on body changes.

### Applications

NM-3 in combination with carboplatin may be effective against gastric cancer.

## Peer review

This is a well designed experimental study of apoptosis and effects of NM-3 and carboplatin on gastric cancer model (SGC-7901). There is some experience in NM-3 as an apoptotic and antiangiogenic inducer in other types of tumors such as lung and prostatic cancers, but not in gastric cancer which is associated with high chemotherapy resistance. The paper is interesting.

## Abstract

**AIM:** To assess the usefulness of two independent histopathological classifications of rectal cancer regression following neo-adjuvant therapy.

**METHODS:** Forty patients at the initial stage cT3NxM0 submitted to preoperative radiotherapy (42 Gy during 18 d) and then to radical surgical treatment. The relationship between "T-downstaging" versus regressive changes expressed by tumor regression grade (TRG 1-5) and Nasierowska-Guttmejer classification (NG 1-3) was studied as well as the relationship between TRG and NG versus local tumor stage ypT and lymph nodes status, ypN.

**RESULTS:** Complete regression (ypT0, TRG 1) was found in one patient. "T-downstaging" was observed in 11 (27.5%) patients. There was a weak statistical significance of the relationship between "T-downstaging" and TRG staging and NG stage. Patients with ypT1 were diagnosed as TRG 2-3 while those with ypT3 as TRG5. No lymph node metastases were found in patients with TRG 1-2. None of the patients without lymph node metastases were diagnosed as TRG 5. Patients in the ypT1 stage were NG 1-2. No lymph node metastases were found in NG 1. There was a significant correlation between TRG and NG.

**CONCLUSION:** Histopathological classifications may be useful in the monitoring of the effects of hyperfractionated preoperative radiotherapy in patients

with rectal cancer at the stage of cT3NxM0. There is no unequivocal relationship between "T-downstaging" and TRG and NG. There is some concordance in the assessment of lymph node status with ypT, TRG and NG. TRG and NG are of limited value for the risk assessment of the lymph node involvement.

## INTRODUCTION

Colorectal cancer is the third most common malignancy diagnosed in the USA<sup>[1]</sup>. The estimated colorectal cancer mortality in the USA in 2006 is 55 170<sup>[2]</sup>. The primary treatment method for rectal cancer is surgery, namely anterior rectal resection, abdomino-perineal resection or local excision<sup>[3-6]</sup>. Preoperative radiotherapy and radiochemotherapy play an increasing role in the treatment of rectal cancer<sup>[7-13]</sup>. The effectiveness of neo-adjuvant therapy may be assessed and monitored by means of long-term survival follow up, incidence of local recurrence, estimation of the percentage of patients with primary high stage tumor suitable for radical surgery, estimation of the percentage of patients suitable for sphincter-saving surgery or by monitoring the tumor stage using visualizing diagnostic methods<sup>[14,15]</sup>. Transrectal ultrasound (TRUS) is a useful method for the assessment of the local tumor stage and the regional lymph node status prior to neo-adjuvant therapy<sup>[3,4,6,16]</sup>. Basing on TRUS and histopathological examination one can define the tumor regression parameter "T-downstaging". Lower ypT parameter value (local tumor stage assessed by the pathologist in surgical specimen following neo-adjuvant therapy) than uT (local

tumor stage assessed by surgeon with use of TRUS prior to neo-adjuvant therapy) is considered an evidence of tumor regression. The value of ypT parameter equal or higher than uT indicates lack of tumor regression<sup>[11,14,17-21]</sup>.

This parameter may also be applied to the regression of metastatic regional lymph nodes in rectal cancer, "N-downstaging"<sup>[17,20,22-26]</sup>.

Preoperative radiotherapy and radiochemotherapy evokes a range of morphological changes in the microscopic picture of rectal cancer including increased tumor necrosis, cellular and nuclear atypia, endocrine differentiation of tumor cells, increased stromal fibrosis, quantitative and qualitative changes of the stromal inflammatory exudates, formation of mucin pools, surface ulceration, peritumoral eosinophilic infiltrate, dysplastic and adenomatous changes (high-grade dysplasia, and low-grade adenoma component in the intestinal mucosa)<sup>[5,27,28]</sup>. Several histopathological classifications of rectal carcinoma response to neo-adjuvant therapy have been proposed<sup>[5,20,29-33]</sup>. However, none of these classifications is used in routine histopathological diagnostics. This results from the fact that macro- and microscopic changes within the tumor structure and surrounding tissues are not a specific response to ionizing radiation but also may result from the non-specific inflammation, hormonal therapy and local immune reaction<sup>[5,7]</sup>. Tumor regression grade (TRG) is a semi-quantitative parameter describing a relative proportion of residual tumor and stromal fibrosis. It is regarded a useful parameter for the assessment of histopathological changes in tumor following neo-adjuvant therapy<sup>[14,18,19,21,22,29,34-38]</sup>. There are five grades of cancer response to treatment in TRG staging, ranging from TRG 1-no residual cancer cells in the intestinal wall, replaced by fibrous tissue, through TRG 2-presence of occasional residual cancer cells, scattered in fibrous stroma, TRG 3-fibrosis dominating over residual cancer, TRG 4-residual cancer outgrowing fibrosis, to TRG 5-no tumor response or regression, no fibrosis with extensive residual cancer<sup>[29]</sup>. Another classification, proposed by Nasierowska-Guttmejer (NG) distinguishes three degrees of cancer response to neo-adjuvant therapy depending on the intensity of the morphological changes. At present one should assess cancer cell degeneration (no cancer cells, high, moderate and low-grade degeneration), mucus pools (present or absent) and necrosis (absent,  $\leq 50\%$  cancer tissue,  $> 50\%$  cancer tissue). Point scores are designated to each parameter of tumor response to neo-adjuvant therapy and then are summarized<sup>[5]</sup>.

Some authors believe that "T-downstaging" does not precisely reflect cancer regression following neo-adjuvant therapy. They state that residual cancer has a form of rather small foci surrounded by fibrous tissue and they are localized in all layers of the rectal wall. Such a deep localization results in diagnosis of high tumor stage despite a good response to radiotherapy. This phenomenon justifies the search for the histopathological tumor regression grading systems<sup>[14,20,35,39]</sup>. Rodel *et al*<sup>[40]</sup> suggest that tumor regression following radiotherapy reflects its less aggressive potential resulting from the molecular profile. Particular biological properties of a tumor

influencing its chemo-radiosensitivity may also prove to be of long-term prognostic significance, especially in cases submitted to neo-adjuvant therapy.

TRG classification is probably superior versus "T-downstaging" in terms of the evaluation of neo-adjuvant therapeutic effects<sup>[14]</sup>. Reports on the relationship between "T-downstaging" or ypT and TRG are not numerous, and are with regard to preoperative long-term radiotherapy and chemoradiotherapy<sup>[21,22,35,36]</sup>. The relationship between TRG and the probability of lymph nodes involvement has been described in detail only in patients with rectal cancer submitted to long-term radiochemotherapy<sup>[22,41]</sup>. So far, no results have been published comparing the NG with other rectal cancer regression assessment systems following neo-adjuvant therapy.

The aim of the present study is to evaluate if two independent histopathological classifications based on semiquantitative assessment of regressive changes may prove useful for the monitoring of patients with rectal adenocarcinoma, initial stage cT3NxM0 submitted to preoperative hyperfractionated radiotherapy.

Our particular aim was to assess whether there is any relationship between: (1) "T-downstaging" and histopathological staging systems of cancer response to neo-adjuvant treatment (TRG and NG systems); (2) "T-downstaging" and local tumor stage and lymph node status; (3) TRG and NG classification and local tumor stage and lymph node status; (4) mutual relationships between TRG and NG systems.

## MATERIALS AND METHODS

### Patients

The study encompassed patients with rectal adenocarcinoma submitted to hyperfractionated preoperative radiotherapy, with perirectal tissue invasion assessed with ultrasound examination prior to neo-adjuvant treatment (TRUS: uT3). Patients' general performance status according to the Eastern Cooperative Oncology Group classification ranged from 0 to 2 points. Patients with distant metastases found on chest X-ray, and abdominal and pelvis CT examination were excluded from the study. Also, patients formerly submitted to radiotherapy due to present disease or another neoplasm were not included into the study. None of the patients had a history of inflammatory bowel disease.

Forty patients were included into the study. Median age was 64 (range 45-75) years. Ultrasound examination protocol has been described previously<sup>[6]</sup>. All patients were submitted to preoperative hyperfractionated radiotherapy. A total dose of 42 Gy in 28 fractions during 18 d (twice a day, 1.8 Gy, 5 d/wk, and with a minimum 6 h interval between doses) using a three-field isocentric technique-one posterior and two lateral portals. Photon rays of 20 (10-23) MV were used. The edge of the posterior field was situated 5 cm below the lower tumor margin. The lateral margins of the lateral fields extended beyond the pelvic inlet. The upper edge was at the top of the fifth lumbar vertebra. The target volume included the tumor and regional lymph nodes. The standard size of the posterior

Table 1 Clinicopathological characteristics of study patients

field was 12 cm × 15 cm and 10 cm × 15 cm for the lateral fields. Surgery was performed 1-7 d (mean, 5 d) following radiotherapy. Thirty one (77.5%) anterior resections, 8 (20.0%) abdomino-perineal resections and 1 (2.5%) Hartmann's operation, were performed.

### Pathological examination

Surgical specimens were submitted to histopathological examination according to standard protocol<sup>[42]</sup>. Special attention was paid to definite, probable and potential prognostic factors<sup>[43]</sup>. The following pathological parameters were evaluated: local tumor stage (ypT), regional lymph node status (ypN), tumor grade (G1, G2, G3), number of metastatic lymph nodes, and parameters of the tumor response to radiotherapy. The latter included: cancer cell degeneration (severe, moderate, mild), mucin pools (absent, present), tumor necrosis (absent, ≤ 50%, > 50% of the tumor), tumor response to radiotherapy according to NG (1-3)<sup>[5]</sup>, and TRG (1-5)<sup>[29]</sup> classification. In cases with non-homogeneous tumor response pattern to radiotherapy, the area of the weakest response was taken into account<sup>[38]</sup>. Routine surgical specimens submitted for histopathological examination were evaluated retrospectively. Concerning radiotherapy and surgery, the nature of the study was observatory and not experimental.

### Statistical analysis

A study population was divided into 2 groups upon the "T-downstaging" tumor regression parameter. A group with features of cancer regression, ypT < uT (R group) and with no regression, ypT ≥ uT (NR group) were distinguished. The differences between groups in parameters studied were tested using Pearson's  $\chi^2$  test,

## RESULTS

Demographic data and staging parameters are presented in Table 1. Local tumor stage, ypT3 was found in 29 (72.5%) patients. "T-downstaging" was observed in 11 out of 40 (27.5%) patients. Six (15.0%) of them showed downstaging to ypT2, and 4 (10.0%) to ypT1. In one case, histopathological examination has shown no evidence of carcinoma in the intestinal wall (ypT0, TRG 1). Also, no lymph node involvement was found in this patient (ypT0N0). TRUS examination showed features of lymph node involvement in 15 (37.5%) patients. In 8 (20%) of 15 patients in whom TRUS examination showed lymph node involvement, microscopic examination revealed stage ypN0. In 7 (17.5%) out of 25 patients with no evidence of lymph node involvement in TRUS examination, histopathological examination showed presence of metastases. TRG grades 2, 3 and 4 were diagnosed in 3 (7.5%), 17 (42.5%) and 16 (40.0%) patients, respectively. No tumor regression (TRG 5) was found in 3 (7.5%) patients. Features of moderate or severe cancer cell degeneration were observed in 17 (42.5%) patients. Mucus lakes were seen in 22 (55.0%) cases. Necrosis was present in 27 (67.5%) of cases including 1 case with more than 50% of tumor involvement. Stage 1, 2, and 3 of NG classification was reported in 9 (22.5%), 6 (15.0%), and 25 (62.5%) patients, respectively.

Median age (range) in the group with tumor regression was higher than those of patients with no evidence of regression (Table 2). Groups R and NR included 5 (45.5%) and 15 (51.7%) men (NS), respectively. TRUS examination performed prior to neo-adjuvant therapy revealed lymph node involvement in groups R and NR in 4 (36.36%) and 11 (37.93%) patients (NS), respectively. Stage ypN0, ypN1 and ypN2 was found in 9 (81.8%), 2 (18.2%), and

<sup>1</sup>Spearman R correlation  $r = 0.42$ ; <sup>b</sup> $P < 0.01$ , comparison between different local tumor stages. <sup>2</sup>Spearman R correlation  $r = 0.45$ ; <sup>a</sup> $P < 0.005$ , comparison of lymph node involvement.

0 patients in group R and 17 (58.6%), 6 (20.7%) and 6 (20.7%) in group NR (NS). A trend ( $P < 0.12$ ) indicating a relationship between the number of lymph nodes assessed and “T-downstaging” was found. Median (range) number of lymph nodes in group R was 11 (3-35), and 17 (3-41) in group NR. The number of involved lymph nodes in the group R (median, range) did not differ from the number of nodes in group NR, 0 (0-1) and 0 (0-35) (NS), respectively. Tumor grade G1 was found in 2 (20.0%) patients, G2 in 7 (70.0%), and G3 in 1 (10.0%) patient in the R group, and in 3 (10.3%), 25 (86.2%), and 1 (3.5%) patients in the NR group (NS); one (2.5%) case at the ypT0 stage had not been taken into account. Median (range) tumor diameter in groups R and NR was 26 (10-65) mm and 35 (10-70) mm, respectively (NS). The relationship between “T-downstaging” and TRG staging as well as the NG stage was at the borderline of statistical significance. The relationship between TRG and NG *vs.* local tumor stage and lymph node status is shown in Tables 3 and 4. Patients with ypT1 were diagnosed as TRG 2-3. Patients with TRG5 were classified as ypT3. No lymph node metastases were found in patients with TRG 1-2 (ypN0). None of the patients without lymph nodes metastases were diagnosed as TRG 5. Patients in the ypT1 stage were diagnosed as NG 1-2. No lymph node metastases were found in NG 1. There was a relationship between TRG and NG (correlation  $R = 0.58$ ,  $P < 0.01$ ). Patients with TRG 1-2 were classified as NG 1. Patients with TRG 5 were diagnosed as NG 3.

## DISCUSSION

Ultrasound-histopathological tumor regression parameter, “T-downstaging” represents a simple marker of rectal cancer radiosensitivity both in patients submitted to short-term preoperative radiotherapy<sup>[11,18,19,44,45]</sup> as well as in patients with surgery delayed by 1 to 8 wk following irradiation<sup>[17,20,21,23,25-28,34-36,39,46-49]</sup>. Reports have been published showing the prognostic value of “T-downstaging” for overall survival<sup>[17,28,34]</sup>, cancer-specific survival<sup>[48]</sup>, recurrence-free survival<sup>[48]</sup>, disease-free survival<sup>[25,28]</sup>, local recurrence risk<sup>[26,34,48]</sup>, and the risk of distant metastases<sup>[48]</sup>. Read *et al*<sup>[50]</sup> showed that the local staging following neo-adjuvant therapy enables the risk assessment of

lymph node metastases. This finding may prove to be of significance during planning of surgical treatment. The percentage of patients with “T-downstaging” in the group submitted to long-term radiotherapy and radiochemotherapy ranged from 23/88 (26.0%) to 15/20 (75.0%)<sup>[14,17,20-24,27,34-36,39,46-49,51,52]</sup>. Among patients submitted to short-term preoperative radiotherapy “T-downstaging” ranged between 10/28 (35.7%) and 44/104 (43%)<sup>[11,14,18,19]</sup>. An alternative way for the assessment of local tumor stage decrease is comparison of ypT in patients from study groups and control groups in randomized trials on the effects of neo-adjuvant therapy<sup>[53]</sup>. Results of randomized studies on effects of short-term preoperative radiotherapy with a dose of 25 Gy on local tumor stage were discrepant<sup>[8,44]</sup>. In the presented material, “T-downstaging” was achieved in 11/40 (27.5%) patients. No correlation between “T-downstaging” and lymph node involvement, tumor grade and its diameter were found. In patients submitted to neo-adjuvant therapy the number of assessed lymph nodes is usually lower than in patients treated with surgery only<sup>[54]</sup>. In the present study, a tendency towards statistical significance ( $P < 0.12$ ) of the correlation between “T-downstaging” and the number of evaluated lymph nodes was observed. More lymph nodes were found in patients with local stage ypT3 (group NR) than in those with ypT0-2 stage. Joseph *et al*<sup>[55]</sup> showed that in patients with colon cancer at T1/T2 stage more lymph nodes must be studied than in patients with T3/T4 in order to reliably define stage pN0. However, frequently the surgical approach is completely different in patients with lower local stage a limited lymph node resection is performed<sup>[57]</sup>.

In the presented study, “downstaging” parameter was evaluated exclusively in order to show cancer regression within the rectal wall (“T-downstaging”). This results from the fact that the sensitivity of ultrasound evaluation of affected lymph nodes prior to radiotherapy is probably not sufficient to make a reference point for other, strictly histopathological tumor regression classifications. The accuracy of ultrasound examination in the evaluation of lymph node involvement is 65%-81% and the accuracy of the local tumor stage assessment is 82% to 93%<sup>[3]</sup>. Another argument against uN parameter in the evaluation of rectal cancer regression is that uN is of

no prognostic significance<sup>[17,49]</sup>. Some authors studied “N-downstaging” parameter<sup>[17,20,22-26,36,47]</sup> and showed its prognostic value<sup>[17]</sup>. The percentage of patients submitted to radiochemotherapy or radiotherapy with long time intervals between neo-adjuvant treatment and surgery, in which “N-downstaging” was noted, ranged from 13/26 (50.0%) to 38/42 (90.4%)<sup>[17,20,22-26,36,47]</sup>. Tumor size decrease, ‘sterilization’ and lymph node atrophy are the classic effects of radiotherapy<sup>[20,44,45]</sup>. Graf *et al.*<sup>[53]</sup> showed that short-term preoperative radiotherapy results in decreased risk of lymph node involvement.

TRG 1 indicates that no cancer cells have been identified in the rectal wall<sup>[18,19,21,29]</sup>. Some researchers refer TRG 1 to patients with no cancer cells in the entire post-surgical specimen<sup>[37]</sup>. The term-pathological complete response (pCR) of rectal cancer to preoperative radiotherapy regards the situation in which histopathological examination does not show the neoplasm in the rectal wall, lymph nodes and mesorectum<sup>[25,26,35-38,46,48-50,57-61]</sup>. This is in accordance with the definition developed by the WHO initiative<sup>[62]</sup>. A stage of pCR is sometimes identified with ypT0N0 - the situation in which there is no evidence of neoplastic tissue in the rectal wall and in the lymph nodes<sup>[17,23]</sup>. Cases with only a few residual cells or small clusters of cells detected in histopathological examination of surgical specimens are by some authors classified as pCR<sup>[63]</sup>. In the presented study, the authors have assumed that the term pCR represents the situation in which no cancer cells were found in the surgical specimen. There is no absolute concordance between pCR and clinical complete response (assessed by per rectum digital examination and in proctoscopy): pCR may regard barely 25.0% of patients submitted to long-term preoperative chemoradiotherapy with clinical complete response<sup>[61]</sup>. A complete response to radiotherapy in comparison with the presence of residual cancer tissue is associated with better overall survival rate<sup>[46]</sup>, longer disease-free survival<sup>[25]</sup>, and lower risk of local recurrence<sup>[46]</sup>. However, some authors claim that complete regression is of no prognostic significance<sup>[37]</sup>. Guillem *et al.*<sup>[59]</sup> did not show any differences in long-term prognosis among patients with complete cancer regression in comparison with almost complete response ( $\geq 95.0\%$  regression) to neo-adjuvant therapy.

Demonstrating a complete remission is important not only because of its prognostic value but also because of the need of assessment of indications for the postoperative chemotherapy or radiotherapy, for the decision about the appropriate method of surgery<sup>[20,37,45,46,49,57,58,63,64]</sup> or to compare the effects of different treatment methods<sup>[45]</sup>. Zmora *et al.*<sup>[58]</sup> showed that metastases to regional lymph nodes and cancer cells in the mesorectal tissue may be present in patients with complete tumor regression within the rectal wall (TRG 1, ypT0)<sup>[58]</sup>. However, neo-adjuvant therapy makes it possible to reduce the percentage of patients submitted to abdomino-perineal resection and, in some cases, to perform local tumor excision<sup>[15,25,41,49,64-67]</sup>. Randomized study conducted by Polish researchers on a group of 316 patients treated with long-term radiochemotherapy or short-term

preoperative radiotherapy did not show differences in terms of sphincter preservation rate (58% *vs* 61%,  $P = 0.57$ )<sup>[67]</sup>. Appropriate selection of the study patients treated with local excision is a very important issue<sup>[41,64-66,68]</sup>. The local tumor stage seems to be a reliable predictor of lymph node regression in these patients<sup>[41,64]</sup>. The assessment of eventual residual cancer, local stage (ypT), surgical clearance in the resection margins in patients submitted to local resection may reveal the necessity of immediate radical resection (performed within 30 d after the primary surgery)<sup>[65,66,68]</sup>. Also, intraoperative frozen section may prove useful for the assessment of tumor stage and margins’ status. In cases in which a more advanced stage (pT2 or pT3) is likely to be found at the time of surgery or where the surgical clearance could be doubtful, the patient should be prepared for the possibility of wide excision at the same operation<sup>[66]</sup>.

Another interesting issue is the assessment of cancer regression following neo-adjuvant therapy with use of TRG classification on intraoperational microscopic examination. In particular, this regards patients with an evident but incomplete regression. One could expect that the lacking concordance between local tumor stage ypT and TRG in post-operative histopathological examination, as mentioned above, apply also to intra-operation evaluation<sup>[20,35,39]</sup>. Considering the fact, that local excision following neo-adjuvant treatment is a therapeutic option for carefully selected patients, it could be eventually considered in patients with an evident but incomplete tumor regression. These patients are characterized by a low risk of local recurrence<sup>[18,22]</sup>. In the present study we have observed 1 case of coincidence of ypT3 and TRG 2. In the absence of reliable alternative methods, microscopic examination plays an important role in the evaluation of cancer regression following neo-adjuvant treatment. Digital rectal examination, computerized tomography, transrectal ultrasound examination and magnetic resonance are of limited value in terms of assessment of residual cancer following long-term pre-operative radio- and radiochemotherapy, especially to demonstrate pCR<sup>[61,69]</sup>. However, Gavioli *et al.*<sup>[70]</sup> believe that TRUS is a very useful tool, when the same experienced operator performs it before and after neo-adjuvant treatment since it leads to demonstrate tumor regression in a qualitative and quantitative way. Moreover, they proposed that TRUS performed 6-8 wk following irradiation makes it possible to visualize fibrous changes only, which does not, however, disqualify this diagnostic method. The extent of fibrosis indicates the possible depth of residual cancer infiltration-cancer cells are believed to be present within fibrous areas only<sup>[70]</sup>. The use of magnetic resonance volumetry may also be useful in quantitative assessment of cancer regression following neo-adjuvant treatment<sup>[71]</sup>. The difficulties in achieving high level of reliability of visualizing diagnostic methods result from similar signal intensity (echogenity) between residual cancer, fibrous tissue, mucus pools and peritumoral inflammatory infiltration<sup>[71]</sup>. The use of 18-fluorodeoxyglucose positron emission tomography may prove effective in assessment of tumor response to neo-adjuvant therapy<sup>[33]</sup>. Full thickness local excision still

remains an experimental treatment method<sup>[64]</sup>.

The significance of pCR following radiotherapy has not been ultimately confirmed. It is possible that better long-term survival in patients with pCR results from different biological properties of the tumor. Also, interesting reports have been presented, showing that patients submitted to neo-adjuvant chemotherapy and receiving statins showed higher a pCR rate<sup>[72]</sup>. The percentage of patients with complete regression following long-term radiochemotherapy and radiotherapy ranged from 1/43 (2.3%) to 7/20 (35.0%)<sup>[5,17,20-21,23-27,35-37,47-52,57-61,67,73]</sup>. The percentage of patients presenting complete cancer regression following short-term radiotherapy ranges between 0% and 10/191 (5.2%)<sup>[10,11,18,19,50]</sup>. In the present study we have observed 1 case (2.5%) with complete tumor regression.

The period between the termination of neo-adjuvant therapy and surgery in long-term radiochemotherapy and radiotherapy schemes is a few days and a few weeks, respectively. One may assume that short-term radiotherapy will result in relatively lesser tumor regression<sup>[10,23,63]</sup>. The results obtained in large study groups indicate that the short-term radiotherapy results not only in a decrease of the tumor diameter<sup>[44,45,53]</sup>, but also in decreased number of affected lymph nodes<sup>[53]</sup>. A decrease in tumor diameter is not, however, equivalent with the decrease in local extent of tumor. Some authors believe that the period shorter than 10 d is insufficient to achieve tumor regression following radiotherapy with a dose of 25 Gy<sup>[45]</sup>. The proposition of the role of the time period between neo-adjuvant treatment and the percentage of pCR has its supporters<sup>[26,63]</sup> and opponents<sup>[24,73]</sup>. It was, however, shown that the period of a few days between the termination of neo-adjuvant therapy and surgery is sufficient enough for the development of morphological changes within the tumor and in its gene expression profile<sup>[44,74]</sup>.

It was demonstrated that there is a relationship between TRG and overall survival, disease-free survival, and the risk of local tumor recurrence<sup>[18,22]</sup>. Other authors suggest that TRG estimation does not enable long-term prognosis in patients with rectal cancer<sup>[37]</sup>. There are some doubts regarding the reliability of this classification due to its subjective nature<sup>[20]</sup>. Interobserver variability of the TRG system was found to be satisfactory (kappa 0.64) or mediocre (kappa 0.44). It is higher when a 5-point system is simplified to 3-point<sup>[21,38]</sup>. For the reliability assessment it is important that significant fibrosis may accompany neoplastic tissue even when no neo-adjuvant therapy had been administered<sup>[38]</sup>. In the presented study, we have not shown unequivocal correlation between "T-downstaging" and TRG. We have found a correlation of TRG and ypT parameters. The reliability of TRG as a lymph node predictor is not unequivocal. Veccio *et al*<sup>[22]</sup> showed that lymph node involvement is not observed in 41/45 (91.0%) patients submitted to long-term preoperative chemoradiotherapy at TRG 1-2 stage. Kim *et al*<sup>[41]</sup> showed that histopathological assessment of tumor response to preoperative long-term radiochemotherapy (performed with use of the method described by Dworak *et al*<sup>[32]</sup>, similar to the TRG system) is, along with ypT,

an independent predictor of lymph node involvement. In the present study, ypN0 stage was observed in all patients with TRG 1-2. We have not found any definite relationship between "T-downstaging" and the NG stage. The results indicate the correlation between TRG and NG. However, these classifications are based on the evaluation of different morphological parameters. Rectal Cancer Regression Grade (RCRG) classification proposed by Wheeler *et al*<sup>[20,39]</sup> is next to the TRG system and Dworak *et al*<sup>[32]</sup> classification, one of the most widely used in studies documenting rectal cancer regression following neo-adjuvant therapy. It defines 3 degrees of tumor regression: 1, no cancer nests or microscopic collections of cancer cells embedded in fibrous stroma; 2, residual neoplasm seen grossly but with evident fibrosis; 3, carcinoma seen grossly with discreet or absent fibrosis. According to some researchers, such distinguishing of neoplastic tissue and fibrosis is not reliable<sup>[38,58]</sup>. Due to these reservations and the retrospective nature of the study, this grading system had not been taken into consideration in the present study.

At present, there is no uniform, widely accepted histopathological classification used for the evaluation of rectal cancer regression following preoperative radiotherapy. As far as the need for evaluation of residual cancer raises no objections, its interpretation and clinical consequences of radiation-induced changes in the rectal wall and within the tumor are not clear<sup>[5,27,44,74]</sup>. It is also unclear to what extent the presence of necrosis one may assign to its radiotherapeutic effect and to what extent it is a result of ischemic changes due to local perfusion disturbance. Fibrosis that accompanies neoplastic tumor may reflect both natural protective body mechanisms as well as being a result of chronic inflammation<sup>[7]</sup>. Mucin pools in tissues previously occupied by neoplastic tissue are qualitatively different from changes described as colitis cystica profunda, which may develop within the normal intestinal wall following radiotherapy<sup>[20]</sup>. The presence of mucin pools (induced mucinous carcinoma, colloid response) should be taken into account in the differential diagnosis of mucus-secreting adenocarcinoma<sup>[28,74]</sup>. The prognostic value of other morphological changes observed within the residual neoplastic tissue (the intensity and the nature of inflammatory infiltrations accompanying fibrous tissue and cancer cell clusters, cancer cell nuclear pleomorphism and hyperchromasia, mucinous cancer component, low tumor histological grade) and in the intestinal wall (surface ulceration, dysplastic changes, low-grade adenoma component) has not been unequivocally established<sup>[27,44,74]</sup>. Figures 1-6 show examples of neo-adjuvant therapy induced changes.

The retrospective nature of the presented study and the relatively small group of study patients impose careful interpretation of the presented results. Few reports on "T-downgrading", TRG and NG in patients submitted to short-term radiotherapy according to the regimen presented make the presented results suitable for further prospective studies on a larger population.

In conclusion, histopathological classifications based on the assessment of regressive changes may be useful in the

**Figure 1** Acellular mucin pools in the intestinal wall (HE x 200).

**Figure 2** Complete tumor regression following radiotherapy. Inflammatory infiltrations, mucin pool and focal fibrosis in the stroma (HE x 64).

**Figure 3** Degeneration and necrosis of tumor cells following radiotherapy (HE x 250).

monitoring of effects of hyperfractionated preoperative radiotherapy in patients with rectal cancer at the initial stage of cT3NxM0. There is no unequivocal relationship between “T-downstaging” and the tumor regression assessed with TRG and Nasierowska-Guttmejer classification. Poor tumor regression was seen more frequently in patients with no evident “T-downstaging”. No relationships have been found between “T-downstaging” and lymph node involvement, tumor histological grade or tumor diameter. There is a clear but limited concordance in the assessment of regressive changes with ypT and TRG or NG. TRG

**Figure 4** Degenerated adenocarcinoma cells following radiotherapy (HE x 125).

**Figure 5** Dispersed degenerated adenocarcinoma cells following radiotherapy (HE x 125).

**Figure 6** Macrophages and multinucleated (giant) cells close to necrotic tumor areas (HE x 200).

and NG classifications are probably of limited predictive value in terms of lymph node involvement. There is a non-coincidental relationship between the assessment of radiation-induced regressive changes with use of TRG and NG classifications.

It is possible that immunohistochemical evaluation or molecular biology techniques applied to pre-operative biopsy samples may prove to be of predictive value in the future<sup>[21,34,52,75]</sup>. Undoubtedly, histopathological evaluation of the neoplastic tissue regression following preoperative radiotherapy is very important and necessary,

since ultrasound examination here is of limited reliability. Histopathological evaluation of rectal cancer regression may also prove to be useful for the evaluation of the effectiveness of future radio- and radio-chemotherapeutic treatment methods. It might also enable to isolate the population of rectal cancer patients in whom the adjuvant treatment would be especially justified.

## Abstract

**AIM:** To assess the performance of several non-invasive markers and of our recently proposed stepwise combination algorithms to diagnose significant fibrosis ( $F \geq 2$  by METAVIR) and cirrhosis ( $F4$  by METAVIR) in chronic hepatitis B (CHB).

**METHODS:** One hundred and ten consecutive patients (80 males, 30 females, mean age:  $42.6 \pm 11.3$ ) with CHB undergoing diagnostic liver biopsy were included. AST-to-Platelet ratio (APRI), Forns' index, AST-to-ALT Ratio, Goteborg University Cirrhosis Index (GUCI), Hui's model and Fibrotest were measured on the day of liver biopsy. The performance of these methods and of sequential algorithms combining Fibrotest, APRI and biopsy was defined by positive (PPV) and negative (NPV) predictive values, accuracy and area under the curve (AUC).

**RESULTS:** PPV for significant fibrosis was excellent (100%) with Forns and high ( $> 92\%$ ) with APRI, GUCI, Fibrotest and Hui. However, significant fibrosis could not be excluded by any marker ( $NPV < 65\%$ ). Fibrotest had the best PPV and NPV for cirrhosis (87% and 90%, respectively). Fibrotest showed the best AUC for both significant fibrosis and cirrhosis (0.85 and 0.76, respectively). Stepwise combination algorithms of APRI, Fibrotest and biopsy showed excellent performance (0.96 AUC, 100% NPV) for significant fibrosis and 0.95 AUC, 98% NPV for cirrhosis, with 50%-80% reduced need for liver biopsy.

**CONCLUSION:** In CHB sequential combination of APRI, Fibrotest and liver biopsy greatly improves the diagnostic performance of the single non-invasive markers. Need for liver biopsy is reduced by 50%-80% but cannot be completely avoided. Non-invasive markers and biopsy should be considered as agonists and not antagonists towards the common goal of estimating liver fibrosis.

## INTRODUCTION

Chronic hepatitis B (CHB) remains a serious global health concern. Approximately 350 million people are chronically infected, and 500 000 to 1.2 million deaths per year are attributed to HBV-associated complications<sup>[1]</sup>. Among patients with active viral replication, cirrhosis will develop in 15 to 20 percent within five years<sup>[2]</sup>. For patients with cirrhosis, acute exacerbation can occur and the disease may progress to end stage complications<sup>[2]</sup>. The histopathological pathway of progressive liver disease is characterised by the formation and accumulation of fibrosis, leading to increasing distortion of the hepatic architecture, that is the hallmark of evolution to cirrhosis. Liver fibrosis is the result of chronic injury and plays a direct role in the pathogenesis of hepatocellular dysfunction and portal hypertension. Current guidelines recommend that patients with HBV-DNA  $> 10^5$  copies/mL and persistent or intermittent elevation in aminotransferase levels should be evaluated further with liver biopsy, that is the gold standard for the assessment of fibrosis<sup>[3]</sup>. This procedure provides information on the severity of necroinflammatory activity and on the stage of fibrosis, features which are essential for estimating prognosis and the need for antiviral therapy<sup>[2,4,5]</sup>. However, biopsy is a costly procedure associated with side effects and some risks<sup>[6-8]</sup>. It also has limitations in underestimating liver fibrosis with small samples and is prone to intra- and inter-observer variation<sup>[9-12]</sup>. Moreover, several studies suggested that liver biopsy is far away from being a perfect gold standard since its performance is size-dependent<sup>[9,13-14]</sup>. Some studies would suggest that an adequate liver biopsy sample should contain more than 5 portal tracts and be at least 15 mm in length<sup>[11,15,16]</sup>. In a critical review of the literature concerning the use of liver biopsy in chronic viral hepatitis,

Guido and Rugge suggest that in an era of evidence-based medicine the use and interpretation of liver biopsy is very often flawed by unacceptable methodological limits and that a biopsy sample of 20 mm or more containing at least 11 complete portal tracts should be considered reliable for adequate grading and staging<sup>[14]</sup>. Other authors have recommended even bigger samples<sup>[17]</sup>. The pathologist need for obtaining a liver sample of adequate size is in contrast with the patient's need of a procedure causing limited pain and with the clinician's need of a safe procedure. A French survey which interviewed 1177 general practitioners concluded that liver biopsy may be refused by up to 59% of patients with chronic hepatitis C and that 22% of the physicians share the same concern regarding this invasive procedure<sup>[18]</sup>. In this regard, a recent survey assessing the consensus among Italian hepatologists on when and how to take a liver biopsy in chronic hepatitis C showed great divergence in the management of the same subgroup of patients<sup>[19]</sup>. Considering these limitations and patient reluctance to undergo liver biopsy, a great interest and many studies have been recently dedicated to the development of non-invasive markers as surrogates of liver biopsy. Most of the studies on non-invasive markers of liver fibrosis have been conducted in chronic hepatitis C and few data are available on the applicability of this approach to patients with CHB. Several markers have been described with variable diagnostic accuracy in hepatitis C, but the expected rate of misdiagnosis for each single test is still around 20%<sup>[11,20]</sup>. To overcome this limitation, recently we have developed and validated sequential algorithms that combine non-invasive markers with liver biopsy<sup>[21]</sup>. This approach allowed us to reach excellent diagnostic accuracy (> 95%) for both significant fibrosis and cirrhosis in patients with chronic hepatitis C with around 50%-70% reduced need of taking a liver biopsy. We have now assessed the performance of several non-invasive markers and of our stepwise algorithms in patients with CHB.

## MATERIALS AND METHODS

### Patients

This study included 110 consecutive patients with a diagnosis of chronic HBV infection, as defined by positive hepatitis B surface (HBsAg) for at least 6 mo, who underwent a diagnostic percutaneous liver biopsy at the Department of Clinical and Experimental Medicine at the University of Padova between March 2003 and June 2005. All patients were positive for serum HBV-DNA by polymerase chain reaction (PCR) and had compensated chronic HBV infection. The exclusion criteria were any other cause of chronic liver disease, and clinical signs of liver cirrhosis, co-infection with HCV or HIV and comorbidities that could confound the results of the non-invasive markers adopted, clinical signs of liver cirrhosis. These included current alcohol intake (> 20 g/die), haemolysis, Gilbert's syndrome, and hematologic causes of thrombocytopenia. All biopsies were obtained with the 16G Menghini type needle. To limit the risk of fibrosis underestimation, patients with biopsy samples shorter than 1.5 cm or containing less than 7 portal tracts were

excluded<sup>[11,15,16,22]</sup>. Informed consent was obtained from all patients participating in the study that was conducted according to the rules of the Declaration of Helsinki.

### Virologic assays

HBsAg, hepatitis Be antigen (HBeAg), and antibodies to HBeAg and HDV were determined using commercial assays (Roche Diagnostics, Basel, Switzerland). HBV DNA level was measured by real-time PCR and expressed as log<sub>10</sub> copies/mL.

### Histological assessment

Liver biopsies were fixed in formalin and embedded in paraffin. The slides were stained with hematoxylin-eosin, van Gieson stain for collagen, PAS after diastase digestion and Perls' Prussian blue method. The slides were evaluated by a single Pathologist (MG) who was unaware of the clinical data. Fibrosis was scored according to the METAVIR system, which was previously applied in other reports on CHB<sup>[23-25]</sup>. Fibrosis was staged from F0 to F4: F0, no fibrosis; F1, portal fibrosis without septa; F2, portal fibrosis with few septa; F3, numerous septa without cirrhosis; and F4, cirrhosis. Significant fibrosis was defined as a METAVIR score of F2 or more ( $F \geq 2$ ), cirrhosis was defined as a METAVIR score of F4.

### Non-invasive markers of liver fibrosis

All patients were evaluated for AST-to-Platelet Ratio Index (APRI), Forns' index, AST-to-ALT ratio (AAR), Hui's model, Goteborg University Cirrhosis Index (GUCI), Fibrotest. The rationale for the choice of the non-invasive markers was their simplicity together with a reported good performance for APRI, Forns' index, AAR and GUCI, and the high number of validation studies reported together with a good performance for Fibrotest<sup>[26-30]</sup>. Hui's model, based on a combination of body mass index, total bilirubin, platelets and albumin, was chosen since it is the only non-invasive marker developed in patients with hepatitis B<sup>[31]</sup>. The markers were all calculated using fasting serum samples obtained on the same day of liver biopsy. For this purpose platelet count, aspartate aminotransferase (AST), alanine aminotransferase (ALT), gamma-glutamyltranspeptidase ( $\gamma$ GT), cholesterol levels, haptoglobin, apolipoprotein A1, alpha-2-macroglobulin, total bilirubin, prothrombin time (international normalised ratio, INR), albumin were routinely determined using validated methods. Fibrotest results were kindly provided by T. Poinard, Universite Paris VI, Paris, France. For all the non invasive methods the cut-off values indicated in the original reports were applied<sup>[26-31]</sup>.

### Stepwise combination algorithms for liver fibrosis

The algorithms recently developed by us for patient with chronic hepatitis C were applied to this cohort of hepatitis B patients. The diagnostic algorithms were developed by modelling the best algorithm for liver fibrosis in different clinical scenarios, as described in a previous study<sup>[21]</sup>. Algorithm A (for significant fibrosis,  $F \geq 2$  by METAVIR) and algorithm B (for cirrhosis, F4 by METAVIR) are described in Figure 1A and B.

**Figure 1** **A:** Algorithm A for detection of significant fibrosis ( $F \geq 2$  by METAVIR) in HBV patients. F0-1 by APRI is intended as  $APRI < 0.5$ .  $F \geq 2$  by APRI is intended as  $APRI > 1.5$ . n.c. by APRI is intended as  $APRI > 0.5$  and  $< 1.5$ ; **B:** Algorithm B for detection of cirrhosis (F4 by METAVIR) in HBV patients. F0-1 by APRI is intended as  $APRI < 0.5$ .  $F \geq 2$  by APRI is intended as  $APRI > 1.5$ . F4 by APRI is intended as  $APRI \geq 2$ . n.c. by APRI is intended as  $APRI > 0.5$  and  $< 1.5$ .

### Statistical analysis

The primary endpoints were the detection of significant fibrosis ( $F \geq 2$ ) and cirrhosis (F4). These thresholds were selected since the first is generally considered an indication for antiviral therapy and the second requires a specific management and follow-up. Descriptive results were expressed as mean  $\pm$  standard deviation (SD) or number (percentage) of patients with a condition. Kappa statistics was used to measure intra-observer variation in the histopathological evaluation of the degree of fibrosis. The performance of the non-invasive methods for liver fibrosis was measured as sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), accuracy, and likelihood ratios (LR). Sensitivity, specificity, PPV, NPV and accuracy were expressed as percentage. The diagnostic value of the non-invasive methods was expressed using the Area Under the receiver operating characteristic Curve (AUC) and its corresponding 95% confidence intervals (CI).

**Table 1** Demographic, laboratory and histological characteristics of the 110 patients with chronic hepatitis B

Males <i>n</i> (%)	80 (72.7)
Age (mean yr $\pm$ SD)	42.6 $\pm$ 11.3
BMI (kg/m <sup>2</sup> )	24.2 $\pm$ 3.3
AST (mean IU/L $\pm$ SD)	73.4 $\pm$ 61.2
AST / ULN ratio (mean $\pm$ SD)	1.75 $\pm$ 1.47
ALT (mean IU/L $\pm$ SD)	144.5 $\pm$ 148.0
ALT / ULN ratio (mean $\pm$ SD)	3.14 $\pm$ 3.3

## RESULTS

Demographic, laboratory and histological features of the 110 patients with CHB are described in Table 1. Mean age was  $42.6 \pm 11.3$  years and 80 patients (72.7%) were males. Twenty cases (18.2%) were HBeAg positive and 8 cases (7.3%) were co-infected with HDV. Prevalence of significant fibrosis ( $F \geq 2$ ) and cirrhosis was 68.2% and 20%, respectively. The mean length of liver specimens was  $1.69 \pm 0.29$  cm and mean complete portal tracts number was  $9.9 \pm 3.6$ . Intra-observer agreement was assessed by re-evaluating a subset of 50 randomly chosen samples: kappa value was higher than 0.90.

### Performance of non-invasive methods for the diagnosis of significant fibrosis ( $F \geq 2$ )

Seventy-five patients (68.2%) had significant fibrosis as defined by METAVIR fibrosis stage  $F \geq 2$ . The performance of the non-invasive markers in diagnosing significant fibrosis is shown in Table 2. AAR was not included here since it identifies cirrhosis but does not discriminate significant fibrosis. Fibrotest, GUCI and Hui's model classified all cases while both APRI and Forns' index were unable to classify one third of the patients. All the methods showed high PPV ( $> 90\%$ ) for significant fibrosis. Forns' index had an excellent 100% PPV with a 6.9 cut-off but its diagnostic value was quite low, at 0.63 AUC (95% CI: 0.50-0.76). The NPV was quite low for all the non-invasive markers (always  $< 65\%$ ), so that significant fibrosis could not be reliably excluded by any of these markers. Fibrotest, APRI and GUCI showed good overall

**Table 3** Performance of the non-invasive methods and of the algorithm B in detecting cirrhosis (F4 by METAVIR) in patients with CHB

	Fibrotest	APRI	AAR	GUCl	Algorithm B
Classified cases (%)	100	66.2	100	100	100
Cut-off	F4	2	1	1	na
Sensitivity (%)	55.6	42.9	7.1	21.4	92.9
Specificity (%)	96.3	85.4	94.7	91.2	96.5
PPV (%)	90	53.8	82.4	73.7	87.5
NPV (%)	87.1	91.1	81.4	83.8	98.3
LR +	15	2.94	1.34	2.43	26.5
LR -	0.46	0.67	0.98	0.86	0.07
Accuracy (%)	86.1	79.2	77.5	77.5	95.8
AUC (95% CI)	0.76 (0.67-0.85)	0.64 (0.53-0.75)	0.51 (0.39-0.62)	0.56 (0.47-0.65)	0.95 (0.90-1)

accuracy (83.3%, 76.1% and 76.1% respectively). Among the non-invasive methods, Fibrotest showed the best diagnostic value as indicated by an AUC of 0.85 (95% CI: 0.75-0.95).

### Performance of non-invasive methods for the diagnosis of cirrhosis (F4)

Twenty-two patients (20%) had cirrhosis as defined by METAVIR fibrosis stage F4. The performance of the non-invasive markers in diagnosing cirrhosis is shown in Table 3. Forns' index and Hui's model were not considered here since they do not discriminate between significant fibrosis and cirrhosis. Fibrotest had the best PPV (90%) and very good accuracy (86.1%). The overall diagnostic value of Fibrotest was quite good, with 0.76 AUC (95% CI: 0.67-0.85). APRI showed good NPV and accuracy but the diagnostic value, described by AUC, was rather low (0.64; 95% CI: 0.53-0.75). The other markers showed an even lower diagnostic value, with AUCs around 0.5.

### Performance of stepwise algorithms for the diagnosis of significant fibrosis and cirrhosis

The performance of stepwise algorithms for the detection of significant fibrosis (algorithm A) and cirrhosis (algorithm B) is reported in Tables 2 and 3, respectively. Table 4 describes in details the number of tests and of liver biopsies needed when the two algorithms were applied to our cohort of patients with CHB. The stepwise algorithm

for significant fibrosis (algorithm A) excluded the presence of  $F \geq 2$  by METAVIR with excellent 100% NPV. It also showed a very high accuracy, with excellent 97.2%, and it presented with an excellent diagnostic value, with 0.96 AUC (95% CI: 0.92-1). This algorithm permitted avoidance of liver biopsy in about half of the cases (Table 4). Algorithm B showed excellent 95.8% accuracy and 0.95 AUC (95% CI: 0.90-1) in the identification of cirrhosis. Furthermore, this algorithm reduced by more than 80% the need for liver biopsy (Table 4).

## DISCUSSION

Several non-invasive markers of liver fibrosis have been recently described, mainly in patients with hepatitis C, but their implementation in clinical practice as a substitute for invasive liver biopsy has been delayed by lack of adequate accuracy in assessing individual patients. Indeed, according to the most recent International Guidelines and Recommendations, inter-laboratory variability, lack of reproducibility and, most important, an expected rate of misdiagnosis of at least 20% do not yet allow the use of these methods in clinical practice<sup>[11,32]</sup>. Since the diagnostic performance of described non-invasive markers is variable depending on the stage of fibrosis and other patient characteristics, they can be used to reduce rather than completely substitute the need for liver biopsy. Recently we have described stepwise combination algorithms based on

the use of two non-invasive markers (APRI and Fibrotest) and liver biopsy<sup>[16]</sup>. When applied to patients with chronic hepatitis C these algorithms were proven to correctly identify significant fibrosis and cirrhosis with high (> 95%) accuracy and 50%-70% reduction in liver biopsy. Very few studies have investigated the role of non-invasive markers of liver fibrosis in hepatitis B. Indeed, significant differences exist between CHB and chronic HCV infection in natural history, laboratory parameters, liver histology and associated comorbidities. For example, elevated ALT reflects accurately the necroinflammatory activity of CHB and is used as one of the criteria for antiviral therapy while the same could not be applied to hepatitis C<sup>[3]</sup>. Steatosis is an important feature of chronic HCV infection while its role in CHB is unclear<sup>[33]</sup>. The association of diabetes mellitus with chronic hepatitis C has not been found in CHB<sup>[34]</sup>. Since CHB has specific pathogenetic mechanisms and is associated strongly with liver disease, the results of the studies on hepatitis C cannot be directly transferred to hepatitis B and a dedicated validation of the markers should be provided. The latest AASLD guidelines on management of chronic hepatitis B recommend that patients with HBV-DNA > 10<sup>5</sup> copies/ml and persistent or intermittent elevation in transaminase levels should be evaluated further with liver biopsy<sup>[3]</sup>. Moreover, prior to consider of antiviral treatment, liver biopsy is still recommended. Assessment of the stage of liver disease is indeed fundamental for treatment decision in any patient presenting with compensated chronic HBV infection. The available evidences suggest that non-invasive markers of liver fibrosis in hepatitis B present with a similar accuracy to hepatitis C. Lebensztejn *et al*<sup>[35]</sup> assessed the value of some non-invasive markers of liver fibrosis in few children with chronic hepatitis B and found that a combination of hyaluronan and laminin had 0.84 AUC. Hui and colleagues developed a predictive model based on body mass index and three routine laboratory tests, which showed 0.79 AUC<sup>[31]</sup>. Two recent reports applied Fibrotest in CHB showing 0.77 and 0.78 AUC for detection of significant fibrosis and cirrhosis, respectively<sup>[24,25]</sup>. Our results, based on an independent application of Fibrotest to CHB patients, showed an accuracy that is similar to that reported by Poynard's group. A very recent study by Zeng *et al*<sup>[36]</sup> proposed a non-invasive combination model based on alpha-2-macroglobulin, hyaluronan, age and  $\gamma$ GT and it showed an AUC between 0.77 and 0.84. For all these markers, the expected rate of misdiagnosis was around 20%, thus similar to that reported for hepatitis C which is considered not satisfactory by many clinicians. Very recently the use of "proteome" technology has been introduced in studying liver fibrosis. In 46 patients with chronic hepatitis B, 30 features predictive of significant fibrosis and cirrhosis were identified. The AUC for this analysis was very promising, being 0.906 and 0.921 for advanced fibrosis and cirrhosis, respectively<sup>[37]</sup>. However, this is a quite complicated method that might not be available for large scale testing. Moreover, the excellent performance reported in that preliminary study should be confirmed by others. In our study we found that Fibrotest had the best performance when compared to other non-invasive methods. However, none of the investigated

**Table 4** Features of clinical interest of stepwise algorithms in chronic hepatitis B

	Algorithm A	Algorithm B
Saved biopsies (%)	48	81
APRI performed (%)	100	100
Fibrotest performed (%)	34	52
Under-diagnosed and unclassified (%)	0	0
Over-diagnosed (%)	3	3

Algorithm A: algorithm for significant fibrosis ( $F \geq 2$  by METAVIR); Algorithm B: algorithm for cirrhosis ( $F4$  by METAVIR); APRI: aspartate aminotransferase to platelets ratio.

non-invasive markers of liver fibrosis had adequate accuracy for universal use in substitution of liver biopsy, the expected rate of misdiagnosis being 15%-35% for significant fibrosis and 25%-45% for cirrhosis. On the other hand, when APRI and Fibrotest were combined with liver biopsy in sequential algorithms, we could reach > 95% accuracy for detecting significant fibrosis or cirrhosis, with a 50%-80% reduced need for liver biopsy, as already described previously in patients with compensated chronic hepatitis C. With this approach, the number of liver biopsies needed decreased especially for the patients at higher risk of cirrhosis and this appears particularly important since the risk of liver biopsy complications is increased in cirrhotic cases. The overall cost of these algorithms appears favourable compared to universal use of liver biopsy. Indeed, for a cohort of one hundred patients algorithm A requires 100 APRI, 34 Fibrotests and 52 biopsies while algorithm B requires 100 APRI, 52 Fibrotests and 19 biopsies (Table 4). A cost-benefit analysis indicates that in the US a liver biopsy costs 1032 USD, which increases to 2745 USD when a complication occurs<sup>[8]</sup>. Fibrotest-Fibrosure is a commercialised method with a cost of around 90 euros (Biopredictive, Houilles, France). According to these values, algorithm A and algorithm B would result in a 50% and 75% reduction in cost compared to liver biopsy, respectively.

There are some limitations in our study. This was in fact a retrospective study, with a quite limited number of cases. Another limitation could be in the choice of the dimension of biopsy sample. We have here included specimens of at least 1.5 cm length and containing 7 portal tracts on the basis of the recommendations of some authors<sup>[11,15,16,22]</sup>. However, several observations from the pathologists would suggest even bigger samples for a correct staging of liver fibrosis<sup>[13,14,17]</sup>. Finally, recent criticisms suggested that liver biopsy is not a perfect gold standard for fibrosis evaluation due to its large variability (sampling error plus observer error). Indeed, Bedossa *et al*<sup>[13]</sup> indicated that biopsy is an estimate of liver fibrosis which, when compared with the whole liver, showed a coefficient of variation greater than 40% with length greater than 15 mm with 80% accuracy.

In conclusion, this study suggests that in hepatitis B currently available non-invasive tests do not show a diagnostic performance that would be considered adequate by many clinicians. However, their stepwise combined use can be most useful to reduce the need for liver biopsy

without losing diagnostic accuracy. In this respect liver biopsy and non-invasive markers should be considered as agonists and not as antagonists towards the common goal of correctly classifying the stage of liver fibrosis. Priority should be given to large scale validation studies of these algorithms in different patient populations inclusive of all major etiologies of chronic liver disease and most frequent cofactors, which may affect the diagnostic performance of fibrosis markers.

## COMMENTS

### Background

Non-invasive markers of liver fibrosis have been recently proposed as substitutes for liver biopsy but their reported accuracy was around 80%. They have been mostly validated in hepatitis C while few studies have been conducted in hepatitis B. We have recently shown that stepwise combination of non-invasive markers and liver biopsy permitted to obtain excellent accuracy (> 95%) by saving 50%-70% liver biopsies in hepatitis C. We applied our method to a cohort of patients with chronic hepatitis B.

### Research frontiers

Nowadays many clinicians show concerns about the role of liver biopsy in chronic viral hepatitis due to side effects, intra- and inter-observer variation and costs. Some non-invasive methods for liver fibrosis have been proposed but International Guidelines still do not recommend a routine use of the markers due to lack of reproducibility and an expected misdiagnosis rate of 20%. Thus, a trusted method that avoids a number of liver biopsies by maintaining excellent accuracy is urgently needed.

### Innovations and breakthroughs

In this article we validated in hepatitis B a recently proposed method for the detection of liver fibrosis and cirrhosis in hepatitis C. This is the first sequential approach based on a first line assessment by non-invasive markers of liver fibrosis followed by liver biopsy in unclassified cases or cases in which non-invasive methods do not reach a satisfactory accuracy. The overall accuracy of this method is > 95% and it saved 50%-80% liver biopsies. This is a rational and practical way to apply non-invasive markers in hepatitis B and it introduces a new concept: non-invasive markers and liver biopsy are agonists and not antagonists towards the common goal of classifying liver fibrosis.

### Applications

The most accurate non-invasive markers should be used as a first line assessment, limiting liver biopsy to the cases in whom they are unclassified or show low predictive value. For the future, priority should be given to large scale validation studies of these algorithms and the most promising non-invasive markers in different patient populations inclusive of all major etiologies of chronic liver disease and most frequent cofactors which may affect the diagnostic performance of fibrosis markers.

### Terminology

(1) Fibrotest: a commercial panel of serum markers combining  $\gamma$ GT, alpha-2-macroglobulin, haptoglobin, apolipoprotein A1, total bilirubin for the non invasive assessment of liver fibrosis. It has been extensively validated in hepatitis C. The overall accuracy of the panel is good but it combines also uncommon parameters. Only two, not independent, validation studies on hepatitis B have been so far conducted. (2) APRI: a simple test combining AST and platelet count group for the non-invasive prediction of significant fibrosis and cirrhosis in hepatitis C. It is a very simple and economic tool but it is somehow less accurate than fibrotest and it presents with a significant percentage of unclassified cases. To our knowledge, this is the first validation of APRI in an independent series of HBV patients. (3) Forns' index: an index combining, age, platelet,  $\gamma$ GT, cholesterol for the non-invasive prediction of significant fibrosis in hepatitis C. It is a quite simple index, combining common parameters (except for cholesterol) but it showed a significant number of unclassified cases. To our knowledge, this is the first application of Forns' index to a cohort of patients with CHB. (4) GUCI: a simple index combining AST, platelets and INR. It showed good accuracy in hepatitis C for both significant fibrosis and cirrhosis. It has never been applied to HBV cases. (5) Hui's model: a

panel combining albumin, BMI, total bilirubin and platelet count for the prediction of significant fibrosis. It has been developed for hepatitis B patients and no validation study has to date been conducted.

### Peer review

Evaluate the applicability and prognostic value of a previously developed algorithm that includes a combination of two different serum marker tests for the detection of liver fibrosis to avoid liver biopsies in patients with chronic HBV infection. This is an excellent paper that investigates the performance of non-invasive tests for estimating liver fibrosis in patients with chronic hepatitis B. The study is timely and provides useful information.

### Abstract

**AIM:** To perform a long culture passage of *H pylori* without serum, taking into account its cytotoxicity and the presence of the probable new cytotoxic factor.

**METHODS:** One sample of *H pylori* 60190 (ATCC 49503) was grown on Brain Heart Infusion (BHI) agar containing 0.5% 2,6-di-O-methyl- $\beta$ -cyclodextrin without any serum, being passaged 70-100 times every 3-4 d for approximately 2 h, while another sample of *H pylori* contained 70 mL/L fetal calf serum without 2,6-di-O-methyl- $\beta$ -cyclodextrin. Their supernatant and extract after 16 h in culture were evaluated for changes in cell morphology and for cell viability using HeLa cells. Furthermore, the characteristics of the probable cytotoxic factor in the extract were examined on partial purification studies and its cytotoxicity was evaluated in various human cells.

**RESULTS:** The supernatant and the extract of the bacterium grown on serum-free medium had strong cytotoxicity compared with those grown on serum-containing medium. They irreversibly damaged HeLa cells without vacuolation that was altogether different from that of the bacterium when grown with serum. Their cytotoxicity was easily measured by cell viability assay. The probable cytotoxic factor partially purified and detected by chromatography had characteristics difference from that of vacuolating toxin and a broad cytotoxicity toward various cell lines.

**CONCLUSION:** Serum-free long culture method of *H pylori* makes its supernatant and its extract cytotoxic enough to be easily measured by cell viability assay. The probable cytotoxic factor has a unique characteristic and might be a new cytotoxin.

### INTRODUCTION

Irreversible degeneration and cell death were induced in gastric mucous epithelium infected with *H pylori* both in an *in vitro* and an *in vivo* study, including electron microscopic examination. These cells deteriorated without vacuolations, and biopsy specimens containing the organism obtained from gastric mucosa demonstrated a loss of microvilli and irreversible cell damage<sup>[1-4]</sup>. Even after eradication therapy of the bacterium, there were no significant differences in the histological scores and atrophic scores in the inflammation of the gastric body and the atrophy of the antrum<sup>[5-9]</sup>. However, the only known cytotoxic factor of *H pylori* is vacuolating toxin (Vac A), which causes vacuolations in assay cells 18-24 h after addition, but is a reversible and weak cytotoxin<sup>[10,11]</sup>. The clinical findings that the bacterium caused irreversible and severe destruction to the gastric lineage appear incompatible with the *in vitro* observations that *H pylori* produces only a reversible and comparatively weak cytotoxin that induces vacuolations. Whether there is any direct irreversible cytotoxic factor of *H pylori* remains to be determined. Although, so far, none of the studied factors met these requirements, there is some evidences that indicated cytoskeletal cell death or round-formed cell death differed from vacuolation-formed cell death<sup>[3,12,13]</sup>.

To our best of knowledge, this is the first report about the cytotoxicity of *H pylori* after a long duration of culture without serum. We cultured *H pylori* 60190, plating many passages without serum for approximately two years, considering that the cell growth environments should be as near as possible to the actual intragastric ones. Here, we showed serum-free long period culture made the supernatant and the extract of *H pylori* dramatically cytotoxic such that it induced irreversible decayed cell death easily measurable with a cell viability assay. Cell death induced by these samples showed a rapid development of the cell death process and was rarely accompanied by vacuolation. These observations might explain clinical findings and develop into a new field of the bacterium's cytotoxicity.

## MATERIALS AND METHODS

### Materials

The *H pylori* strain 60190 was obtained from American Type Culture Collection. Brain Heart Infusion (BHI) was purchased from DIFCO Laboratories and 2,6-di-O-methyl- $\beta$ -cyclodextrin was purchased from Wako Pure Chemical Industries Ltd.

### Culture conditions and preparation of bacterial extract

*H pylori* 60190 (ATCC49503) was the source for purification. Bacterial cells were grown on Brain Heart Infusion (BHI) agar containing 5% fetal calf serum for 7–10 d, then transferred to BHI broth containing 2,6-di-O-methyl- $\beta$ -cyclodextrin with gradual stepwise decreases, i.e., 5%, 2%, 1%, 0.5%, of the concentration for 2–4 d without serum and maintaining stable growth conditions, being passaged 100–120 times every 3–4 d. Then bacterial cells were scraped and cultured for 16 h at 37°C in the liquid medium of BHI containing 0.5% 2,6-di-O-methyl- $\beta$ -cyclodextrin without serum in an ambient atmosphere containing 50 mL/L CO<sub>2</sub>, while agitating with a rotary shaker. Bacterial cells were collected by centrifugation at 12 000 *g* for 20 min at 4°C and suspended in 10 mmol/L Tris-HCl buffer (pH 7.7). The cells were washed once and sonicated at 54% effect for 30 s  $\times$  6 sets in Ultrasonic Disruptor (Tomy Seiko Co., Ltd.) and stored at -80°C overnight. Sonically disrupted cells were thawed and sonicated again under the conditions previously described and centrifuged at 100 000 *g* for 60 min at 4°C. The aliquots of the most upper layer were stored at -80°C until use.

### Cytotoxicity assay with cell viability

HeLa cells (Cell Resource Center for Biomedical Research, Tohoku University) cultured in Eagle's modified minimal essential medium containing 100 mL/L fetal bovine serum (MEM-FBS) were seeded into 96-well plates at a density of 10<sup>4</sup> cells per well. After 24 h, the cells were washed twice with PBS and challenged with 10  $\mu$ L of aliquots of serial fraction or serial dilution of protein solution with 90  $\mu$ L of MEM-FBS for a total volume of 100  $\mu$ L per well. Cells were incubated at 37°C for 24 h and cell viability was evaluated by WST-1 assay using Cell Counting kits (DOJINDO Laboratories). Each determination was performed in triple wells.

### Purification of cytotoxic factor

Proteins in the bacterial extract were precipitated with a 700 g/L saturated solution of ammonium sulfate. After centrifugation at 12 000 *g* for 20 min, the pellets were resuspended in 10 mmol/L Tris-HCl buffer (pH 7.7) and dialyzed against the same buffer.

The anion exchange chromatography was performed on DEAE Sephacel (Amersham Pharmacia Biotech UK Ltd.) with 10 mmol/L Tris-HCl buffer (pH 7.7). The cation exchange chromatography was CM Sepharose Fast Flow (Amersham Pharmacia Biotech UK Ltd.) with 10 mmol/L Tris-HCl buffer (pH 5.8). The proteins were eluted with the same buffer containing a linear gradient of 0–0.3 mol/L NaCl and 0–1.0 mol/L NaCl, respectively. Size exclusion chromatography was performed on a Superose

12 HR 10/30 column (Pharmacia) with buffer containing 10 mmol/L Tris-HCl (pH 7.7) and 0.15 mol/L NaCl at a flow rate of 0.25 mL/min.

## RESULTS

### Morphological change of HeLa cells

We cultured *H pylori* 60190 with or without serum for approximately two years. The serum-free culture method using 0.5% 2,6-di-O-methyl- $\beta$ -cyclodextrin was less favorable for the bacterium and made it inclined to be easily autolysed in the culturing process. In this study, we defined the serum-free method to culture the bacterium using Brain Heart Infusion (DIFCO) and 0.5% 2,6-di-O-methyl- $\beta$ -cyclodextrin without serum for approximately two years in semisolid medium, and the conventional method using Brain Heart Infusion and 70 mL/L serum without cyclodextrin in semisolid medium. After more than approximately 100 passages, both the supernatant and the extract of the bacterium cultured with the serum-free method induced characteristic morphological changes in HeLa cells, compared to the supernatant and the extract cultured using serum; the cells exposed to its supernatant showed a round-formed shape or small debris with a destroyed contour without vacuolation and the cells exposed to its extract showed an elongated or spindle-like shape with a decrease in cell number in 24 h, while the control cells exposed to the supernatant and the extract had scarcely changed, except for some vacuolations that were similar to the previously reported morphological change (Figure 1).

We observed that both HeLa cells exposed to the supernatant and the extract of the bacterium cultured without serum showed the round-formed change or round debris through the elongated and spindle-like shape without vacuolation. We examined whether HeLa cells exposed to the extract had undergone the same changes using a denser extract. We found that both of the HeLa cells exposed to the supernatant and the extract finally showed the round-formed or shrunken-formed change through the elongated or spindle-like form after 24 h. We compared the morphologic change of HeLa cells exposed to the extract cultured with serum and cultured for approximately one year without serum (Figure 2), and considered that both contained probably a similar cytotoxic factor.

The conventional search of cytotoxin in *H pylori* used the uptake of neutral red into the vacuole of sample-treated cells because the supernatant of the bacterium caused some vacuolations in cells<sup>[14]</sup>, but scarcely any degeneration or remarkable decrease of the number of assay cells. No direct cell viability assay, therefore, was used in search of the cytotoxic factor of *H pylori*. However, we were able to successfully adopt this cell viability assay in place of the neutral red uptake method because of the radical cytotoxicity of the supernatant and the extract cultured without serum.

### Cytotoxicity measured by cell viability assay

The cytotoxicity was determined with an assay using HeLa cell viability with WST-1 tetrazolium and a lactate

**Figure 1** Morphologic change of HeLa cells caused by the supernatant and the extract of *H. pylori* with or without serum after 24 h. HeLa cells were seeded at 5000 cells per well in every plate. The concentration of the supernatant cultured with or without serum was 2.1 mg/mL and the concentration of the respective extract was 0.5 mg/mL. **A:** HeLa cells exposed to the supernatant of the method using serum showed little change and the ones exposed to the extract also showed no remarkable changes but included a few minor vacuolations compared to the control; **B:** HeLa cells exposed to the supernatant of the method without serum showed a round-formed shape and a decayed contour with greatly decreased cell number, and those exposed to its extract showed an elongated or spindle-like shape with a decrease in cell number. Scale bar, 200  $\mu$ m.

**Figure 2** Morphologic change of HeLa cells caused by *H. pylori* 1.0 mg/mL cell extract with or without serum. HeLa cells exposed to the extract cultured without serum showed the characteristic morphological changes in 12 h. **A:** HeLa cells exposed to the extract cultured with serum 6 h and 12 h after addition of the extract showed no remarkable changes but a small decrease in cell number; **B:** HeLa cells exposed to the extract cultured without serum 6 h and 12 h after addition of the extract showed the round-formed shape or round debris with a decayed contour through the elongated or spindle-like shape without vacuolations. Scale bar, 200  $\mu$ m.

dehydrogenase release assay. This cell viability assay revealed the intense cytotoxicity toward HeLa cells, as we predicted. Both the supernatant and the extract cultured without serum had a greater cytotoxicity toward HeLa cells than the ones cultured with serum. The extract, especially of that cultured without serum, had a far greater cytotoxicity than that cultured with serum (Figure 3). This cytotoxicity was thought to be irreversible because the viability assay used measured the intracellular enzyme in the dead or destroyed cells. No cell reversibility could be ascertained for certain when we removed the supernatant and the extract from the cells at 6 h and 12 h after the addition and replaced it with the control lysate for a further 24 h observation (data not shown).

### Purification in accordance to the passage time

We pursued the growing cytotoxicity of the extract using a cell viability assay and anion exchange chromatography in accordance to the passage time without serum. The extract at the onset of culturing without serum showed two minor dips of cell viability at approximately 0.1 mol/L NaCl and 0.2 mol/L NaCl with gradient elution, respectively. The extract after approximately 6 mo of culture (approximately 50 passages) from the onset indicated clearer minor dips at the same concentration of the NaCl linear gradient elution; while approximately one year (approximately 100 passages) from its onset without serum, the extract had a major dip at 0.2 mol/L NaCl and a minor dip at 0.1 mol/L NaCl with far less elution protein. We found that the putative cytotoxic

**Figure 3** Cell viability assay of the supernatant and the extract of serum-free cultured *H pylori* at the onset of culturing and long cultured *H pylori*, approximately 100 passages after the onset of culturing. **A:** Long serum-free cultured supernatant showing dose-dependent decrease curves of cell viability; **B:** Long serum-free cultured extract showing further dose-dependent decrease curves of cell viability. Each point represents the mean  $\pm$  SD from three separate experiments.

factor had an isoelectric point less than pH 7.7 due to the use of the buffer with pH 7.7 (Figure 4).

### Purification on cation exchange chromatography and size exclusion chromatography

In addition, we examined the extract cultured approximately one year (approximately 100 passages) from its onset without serum using cation exchange chromatography and size exclusion chromatography. Cation exchange chromatography showed one clear dip at around 0.3 mol/L NaCl in the gradient elution that indicated that the putative cytotoxic factor had an isoelectric point of more than pH 5.8 due to the use of the buffer with pH 5.8. Size exclusion chromatography showed a sharp dip at around 37-45 ku, which was different from the molecular mass of the vacuolating toxin (87 ku) (Figure 5).

### Cytotoxicity toward human cells

These extracts partially purified by anion exchange chromatography showed robust cytotoxicity toward HeLa cells and other human cells, including AZ521 (gastric carcinoma cells), HLF (hepatocellular carcinoma cells), Caco2 (colorectal carcinoma cells), and HL60 (promyeloblastic leukemia cells) (Figure 6).

## DISCUSSION

This is probably the first report about serum-free long culture method of *H pylori*. We showed that the established strain, *H pylori* 60190, could be converted to a far more cytotoxic strain with a serum-free long culture method that was altogether different from that obtained using conventional culture methods including serum. This cytotoxicity was acquired by the long process of culturing it without serum. Both the supernatant and the extract cultured without serum caused cytotoxicity toward HeLa cells that was distinctly different from the cytotoxicity of *H pylori* cultured using serum of the conventional method to help the feeble growth of *H pylori*. The conventional method using serum certainly may ultimately help the growth state<sup>[15]</sup> but was considered to be very much unlike the actual growing environment. 2,6-Di-O-methyl- $\beta$ -cyclodextrin (CD) is considered to reduce the toxic effect

**Figure 4** Analysis of the column anion exchange chromatography of the extract cultured without serum. Cell viability that represents the putative cytotoxic factor was measured for cell viability at A<sub>415</sub> using the WST1 method. Column eluates that represent the protein densities were monitored at A<sub>280</sub> for each of the filtrated fractions. Proteins were eluted with a linear gradient of 0-0.3 mol/L NaCl. **A:** Anion exchange chromatography of the cell extract protein at the onset of culturing without serum. Two minor dips of cell viability are indicated (arrows); **B:** Anion exchange chromatography of the cell extract protein approximately 50 passages (approximately 6 mo) after the onset of culturing without serum. Two clearer minor dips of cell viabilities are indicated (arrows); **C:** Anion exchange chromatography of the cell extract protein approximately 100 passages (approximately one year) after the onset of culturing without serum. One minor dip and one major dip are at 0.1 mol/L NaCl and 0.2 mol/L NaCl, respectively (arrows).

of fatty acids as well as bovine serum albumin (BSA)<sup>[16,17]</sup>. Although blood and serum may contain growth-stimulatory factors required by the organism<sup>[14]</sup>, the strain 60190, we used, grew in media with CD without any serum, but did not grow in media without sera or CD as the other strains were reported<sup>[18]</sup>.

The supernatant of the serum-free culture was reported to cause epithelial cytoskeletal disruption<sup>[13]</sup> after as little as 48 h culture, while 72 h culture decreased the apoptotic signaling of cells, as compared to serum-containing cultures<sup>[19]</sup>. Serum-free culture method may be less favorable to the organism but more useful with the research of its cytotoxic factors.

Most *in vitro* studies hitherto have used *H pylori* strains cultured using serum, and if any serum-free culture of the bacterium was used for a short time<sup>[10,14]</sup>, it may have been that the supernatant caused the morphological cytotoxic change with vacuolations and without any remarkable cell viability loss or any decrease of assay cell number. However, we discovered the supernatant and the extract of the bacterium cultured for long periods of

**Figure 5** Analysis of the extract cultured without serum. Cell viability that represents the putative cytotoxic factor was measured for cell viability at  $A_{415}$  using the WST1 method. Column eluates that represent protein densities were monitored at  $A_{280}$  for each filtrated fraction. **A:** Cation exchange chromatography of the cell extract protein approximately 100 passages (approximately one year) after the onset of culturing without serum. The cell extract proteins were eluted with a stepwise gradient of 0-0.5 mol/L NaCl; **B:** Size exclusion chromatography of the cell extract protein approximately 100 passages (approximately one year) after the onset of culturing without serum.

time without serum had a different cytotoxicity in both the cell morphology and the activity that scaled up with the passage duration for a year or more. Furthermore, the shape of the organism cultured in serum-free medium had seemed to be more cocoid form than that would be in serum-containing medium.

In addition, our chromatography study showed that putative cytotoxic factor had an isoelectric point between pH 5.8 to 7.7, with a molecular mass of approximately 37-45 ku, which was different from that of the vacuolating toxin (87 ku). The anion exchange chromatography study appeared to indicate two cell-viability dips, a minor dip and a major dip. Further investigation will be required to determine the number of possible factors involved.

This experimental method might represent a state closer to that of the actual intragastric state, rather than that obtained by using conventional serum-using studies. The experimental method reported herein may also produce results more closely related to clinical observations, which would redress the conventional concept that *H. pylori* has only a weak and reversible cytotoxin. *H. pylori* might, in fact, be more insidious and more fierce than the researchers had ever conceived.

Our result may provide a new approach to the cytotoxin research and elucidate a pathological mechanism in *H. pylori* using this new method, which is different from that of the vacuolating toxin, the only presently known cytotoxin.

## Abstract

**AIM:** To examine the effects of adenosine and A1 receptor activation on reperfusion-induced small intestinal injury.

**METHODS:** Rats were randomized into groups with sham operation, ischemia and reperfusion, and systemic treatments with either adenosine or 2-chloro-N<sup>6</sup>-cyclopentyladenosine, A1 receptor agonist or 8-cyclopentyl-1,3-dipropylxanthine, A1 receptor antagonist, plus adenosine before ischemia. Following reperfusion, contractions of ileum segments in response to KCl, carbachol and substance P were recorded. Tissue myeloperoxidase, malondialdehyde, and reduced glutathione levels were measured.

**RESULTS:** Ischemia significantly decreased both contraction and reduced glutathione level which were ameliorated by adenosine and agonist administration. Treatment also decreased neutrophil infiltration and membrane lipid peroxidation. Beneficial effects of adenosine were abolished by pretreatment with A1 receptor antagonist.

**CONCLUSION:** The data suggest that adenosine and A1 receptor stimulation attenuate ischemic intestinal injury via decreasing oxidative stress, lowering neutrophil infiltration, and increasing reduced glutathione content.

Ozacmak VH, Sayan H. Pretreatment with adenosine and adenosine A1 receptor agonist protects against intestinal ischemia-reperfusion in rat. *World J Gastroenterol* 2007; 13(4): 538-547

## INTRODUCTION

Ischemia-reperfusion (I/R) injury of the intestine is a significant problem in a numerous situations such as abdominal aortic aneurysm surgery, small bowel transplantation, cardiopulmonary bypass, strangulated hernias, and neonatal necrotizing enterocolitis<sup>[1]</sup>. Decreased contractile activity, increased microvascular permeability, and dysfunction of mucosal barrier are all associated with intestinal I/R<sup>[2,3]</sup>. I/R injury of the intestine is an intricate and multifactorial pathophysiological process that involves the formation and action of oxygen free radicals (OFRs)<sup>[3-9]</sup>, inflammatory cytokines, the complement system<sup>[1,3]</sup> and neutrophil infiltration<sup>[1-3,6,7,10]</sup> at the site of damage.

The purine nucleoside adenosine is one of the major local regulators of normal tissue function, acting in both an autocrine and paracrine fashion. Its regulatory function becomes pronounced especially when energy supply ceases abruptly as in the case of ischemia, and fails to meet cellular energy demand. Adenosine exerts its effects by interacting with its receptors, four of which have been cloned and characterized as adenosine A<sub>1</sub>, A<sub>2a</sub>, A<sub>2b</sub>, and A<sub>3</sub><sup>[11-13]</sup>. The physiological role of adenosine in the gastrointestinal tract is still poorly understood, particularly with regard to colonic and ileal motor functions. It has been reported that A<sub>1</sub> adenosine receptor (A<sub>1</sub>AR) antagonists increase defecation in rats<sup>[13]</sup> and that A<sub>1</sub>AR agonists can inhibit intestinal fluid secretion and peristalsis *via* adenosine A<sub>2B</sub> and A<sub>1</sub> receptors, respectively<sup>[14]</sup>.

One of the cellular events observed during ischemia is the increased consumption of ATP, leading to accumulation of adenosine with thereby elevating extracellular adenosine. The accumulation of adenosine is believed to contribute to cytoprotection in the ischemic tissue<sup>[11,12]</sup>. Furthermore, adenosine which is released during short periods of ischemia followed by reperfusion, provides cytoprotection against a subsequent sustained ischemia in heart, resulting in reduced infarct size<sup>[15-20]</sup>. This is known as the preconditioning effect of adenosine, which is mediated mostly through the activation of cardiac A<sub>1</sub>ARs before ischemia<sup>[11,12,18]</sup>. It is well documented that the early<sup>[19,20]</sup> and late<sup>[11,15,18]</sup> phases of ischemic tolerance are mediated by adenosine in myocardium. That adenosine exerts anti-ischemic actions is indicated by

a number of studies using adenosine receptor agonists and antagonists<sup>[15-18]</sup> as well as animals overexpressing or lacking A<sub>1</sub>AR<sup>[21,22]</sup>. Administration of adenosine either prior to ischemia or during reperfusion has been shown to attenuate myocardial injury<sup>[23,24]</sup>. Treatment with adenosine A<sub>1</sub>AR agonist initiates preconditioning not only in heart<sup>[15-18,25]</sup> but also in tissues such as kidney<sup>[26,27]</sup> and brain<sup>[28,29]</sup>, resulting in attenuation of ischemic injury. One of the underlying mechanisms suggested for adenosine receptor-mediated preconditioning in the heart is through involvement of protein kinase C (PKC) in heart<sup>[11,12,30]</sup>. Activation of PKC induces opening of ATP-sensitive K<sup>+</sup> channels<sup>[11,12,31]</sup>. Among other effectors that most likely contribute to the cytoprotection by adenosine are mitogen activated protein (MAP) kinases<sup>[25,31-33]</sup>, heat shock proteins (HSPs)<sup>[11-15,34]</sup>, antioxidant enzymes<sup>[15,34]</sup> and inducible nitric oxide synthase (iNOS)<sup>[11,12]</sup>. Moreover, induction and activation of manganese superoxide dismutase (Mn-SOD) is also believed to be a significant factor in mediating myocardial adaptation in response to activation of A<sub>1</sub>AR<sup>[15]</sup>.

In the phenomenon of ischemic preconditioning (IPC), a short period of ischemia protects the organs (e.g. heart) against a subsequent more substantial ischemic injury<sup>[35]</sup>. In fact, IPC has been one of the most promising strategies against reperfusion injury during the last few years. It appears to elevate the tolerance of the intestine to I/R injury. A number of experimental studies have shown that reperfusion injury in small intestine is prevented by IPC<sup>[36-40]</sup>. IPC conducted in small intestine reduces postischemic leukocyte adhesion by maintaining the bioavailability of nitric oxide<sup>[41]</sup>. Moreover, it lowers the expression of P-selectin<sup>[38]</sup>, which is a downstream effector target of the adenosine-initiated, PKC dependent, signalling pathway in intestine. Although activation of PKC triggered by adenosine has been a crucial factor for initiating the beneficial actions of IPC in most tissues, the effector of the preconditioning phenomenon appears to vary among tissues. Activated-K<sup>+</sup> channels<sup>[42]</sup>, nitric oxide<sup>[39,41]</sup> and endogenous opioid peptides<sup>[43]</sup> have reported to be the other downstream effectors of IPC in intestine. Based primarily on animal experiments, the identification of the molecular mechanisms that are responsible for protection by IPC, has provided opportunities to consider several rational targets for pharmacological intervention. Consequently, a variety of drugs have been demonstrated to be able to mimic IPC when applied instead of ischemia. This is known as pharmacological preconditioning (PPC). Recently, various studies carried out in rat small intestine have demonstrated that establishing PPC by administration of either adenosine<sup>[37]</sup> or A<sub>1</sub>AR agonist<sup>[38]</sup> mimics the protective effects of IPC. Intensive investigation has been focused on explaining how adenosine accomplishes the beneficial effect of preconditioning. For instance, currently published studies suggest important anti-ischemic roles of the A<sub>1</sub><sup>[18,25,30]</sup>, A<sub>3</sub><sup>[17,21]</sup> or A<sub>2a</sub><sup>[44,45]</sup> adenosine receptors in heart. On the other hand, relatively little data are available on the role of the different adenosine receptors in mediating cytoprotection in intestinal tissue which is exposed to I/R. The majority of studies strongly suggest that adenosine can promote protection against I/R injury via activation of different adenosine receptors in various

tissues. A substantial number of studies report that IPC has been beneficial in human heart and the liver. However, both prospective controlled studies in human and experimental studies in animals are lacking<sup>[1]</sup>. Furthermore, research based on administration of drugs that can mimic the effects of IPC is required further to explore the cellular events during I/R injury of the intestine. To date, there is no direct evidence showing possible effects of adenosine and A<sub>1</sub>AR activation on reduced contractility of intestinal smooth muscle due to I/R injury. Therefore, the present study was constructed to explore the possible effects of adenosine and A<sub>1</sub>AR activation on reperfusion injury of small intestinal tissue by evaluating contractile response and levels of thiobarbituric acid-reactive substances (TBARS, a marker of lipid peroxidation), reduced glutathione (GSH, an endogenous antioxidant), and myeloperoxidase (MPO an index of neutrophil infiltration), in terminal ileum subjected to I/R.

## MATERIALS AND METHODS

### Animals

Following Ethical Committee approval, forty adult male Wistar rats, weighing 200-230 g, were obtained from the Experimental Research Section of Zonguldak Karaelmas University, where animals have been reared and maintained under standard conditions, such as stable room temperature (23 ± 2°C), a 12 h light: 12 h dark cycle, and feeding with commercial rat chow and tap water *ad libitum*. Experimental manipulations and surgical operations were approved by the Animal Ethical Committee of the University. Maximum care and a humane approach to use of animals was of primary consideration.

### Experimental groups and operative procedures

The surgical goal was to induce mesenteric ischemia in rats for 30 min followed by a 180 min reperfusion period. On the day before surgery, each animal was fasted overnight with unlimited access to water. Briefly, each animal was anesthetized by an intraperitoneal injection of 50 mg/kg sodium thiopental followed by a midline incision made into the peritoneal cavity. The small bowel was exteriorized gently to the left onto moist gauze, and then the superior mesenteric artery (SMA) was carefully exposed, isolated, and clamped using a microvascular clamp. Intestinal ischemia was confirmed by obvious lack of pulse in the SMA and paleness of the jejunum and ileum. The intestines were then meticulously placed back into the abdomen which was closed with two small clamps. Following 30 min of occlusion time, the clamping was gently released and the intestine inspected for proper reperfusion characterized by regular pulsation. Throughout the surgical procedure, each animal was placed under a heating lamp to maintain constant body temperature (e.g. 37°C). For the purpose of assessing the roles of adenosine and A<sub>1</sub>AR agonist, animals were randomly divided into five groups: (1) Sham-operated group, subjected to laparotomy without performing the occlusion of the SMA; (2) I/R group, subjected to the occlusion of SMA followed by reperfusion; (3) CPA-treated group (0.1 mg/kg, 5 min prior to ischemia) + I/R; (4) Adenosine-treated group (10 mg/kg, 5 min prior

to ischemia) + I/R; (5) DPCPX pretreatment (1 mg/kg, 15 min prior to adenosine administration) + adenosine treatment (10 mg/kg, 5 min prior to ischemia) + I/R. In the last group, confirming the possible effect of selective A<sub>1</sub>AR agonist CPA on reperfusion injury, the selective A<sub>1</sub>AR antagonist DPCPX was administered 15 min prior to adenosine treatment. The route and volume for drug administration were the tail vein and 200  $\mu$ L, respectively. To animals in both sham-control and I/R-control groups were given sterile serum physiological solution in the same volume instead. Choice of dose regimen for the drugs was based on published studies in the literature<sup>[22,37,38]</sup>.

### Preparation of terminal ileum

Upon completion of the I/R period, and whilst still unconscious, the animals were sacrificed by exsanguination of the abdominal aorta. Strips of terminal ileum of 10 mm length were immediately removed 10 cm oral to the ileocecal junction and transferred into a Petri dish containing Krebs solution (in mmol/L: NaCl 118, NaHCO<sub>3</sub> 24.88, KH<sub>2</sub>PO<sub>4</sub> 1.18, KCl 4.7, MgSO<sub>4</sub> 1.16, CaCl<sub>2</sub> 2.52 and glucose 11.1). Then, tissue was longitudinally suspended in a standard organ chamber, and continuously perfused with 20 mL of preoxygenated Krebs solution (pH 7.4), which was bubbled constantly with a mixture of 950 mL/L O<sub>2</sub> and 50 mL/L CO<sub>2</sub> gas and maintained at a temperature of 37°C. One end of the tissue strip was tied to a fixed post and the other attached to an isometric force transducer under a resting tension of 2 g. Isometric responses were monitored by external force displacement transducer (FDA-10A, Commat Iletisim Co., Ankara, Turkey) and recorded on the computer using MP 30 software (Biopac Systems Inc., Santa Barbara, CA, USA). In the organ bath, each strip was allowed to equilibrate for 1 h with intervening washes every 15 min before adding any compound. Tissue samples also obtained from small intestine approximately 10 cm proximal to the ileocecal area were frozen immediately and stored at -40°C for biochemical measurements.

### Concentration-response curves

At the beginning of each experiment to observe dose-contractile response relationship, KCl was added to the organ chamber to a final concentration of 30 mmol/L. For the preparation of high K<sup>+</sup> solutions, NaCl was exchanged for an equimolar amount of KCl to maintain the physiological osmolality of the Krebs solution. The contraction recorded in response to KCl was considered as a reference response. Afterwards, the contractions in response to carbachol and substance P at various final concentrations ranging from 10<sup>-9</sup> mol/L to 10<sup>-2</sup> mol/L were recorded by pipetting these compounds into the organ bath in a cumulative fashion at equal intervals. At the end of the experiment, the response to 30 mmol/L KCl was measured again to confirm and evaluate the degree of tissue viability. The amplitude of all contractions was then normalized for each g of tissue and expressed as percentage of the initial KCl-reference response. The number of experiments, represented as “n”, indicates that each experiment was performed with a tissue sample taken from one animal.

All experiments were conducted in a paired way. For the purpose of evaluating the effects of ligand, agonist, and antagonist, the maximum response ( $E_{max}$ ) and pD<sub>2</sub> values (e.g. the negative logarithm of the concentration for the half-maximal response, ED<sub>50</sub>) were computed by using GraphPad Prism Software 3.02 (GraphPad Prism Inc., San Diego, CA, USA)<sup>[46]</sup>. The pD<sub>2</sub> values (apparent agonist affinity constants) were calculated from each agonist concentration–response curve by linear regression of the linear median part of the sigmoid curve and taken as a measure of the sensitivity of the tissues to each agonist.

### Drugs

Adenosine, CPA, DPCPX, carbachol and substance P were purchased from Sigma (Sigma Chemical Co., St. Louis, MO, USA). They were dissolved in double distilled water, except for CPA and DPCPX which were initially prepared in dimethyl sulphoxide and then diluted in physiological saline. Adenosine, CPA, and DPCPX were prepared fresh just before usage. Carbachol and substance P were made up at different concentrations and kept frozen in aliquots. Compounds, which were used for preparing Krebs solution, were purchased from Merck (Merck KGaA, Darmstadt, Germany). All other reagents, including trichloroacetic acid (TCA), thiobarbituric acid (TBA), butylated hydroxy toluene (BHT), and dithiobisnitrobenzoate (DTNB) were obtained from Sigma.

### Determination of tissue TBARS and GSH

Tissue TBARS content was measured in order to estimate the extent of lipid peroxidation in the injured terminal ileum. Samples obtained from each group were stored at -40°C until assayed. Tissue samples were washed in ice-cold Krebs solution, blotted on absorbent paper and weighed. Afterwards, each sample was minced followed by homogenization with 10 mL of 100 g/L TCA per g of tissue, using a motor-driven homogenizer (Heidolph Diox 900, Heidolph Elektro GmbH&Co.KG, Kelheim, Germany). Then, the tissue TBARS levels were measured spectrophotometrically based on a method described by Casini *et al*<sup>[47]</sup> and expressed as nmol/g of tissue weight. Briefly, following two consecutive centrifugations at 3000 g for 15 min, 750  $\mu$ L supernatant was added to equal volume of 6.7 g/L TBA and heated to 100°C for 15 min. The absorbance of the samples was then measured spectrophotometrically at 535 nm (Smart Spectro, LaMotte Co., Chestertown, MD, USA).

The GSH content of the samples were measured by applying a modified Ellman method<sup>[48]</sup>. In brief, 2 mL of 0.3 mol/L Na<sub>2</sub>HPO<sub>4</sub> solution was mixed with 0.5 mL of supernatant obtained by employing the homogenization procedure described above. Into the mixture, 0.2 mL of DTNB solution was added followed by reading absorbance at 412 nm. The tissue GSH levels were expressed as  $\mu$ mol/g of tissue weight.

### Measurement of tissue MPO activity

The degree of neutrophil accumulation in the intestinal tissue samples was measured by assaying MPO activity as described by Bradley *et al*<sup>[49]</sup>. Briefly, upon thawing, each

Table 1  $E_{\max}$  and  $pD_2$  values of carbachol and substance P ( $n = 8$ , means  $\pm$  SE)

	Sham Control	I/R Control	CPA-I/R	ADO-I/R	DPCPX + ADO-I/R
Carbachol

<sup>a</sup> $P < 0.05$  vs sham-operated control group, <sup>c</sup> $P < 0.05$  vs I/R control group.

sample was very finely minced with surgical blade in a petri dish containing 50 mmol/L potassium phosphate buffer (PB, pH 6.0) at a volume 20 times the tissue weight (e.g. 1 mL) followed by homogenization for 5 min in ice-cold PB by means of motor driven homogenizer. The homogenate was centrifuged at 40 000 g for 15 min at 4°C. The homogenized tissue pellet was suspended in 50 mmol/L PB containing 5 g/L hexadecyltrimethylammonium bromide (HETAB) and then homogenized again. Following three freeze and thaw cycles with sonication (Bandelin Sonopuls HD2070, Bandelin Electronic GmbH&CO.KG, Berlin, Germany) between cycles, the samples were centrifuged at 40 000 g for 10 min. Aliquots of supernatant (0.1 mL) were added to 2.9 mL of reaction mixture containing 0.167 mg/mL of *o*-dianisidine, and 20 mmol/L H<sub>2</sub>O<sub>2</sub> solution, which were prepared in 50 mmol/L of PB. Immediately after adding the aliquot to the mixture, the change in absorbance at 460 nm was measured for 5 min. One unit of MPO activity was defined as that degrading 1  $\mu$ mol of peroxide per min at 25°C. The activity was then normalized as unit per mg of tissue (U/mg).

### Statistical analysis

Values for the experiments dealing with contractility were normalized for per g of tissue followed by expressing them as percentage of KCl response. Each data point represents mean  $\pm$  SE. For statistical evaluation, SPSS 11.0 statistical software package programme was used (SPSS Inc., Chicago, IL, USA). One-way analysis of variance (ANOVA) was applied for statistical comparison of groups, followed by analysis with Tukey-Kramer test so as to determine differences between the groups. Probability value ( $P$ ) of 0.05 or less was considered statistically meaningful.

## RESULTS

### Ileal longitudinal muscle contractility

For longitudinal ileum muscle collected from sham control, CPA-treated, adenosine-treated, and DPCPX-adenosine-treated animals, mean contraction responses to 30 mmol/L KCl were measured as 0.59  $\pm$  0.01 g; 0.40  $\pm$  0.09 g; 0.50  $\pm$  0.22 g; and 0.44  $\pm$  0.21 g, respectively, which were statistically indistinguishable (Figure 1). In I/R control group however, the contractile response (0.26  $\pm$  0.08 g) was significantly reduced when compared to that in sham-operated control group ( $P = 0.012$ ).

The addition of carbachol at concentrations from 10<sup>-9</sup> mol/L to 10<sup>-2</sup> mol/L into the organ bath resulted

**Figure 1** Mean contraction of longitudinal ileum muscle isolated from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R rats in response to 30 mmol/L KCl. Data are expressed as means  $\pm$  SE ( $n = 8$ ). <sup>a</sup> $P < 0.05$  vs sham-operated control group.

in a dose-dependent contractile effect on the terminal ileum segments from all groups (Figure 2), providing sigmoid curves with  $E_{\max}$  and  $pD_2$  values (Figure 3).  $E_{\max}$  value for carbachol was significantly lower in the I/R control group than in the sham-operated control group (157.04%  $\pm$  41.35% vs 488.66%  $\pm$  47.01%, respectively). In other words, contraction in response to carbachol was significantly reduced by induction of I/R. Statistical difference between the groups appeared to be meaningful at 10<sup>-6</sup> mol/L ( $P = 0.02$ ), reaching a maximal level at 10<sup>-3</sup> mol/L of carbachol ( $P = 0.0001$ ). The I/R-induced reduction in contractility was significantly restored by treatments with both CPA and adenosine but not by pretreatment with DPCPX. Amelioration of reduced contractions with CPA and adenosine therapies became statistically significant at millimolar doses of carbachol ( $P = 0.03$  at 10<sup>-3</sup> mol/L and 10<sup>-2</sup> mol/L).

Comparison of the  $E_{\max}$  values showed that average contraction of ileum samples in I/R group was just 32% of that in sham-operated control group, while those in CPA- and adenosine-treated groups were approximately 81% and 76%, respectively (Table 1). In the group pretreated with DPCPX,  $E_{\max}$  was found to be approximately 60% of that in sham control group, which was statistically significant ( $P < 0.05$ ). On the other hand, no statistically significant change was detected in the corresponding  $pD_2$  values in any group (Table 1).

In response to various concentrations of substance

**Figure 2** Representative traces showing responses generated by various concentrations of carbachol in longitudinal ileum muscle isolated from sham-operated control (A), I/R control (B), CPA-I/R (C), adenosine-I/R (D), and DPCPX-adenosine-I/R (E) rats.

**Figure 3** Dose-response curves of carbachol in longitudinal ileum muscle isolated from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R rats. Data are expressed as means  $\pm$  SE ( $n = 8$ ). <sup>a</sup> $P < 0.05$  vs sham-operated control, <sup>c</sup> $P < 0.05$  vs I/R control groups.

P ranging from  $10^{-9}$  mol/L to  $10^{-2}$  mol/L, terminal ileum samples contracted in a dose-dependent fashion in all groups (Figure 4), rendering sigmoid curves with  $E_{max}$  and  $pD_2$  values (Figure 5). The contractile response induced by substance P was significantly and dose-dependently inhibited by induction of I/R. Statistical difference between sham-operated control rats and I/R control animals was significant at  $10^{-6}$  mol/L and over doses of substance P ( $P < 0.05$ ). Reduced contractility due to I/R was alleviated significantly by adenosine treatment ( $P < 0.05$ ). This effect of adenosine was completely lost once DPCPX was given prior to adenosine administration. However, the exacerbating effect of DPCPX was significantly evident in response to substance P at doses lower than  $10^{-5}$  mol/L (Figure 5). Above this concentration, as shown in the ascending part of the curve, responses in both adenosine- and DPCPX-adenosine-treated groups were statistically indistinguishable. Accordingly, there was a statistically significant difference between I/R control group and DPCPX-adenosine-treated group in response

**Figure 4** Representative traces showing responses generated by various concentrations of substance P in longitudinal ileum muscle isolated from sham-operated control (A), I/R control (B), CPA-I/R (C), adenosine-I/R (D), and DPCPX-adenosine-I/R (E) rats.

**Figure 5** Dose-response curves of substance P in longitudinal ileum muscle isolated from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R rats. Data are expressed as means  $\pm$  SE ( $n = 8$ ). <sup>a</sup> $P < 0.05$  vs sham-operated control, <sup>c</sup> $P < 0.05$  vs I/R control groups.

to  $10^{-4}$  mol/L ( $P = 0.022$ ),  $10^{-3}$  mol/L ( $P = 0.004$ ), and  $10^{-2}$  mol/L ( $P = 0.011$ ) of substance P. Regarding the corresponding  $pD_2$  values, no statistically significant change was detected in any group (Table 1).

### TBARS level

Average TBARS content of intestinal samples from sham-operated animals was  $54.18 \pm 3.26$  nmol/g tissue, while that from I/R control rats was  $78.27 \pm 7.60$  nmol/g tissue (Figure 6). I/R caused approximately 1.45 fold increase in TBARS content of the tissue, which was significantly different from that measured in samples from sham-operated animals ( $P = 0.002$ ). Administration of either CPA or adenosine prior to the induction of ischemia significantly reduced the elevated TBARS content to the levels observed in sham control rats. Mean values of the both groups ( $39.87 \pm 11.02$  nmol/g tissue and  $56.49 \pm 7.03$  nmol/g tissue, respectively) were significantly different from that of the I/R control group ( $P = 0.001$ ). On the other hand, in the case of DPCPX pretreatment before

**Figure 6** TBARS content of ileum samples from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R rats. Data are expressed as means  $\pm$  SE ( $n = 8$ ). <sup>a</sup> $P < 0.05$  vs sham-operated control, <sup>c</sup> $P < 0.05$  vs I/R control groups.

adenosine administration followed by I/R, the average TBARS content was  $72.02 \pm 4.34$  nmol/g tissue, which was not significantly different from that in the I/R control group.

#### GSH level

As shown in Figure 7, the amount of GSH measured in tissues subjected to I/R ( $1.29 \pm 0.19$   $\mu$ mol/g tissue) decreased approximately 58% compared to that measured in the tissues from the sham-operated group ( $3.08 \pm 0.27$   $\mu$ mol/g tissue) ( $P < 0.001$ ). Levels of tissue GSH were statistically indistinguishable when comparing the samples from I/R control group with those from CPA-treated group. In contrast, treatment with adenosine significantly ameliorated the decreased amount of GSH. Mean GSH content was  $2.34 \pm 0.31$   $\mu$ mol/g tissue, which was significantly different from that measured in I/R control animals ( $P = 0.002$ ). However, pretreatment with DPCPX prevented this effect of adenosine, reducing GSH content to the levels observed in I/R control animals.

#### MPO activity

MPO enzyme activities in the terminal ileum samples from animals subjected to sham operation, I/R, CPA treatment, adenosine treatment, and DPCPX-adenosine treatment averaged  $6.09 \pm 1.04$  U/mg tissue,  $18.19 \pm 6.57$  U/mg tissue,  $10.80 \pm 3.66$  U/mg tissue,  $5.58 \pm 2.89$  U/mg tissue, and  $21.45 \pm 9.61$  U/mg tissue, respectively (Figure 8).

I/R caused approximately a 3 fold increase in MPO activity of terminal ileum tissue compared to the basal level of the activity ( $P < 0.0001$ ), which was measured in tissues of sham control animals (Figure 8). As MPO activity of samples from animals treated with CPA or adenosine were significantly different from that in I/R group ( $P = 0.056$  and  $P = 0.0001$ , respectively), it appeared that pretreatment with DPCPX completely abolished the reducing effect of adenosine on MPO activity. Clearly, no statistical difference was observed in MPO activity between I/R control animals and DPCPX-pretreated rats, while there was a significant difference between CPA-treated animals and DPCPX-pretreated animals ( $P = 0.023$ ) as well as between adenosine-treated group and DPCPX-

**Figure 7** GSH content of ileum samples from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R rats. Data are expressed as means  $\pm$  SE ( $n = 8$ ). <sup>a</sup> $P < 0.05$  vs sham-operated control, <sup>c</sup> $P < 0.05$  vs I/R control groups.

**Figure 8** MPO level of ileum samples from sham-operated control, I/R control, CPA-I/R, adenosine-I/R, and DPCPX-adenosine-I/R animals. Results are the means  $\pm$  SE of 6 to 8 animals in each group. <sup>a</sup> $P < 0.05$  vs I/R control, <sup>b</sup> $P < 0.001$  vs sham-operated control.

pretreated group ( $P < 0.0001$ ).

## DISCUSSION

The major findings of the present study can be summarized as follows: (1) I/R resulted in reduced ileal contractility in response to KCl, carbachol, and substance P as well as elevating oxidative stress and neutrophil infiltration; (2) These disturbances were significantly ameliorated by either adenosine administration or A<sub>1</sub>AR activation in the preischemic period; (3) Adenosine and A<sub>1</sub>AR-mediated protection against I/R injury seemed to be associated with decreased oxidative stress and MPO activity; (4) A<sub>1</sub>AR antagonist DPCPX diminished the injury-sparing effect of PPC with adenosine as observed in other tissues. Pharmacological blockade of A<sub>1</sub>ARs exacerbated the contractile response of small intestinal smooth muscle.

I/R results in disrupted exogenous electrical activity and contractile response of ileum<sup>[8-10]</sup>. A substantial amount of evidence indicates that the pathogenesis of I/R and I/R-induced motor alterations have been related to OFRs<sup>[1-3,6,8]</sup> and activated neutrophils<sup>[1-3,10]</sup>. Intestinal I/R sets the groundwork for an inflammatory response in

the vicinity of muscularis cells, provoking the recruitment and extravasation of leukocytes into smooth muscle syncytium<sup>[2,10]</sup>. A number of experimental studies have been conducted in order to test various pharmacological agents that might reduce reperfusion injury of the intestinal mucosa<sup>[4,5,7,9,50,51]</sup> with the intention of improving life-span after acute mesenteric ischemia.

Our results showed that intestinal I/R resulted in decreased ileal contractility in response to carbachol, substance P, and KCl; therefore influencing both receptor-mediated induction and non-receptor-mediated induction. That the  $pD_2$  values in all groups were statistically indifferent from each other however, suggest that I/R does not alter agonist-receptor interaction. Hence, the reduced  $E_{max}$  value in I/R group may be dependent partly on change in the regulation of postreceptor processes (e.g. excitation-contraction coupling)<sup>[9,46]</sup>. Furthermore, the decreased contraction response also observed in non-receptor-mediated induction strongly supports this possibility.

IPC makes reference to a phenomenon in which the harmful effects of prolonged ischemia is prevented by exposure of a tissue to brief periods of ischemia<sup>[35]</sup>. In spite of the fact that it is highly complicated in nature, IPC has been successfully applied to various animal models of intestinal I/R, resulting in attenuation of the reperfusion injury<sup>[37-40,52]</sup>. However, although IPC has been shown to be beneficial in the human heart and liver, prospectively controlled studies in both humans and animals involving IPC and PPC of the intestine are inadequate. More research focused on the application of drugs that can mimic the effects of IPC is needed to analyze the cellular and molecular events during I/R injury of the intestine so as to attenuate I/R injury<sup>[1]</sup>. Both animal and human studies have revealed that adenosine is one of the major triggers for IPC. A study done by Unal *et al*<sup>[37]</sup> has demonstrated that administration of adenosine prior to ischemia is as effective as IPC for inducing ischemic tolerance in rats. Data gathered in the present study confirms this finding and show that the treatment with adenosine significantly restored I/R-reduced contractile response. Furthermore, the treatment also provided such beneficial effects such as elevating GSH content, lowering lipid peroxidation, and reducing neutrophil infiltration. In addition, that the  $A_1AR$  antagonist DPCPX significantly blocked these protective effects of adenosine is consistent with the hypothesis that PPC with adenosine is primarily mediated via  $A_1AR$ s.

The findings of the present study revealed that non-receptor mediated (e.g. KCl-induced) and receptor mediated (e.g. carbachol- and substance P-induced) ileal contractions that were reduced significantly due to I/R, were improved remarkably and returned to sham-control levels by systemic administration of adenosine or CPA. During the process of preconditioning, adenosine is generated in the ischemic tissue. The endogenous adenosine or selective pharmacological agonists activate  $A_1AR$ s. Preischemic activation of  $A_1AR$ s has been demonstrated to prevent from I/R damage in various organs including heart<sup>[15-18,25]</sup>, kidney<sup>[26,27]</sup> and brain<sup>[28,29]</sup>. In these studies, the activation of  $A_1AR$ s has been

strongly implicated in the mediation of IPC. Adenosine therapy before induction of ischemia has been reported to attenuate ischemic injury in heart<sup>[23,24]</sup> and intestine<sup>[37]</sup>. Furthermore, pharmacological blockade of  $A_1AR$  during preconditioning eliminates the achievement of protection<sup>[15-18]</sup>. The protective effect of  $A_1AR$  activation is accomplished through the activation of PKC, leading to translocation of PKC to sarcolemmal and to mitochondrial membranes. Activated PKC then induces an increase in opening of ATP-sensitive  $K^+$  channels in heart<sup>[11,12]</sup>. Stimulation of  $A_1AR$ s also precedes the early activation of some other kinases such as tyrosine kinases, p38, MAPK<sup>[11,19,25,31,33]</sup>, ERK<sup>[32]</sup>, and Akt<sup>[20]</sup>. Additionally, in protection obtained by agonist-induced stimulation of  $A_1AR$ , elevated content or activity of many proteins have been demonstrated such as HSP 27<sup>[11]</sup> and Mn-SOD<sup>[15]</sup>. Despite the existence and involvement of relatively large number of effector molecules, it appears that they vary among tissues. In small intestine, for instance, Davis *et al*<sup>[38]</sup> report that pharmacological modulation of  $A_1AR$ s is involved in reduced expression of P-selectin, which is a downstream effector target of the adenosine-initiated, PKC dependent, anti-inflammatory signaling pathway in preconditioning. In our study, I/R of small intestine elevated the tissue TBARS content, indicating enhanced generation of OFRs; therefore, inducing lipid peroxidation. Systemic administration of adenosine or CPA appeared to be protective against I/R-induced reduction of contractility via, at least, inhibiting lipid peroxidation and neutrophil infiltration as confirmed by reduction of TBARS and MPO levels, respectively. Another significant observation reported recently is that activation of  $A_1AR$ s *in vitro* prevents cellular functions from  $H_2O_2$ -induced injury through signaling pathways related to PKC in renal proximal tubular cells<sup>[53]</sup>. The same observation has been demonstrated in other studies on heart<sup>[54,55]</sup> and kidney<sup>[53]</sup>. In these studies, activation of  $A_1AR$ s *in vivo* and *in vitro* is reported to be associated with protection against  $H_2O_2$ -induced oxidative injury by modulation of the detrimental increases in intracellular calcium concentration and by means of activation of cardiomyocyte  $K^+$  channels after  $H_2O_2$  exposure.

GSH is an endogenous antioxidant and present in all animal cells. Reacting with free radicals, it can provide protection from singlet oxygen, hydroxyl radical and superoxide anion<sup>[31]</sup>. Many published studies indicate that tissue injury, induced by various stimuli (e.g. I/R), is coupled with glutathione depletion<sup>[9]</sup>. In the present study, we showed that depleted GSH content in ischemic ileal tissue was recovered by adenosine or CPA therapies. In other words, inducing PPC with these drugs maintained GSH content during reperfusion. This effect may be related to activation of PKC since adenosine has been reported to induce the activation of antioxidant enzymes *in vitro* and since it is suggested that the stimulatory action of adenosine is likely involved in PKC-mediated phosphorylation. Such a mechanism could serve to decrease the levels of OFRs, which would otherwise be harmful to the cell. This very effect of adenosine is also evident *in vivo*, and may account for adenosine-induced reduction of lipid peroxidation in cochlea<sup>[34]</sup>. Although the

present study has not examined antioxidant enzymes or PKC, the elevated level of GSH implicates the potential involvement of a cytoprotective mechanism related to adenosine and A1 receptor activation.

Modulation of the inflammatory response following I/R injury is an important component of tissue defense, mostly because inflammation is the major component of cell death and motor alteration in intestine subjected to intestinal injury. In the initial period of I/R, generation of OFRs occurs, which is the most likely the initial factor responsible for the induction of neutrophil chemotactic activity. Afterwards an influx of leukocytes during reperfusion triggers an intricate cascade of proinflammatory events associated with cytokine/chemokine release and free radical-mediated intestinal injury<sup>[1,3]</sup>. Upon attachment to endothelium, neutrophils cause the secretion of additional OFRs, contributing to the damage. At this point, the enzyme MPO, found largely in leukocytes particularly in neutrophils, provides an opportunity to check the tissue level of the cells since it is a marker of neutrophil infiltration and accumulation into tissues<sup>[27]</sup>. In the present study, we have demonstrated that the therapy with A<sub>1</sub>AR agonist CPA prevented neutrophil infiltration into the reperfused-intestine as shown by the decrease in MPO content. This finding is in agreement with those of previous studies which reports that A<sub>1</sub>AR stimulation is associated with decreased inflammation and MPO levels<sup>[22,27,38]</sup>.

In the present study, we have demonstrated that administration of adenosine and the A<sub>1</sub>AR agonist CPA ameliorated intestinal contractile dysfunction induced by I/R. The outcome of the study suggests that preischemic administration of adenosine or CPA may protect intestine, as indicated by recovery of contractile response, possibly through decreasing oxidative stresses and reducing neutrophil infiltration. In conclusion, our findings suggest the cellular mechanism by which adenosine and pharmacological stimulation of A<sub>1</sub>ARs attenuate intestinal injury, which may indicate the possible therapeutic usage of adenosine as an adjunct for ischemia and ischemia related small bowel diseases.

## COMMENTS

### Background

A number of experimental studies have shown that reperfusion injury in the small intestine is prevented by ischemic preconditioning (IPC). Moreover, various studies using rat small intestine have demonstrated that establishing pharmacological preconditioning (PPC) by administration of either adenosine or adenosine A1 receptor agonist mimic the protective effects of IPC. On the other hand, relatively little data is available on the role of the different adenosine receptors in mediating cytoprotection during intestinal I/R injury. There is no direct evidence which confirms the possible effects of adenosine and adenosine A1 receptor activation on I/R injury-related decreased in contractility of intestinal smooth muscle.

### Research frontiers

That adenosine exerts anti-ischaemic actions is indicated by a number of studies using adenosine receptor agonists and antagonists as well as animals overexpressing or lacking the adenosine A1 receptor. Administration of adenosine either prior to ischemia or during reperfusion has been shown to attenuate myocardial injury. Treatment with adenosine A1 receptor agonist initiates preconditioning not only in heart but also in such tissues as kidney and brain, resulting in attenuation of ischemic injury.

### Innovations and breakthroughs

IPC of the small intestine reduces postischemic leukocyte adhesion by maintaining the bioavailability of nitric oxide. Moreover, it lowers the expression of P-selectin, which is a downstream effector target of the adenosine-initiated, PKC dependent, signalling pathway in intestine. Although activation of PKC triggered by adenosine is a crucial factor for initiating the beneficial actions of IPC in most tissues, the effector of the preconditioning phenomenon appears to vary among tissues. Activated-K<sup>+</sup> channels, nitric oxide, and endogenous opioid peptides have reported to be the other downstream effectors of IPC in intestine. Furthermore, currently published studies suggest important anti-ischemic roles of the A<sub>1</sub>, A<sub>3</sub> or A<sub>2a</sub> adenosine receptors in heart.

### Applications

The therapeutic efficacy of adenosine and the adenosine A1 agonist, 2-chloro-N<sup>6</sup>-cyclopentyladenosine (CPA) should be examined for potential clinical application in the treatment of conditions related to intestinal ischemia-reperfusion injury, such as small bowel transplantation, strangulated hernias, and abdominal aortic aneurysm. In addition, it would be worthwhile to focus on the possible effector molecules (e.g. involvement of PKC, opening of mitochondrial ATP-sensitive K<sup>+</sup> channels, or activation of Akt) which underlie the mechanism(s) responsible for the beneficial effects of adenosine and CPA observed in the present study.

### Terminology

Ischemia: deficient supply of blood to a body part (e.g. any organ) that is due to obstruction of the inflow of arterial blood (for example, by narrowing of arteries as a result of spasm or disease); Ischemia-reperfusion: interruption of the blood flow to a tissue for a period of time followed by restoration of blood flow. During the ischaemic period, a sequence of events is initiated that may ultimately lead to cellular dysfunction or even cell death; Reperfusion injury: When ischemia is ended by restoration of blood flow, a second series of injurious events ensue producing additional damage. The injury produced by reperfusion is more severe than that induced by ischemia and is called reperfusion injury. The primary harmful events are the formation of cytotoxic oxidants (also commonly called oxygen free radicals) derived from molecular oxygen, oxygen free radical-mediated damage to cellular membranes via lipid peroxidation, loss of cellular calcium balance, and generation of inflammatory reaction at the site of damage; Oxidative stress: stress on the body or organism that results from the cumulative damage done by oxygen free radicals which are inadequately neutralized by antioxidants; Agonist: a chemical substance capable of combining with a receptor on a cell and initiating the same reaction or activity typically produced by the binding of an endogenous substance; Antagonist: a chemical substance that acts through receptor to reduce the physiological activity of another chemical or endogenous substance.

### Peer review

The present study is interesting, well designed, and contained novel findings. The study is set up thoroughly and the paper is well written. The conclusions are well based and are of clinical value.

## Abstract

**AIM:** To observe the therapeutic effects of dexamethasone on rats with severe acute pancreatitis (SAP) and investigate the influences of dexamethasone on the inflammatory mediators and NF- $\kappa$ B expression in multiple organs of SAP rats as well as the mechanisms involved.

**METHODS:** Ninety Sprague-Dawley (SD) rats with SAP were randomly divided into the model group ( $n = 45$ ) and dexamethasone treatment group ( $n = 45$ ), and another 45 rats were selected for the sham operation group. All groups were randomly subdivided into the 3 h, 6 h and 12 h groups, each group containing 15 rats. The survival of all groups and pathological changes of multiple organs (liver, kidney and lung) were observed at different time points after the operation. The pathological

score of multiple organs was carried out, followed by the determination of amylase, endotoxin and TNF- $\alpha$  contents in blood. The tissue microarray was used to detect the expression levels of NF- $\kappa$ B p65 protein in multiple organs.

**RESULTS:** There was no marked difference between the model group and treatment group in the survival rate. The amylase content of the treatment group was significantly lower compared to the model group at 12 h ( $P < 0.01$ , 7791.00 vs 9195.00). Moreover, the endotoxin and TNF- $\alpha$  levels of the treatment group were significantly lower than that of the model group at 6 h and 12 h ( $P < 0.01$ , 0.040 vs 0.055, 0.042 vs 0.059 and  $P < 0.05$ , 58.30 vs 77.54, 38.70 vs 67.30, respectively). Regarding the changes in liver NF- $\kappa$ B expression, the model group significantly exceeded the sham operation group at 3 h ( $P < 0.01$ , 1.00 vs 0.00), and the treatment group significantly exceeded the sham operation group at 12 h ( $P < 0.01$ , 1.00 vs 0.00), whereas no marked difference was observed between the model group and treatment group at all time points. The kidney NF- $\kappa$ B expression level in the treatment group significantly exceeded the model group ( $P < 0.05$ , 2.00 vs 0.00) and the sham operation group ( $P < 0.01$ , 2.00 vs 0.00) at 12 h. No NF- $\kappa$ B expression in the lung was found in any group.

**CONCLUSION:** Dexamethasone can lower the amylase, endotoxin and TNF- $\alpha$  levels as well as mortality of SAP rats. NF- $\kappa$ B plays an important role in multiple organ injury. Further studies should be conducted to determine whether dexamethasone can ameliorate the pathological changes of multiple organs by reducing the NF- $\kappa$ B expression in the liver and kidney. The advantages of tissue microarrays in pancreatitis pathological examination include time- and energy- saving, and are highly efficient and representative. The restriction of tissue microarrays on the representation of tissues to various extents due to small diameter may lead to the deviation of analysis.

## INTRODUCTION

Severe acute pancreatitis (SAP), as one of the common presentations of clinically acute abdomen is a systemic disease in which the local inflammatory pathological changes of pancreas involve multiple organs<sup>[1]</sup>. It is recently believed the systemic inflammatory response syndrome (SIRS) due to the excessive inflammatory reactions plays an extremely important role in SAP pathogenesis, which is relatively complicated<sup>[2,3]</sup>. Although the exact pathogenesis remains unclear<sup>[4]</sup>. Studies in recent years have found that NF- $\kappa$ B (nuclear factor kappa-B) which is a main factor in the genetic transcription of inflammation, presents high expression state in acute pancreatitis and plays an important role in the onset and turnover of acute pancreatitis together with other inflammatory cytokines<sup>[5-7]</sup>. Dexamethasone is the antagonist of a non-specific inflammatory mediator<sup>[8]</sup>. Studies have shown that dexamethasone can lower the expression level of NF- $\kappa$ B by inducing the release of NF- $\kappa$ B profilin (I $\kappa$ B)<sup>[9]</sup>. In this study, we prepared rat SAP models by using the improved Aho's method<sup>[10]</sup>, and investigated the therapeutic effects of dexamethasone on the SAP rats and examined the influences of dexamethasone on the inflammatory mediators and NF- $\kappa$ B expression in multiple organs of the rats.

## MATERIALS AND METHODS

### Materials

Clean grade healthy male Sprague-Dawley (SD) rats weighing 250-300 g were purchased from the Experimental Animal Center of Medical School, Zhejiang University, China. Sodium taurocholate and sodium pentobarbital were purchased from Sigma Company, USA. Dexamethasone injection was purchased from Zhejiang Xinchang Pharmaceutical Company. NF- $\kappa$ B p65 antibody was purchased from Santa Cruz Company, USA. The full automatic biochemical analyzer was used to determine the plasma amylase level (U/L). Plasma endotoxin Tachypleus Amebocyte Lysate Kit was purchased from Shanghai Yihua Medical Science and Technology Corporation (Institute of Medical Analysis in Shanghai, China), the calculation unit for content is EU/mL. TNF- $\alpha$  ELISA kit was purchased from Jingmei Bioengineering Corporation, China, the calculation unit for content is pg/mL (ng/L).

### Animal grouping

We adopted the improved Aho's method<sup>[10]</sup> to prepare 90 SAP rat models and randomly divided into the model group (45 rats) and treatment group (45 rats). Another 45 rats were selected as the sham operation group. All groups were randomly subdivided into the 3, 6 and 12 h groups, each group containing 15 rats. The dexamethasone

treatment group was injected once with dexamethasone (1 mL = 5 mg) *via* the vena caudalis, 0.5 mg/100 g body weight 15 min after successful preparation of SAP model. During the laparotomy in the sham operation group, we performed pancreas and duodenum manipulation, observed pathological changes of multiple organs and finally closed the abdomen. The sham operation group and model group were injected with same amount of normal saline (0.1 mL/100 g body weight) *via* the vena caudalis 15 min after the operation.

### Animal model preparation

Fasting and water restriction was imposed on all rat groups 12 h prior to the operation. The rats were anesthetized by intraperitoneal injection of 20 g/L sodium pentobarbital (0.25 mL/100 g body weight) and the operation was performed under aseptic conditions. Model group: After entering the abdomen *via* median epigastric incision, the bile-pancreatic duct, hepatic hilus and common hepatic duct were identified; the duodenal papilla inside the duodenum duct wall was identified, and then a No. 5 needle was used to drill a hole in the mesenteric avascular area. A segmental epidural catheter was inserted into the duodenum cavity *via* the hole, and then inserted into the bile-pancreatic duct toward the direction of papilla in a retrograde way, a microvascular clamp was used to nip the catheter head temporarily. Meanwhile, another microvascular clamp was used to temporarily occlude the common hepatic duct at the confluence of the hepatic duct. After connecting the epidural catheter end with the transfusion converter, 3.5% sodium taurocholate (0.1 mL/100 g) was transfused *via* the microinjection pump at a speed of 0.2 mL/min, stayed for 4 min after injection, and then the microvascular clamp and epidural catheter were removed. After checking for bile leakage, the hole in the lateral duodenal wall was sutured. A sterile cotton ball was used to absorb up the anaesthetic in the abdominal cavity and then the abdomen was closed.

### Preparation of tissue microarrays of multiple organs

We fixed the tissue sample with neutral formalin, prepared the routine paraffin block (named donor block), cut the donor block into 5- $\mu$ m thick tissue section and carried out routine hematoxylin-eosin (HE) staining as well as microscopic morphological observation under microscope, and then selected the required representative area, marked the locations on the HE sections and also on the corresponding part of the donor block. We prepared the blank block as the recipient block in the size of 45 mm  $\times$  20 mm  $\times$  15 mm and drilled the recipient block with the tissue microarrays section (Beecher Instruments, USA), the diameter of the drilling needle is 2.0 mm. In obtaining of the donor block tissue microarrays, we used another drilling needle (its inner diameter is equal to the outer diameter of the former drilling needle) to drill the marked location of paraffin block and collected the tissue microarray. Its length was about 0.1 mm shorter than the depth of hole. The tissue microarrays collecting method was just the same as that of drilling the recipient block. After pushing out the tissue microarrays, we directly

inserted it or inserted it with forceps into the hole of recipient block. After pressing the tissue microarrays downwards with common glass slide, we used the distance adjuster to correctly move the drilling needle to a proper distance forward and back or right and left. This process was repeated and could insert tens of tissue microarrays into the recipient block in an orderly fashion. Finally, we piled up three glass slides to press all the tissue microarrays and thus the prepared tissue microarrays section block had flat and smooth surface. We put the prepared tissue microarrays section block into the paraffin block again to make the mold, and put it into a 60°C oven for 1 h so that the paraffin of the tissue microarrays and recipient block could be melted together. We took the mold out of the oven gently, cooled the half melted paraffin at the room temperature (about 30 min) and then cooled it in a -20°C refrigerator for 6 min. Later, we took the tissue microarrays section block out of the mold and stored it in a 4°C refrigerator for later use. We took out the standby paraffin block and rapidly nipped it on the sectioning machine for correction till all the tissue microarrays were on the same plane, then stuck the ice block on the paraffin block for about 5 min and cut into 10-30 successive sections of 5-μm thickness and used the ice block to freeze the paraffin block. We repeated the above process until finishing sectioning of the tissue, floated the successive sections on the cool water and let it spread naturally. Then we used the ophthalmic elbowed forceps and glass slide to separate the sections during which the first section on the head part of the successive sections could be stuck to the glass slide, fixed and separated it with forceps to avoid loss of tissue microarrays sample due to the leakage of tissue section during separation. The sections were transferred into 45°C warm water to spread for 1 min to ensure their full spreading without scattering. The sections were backed by the glass slide processed by 10% APES acetone solution for staining. We incubated the prepared tissue microarrays sections into a 60°C oven for 1 h, took them out, cooled it at room temperature and put it into a -20°C refrigerator for later use.

#### **NF-κB p65 immunohistochemical staining (supersensitive S-P method)**

We baked the section at 60°C for 16 h and dewaxed in a routine fashion. We carried out antigen retrieval at high temperature and high pressure for 2 min, dropped reagent A to block the endogenous peroxidase, incubated at room temperature for 10 min, followed by washing with distilled water thrice, with biotin blocking reagent A at room temperature for 10 min, twice with PBS for 5 min each, with biotin blocking reagent B, at room temperature for 10 min, and twice with PBS for 5 min each. We added the normal goat serum-blocking liquid, incubated at room temperature for 20 min and removed the extra liquid, then added primary antibody (1:100 dilution), incubated over night at 4°C, washed thrice with PBS for 5 min each, and again incubated with secondary antibody at room temperature for 10 min, washed thrice with PBS for 5 min each. We added streptomycete antibiotin-peroxidase solution, put at room temperature for 10 min, washed four

**Table 1 Comparison of plasma amylase [*M* (*Q<sub>e</sub>*)]**

Group (time/h)	3 h	6 h	12 h
Sham operation	2038.00 (346.00)	2117.00 (324.00)	1725.00 (434.00)
Model	7423.00 (2275.00)	8149.00 (1540.00)	9195.00 (1298.00)
Treatment	6739.00 (2310.00)	7839.00 (2258.00)	7791.00 (1863.00)

times with PBS for 5 min each, and then added freshly prepared DAB solution for coloration. The sections were observed under microscope and washed with distilled water.

#### **Observational index**

**Survival rate:** The rat mortality observed at 3 h, 6 h, and 12 h after operation and the survival rate was calculated.

**Pathological changes of mutiple organs:** After mercy killing the rats anesthetized by sodium pentobarbital in batches, the gross samples of mutiple organs (liver, kidney, lung) were collected and observed for the pathological changes.

**NF-κB p65 protein expression in the mutiple organs:** We applied tissue microarrays to prepare microarray sections of the mutiple organs, and, using immunohistochemical S-P method, observed the NF-κB p65 protein expression and carried out the comprehensive assessment according to the positive cell percentage: < 10% (-); 10%-20% (+); 20%-50% (++); > 50% (+++).

#### **Statistical analysis**

The statistical analysis was conducted using the SPSS11.5 software. The Kruskal-Wallis test was applied for comparison of the three groups. The Bonferroni test was applied to the two-group comparison. The likelihood ratio Chi-square test was applied to compare the survival rate.  $P < 0.05$  was considered statistically significant.

## **RESULTS**

#### **Survival rate**

The 3 h, 6 h and 12 h mortality of the model group were 0% (0/15), 0% (0/15), 13.33% (2/15), respectively. The entire survival rate was 86.67%, while the survival rate of sham operation group and treatment group at all time points were 100%. But the survival rate at different time points was not significantly different between the model group and treatment group.

#### **Comparison of plasma amylase content of all groups**

Plasma amylase content was significantly increased in the model group and dexamethasone treatment group compared to the sham operation group at all time points ( $P < 0.001$ ). No marked difference was observed in plasma amylase content between the dexamethasone treatment group and model group at 3 h and 6 h. However, plasma amylase content was found to be significantly less in the dexamethasone treatment group than the model group at 12 h ( $P < 0.01$ ) (Table 1).

#### **Comparison of plasma endotoxin content of all groups**

Plasma endotoxin content was significantly increased in

Table 2 Comparison of plasma endotoxin [ $M(Q\%)$ ]

Group (time/h)	3 h	6 h	12 h
Sham operation	0.015 (0.007)	0.015 (0.007)	0.016 (0.005)
Model	0.035 (0.0170)	0.055 (0.025)	0.059 (0.020)
Treatment	0.030 (0.0140)	0.040 (0.012)	0.042 (0.018)

the model group and dexamethasone treatment group than the sham operation group at all time points ( $P < 0.001$ ). No marked difference was observed in plasma endotoxin content between the dexamethasone treatment group and model group at 3 h. However, plasma endotoxin content was found to be significantly less in the dexamethasone treatment group compared to the model group at 6 h and 12 h ( $P < 0.01$ ) (Table 2).

#### Comparison of serum TNF- $\alpha$ content of all groups

Serum TNF- $\alpha$  content was obviously increased in the model group and dexamethasone treatment group compared to the sham operation group at all time points ( $P < 0.001$ ). No obvious difference was observed in serum TNF- $\alpha$  content between the dexamethasone treatment group and model group at 3 h. Serum TNF- $\alpha$  content was found to be significantly less in the dexamethasone treatment group compared to the model group at 6 h and 12 h ( $P < 0.05$ ) (Table 3).

#### Macroscopic and microscopic changes of the liver

**Sham operation group:** Macroscopically, we observed normal color without obvious swelling of the liver in all groups. Microscopically, roughly normal hepatic tissue, slight inflammatory cell infiltration in the portal area, normal morphous of most liver cells, some with acidophilia apomorphosis or slight expansion and congestion of sinus hepaticus were observed.

**Model group:** Macroscopically, in the 3 h group, slight swelling of the liver was observed, and some rats had local grey plaques with unclear boundary, while in the 6 h and 12 h groups, pale, turbid color or congestion on the liver, and some with scattered grey plague in irregular shape or necrosis were observed. Microscopically, we observed swelling or acidophilia apomorphosis of the liver cells, inflammatory cell infiltration in the portal area, expansion and congestion of sinus hepaticus, and scattered spotty necrosis in the hepatic lobule in the 3 h group, obvious swelling of the liver cells, increased range and area of the liver cell necrosis, visible focal or massive hemorrhagic necrosis, inflammatory cell infiltration in necrosis focus, obvious congestion of partial sinus hepaticus, bile duct proliferation and scattered necrosis of single cell in the portal area (concentration and fragmentation of nucleus) in the 6 h group, obviously damaged structure of the hepatic lobule, further increased necrosis range and area of the liver cells, more inflammatory cell infiltration in the lobule and/or portal area, and obvious congestion of sinus hepaticus in the 12 h group.

**Dexamethasone treatment group:** Macroscopically, the gross liver pathological changes of the dexamethasone treatment group at 6 h and 12 h were milder than

Table 3 Comparison of serum TNF- $\alpha$  [ $M(Q\%)$ ]

Group (time/h)	3 h	6 h	12 h
Sham operation	3.30 (3.60)	4.90 (2.60)	3.70 (2.30)
Model	46.13 (37.95)	77.54 (42.16)	67.30 (32.13)
Treatment	38.40 (26.60)	58.30 (26.40)	38.70 (28.50)

those of the model group, most significantly at 12 h. Microscopically, we observed slight swelling of the liver cells, slight expansion and congestion of the sinus hepaticus, scattered inflammatory cell infiltration but with significantly less scale in the portal area at all time points in the dexamethasone treatment group, while more limited necrosis range of the liver cells, no obvious lamellar necrosis at 6 h and 12 h groups. The gross pathological changes of the dexamethasone treatment group were milder than those of the model group at 6 h and 12 h, most significantly at 12 h.

#### Macroscopic and microscopic changes of the kidney

**Sham operation group:** Macroscopically, no swelling of the kidney with normal morphous, and no bleeding point on the renal cortex surface were observed. Microscopically, normal structures of renal glomerulus, renal tubule and renal interstitium without any obvious pathological changes were observed in most of the rats, while unclear boundary of the renal tubular epithelial cells (especially proximal tubule), stenosis and atresia of lumens, congestion of renal glomerulus and interstitial edema were observed in a small number of rats.

**Model group:** Macroscopically, in the 3 h group, no obvious gross changes in the kidney, while in the 6 h and 12 h groups, renal swelling, tension of the kidney envelope, scattered bleeding points on surface of the kidney envelope in some rats and slight hemorrhagic urine within the pelvis in severe cases were observed. Microscopically, in the 3 h group, congestion of glomerular capillary, swelling of the renal tubular epithelial cells, scattered necrosis, unclear cell boundary, stenosis or atresia of lumens, visible protein cast, interstitial edema and inflammatory cell infiltration, while in the 6 h and 12 h groups, obvious congestion of glomerular capillary, swelling of the renal tubular epithelial cells, scattered necrosis, interstitial edema, inflammatory cell infiltration were observed. Moreover, eosinophilic staining floss, red cells and eosinophilic staining homogen cast or red cell cast in the glomerular capsule were observed. There were expansion of renal tubule lumens in medulla, atrophia of endothelial cells and the pathological changes grew worse with time; lamellar necrosis of the renal tubular epithelial cells in a small number of rats.

**Dexamethasone treatment group:** Macroscopically, in the 6 h and 12 h groups, the gross pathological changes of the dexamethasone treatment group were milder than those of the model group. Microscopically, we observed milder congestion of glomerular capillary, swelling of the renal tubular epithelial cells as well as less eosinophilic staining floss and red cells in the renal capsule and less inflammatory cell infiltration than those of the model group; edema of renal interstitium and scattered necrosis

Table 4 The changes of expression level of NF- $\kappa$ B in the liver

Model	1.00 (2.00)	0.00 (1.00)	0.00 (0.00)
Treatment	0.00 (0.00)	0.00 (1.00)	0.00 (1.00)

in a small part of the renal tubular epithelial cells.

#### Macroscopic and microscopic changes of the lung

**Sham operation group:** Macroscopically, normal color and structure of the lung on both sides, no bleeding point on the surface and no effusion in the thoracic cavity were observed. Microscopically, normal function of the most lung tissues, but quite few with slight edema and inflammatory cell infiltration of interstitium were observed.

**Model group:** Macroscopically, in the 3 h group, obvious hyperemia and edema of the pulmonary lobes on both sides, dark red bleeding points on the local pulmonary lobe surface, small amount of amber and dilute effusion in the thoracic cavity, while in the 6 h and 12 h groups, aggravated pathological changes of the lung on both sides with prolonged time after modeling, lump-like pruinous plaque on the lung surface, increased effusion in the thoracic cavity, and some hemorrhagic changes were observed. Microscopically, in the 3 h group, edema of the lung interstitium and alveolar space, widened interstitium of alveolar wall, visible inflammatory cell infiltration, telangiectasis and congestion of alveolar wall and widened alveolar septum, while in the 6 h and 12 h groups, further increased range of pathological changes of pulmonary lobes, obviously increased effusion in alveolar space, edema and bleeding of interstitium and alveolar space, obviously widened alveolar septum, more inflammatory cell infiltration and lucent kytoplasm of local tunica mucosa bronchiorum epithelium were observed.

**Dexamethasone treatment group:** Macroscopically, no obvious bleeding point on the pulmonary lobe surface, sound elasticity of pulmonary lobes, no obvious effusion in the thoracic cavity were observed; the gross lung pathological changes were milder than those of the model group at all time points, indicating obvious therapeutic effects. Microscopically, most lung tissue restored normal

structures, and few with slight edema of interstitium and alveolar space were observed, indicating obvious therapeutic effects.

#### Changes of NF- $\kappa$ B expression levels in the liver of all groups

The positive NF- $\kappa$ B staining was located in the cytoplasm of the liver cells. The NF- $\kappa$ B expressions were all negative in the sham operation group at different time points, partly negative and partly + or ++ at 3 h in the model group. Most expressions of the model group were negative at 6 h and 12 h and a small part + or ++, while the negative rate of the model group at 12 h surpassed that at 6 h. There was no marked difference among all groups at 6 h. There was no marked difference between the model group and treatment group at all time points. However, the model group significantly exceeded the sham operation group at 3 h ( $P < 0.01$ ) and the treatment group significantly exceeded the sham operation group at 12 h ( $P < 0.01$ ) (Tables 4 and 5, Figure 1A and B).

#### Changes of NF- $\kappa$ B expression levels in the kidney of all groups

The positive NF- $\kappa$ B staining was located in the cytoplasm of renal tubular epithelial cells (Table 3). The expressions of the sham operation group were all negative at different time points. Most expressions of the model group were negative at 3 h and 6 h and a small part + or ++. The expressions of the model group were all negative at 12 h. Most expressions of the treatment group were negative at 3 h and a quite small part + or ++. Most expressions of the treatment group were negative at 6 h and a quite small part ++. The expressions of the treatment group were partly negative and partly + or ++ at 12 h. There were no marked differences between the model group and

**Table 6** The changes of expression level of NF- $\kappa$ B in the kidney

treatment group at all time points, moreover, no obvious differences among all groups at 3 h and 6 h. However, the treatment group significantly exceeded the model group ( $P < 0.05$ ) and sham operation group ( $P < 0.01$ ) at 12 h (Tables 6 and 7, Figure 2A, B and C).

### Changes of NF- $\kappa$ B expression levels in the lung of all groups

NF- $\kappa$ B expressions in the lung of all groups were negative (Figure 3).

## DISCUSSION

As one of the common clinical acute abdomen, severe acute pancreatitis (SAP) usually accompanied by the obvious inflammatory reactions besides local pathological injuries can lead to systemic inflammatory response syndrome (SIRS) or even the complication of multiple organ injury, further multiple organ dysfunction syndrome (MODS)<sup>[11]</sup>, resulting in quite high mortality. Although people have conducted enormous studies on AP pathogenesis and brought forward many valuable theories such as the theory of oxygen-free radicals<sup>[12]</sup>, the exact mechanism remains unclear. Studies in recent years have proven that the activation of NF- $\kappa$ B plays an extremely important role in the onset process of SAP<sup>[7,13,14]</sup>.

NF- $\kappa$ B, a protein with multi-attribute transcription-regulating effect, consists of NF- $\kappa$ B/Rel protein family members. NF- $\kappa$ B is usually combined with NF- $\kappa$ B profilin (I $\kappa$ B) to form an inactive trimer that cannot enter the cell nucleus but exists in the cytoplasm<sup>[15,16]</sup>. A series of enzymes can be activated through signal transduction pathway after the stimulation of TNF- $\alpha$ , IL-1, LPS<sup>[17]</sup> to activate NF- $\kappa$ B and next I $\kappa$ B kinase to realize the phosphorylation of I $\kappa$ B. When I $\kappa$ B falls off the NF- $\kappa$ B complex, the activated NF- $\kappa$ B will move into the cell nucleus, bind to the  $\kappa$ B structural domain of the promoter

**Figure 2** NF- $\kappa$ B expressions in the kidney in the sham operation group-12 h, (-)  $\times$  200 (A), model group-6 h, (++)  $\times$  200 (B) and model group-12 h, (++)  $\times$  200 (C).

**Figure 3** NF- $\kappa$ B expressions in the lung in the sham operation group-3 h, (-)  $\times$  200.

or enhancer of target gene and cause the transcription of many factors<sup>[18-20]</sup>, including cytokines, chemotactic factor, macrophage chemotactic peptide, cellular adhesion molecule, growth factor, immune receptor and acute phase reactive protein.

The NF- $\kappa$ B p65 involved in this experiment is one of the important composing members of NF- $\kappa$ B/Rel family with 65 000 of relative molecular weight. Its most common

form in cell is the heterotetic dimer of NF- $\kappa$ B consisting of p65 and p50. When resting, it is combined with its inhibitor I $\kappa$ B to exist in the cytoplasm. When stimulated, the NF- $\kappa$ B will be transferred into nucleus through I $\kappa$ B degradation to combine the  $\kappa$ B sequence of the promoter and enhancer area of the regulated gene, promote the transcription of these genes<sup>[5]</sup> and participate in the tissue injury caused by manifold factors<sup>[21]</sup>. Tietz *et al*<sup>[22]</sup> respectively determined the serum concentration of TNF- $\alpha$  and IL-6 as well as their mRNA expression levels in mice with acute pancreatitis through ELISA and RT-PCR methods, and found that the genetic expression of inflammation promoting cytokines like TNF- $\alpha$  and IL-6 played an extremely important role in the progression of acute pancreatitis.

Dexamethasone, a kind of glucocorticoid, can inhibit the gene synthesis of manifold inflammatory mediators and inhibit inflammatory mediators by increasing the synthesis of anti-inflammatory protein<sup>[8]</sup>. The possible mechanism for dexamethasone inhibition of NF- $\kappa$ B activation could be: (1) As a hormone where the ligand binds to its corresponding receptor and activates it. The activated glucocorticoid receptor directly couples the RelA subunit of NF- $\kappa$ B in the cell nucleus to inhibit the functions of NF- $\kappa$ B. (2) The activated glucocorticoid receptor blocks the nucleus shifting of NF- $\kappa$ B and its combination with DNA by enhancing the genetic transcription of I $\kappa$ B and raising its level.

Acute liver injury is also a common complication of SAP. Studies found that NF- $\kappa$ B plays an important role in the liver injury process of SAP rats<sup>[23,24]</sup>. NF- $\kappa$ B after activation can promote liver injury by promoting the genetic transcription of TNF- $\alpha$  and IL-6<sup>[25]</sup>. NF- $\kappa$ B inhibitor can protect the liver by inhibiting the activation of NF- $\kappa$ B. Some studies believe liver cells are not only target cells of SAP liver injury but also could be the effector cells of inflammatory reactions secreting cytokines. They can act on the liver cells through autocrine or paracrine fashion to aggravate the liver injury<sup>[26]</sup>. In this experiment, we observed the rise of NF- $\kappa$ B p65- positive cell percentage and expression of manifold inflammation-inducing factors which participated in the liver injury complicated with SAP. The positive cell percentage of the dexamethasone treatment group dropped at 3 h and 6 h possibly because dexamethasone had inhibited the activation of NF- $\kappa$ B, reduced the expression of relevant cytokines and thereby alleviated the liver injury. It should be mentioned that the positive cell rate of the treatment group had risen compared with the model group at 12 h, while the statistical results showed no marked difference between the model group and treatment group at all time points. Theoretically, the positive cell rate should decline possibly due to the following factors: (1) With features like time- and energy- saving and high efficiency, the tissue microarray sections of 2.0 mm in diameter may not reflect the whole tissue picture and, to a certain extent, its representation is limited. (2) With different case numbers, the two groups cannot be compared directly. Statistical results showed no marked difference between the model group and treatment group at all time points; (3) There were also possible faults in reagent selection and staining.

Acute kidney injury is also one of the common complications of SAP with few relevant reports currently. In this experiment, the NF- $\kappa$ B expression level of the treatment group significantly exceeded that of the model group at 12 h after dexamethasone treatment, which is contradictory to the theory to certain extent and we can hardly understand. The reason could resemble that of the aforementioned liver. The main reason is still that the representation of tissue microarrays sections of 2.0 mm in diameter is doubtful and could lead to the deviation of the experimental results. We have planned to select three 2.0-mm points for each tissue in subsequent studies to ensure the representation of tissue. In common studies, the determination and analysis of a single index usually could pose many limitations. Therefore, we add the determination of multiple indexes into the experiment including the plasma amylase content, plasma endotoxin content and serum TNF- $\alpha$  content in order to completely evaluate the therapeutic effects and mechanism of dexamethasone.

Acute lung injury is one of the most common severe complications of SAP<sup>[27]</sup>. The mechanism responsible for acute lung injury caused by SAP is quite complicated and remains unclear till now. It is now believed that pancreatin, adhesion molecule, neutrophil, various inflammatory mediators, etc play extremely important roles in the onset process<sup>[28-30]</sup>. It has been shown an increase in expression of manifold inflammation-inducing cytokines in the lung tissue at early injury stage, while the activation of transcription factor NF- $\kappa$ B can stimulate the expression of manifold cytokines. Studies show the selective use of NF- $\kappa$ B inhibitor can markedly lower the injury degree of the pancreas and lung, indicating the important role of NF- $\kappa$ B in SAP complicated with the lung injury<sup>[31-33]</sup>. This experiment has observed the NF- $\kappa$ B p65 expression in the lung tissue but the NF- $\kappa$ B expression levels in the lungs of all groups were negative, indicating that the non-expression of NF- $\kappa$ B p65 in the lung could be related to the reagents. The reagents used in this experiment did not stain in the lung.

In conclusion, NF- $\kappa$ B plays an important role in multiple organ injury. Further studies should be conducted to determine whether dexamethasone could alleviate the pathological changes of multiple organs by reducing the NF- $\kappa$ B expression of the liver and kidney. The advantages of tissue microarrays in pancreatitis pathological examination include saving time and energy, they are highly efficient and representative. The restriction on the representation of tissues to various extents due to small diameter may lead to the deviation of analysis.

Produced mainly by the pancreas, amylase (AMS) has an important effect on digestion of polysaccharide in food and acute pancreatitis is the most common cause of its rise. The rising degree of AMS activity is not certainly related to the injury degree of pancreatic tissue. But the more obviously AMS rises, the more severe the injury becomes. Our study showed that the amylase content of the model group increased with time and the amylase content in plasma dropped after treatment.

Endotoxin is a kind of compound of lipopolysaccharide (LPS) and small protein (Protein) on the cell wall of Gram-

negative bacteria. It is specific not because it is a bacteria or metabolite of bacteria but a substance with endotoxin bioactivity only released after death or disintegration of bacteria. Its chemical composition mainly consists of O-specific chain, core polysaccharide and lipoid A. Endotoxemia results when the endotoxin can be detected in the circulatory blood, which could cause a series of pathophysiological changes including sepsis, shock, and diffuse intravascular coagulation and multiple organ dysfunction syndrome (MODS). The role of endotoxin in onset of acute pancreatitis covers the following aspects: (1) Interfering the normal function of cell membrane by non-specific combination with it; (2) Directly destroying the lysosomal membrane within cells of mononuclear phagocytic system to cause cell damage; (3) Damaging mitochondria structure, affecting the coupling process of ATP enzyme and oxidative phosphorylation and causing disturbance in energy metabolism; (4) Changing the immune function of body; (5) Causing a series of pathological or pathophysiological changes of body, affecting the vasomotor function, activating vasoactive substance, reducing platelet and leukocyte, lowering blood pressure or even causing DIC, MOSF, etc.

Mainly generated from the activated mononuclear macrophage, TNF- $\alpha$  is a kind of polypeptide cytokine with extensive biologic activities. The secretion of appropriate amounts of TNF- $\alpha$  had protecting effects and can promote the chemotaxis and antimicrobial effects of PMN, macrophage and eosinophile granulocyte and is one of the defense mechanisms of the body. The excessive secretion of TNF- $\alpha$  could cause inflammatory reactions. High concentration of TNF- $\alpha$  entering the blood flow could also cause fever, drop of blood pressure and reduction of tissue perfusion through lowering myocardial contraction force and tension of vascular smooth muscle as well as metabolic disorder, organ injury and even multi-system damage. It has potentially lethal effects.

Our experiment found no marked difference in the plasma amylase content at 3 h and 6 h between the treatment group and model group, while the plasma amylase content of the treatment group was significantly lower than that of the model group at 12 h ( $P < 0.01$ ). The plasma endotoxin content of the treatment group was significantly lower than that of the model group at 6 h and 12 h ( $P < 0.01$ ). The serum TNF- $\alpha$  level of the treatment group was significantly lower than that of the model group at 6 h and 12 h ( $P < 0.05$ ). Thus, it is concluded that dexamethasone can lower the plasma amylase, plasma endotoxin and serum TNF- $\alpha$  content of rats with SAP as well as their mortality.

The tissue microarrays (TMA) technology adopted by us in this study is exactly the new biochip technology currently extensively applied to basic and clinical applications as well as in other fields. The tissue microarray technology has exceeded the traditional histopathological section technology which is single in sample and low in efficiency<sup>[34]</sup>. The advantages of TMA are high-throughput, economic, time-saving, reliable result, convenient for experimental control, etc. Since the most distinguished feature of tissue microarrays is to combine the study of gene and its expression products with histomorphology, it possesses great potential in oncopathology studies<sup>[35,36]</sup>,

and current studies also mainly focus on this area<sup>[37-44]</sup>. The chip preparation, staining, examination, etc have restrained the application of this technology in non-tumor diseases. To the best of our knowledge, there was no study report in literature on applying tissue microarrays to pancreatitis pathological examination before our experiment was conducted. Thus this article has taken the lead.

We used the tissue microarray section maker (Beecher Instruments, USA) to drill a hole of 2.0 mm in diameter on recipient block and combined the immunohistochemical method to examine the NF- $\kappa$ B expression levels of the multiple organs. The experimental results are unsatisfactory mainly because the tissue representation has been restricted to different extents due to the small diameter. However, there are advantages of tissue microarrays shown in its application in the pathological examination of pancreatitis, including time- and energy-saving and high efficiency.

### Abstract

**AIM:** To investigate the suppressive effect of saikosaponin-d (SSd) on hepatic fibrosis in rats induced by CCl<sub>4</sub> injections in combination with alcohol and high fat, low protein feeding and its relationship with the expression of nuclear factor- $\kappa$ B (NF- $\kappa$ B), tumor necrosis factor-alpha (TNF- $\alpha$ ) and interleukins-6 (IL-6).

**METHODS:** Hepatic fibrosis models were induced by subcutaneous injection of CCl<sub>4</sub> at a dosage of 3 mL/kg in rats. At the same time, rats in treatment groups were injected intraperitoneally with SSd at different doses (1.0, 1.5 and 2.0 mg/kg) once daily for 6 wk in combination with CCl<sub>4</sub>, while the control group received olive oil instead of CCl<sub>4</sub>. At the end of the experiment, rats were anesthetized and killed (except for 8 rats which died during the experiment; 2 from the model group, 3 in high-dose group, 1 in medium-dose group and 2 in low-dose group). Hematoxylin and eosin (HE) staining and Van Gieson staining were used to examine the changes in liver pathology. The levels of alanine aminotransferase (ALT), triglyceride (TG), albumin (ALB), globulin (GLB), hyaluronic acid (HA) and laminin (LN) in serum and the content of hydroxyproline (HYP) in liver were measured by biochemical examinations and radioimmunoassay, respectively. In addition, the expression of TNF- $\alpha$  and IL-6 in liver homogenate was evaluated by enzyme-linked immunosorbent assay (ELISA) and the levels of NF- $\kappa$ Bp65 and I- $\kappa$ B $\alpha$  in liver tissue were analyzed by Western blotting.

**RESULTS:** Both histological examination and Van Gieson staining demonstrated that SSd could attenuate the area and extent of necrosis and reduce the scores of liver fibrosis. Similarly, the levels of ALT, TG, GLB, HA, and

LN in serum, and the contents of HYP, TNF- $\alpha$  and IL-6 in liver were all significantly increased in model group in comparison with those in control group. Whereas, the treatment with SSd markedly reduced all the above parameters compared with the model group, especially in the medium group (ALT:  $412 \pm 94.5$  IU/L vs  $113.76 \pm 14.91$  IU/L, TG:  $0.95 \pm 0.16$  mmol/L vs  $0.51 \pm 0.06$  mmol/L, GLB:  $35.62 \pm 3.28$  g/L vs  $24.82 \pm 2.73$  g/L, HA:  $42.15 \pm 8.25$  ng/mL vs  $19.83 \pm 3.12$  ng/mL, LN:  $27.56 \pm 4.21$  ng/mL vs  $13.78 \pm 2.57$  ng/mL, HYP:  $27.32 \pm 4.32$   $\mu$ g/mg vs  $16.20 \pm 3.12$   $\mu$ g/mg, TNF- $\alpha$ :  $4.38 \pm 0.76$  ng/L vs  $1.94 \pm 0.27$  ng/L, IL-6:  $28.24 \pm 6.37$  pg/g vs  $12.72 \pm 5.26$  pg/g, respectively,  $P < 0.01$ ). SSd also decreased ALB in serum ( $28.49 \pm 4.93$  g/L vs  $37.51 \pm 3.17$  g/L,  $P < 0.05$ ). Moreover, the expression of NF- $\kappa$ B p65 in the liver of treated groups was lower than that in model groups while the expression of I- $\kappa$ B $\alpha$  was higher in treated group than in model group ( $P < 0.01$ ). The expression of NF- $\kappa$ Bp65 and TNF- $\alpha$  had a positive correlation with the level of HA in serum of rats after treatment with CCl<sub>4</sub> ( $r = 0.862$ ,  $P < 0.01$ ;  $r = 0.928$ ,  $P < 0.01$ , respectively).

**CONCLUSION:** SSd attenuates CCl<sub>4</sub>-induced hepatic fibrosis in rats, which may be related to its effects of hepato-protective and anti-inflammation properties, the down-regulation of liver TNF- $\alpha$ , IL-6 and NF- $\kappa$ Bp65 expression and the increased I- $\kappa$ B $\alpha$  activity in liver.

### INTRODUCTION

Hepatic fibrosis represents the wound healing response of the liver to repeated liver injuries, and is associated with increased inflammatory cell infiltration and may involve the interplay of different inflammatory mediators, which is a common stage in most chronic liver diseases<sup>[1-5]</sup>. If treated properly in this stage, hepatic fibrosis can be

reversed and its progression to irreversible cirrhosis often leading to lethal complications and high mortality may be prevented<sup>[6-9]</sup>. Nuclear factor- $\kappa$ B (NF- $\kappa$ B) as a critical component in inflammatory conditions can produce proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6), which are involved in the process of fibrogenesis<sup>[10-13]</sup>. Therefore, suppressing the inflammatory response and reducing the release of proinflammatory cytokines such as NF- $\kappa$ B, TNF- $\alpha$  and IL-6, may prevent and reverse hepatic fibrosis. Saikosaponin-d (SSd) is a major active component extracted from the root of *Bupleurum falcatum*. It has been demonstrated that SSd has a wide variety of pharmacological activities, such as liver-protective activity, and anti-hepatic fibrosis or anti-microbial or anti-tumor and anti-inflammatory activities<sup>[14-17]</sup>. However, its molecular mechanism involved in therapeutic effects of SSd on hepatic fibrosis has not been completely elucidated. Our present study was designed to further evaluate the effect of SSd on hepatic fibrosis in rats induced by CCl<sub>4</sub> and its relationship with the expression of NF- $\kappa$ B, TNF- $\alpha$  and IL-6.

## MATERIALS AND METHODS

### Reagents

SSd was purchased from Jiangxi Herbfine Hi-tech Co. Ltd. CCl<sub>4</sub> (Xi'an Chemical Factory) was diluted into 400 g/L in olive oil before it was used. Enzyme-linked immunosorbent assay (ELISA) kit for mouse TNF- $\alpha$  and IL-6 was purchased from R&D Systems Co. Ltd (USA). Hydroxyproline (HYP) assay kit was a product of Nanjing Jiancheng Bioengineering Institute. Kits for HA and LN were bought from Senxiong Company, Shanghai, China. Polyclonal rabbit anti-rat P65 and I- $\kappa$ B $\alpha$  were purchased from Santa Cruz Biotechnology (USA). HRP-labeled goat-anti-rabbit IgG was obtained from HuaMei Company, Shanghai, China.

### Animals

Seventy-five adult male SD rats weighing 160-200 g were provided by the Laboratory Animal Center of Medical College, Xi'an Jiaotong University. The rats were randomly divided into 5 groups ( $n = 15$ ): control group, model group, and three treatment groups. Except for the control rats, all rats were subcutaneously injected with 400 g/L CCl<sub>4</sub> (CCl<sub>4</sub>: olive oil = 2:3), 3 mL/kg, b.w, at every 3 d for 6 wk, and fed with high fat, low protein diet (75% pure maize plus 20% lard and 0.5% cholesterol) and 300 mL/L alcohol in the drinking water. In the 3 treatment groups, SSd was administered daily, *via* intraperitoneal injection at a dosage of 2.0, 1.5 and 1.0 mg/kg for 6 wk, respectively. After 6 wk, all rats were anesthetized with 200 g/L urethane (5 mL/kg, abdominal injection). Blood was taken from the abdominal aorta. Serum was separated by centrifugation at 4°C and kept at -20°C for assay. Liver tissue was homogenized in cold saline for pathological diagnosis.

### Light microscopic examination

Liver tissue was fixed in a 40 g/L solution of formaldehyde

in 0.1 mol/L phosphate-buffered saline (pH 7.4), and embedded in paraffin. Five-micrometer thick sections were prepared. All the sections stained with HE and standard Van Gieson (VG) were coded and scored by blind reading. Van Gieson's method was used to detect collagen fibers<sup>[18]</sup>. Liver condition was classified according to the standard formulated by China Medical Association in 1995<sup>[19]</sup>, and fibrosis was graded from 0 to 4 (0: no fibrosis; 1: portal area fibrosis; 2: fibrotic septa between portal tracts; 3: fibrosis septa and structure disturbance of hepatic lobule and 4: cirrhosis).

### Biochemical determination

Serum levels of alanine transaminase (ALT), albumin (ALB), triglyceride (TG) and globulin (GLB) were measured by routine laboratory methods using a 7170-automatic biochemistry analyzer (Tokyo, Japan). Serum hyaluronic acid (HA) and laminin (LN) were detected by radioimmunoassay, and the content of hydroxyproline (HYP) in liver was determined according to the method described by Jamall *et al*<sup>[20]</sup>. The contents of TNF- $\alpha$  and IL-6 protein in liver homogenate were determined by ELISA according to the corresponding protocols of the kits.

### Western blotting detection

Nuclear and cytosolic protein extracts were prepared according to manufacturer's instructions provided with the kits (Active Motif Corp, USA). Nuclear or cytosolic proteins (100  $\mu$ g each) were run on a 10% SDS-PAGE gel and transferred electrophoretically onto a nitro-cellulose membrane respectively (Shanghai Huashun Corp, China). The membrane was blocked overnight with 10% nonfat milk prior to incubation with polyclonal rabbit anti-rat I- $\kappa$ B $\alpha$  antibody (1:800) or anti-NF- $\kappa$ Bp65 antibody (1:1000) at room temperature for 2 h. After washed with PBS, the blots were incubated with HRP-labeled goat-anti-rabbit serum for 1 h and colored on X-ray film by ECL.

### Statistical analysis

Quantitative data were analyzed using ANOVA by SPSS 13.0 statistic package and RIDIT test was used for statistical analysis of the qualitative data. All data were expressed as mean  $\pm$  SD. The correlation was analyzed by Spearman's correlation analysis. All *P* values were two-tailed. *P* < 0.05 was considered statistically significant.

## RESULTS

### Pathological assay

At the end of the experiment, liver tissue samples from control rats showed normal lobular architecture with central veins and radiating hepatic cords (Figure 1A). Liver tissue samples from model group showed that more fibrous tissues were formed extending into the hepatic lobules to separate them completely. A large number of inflammatory cells infiltrated in the intralobular and interlobular regions. The liver structure was disordered and there were more necrotic and fatty degenerated liver cells compared with the controls (Figures 1B and 1D). In the 3 treatment groups, however, hepatocyte degeneration,

**Figure 1** Light microscopy showing normal liver tissue in control group (A) (HE × 100), degenerated and necrotic liver cells associated with inflammatory cells in model group (B) (HE × 40), attenuated necrosis and infiltration of inflammatory cells after SSd treatment (C) (HE × 40), collagen fibers deposited in spaces of Disse and formation of pseudoculi in model group (D) (Van Gieson × 40), and liver fibrosis tissue in SSd group (E). The pathological change of liver was much milder in SSd group than in model group (Van Gieson × 40).

necrosis and infiltration of inflammatory cells were all apparently ameliorated and collagen deposition was also markedly reduced (Figures 1C and 1E). Compared with model group, the liver condition of rats in SSd treatment groups was significantly improved (Table 1).

#### Detection of serum HA, LN and liver function

As is shown in Figure 2A, HA and LN levels in serum were significantly higher in model group than in the controls, but they were markedly decreased in 3 treatment groups compared with the model group. Compared with the controls, the serum ALT, TG and GLB levels in model group were all significantly increased while the level of ALB was decreased ( $P < 0.001$ ,  $P < 0.05$ ), respectively. However, the levels of ALT, TG and GLB were all in the 3 treatment groups, especially in the group receiving the middle dose of SSd, and the level of ALB was increased compared with the model group ( $P < 0.05$ ) (Table 2).

#### TNF- $\alpha$ , IL-6 and HYP contents in liver tissue

The contents of TNF- $\alpha$ , IL-6 and HYP were all significantly lower in SSd treatment groups than in the model group (Figures 2B and 2C). Furthermore, among the 3 treatment groups the high-dose group showed the best effect. The liver HYP level in three SSd treatment groups and TNF- $\alpha$ , IL-6 content in high-dose group were higher than those in the controls, with no significant difference between them ( $P > 0.05$ ). However, there was a significant difference in the contents of TNF- $\alpha$ , IL-6 between low- and medium-SSd treatment groups and control group ( $P < 0.05$ ).

#### Western blot analysis

NF- $\kappa$ Bp65 expression was increased significantly in model group compared with the control group, whereas it was

**Table 1** Pathological observation of liver condition

Group	n	Liver condition					U
		0	I	II	III	IV	
Model	13	0	0	0	4	9	
High-dose	12	0	5	3	2	2	3.26 <sup>a</sup>
Medium-dose	14	0	6	4	3	1	4.17 <sup>b</sup>
Low-dose	13	0	3	2	6	2	2.96 <sup>a</sup>

U represents the RIDIT value of the two groups,  $P < 0.05$  indicates  $U > 1.96$ ,  $P < 0.01$  indicates  $U > 2.58$ . <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs model group.

markedly decreased in all SSd treatment groups ( $P < 0.01$ ), especial in the high-dose group. There was no significant difference in the expression of NF- $\kappa$ Bp65 between SSd treatment groups and control group ( $P > 0.05$ ) (Figure 2D). On the contrary, its inhibitory I $\kappa$ B $\alpha$  was significantly decreased in model group while increased in SSd treatment group compared with the model group ( $P < 0.01$ ) (Figures 3A and 3B). Therefore, SSd could significantly inhibit the activation of NF- $\kappa$ B, which might be associated with increased I- $\kappa$ B $\alpha$  degradation.

#### Correlation analysis

Correlation analysis revealed that NF- $\kappa$ Bp65 had a highly positive correlation with the expression of TNF- $\alpha$  protein ( $r = 0.823$ ,  $P < 0.01$ ). Both NF- $\kappa$ Bp65 and TNF- $\alpha$  had a strong positive correlation with the levels of HA in serum of rats induced by CCl<sub>4</sub> ( $r = 0.862$ ,  $P < 0.01$ ;  $r = 0.928$ ,  $P < 0.01$ , respectively).

## DISCUSSION

Hepatic fibrosis is a chronic inflammation-associated

ALT: Alanine aminotransferase; ALB: Albumin; GLB: Globulin; TG: Triglyceride; HYP: Hydroxyproline. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs control group; <sup>c</sup>*P* < 0.05, <sup>d</sup>*P* < 0.01 vs model group.

**Figure 2** Analysis of serum LN and HA levels (A), expressions of TNF- $\alpha$  (B), IL-6 (C), and NF- $\kappa$ Bp65 and I- $\kappa$ B $\alpha$  (D) in liver tissue after treatment with SSd. <sup>b</sup>*P* < 0.01 vs control group; <sup>d</sup>*P* < 0.01 vs model group.

disease, which is involved in the infiltration of inflammatory cells and releasing of proinflammatory cytokines, such as TNF- $\alpha$  and IL-6. As a result, hepatic stellate cells (HSCs) are transformed into myofibroblast cells to synthesize more collagen and proteoglycans, increasing deposition and altered composition of extracellular matrix (ECM) in liver<sup>[21-24]</sup>. Based on the current knowledge, a “three-step cascade theory of inflammation involving in liver fibrogenesis” including preinflammatory phases 1-3, has been proposed by Gressner<sup>[25]</sup>, which implies that multiple inflammatory cell interactions with Kupffer cells, platelets, endothelial cells and hepatocytes mediated by various cytokines and growth factors (TNF- $\alpha$ , IL-6 and TGF- $\beta$ ) are involved in the mechanism of fibrogenesis. Therefore, suppressing the inflammatory response can prevent and reverse hepatic fibrosis. Our

study showed that, 6 wk treatment with SSd, especially at the middle dose used, could decrease serum levels of ALT, TG, GLB and ALB in rats with hepatic injury caused by CCl<sub>4</sub>. Histological examination also demonstrated that a large number of inflammatory cells infiltrated the intralobular and interlobular regions, more fibrous tissue was formed and the margin of liver was uneven in model group compared with the control group. In contrast, SSd especially its medium-dose could obviously attenuate the extent of necrosis and reduce the immigration of inflammatory cells compared with the model group, and no pseudocyst could be observed. Moreover, SSd could decrease the scores of hepatic fibrosis grading (Table 1), indicating that SSd can significantly protect liver against fibrosis, which may be related to its inhibitory effects on inflammation. These findings are consistent with

previously reported results<sup>[26]</sup>. It has been demonstrated that SSd has marked inhibitory actions on the processes of inflammation, including capillary permeability, releasing of inflammation mediators, leukoplasia and desmoplasia<sup>[15,27,28]</sup>. In addition, SSd can increase serum concentrations of adrenocorticotrophic hormone and corticosterone<sup>[29]</sup> as well as corticotropin-releasing factor (mRNA) level in the hypothalamus<sup>[16]</sup>.

HA and LN levels in serum and HYP in liver are the important indices reflecting the degree of hepatic fibrosis<sup>[30-32]</sup>. In this study, the contents of HA and LN in serum and HYP in liver were much higher than those in the controls, but markedly lower in treatment groups ( $P < 0.01$ ), indicating that SSd can prevent hepatic fibrosis due to chronic liver injury, thus delaying the development of cirrhosis.

Recent studies have identified NF- $\kappa$ B as a critical component to bridge inflammation by producing proinflammatory cytokines (such as TNF- $\alpha$  and IL-6) and more ECM in liver, thus further boosting inflammatory processes and activating HSCs<sup>[21-23,33-36]</sup>. It was also reported that TNF- $\alpha$  released from activating macrophages can turn up NF- $\kappa$ B activity both in target tissue cells and in macrophages themselves<sup>[37-40]</sup>.

NF- $\kappa$ B is a transcription factor consisting of p65 and p50 subunits of the Rel protein family<sup>[41]</sup>. In most cells, it binds to its inhibitory counterpart I- $\kappa$ B $\alpha$  and other I $\kappa$ B proteins to form P65-P50-I $\kappa$ B trimer which is located in the cytoplasm as an inactive complex. Following I- $\kappa$ B $\alpha$  degradation by a complex signaling cascade initiated on the cell surface, the activated NF- $\kappa$ Bp65 disassociates from I- $\kappa$ B $\alpha$  and shifts into nuclei where it binds to specific DNA motifs to regulate transcriptional activity of its target genes involved in HSC activation<sup>[42]</sup>, releasing of proinflammatory cytokines including IL-6 and TNF- $\alpha$ . Thus, inhabiting I $\kappa$ B $\alpha$  phosphorylation is an indispensable step to activate the NF- $\kappa$ B signaling pathway<sup>[43-46]</sup>. In the present study, NF- $\kappa$ Bp65 expression increased significantly in model group compared with normal control group, whereas it was markedly decreased in all SSd treatment groups, especial in the high-dose group. There was no difference in the expression of NF- $\kappa$ Bp65 between SSd treatment groups and control group. On the contrary, its inhibitory I- $\kappa$ B $\alpha$  was significantly lower in model group but higher in SSd treatment group, suggesting that SSd can significantly inhibit the activation of NF- $\kappa$ Bp65, which may be associated with a reduction in I- $\kappa$ B $\alpha$  degradation.

In addition, Spearman's correlation analysis showed that NF- $\kappa$ Bp65 was highly correlated with the expression of TNF- $\alpha$  protein ( $r = 0.823$ ,  $P < 0.01$ ) and both of them had a strong positive correlation with the serum levels of HA induced by CCl<sub>4</sub> ( $r = 0.862$ ,  $P < 0.01$ ;  $r = 0.928$ ,  $P < 0.01$ , respectively).

In conclusion, SSd has beneficial effects on hepatic fibrosis. Down-regulation of TNF- $\alpha$ , IL-6 and NF- $\kappa$ Bp65 expression and increased I- $\kappa$ B $\alpha$  activity of SSd in rat liver may play an important role in the improvement of hepatic fibrosis induced by CCl<sub>4</sub>. Since hepatic fibrogenesis is a very complicated process, the underlying mechanisms of SSd remain to be further explored.

**Figure 3** Images of Western blotting of NF- $\kappa$ Bp65 (A) and I- $\kappa$ B $\alpha$  (B) in liver tissue of rats. Lane 1: NF- $\kappa$ Bp65 and I- $\kappa$ B $\alpha$  protein in control group; lane 2: NF- $\kappa$ Bp65 and I- $\kappa$ B $\alpha$  in model group; lanes 3-5: NF- $\kappa$ Bp65 and I- $\kappa$ B $\alpha$  in SSd group (from low to high-dose group).

## COMMENTS

### Background

Hepatic fibrosis is a chronic inflammation-associated disease, which is involved in the infiltration of inflammatory cells and releasing of proinflammatory cytokines, such as NF- $\kappa$ B, TNF- $\alpha$  and IL-6. Recently, more and more clinical and experimental observations have demonstrated that SSd, a traditional Chinese medicine, is of some preventive and therapeutic values against liver fibrosis, whereas, the molecular mechanism involved in therapeutic effects of SSd on hepatic fibrosis has not been completely elucidated. Therefore, the aim of our study was to further evaluate the anti-hepatic fibrosis effect of SSd in rats and to study its relationship with the expression of NF- $\kappa$ Bp65, TNF- $\alpha$  and IL-6.

### Research frontiers

NF- $\kappa$ B as a critical component to bridge inflammation, can produce proinflammatory cytokines such as TNF- $\alpha$  and IL-6, which are involved in the process of fibrogenesis. Our study aimed at investigating the suppressive effect of SSd on hepatic fibrosis in rats induced by CCl<sub>4</sub> from the level of cytokine and its relationship with the expression of NF- $\kappa$ Bp65, TNF- $\alpha$  and IL-6.

### Innovations and breakthroughs

SSd has beneficial effects on hepatic fibrosis, and the down-regulation of TNF- $\alpha$ , IL-6 and NF- $\kappa$ Bp65 expression and increased I- $\kappa$ B $\alpha$  activity of SSd in rat liver may play an important role in the improvement of hepatic fibrosis induced by CCl<sub>4</sub>.

### Applications

SSd may play a role in antifibrotic therapy. It protects liver cells against fibrosis and inhibits collagen fiber deposition in liver, and therefore can be used in the treatment of cirrhosis in clinic practice.

### Terminology

Nuclear factor- $\kappa$ B (NF- $\kappa$ B) is a transcription factor consisting of p65 and p50 subunits of the Rel protein family. In most cells, it binds to its inhibitory counterpart I- $\kappa$ B $\alpha$  and other I- $\kappa$ B proteins to form P65-P50-I $\kappa$ B trimer that is located in the cytoplasm as an inactive complex. Following I- $\kappa$ B $\alpha$  degradation by a complex signaling cascade initiated at the cell surface, the activated NF- $\kappa$ Bp65 disassociates from I- $\kappa$ B $\alpha$  and shifts into nuclei where it binds to specific DNA motifs to regulate transcriptional activity of its target genes involved in HSC activation, releasing of proinflammatory cytokines.

### Peer review

In this study, rats with liver fibrosis were treated with CCl<sub>4</sub> in combination with ethanol, high fat and low protein diet. Rats receiving SSd in combination with CCl<sub>4</sub> injection developed less liver fibrosis. The effect was associated with less liver damage indicated by lower transaminase and higher albumin levels. Additionally, less activation of NF- $\kappa$ B was observed in the liver of treated rats, suggesting that SSd could attenuate CCl<sub>4</sub>-induced liver fibrosis by down-regulating the inflammatory response in the liver. The study addresses an interesting issue, but the value of this study in its current form is limited. The data provided are preliminary but do not sufficiently support the conclusions drawn by the authors.

### Abstract

**AIM:** To investigate the protective effects and possible mechanisms of *Veratrum nigrum* L. var. *ussuriense* Nakai alkaloids (VnA) on hepatic ischemia/reperfusion (I/R) injury in rats.

**METHODS:** Forty male Wistar rats were randomly divided into four experimental groups ( $n = 10$  in each): (A) Control group (the sham operation group); (B) I/R group (pretreated with normal saline); (C) Small-dose ( $10 \mu\text{g/kg}$ ) VnA pretreatment group; (D) Large-dose ( $20 \mu\text{g/kg}$ ) VnA pretreatment group. Hepatic ischemia/reperfusion (Hepatic I/R) was induced by occlusion of the portal vein and the hepatic artery for 90 min, followed by reperfusion for 240 min. The pretreatment groups were administered with VnA intraperitoneally, 30 min before surgery, while the control group and I/R group were given equal volumes of normal saline. Superoxide dismutase (SOD) activity, myeloperoxidase (MPO) activity and nitric oxide (NO) content in the liver tissue at the end of reperfusion were determined and liver function was measured. The expression of intercellular adhesion molecule-1 (ICAM-1) and E-selectin (ES) were detected by immunohistochemical examinations and Western blot analyses.

**RESULTS:** The results showed that hepatic I/R elicited a significant increase in the plasma levels of alanine aminotransferase (ALT:  $74.53 \pm 2.58 \text{ IU/L}$  vs  $1512.54 \pm 200.76 \text{ IU/L}$ ,  $P < 0.01$ ) and lactic dehydrogenase (LDH:  $473.48 \pm 52.17 \text{ IU/L}$  vs  $5821.53 \pm 163.69 \text{ IU/L}$ ,  $P < 0.01$ ), as well as the levels of MPO ( $1.97 \pm 0.11$

$\text{U/g}$  vs  $2.57 \pm 0.13 \text{ U/g}$ ,  $P < 0.01$ ) and NO ( $69.37 \pm 1.52 \mu\text{mol/g protein}$  vs  $78.39 \pm 2.28 \mu\text{mol/g protein}$ ,  $P < 0.01$ ) in the liver tissue, all of which were reduced by pretreatment with VnA, respectively (ALT:  $1512.54 \pm 200.76 \text{ IU/L}$  vs  $977.93 \pm 89.62 \text{ IU/L}$ ,  $909.81 \pm 132.76 \text{ IU/L}$ ,  $P < 0.01$ ,  $P < 0.01$ ; LDH:  $5821.53 \pm 163.69 \text{ IU/L}$  vs  $3015.44 \pm 253.01 \text{ IU/L}$ ,  $2448.75 \pm 169.4 \text{ IU/L}$ ,  $P < 0.01$ ,  $P < 0.01$ ; MPO:  $2.57 \pm 0.13 \text{ U/g}$  vs  $2.13 \pm 0.13 \text{ U/g}$ ,  $2.07 \pm 0.05 \text{ U/g}$ ,  $P < 0.01$ ,  $P < 0.01$ ; NO:  $78.39 \pm 2.28 \mu\text{mol/g protein}$  vs  $71.11 \pm 1.73 \mu\text{mol/g protein}$ ,  $68.58 \pm 1.95 \mu\text{mol/g protein}$ ,  $P < 0.05$ ,  $P < 0.01$ ). The activity of SOD ( $361.75 \pm 16.22 \text{ U/mg protein}$  vs  $263.19 \pm 12.10 \text{ U/mg protein}$ ,  $P < 0.01$ ) in the liver tissue was decreased after I/R, which was enhanced by VnA pretreatment ( $263.19 \pm 12.10 \text{ U/mg protein}$  vs  $299.40 \pm 10.80 \text{ U/mg protein}$ ,  $302.09 \pm 14.80 \text{ U/mg protein}$ ,  $P < 0.05$ ,  $P < 0.05$ ). Simultaneously, the histological evidence of liver hemorrhage, polymorphonuclear neutrophil infiltration and the overexpression of ICAM-1 and E-selectin in the liver tissue were observed, all of which were attenuated in the VnA pretreated groups.

**CONCLUSION:** The results demonstrate that VnA pretreatment exerts significant protection against hepatic I/R injury in rats. The protective effects are possibly associated with enhancement of antioxidant capacity, reduction of inflammatory responses and suppressed expression of ICAM-1 and E-selectin.

### INTRODUCTION

Re-establishment of blood flow to the ischemic tissue is the therapeutic goal in the treatment of arterial occlusion.

However, surgically restoring the blood flow often leads to continued or accelerated local tissue injury and systemic toxicity<sup>[1]</sup>. Hepatic ischemia/reperfusion (Hepatic I/R) injury is an important non-immunologic problem and a limiting factor in liver transplantation and it may result in liver dysfunction, liver failure, and even death<sup>[2]</sup>. Hepatic I/R injury is one of the major complications of hepatic resection, hemorrhagic shock with fluid resuscitation, and liver transplantation, particularly with grafts from marginal donors<sup>[3]</sup>. The mechanisms underlying ischemia/reperfusion induced organ damage are likely multifactorial and interdependent. Previous studies have identified many mediators involved in the pathogenesis of hepatic I/R injury. Among them, reactive oxygen species (ROS)<sup>[4]</sup> released by active Kupffer cells, and proinflammatory cytokines<sup>[5-7]</sup> are central to this process. Expression of the adhesion molecules is up-regulated by cytokines and mediates the recruitment of neutrophils to the liver resulting in hepatic injury<sup>[8-9]</sup>. In addition, selectins are also up-regulated during this process<sup>[10]</sup>.

It has been shown that short episodes of liver ischemia confer protection against longer ischemic insults and subsequent I/R injury. This phenomenon is called ischemic or mechanical preconditioning<sup>[11-12]</sup>. Pharmacological preconditioning can be an effective alternative to ischemic preconditioning. With pharmacological preconditioning, liver protection is achieved by the administration of substances before or at the early phase of the I/R process.

*Veratrum nigrum* L. var. *ussuriense* Nakai alkaloids (VnA) is the total alkaloid extracted from the root of *Veratrum nigrum* L. var. *ussuriense* Nakai of Mount Qian in Liaoning Province, China. VnA contains at least eleven alkaloids featuring an ester-type isosteroidal structure identified by modern analytical techniques such as HPLC-MS, NMR, *etc.* The principal components of VnA include verussurien, verbenzoamine, verazine, germidine, jervine, germerine, 15-O-(methylbuty-royl)-germine, verussurinine, neogermbudine, zygadenine and echinuline<sup>[13-15]</sup>. Some researchers have demonstrated that VnA has powerful inhibitory effects against both arterial and venous thrombosis, and it could produce beneficial effects on brain I/R injury<sup>[16-18]</sup>. In this study, we investigated whether VnA had a protective effect against liver injury induced by hepatic I/R and explored its putative protective mechanism.

## MATERIALS AND METHODS

### Reagents

The VnA hydrochloride injection (100 mg/L) was prepared by the Department of Pharmaceutical Engineering, Dalian University of Science and Technology. It was diluted to the required concentrations with sterile saline solution prior to use.

### Animals

Male Wistar rats (Experimental Animal Center of Dalian Medical University, Dalian, China) weighing  $220 \pm 20$  g were used in this study. All rats were fed with standard laboratory chow and water, and housed in accordance with institutional animal care guidelines.

### Experimental design

Male Wistar rats were fasted overnight but had free access to tap water. The rats were assigned randomly into four experimental groups ( $n = 10$  in each): (A) Control group (the sham operation group); (B) I/R group (pretreated with normal saline); (C) Small-dose (10  $\mu\text{g/kg}$ ) VnA pretreatment group; (D) Large-dose (20  $\mu\text{g/kg}$ ) VnA pretreatment group. The model of hepatic I/R injury was established by the clamping and unclamping of the vessels supplying the left lateral and median hepatic lobes, which account for 70% of the rat liver mass, according to the published method<sup>[12]</sup>. We reproduced a lobar rather than a total hepatic I/R injury model to induce a severe hepatic ischemic insult without mesenteric venous congestion to avoid the development of intestinal congestion and leakage of bacteria or bacterial products into the circulation<sup>[6,19]</sup>. Briefly, 30 min before operation, the rats received intraperitoneally VnA (10  $\mu\text{g/kg}$ , 20  $\mu\text{g/kg}$ ) or equal volumes of normal saline solution. A midline laparotomy was performed and a microvascular clip was placed to interrupt the arterial and portal venous blood flow to the left and middle lobes of the liver. Reflow was initiated after 90 min of hepatic ischemia by removing the clamp. The doses of VnA administration were determined according to previous studies, combined with our preliminary experiments<sup>[17-18]</sup>. All rats were killed at 240 min of reperfusion, and blood and liver samples were obtained for the following analyses.

### Histopathological assessment

Liver samples were fixed in 10% formalin and embedded in paraffin. Five-micrometer sections of liver tissue were stained with hematoxylin and eosin according to standard procedures. Light microscopy was used to assess the degree of liver damage.

### Measurement of plasma alanine aminotransferase (ALT) and lactic dehydrogenase (LDH) level

The abdominal aorta was punctured and 5 mL of blood was taken and put into heparinized tubes. The blood sample was centrifuged at 3000 r/min for 15 min at a room temperature to separate plasma for analyses. The plasma concentrations of ALT (a specific marker for hepatic parenchymal injury), and LDH were measured with an OLYMPUS AU5400 automatic analyzer. Both values were expressed as U/L.

### Liver superoxide dismutase (SOD), myeloperoxidase (MPO) and nitric oxide (NO) assay

Liver samples were homogenized on ice in 5 volumes of normal saline and centrifuged at 3000 r/min for 15 min. Liver SOD, MPO and NO levels were measured using an assay kit (Nanjing Jiancheng Bioengineering Institute, Nanjing, China) following the manufacturer's instructions. The levels of SOD, MPO and NO were expressed as U/mgprot, U/g and  $\mu\text{mol/gprot}$ , respectively.

### Immunohistochemical analyses

Formalin-fixed, paraffin-embedded liver specimens were stained by streptavidin/peroxidase immunohistochemistry

**Figure 1** Changes of histology in the liver tissue 90 min after ischemia and 240 min after reperfusion in rats ( $\times 400$ ). Five  $\mu\text{m}$  sections of liver tissue were stained with hematoxylin and eosin according to standard procedures. For all groups,  $n = 10$ . **A:** Control group: Normal appearance of hepatocytes and sinusoids; **B:** I/R group: Histological edema, hemorrhage, partial exfoliation of blood vessel endothelium and infiltration with inflammatory cells; **C:** I/R + VnA (10  $\mu\text{g/kg}$ ) group: A significant amelioration of histological edema, hemorrhage, and exfoliation of blood vessel endothelium; **D:** I/R + VnA (20  $\mu\text{g/kg}$ ) group: Slight inflammatory cell infiltration with most hepatocytes in normal appearance.

technique for intercellular adhesion molecule-1 (ICAM-1) and E-selectin (ES) detection. Five-micrometer sections were treated with 0.3%  $\text{H}_2\text{O}_2$  in methanol to block endogenous peroxidase activity and then incubated with the polyclonal rabbit anti-rat ICAM-1 and E-selectin antibody (Wuhan Boster Biological Technology Co., Ltd, Wuhan, China, both 1:500 dilution). Biotinylated anti-rabbit immunoglobulin was added as a secondary antibody. The horseradish peroxidase labeled streptomycin-avidin complex was then used to detect the second antibody. Finally, slides were stained with 3,3'-diaminobenzidine, which was used as a chromagen, and the sections were counterstained with hematoxylin before being examined under a light microscope. The brown or dark brown stained cells were considered as positive. The results were evaluated semi-quantitatively according to the percentage of positive cells in 5 high power fields at 400 multiple signal magnification: 0, less than 5%; 1, from 6% to 25%; 2, from 26% to 50%; 3, from 51% to 75%; 4, more than 75%<sup>[20]</sup>.

#### ICAM-1 and E-selectin Western blot analysis

Frozen liver tissue was homogenized with PBS ( $\text{pH} = 7.2$ ) and centrifuged at  $4^\circ\text{C}$ , 10 000  $g$  for 10 min. After precipitation the insoluble fraction was discarded, and the protein concentration in the supernatant was determined by a spectrophotometer. Aliquots (20  $\mu\text{g}$ ) of protein from each sample were loaded into each lane of 10% SDS-PAGE gel electrophoresis and then electroblotted onto nitrocellulose membranes (Millipore, Bedford, MA). The membranes were then probed with the rabbit antibody against rat ICAM-1 (intercellular adhesion molecule-1) or E-selectin (Boster Biological Technology Co., Ltd, Wuhan, China, both 1:1000 dilution) and biotin-conjugated anti-rabbit IgG (Fuzhou Maixin Biological Technology Co.,

Ltd, Fuzhou, China) according to the manufacturer's recommendations. The signals were visualized by a DAB assay kit (Fuzhou Maixin Biological Technology Co., Ltd, Fuzhou, China) and analyzed with a gel imaging system (Kodak system EDAS120, Japan).

#### Statistical analyses

All data were presented as mean  $\pm$  SD. Statistical analyses were performed using one-way analysis of variance (ANOVA) with the SPSS 11.5 statistical software package. The differences between means were analyzed using Student-Newman-Keuls (SNK) test for multiple comparisons.  $P$  values less than 0.05 were considered statistically significant.

## RESULTS

#### Pathological alterations of liver tissue

The histological structure of cells was normal in the control group. After 90 min of hepatic ischemia followed by 240 min of reperfusion, the occluded liver tissue appeared as dark color with an obtuse fringe. Compared with the control group, the liver tissue from the I/R group was markedly damaged characterized by edema, hemorrhage, partial exfoliation of vascular endothelium and infiltration with inflammatory cells under the microscope. Pretreatment of rats with 10 or 20  $\mu\text{g/kg}$  VnA resulted in a significant amelioration of hepatic injury (Figure 1).

#### Levels of plasma liver enzymes

Liver function was tested by measuring plasma levels of ALT and LDH. Hepatic I/R led to a marked elevation of plasma ALT and LDH activity (ALT:  $74.53 \pm 2.58$  IU/L vs  $1512.54 \pm 200.76$  IU/L,  $P < 0.01$ ; LDH:  $473.48 \pm 52.17$

**Figure 2** Plasma aminotransferase (ALT) (A) and acetic dehydrogenase (LDH) (B) levels in different groups (mean  $\pm$  SD,  $n = 10$ ). After 90 min of hepatic ischemia and 4 h of reperfusion, plasma levels of ALT and LDH were determined with an OLYMPUS AU5400 automatic analyzer. <sup>b</sup> $P < 0.01$  vs control group; <sup>d</sup> $P < 0.01$  vs I/R group.

**Figure 3** Activity of superoxide dismutase (SOD) in the liver tissue in different groups (mean  $\pm$  SD,  $n = 10$ ). After 90 min of ischemia and 4 h of reperfusion, the liver tissue was homogenized and assayed for SOD levels with an SOD assay kit as the index of hepatic oxidative stress. <sup>b</sup> $P < 0.01$  vs control group; <sup>c</sup> $P < 0.05$  vs I/R group.

IU/L *vs*  $5821.53 \pm 163.69$  IU/L,  $P < 0.01$ , Figure 2). The increase in plasma ALT activity elicited by hepatic I/R was significantly attenuated by administration of VnA at doses of 10 and 20  $\mu\text{g/kg}$  by about 35.35% and 39.85%, respectively ( $1512.54 \pm 200.76$  IU/L *vs*  $977.93 \pm 89.62$  IU/L,  $909.81 \pm 132.76$  IU/L,  $P < 0.01$ ,  $P < 0.01$ ); and the activity of LDH was reduced by administration of VnA at doses of 10 and 20  $\mu\text{g/kg}$  by about 48.20% and 57.94%, respectively ( $5821.53 \pm 163.69$  IU/L *vs*  $3015.44 \pm 253.01$  IU/L,  $2448.75 \pm 169.4$  IU/L,  $P < 0.01$ ,  $P < 0.01$ ). This result demonstrated the dose-dependent protective effects of VnA on liver injury.

#### SOD activity in liver tissue

Compared with the control group, the level of liver SOD in the I/R group reduced significantly ( $361.75 \pm 16.22$  U/mg protein *vs*  $263.19 \pm 12.10$  U/mg protein,  $P < 0.01$ ). After administration of VnA at doses of 10 and 20  $\mu\text{g/kg}$ , respectively, the liver SOD activity was elevated significantly ( $263.19 \pm 12.10$  U/mg protein *vs*  $299.40 \pm 10.80$  U/mg protein,  $302.09 \pm 14.80$  U/mg protein,  $P < 0.05$ ,  $P < 0.05$ , Figure 3).

**Figure 4** Activity of myeloperoxidase (MPO) in the liver tissue in different groups (mean  $\pm$  SD,  $n = 10$ ). MPO contents in liver tissue were analyzed with an MPO assay kit as the index of neutrophil recruitment. <sup>b</sup> $P < 0.01$  vs control group; <sup>d</sup> $P < 0.01$  vs I/R group.

#### MPO activity in liver tissue

Hepatic neutrophil recruitment was determined by liver MPO content. Hepatic I/R caused a marked increase in liver MPO content compared with the control group ( $1.97 \pm 0.11$  U/g *vs*  $2.57 \pm 0.13$  U/g,  $P < 0.01$ ). Administration of VnA at doses of 10 and 20  $\mu\text{g/kg}$  resulted in a marked reduction of MPO in a dose-dependent manner ( $2.57 \pm 0.13$  U/g *vs*  $2.13 \pm 0.13$  U/g,  $2.07 \pm 0.05$  U/g,  $P < 0.01$ ,  $P < 0.01$ ), suggesting that VnA prevents leukocyte recruitment to the liver tissue (Figure 4).

#### NO content in liver tissue

The level of NO in the liver tissue was significantly higher in the I/R group compared with the control group ( $69.37 \pm 1.52$   $\mu\text{mol/g}$  protein *vs*  $78.39 \pm 2.28$   $\mu\text{mol/g}$  protein,  $P < 0.01$ ). Pretreatment with VnA at both 10 and 20  $\mu\text{g/kg}$ , however, caused an obvious reduction in a dose-dependent manner when compared with the I/R group ( $78.39 \pm 2.28$   $\mu\text{mol/g}$  protein *vs*  $71.11 \pm 1.73$   $\mu\text{mol/g}$  protein,  $68.58 \pm 1.95$   $\mu\text{mol/g}$  protein,  $P < 0.05$ ,  $P < 0.01$ , Figure 5).

#### Immunohistochemical analysis for liver ICAM-1 and E-selectin

The expression of ICAM-1 and E-selectin in the control

**Figure 5** Content of nitric oxide (NO) in the liver tissue in different groups (mean  $\pm$  SD,  $n = 10$ ). After 90 min of ischemia and 4 h of reperfusion, the liver tissue was homogenized and assayed for NO levels with an NO assay kit as the index of hepatic oxidative stress. <sup>b</sup> $P < 0.01$  vs control group. <sup>a</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs I/R group.

group showed as light brown immunostaining. However, their expression was highly up-regulated after 90 min of ischemia and 240 min of reperfusion ( $P < 0.01$ ). Compared with the I/R group, the increase of ICAM-1 and E-selectin expression was significantly suppressed by VnA in a dose-dependent manner ( $P < 0.05$ ,  $P < 0.01$ ;  $P < 0.05$ ,  $P < 0.05$  respectively) (Figure 6, Figure 7 and Figure 8).

#### Western blot analysis for liver ICAM-1 and E-selectin

Western blot showed weak positive ICAM-1 and E-selectin signals in the control group. In contrast, a marked increase in ICAM-1 and E-selectin protein expression in the liver tissue was found in the I/R group. Compared with the I/R group, the signals were weakened obviously in the VnA pretreated group (Figure 9).

## DISCUSSION

Liver I/R injury occurs in a number of clinical settings including liver surgery, transplantation, and hemorrhagic shock. A major disadvantage of this event is an acute inflammatory response that may cause significant organ damage or dysfunction. Experimental evidence demonstrates that kupffer cells play an important part in mediating hepatic I/R<sup>[21-22]</sup>. Kupffer cell activation leads to structural changes, formation of vascular ROS and production of proinflammatory cytokines, which in turn induce the expression of adhesion molecules in vascular endothelial cells and stimulate the production and release of neutrophil-attracting chemokines. Neutrophil recruitment in the liver tissue causes direct hepatocellular damage through exhaustion of hepatic microcirculation by blocking the capillary perfusion and releasing ROS and proteases<sup>[23-24]</sup>.

VnA is a well known herbal plant widely distributed in the northeast region of China and has various pharmacological effects including antithrombotic and antihypertensive properties<sup>[15,17]</sup>. Some researchers have also demonstrated that VnA exerted beneficial effects on brain I/R injury by inhibiting oxidation and leukocyte priming and expression of inflammatory mediators<sup>[18]</sup>. In the present study, we demonstrated that VnA pretreatment at doses of 10 and 20  $\mu\text{g/kg}$  could attenuate hepatic I/R

injury, indicated by improved alteration in liver tissue pathology and liver function, by an enhanced antioxidant capacity with augmentation of free radical scavengers and reduced polymorphonuclear neutrophil (PMN) infiltration, as well as by suppressed overexpression of adhesion molecules and selectins.

Reperfusion of the ischemic liver in rats resulted in hepatic damage with histological evidence of liver hemorrhage, edema, accumulation of adherent leukocytes in sinusoids and terminal hepatic vein (THV), as well as partial exfoliation of blood vessel endothelia. Furthermore, hepatic I/R caused the release of liver enzymes into the blood stream, thereby eliciting a significant increase in plasma levels of ALT and LDH. VnA pretreatment abated liver pathologic injury and reduced plasma ALT and LDH activity, thus liver function was ameliorated.

SOD catalyses the dismutation of the superoxide anion ( $\text{O}_2^-$ ) into  $\text{H}_2\text{O}_2$ , which can be transformed into  $\text{H}_2\text{O}$  and  $\text{O}_2$  by catalase (CAT). In this study, we found that I/R impaired SOD activity, as indicated by the markedly lowered activity compared with the control group. But in the VnA pretreated group, the decrease of SOD activity was significantly counteracted. In addition, the hepatic I/R increased the levels of nitric oxide (NO), an important ROS product. This result is consistent with a previous report<sup>[25]</sup>. NO may combine with superoxide radicals to form peroxynitrite, a substance extremely toxic to cells<sup>[26]</sup>. VnA pretreatment significantly decreased liver NO content, resulting in a significant reduction in liver damage when compared with the control group. These data indicated that VnA might confer protection on the liver during I/R injury in part by improving activity of the endogenous antioxidant enzyme, which scavenges ROS and reduces their effects.

Because MPO is an enzyme restricted mainly to PMNs, the increase in MPO activity reflects neutrophil tissue infiltration. The significant increase in MPO activity in the liver tissue after hepatic I/R in the present study is consistent with another study<sup>[27]</sup>. However, VnA significantly blunted the increase of liver MPO activity compared with the I/R group. That is to say, VnA reduced infiltration of leukocytes into the inflammatory sites.

ICAM-1 is a member of the immunoglobulin superfamily that mediates firm adhesion and emigration of activated leukocytes in postcapillary venules, which process may be one of the important steps in the development of tissue injury and organ dysfunction<sup>[28]</sup>. Previous studies have shown an upregulation of ICAM-1 expression following endothelial cell activation with cytokines or LPS, accompanied by an increased binding of neutrophils and lymphocytes to endothelial cells. An anti-ICAM-1 monoclonal antibody inhibited neutrophil infiltration into pericentral sinusoids and improved and restored liver integrity in I/R injury<sup>[29]</sup>. In this study we detected overexpression of ICAM-1 after hepatic I/R, which was significantly decreased in the VnA pretreated groups. This indicated that VnA could suppress leukocyte adhesion to endothelia.

Murine E-selectin is a 110 kDa, type-1 transmembrane glycoprotein expressed only in endothelial cells after cytokine activation<sup>[30]</sup>. E-selectin participates in leukocyte

**Figure 6** Immunohistochemical staining of adhesion molecule-1 (ICAM-1) expression in the liver tissue after 90 min of ischemia and reperfusion for 240 min in rats ( $\times 400$ ). Formalin-fixed, paraffin-embedded liver specimens were stained by streptavidin/peroxidase immunohistochemistry technique. For all groups,  $n = 10$ . **A:** Control group; **B:** I/R group; **C:** I/R + VnA (10  $\mu\text{g/kg}$ ) group; **D:** I/R + VnA (20  $\mu\text{g/kg}$ ) group.

**Figure 7** Immunohistochemical staining of E-selectin in liver tissue after ischemia for 90 min and reperfusion for 240 min in rats ( $\times 400$ ). Formalin-fixed, paraffin-embedded liver specimens were stained by the streptavidin/peroxidase immunohistochemistry technique. For all groups,  $n = 10$ . **A:** Control group; **B:** I/R group; **C:** I/R + VnA (10  $\mu\text{g/kg}$ ) group; **D:** I/R + VnA (20  $\mu\text{g/kg}$ ) group.

**Figure 8** Immunohistochemical results (semi-quantitative analysis) of adhesion molecule-1 (ICAM-1) (**A**) and E-selectin (**B**) in liver tissue in different groups. Data were presented as mean  $\pm$  SD. <sup>b</sup> $P < 0.01$  vs Control group; <sup>a</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs I/R group.

rolling and firm adhesion *in vitro*<sup>[31]</sup> and *in vivo*<sup>[32]</sup>. It is down-regulated by re-internalization and by shedding from the endothelial surface into the plasma<sup>[33]</sup>. Previous studies revealed that blockade of E-selectin protected from severe

acute renal failure induced by ischemia-reperfusion<sup>[34]</sup>. In our study, E-selectin was also found to be overexpressed after hepatic I/R, however, this was attenuated in the VnA pretreated groups as compared with the I/R group.

**Figure 9** Liver adhesion molecule-1 (ICAM-1) (A) and E-selectin (ES) (B) protein signals of Western blot analyzed with a gel imaging system (Kodak system EDAS120, Japan). For all groups,  $n = 10$ . L1: Control group; L2: I/R group; L3: VnA (10 µg/kg) group; L4: VnA (20 µg/kg) group. Compared with the control group, the signals in I/R group increased and weakened in the VnA pretreated group in a dose-dependent manner.

The above results suggested that ICAM-1 and E-selectin dependent neutrophil recruitment into the liver tissue was responsible partially for hepatic I/R. The dose-dependent protective effects of VnA were likely related to the suppression of ICAM-1 and E-selectin expression. This suppression reduced the neutrophil recruitment associated with the hepatic I/R, and effectively protected the liver against ischemia/reperfusion.

In conclusion, VnA has protective effects against liver injury induced by hepatic I/R. The protective effects are probably associated with enhancement of antioxidant capacities, reduction of inflammatory responses and suppressed expression of ICAM-1 and E-selectin. These findings may be useful for clinical management to reduce I/R related hepatic damage. However, the precise mechanisms of VnA protecting against hepatic I/R still need to be clarified in further studies.

## ACKNOWLEDGMENTS

The authors thank Professors Sen Lü and Min Liu, Laboratory of Molecular Biology (State Administration of Traditional Chinese Medicine), Second Affiliated Hospital of Dalian Medical University for their technical assistance. The excellent technical assistance of Dr. Yu-Zhong Li and Zhen-Guo Li (Department of Docimasiology, Second Affiliated Hospital of Dalian Medical University) are acknowledged.

**CONCLUSION:** Gastrointestinal symptoms are common in the Japanese population, with an incidence of 25%. Abdominal pain, diarrhea, nausea, constipation and dyspepsia are the most frequent symptoms. Risk factors for developing these symptoms include female gender, younger age, and low baseline quality of life.

Tokuda Y, Takahashi O, Ohde S, Shakudo M, Yanai H, Shimbo T, Fukuhara S, Hinohara S, Fukui T. Gastrointestinal symptoms in a Japanese population: A health diary study. *World J Gastroenterol* 2007; 13(4): 572-578

<http://www.wjgnet.com/1007-9327/13/572.asp>

### Abstract

**AIM:** To investigate the incidence of gastrointestinal symptoms and the nature of consequent utilization of health care services in a Japanese population.

**METHODS:** Using self-report, we conducted a prospective cohort study of a nationally representative sample of the Japanese population over a one-month period to determine the incidence of gastrointestinal symptoms of all kinds and resultant health care utilization. Both information on visits to physicians and use of complementary and alternative medicine therapies were collected.

**RESULTS:** From a total of 3568 in the recruitment sample, 3477 participants completed a health diary (response rate 97%). The data of 112 participants with baseline active gastrointestinal diseases were excluded from the analysis, leaving 3365 participants in the study. The incidence of gastrointestinal symptoms was 25% and the mean number of symptomatic episodes was 0.66 in a month. Abdominal pain, diarrhea, nausea, constipation and dyspepsia were the most frequent symptoms. Female gender, younger age, and low baseline quality of life were risk factors for developing these symptoms. The participants were more likely to treat themselves, using dietary, complementary or alternative medicines, than to visit physicians, except in the case of vomiting.

### INTRODUCTION

Although the prevalence of gastrointestinal disease in the Japanese population is known to be high, its epidemiology, incidence, and the consequent utilization of health care services are not well described<sup>[1-3]</sup>. An accurate analysis of the incidence of the various symptoms and of the health care services utilized in relation to them would clarify the public health consequences of gastrointestinal symptoms and assist in the setting of priorities in the allocation of health care services and future research funding. There is also little information on the use of complementary and alternative medicine as compared with conventional medicine in the treatment of the various symptoms of gastrointestinal disease. This prospective cohort study was designed to ascertain the incidence of gastrointestinal symptoms in the Japanese general population and to document the subsequent use of health care, as recorded by the participants in a health diary.

### MATERIALS AND METHODS

#### Participants

This analysis of the incidence of gastrointestinal symptoms and subsequent health care practices in Japan is drawn from a prospective cohort study, using participants' health diaries established for the ecological analysis of

medical care in Japanese communities<sup>[4]</sup>. A population-weighted random sample of households was selected by controlling for the size of cities, towns and villages. Participants who had baseline active gastrointestinal diseases were excluded from the analysis. Because of the national policy of universal health insurance coverage in Japan, all households sampled were covered by health insurance. Prior ethical approval from the Research Ethics Committee of Kyoto University Graduate School of Medicine was obtained.

There are advantages to using health diaries when investigating individual health and related behavior<sup>[4-8]</sup>. Health diaries can provide an immediate and continuous record of daily health events and behaviors, and minimize recall bias<sup>[4]</sup>, without the intervention of direct observational measures<sup>[7,9]</sup>. The methodology of this health diary study is described in detail elsewhere<sup>[4]</sup>.

### Data collection

For the purposes of the study, the independent variables were baseline demographic and clinical data. The dependent variables were self-reported gastrointestinal symptoms, which were categorized and coded based on the ICPC-2 (International Classification of Primary Care second edition). They included diffuse abdominal pain, upper abdominal pain, diarrhea, nausea, constipation, dyspepsia, vomiting, abdominal fullness, heartburn, lower abdominal pain, hematemesis, and hematochezia.

The health diary procedure required the keeping of a daily record for one month, from October 1 to October 31, 2003, of all health-related events, including gastrointestinal symptoms, health care accessed, and anything else of relevance. The health diary format specifically sought responses to the following questions: (1) Did you have any pain or other health symptoms that caused you discomfort? (2) If so, what kind of symptoms did you have? (3) If the answer to the first question was yes, did you consult a physician? Did you use dietary supplements such as nutritional drinks, vitamins, and calcium? Did you undergo any physical remedy, such as acupressure, acupuncture, or massage? Subjects younger than 15 years old were also included in this study. The parents of these children were requested to ask the questionnaires and record them accordingly. We did not include the use of over-the-counter-medications as utilizations of health care services in this study.

Data was extracted on the number of days in which symptom-related visits to a physician occurred during the study period, whether to a primary care physician, a community hospital, a university hospital, or an emergency department. Data was also collected on the number of days complementary and alternative medicines were used, whether dietary supplements or physical remedies. The use of complementary and alternative medicine was divided into two categories: (1) Dietary complementary and alternative medicine, such as nutritional drinks, herbs, kampo, supplements, vitamins, minerals, and other dietary substances; (2) Physical complementary and alternative medicine, such as massage, acupuncture, acupressure, Judo-seifuku, moxibustion, chiropractic, and similar physical manipulations.

Baseline data, including demographic, health-related, and socioeconomic information, was also collected. The SF-8 instrument was used to measure baseline health-related quality of life. The SF-8 generates a health profile consisting of eight scales and two summary measures: a physical component summary (PCS8) and a mental component summary (MCS8)<sup>[10]</sup>. The SF-8 is scored by assigning the mean SF-36 scale score for the Japanese population as measured in 2002 to each response category of the SF-8 measuring the same concept. A higher or lower individual score indicates a better or worse health status than the mean, respectively<sup>[11]</sup>. We also included the baseline number for comorbidity as a covariate. The number of co-morbidities was calculated by counting the number of diseases present with no weights<sup>[12]</sup>.

Data on a number of characteristics was collected as socioeconomic baseline measurements. Annual household income was divided into 6 categories. Employment status was recorded as one of 6 categories: student, homemaker, jobless or not able to work, retiree, part-time employee, and full-time employee or self-employed worker. Self-reported educational attainment was also classified at 6 levels: junior high school or below, high school graduate, vocational college, 1-2 years college, college degree, graduate school degree or higher.

### Statistical analysis

The incidence (proportions) and the number of episodes (days with the symptom) of individual gastrointestinal symptoms were calculated during the one-month study period. Multivariable adjusted Poisson regression models were constructed to obtain adjusted rate ratios for the number of episodes of the various gastrointestinal symptoms in relation to baseline demographic and clinical factors. Health care utilization for one month of participants who developed gastrointestinal symptoms was also calculated. A two-tailed *P*-value of 0.05 was regarded as statistically significant. The STATA software version 8.2 (College Station, Texas, USA) was used for all statistical analyses.

## RESULTS

From a total of 3568 in the study recruitment sample, 3477 participants completed the diary (97.4%). Of these, 112 with baseline active gastrointestinal diseases were excluded and the remaining 3365 participants were enrolled in the study (Table 1). 1573 (46%) were men. The mean age was 34 years (range 0-96 years). 17% of the 3365 participants lived in large cities, 24% in medium-sized cities, 38% in small cities, and 21% in rural areas. Table 1 shows the demographic, socioeconomic and clinical characteristics of the participants in two groups: those who developed any gastrointestinal symptom and those who recorded none. A univariate analysis showed no significant differences in socioeconomic characteristics between the two groups. A trend test yielded *P* = 0.212 for annual household income, *P* = 0.143 for occupational status, and *P* = 0.719 for educational attainment. Chi-square tests showed significant differences between the two groups on the variables of gender (*P* < 0.001), past history of gastrointestinal disease

SD: standard deviation. There were no participants with hematochezia.

( $P < 0.001$ ), MCS8 ( $P < 0.001$ ), and PCS8 ( $P = 0.008$ ).

Table 2 shows the incidence per month for 3365 participants and the number of episodes of gastrointestinal symptoms of these participants during the one month study period. 856 (25%) developed one or more gastrointestinal symptoms. The symptoms of high incidence ( $\geq 1\%$ ) were diffuse abdominal pain (12%), upper abdominal pain (5%), diarrhea (5%), nausea (4%), dyspepsia (3%), constipation (2%), vomiting (1%), and abdominal fullness (1%). The mean number of episodes of gastrointestinal symptoms of any kind was 0.66 in the one-month period. The symptoms with a high number of episodes were diffuse abdominal pain (0.21), upper abdominal pain (0.11), diarrhea (0.10), nausea (0.07), constipation (0.06), dyspepsia (0.05), vomiting (0.02), and abdominal fullness (0.01).

Table 3 shows rate ratios based on multivariable adjusted Poisson regression analyses. Age and the number of comorbidity are treated as continuous variables in this Table. Gastrointestinal symptoms were reported more commonly by women than men. Symptoms with a significantly higher number of episodes in women were diffuse abdominal pain, upper abdominal pain, nausea, and constipation, and symptoms with a significantly higher number of episodes in men were diarrhea and heartburn.

Gastrointestinal symptoms were reported more often in younger than in older age groups. Symptoms associated with older age were upper abdominal pain, dyspepsia, constipation, abdominal fullness, and heartburn, while symptoms associated with younger age were diffuse abdominal pain, diarrhea, nausea, and vomiting. The symptoms that featured in comorbidity were nausea and constipation.

Gastrointestinal symptoms were reported more often by participants with poor baseline quality of life scores. Diffuse abdominal pain, diarrhea and dyspepsia were symptoms associated with a poor baseline score on the physical component of the health-related quality of life test. Symptoms associated with a poor baseline score on the mental component of the health-related quality of life test were diffuse abdominal pain, upper abdominal pain,

nausea, constipation, and abdominal fullness.

Table 4 shows the health care utilization characteristics of participants with one or more gastrointestinal symptoms in the survey month. Overall, use of dietary complementary and alternative medicine was more frequent than visiting a physician (Bonferroni pair-wise comparison,  $P < 0.001$ ), but visiting a physician was more frequent than use of physical forms of complementary and alternative medicine (Bonferroni pair-wise comparison,  $P < 0.001$ ). However, visiting a physician was more frequent than use of dietary complementary and alternative medicine in those whose symptom was vomiting. Among those with dyspepsia and heartburn, use of both dietary and physical complementary and alternative medicine was more frequent than visiting a physician.

## DISCUSSION

Our results indicate that gastrointestinal symptoms are of common occurrence in the Japanese general population, with about a quarter developing a gastrointestinal symptom of some kind in a month. Abdominal pain, diarrhea, nausea, constipation and dyspepsia were the most frequent gastrointestinal symptoms in our sample. Risks for developing these symptoms differ in relation to the baseline factors of gender, age, and quality of life. Japanese who develop gastrointestinal symptoms are more likely to treat themselves with dietary forms of complementary and alternative medicine than to visit physicians, except in the case of vomiting.

Gastrointestinal symptoms with a high incidence were, in order, diffuse and upper abdominal pain, diarrhea, nausea, constipation, and dyspepsia. These findings are consistent with those of one previous study<sup>[2]</sup>, while another found that diarrhea was more common than abdominal pain<sup>[3]</sup>. It may be that self-reporting of diarrhea underestimates its actual incidence<sup>[13]</sup>. A study that asks about diarrhea and loose stools separately obtains a lower incidence of diarrhea than one in which participants include loose stool in their definition of diarrhea<sup>[3]</sup>. Thus differences in participants' definitions could account for differences in the estimated incidence of diarrhea between previous studies<sup>[14]</sup>.

Our study found that women were more likely to develop diffuse and upper abdominal pain, nausea, and constipation than men. Previous studies suggest that the incidence of many gastrointestinal symptoms is higher in women than in men<sup>[1,3,15-18]</sup>, and many studies indicate that abdominal pain, specifically, is more common in women<sup>[1,3,15-18]</sup>, although two studies have shown no gender difference<sup>[19,20]</sup>. Abdominal fullness, also, is more common in women than in men<sup>[21]</sup>. A higher prevalence of occult irritable bowel syndrome in women could account for the higher incidence and prevalence of such symptoms as abdominal pain, nausea, and constipation<sup>[3,22]</sup>. Alternatively, a higher sensitivity in the perception of such symptoms in women could also contribute to the difference<sup>[3]</sup>.

Our study found that men were more likely to develop diarrhea and heartburn than women. This finding differs from a number of studies indicating no gender difference for diarrhea<sup>[3,16,18]</sup>, while a recent international study found

Table 3 Rate ratios based on multivariable adjusted poisson regression analyses

Variable symptom	Female gender	Older age	Previous GI disease	No. of comorbidity	Better PCS8	Better MCS8

Lower abdominal pain	0.63	1.628	2.06	7.206	0.19	0.750
Hematemesis	0.00	0.000	0.00	0.000	0.00	0.000

CAM: complementary and alternative medicine; SD: standard deviation. Hematochezia could not be analyzed because of few incidence.

that the incidence of diarrhea was higher in women in a number of countries, including Australia, Canada, Ireland, and the United States<sup>[23]</sup>. Gastroesophageal reflux disease symptoms, such as heartburn and acid regurgitation, showed no gender difference in an earlier Japanese study<sup>[24]</sup>, and studies in Sweden and Belgium also found no gender difference in the prevalence of heartburn<sup>[1,25]</sup>. These conflicting results suggest the need for further investigation.

Overall, gastrointestinal symptoms were reported more commonly in younger than in older participants in the

current study. Previous studies have shown a significantly higher prevalence of abdominal symptoms in young women, which decreases with age<sup>[1,3,26]</sup>. Nevertheless the current study found that older individuals are more likely to suffer upper abdominal pain, dyspepsia, constipation, abdominal fullness, and heartburn than the young. The young are more likely to report diffuse abdominal pain, diarrhea, nausea, and vomiting than the old. This difference between the old and the young in the incidence of many gastrointestinal symptoms may derive from an age-associated change in visceral sensitivity<sup>[3]</sup>, but the

source of the difference has not yet been established.

Our study found that those with a poor baseline score on the physical component of quality of life had a higher likelihood than those with an average score of developing diffuse abdominal pain, diarrhea and dyspepsia, while those with a poor baseline score on the mental component of quality of life were more likely than those with an average score to report diffuse and upper abdominal pain, nausea, constipation, and abdominal fullness. To our knowledge, this study is the first prospective cohort study to analyze baseline quality of life scores as predictors of gastrointestinal symptoms. A possible higher prevalence of occult irritable bowel syndrome in those with a poor score on the mental component of the quality of life measure may explain their higher incidence and prevalence of such symptoms as abdominal pain, nausea, constipation, and abdominal fullness<sup>[3,22]</sup>. This finding requires further study for confirmation.

The current study may be the first prospective cohort study to describe health care utilization in individuals in response to gastrointestinal symptoms. Our results indicate that self-treatment with dietary complementary and alternative medicine is more frequent than visiting a physician regarding all symptoms except vomiting. Recourse to physical as well as dietary complementary and alternative therapies was more frequent than visiting a physician in the case of dyspepsia and heartburn.

Complementary and alternative therapies, some of which had their origins in Japan, are increasingly used by the general population in industrialized countries<sup>[27-29]</sup>. This is true of a substantial proportion of the Japanese population, who use them frequently at a high cost to personal income<sup>[30]</sup>. Patients with functional and general gastrointestinal disorders are likely to turn to complementary and alternative medicine when conventional therapies fail to relieve their symptoms<sup>[31]</sup>. Therefore physicians need to keep their knowledge up to date on the regulations, side effects, and possible benefits of specific herbal products used by patients<sup>[32]</sup>. Studies of the effectiveness of complementary and alternative therapies for functional gastrointestinal disorders have, however, often been limited by study designs<sup>[33]</sup>.

It should be borne in mind that the health diaries in this study were self-reports and therefore subjective. A further limitation is that information on the severity of symptoms was not requested. As symptoms were not classified as less or more severe, there was no means of determining whether severity differentially influenced decisions to note them in the diaries or to seek different forms of treatment. This may have resulted in misclassification biases<sup>[14]</sup>.

In summary, gastrointestinal symptoms are of common occurrence in the Japanese population. Overall, the mean number of episodes of gastrointestinal symptoms was 0.66 in a month. About a quarter of respondents developed at least one gastrointestinal symptom in the course of the month. Abdominal pain, diarrhea, nausea, constipation and dyspepsia were the most frequent gastrointestinal symptoms. Female gender, younger age, and low baseline quality of life are risk factors for developing gastrointestinal symptoms. Japanese with gastrointestinal symptoms other than vomiting are more likely to resort to

dietary forms of complementary and alternative medicine than to visit physicians.

We thank Kenji Sakurai MD FACS for his support of our research, and we thank Mikio Kumagai, Riki Tanaka, Yumiko Yotsumoto, Yuko Iwasawa, and Sayoko Yamauchi for their excellent secretarial assistance.

## COMMENTS

### Background

The incidence of gastrointestinal symptoms and the nature of consequent utilization of health care services in the Japanese population are not well documented. Our aim was to provide better description in this epidemiology of gastrointestinal symptoms.

### Research frontiers

The prevalence of gastrointestinal disease in the Japanese population is known to be high. However, its epidemiology, its incidence, and the consequent utilization of health care services are not well described. There is also little information on the use of complementary and alternative medicine as compared with conventional medicine in the treatment of the various symptoms of gastrointestinal disease.

### Innovations and breakthroughs

In this study of Japan, the incidence of gastrointestinal symptoms was 25% and the mean number of the symptomatic episodes was 0.66 in a month. Abdominal pain, diarrhea, nausea, constipation and dyspepsia were the most frequent symptoms. Female gender, younger age, and low baseline quality of life were risk factors for developing these symptoms. The participants were more likely to treat themselves, using dietary complementary or alternative medicines, than to visit physicians, except in the case of vomiting.

### Applications

Gastrointestinal symptoms are very common in the Japanese general population. The most frequent symptoms include abdominal pain, diarrhea, nausea, constipation and dyspepsia. Risk factors for developing these symptoms are female gender, younger age, and low baseline quality of life. These results may help to understand the public health consequences of gastrointestinal symptoms and to assist in the setting of priorities in the allocation of health care services and of future research funding.

### Terminology

**Health diary:** a daily record of daily health events and behaviors. This research methodology can provide an immediate and continuous record of daily health events and behaviors and minimize recall bias without the intervention of direct observational measures.

### Peer review

This article documented about epidemiology of gastrointestinal symptom among Japanese. Study period is relatively short. Generally, it is well designed and clarified the incidence of gastrointestinal symptom among Japanese. The study also revealed Japanese actions to gastrointestinal symptoms.

### Abstract

**AIM:** To investigate the use of high dose consensus-interferon in combination with ribavirin in former iv drug users infected with hepatitis C.

**METHODS:** We started, before pegylated (PEG)-interferons were available, an open-label study to investigate the efficacy and tolerability of high dose induction therapy with consensus interferon (CIFN) and ribavirin in treatment of naive patients with chronic hepatitis C. Fifty-eight patients who were former iv drug users, were enrolled receiving 18 µg of CIFN daily for 8 wk, followed by 9 µg daily for up to wk 24 or 48 and 800 mg of ribavirin daily. End point of the study was tolerability and eradication of the virus at wk 48 and sustained virological response at wk 72.

**RESULTS:** More than 62% of patients responded to the treatment with CIFN at wk 24 or 48, respectively, showing a negative qualitative PCR [genotype 1 fourteen patients (56%), genotype 2 five (50%), genotype 3 thirteen (87%), genotype 4 four (50%)]. Forty-eight percent of genotype 1 patients showed sustained virological response (SVR) six months after the treatment.

**CONCLUSION:** CIFN on a daily basis is well tolerated and side effects like leuko- and thrombocytopenia are moderate. End of therapy (EOT) rates are slightly lower than the newer standard therapy with pegylated interferons. CIFN on a daily basis might be a favourable therapy regimen for patients with GT1 and high viral load or for non-responders after failure of standard therapy.

### INTRODUCTION

Under physiological conditions, interferon- $\alpha$  (IFN- $\alpha$ ) is a key cytokine produced by virtually all cells in the mammalian organism in response to a variety of bacterial and viral stimuli. In response to viral infection, IFN- $\alpha$  produced by the infected target cells induces a number of cellular genes involved in inhibition of viral replication. In addition, IFN- $\alpha$  is secreted by stimulated NK-cells and T-cells and exerts a multitude of immune stimulatory effects of innate and adaptive immunity<sup>[1]</sup>.

The current standard of treating patients with chronic hepatitis C infection is using IFN- $\alpha$  with or without ribavirin and great advances have been achieved<sup>[2]</sup>. So far two allelic  $\alpha$ -2 species, interferon  $\alpha$ -2a and interferon  $\alpha$ -2b, have been used. Introduction of pegylated IFN in 2001 showed a slight increase in the overall sustained virological response rates (approximately 55%) compared to conventional IFN- $\alpha$ <sup>[3,4]</sup>. However, recent studies showed that these response rates depend on several factors, including HCV genotype, baseline viral load, ethnicity, body weight and presence of advanced liver disease<sup>[5]</sup>. More than 75% of patients in western Europe are infected with genotype 1 often showing a high viral load and these patients are so called "difficult to treat" and therefore remain at risk not to respond to standard HCV treatments<sup>[5]</sup>.

Before pegylated IFN was available, we introduced a study using IFN-alfacon-1, a second-generation cytokine that was engineered to contain the most frequently occurring amino acids among the non-allelic IFN- $\alpha$  subtypes in humans<sup>[6]</sup>. *In vitro* studies showed that IFN-alfacon-1 induces a more dramatic decrease of HCV-

RNA compared to IFN-2b<sup>[7]</sup> and shows a 10-time higher antiviral efficacy<sup>[6]</sup>. The rationale for daily dosing in our study was the fact that serum levels of IFN- $\alpha$  given three times a week were dropping almost below the detection limit every other day and therefore reducing the antiviral capability. High initial dosing would reduce the viral load even further and early virological response (EVR) would lead to a higher SVR than 9  $\mu$ g daily<sup>[8]</sup>. Taking these results into account, the aim of this study was to look at the efficacy, tolerability and safety of high dose IFN-alfacon-1 plus ribavirin combination therapy in patients with chronic hepatitis C.

## MATERIALS AND METHODS

### Patient population

Patients aged 18 years and older with a serological and histological diagnosis of chronic HCV infection were asked to participate in the study. All patients were naïve to antiviral treatment and were recent iv drug users referred by a clinic with a detoxification program. Each individual had to be off drugs for at least 4 to 6 mo, and replacement medication (e.g. buprenorphine) was allowed. The local ethics committee approved the study and informed consent of patients was obtained prior to serological and histological testing and antiviral therapy. The study protocol was in accordance to the 1975 Declaration of Helsinki.

Inclusion criteria required that patients had detectable serum HCV-RNA and liver biopsy compatible with a diagnosis of chronic HCV infection. Exclusion criteria included decompensated liver disease, hemoglobin < 12 g/dL for men and women, white blood cell count < 3000/ $\mu$ L, neutrophil count < 1500/ $\mu$ L, and platelet count < 70 000/ $\mu$ L. Patients with hepatitis B virus (HBV) or HIV infection were excluded. Similarly, patients with antinuclear antibody  $\geq$  160 or diagnosis of other chronic liver diseases (hemochromatosis, alpha1-antitrypsin deficiency, Wilson's disease, or other chronic liver diseases), or who had prior organ transplantation or hyper- or hypothyroidism were also excluded. A history of major depression or ongoing alcohol or drug abuse within the previous 6 mo, renal insufficiency, hemophilia, poorly controlled diabetes, cardiac disease, immunologically mediated diseases, active seizure disorders or brain injury requiring medication for stabilization and pregnancy were further criteria for not being included in the study. Eleven patients were on replacement medication including methadone and codeine.

### Study design

The study was a mono-center clinical trial with consecutive and prospective enrolment. All patients were naïve to antiviral therapy including IFN and ribavirin. All patients received a high induction therapy with IFN-alfacon-1, 18  $\mu$ g (Inferax<sup>®</sup>; Yamanouchi Pharma GmbH, Heidelberg, now Astellas Pharma GmbH, Munich) subcutaneously daily for eight weeks, followed by 9  $\mu$ g subcutaneously daily until the end of treatment. Ribavirin (Meduna Pharma GmbH, Isernhagen, Germany), 800 mg daily,

was administered bid over the whole treatment period. If HCV RNA levels were detectable after 24 wk, treatment was considered as failure and stopped; if HCV RNA was undetectable at wk 24, treatment was continued for a total of 48 wk in HCV genotypes 1 and 4. Treatment of genotypes 2 and 3 was stopped after 24 wk in general. After therapy was ended, patients were followed up for an additional 24 wk.

It was initially planned to treat 100 patients. However, after 58 subjects were enrolled, recruitment was suspended because of ethical concern following the release of pegylated IFN  $\alpha$ -2b which became the standard of treatment.

### Identification of genotype

HCV genotyping was performed using the INNO-LiPA HCV II kit assay (Innogenetics, Gent, Belgium).

### Serum HCV RNA

Reverse-transcription polymerase chain reaction was performed using the Cobas Amplicor hepatitis C monitor test (v2.0, Roche Diagnostics, Grenzach-Wyhlen, Germany). The results of HCV RNA are expressed as international units per millilitre based on published formulas where 2 000 000 copies are equivalent to 800.000 IU/mL<sup>[9]</sup>.

### Assessment of efficacy

The primary end point of the study was assessment of sustained virological response rate defined as loss of detectable HCV RNA by RT-PCR at wk 72 [24 wk after end of therapy (EOT)]. A secondary end point was assessment of the sustained biochemical response (SBR), defined as normalization of serum alanine aminotransferase (ALT) at wk 72. No second histological end point was sought. Early virological response (EVR) at wk 4 was not determined.

### Assessment of safety and tolerability

Safety and tolerability assessments were performed at 0, 2, 4, 8, 12, 24, and 48 wk of therapy and then 12 and 24 wk post-treatment. All adverse events, laboratory test-results, discontinuation or withdrawal due to adverse events, and dose reduction were recorded and evaluated.

### Statistical analysis

Analysis was based on the intent to treat 48 patients enrolled in the study. Data were described by rates, means with standard deviation, medians, and ranges. In addition, multivariate step-wise logistic regression was used to identify independent predictors from baseline characteristics which were associated with SVR in univariate analysis. All *P*-values reported were two-sided and *P*-values below 5% were considered statistically significant.

## RESULTS

### Patients

Between July 2000 and May 2003, 58 patients with chronic

**Figure 1** Response rates (in percent) after end of therapy (EOT) at wk 24 or 48 and sustained virological response (SVR) after 48 or 72 wk after beginning of antiviral therapy. Two patients with genotype 1 showed a relapse of the hepatitis C virus during 6 mo of follow at wk 72. In two patients genotype was not evaluated prior to therapy. Patients got antiviral treatment for 48 wk and both achieved SVR at wk 72.

HCV infection were enrolled at our site in Luebeck. Of these patients, 57% were men and 43% women. All patients were of Caucasian origin and the mean age was 36 years. Ninety percent of the patients showed a histological diagnosis of chronic hepatitis and only 2% showed histologically cirrhosis that was deemed clinically compensated. The mean serum HCV RNA concentration was 617.000 IU/mL. Fifty-two percent of the patients were infected with genotype 1. Genotypes 2 and 3 were present in 39% of the patients and 4% of the patients showed genotype 4. The baseline characteristics are shown in Table 1.

### Efficacy

Overall, 62% of the patients showed a sustained virological response (SVR) at the end of therapy, whereas 16 individuals did not respond to the therapy. ALT levels dropped significantly from initially elevated levels during the first 12 wk of therapy, whereas AST and bilirubin were stable in the normal laboratory range. Fifty-six percent and 50% of the patients with genotypes 1 and 4, respectively, showed a virological response at the end of treatment, while 48% and 48% respectively, reached a sustained virological response at wk 72. In the group of patients with easy to treat genotypes 2 and 3, 50% and 87% respectively, achieved a negative HCV-PCR at the end of treatment and no relapse occurred in these 19 patients until wk 48 (Figure 1). The patients with a low viral load (< 800.000 IU/mL) initially had a slightly greater chance of achieving SVR compared to those with a high viral load (48% *vs* 40%) irrespective of their genotype (Table 2). Women responded slightly better to therapy than men. The drop in viral load was accompanied with a significant decrease in ALT levels throughout the first three months of therapy (57 U/L to 22 U/L). AST levels were in their normal range at the beginning of treatment and there was only little if any further normalisation (25 U/L to 17 U/L). In some patients bilirubin was slightly elevated as well

Female	14/25 (56)

Sixteen patients who failed to follow up, dropped off the study due to side effects or died and were taken as non-responders, *n* = 58.

but showed normal levels at the end of therapy (data not shown). There was no positive correlation between either genotype or ALT or SVR (data not shown).

Neither consensus interferon (CIFN) nor ribavirin dosing had to be modified throughout the therapy in any patient.

Co-medication with either methadone or codeine did not play a role in treating patients with HCV. Neither dosage nor application of replacement medicine had to be adjusted. The patients on replacement medication did not succeed in regard to SVR compared to those without methadone or codeine (data not shown). Ninety-two percent of the patients, who did achieve sustained virological response, took more than 80% of medication throughout the whole treatment period, demonstrating a remarkably high adherence to antiviral therapy.

However, only 2 out of all patients (all genotype 1) with negative PCR at wk 48 (EOT) had a virological relapse during the follow-up period between wk 48 and 72.

### Tolerability

Seven patients showed a relapse of their intravenous drug abuse prior to the end of therapy and one 28-year old male patient died due to a heroin overdose. Six patients stopped therapy due to treatment-related side-effects (bleeding due to low platelets). Two patients did not show up for follow-up visits during antiviral treatment. No patient showed evidence of hypocalcemia, previously reported for daily dosing of CIFN<sup>[10]</sup>. Liver function in all patients was stable as measured clinically and by testing of coagulation function and serum albumin (data not shown).

### Safety and adverse events

There was one serious adverse event 8 wk after beginning of therapy, leading to a death due to an overdose of intravenous heroin abuse. Six patients showed a restart of their iv drug abuse while on combination therapy. One patient developed a major depression, one female patient showed a significant drop in platelets (43.000/ $\mu$ L), one showed recurrent epistaxis (89.000/ $\mu$ L) and one male patient showed a long-lasting episode of arthritis and suicidal thoughts. Otherwise dose modifications due to adverse events were not necessary in any patient.

The spectrum of side effects of daily high dose induction therapy with CIFN was similar to previous trials with IFN and ribavirin. All the 58 patients were included in safety analysis. All the patients experienced flu-like symptoms (100%). Most of them experienced fatigue (93%), headache (91%), cough (72%), and mood disorders (87%). Two patients experienced bleeding disorders due to low platelets [e.g. bleeding gingivitis (101/nL), epistaxis (89/nL)] and one patient was taken off antiviral medication due to a significant drop of WBC (Table 3). One patient did not receive further treatment at wk 8 due to impaired vision, myalgia, and suicidal thoughts. None of the patient experiencing mood disorders required any psychopharmacological co-medication.

In patients with significant neutropenia, this side effect occurred mostly during wk 6 and 8 of therapy, after being treated with high dose CIFN for the first 8 wk. GM-CSF was not administered since low neutrophil count always returned to almost normal level in all patients by reducing daily CIFN dosing to 9  $\mu$ g daily according to the study protocol. Neither platelets nor blood transfusion was given in patients with low platelets due to CIFN or anemia due to ribavirin.

One severe adverse event occurred due to the relapse

Table 4 Questionnaire (Int. Quality of Life Assessment SF-36). Listed are those answers presenting the majority of possible answers (%)

	wk 0	wk 12
Personal feeling	Very good (76)	Good (63)
Personal feeling compared to last week	Good (77)	Better (55)
Impaired physical activity	Never (90)	Slightly (77)
Impaired physical activity compared to last week	Never (88)	Slightly (73)
Emotional problems	Never (93)	Never (48)
Pain	None (90)	None (30)
Pain last week	None (83)	None (54)
Feeling depressed	Never (88)	Seldom (45)
Feeling happy	Often (85)	Sometimes (50)
Feeling tired	Seldom (77)	Sometimes (51)
Impaired personal contact to relatives and friends due to disease	Never (88)	Seldom (71)

"I'm feeling healthy"	Mostly (78)	No (65)
"I expect not to feel healthy"	Do not know (44)	No (32)

of intravenous drug use followed by a lethal overdose injection. Five other patients took intravenous drugs as well and were immediately taken off the antiviral study drugs.

### International quality of life assessment

Because personal mental and physical components of health of a patient undergoing such an antiviral therapy is important, each patient was requested to answer a widely accepted questionnaire (IQOLA SF-36, German Acute version 1.0) with respect to the quality of life at wk 0 and 12.

There was a decrease in well being after 12 wk of therapy, but a significant number felt better after finishing the high induction treatment period. The physical activity in most patients was slightly impaired 3 mo after therapy (Table 4). There was a significant increase in emotional distress at wk 12 compared to wk 0, possibly due to CIFN. More patients experienced physical pain (70%), depression (50%), unhappiness (50%) and tiredness (51%) at wk 12, while personal contact to friends and relatives was not influenced by therapy (29%). Due to the side effects, fewer people (35%) felt healthy three months after the beginning of treatment and 68% did not feel healthy during the upcoming treatment phase.

## DISCUSSION

Chronic hepatitis C virus infection is responsible for an increase in morbidity and mortality. This is the first study on the treatment of naïve patients with chronic HCV infection with high-dosing of IFN- $\alpha$ 1a in combination with ribavirin. Recent intravenous drug addicts can be successfully treated for HCV and the response rates are as good as in patients without iv drug history.

The goal of our study was to address the issue of efficacy, tolerability and safety of daily high dose induction therapy with consensus-interferon (CIFN) and ribavirin in naïve HCV-infected patients. However, the usually recommended dosing of CIFN is 9  $\mu$ g, three times a week

at the beginning of the trial. Ribavirin was given on a daily basis at 800 mg, irrespective of the genotyping. Weight-based dosing of ribavirin for therapy in HCV genotypes 1 and 4 has been introduced after several studies were conducted in 2001<sup>[3]</sup>.

All patients received a higher dosage of interferon (18 µg of CIFN subcutaneously daily for up to 8 wk followed by 9 µg daily) in combination with ribavirin for 24 or 48 wk. The patients were then carefully followed up for an additional 24 wk.

The overall response rate was 62 % showing a sustained virological response (SVR) 24 wk after the EOT. There was a slight difference ( $P < 0.05$ ) in response rates in regard to the initial viral load. The patients with a low viral load ( $< 800,000$  IU/mL) responded better (70% *vs* 52%) than those with a high viral load. These results are comparable to data (54%) obtained with pegylated  $\alpha$ -2b/ribavirin<sup>[3]</sup>.

There was a significant difference ( $P < 0.01$ ) in response rates for the patients with a high viral load. With respect to genotyping, the patients with non-genotype 1 showed a SVR rate of 67% compared to 47% in the genotype 1 patients, even though the number of patients in the later group was quite small. In contrast, different response rates were obtained for HCV-infected patients presenting a low viral load initially. The non-genotype 1 patients showed a 64% SVR rate compared to 83% for the genotype 1-infected individuals. This fact might be explained by the small number of patients presenting genotype 1 and low-viral load. Overall, the patients with genotype 1 and high viral load showed an acceptable response rate, which is in accordance to Sjögren *et al*<sup>[11]</sup>, showing a higher response rate for this population treated with CIFN and ribavirin instead of pegylated interferon  $\alpha$ -2b and ribavirin (46% *vs* 14%).

In this treatment-naïve patient population, neither baseline ALT nor genotype was significantly associated with SVR, similar to other reports comparing treatment of non-responders with either CIFN or pegylated interferon  $\alpha$ -2b in combination with ribavirin<sup>[15]</sup>.

Adherence to therapy is another important issue for success of treatment<sup>[12]</sup>. Therapy with a wide range of side effects is less favourable and therefore less successful in achieving SVR. In our study, the overall adherence was good and comparable to previous studies<sup>[13]</sup>. It is known that HCV-1-infected patients maintained on  $> 80\%$  of their interferon or peginterferon  $\alpha$ -2b and ribavirin dosage for the duration of treatment have enhanced sustained response rates. In addition, some results suggest that adherence enhances the likelihood of achieving an initial virologic response<sup>[12]</sup>.

However, the rate of reuse of intravenous drugs in almost 10% of patients (6 out of 58 patients) is substantial and accounts partly for the high drop-out rate in our study even though former iv drug users had to be off active drug use for at least 6 mo prior to study enrolment.

The increased side effects in patients treated with CIFN at a high induction rate (18 µg *vs* 9 µg daily) can result in a higher drop out rate<sup>[14,15]</sup>. The initial rapid decline in viral load at wk 4 is counteracted by increased side effects, resulting in a lesser SVR rate, at least in non

responders<sup>[15]</sup>.

In conclusion, the safety and tolerability profile of this treatment is reasonable in a certain subset of patients, but might be difficult to tolerate in some individuals, resulting in discontinuation of therapy. However, these data suggest that CIFN may be safely combined with ribavirin and enhance the sustained response rate when close monitoring of side-effects and laboratory results are obeyed<sup>[10]</sup>. Patients with chronic hepatitis C and genotype 2 or 3 should be treated with pegylated interferon  $\alpha$ -2a or 2b in combination with ribavirin for up to 24 wk<sup>[16]</sup>, respectively. In difficult-to-treat patients with genotype 1 and high viral load, a daily therapy regimen with consensus interferon in combination with ribavirin might be of choice as well as in non-responders to combination therapy<sup>[15,17]</sup>.

This is the first study showing that recent iv drug users can be safely and successfully treated for HCV if they are closely monitored.

## Abstract

**AIM:** To compare rigid proctoscope and flexible endoscope for elastic band ligation of internal hemorrhoids.

**METHODS:** Patients between 18 and 80 years old, with chronic complaints (blood loss, pain, itching or prolapse) of internal hemorrhoids of grade I-III, were randomized to elastic band ligation by rigid proctoscope or flexible endoscope (preloaded with 7 bands). Patients were re-treated every 6 wk until the cessation of complaints. Evaluation by three-dimensional anal endosonography was performed.

**RESULTS:** Forty-one patients were included (median age 52.0, range 27-79 years, 20 men). Nineteen patients were treated with a rigid proctoscope and twenty two with a flexible endoscope. Twenty-nine patients had grade I hemorrhoids, 9 patients had grade II hemorrhoids and 3 patients had grade III hemorrhoids. All patients needed a minimum of 1 treatment and a maximum of 3 treatments. A median of 4.0 bands was used in the rigid proctoscope group and a median of 6.0 bands was used in the flexible endoscope group ( $P < 0.05$ ). Pain after ligation tended to be more frequent in patients treated with the flexible endoscope (first treatment: 3 vs 10 patients,  $P < 0.05$ ). Three-dimensional endosonography showed no sphincter defects or alterations in submucosal thickness.

**CONCLUSION:** Both techniques are easy to perform, well tolerated and have a good and fast effect. It is easier to perform more ligations with the flexible endoscope. Additional advantages of the flexible scope are the maneuverability and photographic documentation. However, treatment with the flexible endoscope might be more painful and is more expensive.

## INTRODUCTION

The initial treatment of symptomatic internal hemorrhoids is conservative and consists of a fiber enriched diet, increased fluid intake, prevention of straining and local hygiene, which may be combined with local anesthetic and antiphlogistic medication<sup>[1,2]</sup>. Over 90% of patients with symptomatic hemorrhoids can be treated conservatively or by rubber band ligation. Infrared coagulation and cryotherapy are also options, but are no longer commonly applied<sup>[3]</sup>. Surgery is reserved for the most severe cases. Since the early sixties the treatment of choice for persisting internal hemorrhoids is elastic band ligation by means of a rigid proctoscope (Barron ligation)<sup>[4,5]</sup>. Wroblewski *et al*<sup>[6]</sup> reported results of long term follow up (mean of 60 mo) of 266 patients; 80% had fewer symptoms and 69% had no symptoms. The procedure is usually safe and can be easily repeated<sup>[7]</sup>. Some studies evaluated the use of a flexible endoscope equipped with a ligation cap, normally used for ligation of esophageal varices, in treating hemorrhoids<sup>[8-11]</sup>. A flexible endoscope could have some advantages such as more maneuverability, a wider view and photographic documentation. The present prospective randomized trial was performed to compare both techniques in effectiveness. Additionally we used a three-dimensional endosonography to evaluate changes in the submucosa and sphincter defects.

## MATERIALS AND METHODS

Patients between 18 and 80 years old, with chronic complaints (blood loss, pain, itching or prolapse) of internal hemorrhoids grade I-III, were randomized by computer software to elastic band ligation by rigid proctoscope or gastroscope (Olympus Excera<sup>®</sup>). Patients were re-treated every 6 wk till the cessation of complaints.

The rigid proctoscope was gently introduced and then

Table 1 Patient characteristics and results

	Proctoscope	Gastroscope
<i>n</i>	19	22
Age [median (range)]	53 (27-75)	50.5 (33-79)
Male/Female	7/12	13/9
Hemorrhoids grade I	15	14
Hemorrhoids grade II	4	5
Hemorrhoids grade III	0	3
No of treatments [median (range)]	1.0 (1-3)	1.0 (1-3)
No of total ligations [median (range)]	4.0 (2-10)	6.0 (1-15) <sup>a</sup>
Pain after treatment	3	10 <sup>a</sup>
Cost	3 euro	150 euro

<sup>a</sup>*P* < 0.05 vs proctoscope.

elastic bands were applied using a standard elastic band applicator in antegrade fashion. For endoscopic ligation, a single-use multiband ligator device (Sevenshooter<sup>®</sup>, Boston Scientific, USA) was attached to the end of a gastroscope. The device can only be attached to a gastroscope. The Sevenshooter is provided with 7 bands. The hemorrhoids were suctioned into the ligation cap in either retrograde or antegrade fashion. The number of bands applied depended on the amount of hemorrhoidal tissue present. All treatments were performed in an outpatient setting.

A three-dimensional anal endosonography was made before the first treatment and 6 wk after the last treatment. Endosonography was performed, using a three dimensional diagnostic ultrasound system (Hawk type 2102, B-K Medical) with a 16 MHz rotating endoprobe (type 1850, focal range 2 to 4.5 cm) covered by a hard sonolucent cone (diameter 1.7 cm) filled with water, producing a 360° view. Three dimensional anal endosonography was performed according to a standard procedure. The endoprobe was covered with a lubricated condom which was filled with ultrasound gel. The probe was then introduced into the rectum and a recording was made of the distal part of the rectum, the puborectalis muscle and the anal canal. After the endosonography, images were reconstructed to three dimensional images by computer software. The Medical Ethical Committee granted approval for this study.

### Statistical analysis

Data are presented as a median with range. Differences between groups were assessed with a Mann-Whitney test, Chi square test or Fischer's exact test when appropriate. *P* < 0.05 was taken as significant.

## RESULTS

Detailed demographic and clinical data are shown in Table 1. Forty-one patients (median age 52, range 27-79 years, 20 men) with recurrent rectal bleeding, pain, itching or prolapse underwent ligation. Nobody had been treated previously. All procedures were easy to perform. Sometimes, in patients treated with the flexible endoscope, a rectal enema was needed when the rectum was not clean.

Nineteen patients were treated with a rigid proctoscope and twenty two with a flexible endoscope. Twenty-nine, 9, and 3 patients had grade I, II and III hemorrhoids,

Figure 1 Picture showing the retroflexed endoscopic view after ligation.

respectively.

Patients treated with a proctoscope needed a median of 1 treatment (range 1-3) and patients treated with an endoscope also needed a median of 1 treatment (range 1-3, *P* = 0.664).

A median of 4 bands (range 2-10) was used in the rigid proctoscope group and a median of 6 bands (range 1-15) was used in the flexible endoscope group (*P* < 0.05) (Figure 1).

In the group treated with a rigid proctoscope, 5 patients needed 1 re-treatment and 1 patient needed 2 re-treatments. In the group treated with a flexible endoscope, 2 patients needed 1 re-treatment and 1 patient needed 2 re-treatments.

**Two patients were excluded from follow up:** One patient had a rupture of an abdominal aortic aneurysm and 1 patient developed an anal fissure.

Pain after ligation was more frequent in patients treated with the flexible endoscope (first treatment: 3 vs 10 patients, *P* < 0.05). The single-use ligation device (Sevenshooter<sup>®</sup>) costs approximately 150 euro for one set (2005). One elastic band for the rigid proctoscope costs approximately 0.50 euro. Further costs (cleaning of the gastroscope and proctoscope, personnel costs) did not substantially differ between both techniques.

With three-dimensional endosonography 30 patients were evaluated before and after treatment. Hemorrhoidal tissue was clearly visible in all patients. No sphincter defects were found before and after treatment and there was no significant change in submucosa thickness after endoscopic/proctoscopic treatment (Figure 2). After one year follow up, 5 patients needed re-treatment (2 proctoscope, 3 gastroscope).

## DISCUSSION

Hemorrhoids are a major health problem; the community-wide prevalence in the Western World is reported to be around 4%. Adequate intake of fluids and fiber, use of suppositories, stool softeners and topical creams are important in the treatment of hemorrhoids, especially in grade I disease. When conservative treatment fails, there are still options, including surgical therapy.

Rubber band ligation with a proctoscope is very effective and inexpensive. Since 2005, it has been the treatment of choice. Studies have been undertaken investigating effectiveness and new techniques<sup>[12-14]</sup>.

There have been 4 studies that analyzed the use of

**Figure 2** Endosonographic image showing thickening of the submucosa. IAS: Internal anal sphincter; EAS: External anal sphincter; SM: Submucosa (hypoechoic area is hemorrhoidal).

a flexible endoscope for hemorrhoidal elastic band ligation<sup>[8-11]</sup>. These studies conclude that it is a safe and efficient method with some advantages, although costs are still a major drawback. Only one study compared endoscopic band ligation (reusable) with the conventional rubber band ligation through a rigid proctoscope<sup>[10]</sup>.

In our pilot study we found that both techniques were easy to perform, well tolerated and had a good and fast effect. It was easier to perform more ligations with the flexible endoscope. No serious adverse events were reported. Additional advantages of the flexible scope were the maneuverability and photographic documentation.

However, treatment with the flexible endoscope seemed to be more painful and was more expensive. More pain sensation can be explained by the learning curve we had to deal with and that more bands could be applied. In contrast, Wehrmann *et al.*<sup>[10]</sup> found no significant difference in pain and reported that the total number of bands applied was significantly lower in the group treated with the endoscope.

So far as we know, this is the first study that evaluated with three-dimensional endosonography the presence of possible sphincter defects and changes in the submucosa. Poen *et al.*<sup>[15]</sup> already found, with two-dimensional endosonography, no difference in appearance of the anal configuration after treatment with either rubber band ligation or infrared coagulation. In our study no significant alterations or sphincter defects were found and these endosonographic findings confirmed that band ligation is a safe technique.

When costs can be reduced the endoscopic treatment of hemorrhoids can be a good alternative for ligation with the rigid proctoscope.

In summary, endoscopic ligation is an effective, safe

treatment and is comparable with proctoscopic ligation. However, the treatment is more expensive.

## Abstract

**AIM:** To study the effect of some genes especially those involved in cell cycle regulation on hepatocellular carcinoma.

**METHODS:** Paraffin-embedded tissue samples of 25 patients (18 males and 7 females) with hepatocellular carcinoma were collected from 22 pathology centers in Tehran during 2000-2001, and stained using immunohistochemistry method (avidin-biotin-peroxidase) for detection of p53, cyclinD1, RB1, c-fos and N-ras proteins.

**RESULTS:** Six (24%), 5 (20%), 12 (48%) and 2 samples (8%) were positive for p53, cyclinD1, C-fos and N-ras expression, respectively. Twenty-two (88%) samples had alterations in the G1 cell-cycle checkpoint protein expression (RB1 or cyclinD1). P53 positive samples showed a higher (9 times) risk of being positive for RB1 protein than p53 negative samples. Loss of expression of RB1 in association with p53 over-expression was observed in 4 (66.7%) of 6 samples. Loss of expression of RB1 was seen in all cyclinD1 positive, 20 (90.9%) N-ras negative, and 11 (50%) C-fos positive samples, respectively. CyclinD1 positive samples showed a higher (2.85 and 4.75 times) risk of being positive for c-fos and N-ras expression than cyclinD1 negative samples.

**CONCLUSION:** The expression of p53, RB1 and c-fos genes appears to have a key role in the pathogenesis of hepatocellular carcinoma in Iran. Simultaneous overexpression of these genes is significantly associated with their loss of expression during development of hepatocellular carcinoma.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the most common primary malignant tumor of the liver and the fourth most common cause of cancer-related death in the world<sup>[1]</sup>. Male predominance is, however, more obvious in populations at high risk of developing this tumor (mean ratio 3.7:1.0) than in those at low or intermediate risk (2.4:1.0)<sup>[2]</sup>.

HCC has a heterogeneous geographical distribution. Countries or regions with the highest incidence (50-120 cases per 100 000 population per year) include China, Taiwan, Korea and other Southeast Asian countries, as well as Sub-Saharan Africa. HCC is linked to environmental, dietary, and lifestyle factors, so that its incidence and distribution vary widely among ethnic groups, geographic regions, and the two sexes<sup>[3]</sup>. Tumor suppressor genes such as RB1 and p53 may play a significant part in hepatocarcinogenesis<sup>[3]</sup>. As a favorable background for neoplastic transformation, cirrhosis is expected to harbor early genetic changes, but very few studies have been conducted thus far to address this issue. Ashida *et al*<sup>[4]</sup> have reported in both HCC and adjacent cirrhosis a 60% rate of loss of heterozygosity (LOH) at 13q, the site of the RB1 gene. The loss of heterozygosity and abnormalities in structure and function of the p53 gene are also frequently found in HCC patients<sup>[5]</sup>. A specific p53 mutation is found in more than 50% of HCC patients from India, China and South Africa, where dietary aflatoxins are suspected to be the major liver specific carcinogens<sup>[5-11]</sup>. However, it occurs less frequently in Western countries<sup>[3,5]</sup>. Activation of oncogenes of the "ras" family and others has been detected during chemically induced HCC in rodents, but there is little evidence of such activation in human tumors<sup>[12]</sup>. CyclinD1 over-expression may be an early event in hepatocarcinogenesis and plays a role in tumor differentiation<sup>[13]</sup>. Yuen *et al*<sup>[14]</sup> reported that the expression of c-fos is significantly higher in tumor tissue than in non-

tumor tissue. Specific mutations of the p53, cyclinD1, RB1, c-fos, and N-ras genes and their expression in HCC have been reported from several parts of the world, but to the authors' knowledge to date, the expression status of these genes has not been studied in HCC patients in Iran, where the frequency of chronic hepatitis B and C virus infection as well as exposure to dietary aflatoxin is very high<sup>[15]</sup>.

## MATERIALS AND METHODS

### Sample collection

Formalin-fixed and paraffin-embedded tissue samples of 25 patients (18 males and 7 females) with documented HCC (surgically resected material or biopsy) were provided for analysis. The samples were collected from 22 pathology centers in Tehran during 2000-2001. The study was approved by the Medical Ethics Committee, Ministry of Health, Iran, as conforming to the ethical guidelines of the 1975 Declaration of Helsinki. Hospital records were used to verify age, sex and other demographic items.

### Tissue preparation

These samples were sectioned and stained with hematoxylin and eosin (HE). Diagnosis of HCC was confirmed and the grade of tumor was determined according to the criteria proposed by the World Health Organization by the collaborating pathologist in Research Center for Gastroenterology and Liver Disease.

HCC was considered to be adequate for immunohistochemical study only if the block was of adequate size (surface area of section > 4 cm<sup>2</sup> and > 10% of the surface area of the block was occupied by the tumor).

### Immunostaining

The technique was based on avidin-biotin-peroxidase method using 10% formaldehyde-fixed and paraffin-embedded sections. The selected paraffin blocks were cut into 5 µm-thick sections. The sections were applied to precoated glass slides to avoid becoming detached, then dried at 37°C overnight followed by drying at 56°C for 60 min, deparaffinized with xylene and rehydrated through graded concentrations of alcohol. Antigen retrieval was performed by 3 × 5-min cycles of microwave oven heating (750W) at 100°C in 0.01 mol/L citrate buffer at pH 6. After washing and rinsing with Tris-buffered saline (TBS, 0.05 M, pH 7.2-7.6), endogenous-peroxidase activity was blocked with 3% hydrogen peroxide for 10 min at room temperature and then rinsed with distilled water. Subsequently, sections were treated for 10 min with 10% bovine serum albumin (BSA) at room temperature for blocking nonspecific background staining. Afterward, primary monoclonal mouse antihuman-p53 protein, clone DO-7, isotype IgG2bkappa (DAKO, Lot 108) at dilution 1:100, primary monoclonal mouse antihuman-RB1 gene product, clone RB1, isotype IgG1kappa (DAKO, Lot 019) at dilution 1:50, primary monoclonal mouse antihuman-cyclinD1, clone DCS-6, isotype IgG2a kappa (DAKO, Lot 012) at dilution 1:50, primary monoclonal mouse antihuman-c-fos, clone D-1, isotype IgG2b (Santa

Cruz Biotechnology Inc., Lot J 251) at dilution 1:100 and primary monoclonal mouse antihuman-N-ras, clone F155, isotype IgG1 (Santa Cruz Biotechnology Inc., Lot I 251) at dilution 1:100 were added and incubated in a moist chamber overnight at 4°C. The sections were again washed three times in TBS for 5 min using the DAKO LSAB2 system (Universal, HRP, Lot 10106). Goat anti-mouse and anti-rabbit biotinylated IgG (diluted in PBS containing carrier protein and 0.015 mol/L sodium azide) and preincubated streptavidin conjugated to horseradish peroxidase (diluted in PBS containing carrier protein and anti-microbial agents) were added for 30 min at room temperature. The sections were washed in TBS as before and then developed in prepared 3-amino-9-ethylcarbazole substrate chromogen (AEC/H<sub>2</sub>O<sub>2</sub>) for p53 and RB1 and in prepared 3,3'-diaminobenzidine chromogen solution (DAB/H<sub>2</sub>O<sub>2</sub>) for cyclinD1, c-fos and N-ras for 10 min at room temperature. The sections were then washed in water, counterstained with Mayer's hematoxylin for 2-5 min at room temperature, dehydrated, cleared with 37 mmol/L ammonia water, rinsed in a bath of distilled water for 2-5 min, finally mounted and coverslipped with Faramount aqueous-based mounting medium (DAKO, Lot 00029). A section of the same tumor incubated in BSA instead of the primary antibody was included as the negative control. We used one standard p53 positive section of human SCC (DAKO, Lot 071-1), one known RB1 negative retinoblastoma section, one known cyclin D1 positive breast tumor section, one known c-fos positive astrocytoma section and one known N-ras positive lymphoma section as a positive control for each staining.

### Assessment of immunostaining

Staining of p53, RB1, cyclinD1, c-fos and N-ras genes was examined at high power fields (× 400) under a standard light microscope. Nuclear staining was regarded as positive if there was homogeneous staining or > 10% of the cancer cells were heterogeneously stained.

### Statistical analysis

The results were expressed as frequency for gene expression changes and odds ratio for association between expression changes of these five genes. All statistical tests were performed with the Program Statistical Package for the Social Sciences (SPSS version 11, Chicago, IL).

## RESULTS

The mean ± SD age of our patients was 60.56 ± 12.52 years and the highest frequency (44%) was seen in the sixth decade of life. Male to female ratio was 2.57 (18 males and 7 females) and mean ± SD age of patients in each sex was 62.72 ± 10.43 years and 55 ± 16.4 years, respectively.

### Histopathology

All the 25 samples were well differentiated (grade I).

### Accumulation of p53, RB1, cyclinD1, c-fos and N-ras proteins

Intense immunostaining of p53, RB1, cyclinD1, c-fos and

Table 1 Expression of p53 gene in relation to the expression of RB1, cyclinD1, c-fos and N-ras genes, *n* (%)

Gene expression	RB1		Cyclin-D1		c-fos		N-ras	
	Positive	Negative	Positive	Negative	Positive	Negative	Positive	Negative
P53 positive	2 (33.3)	4 (66.7)	2 (33.3)	4 (66.7)	4 (66.7)	2 (33.3)	1 (16.75)	5 (83.3)
P53 negative	1 (5.3)	18 (94.7)	3 (15.8)	16 (84.2)	8 (42.1)	11 (57.9)	1 (5.3)	18 (94.7)
	OR: 0.1, 95% CI: 0.0-1.5		OR: 2.6, 95% CI: 0.3-21.7		OR: 2.7, 95% CI: 0.4-18.8		OR: 3.6, 95% CI: 0.1-68.3	

Table 2 RB1 gene expression in relation to the expression of c-fos and N-ras genes, *n* (%)

Gene expression	c-fos		N-ras	
	Positive	Negative	Positive	Negative
RB1 positive	1 (33.3)	2 (66.7)	0	3 (100)
RB1 negative	11 (50)	11 (50)	2 (9.1)	20 (90.9)
	OR: 0.5, 95% CI: 0.0-6.3		OR: 1.1, 95% CI: 0.9-1.2	

Table 3 G1 checkpoint protein expression in relation to p53, *n* (%)

Expression pattern of G1 checkpoint proteins	P53 (+)	P53 (-)	<i>P</i>
Rb+/cyclinD1+	Zero	Zero	0.02
Rb-/cyclinD1+	2 (40)	3 (60)	
Rb-/cyclinD1-	2 (11.8)	15 (88.2)	
Subtotal	4 (66.6)	18 (94.7)	
Rb+/cyclin D1-	2 (66.7)	1 (33.3)	
Total	6 (24)	19 (76)	

N-ras proteins was observed in the cell nuclei of tissues. Overall, six (24%) samples showed nuclear accumulation of p53 protein in varying proportions of tumor cells, the rest of the samples (76%) were negative. Twenty-two (88%) samples showed complete loss of RB1 protein expression in the primary tumor, the rest of the tumors (12%) displayed variable proportions of RB1 protein positive tumor cells. The intensity and subcellular location of the staining in the tumor were similar to those observed in the normal epithelia. We detected high levels of cyclinD1 protein in 5 (20%) samples while 20 (80%) samples were negative for cyclinD1 expression. The frequency of c-fos and N-ras positive staining was 48% (12 samples) and 8% (2 samples), respectively. The expression of p53 gene in relation to the expression of RB1, cyclinD1, c-fos and N-ras genes is depicted in Table 1. The RB1 gene expression in relation to the expression of c-fos and N-ras genes is shown in Table 2. Of those samples positive for the c-fos gene, 1 (8.3%) was N-ras positive and 11 (91.7%) were N-ras negative. On the other hand, among the c-fos negative samples, 1 (7.7%) was N-ras positive and 12 (92.3%) were N-ras negative.

When overexpression of p53 was seen, loss of expression of RB1 was found in 4 (66.7%) samples. Loss of expression of RB1 was observed in all those with positive cyclinD1 (5 samples), while expression of RB1 was found in 17 (85%) with negative cyclinD1, and in 3 (15%) samples with positive RB1. CyclinD1 positive samples showed a higher risk of being positive for C-fos and N-ras (2.85 and 4.75 times, respectively) than cyclinD1 negative samples. Finally, loss of expression of RB1 was detected in 2 samples with overexpression of N-ras. On the other hand, among the samples with loss of expression of RB1, overexpression of c-fos was found in 11 (50%).

Overall, 22/25 (88%) samples had alterations in the G1 cell-cycle checkpoint proteins, as assessed by means of cyclinD1 and RB1 expression (Table 3). These occurred in 4 (66.6%) of 6 p53-positive samples and in 18 (94.7%) of 19 p53-negative samples. P53-negative samples showed absence of the RB1 protein more frequently. P53 positive samples showed a higher (9 times) risk of being positive

for RB1 than p53 negative samples, being 3.6, 2.75, and 2.66 for N-ras, c-fos, and cyclinD1, respectively. In samples with cyclinD1 positive staining, the risk of being positive for N-ras was 4.75 times higher in samples with cyclinD1 positive staining than in samples with negative cyclinD1 staining for this protein.

## DISCUSSION

Several oncogenic pathways have been implicated in malignant transformation of liver cells. Inactivation of the p53 tumor suppressor gene by mutations and allelic deletions in about 30% of HCC cases has been associated predominantly with exposure to aflatoxin B1 and hepatitis B virus infection<sup>[16]</sup>. Activation of cyclinD1, c-fos and N-ras and disruption of the RB1 pathway are also commonly involved in liver tumorigenesis. New major challenges include the identification of candidate genes located in frequently altered chromosomal regions and oncogenic pathways driven by different risk factors. Deranged expression of cell cycle modulators has been reported to contribute to the development and progression of HCC<sup>[17]</sup>. In human HCC, high frequencies of aberration have been detected in the p53 and RB1 genes<sup>[14]</sup>. Mutations of the p53 tumor suppressor gene have been reported to occur with varying frequency in different geographic regions, which might be a different etiology for HCC<sup>[18]</sup>. In our study, nuclear accumulation of p53 protein was seen in 24% of samples. Mutations of this gene have been identified in 30%-50% of HCC patients in some geographic areas<sup>[19]</sup>. An *et al*<sup>[20]</sup> reported that there is histological heterogeneity in established HCC, which is accompanied with increased proliferative activity and p53 overexpression. Overexpression of p53 has identified in 37.5% of Japanese HCC patients and 62.5% of Indonesian HCC patients<sup>[18]</sup>. Recently, Ming *et al*<sup>[21]</sup> also showed that the frequency of mutation of p53 gene is much higher in high prevalent HCC area than in the low-risk HCC area in China. More than 95% cancer specimens

exhibit strong intranuclear accumulation of p53 protein, which can be detected by immunohistology. However, Biersing *et al*<sup>[22]</sup> and Vesey<sup>[23]</sup> have found little or no point mutations of p53 gene in human hepatocarcinoma in Swedish and Australian patients. Therefore overexpression of p53 protein in hepatocarcinoma specimens can be used as the mutant p53 biopathological marker in tumor tissues. Qin *et al*<sup>[8]</sup> reported that accumulation of p53 is a valuable marker for predicting the prognosis of HCC patients. Lin GY *et al*<sup>[7]</sup> reported that inactivation of the tumor suppressor genes p53 and RB1 has been demonstrated in different forms, and implies the pathogenesis of human malignant diseases. The study of Kondoh *et al*<sup>[24]</sup> supports the idea that deletion or inactivation of tumor suppressors including RB1, p53 and other candidate genes seems to be common events in HCC development. Abnormalities of the RB1 tumor suppressor gene have been found in 20%-25% of HCCs, including 80%-86% of HCCs with p53 mutations<sup>[19]</sup>. Nishida *et al*<sup>[25]</sup> reported that RB1 protein is positive in 85.6% of HCC cases but is not related to any clinicopathological parameters. Positive immunostaining for RB1 and mutant p53 protein is detectable in 58% and 37% of HCCs, respectively<sup>[26]</sup>. Loss of expression of RB1 in HCC has been reported in several studies<sup>[21,27]</sup>. In this study, loss of expression of RB1 gene was found in 88% of samples. The proto-oncogene c-fos is involved in cell cycle progression and cellular proliferation<sup>[14]</sup>. Abuthnot *et al*<sup>[28]</sup> reported that c-myc and c-fos mRNA, as well as their protein products, are increased in human liver cancers. Wang *et al*<sup>[29]</sup> have also found an apparently higher expression of N-ras and c-fos in human hepatoma than in its adjacent liver tissue. Recently, Feng *et al*<sup>[30,31]</sup> reported that the positive rates and signal intensity of c-fos and some other proteins in HCC are significantly higher than those in pericarcinomatous tissues. Yuen *et al*<sup>[14]</sup> found that the expression of c-fos was significantly higher in tumor tissue than in nontumor tissue (91% *vs* 0%,  $P < 0.0001$ ). C-fos primarily induces cyclinD1 up-regulation by a mediator called MAPK/ERK<sup>[32]</sup>. In our study, the expression of c-fos gene was detected in 48% of patients with documented HCC. There was no significant relationship between c-fos and Cyclin-D1 expressions. Aflatoxin B1 may evoke an intense and prolonged expression of c-fos, including persistent signals for regeneration, which in turn may activate the replication of immature cells<sup>[33]</sup>. CyclinD1 is frequently overexpressed in a variety of cancers, including HCC, as a result of gene amplification. Overexpression of cyclinD1 protein, through gene amplification, correlates with poor prognosis of several cancers, but its role in HCC is the subject of controversy. Increased expression of cyclinD1 may play an important role in the development of HCC owing to the perturbation of normal control of the cell cycle<sup>[34]</sup>. On the other hand, Azechi *et al*<sup>[35]</sup> reported that cyclinD1 is a known oncogene and a key regulator of cell cycle progression. Amplification of the cyclinD1 gene and its overexpression are associated with aggressive forms of HCC. Overexpression of cyclinD1 is sufficient to initiate hepatocellular carcinogenesis. Choi *et al*<sup>[17]</sup> and Deane *et al*<sup>[36]</sup> have found a positive relationship between cyclinD1 overexpression and advanced tumor stage and aberrant

p53 expression in HCC ( $P < 0.05$ ). Joo *et al*<sup>[13]</sup> reported that cyclinD1 overexpression may confer additional growth advantages to the tumor in addition to protein RB1 inactivation in HCC. On the contrary, Sato *et al*<sup>[37]</sup> have found no significant relationship between the expressions of cyclinD1 and p53. Ito *et al*<sup>[38]</sup> conducted a simultaneous immunohistochemical study with p53 and cyclinD1 antibody in the same series of HCC and revealed that 88% of the patients positive for cyclinD1 also expressed p53 and 91% of the patients negative for p53 did not express cyclinD1, suggesting that cyclinD1 is expressed later than the alteration of p53 in the progression of human HCC. In our study, cyclinD1 was positively related to aberrant p53 expression. In HCC, N-ras was first proved as one of the transforming genes<sup>[39]</sup>, which belongs to the G protein family. When it is converted to an active oncogene by point mutation, chromosome rearrangement or gene amplification, the signal transmission of cell membranes may change, which drives cell division, leading to abnormal differentiation and formation of neoplasm. Cerruti<sup>[40]</sup> and Tada<sup>[41]</sup> reported that the mutagenesis of a proto-oncogene from "ras" family and p53 tumor suppressor gene might be the most important event in HCC. Tabor<sup>[19]</sup> reported that overexpression of oncogenes N-ras and c-fos has been found in high percentages of HCC patients. Imai *et al*<sup>[42]</sup> and Tamano *et al*<sup>[43]</sup> found that mutations of ras oncogene may be the early events, and the expression in tumor or non-tumor tissues can be detected with different rates. Luo *et al*<sup>[26]</sup> reported that N-ras and p53 genes might be involved in the carcinogenesis and development of HCC. They also showed that mutation of the tumor suppressor gene p53 can convert ras gene into oncogene. In their study, 38% of HCCs with N-ras gene mutation did not express p53 protein, indicating that some other genes or factors may participate in the carcinogenesis and development of HCC. In our study, 83% of p53 positive samples did not show N-ras mutation. Chao *et al*<sup>[9]</sup> suggested that activation of the ras gene might not be a major event in aflatoxin-related human hepatocarcinogenesis. This hypothesis is supported by another study<sup>[44]</sup> conducted in southern Africa on Blacks, where dietary exposure to aflatoxin is a risk factor.

In conclusion, as in other parts of the world, the change in expression pattern of these genes especially p53, RB1 and c-fos, appears to have a key role in the pathogenesis of HCC in Iran. There is likely a relation between the simultaneous changes in these genes during development of HCC. This research might shed some light on the carcinogenic role of the expression of p53, RB1, cyclinD1, c-fos and N-ras genes. Besides, in order to understand the exact role of these changes in development of HCC, further studies with a larger number of samples are essential.

### Abstract

**AIM:** To investigate some possible etiologies of achalasia by screening patients with achalasia for some autoimmune diseases such as thyroid disease.

**METHODS:** We examined 30 known cases of achalasia (20 females, 10 males). Their age ranged 15-70 years. All of them were referred to our institute for treatment. Their sera were evaluated to detect some possible associations with rheumatoid disease, thyroid disease, inflammatory process, anemia, etc.

**RESULTS:** Seven out of 30 patients (23%) had thyroid disease including four patients with hypothyroidism (13.3%), two patients with hyperthyroidism (6.6%), and one had only thyroid nodule but was in euthyroid state (3.3%). Two of these hypothyroid patients had no related clinical symptoms (subclinical) and two had clinical manifestations of hypothyroidism. There were no correlations between the intensity of thyroid diseases and the severity of achalasia symptoms.

**CONCLUSION:** The etiology of achalasia is unknown although autoimmunity has been implicated and is supported by several studies. Thyroid disease presents concomitantly with achalasia in about one fourth of our patients who may have a common etiology.

### INTRODUCTION

Achalasia is a common and well characterized primary motility disorder of the esophageal body and lower esophageal sphincter (LES), causing impaired progressive peristalsis in the esophageal body, incomplete relaxation of LES during swallowing, and sometimes increased abnormal relaxation of the LES pressure. Previous studies evaluating esophagomyotomy and esophageal resection specimens have shown that the presence of myenteric inflammation is a consistent and early pathologic change in patients with achalasia<sup>[1,2]</sup>. The disorder is observed in both genders primarily in the fifth and sixth decades of life, although achalasia can present at any age<sup>[3,4]</sup>. The cause of the degeneration of neurons in achalasia is not known. The observations that achalasia is associated with HLA-DQw1 and that affected patients often have circulating antibodies to enteric neurons suggest that achalasia may be an autoimmune disorder<sup>[5-7]</sup>. Nonspecific degeneration of smooth muscle cells and a loss of small nerve fibers have been reported<sup>[8-10]</sup>. Another controversial issue is the role of inflammatory infiltrates in the pathogenesis of the disease. A study has suggested that complement activation is involved in the autoimmune pathogenesis of achalasia<sup>[11]</sup>. Achalasia is associated with extra esophageal autonomic nervous dysfunction that involves cardiovascular and papillary function as well as regulation of mesenteric arterial blood flow<sup>[12]</sup>. Some investigators have proposed that achalasia may result from chronic infections with herpes zoster or measles viruses, but modern studies have not confirmed an association between achalasia and any recognized viral disease<sup>[13,14]</sup>. However, a recent study also showed that there is no association between the most common viruses and achalasia<sup>[14]</sup>. As myenteric neurons synthesizing nitric oxide are responsible for the inhibitory component of esophageal peristalsis and LES relaxation, it is considered likely that these neurons are involved in this disease<sup>[15,16]</sup>.

Since there is no consistent single abnormality in achalasia, this study was designed to evaluate the relationship between achalasia and some of the commonest autoimmune diseases.

### MATERIALS AND METHODS

#### Patients

All 42 newly diagnosed patients referred between 2001 and 2005 to our research center (Poursina Hakim Research Institution, Gastroenterology Division, Isfahan, Iran) were examined prospectively and enrolled in the study. Poursina

Hakim Institution is a reference tertiary care center that services a population of about 4 000 000 individuals in the central area of Iran. Of the 42 enrolled cases in the study based on clinical and radiological findings, 6 patients with pseudoachalasia but without endoscopic features of achalasia were excluded due to non-compliance (one case) or some other reasons such as loss of follow-up due to changing their address or phone number, immigration to other provinces and admission by other physicians far from our institution. Finally 30 cases were included. Their symptoms, laboratory results, and historical and functional data were recorded. Achalasia was defined by clinical criteria, namely prolonged (more than 1 year) intermittent or progressive dysphagia to liquids and solids in addition to some other minor symptoms such as regurgitation, chest pain and nocturnal cough plus barium swallow with a typical beak like appearance. We obtained posterior-anterior chest x ray radiographies at 1, 5, and 20 min after a single barium meal to assess barium column and measure its heights and widths as well as the delay time of esophageal clearance (timed barium swallow). Upper gastrointestinal endoscopy was done to confirm the diagnosis and to rule out secondary achalasia (such as esophageal tumors of cardia and fundus, submucosal tumor of distal esophagus, peptic stricture and other mucosal or infiltrative lesions of the esophagus or gastric cardia). Endoscopic findings suggestive of achalasia may be seen and are very helpful if endoscopy is done carefully by experts in this field. Some of the suggestive criteria for achalasia are as following: esophageal dilation, esophageal dysmotility or aperistalsis in response to air insufflations, abnormal LES opening and high pressure LES during scope passage. Manometry although very helpful especially in early stages of the disease, was not available in our province at the time of the study, so it was not done for most of them.

Exclusion criteria included those found to have an underlying malignancy during the study, any types of generalized neuropathies, diabetes mellitus, non-compliance or unwillingness of patients to continue the study, and finally those lost to follow up by any reason.

The patients' history was taken using a structured questionnaire. We interviewed, examined and completed a questionnaire designed to detect possibility of connective tissue and autoimmune diseases, other gastrointestinal motility disorders, diabetes mellitus, use of immunosuppressive medications, chronic viral illnesses, thyroid problems, usage of a regular immunosuppressive medication and also habits and addictions for all patients. Informed consent was obtained from all patients. None of the patients underwent surgical therapy.

### Laboratory methods

After diagnosis of achalasia, all patients were screened for a set of selected autoimmune disease and other markers as shown in Table 1. Serum factors were evaluated by biochemical techniques. A double check of laboratory tests was conducted by a second laboratory to assure validity of abnormal results. Equivocal laboratory results were rechecked by a reference laboratory.

### Symptoms

Clinical data regarding symptoms of dysphagia,

Table 1 Test and methods used in this study

Test title	Kit	Manufactured country
Anti nuclear anti body (ANA)	Biostems	Spain
Antineutrophil cytoplasm antibody (c-ANCA)	Binding site	England
Calcium	Man	Iran
Phosphorus	Man	Iran
Alkaline phosphatase	Man	Iran
Thyroid stimulating hormone(TSH)	Isfahan pharmacology faculty	Iran
T3 Resin uptake	kavoshiar	Iran
T3, T4	Isfahan pharmacology faculty	Iran
Albumin	Man	Iran
Globulin	Man	Iran
Rapid plasmin reagin (RPR)	Anison	Iran
Urine analysis	Combi	Germany
Complete blood count	-	Germany

All tests except for urine analysis were performed on blood or serum samples.

regurgitation, and chest pain, nocturnal cough and pyrosis were collected by means of a validated questionnaire. Dysphagia was described as difficulty in swallowing, and regurgitation as the sensation of stomach contents going up the esophagus. The frequency of each symptom was graded on a scale ranging from 0 to 5 (0 = none, 1 = once per month or less, 2 = once per week up to three to four times a month, 3 = two to four times per week, 4 = once per day, 5 = several times per day). This scoring system is similar, but with some modifications, to that used by Eckardt *et al.*<sup>[17]</sup> and modified by Vaezi *et al.*<sup>[18]</sup>.

### Statistical analysis

For comparison between patients with achalasia and normal population, Student's *t*-test assuming equal variance was used. In addition, we analyzed the symptoms using the non-parametric Mann-Whitney test, because the data were not normally distributed.

## RESULTS

Of the 42 newly suspected achalasia patients referred to our institution, 36 (11 men and 25 women) fulfilled the participating criteria in the study, but only 30 (20 females, 10 males) finished the study. The remaining six patients were statistically similar by age and gender to the 30 cases and they had no unusual reason for their loss of follow-up.

### Thyroid disease

Of the 30 patients, 7 had thyroid disease (23.7%), 4 had hypothyroidism (13.3%), 2 had hyperthyroidism (6.7%) and one (3.3%) had only a thyroid nodule in euthyroid state. Two of these hypothyroidism patients had no related clinical symptoms (subclinical) and two had clinical manifestations of hypothyroidism. Both patients with subclinical hypothyroidism were diagnosed in our

Table 2 Average score of all patients and those suffering from thyroid disease respectively (mean  $\pm$  SD)

	Patients with hypothyroidism	Patients with benign thyroid diseases <sup>1</sup>	Patients without thyroid problems	Mean score of all patients
Age	39.5 $\pm$ 14.3 <sup>a</sup>	35.8 <sup>b</sup> $\pm$ 11.9 <sup>b</sup>	38.5 $\pm$ 18.1	37.9 $\pm$ 16.7

Ethnicity <sup>2</sup>	F: 3 B: 1	F: 75 B: 25	F: 5 B: 2	F: 71 B: 28	F: 16 B: 5	F: 69 B: 21	F: 21 B: 7	F: 70 B: 23

<sup>1</sup>Composed of thyroid nodules, hypothyroidism and hyperthyroidism. <sup>2</sup>Composed of the most common ethnicity in patients, F: Fars; B: Bakhtiari.

screening. One patient experienced hypothyroid shock after balloon dilation therapy (cool skin, hypothermia, hypotension and bradycardia not responsive to volume expansion and intravenous atropine injection). She had clinical symptoms of hypothyroidism which was not detected before balloon dilation therapy. The results of laboratory tests are listed in Table 2.

### Patients' ethnicity

There were 21 (70%) Fars (the major Persian ethnicity), 7 Bakhtiari, an Iranian tribe, living in west of Isfahan Province) (23%), one Gilaki (another group of Iranians originating from northern Iran) (3.3%), and one patient was Turkish inhabitant in the central area of Iran (3.3. 0%).

### Age and symptoms

The median age of onset of symptoms was 37 years (range 15-80 years). The mean age of patients with thyroid disease and other patients with achalasia was 35.8 and 38.5 years (*P*: 0.9). All patients complained of dysphagia to both liquids and solids. Regurgitation, weight loss, chest discomfort and heartburn were reported in 28 (93.3%), 18 (60%), 15 (50%) and 8 (26.6%) patients, respectively.

The symptoms of patients were compared (Table 2). Correlations between the intensity of thyroid disease and the severity of achalasia symptoms were statistically insignificant by Mann-Whitney test.

### Prevalence and incidence of achalasia

In 2002 -2005, 42 cases of suspected achalasia were identified in or referred to our center. Of these, 19 were

residents of Isfahan during the period of the study. The population of Isfahan was about 4 million in 2006. The overall ethnic- and gender-specific incidences of achalasia in our cases are shown in Table 3. No strong history of rheumatic disease or neuropathy in patients and their family was detected in our study.

### Serological study

All serum samples were evaluated with sensitive tests for autoimmune diseases but we did not find any positive test except for 2 positive anti nuclear antibody tests (6.6%). Evaluation for vasculitis, some electrolyte disturbances, and anemia did not show any important finding (Table 4).

## DISCUSSION

Although achalasia is a historically recognized clinical entity, its fundamental pathophysiology remains poorly understood. Primary achalasia accounts for the majority of cases. The etiology of primary achalasia is not entirely clear and probably multidimensional<sup>[19]</sup> including genetic predisposition (supported by the concordance for the disease in monozygotic twins<sup>[20]</sup> and associations with some HLA loci<sup>[7]</sup>), inflammation (myopathy of the smooth muscle cells<sup>[21]</sup>, neuropathy<sup>[22,23]</sup> and inflammatory changes in esophageal specimens<sup>[24]</sup>), infections (virus<sup>[14]</sup>, Chagas' disease, poliomyelitis<sup>[25,26]</sup>, varicella zoster virus<sup>[27]</sup> and Helicobacter<sup>[28]</sup>), ischemia, toxicity and autoimmune disease<sup>[19]</sup>. Some other diseases postulate these etiologies such as concomitant appearance of achalasia and Guillain-Barré syndrome<sup>[29]</sup>, Parkinson's disease<sup>[30]</sup>, triple A syndrome<sup>[31]</sup>, etc.

Table 4 Final result of laboratory evaluation in all patients

Test	Normal (%)	Abnormal (%)
Thyroid function tests	80	20
Calcium and phosphorus	100	-
Alkaline phosphatase	100	-
Albumin	100	-
Globulin	100	-
ANA	93.4	6.6
C-ANCA	100	-
RPR (VDRL)	100	-
Complete Blood Count	100	-
Urine analysis	100	-

All tests except for urine analysis were performed on blood or serum samples.

There are some reports about thyroid and esophageal problems in animals<sup>[32]</sup> but we have not found any reports about such problems in humans in English articles. Although it has been reported that there is a correlation between achalasia and autoimmune diseases, this is the first cross sectional study evaluating the relative prevalence of these problems (rheumatic disease, thyroid disease, inflammatory disease, *etc*) in a consecutive series of patients affected by achalasia which led us to a few interesting points. First, the results of serological tests obtained from this study confirmed some literature data that predict a potential autoimmune etiology of achalasia. Second, an association was found between thyroid problems and achalasia. Third, the frequency of thyroid disease was higher in patients with achalasia than in normal population.

It was reported that the prevalence of hypothyroidism is 4.6% (0.3% clinical and 4.3% subclinical) in the United States of America<sup>[33]</sup>. Whickham showed that the prevalence of spontaneous hypothyroidism in community is 1.5% in females and less than 0.1% in males<sup>[34]</sup>. These prevalence rates are similar to those reported in Finland<sup>[35]</sup>, Japan<sup>[36]</sup>, and in another US survey<sup>[37-39]</sup>. Heydarian and Azizi reported that the prevalence of hyperthyroidism, overt and subclinical hypothyroidism is 0.45%, 0.35% and 2.2% in Iran, respectively<sup>[40]</sup>. The prevalence of hypothyroidism and benign thyroid diseases (hypothyroidism, hyperthyroidism and thyroid nodules) in our patients was significantly higher than that reported in latter study (*P* value and confidence interval for each group were 0.025 and 0.000, 1.3-43.4 and 2.9-76.5 respectively).

The mean age of our patients is one -two decades lower than reported in other studies<sup>[3,4]</sup>. It may have a role in these findings. We found about a 5-fold rise in the prevalence of thyroid dysfunction in this study. Since our center is the only center offering balloon dilation therapy in Isfahan, we can assume that the overall population with achalasia in this area is very similar to that registered in our center and therefore these data are repeatable in our future study, but they may not be generalized in all cases of achalasia in other societies. Hence we suggest a similar study in all centers working in this subject. We should direct our future studies to find the possible genetic and environmental risk factors for earlier disease in this

geographic area.

The reason why there is such a relatively strong association between these diseases can be explained by the literature describing most thyroid problems as probable autoimmune diseases<sup>[41-44]</sup>. Autoimmune etiology of achalasia is also supported by the presence of circulating autoantibodies against the myenteric plexus and inflammatory T-cell infiltrates in the myenteric plexus, as well as the increased prevalence of HLA class II antigens. Possibly the initiating event may be an unknown environmental insult due to a viral infection resulting in inflammation of the myenteric plexus in susceptible patients. Not all affected individuals develop achalasia<sup>[45]</sup>. However, autoimmunity at least has a concomitant or susceptible role in pathogenesis.

Is there a symptomatic mimicry between achalasia and thyroid diseases? There is some evidence in animal model that a mega esophagus may occur in hypothyroidism which is a criterion of achalasia<sup>[32]</sup>. We had one clinical hypothyroid patient and one clinical hyperthyroid patient detected before balloon dilation therapy. We treated these two patients with levothyroxine and methimazole respectively for 6 mo after achievement of euthyroid state. No clinical or radiological improvements were obtained in symptomatology and radiological findings of achalasia after treatment, suggesting that what we found is actually a true association rather than a symptomatic mimicry or a transient neurological dysfunction. We also found a 6% positive ANA in this series which is similar to that in general population<sup>[46]</sup>. These findings may give some stronger evidence for certain autoimmune bases of achalasia. However, more and larger groups are necessary and a larger spectrum of autoimmune markers must be tested to make it possible to establish the utility of the issue in the early diagnosis of achalasia and identification of different etiologic mechanisms, which would allow us to think about novel outline of management since the existing treatments are only partially palliative.

We also found a hypothyroid shock after balloon dilation therapy which was fortunately well managed because we were alert to the problem. Therefore we recommend clinical evaluation of thyroid disease for all patients and thyroid function test for suspicious cases to control thyroid function before any invasive therapy. Clinical severity was statistically similar in both groups of patients with normal and abnormal thyroid function tests. Therefore we cannot predict the possibility of thyroid disease on the basis of severity indexes.

In conclusion, achalasia may be associated with thyroid diseases (hypothyroidism, hyperthyroidism and thyroid nodules), and this association should be kept in mind when a new case of achalasia is diagnosed. More accurate and extensive immunopathological studies should be performed to assess the possibility of a common immunopathogenesis or a cause and effect relationship in these diseases.

### Abstract

**AIM:** To investigate the immunogenicity of *H pylori* proteins, to evaluate the production rate of anti *H pylori* IgG antibodies in relation to time and to demonstrate the fidelity of newly optimized in-house enzyme-linked immunosorbent assay (ELISA) technique as an alternative for *H pylori* infection assay.

**METHODS:** In the present study, 100 µg of formalin-fixed *H pylori* whole cell antigens was injected into an experimental animal (New Zealand white female rabbit) intramuscularly on d 0, 16, 27 and 36. The first two doses were injected with adjuvants. On d 0, a serum sample was collected from the rabbit before immunization and this pre-immunized serum was used as a negative control for the whole study. To evaluate the immunogenic responses of the injected antigen, serum samples were collected from the rabbit at regular intervals up to d 42. The sera were analyzed using in-house ELISA and Western blot techniques.

**RESULTS:** The production of anti *H pylori* IgG antibodies in the rabbit in response to the injected antigen increased almost exponentially up to d 14 and after that it was maintained at the same level until the last day (d 42). By analyzing the immune profiles of immunized sera, 11 proteins were identified to be immunogenic, among them 2 (approximately 100 kDa and 85 kDa) were most prominent.

**CONCLUSION:** Analysis of the immune responses against pathogenic microorganisms like *H pylori* is necessary for the development of various diagnostic and preventive approaches. The results of this experiment reveal that the formalin-fixed *H pylori* whole cell antigens injected into the rabbit are highly immunogenic. These prominent proteins (approximately 100 kDa and 85 kDa) might have higher immunogenic effects among humans

### INTRODUCTION

In the early 1980's, Barry Marshall and Robin Warren of Australia discovered the bacterium *H pylori* in the stomach lining of patients with chronic gastritis and peptic ulcers<sup>[1]</sup>. The discovery of the infective organism *H pylori* and its involvement in these diseases has changed our views on how to diagnose and treat these diseases. Strains carrying the genes encoding the cytotoxin-associated protein (Cag-A) cause chronic active gastritis<sup>[2]</sup>. Gastric infection with *H pylori* is one of the common chronic infections in humans, causing substantial morbidity and some mortality<sup>[3]</sup>. Before an active protective response occurs, the gut must first be exposed to *H pylori*, which is a slowly growing microaerophilic, highly motile, Gram-negative spiral organism whose most striking biochemical characteristic is the abundant production of urease<sup>[4]</sup>. Colonization of *H pylori* in the gastric epithelium leads to a chronic inflammatory reaction<sup>[5-7]</sup>. Such a reaction may involve specific IgG and/or IgA antibody responses against the bacterium both in the peripheral blood and in the gastric mucosa. However, despite the production of such antibodies, the microorganism usually persists and gastritis progresses chronically through unknown mechanisms<sup>[8]</sup>.

*H pylori* infection and peptic ulcer disease are more common in developing countries than in developed countries. Until the mid 1980s, it was felt that one or more of these factors working together could lead to the development of gastritis and ulcers. Since then, evidence has been mounting that *H pylori* has a major role in causing these diseases. Today the standard triple antibiotic

therapy is amoxicillin, clarithromycin and proton pump inhibitors such as omeprazole. Unfortunately, an increasing number of infected individuals are found to harbour bacteria resistant to first-line antibiotics. This results in initial treatment failure and requires additional rounds of antibiotic therapy<sup>[9]</sup>. One of the promising recent developments in medicine is the concept that chronic afflictions, such as peptic ulcer disease and cancer, can be controlled through immunization like classic infectious diseases. One approach has been the oral administration of purified recombinant subunit proteins of *H pylori* and a mucosal adjuvant, the labile toxin (LT) of *Escherichia coli*<sup>[10,11]</sup>. As a single-component vaccine, urease protein has shown some prophylactic and therapeutic activity in animal models and partial therapeutic activity in humans<sup>[12]</sup>. Another research was directed at the comparison of adjuvants and vaccine delivery systems and toward the immunologic mechanisms mediating protection<sup>[13]</sup>.

Serological methods for detection of *H pylori* infection have reached sufficient accuracy and can be used as screening tests before endoscopy or for seroepidemiological surveys<sup>[4]</sup>. A number of different serological techniques have been used to detect antibodies, including haemagglutination, complement fixation, coagglutination, indirect immunofluorescence and latex agglutination<sup>[14]</sup>. Antibodies developed in rabbits against *H pylori* antigen can easily be detected by slide agglutination test. However, immunoblotting and enzyme-linked immunosorbent assay (ELISA) have emerged as the most frequently used techniques. A combination of immunoblotting and ELISA is the most efficient means of detecting serum antibodies to *H pylori* antigens and can be applied to the screening of rabbit sera for *H pylori*-specific antibodies<sup>[15]</sup>. These two techniques can be used in analysis of immune responses against *H pylori* in rabbits.

It is difficult to eradicate *H pylori* by antibiotic therapy and to date no vaccine is available for use in humans<sup>[16]</sup>. An effective vaccine would be a desirable way to control *H pylori*-induced gastric disease. Initial studies in animal models have demonstrated the feasibility of immunization, thus leading to high hopes for a human vaccine. In the mouse model, immunological approaches have to date not brought a satisfactory explanation for the mechanisms of protection against this largely luminal pathogen. In the present study, we used a rabbit model with whole cell extract from *H pylori* as antigen to analyze the immune responses.

## MATERIALS AND METHODS

### Animals

In this study, two healthy New Zealand white female rabbits aged 2 mo (weighing 2 kg) were used for serum antibody response. Although other strains of rabbits (e.g., Californian, Giant blank, Beveren etc) were available, this strain could easily adapt to the tropical area like Bangladesh (studied area). A great care was taken during the study with proper feeding and supplying adequate amount of fresh water daily. Rabbit house was cleaned daily. During the study, the climate was fine. Hygiene condition was

maintained properly.

### Preparation of whole cell antigen

Bacterial cells were grown and harvested from agar plates. Bacterial cells were suspended in phosphate buffered saline (PBS) containing 1% (w/v) formalin and kept at 4°C for 1 h. The cells were then centrifuged at  $12\,500 \times g$  for 5 min and the pellet was resuspended in 1 mL of PBS. The cells were washed 4 times in PBS to remove the formalin. Finally, a suspension of 1 mg/mL cells in PBS was made.

### Preparation of antigen adjuvant mixture

*H pylori* antigens were administered in combination with incomplete Freund's adjuvant (which does not contain killed mycobacteria) to enhance the response to the first two doses. Freund's adjuvant is a water-in-oil emulsion consisting primarily of mineral oil. The oil acts as a repository, which releases the immunogen. The mixture was prepared by taking 250 µL of *H pylori* whole cell antigen (formalin fixed, 1 mg/mL, stored at -20°C) with 250 µL of incomplete Freund's adjuvant and then 200 µL of antigen-adjuvant mixture was injected intramuscularly.

### Immunization of rabbits

Using a 22G needle, rabbits were immunized intramuscularly with whole cell antigen adjuvant mixture on d 0 and 16. Subsequent doses without adjuvant were administered on d 27 and 36. However, before immunization 1.5 mL blood was collected from the marginal vein of the ear for collecting pre-immunization sera. This was used as a negative control.

### Blood collection

After immunization, rabbit blood were collected from marginal ear vein on d 0, 7, 17, 21, 27 and 35. Blood was also collected by cardiac puncture on d 42. Serum was separated from these blood samples and analyzed for antibody response by in-house ELISA and immunoblot techniques.

### In-house ELISA

An aliquot of formalin-fixed bacteria was diluted in coating buffer to a final concentration of 1 µg/100 µL. One hundred µL of antigen preparation was added to all the wells except wells A1 and B1, which were used to calibrate the ELISA reader. The plates were covered with plate sealer and incubated at 4°C overnight. On the following day, the plates were washed 3 times with PBS containing 0.05% Tween-20 (PBS-Tween 20). The wells were blocked with 200 µL of 1% (w/v) bovine serum albumin (BSA) in PBS, and then plates were incubated at 37°C for 30 min. The PBS-BSA was discarded and the plates were washed 3 times with PBS-Tween 20. Then, 100 µL of diluted serum samples (neat, 1:50, 1:100, 1:200, 1:400 and 1:800 dilution in PBS) collected on d 7, 14, 21, 27, 35 and 42 was added into each of two consecutive wells, i.e. duplicate wells were used for each sample and each dilution. To the wells A1 and B1, 100 µL of PBS was added. The plate was covered with the plate sealer and incubated at room temperature for 2 h. The plate was

then washed three times as described above and 100  $\mu$ L of diluted secondary antibody conjugate (1:3000 in PBS) was added (goat anti-rabbit polyvalent antibody conjugated with alkaline phosphatase; A-3937, Sigma Chemical Co, Ltd. UK), and incubated at room temperature for 2 h. The plate was again washed three times with PBS Tween-20 and 200  $\mu$ L of 1 mg/mL substrate (p-nitrophenyl phosphate in diethanolamine buffer) was added to each well. The plate was placed in dark and an optical density ( $A_{405}$ ) was measured after exactly 25 min. In this study, a sample was considered positive for antibodies to *H pylori* if the absorbance of the reaction was  $\geq 1$ . Any value  $< 1$  was considered seronegative<sup>[17]</sup>. For the validation of the experiment, a positive serum sample from humans was tested by in-house ELISA using similar dilution (Neat, 1:50, 1:100, 1:200, 1:400, and 1:800). For ELISA, all the tests were done in duplicate well to minimize the handling error. The average of the two values from duplicate well was used for further data analysis.

### Immunoblot

The 7 serum samples collected from rabbits on d 7, 14, 21, 35 and 42 were examined by immunoblot assay to check the immunological response of the pre-immunized polyclonal rabbit serum to the antigens from whole cell extract of *H pylori*.

### Preparation of whole cell extracts for SDS-PAGE

After confluent growth, bacterial cells were harvested and taken into preweighed, screw-capped Eppendorf tubes. Bacteria were sedimented by centrifugation at  $12500 \times g$  for 2 min and suspended in sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) solubilization buffer<sup>[18]</sup> to a cell concentration of 500  $\mu$ g cells per 5  $\mu$ L. The suspension was incubated at 100°C for 5 min to denature bacterial proteins and DNA was disrupted by brief sonication (30 s). The suspension was reheated at 100°C for 2 min and then diluted in SDS-PAGE solubilization buffer to produce a final concentration of 70  $\mu$ g whole cell extract per 5  $\mu$ L. The aliquots were stored at -20°C for SDS-PAGE.

### SDS-PAGE

The SDS-PAGE profile of whole cell extract was prepared as described previously<sup>[19]</sup>. Gels comprised a 4.5% (w/w) acrylamide stacking gel and a 12.5% (w/w) acrylamide separation gel. Samples were applied to gels alongside protein molecular weight standards (1610305; Bio-Rad, UK). Electrophoresis was performed using a minigel system (Consort, UK) with a constant current of 40 mA for 40 min. Gels were either stained with Coomassie blue<sup>[19]</sup> or used for immunoblotting.

### Immunoblotting

*H pylori* serostatus in all serum samples was determined by immunoblot technique as described previously<sup>[20]</sup>. The SDS-PAGE protein profiles were transferred onto nitrocellulose sheets<sup>[21]</sup> using a semidry electrotransfer apparatus (Bio-Rad). Individual protein profiles were prepared by cutting nitrocellulose sheets into strips. Strips were

incubated separately with different rabbit serum (1:200 dilution in 3% skimmed milk) samples (primary antibody). Antibody-antigen complexes were detected with a goat anti-rabbit polyvalent antibody conjugated with alkaline phosphatase, diluted 1:5000 in 3% skimmed milk. Color development was carried out in a polythene bag at 37°C in the dark for 10 min. Individual serum antibodies binding to five or more protein bands were considered positive results and those binding to less than five protein bands were considered negative results<sup>[20]</sup>.

## RESULTS

The serum collected from two rabbits for six weeks was examined for antibodies specific for antigen using in-house ELISA. Absorbance values  $\geq 1$  at 405 nm were considered seropositive (Table 1). The collected immunized sera from rabbits were evaluated and the result supported that the experimental animal (rabbit) was effectively immunized with *H pylori* whole cell antigen. For the validation of the experiment, a positive serum sample from humans was tested by using similar dilution (Neat, 1:50, 1:100, 1:200, 1:400, 1:800). The ELISA values ( $OD_{405}$ ) from all dilutions showed presence of adequate amount of anti *H pylori* antibody. There was also a negative control serum collected from the rabbit on d 0 (before immunization with formalin-fixed *H pylori* whole cell antigen). The ELISA values from different dilutions showed that the negative control serum had no antibodies against *H pylori* antigen. Using ELISA values for 1:50 dilution on different days (0, 7, 14, 21, 27, 35, and 42) a plot of antibody titer versus time was drawn (Figure 1). Similar results were obtained from other dilutions (neat, 1:50, 1:100, 1:200, 1:400 and 1:800) (data not shown). The graph showed a significant increase in anti *H pylori* antibody production with time. After immunization, the production of anti *H pylori* antibody increased almost exponentially up to d 14 and after that, it maintained at the same level until the last day.

The serum samples collected from the rabbit were examined by immunoblot assay. A variable number of protein bands were observed among the immune profiles (Figure 2). Serum sample collected on d 0 represented pre-immunized serum and no visible protein band was observed, indicating absence of anti *H pylori* antibody. Several protein bands in other samples (collected on d 7, 14, 21, 27, 35 and 42) suggested that tested sera

**Figure 1** Kinetics of anti *H pylori* antibody responses in rabbits. Female rabbits were infected with formalin-fixed *H pylori* whole cell antigens and blood samples were collected at various time points after *H pylori* infection. Sera (1:50 dilution) were subjected to ELISA for antibody titer measurement (in terms of OD). The arrows indicate the time points when rabbits were challenged with antigens (booster dose).

**Figure 2** Western blot with whole cell extracts of *H pylori* against previously immunized rabbit sera and a human serum. Lane 1: molecular weight marker; lanes 2 to 8: serum collected on d 0, 7, 14, 21, 28, 35, and 42 respectively; lane 9: positive human serum.

had antibodies against *H pylori*. Immunoreactivity of the protein bands increased gradually from d 7 to d 42, suggesting that the production of antibody against *H pylori* increased with time in the rabbit. A positive serum sample from humans was also tested and found to have antibodies against that antigen.

The presence or absence of anti *H pylori* antibodies in pre-immunized and immunized rabbits was examined by in-house ELISA and immunoblotting. The findings from the two immunoassays showed a significant correlation ( $P = 0.001$ ) (Table 2).

## DISCUSSION

Current antibiotic regimens against *H pylori* infection may be effective, but complex dosing and development of resistance are always concerns. Animal studies and limited clinical trials of *H pylori* antigens have been conducted, with no final conclusive findings. A number of data now exist, supporting the potential for protection against *H pylori*. However, we are still at a preliminary stage in clinical

development. The best immunogens, the best mode of presentation, the number of doses needed, optimal age at immunization, expected benefit, cost-effectiveness, and other factors involved in vaccine development require further study<sup>[13]</sup>. The present study employed rabbits to clarify the immunogenicity of *H pylori* proteins and to evaluate the production rate of anti *H pylori* IgG antibodies in relation to time.

For serological diagnosis of *H pylori* infection, immune responses against the relevant microorganism can be analyzed in experimental animal models. When endoscopy is not performed, the most commonly used diagnostic approach is the laboratory-based serological test. Enzyme-linked immunosorbent assay (ELISA) detects various classes of antibodies to *H pylori*, indicating current or past infection. Because *H pylori* infection is not known to spontaneously resolve, a positive serologic test suggests active infection in patients who have not undergone eradication therapy<sup>[22]</sup>. Although *H pylori* is not an invasive bacterium, it actively stimulates the immune system in its host by releasing lipopolysaccharides and immunogenic proteins. An immune response accompanies the presence of the bacterium in 98% of the cases<sup>[23]</sup>. The sensitivity and specificity of ELISA to identify infectious microorganisms are quite high. In the present study, since the antibody

response occurred a few days after a new infection or after a booster dose of antigen with or without adjuvant, the subject had to mount a strong immune response

IgG usually appears several days after *H pylori* infection in rabbits. But after eradication of *H pylori*, the drop in antibody titer is not significant until the 6<sup>th</sup> mo in humans<sup>[24]</sup>. In the present study, specific IgG antibodies to *H pylori* were detected in rabbit sera with the help of enzyme immunoassay. Analysis of serum samples by in-house ELISA technique is an alternative for *H pylori* infection assay. The present study evaluated the noninvasive methods to screen for *H pylori* infection in rabbits. The relationship between time course and magnitude of antibody response showed the kinetics of the development of specific antibody responses in the studied animals (Figure 1). A clear kinetics of the development of anti *H pylori* antibody response found in the rabbit showed a significant increase in anti *H pylori* IgG antibody production with time. After immunization, the production of anti *H pylori* antibody increased almost exponentially up to d 14 and after that, it maintained at the same level till the last day of serum collection. The ELISA values from different dilutions showed that the negative control serum had no antibodies against *H pylori* antigen. However, 1:400 dilution of serum (collected at d 14) showed a negative ELISA value, which could be due to the handling error.

A large number of different proteins present in single cells and may play a major antigenic role in infection. The complex pathogenesis of this infection<sup>[25,26]</sup>, including the presence of antigens on *H pylori* in the host<sup>[27]</sup>, demands better approaches to the identification of novel immunogens that would give substantial protection. The selection of defined and well-characterized antigens appears to be the most viable approach. The present in-house ELISA with formalin-fixed whole cell antigens had a high diagnostic value for studied animals. Antibody was raised against whole cell antigens which were at first confirmed by the slide agglutination test. The collected sera subjected to immunoblot analysis showed a number of antibody bands. Some bands were more prominent than others in relation to color intensity. Previous studies revealed that *H pylori* whole cell lysate contains protein bands like CagA (140-121 kDa), VacA (87 kDa), heat-shock protein (60 kDa), two urease subunits of 62 and 26 kDa and thiol peroxidase (18 kDa)<sup>[28]</sup>, suggesting that the concentration of some proteins from the whole cells is high. These proteins might have immunogenic effects in the rabbit. By analyzing the immune profiles of immunized serum samples collected at regular intervals from the rabbit, 11 proteins were identified to be immunogenic, of which 2 were more prominent than others (approximately 100 kDa and 85 kDa). Haque *et al*<sup>[29]</sup> showed that approximately 61 kDa, 58 kDa and 24 kDa proteins from whole cell extract of *H pylori* are immunogenic. However, they could not prove it conclusively. The present study identified two such potential antigens which were proved most potent in eliciting protective immunity.

It is reasonable to assume that more than one protective component is needed in a vaccine<sup>[13]</sup>. Therefore

the previously identified urease<sup>[8]</sup> or catalase<sup>[30]</sup> alone could not be used for final vaccine formulation. There is also concern about inducing an immune response to heat shock protein B (HspB) because this protein has homologies to the GroEL family of heat shock proteins<sup>[31]</sup>. In the present study, we demonstrated some potential immunogens which could give better protection and could be used for diagnosis purpose.

Adjuvant is an important component of any vaccine. It is responsible for stimulating immune system. In some previous trials<sup>[10,30]</sup>, cholera toxin was used as adjuvant for immunization of mice. However this effort might raise multiple problems including safety. *E. coli* heat-labile toxin (LT) that was used as an oral adjuvant in humans does not show a significant decrease in gastric *H pylori* density but is associated with cramping and diarrhea<sup>[32]</sup>. Due to all these adverse effects, no suitable and safe adjuvants are currently available for use in humans<sup>[33]</sup>. However, in the present study an incomplete form of Freund's adjuvant not containing such a cytotoxic agent was used to enhance the immune response. Therefore, this adjuvant could be considered a substitute to cholera toxin or other toxic adjuvants.

The identified proteins might have higher immunogenic effects among humans infected with *H pylori* and some of these immunogenic proteins could be included in diagnostic approaches based on serology and also in vaccine preparation. However, further characterization of these antigens is required. Finally, in-house ELISA and immunoblot can be better applied in analysis of antigenic response in experimental animal model (rabbits).

## COMMENTS

### Background

Gastric infection with *H pylori* is one of the common chronic infections in humans, causing substantial morbidity and some mortality. Still there is still no effective vaccine against *H pylori*, a causative agent of gastric and peptic ulcer. We are still at a preliminary stage in clinical development. The best immunogens, the best mode of presentation, the number of doses needed, optimal age at immunization, expected benefit, cost-effectiveness, and other factors involved in vaccine development require further study. Initial studies in animal models have demonstrated the feasibility of immunization, thus leading to high hopes for a human vaccine. In the mouse model, immunological approaches have to date not brought a satisfactory explanation for the mechanisms of protection against this largely luminal pathogen. In the present study, we used a rabbit model with the whole cell extract antigens from *H pylori*.

### Research frontiers

*H pylori* infection is a newly discovered stomach infection which was first reported by Barry Marshall and Robin Warren of Perth, Western Australia, in 1983, who were awarded the Nobel Prize in Medicine in 2005 for their work on *H pylori*. The Sydney gastroenterologist Thomas Borody invented the first triple therapy in 1987. Such a therapy has revolutionized the treatment of gastric ulcer. Mode of infection, mechanism of pathogenesis, host immune response, chemotherapy and vaccine development are important areas of research.

### Innovations and breakthroughs

Initial studies in animal models have demonstrated the feasibility of immunization, thus leading to high hopes for a human vaccine against *H pylori*. In the mouse model, immunological approaches have to date not brought a satisfactory explanation for the mechanisms of protection against this luminal pathogen. In the present study, we used a rabbit model with the whole cell extract from *H pylori* as antigen. The experiment identified two prominent proteins (approximately 100 kDa and 85 kDa) which have higher immunogenic effects among humans infected with

*H pylori* and some of these immunogenic proteins could be included in diagnostic approaches based on serology and also for vaccine formulation. Most of the previous studies used cholera toxin as adjuvants which have some side effects. In the present study, we used an incomplete form of Freund's adjuvant which does not contain cytotoxic agent. We established and optimized the low cost, non-invasive in-house ELISA technique for the detection of *H pylori* infection in Bangladeshi people.

### Applications

Analysis of the immune responses against pathogenic microorganisms like *H pylori* is necessary for the development of various diagnostic and preventive approaches. The results of our experiment reveal that formalin-fixed *H pylori* whole cell antigens injected into the rabbit are highly immunogenic. These prominent proteins (approximately 100 kDa and 85 kDa) might have higher immunogenic effects among humans infected with *H pylori* and some of these immunogenic proteins could be included in diagnostic approaches based on serology. The in-house ELISA is a promising alternative in the developing countries compared to high cost invasive techniques.

### Terminology

Freund's adjuvant is an antigen solution emulsified in mineral oil, and can be used as an immunopotentiator (booster of the immune system). The so-called complete form (FCA) is composed of inactivated and dried mycobacteria, usually *Mycobacterium tuberculosis* (the pathogenic agent of tuberculosis). The so-called incomplete form (FIA) is the same adjuvant without the mycobacterial components and is named after Jules T. Freund (1890-1960), a Hungarian-born American immunologist.

### Peer review

It is an interesting study. The science seems good and the study is well performed. The results are also of interest.

### Abstract

**AIM:** To examine the anti-ulcerogenic and antioxidant effects of aqueous extracts of *Foeniculum vulgare* (FVE) on ethanol-induced gastric lesions in rats.

**METHODS:** FVE was administered by gavage at doses of 75, 150 and 300 mg/kg, and famotidine was used at the dose of 20 mg/kg. Following a 60 min period, all the rats were given 1 mL of ethanol (80%) by gavage. One hour after the administration of ethanol, all groups were sacrificed, and the gastric ulcer index was calculated; whole blood malondialdehyde (MDA) and reduced glutathione (GSH), serum nitrate, nitrite, ascorbic acid, retinol and  $\beta$ -carotene levels were measured in all the groups.

**RESULTS:** It was found that pretreatment with FVE significantly reduced ethanol-induced gastric damage. This effect of FVE was highest and statistically significant in 300 mg/kg group compared with the control ( $4.18 \pm 2.81$  vs  $13.15 \pm 4.08$ ,  $P < 0.001$ ). Also, pretreatment with FVE significantly reduced the MDA levels, while significantly increased GSH, nitrite, nitrate, ascorbic acid, retinol and  $\beta$ -carotene levels.

**CONCLUSION:** FVE has clearly a protective effect against ethanol-induced gastric mucosal lesion, and this effect, at least in part, depends upon the reduction in lipid peroxidation and augmentation in the antioxidant activity.

### INTRODUCTION

Peptic ulcer is a common disorder of the gastrointestinal system and millions of people suffer from this disease in the world. The medical cost of treating peptic ulcer and its complications amounts to billions of dollars annually. The pathogenesis of peptic ulcer disease is multifactorial, including chronically using non-steroid anti-inflammatory drugs, cigarette smoking, alcohol, and reactive oxygen species (ROS). ROS are generated by cells in some physiological and pathological circumstances. Any derangement between pro-oxidants and antioxidants, in which pro-oxidants prevail is known as oxidative stress<sup>[1]</sup>. Insufficient antioxidant protection or excess production of ROS can result in this condition. ROS can react with all macromolecules, such as lipids, proteins, nucleic acids, and carbohydrates, particularly polyunsaturated fatty acids on cell membranes. After the beginning of an initial reaction with ROS, a continuing chain reaction is started and cell injury and, ultimately, cell death occur<sup>[2]</sup>. Peptic ulcer is produced by the imbalance between gastroduodenal mucosal defense mechanisms and offensive factors. Some studies have revealed that ROS and lipid peroxidation are implicated in the pathogenesis of ethanol-induced gastric lesions and gastrointestinal damage, and they attack and damage many biological molecules such as prostaglandins<sup>[3-5]</sup>. Therefore, treatment with antioxidants and free radical scavengers can decrease ethanol-induced gastric mucosal damage.

*Foeniculum vulgare* (FVE) is a well-known umbelliferous plant. For centuries, FVE fruits have been used as traditional herbal medicine in Europe and China. It is native to southern Europe and the Mediterranean area. The seeds of this plant have been known to be able to regulate menstruation, alleviate the symptoms of female climacteric syndrome, and increase libido<sup>[6]</sup>. FVE also

possesses emmenagogue and galactagogue properties<sup>[7]</sup>. It has been reported that FVE could be used in the pediatric colic and some respiratory disorders due to its antispasmodic effects<sup>[8,9]</sup>. Seeds of it are used in folk remedies for treatment of dysmenorrhea. FVE (in Turkish "Rezene") is natively found in North and West regions of Turkey. It is cultivated for the herb as a spice (flavouring salads) and medicine in Turkey. Powders or tablets (0.5-1 g) of seeds, or its infusion forms (2%) are taken 2-3 times per day. As a medicinal plant, FVE has been used as an antispasmodic, carminative, diuretic, lactation stimulant, and as dressings for wounds in Turkish traditional medicine<sup>[10]</sup>. It contains 1%-3% of a volatile oil, which is composed of 50%-85% of anethole and about 20% of d-fenchone<sup>[11,12]</sup>. Other compounds present in FVE are d- $\alpha$ -pinene, d- $\alpha$ -phellandrene, dipentene, methyl chavicol, feniculun, anisaldehyde, and anisic acid<sup>[11,13]</sup>.

The aim of this work was to assess the gastroprotective activity of FVE in rat models of experimentally ethanol-induced gastric lesions. In particular, we investigated the effects of aqueous extracts of FVE on gross mucosal lesions in the stomach, glutathione (GSH), nitrite, nitrate, ascorbic acid, retinol and  $\beta$ -carotene levels, and changes in lipid peroxidation determined by measuring malondialdehyde (MDA) levels in the blood.

## MATERIALS AND METHODS

### Plant material

The aerial parts of FVE were collected in June 2003 from Bursa. The plant was identified by the Department of Botany of Science and Arts Faculty, Atatürk University, Erzurum, Turkey, where a voucher specimen is kept.

### Extraction and preparation of test samples

Air-dried FVE was pulverized with a blender. Obtained plant material (230 g) was mixed with boiling distilled water and stirred on the hot plate for 15 min. Subsequently, it was filtered over Whatman No.1 paper. Finally, the filtrate was frozen and lyophilized in a lyophilizator (Labconco, Freezone 1L, USA) at a 5  $\mu$ mHg pressure and -50°C (14.9 g).

### Animals

Thirty-five Sprague-Dawley rats with a weight range of 190-225 g were used for the experimentation. The rats were fed with standard laboratory chow and water before the experiment. Rats were divided into 5 equal groups ( $n = 7$ ) and housed in cages. Twenty-four hours before the experiment, the rats were fasted and allowed access to water *ad libitum*. The investigation was conducted in accordance with the Guide for the Care and Use of Laboratory Animals published by the US National Institutes of Health (NIH Publication no. 85-23, revised 1996) and approval has been received from our institutional Animal Ethics Committee.

### Chemicals

Chemicals used in this investigation, GSH, thiobarbituric acid, phosphate buffer, butylated hydroxytoluene, trichloroacetic acid, EDTA, [5,5-dithiobis-(2-nitrobenzoic

acid)], phenylendiamine, sodium azide, 2,4-dinitrophenylhydrazine, ethanol, hexane, sodium nitrite, sodium nitrate, sulfanilamide, N-(1-Naphthyl) ethylenediamine dihydrochloride and vanadium (III) chloride were purchased from Sigma. All the other chemicals and reagents used in this study were of analytical grade.

### Ulcer study

The anti-ulcerogenic effect of FVE was investigated with the ethanol-induced ulcer model. On the first day of the experiment, groups 1, 2 and 3 were administered with 75, 150 and 300 mg/kg FVE, group 4 was administered with 20 mg/kg famotidine, and group 5 was administered with saline solution. All of drugs were administered by gavage at the same volume (0.5 mL). Following a 60 min period, all the rats were given 1 mL of ethanol (80%) by gavage. One hour after the administration of ethanol, rats were injected with a high dose of ketamine (100 mg/kg), blood samples were taken by cardiac punctures, and stomachs were removed and opened along the greater curvature and washed in physiological saline solution. For measurement of the gross gastric mucosal lesions, freshly excised stomachs were laid flat and the mucosal lesions were traced on clear acetate paper. Gross mucosal lesions were recognised as hemorrhage or linear breaks (erosions) with damage to the mucosal surface. The area of stomach tissue and gross lesions were approximately calculated by planimetry using a simple magnifier. The results were translated to the term of "total ulcer area/total gastric area" and these were expressed as an ulcer index (%).

### Biochemical analysis

Fasting blood samples were drawn into heparin-free tubes during routine blood sampling for biochemical analysis. After immediate centrifugation (1000 g for 10 min at 4°C), the serum was stored in polystyrene plastic tubes at -70°C until analysis. Whole blood was collected into heparinized tubes and whole blood MDA and GSH levels were studied on the same day of admission.

Whole blood MDA (as an important indicator of lipid peroxidation) levels were measured according to a method of Jain *et al*<sup>[14]</sup>. The principle of the method was based on the spectrophotometric measurement of the color developed during the reaction of thiobarbituric acid with MDA. Concentrations of thiobarbituric acid reactive substances (TBARS) were calculated by the absorbance coefficient of malondialdehyde-thiobarbituric acid complex and expressed as nmol/mL. Whole blood GSH concentrations were also measured by the spectrophotometric method<sup>[15]</sup>. The concentrations of nitric oxide (nitrate and nitrite) were detected by the methods of Miranda *et al*<sup>[16]</sup>. Nitrite and nitrate calibration standards were prepared by diluting sodium nitrite and sodium nitrate in pure water. After loading the plate with samples (100  $\mu$ L), addition of vanadium (III) chloride (100  $\mu$ L) to each well was rapidly followed by addition of the Griess reagents, sulfanilamide (50  $\mu$ L) and N-(1-Naphthyl) ethylenediamine dihydrochloride (50  $\mu$ L). The Griess solutions may also be premixed immediately prior to application to the plate. Nitrite mixed with Griess

**Table 1** Effects of aqueous extracts of *Foe* FVE and famotidine on ethanol-induced gastric mucosal injury in rats

Groups (n = 7)	Ulcer index (%) (mean $\pm$ SD)	Inhibition (%)
Control (ethanol)	13.15 $\pm$ 4.08	-
75 mg/kg FVE + Ethanol	8.18 $\pm$ 2.66	37.8
150 mg/kg FVE + Ethanol	9.48 $\pm$ 3.78	27.9
300 mg/kg FVE + Ethanol	4.18 $\pm$ 2.81 <sup>b</sup>	68.2
20 mg/kg Famotidine + Ethanol	8.68 $\pm$ 2.63 <sup>a</sup>	34

<sup>a</sup>P < 0.05, <sup>b</sup>P < 0.001, *vs* ethanol.

reagents forms a chromophore from the diazotization of sulfanilamide by acidic nitrite followed by coupling with bicyclic amines, such as N-1-(naphthyl) ethylenediamine. Sample blank values were obtained by substituting diluting medium for Griess reagent. Nitrite was measured in a similar manner except that samples and nitrite standards were only exposed to Griess reagents. The absorbance at 540 nm was read to assess the total level of nitrite and nitrate in all samples<sup>[16]</sup>. Serum vitamin C (ascorbic acid) level was determined after derivatization with 2,4-dinitrophenylhydrazine<sup>[17]</sup>. The levels of  $\beta$ -carotene at 425 nm and vitamin A (retinol) at 325 nm were detected after the reaction of serum: ethanol: hexane at the ratio of 1:1:3, respectively<sup>[18]</sup>.

### Statistical analysis

All values were expressed as mean  $\pm$  SD. Statistical analyses of data were performed using a one-way analysis of variance (ANOVA) and Tukey's posttest. A value of *P* < 0.05 was considered statistically significant.

## RESULTS

### Ulcer study

Ulcer indices (UI) are shown in Table 1. Per-oral administration of 80% ethanol produced multiple mucosal lesions in the rat stomach. Pre-treatment with FVE and famotidine were found to inhibit ethanol-induced gastric mucosal injury. This inhibitor effect of FVE was highest and statistically significant in the 300 mg/kg group and higher than that of famotidine group. In 75 mg/kg and 150 mg/kg of FVE groups, the inhibitor effects on ethanol-induced gastric mucosal injury were similar to famotidine group, which were not significant statistically. Famotidine also significantly inhibited ethanol-induced gastric lesions compared with the control.

### Biochemical analysis

MDA levels of whole blood are shown in Table 2. The administration of ethanol increased the MDA level in whole blood. In contrast, pretreatment with FVE significantly decreased the MDA levels at doses of 150 and 300 mg/kg, compared with ethanol administered alone. Additionally, famotidine was found to prevent the rise in MDA level.

GSH level in whole blood was decreased in the ethanol-administered group. In contrast, GSH levels significantly

<sup>a</sup>P < 0.05, <sup>b</sup>P < 0.01, *vs* ethanol.

increased at doses of 150 and 300 mg/kg FVE and in famotidine groups (Table 2). Nitrite and nitrate levels in serum were decreased in the ethanol administered group, while increased in the FVE groups. This increase was significant only in 75 and 150 mg/kg FVE groups, but not in 300 mg/kg FVE or famotidine groups (Table 2). All doses of FVE and famotidine increased the serum ascorbic acid levels, whereas only 300 mg/kg of FVE induced a significant increase (Table 3). On the other hand, serum  $\beta$ -carotene and retinol levels in FVE groups were higher than that of control, while the difference was significant only in the 150 mg/kg FVE group (Table 3).

## DISCUSSION

For a long time, peptic ulcer has been one of the important causes of morbidities and mortalities. Several factors such as increased vascular permeability, gastric motility and vagal activity, decreased gastric blood flow and protective prostaglandin levels play an important role in gastric ulcer pathogenesis. The treatment of peptic ulcers is still a big challenge and development of new drugs is urgent. There are a number of medicinal plants that have been shown to be effective against ulcer diseases in traditional medicine<sup>[19]</sup>. Because of the folkloric uses, these medicinal plants may be a good source for the development of potential drugs. In recent years, many efforts have been done to explore new anti-ulcer drugs from natural resources, and antiulcer activity of a variety of chemical compounds isolated from medicinal plants have been determined<sup>[20,21]</sup>.

Ethanol is a commonly used ulcerogenic agent and when given by gavage to rats, it produces severe gastric hemorrhagic lesions. The mechanism of ethanol-induced gastric lesions is varied, including the depletion of gastric mucus content, damaged mucosal blood flow and mucosal cell injury. In addition, ethanol-induced gastric mucosal damage is associated with overproduction of free radicals, which lead to an increased lipid peroxidation<sup>[22]</sup>. Increase in lipid peroxide content and oxygen-derived free radicals results in marked changes in cellular levels and causes membrane damage, cell death, exfoliation and epithelial erosion. Accumulation of activated neutrophils in the gastric mucosa may be a source of free radicals. Several studies revealed that some antioxidant drugs such as melatonin and dantrolene have protective effects against ethanol-induced acute gastric injury in rats<sup>[23-25]</sup>. Results of the present study showed that all doses of FVE prevented gastric tissue damage against ethanol-induced stress, only significantly in the highest dose group. Furthermore, FVE decreased the lipid peroxidation and increased the non-enzymatic antioxidant. Antioxidative properties may, at least partially, be one of the possible mechanisms by which FVE ameliorated the ethanol-induced gastric lesions.

GSH is a well-known antioxidant, which is usually present as the most abundant low-molecular mass thiol in most organisms. It has various functions in the defense against oxidative stress and xenobiotic toxicity. It can act as an electron donor for glutathione peroxidase in animal cells, and also directly reacts with ROS. GSH is readily oxidized to glutathione disulfide (GSSG) by glutathione peroxidase, as well as by the reaction with ROS<sup>[26]</sup>, which may subsequently cause the reduction in GSH levels.

Nitrate and nitrite [a marker of endogenous nitric oxide (NO) production], as a free radical, seems to be a potential antioxidant. It takes part in termination of lipid peroxidation (LPO) reactions. NO is an effective chain-breaking antioxidant in free radical-mediated LPO. It reacts rapidly with peroxy radicals as a sacrificial chain-terminating antioxidant. The antioxidant effect of NO on LPO has been explained by terminating the radical chain reaction through the reaction of NO with lipid peroxy radical (ROO·) to form adducts by equation<sup>[27-29]</sup>. The protective effect of NO on LPO has also been shown<sup>[30,31]</sup>.

Aerobic organisms are protected against ROS by enzymatic antioxidant (superoxide dismutase, glutathione peroxidase and catalase) and non-enzymatic antioxidant (such as β-carotene, retinol, vitamin C and GSH) defense systems. Antioxidant vitamins, such as ascorbic acid, retinol and β-carotene play an important acute and chronic role in reducing or eliminating the oxidant damage produced by ROS<sup>[32]</sup>. In the present study, we also measured serum antioxidant vitamin capacity and, levels of all of the antioxidant vitamins were increased in FVE, but not in famotidine treated groups. Increase in vitamin levels in FVE groups may be related to vitamin content in FVE.

The preliminary phytochemical screening of FVE

showed the presence of up to 8% volatile oil (including about 85% of anethole, up to 5% of estragole, and fenchone), flavonoids (rutin, quercetin and kaempferol glycosides), coumarins (bergapten, imperatorin, xanthotoxin and marmesin), sterols and sugars. These are also present in oil of FVE, d-α-pinene, d-α-phellandrene, dipentene, methyl chavicol, anisic acid, anisaldehyde and limonene<sup>[11-13,33]</sup>. Previous studies proved that anethole possesses significant antioxidant, anti-inflammatory and ulcer healing activity in experimental models<sup>[34]</sup>. Additionally, flavonoids, sterols, tannins and coumarins of some plants are also known to possess antiulcer activity<sup>[35-38]</sup>. Therefore, the presence of flavonoids content and other bioactive compounds in FVE may be associated with the ulcer preventing action.

In conclusion, our data show that FVE has an obvious gastroprotective effect and antioxidant properties. Although it is unclear about the exact mechanism underlying these actions, the effects on acute gastric lesions suggest a multifactorial mechanism, involving the antioxidant properties of FVE. FVE may be a new alternative for clinical management of gastric ulcer diseases and/or an antioxidant against oxidative stress. Further studies are required to clarify the anti-ulcer and antioxidant actions of FVE.

### Abstract

**AIM:** To assess whether trace metal concentrations (which influence metabolism as both essential and non-essential elements) are increased or decreased in cancerous tissues and to understand the precise role of these metals in carcinogenesis.

**METHODS:** Concentrations of trace metals including Cd, Ni, Cu, Zn, Fe, Mg and Ca in both cancerous and non-cancerous stomach tissue samples were determined by atomic absorption spectrometry (AAS). Tissue samples were digested using microwave energy. Slotted tube atom trap was used to improve the sensitivity of copper and cadmium in flame AAS determinations.

**RESULTS:** From the obtained data in this study, the concentrations of nickel, copper and iron in the cancerous human stomach were found to be significantly higher than those in the non-cancerous tissues, by using *t*-test for the paired samples. Furthermore, the average calcium concentrations in the cancerous stomach tissue samples were found to be significantly lower than those in the non-cancerous stomach tissue samples by using *t*-test. Exceedingly high Zn concentrations (207-826 mg/kg) were found in two paired stomach tissue samples from both cancerous and non-cancerous parts.

**CONCLUSION:** In contrast to the literature data for Cu and Fe, the concentrations of copper, iron and nickel in cancerous tissue samples are higher than those in the non-cancerous samples. Furthermore, the Ca levels are lower in cancerous tissue samples than in non-cancerous tissue samples.

Yaman M, Kaya G, Yekeler H. Distribution of trace metal

### INTRODUCTION

The importance of essential trace metals in health and disease is indisputable because of their essential role in specific concentration ranges and toxic role at relatively high levels. Essential trace elements have four major functions as stabilizers, elements of structure, essential elements for hormonal function and cofactors in enzymes. As a result, the lack of essential trace elements influences structure alone or alters function of structure through the lack of stabilization, change of charge properties or allosteric configuration<sup>[1]</sup>. It may be expected that deficiency of essential trace elements as cofactors of enzymes could severely impair the host's resistance against carcinogenic stress<sup>[2]</sup>. Among these elements, zinc is a component of more than 3000 zinc-associated transcription factors including DNA-binding proteins with zinc fingers, and more than 300 enzymes including Cu/Zn superoxide dismutase (CuZnSOD) (SOD is an important antioxidant enzyme for cellular protection against reactive oxygen species (ROS) and several proteins involved in DNA repair<sup>[3-5]</sup>). Metallothioneins, being intracellular polypeptides have a remarkable ability to bind to metallic ions including both essential and also toxic metals such as cadmium or lead. Copper is a component of more than 30 enzymes including caeruloplasmine, cytochrome oxidase, lysine oxidase, dopamine-hydroxylase, ascorbate oxidase and tyrosinase in human body, some of which are involved in collagen synthesis, as well as being necessary for the healthy development of connective tissue, nerve coverings and bone<sup>[6,7]</sup>.

The role of metals in the development and inhibition of cancer has a complex character and raises many questions. In the past 25 years, some metals including cadmium, nickel, arsenic, beryllium and chromium (VI), have been recognized as human or animal carcinogens in addition to primary carcinogens such as radiation, viruses and other chemicals<sup>[7,8]</sup>. Their carcinogenic potential depend largely on factors such as oxidation states and chemical species<sup>[9]</sup>. It is supposed that oxidative DNA lesions play an important role in various diseases including cancer and premature aging. The increase in oxidative

DNA lesions are frequently described as being attributable to metal exposure. Metal carcinogenesis is mediated either by the increased generation of highly ROS on the basis of ESR spin trapping studies<sup>[10]</sup> and/or by interference with DNA repair processes<sup>[11]</sup>. Almost all metals are able to generate ROS, which can explain a great part of both their carcinogenicity and their aptitude in the treatment of cancer. Induction of oxidative DNA damage and interaction with DNA repair processes can lead to an enhancement of genotoxicity in combination with a variety of DNA-damaging agents. Nucleotide excision repair (NER) which is the major repair system, is inhibited at low levels as well as at non-cytotoxic concentrations of Ni (II), Cd (II), Co (II) and As (III). The repair of oxidative DNA base modifications is disturbed by Ni (II) and Cd (II) ions. One reason for repair inhibition appears to be the displacement of Zn (II) and Mg (II)<sup>[12]</sup>. Magnesium and Zn, that are cofactors for DNA polymerase, are effective protectors against carcinogenesis *in vivo*. Although Zn and Cu concentrations in serum and tissues of cancer patients have been studied extensively, the precise role of these metals in carcinogenesis is not clearly understood. While a great depth of literature is available regarding the alterations in the levels of trace elements in serum, relatively few studies are available on trace element levels in cancerous and non-cancerous human stomach tissue. Reddy and coworkers reported that the concentrations of essential metals including Fe, Zn and Cu are significantly lower in cancerous stomach tissue than in normal tissues<sup>[13]</sup>. Similarly, the lower Fe and Zn levels in cancerous stomach tissues than in normal tissues are also supported by von Czarnowski and coworkers<sup>[14]</sup>. Few studies have simultaneously determined both toxic and essential trace elements in cancerous and non-cancerous stomach tissues. On the other hand, most studies have been performed on dried and occasionally homogenized samples, that disturb the tissue from its natural physiological state. Ng and coworkers<sup>[15]</sup> reported that the wet-to-dry ratio of tumor (malignant) breast tissues is higher (more 2-times) than that of the normal tissues. Therefore the elevation of elemental contents in tumors is significantly different from that in normal tissues when concentrations are adjusted by using the wet-to-dry ratio of the samples. The same study noted that the wet-to-dry ratio varies significantly amongst specimens, not only of different types but also between samples of the same group<sup>[15]</sup>. Therefore, evaluation of trace element levels in dried samples should be regarded as incomplete in the absence of wet-to-dry ratios for individual specimens. It would appear that study of fresh and unprocessed specimens is preferable. On the other hand, the ratio of Cu to Zn (Cu/Zn) intake is widely utilized to assist diagnosis of various cancers or tumors<sup>[16]</sup>. The usefulness of the tissue-metal determination in cancer prevention, detection, monitoring, treatment and prognosis requires further investigation.

In our laboratory, atomic absorption spectrometry (AAS) being the most common analytical technique has been successfully used for trace metal analysis in biological samples<sup>[17-20]</sup>. To improve the sensitivity of flame atomic absorption spectrometry (FAAS), a slotted tube atom trap

(STAT) has been used for some metals such as Cd, Pb and Cu in biological matrices<sup>[19-22]</sup>. In the current study, the concentrations of various minor and trace metals, including Cd, Ni, Cu, Zn, Fe, Mg and Ca in cancerous and non-cancerous stomach tissues, were determined by atomic absorption spectrophotometry. For digestion of the tissues, a microwave oven was used.

## MATERIALS AND METHODS

### Apparatus and reagents

An ATI UNICAM 929 flame atomic absorption spectrophotometer (FAAS) equipped with ATI UNICAM and KOTTO hollow cathode lamps was used for metal determinations. The optimum conditions for FAAS are given in Table 1. A STAT was used to improve the Cd and Cu sensitivities by FAAS. A domestic microwave oven (Kenwood) was used for digestion of the tissues. Unless stated otherwise, all chemicals used were of analytical grade. Throughout the analysis, doubly distilled water was used. All glass apparatus (Pyrex) were kept permanently full of 1 mol/L nitric acid when they were not used. In the digestion procedures, concentrated nitric acid (65%, Merck) and hydrogen peroxide (35%, Merck) were used. Stock solutions of metals (1000 mg/L) were prepared by dissolving their salts (Merck) in 1.0 mol/L nitric acid.

### Preparation of samples

Fresh stomach tissue samples were taken since fresh and formalin-fixed tissues have been demonstrated to yield virtually the same results for essential and toxic metals including Ca, Mg, Fe, Cu, Zn, As, Cd, Hg and Pb<sup>[23]</sup>. In the current study, the samples were obtained in the formaldehyde solution from private Pathology Laboratories and the pathology laboratories of Firat University in Elazig, Turkey, after surgery and histopathologic examination. A total of eighteen samples were taken, of which four cancerous (malign) stomach tissue samples were taken from patients of different sex, age and living conditions, described as independent samples in this study, the other fourteen samples were taken from both cancerous (malign) and non-cancerous (normal) stomach tissues, described as paired samples in this study. All the patients were diagnosed as grade II-III or III-IV adenocarcinoma except that one patient at the age of 80 years had grade I and poorly differentiated adenocarcinoma. Furthermore, most patients had metastatic and differentiated adenocarcinoma. The tissue samples were cut into small pieces with a stainless steel knife and transferred to a beaker.

### Digestion of tissue samples

Exactly 2.0 mL of the mixture of HNO<sub>3</sub>/H<sub>2</sub>O<sub>2</sub> (2:1) was added to 0.7 g of the tissue samples. The mixture was placed into the water bath at 70°C for 30 min and stirred occasionally. Then, 1.0 mL of the same acid mixture was added, and the mixture was transferred into a Teflon vessel bomb for the microwave oven. The bomb was closed, and the solution was placed inside the microwave

**Table 1** Operation parameters for flame atomic absorption spectrophotometer

Parameter	Cd	Ni	Cu	Zn	Fe	Mg	Ca
Wavelength (nm)	228.8	232	324.8	213.9	248.3	285.2	422.7
HCL current (mA)	4	7.5	3	9.5	15	15	6
Acetylene flow rate (L/min)	0.5	0.5	0.5	0.5	0.5	0.5	4.2
N <sub>2</sub> O flow rate (L/min)	-	-	-	-	-	-	4.7
Air flow rate (L/min)	4	4	4	4	4	4	-
Slit (nm)	0.5	0.2	0.5	0.5	0.2	0.5	0.5

oven. Radiation was applied for 3 min at 450 W. After addition of 0.5 mL of the same acid mixture, radiation was repeated for 3 min. After cooling for 5 min, 2.0 mL of 0.1 mol/L HNO<sub>3</sub> was added, and the solution was transferred into a Pyrex tube. After centrifugation, the clear solution was measured by FAAS. Three different portions of each sample were digested and the average value was calculated for the same tissue. Blank digests were carried out in the same way.

## RESULTS

Calibration curves were obtained by using solutions of the studied elements at different concentrations. The graphs obtained were linear in the concentration range and the equations of the curves are described in Table 2.

### Analytical performance

The accuracy of the method was studied by examining the recovery of metals from stomach tissue samples fortified with various amounts of the studied metals. The following metal amounts were added: 30 ng/g of Cd, 200 ng/g of Ni, 0.3 mg/kg of Cu, 10 mg/kg of Zn, 10 mg/kg of Fe, 100 mg/kg of Mg and 300 mg/kg of Ca. After digestion in microwave oven, the recoveries were found to be at least 90% for all studied metals. Furthermore, the standard addition method was used to remove possible interferences caused by the matrix. The slopes of the calibration curves for all studied elements were compared with those obtained by the standard addition method. The slopes of the calibration curves were found to be the same as those obtained with the standard addition method. In other words, all of the standard addition curves were parallel to the calibration curves. These results indicated the absence of chemical interference.

Levels of the metals including Cd, Ni, Cu, Zn, Fe, Mg and Ca in the reagent blanks in the analytical steps were found to be 0.5, 25, 10, 50, 50, 105 and 190 ng/mL with the standard deviations being 0.1, 4.0, 1.5, 9.0, 8.0, 20 and 35, respectively. Therefore, the detection limits for these elements defined as three times the s values of blanks were calculated as 0.3, 12, 4.5, 27, 24, 60 and 105 ng/mL. The precision of the standard deviations for 10 samples of the same tissue was found to be less than 10% for all studied elements.

**Table 2** Equations of the curves

Equation		
$Y = 2.4972x + 1.12$	$R^2 = 0.99$	For Cd (4-100 ng/mL by STAT-AAS)
$Y = 0.3278x - 0.2083$	$R^2 = 1$	For Cu (25-400 ng/mL by STAT-AAS)
$Y = 85x + 0.5$	$R^2 = 0.99$	For Ni (0.2-2.0 mg/L)
$Y = 302x + 0.75$	$R^2 = 0.99$	For Zn (0.1-1.0 mg/L)
$Y = 64x + 0.43$	$R^2 = 1$	For Fe (0.20-3.0 mg/L)
$Y = 515x + 7.0$	$R^2 = 0.99$	For Mg (0.25-2.0 mg/L)
$Y = 305x + 39$	$R^2 = 1$	For Ca (0.25-2.0 mg/L)

### Comparison of metal levels in cancerous and non-cancerous tissues

Metals are considered to act not only as carcinogens but also as co-carcinogens that activate carcinogenic chemicals. In evaluating the differences in cancerous and non-cancerous tissue samples, two comparisons were conducted: one between paired cancerous and non-cancerous tissue samples, the other between total cancerous and non-cancerous samples. *P* values (obtained by using *t*-test) less than 0.05 were considered significantly different between the two groups. The samples with exceptionally high values were disregarded in calculating the average and range.

Data related with carcinogenic effects of cadmium are available from the literature<sup>[24]</sup>. Multiple studies have linked occupational exposure to Cd with pulmonary cancer in humans, whereas a few studies showed that Cd exposure is associated with cancers of stomach and other sites in humans<sup>[24]</sup>. As it can be seen from Table 3, there was no significant difference in Cd concentrations between cancerous and non-cancerous stomach tissue samples, in the present study.

**Nickel:** The International Agency for Research on Cancer (IARC) has classified the carcinogenic substances in two groups. Group 1 includes substances "known to be human carcinogens or sufficient evidence of carcinogenicity from studies in humans", group 2 includes substances "reasonably anticipated to be a human carcinogen". The chemicals in group 2 are classified in two subgroups by IARC. Group 2A includes substances "probably carcinogenic to humans", and group 2B includes substances "possibly carcinogenic to humans"<sup>[8]</sup>. Kasprzak and coworkers<sup>[25]</sup> have made an overall evaluation of the carcinogenicity of nickel and found that Ni compounds are carcinogenic to humans (group 1), and metallic nickel is possibly carcinogenic to humans (group 2B).

vonCzarnowski *et al*<sup>[14]</sup> showed that Ni levels are lower in cancerous (malign) stomach tissues than in normal stomach tissues, whereas Reddy *et al*<sup>[13]</sup> reported that nickel concentrations are 6-time higher in cancerous stomach tissues than in normal stomach tissues. In this study, the Ni levels in cancerous stomach tissue samples were significantly higher ( $P < 0.05$  for the paired samples) than those in the non-cancerous stomach tissue samples (Tables

**Table 3** Trace metal concentrations in cancerous and non-cancerous stomach tissues. Every single cancerous tissue belongs to a different patient (mean  $\pm$  SD,  $n = 3$ )

		0.025	

3, 4 and Figure 1).

**Copper:** Although copper is an essential element for humans and animals, high concentrations of Cu (above normal) could induce growth proliferation and cancer by damaging DNA with toxic free hydroxyl radicals<sup>[26]</sup>. Conflicting results regarding Cu concentrations have been observed in cancerous and normal stomach tissues<sup>[13,14]</sup>.

VonCzarnowski and coworkers<sup>[14]</sup> reported that there are no differences in Cu concentrations between cancerous (malign) and normal stomach tissue samples, whereas Reddy and coworkers<sup>[13]</sup> described that Cu levels in cancerous stomach tissue samples are 3-time lower than those in normal stomach tissue samples. In the present study, the Cu levels in cancerous stomach tissues were significantly higher ( $P = 8.10^{-4}$  for the paired samples and  $P < 0.05$  for total samples) than those in non-cancerous stomach samples (Tables 3, 4 and Figure 2). The mechanism of copper elevation in cancerous tissues may be explained by modifications in the relationships among trace elements with reduced catabolism or by increased neoplastic synthesis of ceruoplasmin. Metal carcinogenesis is mediated either by the increased generation of highly ROS (Fenton reaction) and/or by interference with DNA repair processes<sup>[11,26]</sup>. Since almost all metals are able to generate ROS, further studies on the determination of trace element levels together with ROS production

**Figure 1** Comparison of Ni levels between cancerous and non-cancerous stomach tissue samples. The concentration of number 19 is average value.

**Figure 2** Comparison of Cu levels between cancerous and non-cancerous stomach tissue samples. The concentration of number 19 is average value.

are needed. Consequently, the physiological processes underlying tumor development can lead to uptake of trace elements by neoplastic cells because of the increased cellular and enzymatic activity.

**Zinc:** It was reported that Zn concentrations in cancerous stomach tissue are lower than those in normal tissues<sup>[13-14]</sup>. It can be seen from Table 3, there was no significant difference in Zn concentrations between cancerous and non-cancerous stomach tissue the paired samples. Excessive zinc concentrations were found in both cancerous and non-cancerous stomach tissues from two patients. Unfortunately, we could not explain these excessive Zn levels.

**Iron:** Although Fe is an essential nutritional element for all life forms, it is known that excess iron and iron deficiency also lead to oxidative DNA damage<sup>[27]</sup>. It was reported that iron levels are significantly decreased in cancerous stomach

tissue in comparison with those in normal stomach tissue<sup>[13-14]</sup>. On the other hand, Hercberg and coworkers<sup>[28]</sup> reported that serum ferritin concentration >160 ng/mL is an increased risk of developing cancer in women but not in men. In this study, Fe levels in the cancerous stomach tissue samples were significantly higher ( $P < 0.05$  for the paired samples and  $P = 0.065$  for all samples) than those in the non-cancerous tissue samples (Tables 3, 4 and Figure 3). These findings can also be explained by the Fenton reaction described above.

**Calcium:** It was reported that calcium concentrations in cancerous stomach tissues are lower than those in the normal tissues<sup>[13]</sup>, whereas steady Ca concentrations are observed in cancerous and normal stomach tissues<sup>[14]</sup>. In this study, Ca levels in the cancerous stomach tissue samples were significantly lower ( $P < 0.01$  for the paired samples) than those in the non-cancerous tissue samples,

**Figure 3** Comparison of Fe levels between cancerous and non-cancerous stomach tissue samples. The concentration of number 19 is average value.

**Figure 4** Comparison of Ca levels between cancerous and non-cancerous stomach tissue samples. The concentration of number 19 is average value.

similar to the results of Reddy coworkers (Tables 3, 4 and Figure 4). It was described that  $\text{Ni}^{+2}$  can block  $\text{Ca}^{+2}$  channels and hence, nickel releases the stored intracellular  $\text{Ca}^{+2}$  via a mechanism underlying the interaction between  $\text{Ni}^{+2}$  ions and the cell surface  $\text{Ca}^{+2}$  receptor<sup>[25]</sup>. The results of this study, involving the lower Ca concentrations in cancerous stomach tissue samples than in the non-cancerous tissue samples, agree with the observed higher Ni levels in cancerous tissues than in non-cancerous tissues.

**Magnesium:** There were no significant differences in the Mg concentrations between cancerous and non-cancerous stomach tissues (Table 3).

The significant and tendentious elements are listed in Table 4. The positive sign was used to illustrate accumulation of the elements in cancerous tissue, and the minus sign was used to indicate the depletion of elements in the cancerous stomach tissue samples in comparison to

the non-cancerous tissue samples.

## DISCUSSION

Reddy and coworkers<sup>[13]</sup> found that the concentrations of trace metals in normal/cancerous tissues (mg/kg) on dry weight basis are as follows: Fe = 2408/684, Cu = 63.5/21.2, Zn = 818/229, Ni = 10.5/60, Pb = 8.8/8.1 and Ca = 647/433. They described that the low iron level observed in carcinoma tissue of stomach might not initiate carcinoma in stomach, but the low absorption of iron may be due to the lack of HCl which in turn may be due to the carcinogenic nature of stomach. The lower iron levels observed in cancer tissue of stomach is supported by vonCzarnowski and coworkers<sup>[14]</sup>. In the present study, copper, iron and nickel concentrations in cancerous stomach tissue samples were higher than those in non-

cancerous stomach tissue samples. Although ROS were not measured in this study, these results are in agreement with the reported data<sup>[29]</sup>. Furthermore, we found that Ca levels in the cancerous stomach tissue samples were lower than those in the non-cancerous stomach tissue samples. It was reported that calcium and magnesium concentrations, similar to iron, nickel and zinc in cancerous prostate tissue are higher than those in non-cancerous prostate tissue<sup>[18]</sup>. The increase in calcium concentration and its heterogeneous distribution in malign prostate tissue in contrast to the data obtained in stomach tissue may be attributed to calcium functions and behaviors depending on the organ type. The organ-dependency on the changes in trace metal concentrations in cancerous and endometrial tissues<sup>[30]</sup> also supports these explanations. We think that the decreased Ca levels and the increased Ni concentrations in cancerous stomach tissues as well as its heterogeneous distribution in comparison to non-cancerous samples are very important for the investigation of cancer mechanism in this organ due to the displacement of Ni with Ca. The results in disagreement with the explanations above may be attributed to their subgroups of cancerous properties because the different mechanisms may be effective in such conditions.

In conclusion, STAT can be used to improve the sensitivity of copper and cadmium. In addition, the tissue digested in a microwave oven has very low blank values and can reduce the risk of metal loss or contaminations. The closed microwave digestion offers an easy and reliable method for the complete dissolution of tissues prior to the determination of trace metals.

rate in < 30% and  $\geq$  30% embolization area groups was 50% and 100%, respectively.

**CONCLUSION:** Partial splenic embolization is an effective method to improve platelet values and GPT values in liver cirrhosis patients with thrombocytopenia and the  $\geq$  30% embolization area is meaningful for platelet values improvement. The relationship between the complication rate and embolization area needs further studies.

### Abstract

**AIM:** To investigate the effect of partial splenic embolization (PSE) on platelet values in liver cirrhosis patients with thrombocytopenia and to determine the effective embolization area for platelet values improvement.

**METHODS:** Blood parameters and liver function indicators were measured on 10 liver cirrhosis patients (6 in Child-Pugh grade A and 4 in grade B) with thrombocytopenia (platelet values <  $80 \times 10^3/\mu\text{L}$ ) before embolization. Computed tomography scan was also needed in advance to acquire the splenic baseline. After 2 to 3 d, angiography and splenic embolization were performed. A second computed tomography scan was made to confirm the embolization area after 2 to 3 wk of embolization. The blood parameters of patients were also examined biweekly during the 1 year follow-up period.

**RESULTS:** According to the computed tomography images after partial splenic embolization, we divided all patients into two groups: low (< 30%), and high ( $\geq$  30%) embolization area groups. The platelet values were increased by 3 times compared to baseline levels after 2 wk of embolization in high embolization area group. In addition, there were significant differences in platelet values between low and high embolization area groups. GPT values decreased significantly in all patients after 2 wk of embolization. The improvement in platelet and GPT values still persisted until 1 year after PSE. In addition, 3 of 4 (75%) Child-Pugh grade B patients progressed to grade A after 2 mo of PSE. The complication

### INTRODUCTION

The spleen is known to be involved in thrombocytopenia associated with liver cirrhosis<sup>[1]</sup>. Thrombocytopenia in patients with liver cirrhosis has been reported to be caused by an increased platelet pool in the enlarged spleen<sup>[2]</sup>, impaired platelet production in the bone marrow<sup>[3]</sup>, decreased platelet function<sup>[4]</sup>, and abnormalities in the platelet membranes<sup>[5]</sup>. Recently, an article<sup>[6]</sup> reported that decreased production of thrombopoietin (TPO) might also promote the development of thrombocytopenia in liver cirrhosis. Partial embolization of the splenic vessels has been used to treat hypersplenism of thrombocytopenia in liver cirrhosis patients. Mozes *et al*<sup>[7]</sup> described the benefit of partial splenic embolization (PSE) in reducing the prevalence of complications from splenic artery embolization. Miyazaki *et al*<sup>[8]</sup> reported the effectiveness of PSE in thrombocytopenia. Their reports suggested that PSE might be a safe and effective alternative to splenectomy in the treatment of thrombocytopenia. The aim of the current study was to investigate the effect of partial splenic embolization on platelet values in liver cirrhosis patients with thrombocytopenia and to determine

the effective embolization area for platelet values improvement.

## MATERIALS AND METHODS

Ten liver cirrhosis patients with thrombocytopenia (platelet value  $< 80 \times 10^3/\mu\text{L}$ ) were transferred to our department to receive partial splenic embolization at Taipei Medical University Hospital from January 2004 to September 2005. All patients gave informed consent before their participation, and the Ethics Committee of Taipei Medical University Hospital approved the study. The Child-Pugh classifications of these 10 patients were grade A in 6 and grade B in 4 patients. They had no other chronic diseases. Before partial splenic embolization, measurements were taken of platelet, white blood counts, hemoglobin, bilirubin, alkaline phosphatase, and liver function indicators [aspartate aminotransferase, ASAT (GOT), and alanine aminotransferase, ALAT(GPT)].

Before the PSE, they underwent computed tomography (CT, HiSpeed CT/I; GE Medical Systems, Milwaukee, WI, USA) to observe the basal status of the spleen and calculate the volume of the spleen using the software of CT. After 2 to 3 d, angiography and PSE were performed, respectively. A femoral artery approach was used for superselective catheterization of the splenic artery. The catheter tip was placed as distally as possible in either the hilus of the spleen or the intrasplenic artery. Embolization was done by injections of a gelatin sponge (Gelfoam cube, Upjohn, Kalamazoo, USA) cut into 1 to 2 mm cube and suspended in 1 g cefazolin-containing solution. When the blood flow in this artery stopped, we finished the embolization. After 2 to 3 wk of PSE, we did CT scan again to confirm the embolization area via calculating the volume of the spleen. In addition, these patients took antibiotics orally to prevent sepsis. During the one year follow up period, we measured the blood parameters mentioned above biweekly, and recorded the blood parameters at every time point.

### Statistical analysis

Blood parameters were compared using paired *t* test.  $P < 0.05$  means significant differences.

## RESULTS

The mean age of our patients was 56 years (from 19 to 71). According to the embolization areas presented on CT, we divided all patients into two groups: low embolization group ( $< 30\%$ ): 2 patients, and high embolization group ( $\geq 30\%$ ): 8 patients. The average embolization areas in these two groups were 20% and 40%, respectively. The effect of PSE on platelet values is listed in Table 1. In high embolization area group, the platelet values after 2 wk and 1 year of embolization were 2 to 3 times the basal values. In addition, we also evaluated the effect of different embolization areas on platelet values. We observed a marked variation of platelet values between low and high embolization groups. We found that an embolization area equal to or higher than 30% is an effective embolization area for improvement of platelet values.

**Table 1** Effects of partial splenic embolization on platelet values

Basal values ( $\times 10^3/\mu\text{L}$ )	Embolization area (%)	After 2 wk ( $\times 10^3/\mu\text{L}$ )	After 1 year ( $\times 10^3/\mu\text{L}$ )
Low embolization			
56	15	69	66
54	25	66	51
Average platelet value		67.5	58.5
High embolization

51	65	159 <sup>1</sup>	141 <sup>1</sup>
Average platelet value		192 <sup>2</sup>	145 <sup>2</sup>

<sup>1</sup>Means significant differences in platelet values between basal values and post-embolization values; <sup>2</sup>Means significant differences in platelet values between low and high embolization areas groups.

**Table 2** Effect of partial splenic embolization on GPT values

Basal values (IU/L)	Embolization area (%)	After 2 wk (IU/L)	After 1 year (IU/L)
Low embolization			
145	15	46 <sup>1</sup>	45 <sup>1</sup>
95	25	57 <sup>1</sup>	51 <sup>1</sup>
Average GPT value		51.5	48
High embolization			
87	35	47 <sup>1</sup>	52 <sup>1</sup>
76	45	50 <sup>1</sup>	51 <sup>1</sup>
102	35	54 <sup>1</sup>	40 <sup>1</sup>
98	30	44 <sup>1</sup>	51 <sup>1</sup>
87	30	56 <sup>1</sup>	44 <sup>1</sup>
116	30	58 <sup>1</sup>	54 <sup>1</sup>
79	50	59 <sup>1</sup>	55 <sup>1</sup>
66	65	45 <sup>1</sup>	35 <sup>1</sup>
Average GPT value		52	48

<sup>1</sup>Means significant differences in GPT values between basal values and post-embolization values.

PSE cannot improve the GOT values markedly; however, the GPT values of these 10 patients after 2 wk of PSE decreased baldly and the range of degradation was from 32% to 68% (Table 2). We also found that the improvement of platelet and GPT values still persisted until 1 year after PSE. In addition, 3 of 4 (75%) Child-Pugh grade B patients progressed to grade A after 2 mo of PSE. It suggested that the PSE may improve the liver function with a long-term efficiency. The PSE procedure did not affect other blood parameters.

Regarding complications, there were fever in 10 (100%), pain in 8 (80%) and ascites in 1 (10%) of patients. Ascites occurred in high embolization group. The complication rate in  $< 30\%$  and in  $\geq 30\%$  groups were 50% and 100%, respectively.

## DISCUSSION

In 1973 Maddison<sup>[9]</sup> reported the first case of splenic

artery embolization. In 1979, Spigos<sup>[10]</sup> cured 14 hypersplenism cases using PSE. Since then, PSE has become a major therapy clinically for hypersplenism. The spleen represents one fourth of the total lymphatic mass, serves as a biological filter for the clearance of bacteria and also is essential for rapid antibody production after challenge with blood-borne particulate antigens in the absence of preexisting antibodies<sup>[11]</sup>. In addition, the spleen appears to be the site of production of a nonspecific leukophilic immunoglobulin, tuftsin, that increases the phagocytic activity of polymorphonuclear leucocytes. Thus, it is apparent that the spleen has important and critical functions and its removal is not to be taken lightly<sup>[12]</sup>. Partial splenic embolization represents a potential alternative method to splenectomy when ablation of the splenic parenchyma is desired, particularly in compromised patients, where splenectomy carries significant morbidity and mortality rates. Partial splenic embolization has been successfully used experimentally in the treatment of thrombocytopenia or splenic trauma. Hematologic changes after embolization have been observed, especially in platelet values. There have also been sporadic reports<sup>[13,14]</sup> of successful splenic embolization in humans with thrombocytopenia due to hypersplenism of portal hypertension. Several studies<sup>[15,16]</sup> demonstrated that PSE could not only improve the symptoms of hypersplenism but also could reserve the spleen for immune function maintenance.

A major finding in this study is the effectiveness of PSE in improving platelet values and the extent of embolization seems to be critical in the efficacy of PSE. According to Bruno's study<sup>[17]</sup>, embolization of 50% or less of the splenic mass was almost invariably associated with an elevation of platelet values. In another study<sup>[18]</sup>, the authors demonstrated that 65%-70% embolization area is effectiveness in platelet values improvement in liver cirrhosis patients with thrombocytopenia. In Kimuro's study<sup>[19]</sup>, the platelet counts were improved from  $5.6 \times 10^3/\mu\text{L}$  to  $36 \times 10^3/\mu\text{L}$  in 80% embolization area group and from  $6.2 \times 10^3/\mu\text{L}$  to  $25 \times 10^3/\mu\text{L}$  in 70% embolization area group, which is significantly higher than the former. According to the studies mentioned above, it is suggested that the improved efficacy of PSE on platelet values relates closely to embolization area. In our study, we observed a marked variation of platelet value between low and high embolization groups. We assume that an embolization area equal to or higher than 30% is an effective embolization area for platelet values improvement. Our result is not similar to previous studies. We presume that the limited patient number results in the fact that we cannot differentiate the age, basal platelet values and Child-Pugh classification of patients. Compared to the Bruno and Miyazaki's large-scale studies, there are more variabilities in our study. The various results probably have multiple causes, but patient selection, with different degrees of hepatic insufficiency, is probably of greatest importance.

The complications after PSE include pneumonia, ascites, bleeding, peritonitis, etc. In our study, there were fever in 10 patients, pain in 8 (7 in high embolization and 1 in low embolization) and ascites in 1 (in high

embolization). The complication rate in  $< 30\%$  and in  $\geq 30\%$  groups was 50% and 100%, respectively. In Mukaiya's study<sup>[20]</sup>, they divided all patients into three groups:  $< 50\%$ , 50%-70% and  $\geq 70\%$  according to the embolization area. The complication rate was 28%, 56% and 95%, respectively. In another study<sup>[18]</sup>, the authors also demonstrated that the complication rate associated with the embolization area, which is similar to our study. However, in Hong's study<sup>[21]</sup>, they conducted linear regression analysis between complication rate and embolization area and the correlation coefficient was 0.587. Hong considered that embolization area will affect the complication rate, however, it is not an absolute factor. The relationship between these two parameters needs further study.

Our results showed that the GPT values of these 10 patients after 2 wk of PSE decreased badly and the range of degradation was from 32% to 68%. We also found that the improvement in GPT values persisted until 1 year after PSE. As compared with GPT, GOT is not a specific indicator for liver function. Generally speaking, GOT and GPT values will increase when hepatitis occurs, however, GOT also exists in erythrocytes, cardiac muscles and skeletal muscles. Some extrahepatic diseases, such as myocardial infarction, myocardial necrosis, hemolysis and several muscle related diseases could result in GOT increase. On the contrary, almost all GPT exists in the liver, so that GPT is more specific than GOT for liver function. This is the reason why PSE improved GPT values markedly while there was no effect on GOT values. In addition, 3 of 4 (75%) Child-Pugh grade B patients progressed to grade A after 2 mo of PSE. We suppose that the PSE may be able to improve the liver function, with a long term efficiency. In Noguchi's study<sup>[22]</sup>, 1 liver cirrhosis patient with Child-Pugh grade C progressed to grade B after 6 mo of PSE; 3 of 5 Child-Pugh grade B patients progressed to grade A. In Vujic's study<sup>[23]</sup>, they found liver function improvement in 56 of 128 patients (43.8%) who underwent PSE and their clinical expression included albumin increase and prothrombin formation time abridgement. According to Wang<sup>[24]</sup>, the mechanism by which PSE improves liver function may involve immunologic mechanisms and hemodynamic changes. Noguchi *et al*<sup>[22]</sup> reported that after PSE the changes in the platelet count as compared with the preoperative value negatively correlate with the change in the platelet-associated immunoglobulin G levels. That study suggested that PSE improves the thrombocytopenia induced by immunologic mechanisms in cirrhotic patients. As for hemodynamic mechanisms, Barcena *et al*<sup>[25]</sup> reported that PSE decreased blood flow in the splenic artery and increased blood flow in the hepatic artery and superior mesenteric artery. In addition, Kato *et al*<sup>[26]</sup> found that the decrease in total portal blood flow and the relative increase in the mesenteric blood flow after PSE may decrease liver congestion, enhance the blood supply, and increase the supply of cytokines derived from the digestive tract.

In conclusion, partial splenic embolization is an effective method to improve platelet values in liver cirrhosis patients with thrombocytopenia. We also find that the  $\geq 30\%$  embolization area is meaningful for

platelet values improvement. The relationship between complication rate and embolization area needs further studies.

## COMMENTS

### Background

The spleen is known to be involved in thrombocytopenia associated with liver cirrhosis. Thrombocytopenia in patients with liver cirrhosis has been reported to be caused by an increased platelet pool in the enlarged spleen, impaired platelet production in the bone marrow, a decreased platelet function, and abnormalities in the platelets membranes. Partial embolization of the spleen vessels has been used to treat hypersplenism of thrombocytopenia in liver cirrhosis patients. Studies suggested that PSE might be a safe and effective alternative to splenectomy in the treatment of thrombocytopenia.

### Innovations and breakthroughs

The focus of most previous studies is to evaluate the effectiveness of partial splenic embolization on blood parameters (especially platelets values). The breakthrough of our article is that we found out the efficient embolization area for platelet value improvement, and this provides a meaningful reference for clinic physicians in their therapy.

### Applications

Clinical physicians should adopt the minimal partial splenic embolization area, which could improve the platelet value for treatment of the liver cirrhosis patients with thrombocytopenia. The major advantage is fewer complications after embolization. The  $\geq 30\%$  efficient embolization area shown in our article is multivariate depending on the techniques and patient status; however, we provide another meaningful cerebation for clinical treatment.

### Terminology

PSE: Partial splenic embolization.

### Peer review

This article evaluated the effect of the degree of partial splenic embolisation on platelet values in cirrhotic patients with hypersplenism. The data suggest that at least 30% of the spleen area must be embolisation area in order to increase platelet counts sufficiently.

## Abstract

**AIM:** To assess the therapeutic effect of Caspase-1 inhibitors (ICE-I) on acute lung injury (ALI) in experimental severe acute pancreatitis (SAP).

**METHODS:** Forty-two SD rats were randomly divided into 3 groups: healthy controls (HC,  $n = 6$ ); SAP-S group ( $n = 18$ ); SAP-ICE-I group ( $n = 18$ ). SAP was induced by retrograde infusion of 5% sodium taurocholate into the bile-pancreatic duct. HC rats underwent the same surgical procedures and duct cannulation without sodium taurocholate infusion. In SAP-S group, rats received the first intraperitoneal injection of isotonic saline 2 h after induction of acute pancreatitis and a repeated injection after 12 h. In SAP-ICE-I group, the rats were firstly given ICE inhibitors intraperitoneally 2 h after induction of pancreatitis. As in SAP-S group, the injection was repeated at 12 h. Serum IL-1 $\beta$  was measured by ELISA. Intrapulmonary expression of Caspase-1, IL-1 $\beta$  and IL-18 mRNA were detected by semi-quantitative RT-PCR. The wet/dry weight ratios and histopathological changes of the lungs were also evaluated.

**RESULTS:** Serum IL-1 $\beta$  levels in SAP-S group were  $276.77 \pm 44.92$  pg/mL at 6 h,  $308.99 \pm 34.95$  pg/mL at 12 h, and  $311.60 \pm 46.51$  pg/mL at 18 h, which were increased significantly ( $P < 0.01$ , vs HC). In SAP-ICE-I group, those values were decreased significantly ( $P < 0.01$ , vs SAP-S). Intrapulmonary expression of Caspase-1, IL-1 $\beta$  and IL-18 mRNA were observed in the HC group, while they were increased significantly in the SAP-S group ( $P < 0.01$ , vs HC). The expression of IL-1 $\beta$  and IL-18 mRNA were decreased significantly in the SAP-ICE-I group ( $P < 0.01$ , vs SAP-S), whereas Caspase-1 mRNA expression had no significant difference ( $P > 0.05$ ). The wet/dry weight ratios of the lungs in the SAP-S group were increased significantly ( $P < 0.05$  at 6 h,  $P < 0.01$  at 12 h and 18 h, vs HC) and they were decreased significantly in the SAP-ICE-I group ( $P < 0.05$ , vs SAP-S).

Caspase-1 inhibitors ameliorated the severity of ALI in SAP.

**CONCLUSION:** Caspase-1 activation, and overproduction of IL-1 $\beta$  and IL-18 play an important role in the course of ALI, and Caspase-1 inhibition is effective for the treatment of ALI in experimental SAP.

## INTRODUCTION

Patients with severe acute pancreatitis (SAP) is often complicated with acute lung injury (ALI), which is difficult to deal with clinically. IL-1 $\beta$  and TNF- $\alpha$  are currently believed to play an important role in promoting local tissue destruction and remote organ failure in the course of SAP<sup>[1,2]</sup>. IL-18 is a novel proinflammatory cytokine, sharing striking structural and functional similarities to IL-1 $\beta$ . Caspase-1, also termed IL-1 $\beta$ -converting-enzyme (ICE), is the first member of the family of cysteine proteases called Caspases, with the functions of proteolytic cleavage of IL-1 $\beta$  and IL-18 precursors into their active forms. Suppression of IL-1 $\beta$  and IL-18 by inhibiting the function of ICE, subsequently alleviating cascade reactions, may have a therapeutic significance for SAP and systemic inflammatory response syndrome (SIRS).

In this study, an experimental model of SAP was induced in SD rats. Serum IL-1 $\beta$  levels, intrapulmonary expression of Caspase-1, IL-1 $\beta$  and IL-18 mRNA were measured respectively, and the wet/dry weight ratios and histopathological alterations in the lungs were observed to assess the therapeutic effect of Caspase-1 inhibitors on ALI in SAP.

## MATERIALS AND METHODS

### Experimental animal models and grouping

Healthy adult male Sprague-Dawley rats weighing 230-250

g were provided by the Experimental Animal Center of Jingling Hospital in Nanjing. All forty-two rats were randomly divided into 3 groups: healthy controls (HC,  $n = 6$ ); SAP-S group ( $n = 18$ ); SAP-ICE-I group ( $n = 18$ ). The latter two groups were further divided into 6, 12, and 18 h time points, and each contained 6 rats. SAP was induced by retrograde infusion of 5% sodium taurocholate into the bile-pancreatic duct in SD rats<sup>[3-7]</sup>. HC rats underwent the same surgical procedures and duct cannulation without sodium taurocholate infusion. In the SAP-S group, the rats received the first intraperitoneal injection of isotonic saline 2 h after induction of acute pancreatitis and a second injection after 12 h. In the SAP-ICE-I group, the rats were firstly given 0.25 mg of an ICE inhibitor (Ac-Tyr-Val-Ala-Asp-2,6-dimethylbenzoyloxymethylketone) dissolved in 1 mL sterile phosphate-buffered saline intraperitoneally 2 h after induction of pancreatitis. As in the SAP-S group, this was repeated at 12 h. Surviving rats were killed at certain time points, and all samples were obtained for subsequent analysis.

### Measurement of serum IL-1 $\beta$ levels

Serum IL-1 $\beta$  levels were measured using a commercial enzyme-linked immunosorbent assay (ELISA) according to the manufacturer's instructions (B&C Co.). All samples were tested in duplicate and expressed as the means.

### RT-PCR examination of intrapulmonary Caspase-1, IL-1 $\beta$ and IL-18 mRNA

**Reagents and primers:** TRIZOL Reagent was purchased from Gibco BRL Life Technologies. One Step RNA PCR kit (AMV) was purchased from TaKaRa Biotechnology (Dalian) Co., Ltd. The sequences of IL-1 $\beta$ , IL-18 and  $\beta$ -actin primers (designed by Primer 3 software, synthesized by Sangon Biotechnology Co. Shanghai) were as follows: upstream and downstream primers, respectively: 5'-AAG GTC CTG AGG GCA AAG AG-3' and 5'-GTG TTG CAG ATA ATG AGG GC-3' for Caspase-1 (500 bp of amplification products); 5'-AGA AGC TGT GGC AGC TAC CT-3' and 5'-TTG GGA TCC ACA CTC TCC AG-3' for IL-1 $\beta$  (400 bp of amplification products); 5'-GCT GCA ATA CCA GAA GAA GG-3' and 5'-AGA TAG GGT CAC AGC CAG TC-3' for IL-18 (300 bp of amplification products); 5'-AGG GTG TGA TGG TGG GTA TG-3' and 5'-CAT AGC TCT TCT CCA GGG AG-3' for  $\beta$ -actin (600 bp of amplification products).

**Total lung RNA extraction:** Total RNA was extracted from the lung tissue by TRIZOL Reagent according to the manufacturer's protocol. One hundred mg of lung tissue was homogenized in 1 mL of TRIZOL Reagent. Following homogenization, insoluble material was removed from the homogenate by centrifugation at 12000 r/min for 10 min at 4°C and the homogenized tissue was incubated for 5 min at a room temperature. Then 0.2 mL of chloroform was then added. The tube was shaken vigorously for 15 s and incubated at room temperature for 3 min. The sample was centrifuged at 12000 r/min for 15 min at 4°C and the upper aqueous phase was transferred to another tube. After that 0.5 mL of isopropyl alcohol was added. The sample was incubated at room

temperature for 10 min and centrifuged at 12000 r/min for 10 min at 4°C. The supernatant was discarded and the RNA pellets were washed with 1 mL of 75% ethanol. The samples were mixed by vortexing and centrifuged at 7000 r/min for 5 min at 4°C. At the end of the procedure, the RNA pellet was air-dried for 10 min, dissolved in 50  $\mu$ L of DEPC water, and stored at -80°C. The A260/280 ratio was measured with an ultraviolet spectrophotometer and the RNA content was calculated (1A260 = 40  $\mu$ g/mL).

RT-PCR was carried out using the One Step method. The total RT-PCR volume of each Eppendorf tube was 50  $\mu$ L, including 5  $\mu$ L of 10  $\times$  One Step RNA PCR buffer, 10  $\mu$ L of MgCl<sub>2</sub> (25 mol/L), 5  $\mu$ L of dNTPs (10 mol/L), 1  $\mu$ L of RNase inhibitor (40 U/ $\mu$ L), 1  $\mu$ L of AMV RTase XL (5 U/ $\mu$ L), 1  $\mu$ L of AMV-Optimized Taq (5 U/ $\mu$ L), 1  $\mu$ L of upstream specific primer, 1  $\mu$ L of downstream specific primer, 1  $\mu$ L of experimental sample ( $\leq 1$   $\mu$ g total RNA), 24  $\mu$ L of RNase Free dH<sub>2</sub>O. Each RT-PCR conditions were as follows: 30 min at 50°C for RT reactions, 2 min at 94°C for RTase inactivation, 30 s at 94°C, 30 s at 51°C, 90 s at 72°C for 30 cycles (Caspase-1); 30 s at 94°C, 30 s at 53°C, and 90 s at 72°C for 30 cycles (IL-1 $\beta$ ); 30 s at 94°C, 30 s at 55°C, and 90 s at 72°C for 30 cycles (IL-18); 30 s at 94°C, 30 s at 55°C, and 90 s at 72°C for 35 cycles ( $\beta$ -actin). RT-PCR was terminated with an elongation step at 72°C for 5 min, and PCR products were stored at 4°C. Five  $\mu$ L of the reaction products was visualized by electrophoresis in 2% agarose gels containing ethidium bromide. Ultraviolet illumination was used to visualize the DNA bands, and the gels were photographed digitally. Band intensity was determined by optical density with individual PCR product/ $\beta$ -actin cDNA ratios.

### W/D ratio of the lung tissue

To assess tissue edema, the right lung was removed after the experiment, then weighed and dried in a 80°C oven for 72 h until the weight was constant, and the ratio of wet weight to dry weight (W/D ratio) was then obtained.

### Histologic examination

According to routine procedures, paraffin sections of the lung tissue samples were prepared by HE staining, and histologic alterations of lung tissue were observed by light microscopy.

### Statistical analysis

All values were presented as mean  $\pm$  SD. Statistical analysis was performed using SPSS 11.0 statistical software applying One-Way ANOVA. A value of  $P < 0.05$  was regarded as statistically significant.

## RESULTS

### Serum IL-1 $\beta$ levels

In the SAP-S group and the SAP-ICE-I group, the serum IL-1 $\beta$  levels at all time points were significantly higher than those of HC ( $P < 0.01$ ), whereas serum IL-1 $\beta$  levels were significantly decreased in the SAP-ICE-I group ( $P < 0.01$ ) in comparison with the SAP-S group (Table 1).

**Table 1** Serum IL-1 $\beta$  levels and W/D ratios of the lungs in rats with SAP (mean  $\pm$  SD)

Group	n	IL-1 $\beta$ (pg/mL)	W/D ratio of lung (g/g)
HC	6	90.13 $\pm$ 21.13	4.32 $\pm$ 0.33

<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs HC group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs SAP-S group.

**Figure 1** Intrapulmonary expression of Caspase-1, IL-1 $\beta$  and IL-18 mRNA in rats with SAP. Lane 1: HC; lanes 2-4: 6-18 h in SAP-S; lanes 5-7: 6-18 h in SAP-ICE-I; lane 8: Marker.

### Intrapulmonary expression of Caspase-1, IL-1 $\beta$ and IL-18 mRNA

Intrapulmonary expression of Caspase-1, IL-1 $\beta$  and IL-18 mRNA were observed in the HC group, which were increased significantly in the SAP-S group ( $P < 0.01$  vs HC). The expression of IL-1 $\beta$  and IL-18 mRNA were significantly decreased with ICE inhibition ( $P < 0.01$ ), whereas Caspase-1 mRNA expression had no significant difference ( $P > 0.05$ ) (Table 2, Figure 1 A-C).

### W/D ratio of the lung tissue

In the SAP-S group, W/D ratios were increased significantly ( $P < 0.05$  at 6 h,  $P < 0.01$  at 12 h and 18 h, vs HC), and those were significantly attenuated with ICE inhibition ( $P < 0.01$ ) (Table 1).

### Pathologic alterations in lung tissue

Observed under a light microscope, the pulmonary structures of the HC group were basically normal. However, characteristics of typical lung injury could be seen in the SAP-S group, represented by marked congestion, edema and masses of inflammatory cell infiltration in pulmonary interstitium and aveoli, thickened alveolar septum, which became progressively severe after SAP induction. Compared with the SAP-S group, such pathologic changes were much less in the SAP-ICE-I group.

## DISCUSSION

SAP is often complicated with multiple systemic organ failure (MSOF), which is the major cause of death in SAP. In extra-pancreatic organs, ALI is most prominent. About 20% of cases with SAP may develop adult respiratory distress syndrome (ARDS). One third of the patients die during the early stages of SAP, a half of which die as a result of ARDS<sup>[8,9]</sup>. At present, the role of cytokines in the pathogenesis of SAP has become a hot issue in the research field. Of the numerous cytokines, IL-1 $\beta$  and TNF- $\alpha$  have been confirmed to play an important role in the development of systemic complications of SAP. However, their roles in mediating ALI during SAP are not completely understood.

Caspase-1/ICE is one member of the family of cysteine proteases called Caspases. One of the major functions of ICE is the proteolytic cleavage of the 31000 molecular weight IL-1 $\beta$  precursor into its biologically active 17000 form. IL-1 $\beta$  is an inflammatory cytokine produced by activated lymphocytes and monocytes. IL-1 $\beta$  and TNF- $\alpha$  are primary inducers of IL-6 and IL-8 production, and are known to cause fever, hypoperfusion, circulatory collapse, shock, metabolic acidosis, cardiac dysfunction, and the occurrence of ARDS. Norman *et al*<sup>[10]</sup> showed that no IL-1 $\beta$  mRNA expression was found in the lungs of healthy mice, and that intrapulmonary IL-1 $\beta$  mRNA and protein expression were increased after SAP

induction. Paszkowski *et al*<sup>[11]</sup> demonstrated that IL-1 $\beta$  mRNA expression could be found in the lungs of healthy rats, and that intrapulmonary IL-1 $\beta$  mRNA expression was upregulated in SAP, in proportion to the severity of ALI, suggesting the existence of a significant correlation between overproduction of IL-1 $\beta$  in the lungs and ALI in SAP.

Ac-Tyr-Val-Ala-Asp-2,6-dimethylbenzoyloxymethylketone used in this study is a highly competitive and irreversible inhibitor of ICE. It inactivates the enzyme and is relatively inert toward other bionucleophiles such as glutathione. Previous studies showed changes in serum amylase and pancreas in SAP<sup>[12,13]</sup>. In this study, the ICE inhibitor was injected into rats intraperitoneally 2 h after SAP was induced by retrograde infusion of 5% sodium taurocholate into the bili-pancreatic duct. A remarkable elevation of serum IL-1 $\beta$  levels, an upregulation of intrapulmonary Caspase-1 and IL-1 $\beta$  mRNA expression, an increased W/D ratio of the lung and obvious pathological changes after induction of SAP were observed; serum and intrapulmonary IL-1 $\beta$  expression were decreased significantly, with an improvement of pathological changes in rats treated with ICE inhibitors. These suggest that the therapeutic effects of ICE inhibitors on ALI in SAP may be associated with a reduced IL-1 $\beta$ -mediated injury. Besides generating large numbers of active IL-1 $\beta$ , ICE is also known to process the inactive precursor of IL-18 into its bioactive forms<sup>[14-17]</sup>. IL-18, formerly called IFN- $\gamma$ -inducing factor, is a novel proinflammatory cytokine with an 18000 molecular weight, sharing striking structural and functional similarities to IL-1 $\beta$ . In addition, the biological activity of IL-18 is closely related to that of IL-1 $\beta$ : IL-18 induces the gene expression and synthesis of IL-1, TNF, and several chemokines by means of a putative IL-18 receptor complex. Also, IL-18 plays an important role in the Th-1 response to the stimulation of virul antigens, primarily because of its ability to induce IFN- $\gamma$  production in T cells and NK cells. Rau *et al*<sup>[18]</sup> reported that local and systemic IL-18 concentrations are significantly elevated in patients with AP, and that serum IL-18 concentrations closely correlate with the development of pancreatic necrosis and remote organ failure. In the current study, intrapulmonary IL-18 mRNA expression was measured by RT-PCR. Marked upregulation of IL-18 mRNA was observed in the lungs after induction of SAP, and intrapulmonary IL-18 expression was significantly decreased in rats treated with ICE inhibitors. In addition, it is well established that IL-1 $\beta$ , IL-18, and TNF- $\alpha$  share a close interrelationship by inducing the synthesis of each other<sup>[14,19,20]</sup>. Paszkowski *et al*<sup>[11]</sup> indicated that intrapulmonary TNF- $\alpha$  mRNA expression was uniformly downregulated in rats receiving the treatment of ICE inhibitors, suggesting that the therapeutic effects of ICE inhibitors on ALI in SAP may correlate with a decrease in TNF- $\alpha$ -mediated injury. Considering that the synthesis of IL-1 $\beta$ , IL-18, and TNF- $\alpha$  could be induced by each other, plus the alterations in W/D ratios of the lungs and histopathologic changes in SAP, we speculate that as with TNF- $\alpha$  and IL-1 $\beta$ , overproduction of IL-18 in the lungs plays an important role in the course of SAP complicated with ALI, and that therapeutic effects of ICE inhibitors on ALI in SAP may be associated with the inhibition of

IL-18.

In summary, activation of Caspase-1/ICE, and overproduction of IL-1 $\beta$  and IL-18 in the lungs play an important role during the course of ALI and ARDS in SAP, and ICE inhibitors are effective against ALI in SAP. The mechanisms for ICE inhibition may be associated with decreased cytokine-mediated injury, such as IL-1 $\beta$ , IL-18 and TNF- $\alpha$ . Therefore, studies of the mechanism for ALI in SAP may shed new light on understanding of SIRS and MSOF, as well as the prevention and treatment for SAP.

### Abstract

**AIM:** To analyze the outcome of patients with severe drug-induced liver disease (DILD) associated with jaundice classified as hepatocellular, cholestatic or mixed liver injury and to evaluate the validity of Hy's rule and the most important predictors for outcome.

**METHODS:** The Adverse Drug Reaction Advisory Committee was set up in 1997 in our hospital to identify all suspicions of DILD following a structured prospective report form. Liver damage was divided into hepatocellular, cholestatic, and mixed types according to laboratory and histologic criteria when available. Further evaluation of causality assessment was performed.

**RESULTS:** From January 1997 to December 2004, 265 patients were diagnosed with DILD, and 140 (52.8%) of them were female. hepatocellular damage was the most common (72.1%), the incidence of death was 9.9% in patients with hepatocellular damage and 9.5% in patients with cholestatic/mixed damage ( $P < 0.05$ ). There was no difference in age of dead and recovered patients. The proportion of females and males was similar in recovered and dead patients, no difference was observed in duration of treatment between the two groups. The serum total bilirubin ( $P < 0.001$ ), direct bilirubin ( $P < 0.001$ ) and aspartate transaminase (AST) ( $P = 0.013$ ) values were higher in dead patients than in recovered patients. Chinese herbal medicine was the most frequently prescribed, accounting for 24.2% of the whole series. However, antitubercular drugs (3.4%) were found to be the primary etiological factor for fatal DILD. Factors associated with the development of fulminant

hepatic failure were hepatic encephalopathy (OR = 43.66, 95% CI = 8.47-224.95,  $P < 0.0001$ ), ascite (OR = 28.48, 95% CI = 9.26-87.58,  $P < 0.0001$ ), jaundice (OR = 11.43, 95% CI = 1.52-85.96,  $P = 0.003$ ), alcohol abuse (OR = 3.83, 95% CI = 1.26-11.67,  $P = 0.035$ ) and direct bilirubin (OR = 1.93, 95% CI = 1.25-2.58,  $P = 0.012$ ).

**CONCLUSION:** Death occurs in 9.8% of patients with DILD. Chinese herbal medicine stands out as the most common drug for DILD. While antitubercular drugs are found to be the primary etiological factor for fatal DILD, hepatic encephalopathy, ascites, jaundice, alcohol abuse and direct bilirubin levels are associated with the death of DILD patients.

### INTRODUCTION

Drug-induced liver disease (DILD) is an adverse drug reaction-induced disease. Almost all drugs can elevate liver enzyme level and cause DILD. However, the majority of drugs exhibit low incidences of hepatic adverse reactions. Therefore, DILD is mostly identified only after broad clinical drug application (phase IV). Well-established causes of DILD include non-steroidal anti-inflammatory drugs (NSAIDs), antibiotics, antiepileptics, statins, tuberculostatics and herbal medicines<sup>[1,2]</sup>.

High serum aminotransferase (hepatocellular injury) and jaundice levels induced by different drugs have been reported to result in a mortality of 10%-50%<sup>[3-5]</sup>. These observations have been named "Hy's rule" after Hyman Zimmerman, who first described them. The rule states that if both drug-induced hepatocellular injury and jaundice occur simultaneously without biliary obstruction, a mortality of at least 10% can be expected<sup>[3,5,6]</sup>. Hy's rule defined as DILD with serum alanine aminotransferase (ALT) levels 3 or more times the upper limit of normal

(ULN) + serum bilirubin levels 2 or more times the ULN level, has been advocated by the US Food and Drug Administration for use in the assessment of hepatotoxicity of newly developed drugs<sup>[5,7]</sup>. However, this rule has never been scientifically validated. The sensitivity and specificity of clinical jaundice for the outcome in patients with drug-induced hepatocellular (HC) injury are unknown. The most important predictors of outcome in DILD with HC injury have not been analyzed in a large number of patients. Furthermore, information about the prognosis in other forms of DILD (e.g., DILD with cholestatic or mixed damage) is limited.

In our hospital, a systematic monitoring system for DILD has been in use since 1997, with regular causality assessment offering the opportunity to evaluate a large number of patients with DILD. The aim of this study was to analyze the outcome of patients with severe DILD associated with jaundice classified as HC, cholestatic (CS), or mixed liver injury and to evaluate the validity of Hy's rule and the most important predictors for outcome.

## MATERIALS AND METHODS

All reports of suspected drug-induced liver injury received by the Adverse Drug Reaction Advisory Committee (ADRAC) in our hospital between 1997 and 2004 have been computerized and are available for legally acceptable users with a password online. Our analysis was restricted to patients with serum bilirubin levels two-fold higher than the ULN level. Furthermore, in patients with HC injury, our analysis was restricted to those patients with ALT levels 3 or more times the ULN level as well as serum bilirubin levels 2 or more times the ULN level.

A total of 301 reports fulfilling these criteria were evaluated using international consensus criteria [RousselUclaf causality assessment method (RUCAM)]<sup>[8,9]</sup> to assess the probability of a causal relationship between drug exposure and liver disease. Causality assessment was performed based on information about the onset time of reaction of the drug, the development of liver tests after cessation of the drug, the presence of risk factors, and known hepatotoxicity of the suspected drug and concomitant drug or drugs<sup>[8]</sup>. Furthermore, investigations were performed to exclude non-drug causes for the reaction. Thus, abnormal liver tests shortly after the use of a new drug, rapid decline of abnormal liver test values after stopping the drug, and exclusion of other causes gave high scores compatible with the drug as a possible, probable, or highly probable cause of the reaction<sup>[8]</sup>. If the report did not receive a high enough score to consider a causal relationship with the suspected drug, the reaction did not likely occur in accordance with the criteria or the relationship was excluded. Each author scored approximately one fifth of the cases. We all performed assessment of 100 cases independently and found very low intraobserver variability with no disagreement in the assessment of cases.

Because many patients had been exposed to several drugs at the time when liver injury occurred, it is not always possible to deduce which drug is most likely responsible for it. In such cases, the reaction was judged to

be potentially caused by more than one drug. On the other hand, if there was a close temporal relationship between the liver injury and treatment of patients with only one of many drugs, which was then considered to be the suspected drug.

The computerized reports include all relevant facts from medical records and the results of laboratory investigations. The following information was collected from the reports: duration of exposure, drug(s) suspected to be responsible, age and sex of the patients, duration of treatment, type of liver injury, results of AST and ALT as well as alkaline phosphatase (ALP) and bilirubin tests, nondrug causes, and outcome of the patients (recovery, death or liver transplantation).

The type of liver damage was classified according to the International Consensus Meeting criteria<sup>[8,9]</sup>, using ALT and alkaline phosphatase activity, expressed as a multiple of the upper limit of normality, to determine the ratio (R) of ALT/AP. The type of liver damage was hepatocellular when  $R > 5$ , cholestatic when  $R < 2$ , and mixed when  $R > 2$  but  $< 5$ . The liver tests used for the classification of liver damage were the first blood test available after liver injury.

## Statistical analysis

For descriptive purposes, Fisher's exact test was used to test differences in dichotomous variables between groups. Mann-Whitney test was used for continuous variables. Stepwise logistic regression was performed for multivariate purposes to predict death. All tests were two-tailed and conducted at a 5% significance level.

## RESULTS

During 1997-2004, ADRAC received 301 reports of suspected DILD. Of which 265 reports of DILD fulfilled the RUCAM criteria for at least a possible relationship. According to the RUCAM criteria, 22 reports (8.3%) had a possible relationship, 183 (69.1%) a probable relationship, and 60 (22.6%) a highly probable relationship. These 265 reports with a possible/probable/highly probable relationship to drug(s) included 191 with HC injury, 51 with CS injury, and 23 with mixed liver injury (Table 1). Table 1 shows the age and sex, duration of treatment, and peak liver test values in patients with different types of DILD.

There were no differences in the age of patients with HC or CS or mixed injury ( $P = 0.127$ ). A higher proportion of females were observed in all different subgroups, in which females accounted for 53%. The total protein was different both in patients with HC and CS injury ( $P = 0.003$ ) and in those with CS and mixed injury ( $P = 0.041$ ). The difference in albumin between patients with HC and CS injury was significant ( $P < 0.001$ ). Total and direct bilirubin levels were higher in patients with CS injury than in those with HC injury ( $P = 0.043$  and  $P < 0.001$  respectively) and mixed injury ( $P < 0.001$  and  $P = 0.01$  respectively). Obviously, the ALT, AST and ALP values were different in patients with mixed injury or with HC or CS injury.

Twenty-six (9.8%) of the 265 patients died of liver

**Table 1** A age and sex, duration of treatment, and peak liver test values in patients with different types of DILD

	Total	Hepatocellular	Cholestatic	Mixed
Number	265	191	51	23
Age ( $\bar{x} \pm s$ )	48.6 $\pm$ 13.7	47.8 $\pm$ 13.8	52.1 $\pm$ 13.0	47.3 $\pm$ 14.0
Sex (F/M)	140/125	100/91	27/24	13/10
Duration of treatment (d)	25.9 (1-121)	24.6 (1-120)	31.4 (8-121)	21.7 (1-47)
Total bilirubin ( $\mu\text{mol/L}$ )	95.7 (7-701)	67.5 (7-701)	236 (11-615)	105.5 (14-630)
Direct bilirubin ( $\mu\text{mol/L}$ )	49.4 (2-461)	31.8 (2-338)	126.8 (3-461)	47.5 (3.3-281)
Total protein (g/L)	66.9 $\pm$ 9.4	67.7 $\pm$ 9.6	63.3 $\pm$ 8.8	68.1 $\pm$ 8.0
Albumin (g/L)	38.1 $\pm$ 7.3	39.1 $\pm$ 6.9	34.9 $\pm$ 8.3	36.4 $\pm$ 6.2
ALT (U/L)	351.5 (13-2652)	313.8 (20-2652)	123.4 (13-1079)	557 (92-1600)
AST (U/L)	230.1 (18-1925)	282.9 (19-1925)	111.8 (18-1165)	393 (48-1553)
ALP (U/L)	141.8 (51-1165)	69.6 (51-370)	117.8 (70-1165)	318.8 (147-801)
GGT (U/L)	200.7 (16-3102)	112.9 (17-788)	254 (16-3102)	241 (87-969)

The laboratory parameters are all peak values before treatment.

**Table 2** Comparison between died and recovered patients with DILD

	Died	Recovered	P
Age	52 $\pm$ 13.8	48 $\pm$ 13.7	0.187
Sex (F/M)	13/13	127/112	NS
Duration of treatment (d)	29 (1-79)	25.7 (1-121)	NS
Total bilirubin	333.3 (38-695)	82.7 (7-701)	< 0.001
Direct bilirubin	218.2 (11.5-330)	44.0 (2-461)	< 0.001
ALT	351 (78-1906)	341.8 (13-2652)	0.293

GGT	124.8 (44-1483)	203.8 (16-3102)	0.193

The laboratory parameters are all peak values. Results are expressed as mean  $\pm$  SD or medians.

failure (Table 2). The following drugs were associated with death: antitubercular drugs ( $n = 9$ ), medicinal herbs ( $n = 5$ ), immunodepressants ( $n = 2$ ), antimycotic drugs ( $n = 2$ ), antiinfection drugs ( $n = 1$ ), nonsteroidal anti-inflammatory drugs ( $n = 1$ ), antidepressant drugs ( $n = 1$ ), antithyroid drugs ( $n = 1$ ), antigout preparation ( $n = 1$ ), and other drugs ( $n = 3$ ). There were no differences in age of the dead and recovered patients. The proportion of females and males was similar in recovered and dead patients, and no difference was observed in duration of treatment between them.

The levels of serum total bilirubin, direct bilirubin and AST were higher in dead patients than in recovered patients, whereas the levels of ALT, ALP and GGT were similar in the two groups.

A comparison between the dead and recovered patients in the HC group revealed no differences in age, sex, duration of treatment, ALT or ALP (Table 3). Total bilirubin and AST levels were higher in deceased patients with HC injury than in those with CS/mixed injury, while total bilirubin levels were significantly higher only in

**Table 3** Comparison between died and recovered patients with hepatocellular injury or with cholestatic/mixed liver injury

	Hepatocellular injury		Cholestatic/mixed injury	
	Died	Recovered	Died	Recovered

ALP	133.7 (51-370)	130.1 (51-266)	268 (70-561)	310.1 (72-1165)

The laboratory parameters are all peak values. Results are expressed as mean  $\pm$  SD or medians. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.001$  vs the control group.

**Table 4** Factors associated with death of the patients with DILD

Independent variables	Coefficient	OR (95% CI)	P
HE	2.232	43.66 (8.47-224.95)	< 0.001
Ascite	2.883	28.48 (9.26-87.58)	< 0.001
Jaundice	1.124	11.43 (1.52-85.96)	0.003
Alcohol abuse	1.511	3.83 (1.26-11.67)	0.035
Direct bilirubin	-0.007	1.93 (1.25-2.58)	0.012

CI = confidence interval; OR = odds ratio, HE = hepatic encephalopathy, Constant = -15.37.

deceased patients (Table 3).

Logistic regression analysis showed that hepatic encephalopathy ( $P < 0.001$ ), ascite ( $P < 0.001$ ), jaundice ( $P = 0.003$ ), alcohol abuse ( $P = 0.035$ ) and direct bilirubin ( $P = 0.012$ ) could independently predict death (Table 4).

The drugs associated with DILD are listed in Table 5. The largest number of reports on drug-induced fatal HC injury was related to antitubercular drugs (because only 2 DILDs were associated with antigout drug, we did not calculate the mortality induced by this drug). In this group, 7 out of the 20 patients died (35%). The second most commonly reported drug type associated with mortality was antifungal agents (33.3%). The mortality ranging from 35% of antitubercular drugs to 0% in reports is related to many other drugs. As in CS/mixed injury, the highest number of reports of death is related to immunosuppressive agent (28.6%). The mortality ranges from 0% with most of the drugs to 28.6%. Overall, antitubercular drugs (32.1%) are the primary etiological factor for fatal DILD.

## DISCUSSION

Drug-induced hepatotoxicity remains a challenge to modern hepatology. Hepatotoxicity is typically detected when several thousands of patients are exposed to drugs, and regulatory authorities are often compelled to make decisions based on scanty, fragmentary, and incomplete

Table 5 Patients with hepatocellular, cholestatic or mixed liver injury and their death due to different drugs

	Hepatocellular	Death	Cholestatic/mixed	Death	Total study group	Death

Others	18	2	9	1	27	3

epidemiologic data. In addition, a major challenge is the ability to identify predisposed subjects before they receive drugs. The susceptibility of individuals to genetic and environmental factors is still poorly understood. In this study, we analyzed cases of toxic liver injury prospectively collected from our hospital during the past 8 years.

Hyman Zimmerman, the pioneer in the field of DILD, observed that combined HC injury (high aminotransferase) and jaundice induced by a drug is associated with the poor prognosis of patients, with a fatality rate of 10%-50% for different drugs involved (Hy's rule)<sup>[3-6]</sup>. It was reported that a new drug should be stopped in patients if their AST and ALT levels are 3-fold higher than ULN level, and bilirubin levels are 2-fold higher than ULN level<sup>[7]</sup>. Concomitant jaundice and hepatocellular injury observed in clinical trials of new drugs are considered to cause serious troubles concerning safety in the postmarketing phase, when a much larger number of patients are exposed to drugs<sup>[5]</sup>.

Our analysis is unique because it was performed in a large cohort of patients with severe DILD, giving the opportunity to elucidate the most important predictors for outcome. Adverse drug reactions are significantly underreported. The true incidence of hepatic adverse drug reactions has been recently observed. However, a recent prospective survey of drug-induced liver injury in the general population in France suggests that at most, only 1 out of 16 cases of DILD in France is actually reported<sup>[10]</sup>.

Heptatotoxicity was found in a higher proportion of females (53%) in our study, which is consistent with the reported epidemiologic data<sup>[10,11]</sup>. No difference was found in age of the deceased and recovered patients in our study. A recent study from Japan reported that there is also no difference in age of deceased and recovered patients with DILD<sup>[12]</sup>. The levels of serum total bilirubin and AST were higher in deceased patients than in recovered patients, whereas ALT, ALP and GGT levels were similar in the two groups in the current study, suggesting that hepatic encephalopathy, ascites, jaundice, alcohol abuse and direct bilirubin increase the risk of death in patients with DILD.

We found that the main causative drugs were Chinese

herbal medicine (24.2%), followed by immunosuppressive agents (12.5%), antituberculous drugs (10.6%), antibiotics (9.4%), antithyroid drugs (8.7%). But antituberculous drugs (32.1%) were the leading cause of fatal DILD.

In summary, Chinese herbal medicine is the most common drug associated with liver injury, and the mortality rate is 9.8% in patients with DILD. Hepatic encephalopathy, ascites, jaundice, alcohol abuse and direct bilirubin are associated with the death of patients with DILD. Our ADRAC has proved to be an effective instrument in detecting cases of idiosyncratic liver disease and delineating a profile of risk factors for severity. Further efforts must be made to prevent hepatic adverse reactions to drugs.

## Abstract

**AIM:** To retrospectively evaluate the preoperative diagnostic approaches and management of colonic injuries following blunt abdominal trauma.

**METHODS:** A total of 82 patients with colonic injuries caused by blunt trauma between January 1992 and December 2005 were enrolled. Data were collected on clinical presentation, investigations, diagnostic methods, associated injuries, and operative management. Colonic injury-related mortality and abdominal complications were analyzed.

**RESULTS:** Colonic injuries were caused mainly by motor vehicle accidents. Of the 82 patients, 58 (70.3%) had other associated injuries. Laparotomy was performed within 6 h after injury in 69 cases (84.1%), laparoscopy in 3 because of haemodynamic instability. The most commonly injured site was located in the transverse colon. The mean colon injury scale score was 2.8. The degree of faecal contamination was classified as mild in 18 (22.0%), moderate in 42 (51.2%), severe in 14 (17.1%), and unknown in 8 (9.8%) cases. Sixty-seven patients (81.7%) were treated with primary repair or resection and anastomosis. Faecal stream diversion was performed in 15 cases (18.3%). The overall mortality rate was 6.1%. The incidence of colonic injury-related abdominal complications was 20.7%. The only independent predictor of complications was the degree of peritoneal faecal contamination ( $P = 0.02$ ).

**CONCLUSION:** Colonic injuries following blunt trauma are especially important because of the severity and complexity of associated injuries. A thorough physical examination and a combination of tests can be used to evaluate the indications for laparotomy. One stage management at the time of initial exploration is most

## INTRODUCTION

Although the colon is often injured in case of penetrating abdominal trauma, a significant proportion of colonic injuries caused by road accidents is a grossly destructive blunt type associated with damage to multiple organs<sup>[1-3]</sup>. The diagnosis and management of blunt colon injuries are still debatable. The aim of this retrospective study was to evaluate the preoperative diagnostic methods and management of colonic injuries following blunt abdominal trauma.

## MATERIALS AND METHODS

### Subjects

All patients with colonic injuries caused by blunt trauma presenting to the Emergency Center of the Second Affiliated Hospital of School of Medicine of Zhejiang University between January 1992 and December 2005 were enrolled. The criterion for inclusion in the study was full thickness perforation of colon injuries requiring surgical repair. Data were collected on clinical presentation, investigations, diagnostic methods, associated injuries, operative management, morbidity and mortality.

Haemodynamic status was determined based on their heart rate and systolic blood pressure (BP) on admission. A systolic BP equal to or  $< 90$  mmHg on admission was interpreted as haemodynamic instability or presence of shock. The time from injury to operation was recorded. The site of colon injury (right colon defined as the right of the middle colic vessels, left colon the left of the vessels) and major associated injuries of the head, thorax, pelvis, axial skeleton, major blood vessels and long bones were recorded.

The severity of colon injury was graded according to the colon injury scale (CIS) score<sup>[4]</sup>. CIS score was defined as follows: grade 1: contusion and serosal tear without devascularization, grade 2: laceration of less than 50% of the wall, grade 3: laceration of 50% or greater of the wall, grade 4: 100% transection of the wall, and grade 5: complete transection with tissue loss and devascularization, an advanced grade for multiple injuries to the colon. The degree of faecal spillage (the gross extent of intra-abdominal faecal contamination) was categorized as mild: stool contamination on local or one quadrant, moderate: stool contamination on 2 to 3 quadrants, and severe: stool contamination on all four quadrants<sup>[5]</sup>.

### Methods

All patients were resuscitated and received intravenous antibiotics in the emergency room. The discretion of operative options was based on Stone's exclusion factors for primary repair<sup>[6]</sup> and surgeons' experience. The outcome variables of the study included colonic injury-related mortality and abdominal complications (anastomotic leak, intra-abdominal abscess or peritonitis, and colon obstruction or necrosis, if it was judged to be directly related to the colonic trauma).

### Statistical analysis

All analyses were carried out by SPSS 12.0 statistical software. Independent predictors for colostomy and post-operative complications were determined by entering potential confounders into a multivariate stepwise (backward elimination) logistic regression. Variables considered in the model for colostomy included age, mechanism of injury, shock on admission, CIS, degree of peritoneal faecal contamination, location of colon injury, and associated intra-abdominal injury.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Demographic data

A total of 82 patients were included in this study. There were 77 males (93.9%) and 5 females (6.1%). Their age ranged 15-67 years with a mean of 37.6 years. Colonic injury was found in 57 patients (69.5%) due to motor vehicle accidents, in 18 (22.0%) due to building accidents, in 6 (7.3%) due to criminal assault, and in 1 (1.2%) due to burst injury.

### Clinical presentation

Abdominal signs could not be detected in 8 cases (9.8%) because of head injuries, intoxication or sedation. Seventy patients (94.6%) had moderate to severe abdominal tenderness, 18 (24.3%) had diffuse peritonism, 23 (28.0%) had shock on admission. In addition, hematuria was found in 12 patients (14.6%), paraplegia in 2 (2.4%), arocele of scroticles in 2 (2.4%) patients. Plain abdominal radiograph was performed to find pneumoperitoneum and intestinal obstruction in 54 patients. Diagnostic peritoneal lavage (DPL) or paracentesis was performed in 65 cases, which was positive in 43 cases (noncongested blood in 20 cases,

**Table 1** Associated injuries in 82 patients with blunt colonic injuries

Fracture pelvis	2

pus in 23 cases). Abdominal ultrasonography (US) and computed tomography (CT) were performed in 58 and 10 cases respectively. Among them, 12 were diagnosed as gastrointestinal injury with intraperitoneal free fluid.

### Associated injuries

Fifty-eight patients (70.3%) were found to have one or more associated injuries (Table 1). The most commonly associated intra-abdominal injury occurred in the small bowel (51.2%), followed by in the spleen, liver, and kidney. Multiple colonic wounds were observed in 4 cases (4.9%), Isolated colon injury in 20 cases (24.4%). The range of intra-abdominal organs injured was 1-4, with a mean of 2.3.

### Timing and indications for laparotomy

Seven patients (8.5%) underwent immediate laparotomy (< 2 h after injury), 4 for severe peritonitis and 3 due to haemodynamic instability. Laparotomy was performed between 2 h and 6 h after injury in 62 cases (75.6%). Of them, 33 had a laparotomy because of abdominal signs with evidence of peritonitis at admission or during observation, 35 because of positive DPL or paracentesis. Eighteen (51.4%) of these patients had more than one significant intra-abdominal injury. An abdominal CT scan or US imaging with diagnostic or suspicious findings was the main reason for laparotomy in 15 cases (18.3%). Colonic injuries were found in 2 patients at diagnostic laparoscopy (Figure 1).

### Site and nature of injuries

A total of 87 colonic injuries were found in 82 patients. The most often wounded site was located in the transverse colon (32 cases, 36.8%). The right colon injury was found in 21 cases, the descending colon injury in 16, the sigmoid colon injury in 13, and the intraperitoneal rectum injury in 5. The mean CIS score was  $2.8 \pm 1.2$ . The degree of faecal contamination was classified by the operating surgeon as mild in 18 cases (22.0%), moderate in 42 (51.2%), severe in 14 (17.1%), and unknown in 8 (9.8%).

### Management and prognosis

Therapeutic options were considered: two-stage management for those with any type of faecal stream diversion, while one stage management for those undergoing primary repair of the injured colon with or without anastomosis. The successful rate for colonic wounds without diversion was 81.7% (67 cases). Primary repair was undertaken in 37 cases with resection and primary anastomosis in a further 30 cases. Two-stage operation was performed in 15 cases (18.3%): repair and protective ostomy in 11 cases, exteriorisation of the repaired bowel in 3 cases, Hartmann's operation in 1 case. The overall mortality rate was 6.1% (5/82). The overall incidence of colonic injury-related abdominal complications was 20.7% (17/82). The most common complications were anastomotic leak (12 cases), intra-abdominal abscess (10 cases), wound infection (12 cases) and colon obstruction or necrosis (4 cases). The only independent predictor of complications was the degree of peritoneal faecal contamination ( $P = 0.02$ ). There was no significant correlation between age, mechanism of injury, shock on admission, location of colon injury, therapeutic options and outcome in terms of morbidity and mortality.

### DISCUSSION

Injuries of the hollow viscera are far less common in blunt abdominal trauma than in penetrating abdominal trauma. Blunt abdominal trauma accounts for approximately 5% to 15% of all operative abdominal injuries<sup>[3,7]</sup>. The majority of colonic injuries caused by penetrating trauma are dominant<sup>[1-3,5]</sup>. Nevertheless, in our experience about 6.5% of patients with blunt trauma at admission had injuries to the colon and rectum, which is slightly higher than the reported 5%<sup>[8]</sup>. Despite their infrequency, traumatic blunt injuries to the colon are extremely destructive and generally associated with damage to multiple organ systems, making diagnosis and treatment difficult. It was reported that delayed management of colonic injuries results in a high incidence of morbidity<sup>[9]</sup>. Therefore, further researches on guidelines for the diagnosis and surgical management of colonic injuries following blunt trauma are especially important.

No clinical investigations are available to compare with gastrointestinal tract injuries. Moreover, clinical assessment can be unreliable in patients following blunt trauma due to distracting injuries, head and spinal cord injuries, and shock. Less than 50% of gastrointestinal tract injuries resulting from blunt trauma are reported to have sufficient clinical findings to indicate the need for laparotomy<sup>[10]</sup>. In this study, 3 patients with unstable haemodynamics undergoing immediate laparotomy (< 2 h) showed marked evidence for abdominal injury. The other 4 patients with gross abdominal distension and marked tenderness were also immediately operated. In 6 patients presented within two hours, abdominal signs were vague at initial evaluation but became marked over a few hours at a repeated examination. The finding of abdominal signs in the other 27 cases presented between two and six hours after trauma resulted in laparotomy. Tenderness or other abdominal findings were usually apparent within 24 h.

**Figure 1** Outcome of 82 patients with colonic injuries. S = survived, D = died.

Physical examination and diagnostic tests can be used to evaluate patients with blunt abdominal trauma, including DPL, US, CT, and diagnostic laparoscopy. Speed and efficiency are important factors in the performing such tests<sup>[3]</sup>. It is reported that peritoneal lavage cell count may also be useful in early detection of hollow viscus injury<sup>[11,12]</sup>. Although DPL is sensitive in identifying haemoperitoneum and associated hollow viscus injury, it has been criticised for its higher rate of non-therapeutic laparotomy (NTL) and inconvenience in practice<sup>[12]</sup>. In this study, the presence of positive DPL or paracentesis was an important clinical finding. The routine use of diagnostic celiocentesis to detect possible intra-abdominal injuries in cardiovascularly stable patients has been used to differentiate between injuries that require a therapeutic laparotomy and those that do not<sup>[13]</sup>. Suspicious diagnosis of gastrointestinal tract injuries was indicated in 35 cases in this study. However, the diagnostic rate of colonic injuries by DPL or celiocentesis was decreased over the study period, which may be due to the increased use of imaging techniques to assess haemodynamically stable trauma patients.

US is convenient, cheap and noninvasive. A positive study is defined as evidence of free fluid or solid-organ parenchymal injury. Abdominal CT is also useful in the diagnosis of abdominal injuries as it accurately delineates solid organ injuries and retroperitoneal lesions. While some advocate limiting imaging tests to evaluation of patients with DPL-positive results and haemodynamic stability, US and CT remain the preferred tool in the evaluation of blunt abdominal trauma<sup>[3,14]</sup>. The accuracy of abdominal US for evaluating blunt abdominal trauma is comparable to the reported accuracy<sup>[15]</sup>. However, only 10 out of the 58 scans in our study could diagnose intra-abdominal gastrointestinal tract injuries with 5 being suspicious of a significant intra-abdominal injury. Some patients with free fluid but no evidence of a solid viscus injury might presumably be overlooked.

Although the role of laparoscopy in abdominal trauma is controversial<sup>[16]</sup>, diagnostic laparoscopy has been introduced in our emergency center. Its indications have expanded from identifying the causative pathology of acute abdominal pain to avoidance of unnecessary laparotomies, treatment of intra-abdominal lesions, and

can be used as a resource for evaluating blunt abdominal trauma. Diagnostic laparoscopy was performed in 2 cases in our study and some direct indications for colonic injuries (such as faecal spillage, colon rupture) were found in both cases. Take together, the indications for laparotomy were determined according one of the following findings: haemodynamic instability with reasonable clinical suspicion of an intra-abdominal cause, positive abdominal signs, positive DPL, positive diagnostic imaging and abdominal finding by laparoscopy.

The management of colonic injuries has changed significantly from "faecal diversion dogma" to primary repair<sup>[2,3]</sup>. Although several studies showed that diversion is not mandatory, additional considerations in management should be taken into account regarding grossly destructive colon injuries. In our study, mild, moderate and severe faecal contamination was found in 22.0%, 51.2%, and 17.1% of patients, respectively at laparotomy. In 15 patients (18.3%), primary laparotomy was terminated before the completion of definitive surgery (abbreviated laparotomy or damage control).

It was reported that the mortality of colonic injuries have declined to 2%-12%<sup>[1,3,17]</sup>. Primary closure or resection and anastomosis can be used in patients with colonic injury. The results are generally favorable, due to the advances in intensive care techniques and antibiotic therapy. Primary repair reduces operation and postoperative complications, avoids a second operation, stoma complications, and the financial burden related to colostomy care. A number of factors have been traditionally accepted to be associated with higher mortality and morbidity of primary colonic repair. It was reported that patients should be excluded from primary repair in the presence of shock, major blood loss, > two organs injured, faecal contamination higher than 'mild', delay of repair > 8 h and destructive wounds of the colon or abdominal wall requiring resection<sup>[6]</sup>. The grade of colonic injuries trends to be independently associated with intra-abdominal complications. In our study, the overall mortality rate was 6.1%. Although neither grade of injury nor ostomy formation demonstrated a significant impact on morbidity, peritoneal faecal contamination has shown its significant predictive value for complications. We advocate that peritoneal faecal contamination should be thoroughly removed during operation to reduce postoperative abdominal septic morbidities. There was no difference between patients with primary repair and faecal stream diversion. However, other organ injuries must be kept in mind. Colostomy may be indicated due to unusual conditions, such as intramural hematomas causing compression ischemia and delayed perforation, mesenteric hematomas causing vascular compression with

subsequent infarction, and perforations in omentum or other surrounding organs<sup>[3]</sup>. All together, the decision for a primary anastomosis, especially after segmental resection in the descending colon, should be individualized according to the injuries in different patients.

### INTRODUCTION

Hepatitis is an important but uncommon manifestation of acute Epstein Barr infection. Infectious mononucleosis is usually a disease of young adults. We report a case of infectious mononucleosis in a 72-year old jaundiced gentleman with ferritin level of 2438 that normalised on clinical improvement.

### CASE REPORT

A 72-year old retired farmer was admitted with a three-week history of feeling generally unwell. He gave a history of loss of appetite with stable weight. He denied any history of fever. Having a long history of prostatism, he

was found to be in urinary retention at the same time for which he was catheterised. He was not started on any new medications and denied taking any over the counter medications. He said his urine was dark and sometimes had dysuria. He denied any gastro-intestinal symptoms.

His past history included osteoarthritis, previous myocardial infarction in 1993, gastro-oesophageal reflux disease and laparoscopic herniorrhaphy.

His medications were 75 mg aspirin, 10 mg atorvastatin, 300 mg quinine sulphate, 20 mg omeprazole and 5 mg amlodipine once daily. He said he was allergic to codeine phosphate. He was living on his own and his wife had recently passed away. His alcohol intake was negligible. There was no family history of any clinical significance.

On clinical examination he was noticed to be jaundiced, afebrile, haemodynamically stable. There were no stigmata of chronic liver disease. His abdomen was soft with mild tenderness elicited in the right hypochondrium. No organomegaly or masses were noted. Examinations of cardiovascular and respiratory systems were normal.

His blood tests were as follows: Hb = 14.7 g/dL (13.5-16.9), WBC = 6.1 (4.5-13.0), platelets = 161 (150-400), MCV = 92 fL (84-99.0), neutrophils = 1.65 (2.0-7.5), lymphocytes = 3.97 (1.5-4.0). A blood film showed a moderate number of atypical lymphocytes.

Serum ferritin was high at 2438 µg/L (25-400). Haemochromatosis screen was negative. PT, APTT and fibrinogen were normal. Sodium was 135 mmol/L (135-145), potassium 4.2 mmol/L (3.5-5.3), urea 6.1 mmol/L (3-7) and creatinine 102 µmol/L (53-115) (Table 1).

Bilirubin was 50 µmol/L (0-20), alanine aminotransferase (ALT) 254 U/L (0-37), alkaline phosphatase (ALP) 677 U/L (39-128), gamma glutamic transpeptidase (GGT) 817, albumin 34 g/dL (35-52), calcium 2.18 mmol/L (2.1-2.6), C reactive protein (CRP) 21 mg/L (0-8), alpha-fetoprotein 3.5 (0-5.8), C3 and C4 (complements) were normal; IgM was 3.73 g/L (0.5-2).

Blood and urine cultures were negative. Hepatitis A, B, C and CMV serology were negative. Anti Epstein Barr virus (EBV) capsid antigens IgG and IgM were detected, Anti EBV nuclear antigen IgG was also detected.

Anti nuclear antibody (ANA) was negative. Anti neutrophil cytoplasmic antibody (ANCA), antimitochondrial, smooth muscle, liver kidney microsomal antibodies were all negative.

Chest and abdominal X-rays showed no radiological abnormalities. He had an abdominal CT showing moderate

Table 1 Abnormal blood tests in patient

splenomegaly and liver changes that were suggested as possibly secondary to hepatitis.

He was managed conservatively, his LFTs improved. He remained very well and was discharged after 2 wk of hospitalisation.

He was seen in Outpatient Follow-up Clinic after 4 mo, he was well and his weight was stable. His ferritin and LFT at that time became normal.

## DISCUSSION

Infectious mononucleosis (IM) was first described in 1920. It was not until 1968 that EBV infection was described as a causative agent of IM. Incubation period is 25-50 d. It is usually a self-limiting disease.

There is a mortality rate of 0.1% associated with IM. Ninety percent of patients have asymptomatic deranged liver function tests, but jaundice is rare. EBV hepatitis is an important cause of viral hepatitis.

Fulminant hepatitis is rare but has been reported<sup>[1]</sup>. Severe hepatitis is rare, although it has been reported. Hepatomegaly is frequently present. Jaundice is rare. Occasionally, jaundice may be due to autoimmune haemolysis. Cholestasis can be noticed<sup>[2]</sup>. Splenomegaly is common and 50%-75% of patients develop it. Dommerby *et al*<sup>[3]</sup> reported that all patients have ultrasonic splenomegaly but that is palpable in only a few. Splenic rupture should be ruled out in patients who present with severe abdomen pain. Rupture can be precipitated by sports activity or can occur spontaneously and 0.1%- 0.5% of cases can result in rupture<sup>[4]</sup>. Spleen is most vulnerable to rupture in the 2<sup>nd</sup> and 3<sup>rd</sup> week of infection. Preparation with amoxicillin can result in rash frequently. Fever can be noted in 90 % of cases, usually low grade. Maculo- popular rash can be noticed in 5%-10% of cases, but is more common in children.

Malaise and fatigue may persist for weeks or months after IM. Persistent EBV infection is not a cause of chronic fatigue syndrome (CFS). High titres of antibodies to EBV may be noticed in patients with CFS that are identical to healthy EBV- sero positive adults.

Table 2 Gastrointestinal manifestations of EBV infection

1	Asymptomatic deranged LFTs
2	Viral hepatitis, usually self limiting
3	Fulminant hepatitis
4	Cholestasis
5	Auto-immune haemolysis causing jaundice
6	Splenomegaly
7	Splenic rupture (rare)

Duncan syndrome, a rare X linked recessive disorder, was reported by Purtilo *et al* in 1975 which is characterised by a defect in the immune response against EBV resulting failure to prevent EBV replication and hence leading to fatal complications<sup>[5]</sup>. Patients with combined immunodeficiency, Wiskott- Aldrich syndrome and Ataxia telangiectasia develop severe IM<sup>[6]</sup>. Likewise, patients with acquired immunodeficiency states like patients with AIDS or those receiving immunosuppressive agents develop severe IM and malignant lymphoma<sup>[7]</sup>.

Treatment for IM is supportive with analgesic as required and rest. Due to the risk of splenic rupture physical activity in excess is to be avoided. There is no place for oral glucocorticoids in uncomplicated IM. In patients with severe tonsillar enlargement that might predispose to airway obstruction, severe thrombocytopenia or haemolytic anaemia, Prednisolone 40 to 60 mg once daily for 2-3 d with tapering over 3 wk is advised.

In conclusion, acute EBV hepatitis should be ruled out in acutely jaundiced patients with high ferritin at any age group (Table 2).

## Abstract

An 81-year-old Japanese man with jaundice was strongly suspected clinically of having primary sclerosing cholangitis based on clinical examinations and later died of hepatic failure. The entire course of the disease lasted about 10 mo. The autopsy revealed extensive fibrinoid necrosis in the liver, kidney, spleen, pancreas, lung, lymph nodes, and pleura. Particularly extensive fibrinoid necrosis in the portal tracts of the liver induced severe stenoses of the intrahepatic bile ducts, resulting in cholestasis in association with prominent liver injury. There were no findings indicating primary sclerosing cholangitis. The hepatic lesions in this case did not coincide with any known disease including collagen diseases. To clarify the cause of irregular stenoses of the intrahepatic biliary trees on cholangiographic findings, we postulate that some form of immunological derangement might be involved in pathogenesis of fibrinoid necrosis. However, the true etiology remains unknown.

## INTRODUCTION

We herein present an unusual autopsy case showing systemic fibrinoid necroses in various organs. The case was strongly suspected clinically of primary sclerosing cholangitis (PSC) based on the cholangiographic findings; however, the autopsy disclosed systemic fibrinoid necroses instead of histological features of PSC. Particularly noteworthy was the presence of fibrinoid necrosis in the portal tracts of the liver caused stenoses of the biliary trees in association with cholestasis. We could not find any similar case reported in the literature. Presently, the etiology remains unknown.

## CASE REPORT

About 10 mo before admission to our hospital, an 81-year-old Japanese man was admitted to a local hospital because of jaundice. Laboratory examinations revealed elevated levels of serum total bilirubin and other serum enzymes such as alkaline phosphatase,  $\gamma$ -glutamyltranspeptidase, leucine aminopeptidase. Serum autoantibodies such as anti nuclear antibody, anti mitochondrial antibody and anti smooth muscle antibody were negative. Endoscopic retrograde cholangiogram showed characteristic irregularity and beading of the intrahepatic biliary tree (Figure 1). No extrahepatic involvement was found. The patient was strongly suspected clinically of PSC. The pathologic diagnosis of the liver biopsy specimen was liver damage with cholestasis. Concentric fibrosis around the bile ducts suggesting PSC was not found. The patient was transferred to our hospital 18 d before death because of aggravation of jaundice, anorexia and easy fatigability. Chronological laboratory data is shown in Table 1. Serum fibrinogen was within normal lower limit. Plasminogen and D-dimer in serum were not examined. Serologic markers for hepatitis B and C viral hepatitis were negative. These findings indicated that the liver cell damage rapidly worsened with aggravation of cholestasis, especially in end stage. Despite symptomatic and supportive treatment, the jaundice became progressively worse, and ascites and hepatic encephalopathy developed. The patient eventually died of hepatic failure.

An autopsy was performed about two hours after his death. The diagnoses at autopsy except for systemic fibrinoid necrosis were cholestatic liver damage, acute

**Figure 1** Endoscopic retrograde cholangiogram. Intrahepatic biliary branches showed irregularity and extensive beading (arrows). The long arrow indicates the dilatation of the bile duct due to stenosis caused by the pressure of cysts.

**Figure 2** Extensive fibrinoid necrosis in large portal tract. Septal bile duct is buried in the fibrinoid material (Masson's trichrome x 1). PT: portal tract, BD: bile duct.

renal swelling, acute pancreatitis, mild cardiac hypertrophy (350 g) and latent adenocarcinoma of the prostate. Pathologic findings concerning fibrinoid necrosis are described as follows.

The liver (1380 g) showed a deeply yellow-brown cut-surface due to cholestasis with scattered simple small cysts. Gross examination could not detect remarkable changes of the common bile duct and bilateral hepatic ducts. Microscopically the most striking feature was a massive deposition of homogeneous material stained scarlet with Masson's trichrome in the portal tracts (Figure 2). Careful examinations disclosed that the material was deposited in the walls of arteries and portal veins as well

as in the connective tissue (Figure 3). In the bile ducts the deposits circumscribed the lumen leaving the epithelial lining intact and caused marked stenosis. The area of the involved vessels and ducts extended from the distal interlobular portion to the proximal septal portion (Figures 2 and 3). The material was stained violet with PTAH and immunohistochemically was positive for fibrinogen and negative for immunoglobulins such as IgG, IgM, and IgA, C3 and C1q (Figure 4A). Electron microscopic findings of the liver were electron dense materials deposited in the involved tissue (Figure 4B). The results of these stainings and electronmicrogram suggested that the lesion with homogeneous material deposition was fibrinoid necrosis. In addition, the portal tracts were enlarged and

**Figure 3** A smaller portal tract. Fibrinoid material is deposited in the connective tissue, walls of the arteries and periductular connective tissue (Masson's trichrome x 20). PV: portal vein, A: artery, BD: bile duct.

infiltrated with lymphocytes and plasma cells with an occasional intermingling of polymorphonuclear cells, ductular proliferation and fibrosis. The histologic features were biliary interface activity, resulting from cholestasis. However, it was noted that the lesion with fibrinoid necrosis was scarcely accompanied by inflammatory reactions. Cholestasis also caused conspicuous parenchymal damage including feathery degeneration or necrosis. Although the liver was extensively examined histologically, there were no detectable features of PSC.

The kidney (250 g, respectively) showed marked swelling. Histologically fresh fibrinoid necrosis was found in various degrees mainly in the wall of the interlobular arteries (Figure 5). However, it was not accompanied by any inflammatory reaction. Elastica-Van Gieson stain also demonstrated the destructive changes of the arterial walls suggestive of old vascular lesions. Occasionally, focal fibrinoid necrosis involved tubules and connective tissue.

Intensive fibrinoid necrosis was noticed in lymph nodes and the spleen. Old vascular lesions were also found frequently in the spleen. The pancreas, lung and pleura showed scattered foci of fresh fibrinoid change.

On re-examination of the liver biopsy specimen, the same fibrinoid necrosis as observed on autopsy materials was seen in the portal tracts.

## DISCUSSION

The case reported here is characterized with unusual systemic fibrinoid necroses in the walls of blood vessels and connective tissue in various organs, especially in the liver. It is clear that massive fibrinoid material around the bile ducts compressed the lumen and caused various degrees of stenoses. It was considered that such stenosis of the bile ducts resulted in the findings similar to those of PSC on the cholangiogram<sup>[1,2]</sup>. Obstructive jaundice over time aggravated and severely damaged the liver parenchyma. This was considered to reflect the progressive deposition of fibrinoid material in the portal tracts.

Klemperer proposed the term, collagen diseases, to describe systemic connective tissue disorders that are characterized histologically by fibrinoid necrosis of the connective tissue<sup>[3,4]</sup>. Thereafter many studies clarified that

**Figure 4** A: Immunohistochemical staining demonstrates the positivity of the fibrinoid material for fibrinogen; B: An electron micrograph shows dense deposit materials suggestive of fibrinoid necrosis around the small bile ducts in the portal tract of the liver (original magnification x 2000).

**Figure 5** Kidney. Fibrinoid necroses were seen in the walls of the interlobular arteries (arrows) (Masson's trichrome x 10).

fibrinoid material is composed mainly of fibrins, while other minor components are immunoglobulins. Although the pathogenesis of fibrinoid necrosis has not yet been fully elucidated, it is assumed to result from the insudation of immunoglobulins into blood vessel walls, leading to activation of the coagulation cascade and deposition of fibrins<sup>[5]</sup>. Furthermore, fibrinoid necrosis of blood vessels is also known to develop in non-autoimmune diseases like malignant hypertension<sup>[6,7]</sup>. In our case laboratory findings or symptoms were not suggestive of any autoimmune disease or malignant hypertension. The liver pathology was also quite different from that of reported cases with collagen diseases<sup>[8-10]</sup>. On a search of the literature using key words such as fibrinoid necrosis, vasculitis, we could not find any case similar to ours.

It is well known that the main cholangiographic features of PSC are a beaded appearance, very short strictures, and diverticulum-like outpourchings<sup>[11]</sup>. Cholangiographic differential diagnosis of PSC involves cholangiocarcinoma, cirrhosis, acute cholangitis, and advanced primary biliary cirrhosis in general<sup>[12]</sup>. In addition, it might be necessary, in diagnosing PSC, to keep in mind that the lesions severely involving the portal tracts like our case also cause severe damage, besides stenosis of the biliary tracts.

## Abstract

We report a case of pouchitis and pre-pouch ileitis, and inflammation in the neo-terminal ileum proximal to the pouch, developed after restorative proctocolectomy for ulcerative colitis. A 35-year old female presented with fever and abdominal pain five weeks after ileostomy closure following proctocolectomy. Computed tomography showed collection of feces in the pouch and proximal ileum. A drainage tube was placed in the pouch perianally, and purulent feces were discharged. With antibiotic treatment, her symptoms disappeared, but two weeks later, she repeatedly developed fever and abdominal pain along with anal bleeding. Pouchoscopy showed mucosal inflammation in both the pouch and the pre-pouch ileum. The mucosal cytokine production was elevated in the pouch and pre-pouch ileum. With antibiotic and corticosteroid therapy, her symptoms were improved along with improvement of endoscopic inflammation and decrease of mucosal cytokine production. The fecal stasis with bacterial overgrowth is the major pathogenesis of pouchitis and pre-pouch ileitis in our case.

## INTRODUCTION

Restorative proctocolectomy with ileal pouch-anal anasto-

mosis has become the surgical procedure of choice for patients with ulcerative colitis (UC)<sup>[1-3]</sup>. Pouchitis is the most common complication following restorative proctocolectomy for UC<sup>[1-3]</sup>. Patients with UC may develop inflammation in the neo-terminal ileum (pre-pouch ileum) proximal to the pouch, so called pre-pouch ileitis. So far, there has been only one study reporting the details of pre-pouch ileitis. Bell and colleagues<sup>[6]</sup> retrospectively investigated the clinicopathological characteristics of pre-pouch ileitis using their pouch database, however the pathogenesis of pre-pouch ileitis is unknown. We have recently experienced one patient in whom both pouchitis and pre-pouch ileitis developed after restorative proctocolectomy for UC. The purpose of this article is to report the case of our patient, and to discuss the pathogenesis of pre-pouch ileitis based on the clinicopathological and immunological findings.

## CASE REPORT

### Clinical presentations

In July 2005, we received a 35-year old female with a six-year history of UC requiring surgical treatment. Small bowel follow-through, barium enema and ileocolonoscopy with histological examinations confirmed UC but not Crohn's disease. She had a history of allergy to sulfasalazine and mesalazine. She was treated with long-term corticosteroid therapy, and the cumulative dose of prednisolone administered before operation was more than 20 g. Selective granulocyte and monocyte adsorption apheresis therapy was not effective. She had no history of extraintestinal manifestations. Endoscopically, the extent of disease was pancolitis without backwash ileitis. The indication for surgery was steroid-dependency and chronic continuous disease. A laparoscopic-assisted proctocolectomy with ileal pouch-anal canal anastomosis was performed. The J-shaped pouch (15 cm in length) was constructed using a linear stapler. A stapled ileo-anal canal anastomosis was performed at approximately 2 cm from the dentate line. There was no difficulty in mobilizing the ileal pouch sufficiently to achieve a tension-free anastomosis. The covering ileostomy was constructed to protect the anastomosis. After operation, she developed no serious complications, and was doing well with her ileostomy. Histological diagnosis of the colectomy specimen was UC, and there were no findings of inflammation in the terminal ileum.

Before ileostomy closure, a pouchgram, pouchoscopy with biopsy, and manometric study were performed. The pouchgram showed no findings of anastomotic leak, fistulae and strictures, decreased pouch compliance, a long efferent loop, or decreased pouch emptying. Both

**Figure 1** Abdominal computed tomography showing a massive collection of feces in the pouch (A) and proximal ileum (B).

**Figure 2** Pouchoscopy showing inflammation conditions such as edema, granularity, friability, loss of vascular pattern, and erosions in both the pouch (A) and the pre-pouch ileum (continuous 30 cm proximal to the pouch) (B).

endoscopically and histologically, there were no findings of inflammation in the pouch and proximal ileum. In the manometric study, the resting anal pressure was 42 mmHg compared with 65 mmHg before pouch construction. The squeezing pressure was 110 mmHg compared with 128 mmHg before pouch construction. In March 2006, she had her ileostomy closed. Postoperatively, she was doing well, and on a normal diet. However, five weeks after operation, she developed high fever (40°C) and severe abdominal pain. Retrospectively, the number of defecations did not change (7-10 times/d), but the fecal volume on each defecation remarkably decreased for several days before her symptoms occurred. Abdominal computed tomography (CT) showed a massive collection of feces in the pouch and proximal ileum (Figure 1). A drainage tube was placed in the pouch perianally, and a large amount of purulent feces were discharged. In fecal culture, *Salmonella*, *Shigella*, *Campylobacter*, *Escherichia coli* O157, *Yersinia*, *Vibrio* and *Clostridium difficile* were negative, whereas *Escherichia coli* and *Staphylococcus aureus* were positive. She was managed with total parenteral nutrition in combination with intravenous antibiotic administration (imipenem, 1.0 g/d for one week). Her symptoms disappeared after the five-day drainage of the feces, and she was back on a normal diet. However, two weeks later, she repeatedly presented with fever (40°C) and severe abdominal pain along with mild anal bleeding. Pouchoscopy showed inflammatory conditions such as edema, granularity, friability, loss of vascular pattern, and erosions in both the pouch and the pre-pouch ileum (continuous 30 cm proximal to the pouch, Figure 2). The inflammation was milder more proximally. Biopsies were taken for histological examination and mucosal

cytokine measurement. Histologically, moderate leukocyte infiltration without crypt abscess formation was observed in both the pouch and the pre-pouch ileum. According to the pouchitis disease activity index by Sandborn<sup>[5]</sup>, her score was 12, and she was diagnosed as having pouchitis ( $\geq 7$  points). Antibiotics (cefmetazone sodium, 2.0 g/d for one week), and prednisolone (30 mg/d for one week) were administered intravenously. Her symptoms were rapidly improved, and pouchoscopy after the one-week treatment revealed improvement in mucosal inflammation. Thereafter, prednisolone was orally given (15 mg/d for two weeks, and then 10 mg/d for two weeks). Four months after ileostomy closure following pouch operation, she was doing well with normal bowel function (defecation, 5-7 times/d; soiling, 1 time/2 wk).

#### Laboratory data

Using the biopsy specimens obtained during pouchoscopy, the mucosal cytokine (interleukin (IL)-1 $\beta$ , IL-6, IL-8, and tumor necrosis factor alpha (TNF- $\alpha$ ) levels were measured by the enzyme-linked immunosorbent assay as previously reported (Table 1)<sup>[7]</sup>. In this patient, the mucosal cytokine levels were examined before ileostomy closure, at the time of diagnosis of pouchitis and pre-pouch ileitis, and one week after the treatment for inflammation, and compared with those in 28 patients without pouchitis or pre-pouch ileitis three months after ileostomy closure following ileal pouch construction for UC in our previous study<sup>[7]</sup>. At the diagnosis of pouchitis and pre-pouch ileitis, the mucosal cytokine levels were remarkably elevated in both the pouch and the pre-pouch ileum compared with those before ileostomy closure. White blood cell (WBC) count

**Table 1** Change of mucosal cytokine production in the pouch and pre-pouch ileum

	Before ileostomy closure	At the diagnosis of pouchitis and pre-pouch ileitis	After treatment	Patients without pouchitis or pre-pouch ileitis <sup>1</sup>
Pouch (pg/mg of tissue)				
IL-1 $\beta$	25	730	98	34.5 (26-39)
IL-6	590	14 000	2700	900 (580-1480)
IL-8	31	840	290	58 (34-76)
TNF- $\alpha$	10	350	67	38.5 (27-60)
Pre-pouch ileum (pg/mg of tissue)				
IL-1 $\beta$	17	560	91	10.5 (5-22)
IL-6	600	17 000	3600	570 (420-720)
IL-8	22	710	190	19.5 (10-41)
TNF- $\alpha$	13	270	82	12 (5-18)

IL: Interleukin; TNF: tumor necrosis factor. <sup>1</sup>Median values (interquartile range) for 24 patients without pouchitis or pre-pouch ileitis three months after ileostomy closure following restorative proctocolectomy for ulcerative colitis<sup>[7]</sup>.

was 12 300/mm<sup>3</sup>, platelet count was 443 000/mm<sup>3</sup>, and C-reactive protein (CRP) level was 19.34 mg/dL. After the one-week administration of antibiotics and prednisolone, the mucosal cytokine levels markedly decreased along with endoscopic improvement of mucosal inflammation. At that time, WBC count was 10 800/mm<sup>3</sup>, platelet count was 506 000/mm<sup>3</sup>, and CRP level was 0.09 mg/dL.

## DISCUSSION

The etiology of pouchitis is still unknown. A variety of factors such as fecal stasis, bacterial overgrowth, immune alternation, bile acid toxicity, short-chain fatty acid deficiency, and ischemia may affect the development of pouchitis<sup>[4,8,9]</sup>. In our research<sup>[7]</sup>, to examine the impact of the fecal stream and stasis on immunological reactions in the pouch and proximal ileum, mucosal cytokine production was measured before and after ileostomy closure following proctocolectomy for UC. No patients developed pouchitis or pre-pouch ileitis during the study period. We found that immunological reactions in the pouch occurred soon after ileostomy closure, and continued thereafter<sup>[7]</sup>. In contrast, cytokine production was not elevated in the proximal ileum, where the fecal stasis does not often occur. Thus, the fecal stasis may play an important part in the pathogenesis of immunological reactions in the pouch<sup>[7]</sup>.

Bell and colleagues<sup>[6]</sup> reported that 15 (2.6%) of 571 inflammatory bowel disease patients undergoing restorative proctocolectomy developed pre-pouch ileitis. However, this incidence may be underestimated because their study was retrospective, and the pre-pouch ileum was not routinely examined. The median age of the 15 patients (eight females) was 36 years, and the median duration from pouch construction to diagnosis of pre-pouch ileitis was three years. The most common clinical presentations were frequency of defecation (40%) and bowel obstruction (40%). Preoperatively, backwash ileitis was observed in 18% of the patients, and 27% had a history of extraintestinal

manifestations. All patients had continuous disease from the neo-terminal ileum-pouch junction for a distance of 1 cm to more than 50 cm proximally becoming milder more proximally. Concomitant pouchitis was observed in 47% of the patients. Nine patients had narrowing of the lumen in the pre-pouch ileum, and in two of these there was a severe stricture. One patient had a fistula from the pre-pouch ileum to the vagina. Eleven patients with symptoms were treated, of whom eight required surgery (resection in six, strictureplasty in one, defunctioning ileostomy in one).

In the study by Bell and colleagues<sup>[6]</sup>, there were no statements about the pathogenesis of pre-pouch ileitis. Only half of their patients with pre-pouch ileitis had concomitant pouchitis. Several patients presented with tight stricture, deep ulcerations or fistula. We suspect that these patients may have Crohn's disease, although the histological diagnosis based on the colectomy specimen was confirmed as UC<sup>[6]</sup>. Wolf *et al.*<sup>[10]</sup> reported that afferent limb ulcers predict Crohn's disease in patients with ileal pouch-anal anastomosis. In our case, findings suggesting Crohn's disease were not observed.

The pathogenesis of pre-pouch ileitis is also unknown. Our patient developed a massive collection of feces in the pouch and pre-pouch ileum in the early postoperative period after ileostomy closure, which was detected by CT. Before her symptoms (fever and abdominal pain) occurred, the fecal volume remarkably decreased, although the number of defecations did not change. The cause of fecal collection is unknown. Before ileostomy closure, pouchogram showed no evidence of anastomotic strictures, decreased pouch compliance, or decreased pouch emptying. The results in our manometric study were similar to those in patients with normal pouch function after restorative proctocolectomy in the previous study<sup>[11]</sup>. Although a longer follow-up was necessary, she had neither evacuation problems nor impaired pouch emptying at the time of our report (four months after ileostomy closure). If she had the similar symptoms such as fever and abdominal pain along with a decrease in volume of feces, further studies were needed to examine her pouch function.

In our case, endoscopic and histological features of mucosal inflammation were similar in the pouch and pre-pouch ileum, although the inflammation was milder more proximally. Bell and colleagues<sup>[6]</sup> also found that the histological findings of pouchitis and pre-pouch ileitis are similar. In our institution, mucosal cytokine production is routinely investigated before and after ileostomy closure following restorative proctocolectomy for UC<sup>[7]</sup>. In this report, at the diagnosis of pouchitis and pre-pouch ileitis, the mucosal IL-1 $\beta$ , IL-6, IL-8, and TNF- $\alpha$  levels were remarkably elevated in both the pouch and the pre-pouch ileum compared with those before ileostomy closure, which were much higher than those in patients without pouchitis or pre-pouch ileitis in our previous study (Table 1)<sup>[7]</sup>, suggesting that both pouchitis and pre-pouch ileitis are associated with increased mucosal cytokine production. There seemed to be no significant difference in cytokine production between pouchitis and pre-pouch ileitis. These cytokine levels remarkably decreased after antibiotic and steroid medication. Purulent feces were discharged through a drainage tube placed in the pouch. In fecal culture, *E.*

*coli* and *Staphylococcus aureus* were detected, which may have caused severe clinical symptoms such as high fever and abdominal pain.

In conclusion, fecal stasis along with subsequent bacterial overgrowth is the major pathogenesis of both pouchitis and pre-pouch ileitis. The pathogenesis may be similar in pouchitis and pre-pouch ileitis due to the similar endoscopic, histological and immunological features. Further studies are needed to fully understand the pathogenesis of pouchitis and pre-pouch ileitis after restorative proctocolectomy for UC.

### Abstract

Cytomegalovirus (CMV) infection in immunocompetent hosts generally is asymptomatic or may present as a mononucleosis syndrome but rarely can lead to severe organ complications. We report a case of simultaneous hepatic and pericardic CMV infection in a 36-year old immunocompetent man. He was admitted to coronary unit with fever, chest pain radiated to shoulders, changes on electrocardiogram with diffuse ST elevation and modest laboratory elevations in the MB fraction of creatine kinase (CK-MB) of 33.77  $\mu\text{g/L}$  (0.1-6.73), serum cardiac troponin T of 0.904 ng/mL (0-0.4), creatine kinase of 454 U/L (20-195) and myoglobin of 480.4  $\mu\text{g/L}$  (28-72). Routine laboratory test detected an elevation of aminotransferase level: alanine aminotransferase 1445 U/L, aspartate aminotransferase 601 U/L. We ruled out other causes of hepatitis with normal results except IgM CMV. The patient was diagnosed with myopericarditis and hepatitis caused by cytomegalovirus and started symptomatic treatment with salicylic acid. In few days the laboratory findings became normal and the patient was discharged.

### INTRODUCTION

Cytomegalovirus (CMV) infection in an immunocompetent host, rarely can lead to severe organ specific complications<sup>[1,2]</sup>. A variety of presentations have been described, ranging from a common form of infectious mononucleosis to systemic disease (gastrointestinal, cardiovascular, hepatic, neurologic manifestations) with significant morbidity. We report a case of simultaneous hepatic and pericardic CMV infection in an immunocompetent host.

### CASE REPORT

A 36-year old man was admitted to our hospital with fever and chest pain radiated to shoulders. He had no other relevant medical history and physical examination was normal. Electrocardiogram showed diffuse ST elevation and laboratory test displayed modest elevations in MB fraction of creatine kinase (CK-MB) of 33.77  $\mu\text{g/L}$  (0.1-6.73), serum cardiac troponin T of 0.904 ng/mL (0-0.4), creatine kinase of 454 U/L (20-195) and myoglobin of 480.4  $\mu\text{g/L}$  (28-72). The patient was diagnosed with myopericarditis and admitted to the coronary unit. Routine laboratory tests detected an elevation of aminotransferase level: alanine aminotransferase 1445 U/L (6-41), aspartate aminotransferase 601 U/L (6-38). Other laboratory parameters were normal including gamma glutamyl transpeptidase, alkaline phosphatase, bilirubin, cholesterol, electrolytes, complete blood cell count and coagulation test. We ruled out other causes of hepatitis: medications, alcohol abuse, hepatitis B, hepatitis C, hereditary hemochromatosis, hepatic steatosis and steatohepatitis, thyroid disorders, celiac disease, autoimmune hepatitis, Wilson's disease and alpha 1 antitrypsin deficiency. Finally we looked for a less common infection etiology (Epstein Barr virus, cytomegalovirus and atypical bacteria). The results were normal except for IgM CMV. The patient was diagnosed with myopericarditis and hepatitis caused by cytomegalovirus and started symptomatic treatment with salicylic acid. In few days the laboratory findings became normal and the patient was discharged.

### DISCUSSION

CMV infection in immunocompetent patients is common with a substantial morbidity and mortality. It is generally asymptomatic in immunocompetent hosts or may present

as a mononucleosis syndrome. Occasionally primary CMV infection can lead to severe organ specific complications<sup>[1,2]</sup>. Although these cases are rare, gastrointestinal, cardiovascular, neurologic, hepatic disorders have been reported.

Liver function abnormalities are frequently encountered in patients with symptomatic CMV infection. Subclinical transaminitis is the most common finding in immunocompetent patients, and elevations of alkaline phosphatase and total bilirubin are less typical<sup>[1,3,4]</sup>. Pericarditis and myocarditis have been described in immunocompetent patients with acute CMV infection<sup>[5,6]</sup>. We have found only one case reporting simultaneous infection of liver and myopericardia with cytomegalovirus<sup>[7]</sup>.

Since symptomatic CMV infection is generally self-limited with complete recovery over a period of days to weeks, it is difficult to prove whether antiviral therapy has a significant impact on the clinical outcome.

### TO THE EDITOR

We read with great interest the article, "Non-alcoholic fatty liver disease may not be a severe disease at presentation among Asian Indians" by Madan *et al*<sup>[1]</sup> in the recent issue of *WJG*. Twenty-eight (55%) out of 51 patients with non-alcoholic fatty liver disease (NAFLD) who presented with abnormal transaminases had histological evidence of nonalcoholic steatohepatitis (NASH). The majority of patients had grade 1 [32 (63%)] or grade 2 [16 (31%)] inflammation and either had no [23 (45%)] fibrosis or stage I [19 (37%)] fibrosis. None of the patients had cirrhosis<sup>[1]</sup>. We agree with Madan *et al*<sup>[1]</sup> that Asian Indians with NAFLD who present with unexplained increase in transaminases may have mild disease at presentation on the basis of similar observations made by us<sup>[2]</sup>. NAFLD has a spectrum which includes patients with only steatosis and NASH that can progress to cirrhotic

and hepatocellular carcinoma<sup>[3]</sup>. Of the 127 NAFLD patients (July 2001-March 2006) who presented with raised transaminases for at least 6 mo with negative viral, autoimmune and metabolic workup analyzed in our study, 43 underwent liver biopsy (Table 1). Only half of them [22 (51%)] had histological evidence of NASH as defined by either class III [8 (19%)] or class IV [14 (32%)] NAFLD according to Matteoni *et al*<sup>[4]</sup>. The other 21 (49%) patients either had class I [2 (5%)] or class II [19 (44%)] disease not amounting to histological NASH (Table 1). In the 22 patients with histological NASH evaluated as per Brunt *et al*<sup>[5]</sup>, the majority had mild to moderate inflammation and either no fibrosis or stage I to II fibrosis. Only 18% patients had stage III fibrosis and none of the patients had cirrhosis of the liver (Table 1).

The majority of patients studied by us were males with a mean age of  $39.2 \pm 10.7$  years (Table 2), which is similar to data shown by Madan *et al*<sup>[1]</sup>. In addition to the mild histological disease at presentation, there are other differences in NAFLD patients from India and those from the West<sup>[2]</sup>. When we used the Asia Pacific criteria<sup>[6,7]</sup>, even though most of our patients had central obesity [104 (82%)] and were either overweight [27 (21%)] or obese [86 (68%)] they did not have the kind of morbid obesity seen in patients from the West (Table 2). The mean body weight and body mass index (BMI) of our patients were 71 kg and  $28.7 \text{ kg/m}^2$  respectively, much less than those reported from the West<sup>[8,9]</sup>, but were similar to the data shown by Madan *et al*<sup>[1]</sup> who also found that the median BMI is  $26.7$  (range  $21.3\text{-}32.5$ )  $\text{kg/m}^2$  and the majority of them are obese (69%) according to the Asian Pacific criteria. When the ATP III criteria with modified waist were used in 81 of our patients to define metabolic syndrome, around half of them [39 (48%)] had metabolic syndrome, also less than reported in patients from the West (Table 2)<sup>[10]</sup>. We attributed low prevalence of metabolic syndrome in our patients to the lower prevalence of diabetes mellitus [16 (13%)] and hypertension [13 (10%)] at presentation, which is similar to the data reported by Madan *et al*<sup>[1]</sup> (10% and 11.8% respectively) in their study. Furthermore, the low prevalence of metabolic syndrome (20.9%) in the study of Madan *et al*<sup>[1]</sup> could be due to their use of BMI as a surrogate marker for waist, which may not always be true. Indians may have a normal BMI with an abnormal waist which is related to more of central obesity rather than overall obesity. It is possible that diabetes mellitus occurs late in the course of this disease when the degree

of insulin resistance increases and our patients could represent patients in the early spectrum of NAFLD with less severe disease and diabetes mellitus at presentation with raised transaminases. Diabetes mellitus is one of the risk factors for severe liver disease in NAFLD and absence of this risk factor in majority of our patients may explain the mild disease on liver biopsy.

Insulin resistance is very common in patients with NAFLD irrespective of the methodology used. Eighty percent of 51 patients in the study by Madan *et al*<sup>[1]</sup> had abnormal homeostasis model assessment for insulin resistance (HOMA-IR). We found insulin resistance in all of our 22 patients initially studied by insulin tolerance test (ITT) and later in 48 (83%) of 58 patients studied by HOMA-IR (Table 2)<sup>[2,11,12]</sup>.

Though not studied by Madan *et al*<sup>[1]</sup>, another difference in Indian patients and those from the West is the presence of serum and liver iron abnormalities and HFE gene mutations<sup>[2,13,14]</sup>. Only 4 (5%) of our 87 patients had abnormal serum ferritin or transferrin saturation and 4 (13%) of 30 patients studied were heterozygotes for H63D mutation. None of the patients had C282Y HFE gene mutation. The majority of our patients had negative Perls' staining for iron on liver biopsy (Table 1) and there was no correlation between the iron staining and degree of necro-inflammation and fibrosis, suggesting that serum and liver iron and HFE gene mutations play a very little role in Indian patients with NAFLD<sup>[2,13,14]</sup>.

In conclusion, Indian patients with NAFLD who present with incidental detection of raised transaminases representing a part of spectrum of patients with NAFLD have a milder disease at presentation. Whether NAFLD in Indian patients is overall mild or overall different from other parts of the world requires analysis of full spectrum of NAFLD patients.

**Table 2** Clinical and laboratory parameters in 127 patients with nonalcoholic fatty liver disease (NAFLD)

mean age ± SD (yr)	39.2 ± 10.7
Males	84
Mean body weight (range) (kg)	71 (45-100)
Mean BMI (range) (kg/m <sup>2</sup> )	28.7 (19-34)
Overweight	27 (21%)
Obesity	86 (68%)
Abnormal waist	104 (82%)
Insulin resistance	48/58 (83%)
Diabetes mellitus	16 (13%)
Hypertension	13 (10%)
Dyslipidemia	67 (53%)
Metabolic syndrome	39/81 (48%)

<http://www.wjgnet.com/1007-9327/13/651.asp>

## TO THE EDITOR

Recently, the paper by Wang *et al*<sup>[1]</sup> published in *World Journal of Gastroenterology* has given rise to great interest of many researchers. It is well known that hepatoma is one of the lethal diseases with a high incidence in the world, especially in Asia. Radiotherapy is the main treatment modality of hepatoma in clinical practice. Unfortunately, intrinsic radiosensitivity of cancer cells is not fully understood, though a large number of papers on it are now available. Yang and colleagues<sup>[2]</sup> have developed the premature chromosome condensation technique for clinical radiotherapy of hepatoma. A precise and quick

measurement of cell radiosensitivity can detect the high-risk results after exposure to a large dose.

Premature chromosome condensation technique can quickly and precisely detect radiation-induced chromosome damage<sup>[3-5]</sup>. Chromatid breaks are regarded as a good radiodosimetry, which highly correlates with cell survival and radiosensitivity<sup>[6]</sup>. However, they are not a negative value as described by Wang *et al*<sup>[1]</sup>. I recommend her to further measure them in order to perfect this promising approach.

## ACKNOWLEDGMENTS

# Acknowledgments to Reviewers of World Journal of Gastroenterology

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

**Katsunori Iijima, Dr**

## Meetings

### MAJOR MEETINGS COMING UP

Meeting Falk Research Workshop: Morphogenesis and Cancerogenesis of the Liver  
25-26 January 2007  
Goettingen  
symposia@falkfoundation.de

Meeting Canadian Digestive Diseases Week (CDDW)  
16-20 February 2007  
Banff-AB  
cagoffice@cag-acg.org  
www.cag-acg.org/cddw/cddw2007.htm

Meeting Falk Symposium 158: Intestinal Inflammation and Colorectal Cancer  
23-24 March 2007  
Sevilla  
symposia@falkfoundation.de

Meeting BSG Annual Meeting  
26-29 March 2007  
Glasgow  
www.bsg.org.uk/

### NEXT 6 MONTHS

Meeting 42nd Annual Meeting of the European Association for the Study of the Liver  
11-15 April 2007  
Barcelona  
easl2007@easl.ch  
www.easl.ch/liver-meeting/

Meeting Falk Symposium 159: IBD 2007 - Achievements in Research and Clinical Practice  
4-5 May 2007  
Istanbul  
symposia@falkfoundation.de

Meeting European Society for Paediatric Gastroenterology, Hepatology and Nutrition Congress 2007  
9-12 May 2007  
Barcelona  
espghan2007@colloquium.fr

Digestive Disease Week  
19-24 May 2007  
Washington Convention Center, Washington DC

Meeting Gastrointestinal Endoscopy Best Practices: Today and Tomorrow, ASGE Annual Postgraduate Course at DDW  
23-24 May 2007  
Washington-DC  
tkoral@asge.org

Meeting ESGAR 2007 18th Annual Meeting and Postgraduate Course  
12-15 June 2007  
Lisbon  
fca@netvisao.pt

Meeting Falk Symposium 160: Pathogenesis and Clinical Practice in

Gastroenterology  
15-16 June 2007  
Portoroz  
symposia@falkfoundation.de

Meeting ILTS 13th Annual International Congress  
20-23 June 2007  
Rio De Janeiro  
www.ils.org

Meeting 9th World Congress on Gastrointestinal Cancer  
27-30 June 2007  
Barcelona  
meetings@imedex.com

### EVENTS AND MEETINGS IN 2007

Meeting Falk Research Workshop: Morphogenesis and Cancerogenesis of the Liver  
25-26 January 2007  
Goettingen  
symposia@falkfoundation.de

Meeting Canadian Digestive Diseases Week (CDDW)  
16-20 February 2007  
Banff-AB  
cagoffice@cag-acg.org

## Instructions to authors

### GENERAL INFORMATION

*World Journal of Gastroenterology* (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

#### Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

#### Published by

The WJG Press

### SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

#### Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com) for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

#### Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or \*.rtf format to:

#### Editorial Office

##### *World Journal of Gastroenterology*

Editorial Department: Apartment 1066, Yishou Garden,  
58 North Langxinzhuang Road,  
PO Box 2345, Beijing 100023, China  
E-mail: [wjg@wjgnet.com](mailto:wjg@wjgnet.com)  
<http://www.wjgnet.com>  
Telephone: +86-10-85381892  
Fax: +86-10-85381893

### MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

#### Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

#### Abstract

An informative, structured abstract of no more than 250 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

#### Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

#### Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

#### Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

#### Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

#### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup>*P*<0.05, <sup>b</sup>*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, <sup>c</sup>*P*<0.05 and <sup>d</sup>*P*<0.01 are used. Third series of *P* values can be expressed as <sup>e</sup>*P*<0.05 and <sup>f</sup>*P*<0.01. Other notes in tables or under

illustrations should be expressed as  $^1F$ ,  $^2F$ ,  $^3F$ ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

### PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

### Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

### Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

### Statistical data

Present as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\gamma$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose)  $6.4 \pm 2.1$  mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6  $24.5 \mu\text{g/L}$ ; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub> not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

**Abbreviations**

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

**Italics**

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

**SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED**

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

**Language evaluation**

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

**Copyright assignment form**

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

**Ms:**

**Title:**

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

**Criteria for authorship:** The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

**Final check list for authors**

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

**Responses to reviewers**

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

## Abstract

Liver ischaemic preconditioning (IPC) is known to protect the liver from the detrimental effects of ischaemic-reperfusion injury (IRI), which contributes significantly to the morbidity and mortality following major liver surgery. Recent studies have focused on the role of IPC in liver regeneration, the precise mechanism of which are not completely understood. This review discusses the current understanding of the mechanism of liver regeneration and the role of IPC in this setting. Relevant articles were reviewed from the published literature using the Medline database. The search was performed using the keywords "liver", "ischaemic reperfusion", "ischaemic preconditioning", "regeneration", "hepatectomy" and "transplantation". The underlying mechanism of liver regeneration is a complex process involving the interaction of cytokines, growth factors and the metabolic demand of the liver. IPC, through various mediators, promotes liver regeneration by up-regulating growth-promoting factors and suppresses growth-inhibiting factors as well as damaging stresses. The increased understanding of the cellular mechanisms involved in IPC will enable the development of alternative treatment modalities aimed at promoting liver regeneration following major liver resection and transplantation.

Gomez D, Homer-Vanniasinkam S, Graham AM, Prasad KR. Role of ischaemic preconditioning in liver regeneration following major liver resection and transplantation. *World J Gastroenterol* 2007; 13(5): 657-670

## INTRODUCTION

Ischaemic-reperfusion injury (IRI) is an inevitable phenomenon that results following major liver surgery, including partial hepatectomy and liver transplantation. As a consequence, parenchymal cell injury and liver dysfunction<sup>[1,2]</sup> of varied severity leads to significant morbidity and mortality post-surgery<sup>[3-5]</sup>, in particular, in patients with liver cirrhosis and steatosis<sup>[6-9]</sup>. In addition, IRI significantly impairs liver regeneration following hepatectomy<sup>[10,11]</sup>.

Due to the inevitability of ischaemia and reperfusion in liver surgery, various investigators have attempted to elucidate methods to limit the detrimental effects of IRI and improve liver function and regeneration of the remnant liver<sup>[12,13]</sup>. These include hypothermic perfusion of the liver<sup>[14]</sup>, intermittent liver inflow occlusion<sup>[15,16]</sup> and ischaemic preconditioning (IPC)<sup>[17]</sup>. Liver IPC is an endogenous mechanism consisting of a short period of vascular occlusion followed by reperfusion that renders the liver more tolerant to subsequent prolonged episodes of ischaemia. Besides having protective effects on IRI following major liver resection and transplantation<sup>[17-19]</sup>, it has been suggested that IPC is also beneficial in liver regeneration<sup>[20]</sup>. This article describes the current understanding of the liver regeneration cascade as published and gives a balanced review on the mechanisms by which IPC influences liver regeneration.

## MECHANISMS OF LIVER REGENERATION

Liver regeneration is a complex and multi-factorial process that is mediated by interactions between regenerative cytokines, growth factors and metabolic demand of the liver following surgery and IRI.

### *The regenerative cytokine network and the priming pathway*

During the first few hours following IRI, regenerative cytokines are produced that render the resting hepatocytes responsive to growth factors required for cellular division and proliferation<sup>[21,22]</sup>. This period is known as the "priming phase". Various mediators have been implicated as possible triggers of the regenerative cytokine network including gastrointestinal lipopolysaccharide (LPS)<sup>[23,24]</sup>, Toll-like receptor-myeloid differentiation factor 88 (Myd88) signaling pathways<sup>[25-27]</sup>, components from the complement cascade<sup>[28]</sup>, nitric oxide (NO)<sup>[29-31]</sup> and prostaglandins<sup>[32]</sup>.

Studies have identified tumour necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6) as important regenerative cytokines<sup>[21,33,34]</sup>. Akerman and co-workers showed that

**Figure 1** Current proposed mechanisms of the priming pathway of liver regeneration. IRI: Ischaemic reperfusion injury; LPS: Lipo-polysaccharide; TLR: Toll-like receptor; MyD88: Myeloid differentiation factor 88; NO: Nitric oxide; PG: Prostaglandins; NPCs: Non-parenchymal cells; TNF: Tumour necrosis factor; TNFR1: TNF receptor type I; NF-κB: Nuclear factor-kappaB; IL-6: Interleukin-6; IL-6 RC: IL-6 receptor complex; ERK-1/2: Extracellular regulated kinases 1/2; STAT-3: Signal transducer and activator of transcription-3.

anti-TNF antibodies led to delayed DNA synthesis in the regenerating rat liver and inhibited the increase in IL-6 levels following partial hepatectomy<sup>[35]</sup>. The initiation of liver growth by TNF- $\alpha$  was shown to be dependent on its binding to TNF-receptor type 1 (TNF-R1)<sup>[36]</sup>. Mice deficient of TNF-R1 exhibited a delay in liver regeneration and increased mortality following liver resection, which was subsequently reversed by recombinant IL-6 injection<sup>[37]</sup>. However, IL-6 lacking mice demonstrated impaired liver regeneration despite the presence of TNF- $\alpha$ , suggesting that TNF-R1 signaling results in the release of IL-6<sup>[38]</sup>. IL-6 deficient mice not only showed impaired ability to regenerate, but also had increased IRI following liver resection<sup>[39]</sup>. However, Wuestefeld *et al*<sup>[40]</sup> reported that mice deficient in IL-6 and its common signal transducer, glycoprotein 130 (gp130) had no defects in DNA replication following partial hepatectomy. The groups of Zimmers and Blindenbacher have suggested that the levels of serum IL-6 present following liver resection in mice are critical in modulating its regenerative effects<sup>[41,42]</sup>. This may account for the difference in results observed in studies attempting to determine the effect of IL-6 in liver regeneration. It has been suggested that other mediators such as stem cell factor and oncostatin M may play a role in enhancing the effects of IL-6 on hepatocyte regeneration<sup>[43-45]</sup>.

Non-parenchymal liver cells [Kupffer cells and sinusoidal endothelial cells (SECs)] are involved in the priming phase (Figure 1)<sup>[46]</sup>. Following stimulation from cytokine triggering mechanisms, TNF- $\alpha$  binds to TNF-R1 on non-parenchymal liver cells and stimulates the production of IL-6<sup>[47]</sup>, *via* the activation of the transcription factor nuclear factor-kappa B (NF-κB)<sup>[48-50]</sup>. Ping and colleagues demonstrated that the secretion of regenerative cytokines, such as IL-6 by rat liver SECs was mediated by the phosphatidylinositol 3-kinase (PI 3-kinase)/Akt signaling pathway<sup>[51]</sup>, *via* NF-κB activation<sup>[50]</sup>. The transcription factor NF-κB is also known to be an important component of pro-survival cellular signaling

responses, and hence its activation will not only stimulate IL-6 production but also activate survival genes<sup>[52,53]</sup>.

IL-6 acts directly on hepatocytes by binding to the IL-6 receptor complex and induces the translocation of signal transducer and activator of transcription-3 (STAT-3) to the nucleus. This initiates a cascade of events that leads to progression of the cell cycle, culminating in the synthesis of DNA and subsequent cellular mitosis<sup>[54,55]</sup>.

### Growth factors and growth-factor signaling systems in liver regeneration

Following this priming phase, cell cycle progression is then dependent on growth factors, such as hepatocyte growth factor (HGF), transforming growth factor- $\alpha$  (TGF- $\alpha$ ) and epidermal growth factor (EGF)<sup>[56,57]</sup>. The two main growth-promoting signaling systems involved in liver regeneration are the HGF and its receptor (Met) and the epidermal growth factor receptor (EGFR) and its relatively large family of ligands. The effect of growth factors and their corresponding signaling systems may be dependent on the metabolic state of the hepatocytes and the presence or absence of other effectors<sup>[58]</sup>.

HGF is produced by non-parenchymal cells of the rat liver following liver injury<sup>[59-61]</sup> and partial hepatectomy<sup>[62]</sup>, and acts on its receptor on hepatocytes. Several authors have demonstrated that HGF is crucial in promoting liver regeneration following partial hepatectomy and transplantation in animal models<sup>[63-67]</sup>. HGF administration to recipients of reduced-size liver grafts in rats illustrated early regeneration and provided hepatoprotection against rejection-related injuries<sup>[64,68,69]</sup>. These essential signals are regulated by HGF, *via c-met*, the gene on the HGF-receptor.

EGF is mainly produced in the salivary glands in rodents and plays an important role in hepatocyte proliferation by binding to the EGFR on hepatocytes<sup>[57]</sup>. Sialoadenectomy-induced decrease in circulating EGF in mice and rat models resulted in impaired liver regeneration following partial hepatectomy, which was reversed by the administration of EGF<sup>[70,71]</sup>. In addition, combined administration of

**Figure 2** Potentiation of growth factor signaling pathways involved in cell cycle progression in liver regeneration. NPCs: Non-parenchymal cells; HGF: Hepatocyte growth factor; EGF: Epidermal growth factor; TGF- $\alpha$ : Transforming growth factor- $\alpha$ ; EGFR: Epidermal growth factor receptor; ERK-1/2: Extracellular regulated kinases 1/2; JNK: c-jun-NH2-terminal kinase; PI 3K/Akt: Phosphatidylinositol 3-kinase/Akt-signal pathway.

EGF and insulin increases the DNA synthesis following liver resection in cirrhotic rats<sup>[72]</sup>. Results from these studies suggest that EGF has a direct effect on hepatocyte proliferation.

TGF- $\alpha$  is produced in non-parenchymal cells, mainly the Kupffer cells. Mead and Fausto demonstrated that TGF- $\alpha$  may function as a physiological inducer of hepatocyte DNA synthesis during liver regeneration by an autocrine mechanism by binding to EGFR in both rat and culture models<sup>[73]</sup>. Besides TGF- $\alpha$ , there are many ligands for EGFR, including EGF, amphiregulin, heparin-binding EGF-like growth factor (HB-EGF) and epiregulin<sup>[57]</sup>. Although TGF- $\alpha$  expression increases following partial hepatectomy in mice, TGF- $\alpha$  lacking mice do not display diminished liver regeneration<sup>[74,75]</sup>. This may be due to the fact that ligands such as EGF can also stimulate EGFR and activate common intracellular growth signaling pathways. Studies have shown that other growth factors, such as HB-EGF<sup>[50,76,77]</sup>, amphiregulin<sup>[78]</sup>, insulin and glucagon<sup>[79,80]</sup> may also play a role in liver regeneration.

Although these two growth-promoting signaling systems are largely independent, some integration may exist. Scheving *et al.*<sup>[81]</sup> demonstrated that EGFR kinase inhibition by PKI166 (selective, potent inhibitor of EGFR kinase) blocked the mitogenic effects of HGF in cultured rat hepatocytes, suggesting EGFR may regulate HGF-mediated hepatocyte proliferation. Nevertheless, various regenerative pathways are initiated by HGF/*c-met* and the EGFR signaling mechanisms (Figure 2), which include the activation of mitogen-activated protein kinases (MAPKs), such as extracellular signal-regulated kinases 1 and 2 (ERK-1/2; aka p42/44 MAPKs), c-jun-NH2-terminal kinases 1 and 2 (JNK-1/2; aka p46/p54 SAPK) and p38 MAPKs. Collectively, these MAPKs have been shown to play essential roles in cell growth, transformation differentiation and apoptosis<sup>[82-84]</sup>.

ERK-1/2 activation has been shown to correlate with hepatocyte proliferation in animal studies and *in vitro* models<sup>[85-87]</sup>. Besides being responsive to growth factor signals, studies have demonstrated that ERK-1/2 activity can also be induced by cytokines such as TNF- $\alpha$ <sup>[88]</sup>. Hence, the

ERK-1/2 may be a signaling pathway that integrates both growth factor and cytokine signaling. Serandour *et al.*<sup>[89]</sup> demonstrated that a combination of EGF and TNF- $\alpha$  induced hepatocyte proliferation by 30%, compared to EGF alone in a hepatocyte-liver epithelial cell co-culture model. This study suggested that TNF- $\alpha$  mediated extracellular matrix remodeling was required for continued hepatocyte replication and proliferation. Hence, this study reiterates the importance of the interaction of cytokines and growth factors in the liver regeneration cascade. Although ERK-1/2 has been identified to have a key role in hepatocyte growth, inhibition of ERK-1/2 does not significantly alter proliferation of regenerating rat hepatocytes. However, inhibition of p38 MAPKs results in decreased DNA synthesis, suggesting that p38 MAPKs activation is prerequisite for hepatocyte proliferation<sup>[90]</sup>. JNK-1 and p38 MAPKs are involved in the regulatory control of the induction of nuclear proteins, such as cyclin D1. The activation of cyclin D1 is one of the earliest steps in the pathway of resting cells to enter the pre-replicative phase of the cell cycle.

### Metabolic demand of the liver

The increased metabolic demand imposed on the remnant liver following partial hepatectomy are likely to be interconnected with the activation of the mechanisms involved in DNA replication to sustain liver function. This is likely to be dependent on energy levels and nutrient availability.

Mitochondria are the predominant source of the high energy phosphates that are essential for energy-dependent processes in cells. Mitochondrial activity has been shown to be correlated with the recovery of liver function and subsequent regeneration<sup>[91,92]</sup>. Maruyama *et al.*<sup>[93]</sup> showed the recovery of liver weight following hepatectomy was proportional to the energy (ATP) levels of the remnant liver in rats.

Amino acid deprivation has been shown to inhibit the regeneration process in rat livers following liver resection<sup>[94]</sup>. Nelsen *et al.*<sup>[95]</sup> showed that selective amino acid deprivation in culture and protein deprivation in mice impaired hepatocyte cyclin D1 expression and that

transfection of cyclin D1 promoted cell cycle progression under these conditions. Hence, amino acids regulate hepatocyte proliferation *via* cyclin D1.

The absence of bile acids in the intestine has been shown to delay liver regeneration following partial hepatectomy in rats<sup>[96]</sup>. Following liver surgery or injury, bile flow is stimulated<sup>[97]</sup> which results in the release of bile from the gallbladder and its return through the entero-hepatic circulation exposes the remnant hepatocytes to an increase in relative bile acid flux. This early phase of bile acid overload and subsequent bile acid signaling is necessary for normal liver regeneration. However, liver-specific functions such as synthesis of clotting factors and albumin and the continuous formation of bile are impaired following partial hepatectomy and results in transient cholestasis<sup>[98]</sup>. The formation of bile is dependent on the active secretion of bile salts and other biliary constituents into the bile canaliculus by specific bile acid and organic anion transporters<sup>[99]</sup>. Gerloff *et al*<sup>[100]</sup> demonstrated that the expression of two ATP-dependent transporters [bile salt acid pump (*Bsep*) and multi-organic anion transporter (*Mrp2*)] was unchanged or slightly increased following partial hepatectomy in rats and this provided a potential mechanism by which the regenerating liver cells maintained or increased bile secretion. The authors in this study also suggested that the down-regulation of certain transporters [sodium-taurocholate cotransporter (*Ntcp*) and organic anion transporting polypeptides (*Oatp1* and *Oatp2*)] could be a protective mechanism against the potentially hepatotoxic bile salts<sup>[100]</sup>. The differential regulation of hepatobiliary transporters during the regeneration process are likely to be mediated by cytokines such as TNF- $\alpha$ <sup>[101]</sup>. Recently, Huang *et al*<sup>[102]</sup> showed that bile acid activation of nuclear receptor-dependent signaling pathways regulated the regeneration process by sensing the liver's functional capacity following partial hepatectomy in mice. When inadequate function causes bile acids to build up, the resultant nuclear receptors activation not only induces negative feedback pathways that protect hepatocytes from bile acid toxicity but also increases the capacity of the liver to manage the overload by promoting liver growth<sup>[102]</sup>.

Results from recent studies have implicated the mammalian target of rapamycin (mTOR) complex as a sensor of nutrient-energy levels and its downstream mediators, such as p70 S6 kinase, are thought to regulate protein translation and cell growth<sup>[103,104]</sup>. Inhibition of the mTOR complex leads to diminish DNA replication following partial hepatectomy in mice and rat models<sup>[105,106]</sup>. The activity of p70 S6 kinase has been shown to increase following partial hepatectomy<sup>[106]</sup> and mice lacking the S6 kinase demonstrated diminished hepatocyte proliferation<sup>[107]</sup>. Hence, energy is required for energy-dependent signaling pathways and processing the available nutrients for the regeneration process to proceed.

## ISCHAEMIC PRECONDITIONING IN LIVER REGENERATION

Since IPC was first described by Murry *et al*<sup>[108]</sup>, this strategy has been developed more widely and is currently

practiced in major liver surgery in several centers. The mechanism of IPC is thought to be divided into two phases; early (classical/acute) pre-conditioning and delayed pre-conditioning. The hepatoprotective effects of early preconditioning occur within minutes after reperfusion and are maintained for 1 to 2 h<sup>[109]</sup>. This phase is thought to be mediated by pre-existing substances. The "second window of protection", delayed pre-conditioning, re-appears 24 to 72 h following IPC. The underlying mechanism is thought to rely on the modification of gene expression resulting in protein production as its effectors<sup>[110]</sup>. Various substances have been implicated as key effectors in liver IPC including adenosine<sup>[111-114]</sup>, protein kinase C<sup>[115-117]</sup>, NO<sup>[118-121]</sup>, heat-shock proteins<sup>[122,123]</sup>, tyrosine kinases<sup>[124]</sup>, MAPKs<sup>[117]</sup>, oxidative stress<sup>[125,126]</sup> and NF- $\kappa$ B<sup>[127,128]</sup>.

The beneficial effects of IPC on the liver following IRI include decrease in severity of liver necrosis<sup>[129]</sup>, anti-apoptotic effects<sup>[130]</sup>, preservation of liver microcirculation<sup>[131,132]</sup> and improvement in survival rate<sup>[119]</sup>, and more recently, its role in liver regeneration is currently being evaluated. For IPC to influence liver regeneration, its key effectors must be involved in either promoting or up-regulating mediators that are involved in the regeneration cascade or exert an inhibitory effect on growth-inhibitory factors of liver regeneration or *vice versa* (Figure 3).

### Up-regulation of the regenerative cytokine network

#### Tumour necrosis factor-alpha and interleukin-6:

The initiation of the regenerative response is dependent on the early activation of TNF- $\alpha$  and IL-6 responsive transcription factors<sup>[38,54]</sup>. Studies evaluating the effect of IPC in stimulating the release of TNF- $\alpha$  and IL-6 have produced conflicting findings. Tsuyama *et al*<sup>[133]</sup> reported that IPC prolonged survival, suppressed liver necrosis induced by IRI and inhibited the release of TNF- $\alpha$  at 1 h, and IL-6 at 2 and 5 h of the reperfusion phase in mice. IPC has also been shown to reduce TNF- $\alpha$  production in normothermic and cold ischaemic conditions<sup>[125,134,135]</sup>.

In contrast, Bedirli and others demonstrated that IPC inhibited the production of TNF- $\alpha$ , but not IL-6 during the late (24 and 48 h) phases of reperfusion in rats following partial hepatectomy<sup>[136]</sup>. This study suggested that IL-6 is an important mediator in IPC-treated rats in promoting hepatocyte proliferation following liver resection<sup>[136]</sup>. Using a TNF gene-deleted mice model, Teoh *et al*<sup>[137]</sup> demonstrated that pre-treatment with low dose IL-6 prior to hepatic ischaemia conferred equivalent hepatoprotection and earlier cell cycle entry as IPC compared to non-IPC-treated mice at 2 h of reperfusion. Taken together, these studies emphasize the importance of IL-6 as a hepatoprotective and pro-proliferative mediator during the early and late phases of reperfusion following IRI. Although IPC attenuates the late onset prolonged release of TNF- $\alpha$  (up to 44 h) that mediates liver IRI in rats<sup>[138,139]</sup> and mice<sup>[140]</sup>, IPC itself is associated with the early increase (10 min) in liver and serum TNF- $\alpha$  following hepatic ischaemia<sup>[140]</sup>. Injection of low dose TNF- $\alpha$  30 min prior to liver ischaemia conferred similar hepatoprotection as IPC<sup>[140]</sup>. Both IPC and pre-treatment with low dose TNF- $\alpha$  injection were shown to stimulate earlier and more

vigorous cell cycle entry following liver IRI compared to naïve mice during the first 24 h of the reperfusion period<sup>[140]</sup>.

The differences reported among studies investigating the influence of IPC on the regenerative cytokine network may be related to the differences in experimental models and protocols employed. In addition, both TNF- $\alpha$  and IL-6 are known to be important components in other cellular signaling responses. For example, high levels of serum TNF- $\alpha$  following liver ischaemia in rats is thought to mediate liver IRI<sup>[138,139]</sup>. Investigators have suggested that the mechanism of action of IL-6 in promoting liver regeneration appear to be separate from those involved in the modulation of IRI<sup>[39,141]</sup>. The hepatoprotective mechanisms against IRI may involve the anti-inflammatory properties of IL-6 and the down regulation of TNF- $\alpha$  production<sup>[39,142,143]</sup>. This could potentially explain the differences in results obtained.

Nevertheless, the influence of IPC in promoting the early release of TNF- $\alpha$  and the up regulation of IL-6 during the reperfusion phase, and subsequent modulation of the hepatocellular proliferation process should not be discounted. In addition, these conflicting results may indicate that IPC can potentiate hepatocyte proliferation *via* at least two different pathways; liver regeneration *via* a TNF- $\alpha$ /IL-6-dependent pathway and a mitogen-induced proliferative pathway that does not require TNF- $\alpha$  or IL-6<sup>[144,145]</sup>.

### Down-regulation of inhibitory mediators of liver regeneration

Hepatocyte growth is controlled by a balance of both growth-promoting and growth-inhibiting factors<sup>[65,146]</sup>. While those cytokines and pathways previously described promote liver regeneration following liver resection, there are various mediators that are involved directly or indirectly in inhibiting the liver regeneration process.

**Interleukin-1 and transforming growth factor-beta as inhibitors of liver regeneration:** IL-1 is a mediator of acute inflammation<sup>[147]</sup> and is a significant down-

regulator of hepatocyte proliferation<sup>[148]</sup>. IL-1 $\beta$  delays and inhibits hepatocyte proliferation in both culture models<sup>[149]</sup> and following partial hepatectomy in rats<sup>[148]</sup>. Other investigators have implicated IL-1 $\alpha$  as a mediator of IRI and an inhibitor of liver regeneration<sup>[150]</sup>. Besides antagonizing the stimulatory effects of growth factors such as HGF<sup>[150]</sup>, IL-1 strongly inhibits hepatocyte DNA synthesis leading to impaired liver regeneration in primary culture models<sup>[149]</sup>. TGF- $\beta$  is another inhibitor of hepatocyte DNA synthesis<sup>[151-153]</sup> and antagonizes the stimulatory effects of HGF during liver regeneration in both *in vitro* and experimental hepatectomy models<sup>[152,154]</sup>. This anti-regenerative effect of TGF- $\beta$  is thought to be modulated by the induction of oxidative stress in hepatocytes<sup>[155,156]</sup>.

Results from several studies have suggested that IPC antagonizes the effects of these inhibitory cytokines. Previous studies have shown that the release of IL-1 is potentially influenced by NO during IRI in a variety of cell types<sup>[157-159]</sup>. In IPC-treated rats that underwent reduced size liver transplantation, an increase in IL-1 $\alpha$  levels were noted following NO synthesis inhibition<sup>[150]</sup>. This practice abolished the benefits of IPC on hepatic IRI, oxidative stress and liver regeneration<sup>[3,150]</sup>. Furthermore, the detrimental effects of NO inhibition were not observed when rats subjected to this treatment were subsequently treated with an IL-1 receptor antagonist (IL-1-RA)<sup>[150]</sup>. IL-1 $\alpha$  has also been shown to be involved in pulmonary injury following liver IRI. IPC mediated by NO, reduced IL-1 $\alpha$  release and protected against pulmonary damage<sup>[160]</sup>. Data from these studies suggests that IPC, through increased NO availability, inhibits the release of IL-1, thereby protecting the liver graft and the lungs against liver IRI and preventing inhibition of liver regeneration. Hence, one proposed mechanism by which IPC promotes liver regeneration is by inhibiting the release of growth-inhibitory cytokines from Kupffer cells, such as IL-1, which is dependent on up-regulation of the NO pathway.

The mechanism by which IPC inhibits IL-1 production may also be related to the induction of intracellular

stress proteins<sup>[161,162]</sup>, such as heat shock protein 70 (HSP 70). IPC induces over-expression of HSP 70 in isolated hepatocytes<sup>[163]</sup>, and reduces liver IL-1 synthesis under normothermic conditions<sup>[164]</sup>. Besides expressing cytoprotective effects<sup>[165,166]</sup>, HSP induction leads to the down-regulation of IL-1 synthesis in pancreatic<sup>[161,167]</sup> and lung<sup>[162,168]</sup> cell studies. The induction of HSP mediated by IPC may be independent of the NO pathway as the increase in HSP by IPC was not modified when NO synthesis was inhibited<sup>[150]</sup>. These results suggest that IPC potentiates the overexpression of HSP, *via* an NO independent pathway, leading to hepato-protection against IRI and ameliorates liver regeneration due to decrease inhibitor production.

Another proposed mechanism by which IPC promotes liver regeneration could be due to the stimulation of IL-1-RA. IL-1-RA is an acute phase protein that has been shown to inhibit the effects of IL-1 $\alpha$  and IL-1 $\beta$  by competing for type I and type II IL-1 receptors<sup>[169]</sup>. This leads to a decrease in the inflammatory response<sup>[169]</sup> and abrogates liver IRI *in vivo*<sup>[170]</sup>. A recent study on gene expression profiling on patients undergoing partial hepatectomy revealed that IPC stimulated the expression of the IL-1-RA gene<sup>[171]</sup>. Hence, liver over-expression of IL-1-RA following IPC directly inhibits the effect of high IL-1 concentrations induced by IRI and results in reduced liver injury and necrosis<sup>[171]</sup>. Although no study has formally assessed the effect of IL-1-RA on markers of liver regeneration, IL-1-RA could be indirectly involved in the regeneration process by antagonizing the inhibitory effects of IL-1 on hepatocyte proliferation.

**Inhibitory binding protein for NF- $\kappa$ B (I $\kappa$ B- $\alpha$ ) and NF- $\kappa$ B activity:** The transcriptional activities of NF- $\kappa$ B are tightly controlled by its inhibitory proteins, especially I $\kappa$ B- $\alpha$ <sup>[172]</sup>. The phosphorylation and subsequent degradation of I $\kappa$ B- $\alpha$  leads to the liberation of NF- $\kappa$ B proteins allowing binding to a variety of promoters and triggers gene expression. Data from studies examining the role of NF- $\kappa$ B as an effector of IPC have demonstrated conflicting results. IPC facilitated the activation of transcription factor NF- $\kappa$ B in an *in vivo* murine model, and this was parallel to the degradation of its inhibitory protein, I $\kappa$ B- $\alpha$ <sup>[173]</sup>. Ricciardi and co-workers found that IPC increased I $\kappa$ B- $\alpha$  phosphorylation and NF- $\kappa$ B concentration prior to cold ischemia in pig liver grafts. Data from this study suggested that the underlying mechanism involved was related to the activation of second messengers of tyrosine kinase<sup>[127]</sup>. Another proposed mechanism for NF- $\kappa$ B activation and degradation of I $\kappa$ B- $\alpha$  could be mediated by TNF- $\alpha$ . The release of TNF- $\alpha$  by IPC and pre-treatment with low-dose TNF- $\alpha$  was shown to increase I $\kappa$ B- $\alpha$  degradation and increase NF- $\kappa$ B DNA binding in a mouse model<sup>[140]</sup>. However, Li *et al*<sup>[174]</sup> observed that IPC inhibited the activity of the transcription factor NF- $\kappa$ B during the early reperfusion phase (1 and 2 h), and this was accompanied by diminished TNF- $\alpha$  expression and reduced IRI in liver transplantation rat model.

One explanation for this contradictory evidence might be the different experimental models and methodology used. Nevertheless, these results indicate that IPC does

attenuate the nuclear levels of the transcription factor NF- $\kappa$ B. It is possible that other mediators may have an effect in determining the increase or inhibition of NF- $\kappa$ B activity and its corresponding cellular signaling responses.

### **Increased production of growth factors**

**Hepatocyte growth factor (HGF):** Franco-Gou *et al*<sup>[175]</sup> demonstrated an increase in both liver and plasma HGF levels following IPC in reduced size liver transplantation rat model, and this was associated with an increase in hepatocyte proliferation. The modulation of HGF levels by IPC could be mediated by the generation of NO and its effect on TGF- $\beta$  and HGF concentrations. IPC reduced the levels of TGF- $\beta$  with an associated increase in HGF levels<sup>[150]</sup>. Similar results were seen with NO preconditioning treatment<sup>[150]</sup>. This suggests that IPC reduced TGF- $\beta$  levels with a parallel increase in HGF and subsequent hepatocyte proliferation, possibly mediated by NO.

HGF may also exhibit the ability to promote hepatocyte survival. In a liver IRI rat model, pre-treatment with HGF inhibited the production of reactive oxygen species and its damaging effects<sup>[176]</sup>. Similar results were observed in a hypoxia-reoxygenation-induced oxidative stress model in hepatocytes<sup>[177]</sup>. These results suggest that the anti-apoptotic effect of HGF could pave the way for hepatocyte proliferation following IRI.

### **Activation of downstream mitogen-activated protein kinases (MAPKs)**

**Extracellular signal-regulated kinases 1 and 2 (ERK-1/2):** ERK-1/2 is predominantly activated by growth-promoting factors. Studies have shown that protein kinase C plays a pivotal role in the activation of ERK-1/2 signaling pathway<sup>[163,178]</sup> that participates in the preservation of hepatocytes<sup>[163]</sup>. A number of reports have indicated that protein kinase C was critical for the development of IPC in rat, rabbit and human myocardiocytes<sup>[179,180]</sup>. Gao and associates showed that the activation of protein kinase C and its downstream ERK-1/2 mediators were increased in IPC-treated *in vivo* and *in vitro* models<sup>[163]</sup>. Data from this study also suggested that the expression of HSP70 was reduced and the protective effect of IPC was diminished when ERK-1/2 activity was reduced by a MAPK inhibitor (PD-98059). HSP70 expression and the cytoprotective effect of IPC were also reduced by a protein kinase C inhibitor (chelerythrine) in both *in vitro* and *in vivo* settings. Hence, this suggests that IPC increased the activation of ERK-1/2, *via* protein kinase C. The increased activation of protein kinase C-dependent ERK-1/2 by IPC may also increase the expression of HSP70. The up-regulation of ERK-1/2 by IPC may help in promoting liver regeneration in both the priming phase and growth factor signaling pathways.

**p38 mitogen-activated protein kinases and c-jun-NH2-terminal kinase 1:** Both p38 MAPKs and JNK-1 are known to modulate proliferative or apoptotic signaling pathways<sup>[181]</sup>. The activation of MAPKs and its corresponding downstream signaling pathway is regulated by specific stimuli and is also dependent on cell type. The co-activation of NF- $\kappa$ B protects the hepatocyte from

apoptosis and is involved in the priming of hepatocytes to enter the cell cycle<sup>[22,182]</sup>.

Carini and co-investigators demonstrated that hypoxic preconditioning activated the p38 signaling pathway in rat hepatocytes subjected to hypoxia-re-oxygenation injury *in vitro*<sup>[117]</sup>. Teoh *et al*<sup>[173]</sup> demonstrated that proliferating hepatocytes were identified earlier in IPC-treated livers in a murine model of partial liver ischaemia, and this corresponded with the earlier activation and sustained maintenance of p38 and JNK-1. This suggests that IPC stimulus could prime quiescent hepatocytes to enter the cell cycle early, hence, setting up a regenerative response to compensate for hepatocyte injury by IRI.

#### **Activation of survival and proliferative pathways**

**Phosphatidylinositol 3-kinase (PI 3-kinase)/Akt signaling pathway:** The activation of the PI 3-kinase/Akt cascade has been shown to have a positive impact on cell survival and proliferation<sup>[183-186]</sup>, inhibition of apoptosis and encourage the uptake of glucose and amino acids following stimulation by various growth-promoting factors in certain cells<sup>[187-189]</sup>. Data from the Izuishi group showed significant Akt activation following IPC in an *in vivo* model and suggested that this might contribute to the up regulation of glucose and amino acid transport after IRI required for liver regeneration<sup>[190]</sup>.

#### **Activation of nuclear proteins**

**Cyclin D1:** Cyclin and cyclin-dependent kinases are involved in cell cycle regulation<sup>[191]</sup>, in particular, the D group cyclins<sup>[192]</sup>. Cyclin D1 is a nuclear protein required for cell cycle progression in the G<sub>1</sub> phase<sup>[192-194]</sup>, and controls hepatocyte proliferation<sup>[195]</sup>. IPC-treated livers showed earlier expression of cyclin D1 protein that corresponded with enhanced entry of hepatocytes into the cell cycle<sup>[173]</sup>. Cai and co-workers demonstrated that IPC stimulated cyclin D1 mRNA and protein expression during the early reperfusion phase in IPC-treated rat livers<sup>[196]</sup>. The early production of cyclin D1 could be mediated by the activation of the p38 MAPK pathway<sup>[182]</sup>. The cyclin D1 promoter region includes binding sites for NF- $\kappa$ B<sup>[197]</sup> and NF- $\kappa$ B activation is evident in hepatocytes during the early phase of regeneration following partial hepatectomy<sup>[48,198]</sup>. There is a close link between the activation of NF- $\kappa$ B by degradation of I $\kappa$ B- $\alpha$  cyclin D1 activation and cell cycle progression. IPC can modulate these transcription factors and increase cell proliferation, which is possibly one of the protective mechanisms against IRI.

#### **Energy metabolism**

Results obtained from an experimental model of 70% hepatectomy indicated that liver regeneration was closely correlated to the ATP levels of the liver remnant<sup>[93]</sup>. Studies have shown that IPC in normothermic conditions preserved the adenine nucleotide pool<sup>[199,200]</sup> and this is thought to be a consequence of the down regulation of cellular metabolism<sup>[199,201]</sup>. In a rat model of hypothermic transplant preservation injury, hepatocytes exposed to IPC had higher ATP concentrations and increased protein synthesis<sup>[202]</sup>. This improvement in energy metabolism is

thought to contribute to hepatocyte viability following IRI<sup>[202]</sup>. Besides improvement in energy metabolism, Yoshizumi *et al*<sup>[203]</sup> also demonstrated an increase in bile production in IPC-treated rats. However, Franco-Gou and colleagues demonstrated similar energy metabolism (ATP, adenine nucleotides, ATP/ADP ratio and energy charge) in the IPC- and non-IPC-treated rat livers<sup>[175]</sup>. The difference in results obtained could be related to the difference in experimental models used. However, the role of IPC in modulating liver energy metabolism, which involves the preservation of ATP should not be discounted.

### **CLINICAL IMPLICATIONS OF ISCHAEMIC PRECONDITIONING IN LIVER SURGERY**

The use of IPC as a surgical strategy to limit the detrimental effects of IRI during liver surgery has been extensively researched. Encouraging findings in animal studies in both warm ischaemia<sup>[203]</sup> and transplantation models<sup>[119]</sup>, led to the first human trial which demonstrated that IPC reduced the severity of post-operative liver injury as well as alleviating endothelial cell injury<sup>[17]</sup>. Further human liver resection studies have shown that IPC reduces post-operative serum aminotransferase levels in both steatotic<sup>[204]</sup> and cirrhotic<sup>[205]</sup> livers and improves post-reperfusion haemodynamic stability<sup>[206]</sup> (Table 1). Although IPC is protective against IRI<sup>[207,208]</sup>, it did not influence the morbidity and mortality rates in human studies<sup>[204,209,210]</sup>. In the transplant setting, Jassem *et al*<sup>[211]</sup> reported lower serum aminotransferase levels and shorter intensive care stay in IPC-treated cadaveric donor allografts. Other studies have not shown IPC to be beneficial in terms of graft function. Azoulay *et al*<sup>[212]</sup> found that although IPC protected cadaveric liver grafts against IRI, this beneficial effect was counter-balanced by decreased early graft function. Cescon and colleagues demonstrated similar protective effects against IRI, but IPC showed no clinical benefit (primary graft function and survival rates) in liver transplantation from deceased donors<sup>[213]</sup>. Although gaining popularity, the incongruous evidence of the clinical effects of IPC has precluded its widespread adoption in liver transplantation units.

Following major liver resection and IRI, the ability of the liver to regenerate is crucial to maintain liver function. This also has implication in live donor orthotopic liver transplantation and transplantation of segmental liver grafts. Since Yamada and co-workers first demonstrated that IPC significantly increased the regenerative capacity of the remaining hepatocytes in a rat model of IRI<sup>[20]</sup>, various investigators have attempted to elucidate the role of IPC on liver regeneration using both culture and animal model studies as described above. At present, although there is no clinical trial published on the effect of IPC on liver regeneration, there are studies evaluating methods of monitoring liver regeneration. Special radiological imaging techniques currently available not only show volume of regeneration, but also determine functional ability of the remnant and regenerated liver<sup>[214,215]</sup>. This is another step towards assessing the role of IPC in liver regeneration in the clinical scenario.

Table 1 Previous published human studies on the results of ischaemic preconditioning following liver resection and transplantation

Study group	Sample <sup>1</sup>	Surgery	IPC <sup>2</sup>	Ischaemia and reperfusion time (min) <sup>3</sup>	Parameters assessed	Outcome of IPC
Clavien <i>et al</i> <sup>[17]</sup> (2000)	24 (12)	Liver resection	10I + 10R	IPC and control (TI: 30)	PT, Bilirubin, ALT, AST, Histology, Caspase-3 and 8 activity, SEC apoptosis, Blood loss, Transfusion, ITU stay, LOS	Protective against IRI Beneficial in patients with steatosis
Clavien <i>et al</i> <sup>[204]</sup> (2003)	100 (50)	Liver resection	10I + 10R	IPC (TI: 36 ± 5.9, Op: 225 ± 73), Control (TI: 35 ± 6.8, Op: 240 ± 92)	PT, Bilirubin, ALT, AST, Histology, Hepatic ATP, Blood loss, Transfusion, ITU stay, LOS	Protective against IRI Beneficial in younger patients, those with steatosis and longer periods of occlusion
Li <i>et al</i> <sup>[205]</sup> (2004)	29 (14)	Liver resection	5I + 5R	IPC (TI: 18 ± 3.6, Op: 191.3 ± 74.9), Control (TI: 17.4 ± 2.3, Op: 208.2 ± 45.3)	Bilirubin, ALT, AST, Histology, Caspase-3 activity, SEC apoptosis, LOS	Protective against IRI, mainly HCC patients with cirrhosis Shorter hospital stay
Nuzzo <i>et al</i> <sup>[209]</sup> (2004)	42 (21)	Liver resection	10I + 10R	IPC (TI: 54 ± 19, Op: 321 ± 92), Control (TI: 36 ± 14, Op: 339 ± 112)	PT, Bilirubin, ALT, AST, Transfusion, Morbidity, Mortality	Reduces operative bleeding Protective against IRI
Chouker <i>et al</i> <sup>[206]</sup> (2004)	68 (22)	Liver resection	10I + 10R	IPC (TI: 32 ± 6.3, Op: 251 ± 46), Control without PR (TI: NA, Op: 52 ± 30), Control with PR (TI: 35 ± 11, Op: 257 ± 83)	ALT, AST, Fluid loss, Transfusion, <sup>4</sup> Cardiovascular status	Protective against IRI Improves haemodynamic stability
Chouker <i>et al</i> <sup>[207]</sup> (2005)	75 (25)	Liver resection	10I + 10R	IPC (TI: 35.5 ± 2.7, LR: 32.2 ± 2.0), Control without PR (TI: NA, LR: 39 ± 4.5), Control with PR (TI: 35.6 ± 2.6, LR: 33.2 ± 2.3)	IL-6, IL-8, Cytochrome c, Adhesion molecules [B <sub>2</sub> -integrins (CD18)], Histology (neutrophil infiltration)	Protective against IRI by attenuating neutrophil activation and IL-8 release
Chouker <i>et al</i> <sup>[208]</sup> (2005)	73 (25)	Liver resection	10I + 10R	IPC (TI: 35.12 ± 13.6, LR: 31.50 ± 9.1), Control without PR (TI: NA, LR: 34.77 ± 16.5), Control with PR (TI: 34.2 ± 10.9, LR: 32.13 ± 10)	PT, ALT, AST, α-GST	Protective against IRI Prevented early rise of α-GST
Koneru <i>et al</i> <sup>[210]</sup> (2005)	62 (34)	Transplant	5I + 5R	IPC (CI: 384 ± 92, WI: 41 ± 5.8), Control (CI: 415 ± 87, WI: 37 ± 5.6)	INR, Bilirubin, ALT, AST, Histology (apoptosis, hepatocyte swelling), LOS, Survival (6 mo)	No beneficial effect
Azoulay <i>et al</i> <sup>[212]</sup> (2005)	91 (46)	Transplant	10I + 10R	IPC (CI: 436 ± 116, Op: 441 ± 119), Control (CI: 461 ± 96, Op: 462 ± 98)	PT, Bilirubin, ALT, AST, Histology, Graft function, Morbidity, Mortality	Better ischaemic tolerance Decreased early graft function
Jassem <i>et al</i> <sup>[211]</sup> (2005)	23 (9)	Transplant	10I + 10R	IPC (CI: 620 ± 190, WI: 43.9 ± 13), Control (CI: 665 ± 280, WI: 40.4 ± 9)	AST, INR, Lactate, ITU stay, Histology (neutrophil infiltration, platelet deposition), Graft function	Protective against IRI Reduces inflammatory response Shorter ITU stay
Cescon <i>et al</i> <sup>[213]</sup> (2006)	47 (23)	Transplant	10I + 15R	<sup>5</sup> IPC [TI: 388 (259-830), Op: 440 (225-725)], Control [TI: 383 (279-695), Op: 465 (280-1015)]	PT, Bilirubin, ALT, AST, Histology (neutrophil, lymphocyte infiltration, iNOS, apoptosis), Graft function, Survival (1 yr)	Protective against IRI No clinical benefit

<sup>1</sup>Patients stated in brackets are the number of patients who had ischaemic preconditioning treatment; <sup>2</sup>IPC was performed by portal triad clamping in all these studies; <sup>3</sup>Ischaemia and operative times are presented as mean ± SD unless otherwise stated; <sup>4</sup>Cardiovascular status refers to mean arterial pressure, central venous pressure, heart rate, stroke volume index, systemic vascular resistance index, fluid infusion and catecholamines requirements; <sup>5</sup>Ischaemia and reperfusion times in this study were presented as median (range). I: Ischaemia; R: Reperfusion; IPC: Ischaemic preconditioning group; PR: Pringle maneuver; TI: Total ischaemia time; CI: Cold ischaemia time; WI: Warm ischaemia time; Op: Total operative time; LR: Liver resection time; ITU: Intensive therapy unit; LOS: Length of hospital stay; PT: Pro-thrombin time; INR: International normalized ratio of pro-thrombin time; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; α-GST: Alpha-Glutathione S-Transferase; iNOS: Inducible form of nitric oxide synthase; ATP: Adenosine triphosphate; HCC: Hepatocellular carcinoma; IL: Interleukin; SEC: Sinusoidal endothelial cell; IRI: Ischaemia-reperfusion injury.

With the increasing laboratory evidence of protection against IRI and improved liver regeneration by IPC, several aspects of this strategy could be developed pharmacologically that may be more clinically applicable than IPC itself. This is especially in cases with a background of chemotherapy-induced steatohepatitis<sup>[216]</sup> and cirrhosis<sup>[217,218]</sup>. Pharmacologic agents targeting mediators of IPC that can be potentially developed include HGF, IL-6 and IL-1-RA. However, several issues such as the timing of administration of these agents, therapeutic doses and immunological response of the recipient need to be determined. Further understanding of the mechanistic pathways of IPC may pave the way for the development of these agents that are capable of conferring protection against IRI and promote liver regeneration.

## CONCLUSION

Liver regeneration is of clinical significance in view of the increasing number of major liver resections and the increasing use of marginal donor liver and split-liver allografts for transplantation. Successful patient outcome often depends on liver regeneration, particularly in patients with cirrhotic and steatotic livers. Regeneration of the liver following IRI and major liver surgery is a complex process that involves the integration of a network of cytokines, growth factors, kinases, transcription factors and metabolic demands of the liver.

In comparison with the evidence available on the effect of IPC on IRI, its role in liver regeneration is still undetermined. However, current research has demonstrated that the beneficial effects of IPC on liver regeneration is mediated by up regulating growth-

promoting factors, suppressing growth-inhibitory factors and preserving energy levels for regeneration. Nevertheless, more studies are still required to further delineate the underlying pathophysiology of IPC and impact on mediators of liver regeneration. It is also important to determine whether the beneficial effect of IPC in the laboratory setting is reproducible in clinical practice. By understanding the underlying mechanisms by which IPC influences liver regeneration, other strategies as alternatives to IPC, could be developed to modulate the regenerative pathways in the clinical setting and improve outcomes of patients following major liver resection and transplantation. The assessment of IPC on liver regeneration in human studies is clearly the next step.

### Abstract

*H pylori* is etiologically associated with gastritis, gastric and duodenal ulcers, gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma. Eradicating *H pylori* may convert rapidly the outcome of related diseases with the use of more accurate diagnostic molecular tests. Indeed some of the tests cannot give the evidence of current infection; *H pylori* can be detected by noninvasive and invasive methods, the latter requiring an endoscopy. Eradication failure is a big problem in *H pylori* infection. Recently, clarithromycin resistance in *H pylori* strains is increasing and eradication therapy of this bacterium is becoming more difficult. Molecular methods have frequently been applied besides phenotypic methods for susceptibility testing to detect clarithromycin resistance due to mutations in the 2143 and 2144 positions of 23S rRNA gene. Fluorescence *in situ* hybridization (FISH) method on paraffin embedded tissue is a rapid, accurate and cost-effective method for the detection of *H pylori* infection and to determine clarithromycin resistance within three hours according to the gold standards as a non-culture method. This method can also be applied to fresh biopsy samples and the isolated colonies from a culture of *H pylori*, detecting both the culturable bacillary forms and the coccoid forms of *H pylori*, besides the paraffin embedded tissue sections. This technique is helpful for determining the bacterial density and the results of treatment where clarithromycin has been widely used in populations to increase the efficacy of the treatment and to clarify the treatment failure *in vitro*.

**Key words:** *H pylori*; Fluorescence *in situ* hybridization method; Clarithromycin resistance

### INTRODUCTION

*H pylori* is etiologically associated with gastritis, gastric and duodenal ulcers, gastric adenocarcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma<sup>[1-3]</sup>. The prevalence of *H pylori* infection is 70%-90% in developing countries and 25%-50% in developed countries<sup>[2,4]</sup>. Person-to-person spread is the most probable mode of transmission. Fecal-oral and oral-oral transmission are also reported<sup>[5]</sup>. *H pylori* has been classified as a class I carcinogen by International Agency for Cancer Research (IACR)<sup>[6]</sup>. *H pylori* can be detected by noninvasive and invasive methods, the latter requiring an endoscopy. Noninvasive testing for *H pylori* can be done by measuring exhaled <sup>13</sup>C urea breath test (UBT), by serology, by stool antigen tests, by stool PCR and by analyzing body materials such as saliva and urine<sup>[2,7]</sup>. Invasive tests include endoscopy, with biopsy of the affected region followed by histopathologic examination of stained specimens to demonstrate the presence of the bacterium, rapid urease test, biopsy PCR and culture of the bacterium<sup>[1]</sup>. UBT, histopathology and culture of the organism, although not easily and routinely performed, are considered the gold standard for the diagnosis of *H pylori* infection<sup>[1,8]</sup>.

Seven and fourteen days of triple therapy are recommended to eradicate *H pylori* according to Maastricht 2-2002 Consensus report. The triple therapy comprises a proton pump inhibitor in combination with two antibiotics, including amoxicillin, clarithromycin, or metronidazole<sup>[9-11]</sup>. Clarithromycin is a key component of most treatment recommendations to eradicate *H pylori*<sup>[12]</sup>. Resistance of *H pylori* to clarithromycin is regarded as a particular dilemma, since this drug is a part of both established therapy regimens. Thus, macrolide resistance is a frequent cause for failure of *H pylori* eradication therapy<sup>[10]</sup>. In industrialized countries approximately 10% of the

*H. pylori* strains are clarithromycin-resistant. In developing countries, resistance rates to clarithromycin are higher, varying between 25% to 50%, while they are 5%-10% in the USA and as high as 10% in Europe<sup>[10,13,14]</sup>. Recently, the clarithromycin resistance rates are reported 16.8% and 52%-56% in Turkey<sup>[15-17]</sup>. In routine clinical laboratories the detection of clarithromycin resistance for *H. pylori* is mainly based on phenotypic methods performed after culture: agar diffusion for the E-test or the agar dilution method, which is preferred as a reference method. However, there are some disadvantages of these methods such as results are not available until 48-96 h after inoculation of the agar plates<sup>[10,18]</sup>. Because *H. pylori* is a fastidious organism, there are also some problems in application of culture and antibiotic susceptibility testing. Therefore easy, cheap and practicable methods are required for the detection of *H. pylori* and determination of resistance, which is very important before the treatment if the resistance reaches 15%-20% in the area<sup>[7,19]</sup>. When the bacterial culture cannot be used routinely, the patient should benefit from the determination of macrolide resistance using non-invasive genotype-based methods<sup>[18]</sup>.

Resistance of *H. pylori* to clarithromycin is mainly due to major point mutations within an adenine-to-guanine transition at positions A2142G, A2143G and A2144G and to an adenine-to-cytosine transversion at positions A2142C and A2143C, which are included in the peptidyltransferase-encoding region of the 23S rRNA<sup>[9,11,20-23]</sup>. Mutations A2142G and A2143G are the most often observed, with the A2142C mutation being less common<sup>[24]</sup>. Other point mutations A2115G, G2141A, and T2717C have also been reported, though they appear to be very rare<sup>[18,25-27]</sup>.

Detection of point mutations conferring resistance to clarithromycin for *H. pylori* by molecular methods may constitute a more reliable approach and is attracting more attention<sup>[18]</sup>. Some molecular-based methods have been developed. PCR-based methods have been used to determine susceptibility to clarithromycin from biopsy specimens or cultured *H. pylori* strains and stool specimens<sup>[7,28-30]</sup>. Fluorescence *in situ* hybridization (FISH) method for detection of *H. pylori* and determination of its genotypic macrolide susceptibility in gastric biopsy specimens is a cultivation independent, reliable, sensitive and specific method<sup>[9,10,24]</sup>. Detection of *H. pylori* and clarithromycin resistance genotype simultaneously in gastric biopsy specimens by FISH method may be a good tool for research in the future for the drug resistance mechanisms and to search for the eradication failure in developing countries, such as clarithromycin and similar antibiotics<sup>[23,31]</sup>.

## CLARITHROMYCIN ACTIVITY AND MECHANISM OF RESISTANCE

### Clarithromycin activity

Clarithromycin is a bacteriostatic antibiotic, which belongs to a group of macrolides binding to peptidyl transferase loop of domain V of the 23S rRNA molecule. This binding interferes with protein elongation, and thus effectively blocks bacterial protein synthesis. The

antibacterial activity of clarithromycin is similar to that of other macrolides, but clarithromycin is better absorbed in the gastric mucus layer, more acid-stable, and therefore more effective against *H. pylori*<sup>[13,26,32]</sup>. Resistance to clarithromycin is thought to develop when substitutions in one amino acid at or near this binding site on the ribosome prevent the drug from binding, thereby making it ineffective<sup>[13]</sup>.

### Clarithromycin resistance

Resistance to clarithromycin in *H. pylori* is caused by point mutations in three adjacent 23S rRNA nucleotides, namely 2142, 2143 and 2144. In *H. pylori* these substitutions cause decreased affinity of the ribosomes for several macrolides, resulting in increased resistance. It can be induced by an adenine (A) to guanine (G) substitution at one of these positions or an adenine (A) to cytosine (C) substitution solely at position 2142. The A2142G and A2142C were significantly more frequently present in isolates with a higher minimal inhibitory concentration (MIC) for clarithromycin (> 64 mg/L), whereas the A2143G substitution was often found in isolates with a lower MIC (< 64 mg/L). Occasionally, other 23S rRNA mutations have also been reported for *H. pylori*; some of them are associated with high-level resistance, while others are associated with low-level resistance<sup>[26,32]</sup>. Occasionally three described mutations, in which the adenine residues at positions 2143 and 2144 are replaced by guanine (A2143G and A2144G) or cytosine (A2143C), are localized within the peptidyl transferase region of the 23S rRNA gene<sup>[9,11,22,31]</sup>.

*H. pylori* contains two 23S rRNA genes and mutations are generally found in both copies, however, heterogeneity has been described. Heterogeneity still results in clarithromycin resistance, but it generally appears to be associated with lower resistance levels than in homogenic isolates. The higher prevalence of homogeneity over heterogeneity in *H. pylori* may reflect a high efficiency of DNA recombination. The mutation in one copy of the 23S rRNA may be easily transferred to the other 23S rRNA gene by efficient homologous DNA recombination under selective pressure, conferring higher levels of clarithromycin resistance<sup>[11,22,24,26,31,32]</sup>. As expected, clarithromycin resistance coincides with resistance to other macrolides. The A2142G and A2142C mutations are linked to high-level cross-resistance to all macrolides, whereas the A2143G mutation gives rise to high-level resistance to erythromycin and intermediate-level resistance to clindamycin and streptogramin<sup>[26,32]</sup>.

## DETECTION OF CLARITHROMYCIN RESISTANCE

### Molecular tests

The association between point mutations in the 23S rRNA gene and macrolide resistance in *H. pylori* potentially provides a new approach for diagnosing macrolide resistant *H. pylori* strains<sup>[33]</sup>. Numerous molecular-based methods are now available to assess clarithromycin in *H. pylori*, such as PCR-RFLP, PCR-OLA, PCR-DEIA, PCR-

LipA, PCR-PHFA, 3M-PCR, real-time PCR hybridization assay, FISH, FRET, DNA sequencing by conventional and real-time (pyrosequencing) techniques. Most assays are polymerase chain reaction (PCR)-based using different methods to study the amplicons. The PCR-based molecular techniques are quicker than microbiological susceptibility testing, and more importantly, they can be performed directly on gastric biopsies and gastric juice<sup>[33]</sup>.

Restriction fragment length polymorphism (RFLP) is a simple method based on the occurrence of restriction site within the amplicon. This assay allows for the detection of the previously mentioned 23S rRNA mutations using the restriction endonucleases, *Mbo*II (A2142G) *Bbs*I (A2142G), *Bsa*I (A2143G) and *Bce*AI (A2142C). As the PCR-RFLP was initially not able to detect the A2142C mutation, a 3'-mismatch reverse primer PCR method (3M-PCR) was developed<sup>[23,25,27]</sup>. However, the mutations are identified by the absence of a band, which is a less preferable endpoint than a positive endpoint<sup>[27]</sup>.

Other methods, such as PCR-DNA enzyme immunoassay (DEIA), PCR oligonucleotide ligation assay (OLA), preferential homoduplex formation (PHFA) and PCR-line probe assay (LipA), include an additional hybridization step after the PCR. The PCR products were hybridized with labeled oligonucleotide probes under highly stringent conditions and hybrids were subsequently detected with specific antibodies or streptavidin-alkaline phosphatase<sup>[13,18,22,27,34,35]</sup>. The PHFA has been applied to direct detection of *H pylori* and clarithromycin resistant mutants in gastric juice samples<sup>[27]</sup>. The PHFA uses double labeled amplicons. Many of the assays are based on the principle of reverse hybridization with labeled probes for up to seven mutations and the wild type, immobilized either in microtitre wells (DEIA) or on nitrocellulose (LIPA). In these assays, PCR products are hybridized to the probes under highly stringent conditions and the resultant hybrids are detected colorimetrically. In the DEIA, the detection system is an enzyme linked immunoabsorbent assay with a labeled anti-double stranded DNA monoclonal antibody. Other more complex microtitre plate based systems such as the OLA use labeled capture and reporter probes<sup>[35]</sup>.

Recently, several real-time PCR hybridization assays have been developed. The real-time PCR technique, which is powerful advancement of the basic PCR method, is developed based on amplification of a fragment of the 23S rRNA gene of *H pylori* followed by the melting curve analysis by biprobes and hypoprobes<sup>[18,36]</sup>. In these assays a 23S rDNA fragment is amplified in the presence of a fluorescent-labeled mutation and anchor probe. Biprobes are sequence-specific probes labeled with the fluorophore Cy5. When the probe hybridizes to the target sequence, Cy5 is excited by the energy transfer from SybrGreen I, resulting in an increase of emitted light<sup>[29,36-38]</sup>. After completion of the PCR, the temperature is increased to determine the melting point of the mutation probe. The temperature at which the fluorescent signal drops indicates the point at which the mutation probe dissociates (melting point). When there are mismatches present in the target sequence, lower melting temperatures are obtained compared to the matched hybrid. This technique is simple and quick, and if applied directly to gastric tissue, results

can be obtained within 3 h<sup>[13,27,29,34-38]</sup>.

A technique named fluorescence resonance energy transfer (FRET) can be applied. In the first article in 1999, a DNA double strand specific fluorophor SYBR Green I and a second fluor dye Cy5 on a probe were used to test *H pylori* strains. This method was then applied to gastric biopsies<sup>[26]</sup>.

In contrast with all the above approaches, DNA sequencing provides the gold standard reference method for mutation detection although it is not technically feasible or cost effective for routine laboratory determination of *H pylori* resistance markers. Nevertheless, knowledge of nucleotide sequences has proved invaluable for validation of the various assays mentioned above, particularly where a resistant phenotype is not associated with any of the more common mutations<sup>[35]</sup>.

A recent development in rapid sequencing based on the principle of pyrosequencing, a real time DNA sequence analysis of short (25-30 bp) DNA stretches, has been applied to rapid identification of *H pylori*. Available data suggest this new technique can offer an accurate and rapid method for sequence analysis of PCR amplicons providing easily interpreted results within hours<sup>[35]</sup>.

### Fluorescence *in situ* hybridization

*In situ* hybridization (ISH) uses a labeled probe to detect and localize specific RNA or DNA sequences in a tissue or on a chromosome. ISH relies on DNA's ability to re-anneal, or hybridize, with a complimentary strand when at the correct temperature. "*In situ*" means "in the original place" in Latin, so ISH involves a labeled nucleic acid probe hybridizing with a DNA or RNA sequence *in situ* (in the cells) so that the location of the sequence of interest can be detected in the cells, tissue, or chromosome. Like Northern and Southern blots, ISH indicates the presence of a particular RNA or DNA sequence, but ISH differs from blots in that the labeled probe reveals the actual location of the sequence in the cells. The probe can be either radioactively labeled and detected by autoradiography or fluorescently labeled (abbreviated FISH) and detected by immunocytochemistry. The specificity of the probe depends on the permeability of the cells, the type of probes, the labeling technique, and the hybridization conditions, so specificity of ISH can be adjusted according to the desired results<sup>[39,40]</sup>.

Fluorescence *in situ* hybridization (FISH) is to identify the presence of specific chromosomes or chromosomal regions through hybridization or fluorescence-labeled DNA probes to denatured chromosomal DNA<sup>[41]</sup>. FISH uses fluorescent molecules to vividly paint genes on chromosomes. This technique is particularly useful for gene mapping and for identifying chromosomal abnormalities. FISH involves the preparation of short sequences of single stranded DNA, called probes, which are complementary to the DNA sequences that researchers wish to paint and examine. These probes hybridize, or bind, to the complementary DNA and, because they are labeled with fluorescent tags, allow researchers to see the location of those sequences of DNA<sup>[41,42]</sup>. This technique allows the detection of whole bacteria in their natural habitat by fluorescence microscopy of prepared

specimens. Fluorescent signals indicate the presence of complementary chromosomal DNA; the absence of fluorescent signals indicates absence of complementary chromosomal DNA<sup>[43]</sup>. Unlike most other techniques used to study chromosomes, which require that the cells be actively dividing, FISH can also be performed on non-dividing cells, making it a highly versatile procedure<sup>[41,42,44]</sup>.

Despite their small size, bacteria are accessible to the tools of cytology, such as immunofluorescence microscopy for localizing proteins in fixed cells with specific antibodies, fluorescence microscopy with the green fluorescent protein for localizing proteins in live cells, and FISH for localizing chromosomal regions and plasmids within cells<sup>[45]</sup>.

The bacterial FISH technology is based on the specific DNA-DNA hybridization of defined oligonucleotides with the abundant copies of ribosomal RNA of a bacterial species (16S rRNA, 23S rRNA). The oligonucleotides, which are labeled with fluorescent dyes, penetrate the bacterial cells and bind to their target sequence. This technique allows the detection of whole bacteria in their natural habitat by fluorescence microscopy of prepared specimens, i.e. the gastric mucosa of infected humans or from animal models<sup>[43,46]</sup>.

FISH is a rapid, accurate and also cost-effective method for the detection of *H. pylori* and determination of macrolide resistance in cultured *H. pylori* colonies. It can also be used directly on biopsy specimens for histopathological and microbiological examination<sup>[12,47]</sup>. In this assay intact *H. pylori* are hybridized with fluorescent-labeled *H. pylori*-specific 16S and 23S rRNA probes. The labeled bacteria were subsequently visualized by fluorescence microscopy. This assay allows detection of *H. pylori* and clarithromycin resistance simultaneously. Moreover, this assay does not require DNA preparation and can directly be applied to gastric biopsy samples<sup>[9,23,26,27,32,35,48]</sup>.

For *H. pylori* a species-specific detection is performed by the 16S rRNA-specific oligonucleotide Hpy-1, labeled in green. Simultaneously to the species detection a genotypic antibiotic resistance determination is possible (labeled in red). The resistance against the macrolide clarithromycin, which is a major antibiotic used in the triple therapy against *H. pylori* infections, is based on three defined point mutations in the 23S rRNA. These point mutations can be targeted specifically with the ClaWT, ClaR1, ClaR2, and ClaR3 probes. Different mutations correlate with different MICs of the antibiotics, ClaR1 > 64 mg/L, ClaR2, and ClaR3 between 8 and 64 mg/L<sup>[46,47]</sup>.

## CONCLUSION

The gold standard for accurate diagnosis of an *H. pylori* infection is either culturing of the pathogen or concordant positive results obtained by histology and the rapid urease test or the <sup>13</sup>C-urea breath test (UBT)<sup>[24]</sup>. After culturing for the pathogen of gastric biopsies, probably most laboratories use disk diffusion or E-test for the determination of macrolide resistance. Both methods require further sub-culturing for several days and cannot identify the type of point mutations present in the strain<sup>[12]</sup>.

The major advantage of FISH is the fact that the rRNA-targeted fluorescence-labeled oligonucleotide probes can be used for accurate determination of macrolide susceptibility, thus providing the clinician with important information with which to make a proper treatment recommendation<sup>[24,49]</sup>. Whilst the E-test is a phenotypic clarithromycin resistance measurement, FISH is an established genotypic technique for the detection of *H. pylori* and discrimination between the clarithromycin-susceptible wild type and clarithromycin-resistant mutants<sup>[11,49]</sup>. FISH is a reliable fast method for the detection of clarithromycin-resistant *H. pylori* mutants, and results are available within 3 h after an endoscopy. The probes are commercially available, and the method is cost-effective and can be applied in any laboratory without the need for special equipment or facilities, except for a fluorescence microscope<sup>[11,47,49]</sup>.

### Abstract

**AIM:** To investigate the role of glutathione S-transferase (GST) and matrix metalloproteinase-9 (MMP-9) expressions in the development and progression of reflux esophagitis-Barrett's metaplasia-dysplasia-adenocarcinoma sequence in the esophagus.

**METHODS:** GST and MMP-9 expressions were analyzed in 51 paraffin-embedded tissue samples by immunohistochemistry including patients with reflux esophagitis ( $n = 7$ ), Barrett's metaplasia ( $n = 14$ ), Barrett and esophagitis ( $n = 8$ ), Barrett and dysplasia ( $n = 7$ ), esophageal adenocarcinoma ( $n = 8$ ) and a control group without any histological changes ( $n = 7$ ). Immunostaining was determined semiquantitatively. Statistical analysis with one-way ANOVA, LSD test and correlation analysis were performed.  $P$  value of  $< 0.05$  was considered significant.

**RESULTS:** GST expression was significantly higher while MMP-9 expression was significantly lower in control group compared to Barrett's metaplasia and the other groups. No major changes were observed between Barrett, esophagitis, and Barrett and concomitant esophagitis. Barrett and concomitant dysplasia, and adenocarcinoma revealed a significant lower expression of GST and higher levels of MMP-9 compared to all other groups. Adenocarcinoma showed almost no expression of GST and significantly higher levels of MMP-9 than Barrett and concomitant dysplasia. Alterations of GST and MMP-9 were inversely correlated ( $r = -0.82$ ).

**CONCLUSION:** Decreased GST and increased expression of MMP-9 in Barrett's metaplasia-dysplasia-adenocarcinoma sequence as compared to normal tissue suggest their association with esophageal tumorigenesis. Loss of GST and gain of MMP-9 in Barrett with dysplasia compared to non-dysplastic metaplasia indicate that

these alterations may be early events in carcinogenesis. Quantification of these parameters in Barrett's esophagus might be useful to identify patients at higher risk for progression to cancer.

### INTRODUCTION

Esophageal cancer is still one of the most widespread diseases, and the early diagnosis of esophageal carcinoma correlates closely with improvement in prognosis. Barrett's esophagus (BE) is a precancerous condition of the lower esophagus in which the normal stratified squamous epithelium is replaced with specialized metaplastic columnar epithelium. Barrett's mucosa represents a type of epithelium that is completely different from the normal esophageal mucosa. BE is the main precancerous condition in the development of esophageal adenocarcinoma<sup>[1,2]</sup>.

BE is diagnosed in up to 20% of patients with documented chronic gastroesophageal reflux disease (GERD). Follow-up studies have shown that BE has a 30- to 125-fold increased risk of developing into an adenocarcinoma, which emerges at a rate of approximately one cancer per 100 patient-years<sup>[3]</sup>. Barrett's adenocarcinoma displays the most rapidly increasing incidence for gastrointestinal tract cancer in the Western world. Diagnosis of Barrett's adenocarcinoma is usually made late, and consequently, is associated with poor prognosis<sup>[4-6]</sup>.

Carcinogens are one of the inducing etiological factors for esophageal adenocarcinoma. Glutathione S-transferase (GST), a family of detoxification enzymes, plays an important role in the prevention of cancer by detoxifying numerous potentially carcinogenic compounds,

which can cause oxidative damage to cells<sup>[7]</sup>. Therefore, a reduction in these anti-oxidant enzymes can increase the risk of carcinogenesis<sup>[8]</sup>. Decreased GST enzyme activity has been reported in BE, and an inverse correlation was demonstrated between GST enzyme activity and tumor incidence in the gastrointestinal tract<sup>[9,10]</sup>. It has been suggested that down-regulation of GST expression could be an early event in the development of BE<sup>[11]</sup>.

The degradation of the extracellular matrix (ECM), including the basement membrane, which is a specialized matrix composed of type IV collagen, laminin, entactin, proteoglycans and glycosaminoglycans, is an important feature of cancer cell invasion, and proteolytic enzymes play an important role in this event<sup>[12]</sup>.

Several human solid tumors have been reported to have increased levels of proteolytic enzymes in cancer tissue, strongly suggesting that proteases may be important in tumor invasion and metastasis. With respect to the gastrointestinal tract, we have previously demonstrated that proteolytic enzymes may have a role not only in the process of gastric<sup>[13]</sup> or colorectal cancer invasion<sup>[14]</sup>, but also in the progression of gastrointestinal precancerous changes into cancer<sup>[15]</sup>.

Matrix metalloproteinases (MMPs) degrade components of the ECM and connective tissue surrounding the tumor cells and the basement membrane. MMPs are classified as gelatinases, collagenases, stromelysins, membrane-type matrix metalloproteinases, based mainly on the *in vivo* substrate specificity of the individual MMP. It was initially believed that MMPs, *via* breakdown of the physical barrier, were primarily involved in tumor invasion<sup>[16]</sup>. There is growing evidence, however, that the MMPs have an expanded role, as they are important for the creation and maintenance of a microenvironment that facilitates growth and angiogenesis of tumors at primary and metastatic sites<sup>[17,18]</sup>.

Type IV collagen is an important protein of the basement membrane. Type IV collagenase, matrix metalloproteinase-9 (MMP-9) (gelatinase B), has been reported to be especially important in the process of tumor invasion and metastasis<sup>[19,20]</sup>. Several MMPs (gelatinase A: MMP-2; stromelysin: MMP-3; matrilysin: MMP-7; metalloelastase: MMP-12; collagenase-3: MMP-13) are expressed by tumor cells in esophageal squamous cell and adenocarcinomas, suggesting that these MMPs are responsible for tumor aggressiveness and prognosis in human esophageal carcinomas<sup>[21-24]</sup>.

In the specific case of MMP-9, increased expressions have been observed in gastric cancer<sup>[25-27]</sup> and esophageal squamous cell carcinoma<sup>[28-30]</sup>, but its behaviour in esophageal adenocarcinoma and in preinvasive lesions of esophageal carcinogenesis is still uncertain.

On the other hand, GST and MMP-9 as actors either in cancer prevention or in carcinogenesis have not been evaluated in the same experimental setting. Therefore, the aim of the present study was to investigate the role of GST and MMP-9 expressions using immunohistochemical analysis in the development and progression of reflux esophagitis-BE-dysplasia-adenocarcinoma sequence in the esophagus.

## MATERIALS AND METHODS

Tissue specimens were obtained endoscopically from in- and outpatients with upper abdominal complaints at the 2<sup>nd</sup> Department of Medicine, Semmelweis University, Budapest.

Informed consent was obtained from all patients involved in the study, and a local ethical permission has been obtained. The patients comprised of 33 males and 18 females. The median age was 64 years with a range from 22 to 83 years. The endoscopic specimens were fixed in formalin and embedded in paraffin wax, sliced serial step sections of 4  $\mu$ m thickness. GST and MMP-9 immunohistochemical expressions were analyzed in a total of 51 paraffin-embedded tissue samples by immunohistochemistry including patients with reflux esophagitis ( $n = 7$ ) (4 males, 3 females, mean age 61 years, range 36-68 years); BE ( $n = 14$ ) (9 males, 5 females, mean age 66 years, range 48-69 years); BE and esophagitis ( $n = 8$ ) (6 males, 2 females, mean age 67 years, range 55-71 years); BE and dysplasia ( $n = 7$ ) (4 males, 3 females, mean age 68 years, range 52-72 years); and esophageal adenocarcinoma ( $n = 8$ ) (6 males, 2 females, mean age 71 years, range 64-83 years). Esophageal biopsies from patients with functional dyspepsia without any histological changes were used as controls ( $n = 7$ ) (4 males, 3 females, mean age 49 years, range 22-56 years).

### GST immunohistochemistry

The 4 micron thick tissue sections were dewaxed and rehydrated. Endogenous peroxidase activity was blocked by incubation for 30 min at room temperature in 3% hydrogen peroxide. After washing the sections 3 times in PBS for 5 min, non-specific blocking was done with 1% BSA-PBS solution for 10 min at room temperature. Next, the slides were incubated with diluted polyclonal rabbit anti-human GSTP1 antibody (1  $\mu$ L GSTP1 antibody and 150  $\mu$ L PBS) (Clone: A3600, DAKO) at 37°C for 60 min in a humidified chamber. After washing the specimens 3 times in PBS, signal conversion was carried out with the LSAB2 system (DAKO) as described in the manual. Finally, haematoxylin co-staining was performed.

### MMP-9 immunohistochemistry

After deparaffinization in xylene and rehydration through graded ethanol, endogenous peroxidase activity was blocked by incubation for 30 min at room temperature in 3% hydrogen peroxide. After washing the sections 3 times in PBS for 5 min, non-specific blocking was carried out with 1% BSA-PBS solution for 10 min at room temperature. Next, the slides were incubated with optimally diluted monoclonal anti-human MMP-9 antibody (Clone: 36020.111, R&D Systems) at 37°C for 60 min in a humidified chamber. After washing the samples 3 times in PBS, signal conversion was carried out with the LSAB2 system (DAKO) as described in the manual. Finally, haematoxylin co-staining was performed.

### Immunohistochemical analysis of GST and MMP-9

Known immunohistochemically-positive tissue sections

**Table 1 GST immunohistochemical expression according to a semiquantitative score in various types of mucosal lesions of the esophagus**

Histology	Score (mean $\pm$ SD)
Normal epithelium (Control group) <sup>a</sup> ( <i>n</i> = 7)	2.85 $\pm$ 0.24
Reflux esophagitis ( <i>n</i> = 7)	1.14 $\pm$ 0.24
Barrett's metaplasia ( <i>n</i> = 14)	1.60 $\pm$ 0.34
Barrett's metaplasia and reflux esophagitis ( <i>n</i> = 8)	1.12 $\pm$ 0.35
Barrett's metaplasia and dysplasia <sup>b</sup> ( <i>n</i> = 7)	0.58 $\pm$ 0.37
Adenocarcinoma <sup>b,c</sup> ( <i>n</i> = 8)	0.18 $\pm$ 0.25

<sup>a</sup>*P* < 0.00001 *vs* the other groups; <sup>b</sup>*P* < 0.005 *vs* the other groups (normal epithelium, reflux esophagitis, barrett's metaplasia, barrett's metaplasia and Reflux esophagitis); <sup>c</sup>*P* < 0.05 *vs* barrett's metaplasia and dysplasia.

were used as positive controls, and negative control sections were processed immunohistochemically after having replaced the primary antibody by PBS. None of the control sections exhibited immunoreactivity. Immunostaining was determined semiquantitatively, as previously described<sup>[31]</sup>. Essentially, the intensity of staining for GST and MMP-9 under a light microscope was graded from 0 to 3, denoting no staining or light, moderate, or intense staining. An immunohistochemical staining score was calculated for each histologic area by multiplying the staining intensity level (0 to 3) by the proportion of cells in each area staining with the given intensity. The immunohistochemical staining score for an area with 100% of cells with intense staining, for example, would be 1  $\times$  3, equalling 3, whereas an area with 50% cells with moderate staining and 40% without any staining would have a score of 0.5  $\times$  2 plus 0.4  $\times$  1, equalling 1.4. Two independent investigators without knowledge of the clinical outcomes evaluated the degree of immunohistochemical staining intensity. There was less than 5% variance between the results of the two counts.

### Statistical analysis

Statistical analysis with one-way ANOVA, LSD test and correlation analysis were performed by the Statistica for Windows 4.3 program package. *P* value of < 0.05 was considered significant.

## RESULTS

The immunohistochemical expression scores of GST and MMP-9 in various types of mucosal lesions of the esophagus (*n* = 51) are shown in Tables 1 and 2.

Expression of GST (Table 1) in normal esophageal epithelium (control group) was significantly higher compared to BE and the other groups (*P* < 0.00001), while no major changes were observed between BE, esophagitis, and BE with concomitant esophagitis.

BE with concomitant dysplasia, and adenocarcinoma revealed a significantly lower expression of GST compared

**Table 2 MMP-9 immunohistochemical expression according to a semiquantitative score in various types of mucosal lesions of the esophagus**

Histology	Score (mean $\pm$ SD)
Normal epithelium (Control group) <sup>b</sup> ( <i>n</i> = 7)	0.28 $\pm$ 0.39
Reflux esophagitis ( <i>n</i> = 7)	1.71 $\pm$ 0.39
Barrett's metaplasia ( <i>n</i> = 14)	1.46 $\pm$ 0.41
Barrett's metaplasia and reflux esophagitis ( <i>n</i> = 8)	1.75 $\pm$ 0.26
Barrett's metaplasia and dysplasia <sup>a</sup> ( <i>n</i> = 7)	2.16 $\pm$ 0.25
Adenocarcinoma <sup>a,c</sup> ( <i>n</i> = 8)	2.62 $\pm$ 0.35

<sup>b</sup>*P* < 0.00001 *vs* the other groups; <sup>a</sup>*P* < 0.05 *vs* the other groups (normal epithelium, reflux esophagitis, barrett's metaplasia, barrett's metaplasia and Reflux esophagitis); <sup>c</sup>*P* < 0.05 *vs* barrett's metaplasia and dysplasia.

to all other groups (*P* < 0.005). Adenocarcinoma showed almost no expression of GST and a significantly lower expression than BE and concomitant dysplasia (*P* < 0.05).

The semiquantitative score of MMP-9 (Table 2) in the normal esophageal epithelium (control group) was significantly lower compared to BE and the other groups (*P* < 0.00001); while no major changes were observed between BE, esophagitis, and BE with concomitant esophagitis.

Significantly higher expression levels of MMP-9 have been observed in BE with concomitant dysplasia and adenocarcinoma compared to all other groups (*P* < 0.05). Finally, MMP-9 expression was significantly higher in adenocarcinoma compared to BE and concomitant dysplasia (*P* < 0.05).

GST and MMP-9 were expressed mainly within the cytoplasm and cytoplasmic membranes of the esophageal epithelium in dysplastic or adenocarcinoma cells (Figures 1 and 2). Immunoexpressions of GST and MMP-9 in the esophageal tissues were inversely correlated (*r* = - 0.82; *P* = 0.001) (Figure 3).

## DISCUSSION

Despite advances in diagnosis and therapy, esophageal adenocarcinoma remains an aggressive and usually lethal tumor. BE is the main precancerous condition in the development of esophageal adenocarcinoma; however, its pathogenesis is poorly understood. BE typically progresses from metaplasia with atypia to dysplasia and adenocarcinoma. It is of great clinical importance to correctly identify changes with a high risk for malignant transformation, as high-grade dysplasias and early adenocarcinomas in patients with BE have a high chance for cure<sup>[32]</sup>. The identification of high-risk lesions in BE by histologic evaluation has drawbacks, especially regarding sampling errors and frequent intra- and inter-observer discrepancies in the histopathologic grading/staging of these lesions. Several new biomarkers are being tested to help in better determining the risk of cancer development.

**Figure 1** Expression of GST in different esophageal tissues. **A:** GST strong positive staining was observed in the normal esophagus (200 ×); **B:** Normal esophageal epithelium (top) with Barrett's metaplasia (bottom) (200 ×); **C:** Normal esophageal epithelium shows strong positive immunostaining compared to the weaker GST expression in Barrett's metaplasia (400 ×); **D:** Adenocarcinoma showing almost no expression of GST (200 ×); GST was mainly expressed within the cytoplasm.

Although most of the biological markers need to be evaluated further, at present, aneuploidy status, p16 and p53 gene abnormalities, or allelic losses are the most extensively documented alterations<sup>[33]</sup>.

**Figure 2** Expression of MMP-9 in different esophageal tissues. Strong positive immunostaining of MMP-9 in **(A)** Barrett's metaplasia (400 ×), **(B)** dysplasia (400 ×) and **(C)** adenocarcinoma (200 ×) of the esophagus. Cytoplasm of the metaplastic and dysplastic cells and cytoplasmic membranes of the esophageal adenocarcinoma cells were stained brown. Barrett's metaplasia with concomitant dysplasia and adenocarcinoma show the most intensive expression of MMP-9.

Immunostaining with a variety of antibodies provides a better understanding of the process of malignant transformation and helps to identify early markers of malignant transformation in BE<sup>[34]</sup>.

Given the lack in the literature of the evaluation of GST and MMP-9 expressions in the same experimental setting, we evaluated the behaviour of detoxification enzyme GST, and one member of the matrix metalloproteinases family, MMP-9, in the development and progression of normal epithelium, reflux esophagitis, BE, dysplasia and adenocarcinoma sequence in the esophagus.

A number of findings in our study confirmed that GST is involved in esophageal carcinogenesis and progression. We have demonstrated that GST expression was significantly higher in normal esophageal epithelium compared to the other groups. On the other hand, BE with dysplasia, and adenocarcinoma revealed a significantly

**Figure 3** The correlation between immunohistochemical expressions of GST and MMP9 in different esophageal tissues. Immunohistochemical expressions of GST and MMP9 were inversely correlated ( $r = -0.82$ ;  $P = 0.001$ ).

lower expression of GST, while adenocarcinoma expressed almost no GST.

Our findings are similar to the results reported by van Lieshout *et al*<sup>[9]</sup> and Cobbe *et al*<sup>[11]</sup>. They reported that the expression of GST appeared to be reduced in BE compared to normal esophageal squamous epithelium. In contrast to the van Lieshout *et al*<sup>[9]</sup> and Cobbe *et al*<sup>[11]</sup> studies, we also demonstrated that BE with concomitant dysplasia, and adenocarcinoma revealed a significantly lower expression of GST. Brabander *et al*<sup>[10]</sup> also found that GST expression was highest in the basal layer of normal esophageal squamous epithelium and lowest in adenocarcinoma cells, with BE cells showing intermediate staining intensity.

These results suggest that decreased GST expression could be an early event in the development of BE and may contribute to the risk of development and progression of adenocarcinoma in BE. The observed reduction in GST expression in BE may, therefore, contribute to the increased risk in this tissue.

Degradation of the ECM and basement membrane by tumor cells is a critical step in the process of tumor invasion and metastasis. MMP-9 is one member of the matrix metalloproteinases family, which is capable of degrading several components of the ECM. Increased expression of MMP-9 has been found in various carcinomas. With respect to the gastrointestinal tract, increased MMP-9 expressions have been observed in gastric<sup>[25-27]</sup> and colorectal cancer<sup>[35-38]</sup>. In the specific case of the esophagus, increased expression of MMP-9 has been demonstrated in esophageal squamous cell carcinoma<sup>[28-30]</sup>, but its role and behaviour in esophageal adenocarcinoma and BE is not well established.

The relatively small number of patients in our study can be explained by the known data about the epidemiology of BE and esophageal adenocarcinoma in Hungary; since only 4% of patients with esophageal cancers were diagnosed to have adenocarcinoma and its proportion remained stable over the observed last decade, it seems that contrary to North American and Western European countries, the prevalence of adenocarcinoma has been, until now, very low in Hungary<sup>[39]</sup>.

In the present study, immunohistochemical analysis revealed a progressive increase in the expression of MMP-9 with increasing severity of esophageal lesions. MMP-9 expression was significantly lower in normal esophageal epithelium compared to other groups. BE with concomitant dysplasia revealed a significantly higher expression of MMP-9 compared to BE, reflux esophagitis or BE with concomitant esophagitis. We observed that MMP-9 expression was significantly higher in adenocarcinoma compared to BE or BE with concomitant dysplasia. These results suggest that over-expression of MMP-9 plays an important role in the progression to esophageal adenocarcinoma, and MMP-9 protein may serve as a marker for invasiveness. Our results indicate that the activation of MMP-9 may be an early event in esophageal carcinogenesis.

Our findings are relevant from both, biological and clinical points of view. Despite the advance in preoperative and postoperative medical care of esophageal carcinoma patients, their prognosis has improved only marginally. Therefore, it would be useful to have additional biomarkers to help clinicians better determine the risk of esophageal cancer development. In esophageal cancer, novel targeted treatments are still in an early phase of development. It can be speculated that the relevance of MMP-9 in esophageal carcinogenesis may also support a possible therapeutic approach<sup>[40]</sup>. Indeed, this can be obtained directly by inhibition of MMP-9. Phase II-trials with the matrix metalloproteinase inhibitor prinomastat in patients with esophageal adenocarcinoma are under evaluation<sup>[41]</sup>.

The present study showed that expressions of GST and MMP-9 were reversely or negatively correlated, thus suggesting a concomitant down-regulation and up-regulation, respectively, of these systems. GST plays an important protective role in the prevention of cancer by detoxifying potentially carcinogenic compounds, while MMP-9 should be considered an aggressive factor, playing a crucial role in the progression of esophageal carcinogenesis.

In conclusion, our results demonstrate a significantly lower expression of GST and a significantly higher expression of MMP-9, respectively, in the BE-dysplasia-adenocarcinoma sequence as compared to normal esophageal tissue. The simultaneous down-regulation of GST and up-regulation of MMP-9 strongly suggest their association with esophageal tumorigenesis and particularly, their specific role in the biology of esophageal adenocarcinoma. Loss of GST and gain of MMP-9 in BE with concomitant dysplasia compared to non-dysplastic BE indicate that these alterations may be early events in esophageal carcinogenesis. Together with other biological markers, quantification of these parameters in BE might be useful to identify patients at higher risk for progression to adenocarcinoma, to prevent tumor development and to improve prognosis.

### Abstract

**AIM:** To develop a conditionally replicative gene-viral vector system called CNHK500-p53, which contains dual promoters within the E1 region, and combines the advantages of oncolytic virus and gene therapies for hepatocellular carcinoma (HCC).

**METHODS:** CNHK500-p53 was constructed by using human telomerase reverse transcriptase (hTERT) promoter to drive adenovirus E1a gene and hypoxia response element (HRE) promoter to drive adenovirus E1b gene. p53 gene expressing cassette was inserted into the genome of replicative virus. Viral replication experiments, cytopathic effect (CPE) and methyl thiazolyl tetrazolium (MTT) assay were performed to test the selective replication and oncolytic efficacy of CNHK500-p53.

**RESULTS:** Immunohistochemistry verified that infection with CNHK500-p53 was associated with selective replication of adenovirus and production of p53 protein in telomerase-positive and hypoxia-inducible factor-dependent HCC cells. p53 protein secreted from HepG2, infected with CNHK500-p53 was significantly higher than that infected with nonreplicative adenovirus Ad-p53 *in vitro* ( $388 \pm 34.6 \mu\text{g/L}$  vs  $76.3 \pm 13.17 \mu\text{g/L}$ ). Viral replication experiments showed that replication of CNHK500-p53 and CNHK500 or WtAd5, was much stronger than that of Ad-p53 in tested HCC cell lines. CPE and MTT assay indicated that CNHK500-p53 selectively replicated in and killed HCC cells while leaving normal cells unaffected.

**CONCLUSION:** A more efficient gene-viral system is developed by combining selective oncolysis with exogenous expression of p53 against HCC cells.

### INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common solid tumor worldwide, accounting for 500 000 new cases annually. The majority of patients presenting with advanced disease are not candidates for liver transplantation, surgical resection, or regional therapy. In 60% to 80% of patients with HCC, underlying liver cirrhosis and hepatic dysfunction complicate its treatment. Systemic treatments have minimal effects with significant toxicity, and cannot improve patient survival<sup>[1]</sup>. The search for alternative treatment modalities has revived the concept of using oncolytic viruses to treat cancer<sup>[2,3]</sup>. In this respect, conditional replicative adenoviruses (CRAds) appear to be attractive anticancer agents that are currently evaluated in clinical trials<sup>[4,5]</sup>. CRAds exert intrinsic anticancer activity through selective replication and lysis in cancer cells. In addition, release of CRAd progeny by infected tumor cells provides a potential to amplify the oncolytic effect by lateral spread through solid tumors.

Recent studies have shown that telomerase activity may serve as a general marker of cancer cells. Its activity in normal cells is restricted to fetal tissue, whereas it is elevated in tumors<sup>[6]</sup>. Although some tumors could activate a yet unknown alternative mechanism of telomere extension, the majority (> 85%) of human HCC cells acquire immortality by expressing telomerase reverse transcriptase (hTERT)<sup>[7]</sup>. It has been shown that hTERT expression is regulated at the transcriptional level, thereby providing a promising tool for tumor-specific gene expression.

Hypoxia occurs in virtually all solid tumors as they outgrow their blood supply. Hypoxia augments cellular levels of hypoxia-inducible factor (HIF), a transcription

factor that regulates target genes through the binding of hypoxia response elements (HRE). Activation of the HIF pathway enables cancer cells to survive and proliferate in a hypoxic environment and contributes to a more aggressive phenotype<sup>[8,9]</sup>. Therefore, the HIF/HRE system of gene regulation, which is active under hypoxia or as a result of genetic alterations during cell transformation, is particularly attractive to specific target solid tumors.

Besides viral oncolysis, CRAds can be exploited as vectors of gene therapies by advanced virology and viral vector design to enhance their oncolysis. Many malignant neoplasms have lost the function of p53. Although many oncolytic adenoviruses use p53-dependent pathways to cause cell death, several studies have shown that replicating adenoviruses kill cells more rapidly when expressing p53<sup>[10,11]</sup>.

Here we have constructed a novel gene-viral vector system called CNHK500-p53, which uses hTERT promoter to drive adenovirus *E1a* gene and HRE promoter to drive adenovirus *E1b* gene. In addition, human p53 gene was cloned into the downstream of E1A of adenovirus. E1A gene is essential for adenoviral replication, and adenovirus can hardly propagate without it. Telomerase and hypoxia are two important features of human solid tumors. Making use of these two promoters, CNHK500-p53 will replicate only in telomerase positive cancer cells undergoing hypoxia in theory. We tested the replication ability and oncolytic activity of CNHK500-p53 in HCC cell lines *in vitro*.

## MATERIALS AND METHODS

### Vectors, cell lines and cell culture

pXC1 (wild-type adenovirus plasmid) and pBGHE3 (a plasmid-containing right arm of adenovirus type 5 with deletion of 188-1339 bp sequence) were purchased from Microbix Biosystems Ltd (Toronto, Canada). pGEM-3ZF and pGEM-3ZF-p53 were purchased from Promega Ltd, USA. Human HCC cell lines HepG2, Hep3B, normal human liver cell line L02, normal human fibroblast cell lines MRC-5 and BJ were purchased from the American Type Culture Collection (Manassas, VA). Human HCC cell lines SMMC-7721, Bel-7402 and wild-type adenovirus 5 (WtAd5) were obtained from Second Military Medical University (Shanghai, China). Human embryonic kidney 293 cell line was obtained from Microbix Biosystems (Toronto, Canada). Hep3B, HepG2, SMMC-7721, Bel-7402 and human embryonic kidney 293 cells were cultured in DMEM (Life Technologies, Rockville, MD). L02 was cultured in RPMI 1640 medium. BJ was cultured in modified Eagle's medium (MEM). All the media were supplemented with 10% heat-inactivated fetal bovine serum (Life Technologies), 4mmol/L L-glutamine, 100 units/mL penicillin, and 100 µg/mL streptomycin and cultured under a 5% CO<sub>2</sub> atmosphere at 37°C.

### Construction of adenovirus vectors

Complete cDNA sequence of p53 gene was amplified by PCR from plasmid pGEM-3ZF-p53 by using the upstream primer VT182 (5'CCG GAA TTC (*EcoRI*) GCC ATG GAG GAG CCG CAG TCA GA3') and downstream primer VT183(5'CGC GGA TCC (*BamHI*)

TTA TCA GTC TGA GTC AGG CCC TTC TG3'). Synthetic DNA sequence was released with endonucleases *EcoRI* and *BamHI* (New England Biolabs, Beverly, MA) and ligated into plasmid pClon15 (made by ourselves, which contains the sequence of mouse cytomegalovirus promoter + multiple clone site + SV40 poly A) to generate pClon15-p53. pClon15-p53 was digested with endonucleases *AgeI* and *NotI* (New England Biolabs), a 1917-bp fragment containing mouse cytomegalovirus promoter + p53 gene + SV40 polyA was excised and inserted into *AgeI* and *NotI* sites of pSG500, which was constructed in our previous study and contained hTERT promoter core sequence with three extra E-boxes downstream and HRE promoter<sup>[12]</sup>. The plasmid resulting from the insertion of p53 gene cassette into the pSG500 in orthograde orientation was designated as pSG500-p53. pSG500-p53 and pSG500 were transfected by Lipofectamine 2000 (Life Technologies) into 293 cells together with pBHGE3. Viral plaques appeared 9-14 d after cotransfection and were sublimated three times. Recombinant adenoviruses, extracted using QIAamp DNA blood mini kit (Qiagen, Valencia, CA), were verified by PCR and named CNHK500-p53 and CNHK500. Ad-p53 was used as a control, which is a nonreplicative adenovirus vector carrying a SV40 early promoter-driven human p53 expression cassette<sup>[13]</sup>. A similar procedure was used by replacing the p53 gene with a 1538-bp fragment of the green fluorescent protein (GFP) expression cassette, obtained from plasmid pCA13-GFP (Takara Ltd, Japan), to derive conditionally replicative adenovirus CNHK500-GFP and nonreplicative adenovirus Ad-GFP. The nonreplicative adenovirus Ad-blank was used as a control.

### Production and purification of adenovirus

Viruses were purified by CsCl density purification and propagated in 293 cells. After 72 h, the detached cells were harvested by centrifugation at 1000 × *g* for 5 min at 4°C, resuspended in 10 mL cold PBS (free Ca<sup>2+</sup> and Mg<sup>2+</sup>), and then lysed with three cycles of freeze and thaw. Lysate was collected by centrifugation at 1500 × *g* for 10 min at 4°C, and the supernatant was placed on a gradient prepared with equal parts of CsCl in PBS and then centrifuged at 15000 × *g* for 2 h at 12°C. The virus band was removed and placed in a preformed CsCl gradient by ultracentrifugation for 18 h and dialyzed into 10 mmol/L Tris-HCl (pH 7.4) containing 10 mmol/L MgCl<sub>2</sub> and 10% glycerol. Titers of the purified adenovirus were determined by plaque assays of the tissue culture infectious dose 50 methods and shown as plaque forming unit per milliliter (pfu/mL). All viral preparations were free of endotoxin.

### Viral replication assay

Monolayer cells, including logarithmically growing Hep3B, HepG2, SMMC-7721 (10<sup>5</sup> cells/well), and contact-inhibition BJ, L02 (10<sup>6</sup> cells/well) were cultured in six-well dishes overnight and infected with CNHK500-p53, WtAd5, Ad-p53 at a multiplicity of infection (MOI) of 5.0 pfu/cell. Virus inocula were removed after 2 h. The cells then were washed twice with PBS and incubated at 37°C for 0, 12, 24, 48, or 96 h. Lysates of cells were prepared with three cycles of freeze and thaw. Serial dilutions of

the lysates were titrated on human embryonic kidney 293 cells with the tissue culture infectious dose 50 methods, normalized with that at the beginning of infection, and reported as multiples.

#### Western blot analysis of E1A and E1B protein

HepG2, Hep3B and BJ were seeded in 6-well plates at a density of  $5 \times 10^5$  cells/well and infected with CNHK500-p53 or wtAd5 at a MOI of 1 after 24 h of incubation. Two days after viral infection, cells were harvested and lysed with M-PER mammalian protein extraction reagent (PI-ERCE, Rockford, IC). Concentration of the extracted protein was measured with a biophotometer (Eppendorf AG, Hamburg, Germany). Total proteins (20  $\mu$ g) were separated on 10% SDS-polyacrylamide gel, electroblotted onto PROTRAN nitrocellulose transfer membrane (Schleicher & Schuell Inc, Dassel, Germany) and blocked with 5% fat-free milk in Tris-buffered saline (TBS: 10 mM Tris, pH 7.5, 0.9% NaCl) containing 0.1% Tween-20 (TBST) at room temperature for 1 h. The membrane was incubated with either rabbit polyclonal antibody against Ad-E1A protein (Santa Cruz Biotechnology) or rat anti-Ad5 E1B 55k monoclonal antibody overnight at 4°C and repeatedly washed in TBST. After incubation for 1 h with appropriate secondary horseradish peroxidase-conjugated anti-bodies and extensive washing with TBST, immunocomplexes on the membrane were detected with LumiGLOTM reagent and visualized with Kodak BiomaxMR film. To detect the expression of E1A and E1B under hypoxic condition, CNHK500-p53 infected cells were exposed to 0.1% hypoxia for 16 h before harvest.

#### ELISA determination of p53 gene expression

HepG2 cells were seeded in 24-well plates at a density of  $5 \times 10^4$  cells/well and cultured for 24 h, followed by infection with CNHK500-p53 and Ad-p53 at a MOI of 0.1. On days 3, 5, 7, and 10 post-infection, the supernatants of cell cultures were collected and assayed for p53 gene expression levels using the ELISA kit of p53 (Chemicon International, Temecula, CA) and the manipulation was done according to the manufacturer's instructions.

#### Evaluation of oncolytic activity of virus vector

**Cytopathic effect (CPE):** Hep3B, HepG2, Bel-7402 ( $2 \times 10^4$  Cells/well) and BJ ( $6 \times 10^4$  cells/well) were dispensed in 24-well plates. The culture solution was removed on the second day, and 1 mL serum free DMEM and virus were added to each well. The multiplicity of infection (MOI) of each well was 0.01, 0.1, 1, 10 and 100, respectively. The culture plate was then incubated for 90 min in a 37°C incubator under the condition of 5% CO<sub>2</sub> in DMEM containing 5% serum.

**Methyl thiazolyl tetrazolium (MTT) assay:** MTT assay was performed to determine cell viability at various viral MOIs. HepG2, Hep3B and BJ cells were plated at a density of  $1 \times 10^4$  cells/well in 96-well plates (Falcon) and 24 h later, the cells were infected with CNHK500-p53 at serial MOIs from 0.001 to 100. After 7 d of incubation, cell viability was measured by MTT

**Figure 1** Schematic diagram of the CNHK500-p53 adenoviral construct. A 310-bp fragment of human telomerase reverse transcriptase (hTERT) promoter with three E-boxes (CACGTG) downstream of the core sequence replaced the endogenous E1A promoter (digested with *NotI* and *XhoI*) to control the expression of E1A. A 241-bp fragment of hypoxia response element (HRE) promoter replaced the endogenous E1B promoter to control the expression of E1B. A 1805-bp fragment of transgene expression cassette containing cytomegalovirus (CMV) promoter + p53 + SV40 poly A was inserted into the downstream of E1A (digested with *AgeI* + *NotI*) to generate CNHK500-p53. ITR, inverted terminal repeat;  $\psi$ , the adenovirus 5' packaging signal.

assay using a non-radioactive cell proliferation kit (Roche Molecular Biochemicals) according to its protocol, and the spectrophotometrical absorbance of samples was measured with a microplate reader model 550 (BIO-RAD Laborato-ries, Tokyo, Japan) at 570 nm with a reference of 655 nm. Percentage of cell survival was calculated using the formula: % cell survival = (OD value of infected cells/OD value of uninfected control cells)  $\times$  100%. Eight replicate samples were taken at each MOI and each experiment was repeated at least 3 times. IC<sub>50</sub> of CNHK500-p53, CNHK500, and WtAd5 was calculated in HepG2 and BJ 7 d after infection. Statistical analysis was performed using Student's *t* test for differences among groups. *P* < 0.05 was considered statistically significant.

#### Replication between CNHK500-GFP and Ad-GFP

HepG2, Bel-7402 ( $1 \times 10^5$  cells/well), and BJ ( $1 \times 10^6$  cells/well) were inoculated into six-well plates, respectively. When the cells were confluent, CNHK500-EGFP or Ad-EGFP was added to each well at the MOI of 1 and then washed with PBS 2 h later. Cells were then coated with 1.25% agarose. On days 3, 7 and 10, the cells were observed under a fluorescence microscope and significant changes were photographed. Fluorescence microscopy was performed with routine methods with fluorescence in isothiocyanate (FITC), with the excitement and emission wavelength being 475 nm and 490 nm, respectively.

## RESULTS

To make a conditional replicative gene-viral vector, we adopted a design as shown in Figure 1, in which the adenovirus *E1a* gene was placed under the control of hTERT promoter plus three extra E-boxes, and *E1b* gene was controlled by HRE promoter, p53 gene-expressing cassette was inserted between E1A and HRE promoter. CNHK500-p53 was successfully made and verified by PCR. We were able to produce the adenovirus with high titers ( $2 \times 10^{10}$  pfu/mL).

**Figure 2** Selective replication of CNHK500-p53 *in vitro*. **A:** Human HCC cell lines HepG2, Hep3B, and SMMC-7721 were infected with CNHK500-p53 at a MOI of 5. Cells and media were harvested, and lysates were prepared from each group at diverse time points 0 h, 24 h, 48 h, and 96 h. Viral titers were measured with the tissue culture infectious dose 50 method, normalized with that at the beginning of infection, and shown as multiples. CNHK500-p53 replicated similarly as CNHK500 and WtAd5 in all of the tested telomerase-positive cancer cells; **B:** Comparison of replication capability of CNHK500-p53, CNHK500 and WtAd5 in telomerase-negative normal cell lines. At diverse time points 0 h, 24 h, 48 h, and 96 h after infection, cells and medium were harvested, and viral titers were measured as described previously. In all of the tested normal cell lines, the replication capability of CNHK500-p53 and CNHK500 was severely attenuated than that of WtAd5; **C:** Forty-eight hours after infection with CNHK500-p53 in HepG2, Hep3B and BJ, CNHK500-p53 showed enhanced replication ability both in HepG2, Hep3B and in BJ under hypoxia condition, but was higher in HepG2, Hep3B than in BJ.

### Selective replication of CNHK500-p53

Selective replication of the new recombinant adenovirus CNHK500-p53 was evaluated using telomerase-positive HCC cell lines Hep3B, HepG2, SMMC-7721 and telomerase-negative normal cell lines BJ, L02. In HepG2, Hep3B and SMMC-7721, the replicative multiples increased to 47230-, 459837- and 669251- fold respectively after 96 h of CNHK500-p53 replication, similar to those of CNHK500 and WtAd5 (Figure 2A). However, in normal cell lines BJ, L02, the replicative multiples of CNHK500-p53 and CNHK500 were only 12.8-, 16.3- and 31-, 53- fold at 96 h, and attenuated as much as 1354-, 1325- and 559-, 407.5- fold when compared with WtAd5 (Figure 2B). CNHK500-p53 showed enhanced replication ability both in HepG2, Hep3B and in BJ under hypoxia condition, but was higher in HepG2 and Hep3B cells than in normal BJ cells (Figure 2C). As hTERT promoter regulates *E1a* gene, E1A protein could be detected in telomerase positive hepatocellular

cells HepG2 and Hep3B, but not in telomerase negative normal cells BJ. Under normoxic condition, E1B protein could hardly be detected due to poor activity of HRE promoter. When HCC cells were exposed to hypoxia, E1B protein was induced as a result of increased activity of HRE promoter (Figure 3A).

### Expression of p53 produced by CNHK500-p53

To verify that the p53 expressed by CNHK500-p53 could secrete efficiently into the media, the conditioned media from  $5 \times 10^4$  HepG2 cells infected with CNHK500-p53 or Ad-p53 at a MOI of 0.1 were collected and analyzed for the presence of p53 protein by ELISA. The quantity of p53 expressed by CNHK500-p53 and Ad-p53 on d 3, 5, 7, and 10 post-infection is shown in Figure 3B, indicating that p53 expression in CNHK500-p53 was 5.1 times more than that in Ad-p53 in HepG2 on d 7. Western blot analysis revealed a clear band of *M<sub>r</sub>* 53000 in the conditioned media after HepG2 cells were infected

**Figure 3** **A:** E1A and E1B expression identified by Western blot demonstrating that all HCC cells infected with CNHK500-p53 or WtAd5 were positive for E1A expression, however, normal BJ cells were negative for E1A expression when they were infected with CNHK500-p53, and positive only when they were infected with WtAd5, while E1B of CNHK500-p53 was only expressed under hypoxia condition in HepG2 and Hep3B, and expressed both under normal and hypoxia condition with WtAd5; **B:** ELISA assay showing that p53 protein secreted from a HepG2, infected with CNHK500-p53, was significantly higher than that infected with nonreplicative adenovirus Ad-p53 and Ad-Blank *in vitro* ( $P < 0.05$ ); **C:** Western blot showing enhanced p53 expression in HepG2 infected with CNHK500-p53.

**Figure 4** Cytopathic effects associated with CNHK500-p53, CNHK500, Ad-p53, and Ad-Blank infection in HCC cell lines HepG2 (**A**), Hep3B (**B**), Bel-7402 (**C**), and normal cell line BJ (**D**). Seven days after virus infection, all the cells were stained with crystal violet and photographed. Comparison with other viruses, CNHK500-p53 showed the strongest selective cytolysis against HCC cell lines. Infection with CNHK500-p53 at MOI of 0.1-1 was sufficient to induce its lytic effects in Bel-7402, HepG2, and Hep3B, although the sensitivity varied among the cell types. In contrast, no apparent cytopathic effects were observed in BJ even at MOI of 100 after CNHK500-p53 infection, which was similar to other viruses.

with CNHK500-p53 or Ad-p53 at a MOI of 1 on d 3, suggesting that the protein in the media was p53 protein (Figure 3C).

### Selective cytolysis of CNHK500-p53

CPE was used to determine whether CNHK500-p53 infection induces selective cell lysis. HCC cell lines (HepG2, Hep3B, and Bel-7402) and the normal cell line (BJ) were infected with CNHK500-p53, CNHK500, Ad-p53, and Ad-Blank at various MOIs, fixed in methanol and stained with crystal violet 7 d after infection to visualize viable cells. CNHK500-p53 showed the strongest selective cytolysis effect among the viruses and killed all cancer cell lines in a dose-dependent fashion (Figure 4). Infection with CNHK500-p53 at a MOI of 0.1-1 was sufficient

to induce its lytic effects, although the sensitivity varied among the cell types. In contrast, no apparent CPE was observed in BJ cells 7 d after CNHK500-p53 infection. Cytotoxicity of CNHK500-p53 was also assessed by MTT assay. HepG2, Hep3B and MRC-5, BJ cells were infected with CNHK500-p53 at various viral MOIs. As shown in Figure 5A, CNHK500-p53 induced more rapid cell death in HCC cells than in normal BJ cells 7 d after infection. Furthermore CNHK500-p53 showed a different ability to kill HepG2 and Bel-7402 with the  $IC_{50}$  being 0.012 and 0.28 of MOI. On the contrary, the  $IC_{50}$  in normal BJ cells was as high as 352.1 of MOI, suggesting that more than 29 341- or 1257-fold of CNHK500-p53 was needed to kill half BJ compared with HepG2 and Bel-7402. Comparison with CNHK500 and WAd5 infection, CNHK500-p53 not

**Figure 5** Oncolytic efficacy induced by CNHK500-p53 infection evaluated by MTT assay. Statistical analysis was performed using Student's *t* test for differences among groups. Statistical significance was defined as  $P < 0.05$ . **A:** HCC cell lines HepG2, Bel-7402 and normal cell lines BJ, MRC-5 were infected at different MOI of 0.001-100 pfu/cell of CNHK500-p53. Cell viability was measured by MTT assay 7 d after infection. CNHK500-p53 induced a more powerful oncolysis in HCC cell lines than in normal cell lines ( $P < 0.05$ ); **B:** Seven days after infection with virus, CNHK500-p53 not only showed more powerful cytotoxicity than CNHK500 and WtAd5 in HepG2, but also less profound cytotoxicity than WtAd5 in BJ ( $P < 0.05$ ); **C:** IC50 of CNHK500-p53, CNHK500, and WtAd5 demonstrated significant differences among groups with <sup>a,c,e</sup> $P < 0.05$ .

only demonstrated more apparent cytotoxicity against HepG2 than CNHK500 and WtAd5 but less profound cytotoxicity than WtAd5 against BJ (Figure 5B and C).

#### Replication of gene-viral system and expression of GFP gene

To determine the selective replication of CNHK500-GFP, HCC cell lines including HepG2, Bel-7402 and normal cell line BJ were observed under fluorescent microscope at different time points after being infected with CNHK500-GFP and Ad-GFP. By conducting GFP expression, CNHK500-GFP demonstrated a greater replicative ability than Ad-GFP in HCC cell lines, with no significant difference in normal cell line. After 3, 7 and 10 d of infection with CNHK500-GFP and Ad-GFP, only a few scattered cells emitted fluorescence in normal cell line. However, in HCC cell lines, CPE such as deformation and aggregation appeared 3 d after infection, and the fluorescence emission spread from a single cell to many cells within a large area 7 d after infection. Bel-7402 cells were particularly sensitive to CNHK500-GFP, many cells

died with GFP degradation and fluorescence extinction 10 d after infection (Figure 6), showing selective replication of CNHK500-derivative and correct insertion of GFP gene.

#### DISCUSSION

Besides conventional approaches, CRAds specifically killing tumor cells while sparing normal cells have been introduced as new agents for cancer therapy in the past decade<sup>[14,15]</sup>. The efficacy of CRAds against cancer, including HCC, is however, limited by several factors, mainly including tumor specificity and oncolysis<sup>[16]</sup>.

With the advancement in molecular biology and understanding of the function of viral genes, it has become possible to genetically re-engineer viruses to make them selectively kill tumor cells over normal tissue. At present, tumor specificity has been achieved in oncolytic adenoviruses mainly (1) by altering viral genes that attenuate replication in normal tissue but not in tumor cells such as ONYX015 with E1B 55KD deleted<sup>[15]</sup>,

**Figure 6** Fluorescent photos of HCC cell lines HepG2, Bel-7402 and normal cell line BJ infected with replicative virus CNHK500-GFP and nonreplicative virus Ad-GFP (200 magnifications).

(2) by placing viral genes that initiate viral replication under the control of promoter sequences that are active in tumor cells such as using AFP promoter to restrict viral replication in AFP-producing HCC<sup>[17,18]</sup>, and (3) by modifying viral coat proteins that function in host cell infection.

Studies showed that adenovirus-induced oncolysis can benefit from combined gene therapy<sup>[11,19]</sup>. Cancer gene therapy typically involves delivery of tumor suppressor, enzyme/pro-drug gene, cytotoxic/pro-apoptotic gene, immunogene, anti-angiogenic gene directly into tumor cells<sup>[20]</sup>. After more than two decades of study, the tumor suppressor p53 gene is widely regarded as the “genome guardian.” It has been estimated that at least half of all

human malignancies, including HCC, are related to a mutation of the p53 gene<sup>[21]</sup>.

In our previous study, we constructed a CRAd containing dual promoters within the E1 region, designated as CNHK500<sup>[12]</sup>, in which the viral *E1a* gene is regulated by hTERT promoter and *E1b* gene by HRE promoter. Since telomerase is highly activated in most malignant tumors but inactive in normal somatic cells<sup>[22]</sup>, CNHK500 can selectively replicate in telomerase-positive cancer cells. At the same time, its replication ability is further attenuated in normal cells as hypoxia microenvironment seldom exists among normal tissues. However, it may propagate very well in solid tumors because HRE promoter is transcriptally activated due to hypoxia, a unique feature

of human solid tumors<sup>[23]</sup>. A further study suggested that CNHK500 is tumor-selective *in vitro* and *in vivo* when compared with CNHK300 and WtAd5<sup>[24]</sup>. To enhance the oncolytic potency of CNHK500, we constructed a new CRAd CNHK500-p53 by combining oncolytic virotherapy with gene therapy, which expresses functional p53 during viral replication in HCC cells as verified by PCR, Western blot, and ELISA assay. We evaluated the efficacy of CNHK500 and CNHK500-p53 against human HCC cell lines *in vitro*.

We found that exogenous expression of p53 by CNHK500-p53 could lead to enhanced oncolytic potency compared with its parent CNHK500 on most HCC cell lines, while the ability of selective replication was not significantly different between them. The superior efficacy of CNHK500-p53 was independent of the cellular p53 genetic background. It was reported that the expressed p53 gene appears to exert its anticancer activities by one or more of the following mechanisms: (1) simultaneously triggering apoptotic pathways in tumor cells by a transcription-dependent mechanism in cell nuclei<sup>[25,26]</sup> and by a transcription-independent mechanism in mitochondria<sup>[27]</sup> and Golgi apparatus<sup>[28]</sup>; (2) activating immune response factors such as natural killer cells<sup>[29]</sup> to exert "bystander effects"; (3) inhibiting DNA repair and antiapoptosis functions in tumor cells<sup>[30]</sup>; (4) down-regulating the expression of multidrug resistance genes<sup>[31]</sup> to revert the resistance of tumor cells against radio- and chemotherapies as well as the vascular endothelial growth factor gene<sup>[32]</sup> to block the blood supply to tumor tissue and matrix metalloproteinase<sup>[33]</sup> to suppress tumor cell adhesion, infiltration, and metastasis; (5) blocking the transcription of survival signals in tumor cells<sup>[34,35]</sup>, thus inhibiting the growth of tumor cells in any stage of the cell cycle. Hence, dysfunctional p53 of HCC cells might delay conditionally replicative adenovirus-induced cell death, thus limiting conditionally replicative adenovirus efficacy.

In conclusion, CNHK500-p53 has the selective replicative ability in HCC cell lines and a higher oncolytic efficacy than its parent CNHK500 *in vitro*. The enhanced oncolytic efficacy may be related to the expression of p53 gene carried by CNHK500-p53. Further experiments are needed to warrant its potential therapeutic effect against HCC.

## ACKNOWLEDGMENTS

We are grateful to Laboratory of Viral and Gene Therapy, Eastern Hepatobiliary Surgery Hospital, Second Military Medical University, Shanghai, China, for its help in constructing recombinant adenoviruses.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is one of the most frequent and lethal malignancies worldwide especially in China. According to the reports of American cancer society (ACS) in 2005, the 5-year survival rate of HCC is only about 8.3%. Therefore, development of effective alternative approaches is needed. Replication-selective virus-mediated gene therapy holds great promise for the treatment of cancer, including HCC.

## Research frontiers

So far, 656 cancer gene therapy clinical protocols are in different phase of evaluation worldwide. Unfortunately, successful delivery and targeted expression of therapeutic gene into cancer cells still are very difficult to achieve. The main problem is due to the very low *in vivo* transduction and expression efficacy of available vectors. In this respect, conditionally replicative adenoviruses appear as attractive vectors. Combination of oncolytic virotherapy and gene therapy may be an effective alternative approach against cancer.

## Innovations and breakthroughs

In order to construct tumor-specific conditionally replicative adenoviruses, adenovirus E1A gene expression was driven by the hTERT promoter and E1B gene by the hypoxia response (HRE) promoter through genetic engineering, which assures adenovirus replication only in telomerase-positive cells exposed to hypoxia. Besides, human p53 gene was cloned into the downstream of E1A of adenovirus to enhance oncolysis. It was different from other study in adenovirus reconstruction methods. Meanwhile, the recombinant adenovirus was verified by PCR assay, and showed tumor-specific replication and enhanced oncolysis against HCC cell lines *in vitro*.

## Applications

The results of our present study demonstrate that p53-expressing conditionally replicative adenovirus has the selectively replicative ability in HCC cell lines and a higher oncolytic efficacy than non-p53-expressing conditionally replicative adenovirus *in vitro*. The enhanced oncolytic efficacy may be related to the expression of p53 gene. Further experiments are needed to warrant its potential therapeutic effect against HCC.

## Terminology

CRAds: conditional replicative adenoviruses, recombinant adenoviruses modified to selectively replicate in cancer cells; Oncolytic virotherapy: one of the cancer therapies by obtaining a virus that replicates and preferentially kills cancer cells, leaving the surrounding normal tissues relatively intact; Cancer gene therapy: Cancer gene therapy can be defined as transfer of nucleic acids into tumor or normal cells to eradicate or reduce tumor mass by direct killing of cells, immunomodulation or correction of genetic errors, and reversion of malignant status. Initially started with lots of optimism and enthusiasm, cancer gene therapy has shown limited success in treatment of patients.

## Peer review

This is an interesting manuscript. In this manuscript, Hing-Chuan Zhao *et al* take advantage of the selective expression of hTERT and HIF in tumoral cells to express under their respective promoters E1A and E1B assuring adenovirus replication only in telomerase cancerous cells exposed to hypoxia. The data are clearly presented. They show the selective replication and expression of adenoviral proteins as well as the selective cytopathic effect of their adenovirus.

### Abstract

**AIM:** To investigate the roles of Bax and p53 proteins in photosensitivity of human colon cancer cells by using lysosome-localizing photosensitizer, ATX-S10Na (II).

**METHODS:** HCT116 human colon cancer cells and Bax-null or p53-null isogenic derivatives were irradiated with a diode laser. Early apoptosis and cell death in response to photodynamic therapy were determined by MTT assays, annexin V assays, transmission electron microscopy assays, caspase assays and western blotting.

**RESULTS:** Induction of early apoptosis and cell death was Bax- and p53-dependent. Bax and p53 were required for caspase-dependent apoptosis. The levels of anti-apoptotic Bcl-2 family proteins, Bcl-2 and Bcl-x<sub>L</sub>, were decreased in Bax- and p53-independent manner.

**CONCLUSION:** Our results indicate that early apoptosis and cell death of human colon cancer cells induced by photodynamic therapy with lysosome-localizing photosensitizer ATX-S10Na (II) are mediated by p53-Bax network and low levels of Bcl-2 and Bcl-x<sub>L</sub> proteins. Our results might help in formulating new therapeutic approaches in photodynamic therapy.

### INTRODUCTION

Photodynamic therapy (PDT) is a therapeutic procedure involving the use of tissue-penetrating laser light after the administration of tumor-localizing photosensitizers, and is used for the efficient treatment of a variety of solid and superficial cancers<sup>[1]</sup>. Tumor cell death in response to PDT is induced *via* apoptosis and/or necrosis, and depends on various conditions, such as tumor cell type, intensity of laser irradiation, and subcellular localization and concentration of the photosensitizer<sup>[2-4]</sup>. Localizing photosensitizers in cytoplasmic organelles generate reactive oxygen species by photochemical reactions, resulting in induction of cell damage<sup>[1,5,6]</sup>. Cell damage modes and the initial subcellular targets are related to the localization sites of the photosensitizers, specifically, mitochondria and lysosomes<sup>[7]</sup>. Mitochondria-localizing photosensitizers, such as silicon phthalocyanine (Pc) 4, cause rapid dissipation of the mitochondrial membrane potential and result in the release of cytochrome *c*<sup>[8]</sup>. In contrast, the hydrophilic chlorine photosensitizer ATX-S10Na (II), localizes mainly in lysosomes<sup>[9,10]</sup> and activates apoptotic pathways *via* mitochondrial destabilization following the photodamage of lysosomes<sup>[11]</sup>. Lysosomal proteases released by lysosomal photodamage, in turn activate caspases directly and/or indirectly subsequent to mitochondrial damage<sup>[12]</sup>. Nonetheless, the mechanisms by which lysosome-localizing photosensitizers activate apoptotic pathways are not fully understood.

Members of the p53 tumor suppressor gene family play various roles in response to DNA damage, such as cell cycle regulation, DNA repair, and induction of apoptosis<sup>[13,14]</sup>. Expression of the wild-type p53 induced by chemotherapy or radiation increases the sensitivity to apoptosis, whereas a mutated or deleted p53 alters the sensitivity<sup>[15]</sup>. Furthermore, p53 regulates pro-apoptotic Bcl-2 family proteins<sup>[16,17]</sup>, and these proteins localize to mitochondria and heterodimerize through a BH3 domain with anti-apoptotic Bcl-2 family members, such as

Bcl-xL<sup>[18,19]</sup>. Bax modulates the mitochondrial pathway of apoptosis by allowing the efflux of apoptogenic proteins. The shift in the balance of the pro-apoptotic and anti-apoptotic Bcl-2 family members regulates the translocation of cytochrome *c* from mitochondria to cytosol<sup>[20]</sup>. Although various studies indicate the involvement of Bax and p53 in PDT-mediated apoptosis<sup>[21-24]</sup>, there are conflicting reports about whether the induction of apoptosis correlates with cell death.

The aim of the present study was to elucidate the roles of Bax and p53 in response to lysosomal photodamage induced by ATX-S10Na (II)-PDT, which might contribute to more effective clinical use of PDT in cancer therapy. We used an established human colon cancer cell line, HCT116, which expresses wild-type Bax and p53, and derivative lines of HCT116 that differ from the parental line by virtue of a selective knockout of either Bax or p53<sup>[25,26]</sup>.

## MATERIALS AND METHODS

### Reagents

ATX-S10Na (II), 13, 17-bis (1-carboxypropionyl) carbamoyl ethyl-8-ethenyl-2-hydroxy-3-hydroxyiminoethylidene-2, 7, 12, 18-tetramethylporphyrin sodium salt was provided by Photochemical Co. (Okayama, Japan), and was dissolved in phosphate-buffered saline (PBS).

### Cell cultures

Bax-null or p53-null derivatives of the wild-type HCT116 cell line, generated by targeted homologous recombination to create homozygous deletion, were a generous gift from B. Vogelstein (Johns Hopkins Oncology Center, Baltimore, MD, USA)<sup>[27,28]</sup>. Cells were maintained in McCoy's 5A medium (GIBCO-BRL, Bethesda, MD, USA) supplemented with 10% fetal calf serum (Thermo Trace, Melbourne, Australia) and 1% penicillin/streptomycin (GIBCO-BRL) in a 37°C, 5% CO<sub>2</sub>, fully humidified incubator and passaged twice weekly.

### PDT protocols

Exponentially growing cells were seeded in 96-well microplates or 35-mm dishes to approximately 30% confluence 48 h before PDT. ATX-S10Na (II) was added to the culture medium to a final concentration of 20 µg/mL 24 h before PDT. Medium was replaced with fresh medium, and the cells were irradiated with a diode laser (Hamamatsu Photonics, Hamamatsu, Japan) at a wavelength of 670 nm. The energy fluence rate was 0.167 W/m<sup>2</sup> as measured using LaserMate power meter (Coherent, Auburn, CA, USA). Exposure for 5 min resulted in an incident energy fluence of 5 J/cm<sup>2</sup>.

### MTT assays

Cytotoxicity of PDT was determined by colorimetric assay with 2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulfophenyl)-2H-tetrazolium, monosodium salt reagent (Cell Counting Kit-8, Wako Pure Chemical Industries, Osaka, Japan). Following PDT, cells were incubated in 96-well microplates for 24 h. Ten microliters of Cell Counting Kit-8 reagent<sup>[27]</sup> were added to each well, and cells were incubated at 37°C for 4 h. After thorough

mixing, the absorbance of each well was measured at 450 nm with an Ultramark microplate reader (Bio-Rad Laboratories, Hercules, CA, USA).

### Annexin V assays

Cells were collected by trypsinization and washed with ice-cold PBS, suspended in 500 µL annexin V binding buffer containing 5 µL of propidium iodide (PI) and 5 µL of annexin V-FITC (BioVision, Mountain View, CA, USA), and incubated for 15 min at room temperature in the dark. Fluorescence was measured on a BD LSR flow cytometer (Becton Dickinson, NY, USA) and processed with Cell Quest software (Becton Dickinson) for analysis.

### Cell cycle analysis

Cells were collected and washed in cold PBS, fixed in 70% ethanol pre-chilled at -20°C, washed, resuspended in 25 µg/mL of PI with 100 µg/mL RNase A, and incubated for 30 min at 37°C. Fluorescence was measured on a BD LSR flow cytometer. Data were analyzed using the MODFIT 2.0 program (Verity Software).

### Transmission electron microscopy assays

Ultrastructural appearances of apoptotic cells were confirmed by electron microscopy. Following PDT, cells were prefixed with 2% glutaraldehyde, post-fixed with 1% osmic acid, dehydrated in graded ethanol, embedded in resin, and cut into sections on an ultramicrotome. The cells were examined by a transmission electron microscope (TEM) (H-7500, Hitachi, Tokyo, Japan).

### Quantification of caspases 3, 8 and 9 activity

Activities of caspases 3, 8 and 9 were measured by Caspase Fluorometric Assay kits (R&D Systems Inc., Minneapolis, MN, USA) according to the instructions provided by the manufacturer. Briefly, cells in 35-mm dishes were washed twice with ice-cold PBS and lysed in 100 µL of lysis buffer. Next, 50 µL of cell lysates were transferred to a 96-well plate containing reaction buffer, and were incubated for 2 h at 37°C with 5 µL of caspase 3-, 8- or 9-specific fluorescent substrate DEVD-AFC, IETD-AFC and LEHD-AFC, respectively. Plates were read with an ARVOsx-2 fluorescence microplate reader (Wallac, Turku, Finland) using an excitation light of 400 nm and an emission light of 505 nm.

### Preparation of protein extracts and immunoblotting

Cells in 35-mm dishes were washed twice with ice-cold PBS, lysed in 100 µL of lysis buffer [50 mmol/L HEPES (pH 7.4), 1% Triton X-100, 0.5% sodium deoxycholate, 150 mmol/L sodium chloride, 5 mmol/L EDTA with protease inhibitors pepstatin A (2 µg/mL), aprotinin (10 µg/mL), leupeptin (10 µg/mL) and phenylmethylsulfonyl fluoride (100 µg/mL)] and sonicated. The lysates were centrifuged at 10 000 × *g* at 4°C for 10 min. The supernatant was recovered and protein concentration was determined by the BCA protein assay (Pierce, Rockford, IL, USA). Twenty microgram of proteins were loaded on an SDS-polyacrylamide gel. After electrophoresis, proteins were electrotransferred onto a nitrocellulose membrane (Bio-Rad). Membranes were blocked with 5% nonfat milk

in Tris-buffered saline with 0.05% Tween-20 (TBS-T) for 2 h at room temperature, and then probed with primary antibodies for 1 h at room temperature or overnight at 4°C. Horseradish peroxidase (HRP)-labeled secondary antibodies were used for signal detection and blots were visualized with Enhanced Chemiluminescence (ECL) Western blotting detection reagents (Amersham Pharmacia Biotech, Piscataway, NJ, USA) and recorded on an X-ray film. For cytosolic fractionation, cells were harvested in digitonin lysis buffer (75 mmol/L NaCl, 1 mmol/L NaH<sub>2</sub>PO<sub>4</sub>, 8 mmol/L Na<sub>2</sub>HPO<sub>4</sub>, 250 mmol/L sucrose and 190 µg/mL of digitonin), supplemented with protease inhibitors, and incubated on ice for 5 min. Samples were centrifuged at 10 000 × *g* at 4°C for 30 min and the resulting supernatant was used for Western blotting. Antibodies were as follows: mouse monoclonal p53 (DO-1) (Calbiochem, San Diego, CA, USA), mouse monoclonal Bcl-2 (100) and rabbit polyclonal Bax (N-20), Bcl-x<sub>s/l</sub> (S-18) and β-tubulin (H-235) (Santa Cruz Biotechnology, Santa Cruz, CA, USA), mouse monoclonal cytochrome *c* (7H8.2C12) (BD Pharmingen, San Diego, CA, USA), and HRP-labeled secondary anti-mouse and anti-rabbit antibodies (Santa Cruz). The image of the specific protein band on the membrane was scanned, and the intensity of the image was analyzed by an NIH Image J program version 1.31.

#### Statistical analysis

Data are expressed as mean ± SD. Differences between groups were evaluated by *t*-test. *P* values < 0.05 were considered statistically significant.

## RESULTS

### Bax- and p53-dependent cell death and apoptosis in response to ATX-S10Na (II)-PDT

To determine the role of Bax and p53 in ATX-S10Na (II)-PDT, we first examined the cells' phototoxicity by MTT assays 24 h after laser irradiation. The extent of ATX-S10Na (II) phototoxicity was dependent on the intensity of laser irradiation (Figure 1A) and the concentration of ATX-S10Na (II) (data not shown). Wild-type HCT116 cells were significantly more sensitive to ATX-S10Na (II)-PDT than Bax-null or p53-null cells at 5 J/cm<sup>2</sup> (Figure 1A). Laser irradiation greater than 10 J/cm<sup>2</sup> resulted in global phototoxic cell death, thereby preventing the accumulation of cells with PDT-mediated regulatory responses. Thus, laser irradiation at 5 J/cm<sup>2</sup> was chosen for further studies. Next, to determine the role of early apoptosis in Bax and p53 dependence of phototoxicity, we examined ATX-S10Na (II)-PDT-mediated apoptosis by flow cytometry with annexin V and cell cycle analysis that determines a population of cells with sub-G<sub>1</sub> DNA content 3 or 6 h after laser irradiation. The percentage of early apoptotic, annexin V-positive and PI-negative, cells was significantly reduced in Bax-null or p53-null cells compared with wild-type HCT116 cells (Figures 1B and D). In contrast, the percentage of late apoptotic or necrotic, annexin V-positive and PI-positive, cells was not significantly different (Figure 1C). These results indicate that Bax and p53 play a central role in early

apoptosis induced by ATX-S10Na (II)-PDT. TEM studies revealed that untreated cells have thickened mitochondria and numerous cytoplasmic vesicles. In contrast, when treated with PDT, the sections contained many apoptotic cells with condensed chromatin, apoptotic bodies in the cytoplasm and cell membrane budding (Figure 1E). The percentage of apoptotic cells was higher in the wild-type than Bax-null or p53-null cells 6 h after laser irradiation.

### Roles of Bax and p53 in caspase-dependent ATX-S10Na (II)-PDT-induced apoptosis

Since caspases are early effectors for triggering PDT-mediated apoptosis<sup>[28,29]</sup>, we examined the roles of Bax and p53 in caspase activation by ATX-S10Na (II)-PDT. Caspase-3 activity increased in intensity in laser irradiation- and time-dependent manners within 24 h following PDT in wild-type HCT116 cells (data not shown). As shown in Figure 2, activities of caspase-3 and -9 apparently increased in wild-type HCT116 cells 6 h after laser irradiation. In contrast, it was significantly inhibited in Bax-null or p53-null cells. These results indicate that the caspase-dependent apoptotic process induced by ATX-S10Na (II)-PDT was Bax- and p53-dependent. Activation of caspase-8 was slightly increased compared with caspase-9, indicating that the mitochondrial pathway of apoptosis is the major process in response to ATX-S10Na (II)-PDT. In Bax-null HCT116 cells, caspase-9 activity was significantly but not completely inhibited, and the protein level of cytochrome *c* released from mitochondria was reduced but not absent (Figure 3), indicating that the mitochondrial pathway of apoptosis is induced by ATX-S10Na (II)-PDT, even though Bax was absent. In p53-null cells, caspase-9 activity was slightly inhibited, and the protein level of cytochrome *c* released from mitochondria was not reduced (Figure 3), indicating that p53 is required for ATX-S10Na (II)-PDT-mediated apoptosis.

### Decreased levels of anti-apoptotic proteins Bcl-2 and Bcl-x<sub>l</sub> in response to ATX-S10Na (II)-PDT play a role in early apoptosis, and are Bax- and p53-independent

Previous studies indicated that the levels of anti-apoptotic proteins Bcl-2 and Bcl-x<sub>l</sub> were reduced and pro-apoptotic proteins Bcl-x<sub>s</sub>, Bak and Bad, but not Bid, were up-regulated in response to PDT<sup>[30-33]</sup>. Therefore, we determined the association of Bax and p53 with anti-apoptotic Bcl-2 family proteins in ATX-S10Na (II)-PDT. Immunoblots demonstrated no significant changes in Bax and p53 expression (Figure 3). In contrast, Bcl-2 and Bcl-x<sub>l</sub> expression were decreased to similar levels in each cell type, indicating that Bax- and p53-independent downregulation of Bcl-2 and Bcl-x<sub>l</sub> plays a role in early apoptosis induced by ATX-S10Na (II)-PDT.

## DISCUSSION

Many studies have shown that PDT kills tumor cells *via* apoptosis and/or necrosis *in vivo* and *in vitro*. Although cell death in response to PDT depends on various conditions, the role of Bax or p53 in PDT remains controversial. This study was designed to determine the role of these proteins in ATX-S10Na (II)-PDT by using an isogenic set

**Figure 1** ATX-S10Na(II)-PDT-mediated cell death and early apoptosis were Bax- and p53-dependent. Cells were treated with, or without, ATX-S10Na(II)-PDT and harvested at each indicated time point following irradiation. **A**: Phototoxicity was determined by MTT assay 24 h after laser irradiation. Data are expressed as a ratio of cell viability relative to untreated control cells. Data represent the mean  $\pm$  SD of three independent experiments ( $^aP < 0.05$  vs wild-type cells). **B, C**: Early apoptotic changes (**B**) and late apoptotic or necrotic changes (**C**) were determined by annexin V apoptosis assays at 3 or 6 h after laser irradiation. Data are expressed as a percentage of annexin V-positive and PI-negative (**B**) or annexin V-positive and PI-positive cells (**C**). Data represent the mean  $\pm$  SD of three independent experiments ( $^bP < 0.05$  vs wild-type cells). **D**: Cell cycle distributions were determined by flow cytometry at 3 or 6 h after laser irradiation. Data are expressed as a percentage of sub-G<sub>1</sub> fraction. **E**: Morphological changes in response to ATX-S10Na(II)-PDT were determined by transmission electron microscopy assays at 3 or 6 h following laser irradiation. Typical subcellular changes in response to PDT are shown (original magnification  $\times 12\,000$ ). Scale bar: 15  $\mu$ m, N: nuclei.

**Figure 2** Induction of apoptosis by ATX-S10Na (II)-PDT was caspase-dependent. Cells were treated with, or without, ATX-S10Na (II)-PDT, harvested and lysed at 6 h after laser irradiation. Induction of caspase activity was assayed. **A:** caspase-3; **B:** caspase-8; **C:** caspase-9. Data represent the mean  $\pm$  SD of three independent experiments (<sup>a</sup> $P < 0.05$  vs wild-type cells).

**Figure 3** Low levels of Bcl-2 and Bcl-xL played a role in ATX-S10Na (II)-PDT. Cells were treated with, or without, ATX-S10Na (II)-PDT, harvested and lysed at 3 or 6 h after laser irradiation. Western blot analysis was performed. Each protein level was quantified by using NIH Image J program. Data represent the mean  $\pm$  SD of three independent experiments.

of human colon cancer cell lines derived from HCT116. Our results indicated that ATX-S10Na (II)-PDT induced Bax- and p53-dependent cell death and early apoptosis of human colon cancer cells. ATX-S10Na (II)-PDT induced caspase-dependent apoptosis and reduced the levels of anti-apoptotic proteins Bcl-2 and Bcl-xL. Apoptosis was mediated mainly through a Bax-regulated mitochondrial

pathway. Taken together, these results suggest that Bax and p53 play a central role in inducing early apoptosis and cell death by ATX-S10Na (II)-PDT.

Various experiments have shown that the pro-apoptotic Bcl-2 family protein Bax plays a role in the mitochondrial pathway of apoptosis by translocating from the cytosol to the mitochondria<sup>[20]</sup>. Our present experiments revealed that

wild-type HCT116 cells were significantly more sensitive to ATX-S10Na (II)-PDT than Bax-null cells, as determined by MTT assays (Figure 1). Induction of early apoptosis by ATX-S10Na (II)-PDT was also Bax-dependent, as determined by the annexin V assay and cell cycle analysis (Figure 1). Bax was required for caspase activation and cytochrome *c* release, but the mitochondrial pathway of apoptosis was not completely inhibited in the absence of Bax (Figures 2 and 3). The protein level of Bax did not apparently change in the wild-type or p53-null cells (Figure 3). These findings suggest that Bax plays a central role in PDT-mediated cell death and the mitochondrial pathway of apoptosis. As Bax was a major mediator of p53-dependent apoptosis, early apoptosis was apparently processed without Bax activation. Contrary to our findings, earlier reports showed that DU-145 human prostate cancer cells that lack Bax expression do not show release of cytochrome *c* from mitochondria, loss of mitochondrial potential, caspase activation or apoptosis, but do have an altered sensitivity to overall cell death<sup>[24]</sup>. In contrast, a comparison of the PDT response of wild-type and Bax-null HCT116 human colon cancer cells showed reduced release of cytochrome *c* but it was not completely blocked in Bax-null cells. In both cell lines, caspase-dependent apoptosis was triggered and cell killing was equally sensitive; however, no significant differences in the activation of caspase-3 were found<sup>[34]</sup>. The authors concluded that the commitment to cell death after PDT occurs at a step prior to and irrespective of Bax activation. Differences between our results and the above findings may be due to cellular differences unrelated to Bax expression, intensity of laser irradiation or type of photosensitizer.

The tumor suppressor protein p53 plays an important role in response to various stress conditions<sup>[13,14]</sup>. Our present experiments revealed that wild-type HCT116 cells were significantly more sensitive to ATX-S10Na (II)-PDT (Figure 1). In addition, induction of early apoptosis by ATX-S10Na (II)-PDT was p53-dependent (Figure 1). p53 was required for caspase-3 activation (Figure 2). The mitochondrial pathway of apoptosis was not significantly inhibited in the absence of p53 (Figures 2 and 3). These findings suggest that p53 might play a role in PDT-mediated early apoptosis and cell death. Consistent with our findings, HL60 human promyelocytic leukemia cells that express wild-type p53 are more photosensitive than p53-deleted or mutated HL60 cells<sup>[21]</sup>. Introduction of the wild-type p53 gene into the HT29 colon cancer cells induced growth arrest but not cell death by PDT<sup>[23]</sup>. In non-isogenic colon carcinoma cell lines, increased photosensitivity of a wild-type p53 phenotype was observed compared with a mutated p53 phenotype<sup>[22]</sup>. Taken together, it is conceivable that Bax and p53 play central roles both, in cell death and in early apoptosis induced by ATX-S10Na (II)-PDT.

The ratio of pro-apoptotic to anti-apoptotic Bcl-2 family members helps determine the threshold for inducing mitochondrial-related apoptosis<sup>[20]</sup>. Overexpression of Bcl-2 in Chinese hamster ovary (CHO) cells inhibited apoptosis and partly protected against cell death induced by PDT<sup>[35]</sup>. Reduction of Bcl-2 protein levels by Bcl-2 antisense oligonucleotides in radiation-induced fibrosarcoma (RIF-1) cells resulted in sensitization to PDT-mediated apoptotic death<sup>[31]</sup>. Our experiments revealed that decreased levels of

Bcl-2 and Bcl-x<sub>L</sub> were Bax- or p53-independent in response to ATX-S10Na (II)-PDT. Cytochrome *c* release from mitochondria was not completely inhibited in the absence of Bax or p53 (Figure 3). These findings suggest that reduced levels of anti-apoptotic Bcl-2 family proteins, that are Bax- or p53-independent, played a role in cytochrome *c* release and apoptosis induced by ATX-S10Na (II)-PDT. Low levels of these proteins could be the result of caspase activation or photochemical targets of PDT. PDT using mitochondrial photosensitizer phthalocyanine Pc 4, directly damaged Bcl-2 and Bcl-x<sub>L</sub>, and contributed in the induction of apoptosis<sup>[33,36]</sup>.

In conclusion, Bax and p53 play a central role in the apoptotic process and cell death induced by ATX-S10Na (II)-PDT in human colon cancer cells. Low levels of anti-apoptotic Bcl-2 family proteins Bcl-2 and Bcl-x<sub>L</sub>, which are Bax- and/or p53-independent, play a role in the early apoptotic process. Bax and p53 can induce apoptosis and cell death in response to ATX-S10Na (II)-PDT, which might help in the design of new therapeutic approaches.

## ACKNOWLEDGMENTS

We thank Yoko Yumoto, Yuko Arai and Eiko Uga for technical help, Hisako Arai and Hiroyuki Sasaki for TEM analysis, Hisao Tajiri for critical reading of the manuscript, Bert Vogelstein for providing the HCT116 cell lines and Photochemical Co. for providing ATX-S10Na (II).

### Abstract

**AIM:** To explore the molecular events taking place during human colon cancer development and progression through high-throughput tissue microarray analysis.

**METHODS:** We constructed two separate tissue microarrays containing 1.0 mm or 1.5 mm cylindrical samples acquired from 112 formalin-fixed and paraffin-embedded blocks, including carcinomas ( $n = 85$ ), adenomatous polyps ( $n = 18$ ), as well as normal paracancerous colon tissues ( $n = 9$ ). Immunohistochemical staining was applied to the analysis of the consecutive tissue microarray sections with antibodies for 11 different proteins, including p53, p21, bcl-2, bax, cyclin D1, PTEN, p-Akt1,  $\beta$ -catenin, c-myc, nm23-h1 and Cox-2.

**RESULTS:** The protein expressions of p53, bcl-2, bax, cyclin D1,  $\beta$ -catenin, c-myc, Cox-2 and nm23-h1 varied significantly among tissues from cancer, adenomatous polyps and normal colon mucosa ( $P = 0.003$ ,  $P = 0.001$ ,  $P = 0.000$ ,  $P = 0.000$ ,  $P = 0.034$ ,  $P = 0.003$ ,  $P = 0.002$ , and  $P = 0.007$ , respectively). Chi-square analysis showed that the statistically significant variables were p53, p21, bax,  $\beta$ -catenin, c-myc, PTEN, p-Akt1, Cox-2 and nm23-h1 for histological grade ( $P = 0.005$ ,  $P = 0.013$ ,  $P = 0.044$ ,  $P = 0.000$ ,  $P = 0.000$ ,  $P = 0.029$ ,  $P = 0.000$ ,  $P = 0.008$ , and  $P = 0.000$ , respectively),  $\beta$ -catenin, c-myc and p-Akt1 for lymph node metastasis ( $P = 0.011$ ,  $P =$

$0.005$ , and  $P = 0.032$ , respectively),  $\beta$ -catenin, c-myc, Cox-2 and nm23-h1 for distance metastasis ( $P = 0.020$ ,  $P = 0.000$ ,  $P = 0.026$ , and  $P = 0.008$ , respectively), and cyclin D1,  $\beta$ -catenin, c-myc, Cox-2 and nm23h1 for clinical stages ( $P = 0.038$ ,  $P = 0.008$ ,  $P = 0.000$ ,  $P = 0.016$ , and  $P = 0.014$ , respectively).

**CONCLUSION:** Tissue microarray immunohistochemical staining enables high-throughput analysis of genetic alterations contributing to human colon cancer development and progression. Our results implicate the potential roles of p53, cyclin D1, bcl-2, bax, Cox-2,  $\beta$ -catenin and c-myc in development of human colon cancer and that of bcl-2, nm23-h1, PTEN and p-Akt1 in progression of human colon cancer.

### INTRODUCTION

Colorectal cancer (CRC) is one of the most frequent cancers in the Western world. At present time, with the development of living conditions and changes of life behaviors, CRC has become more and more frequent in China. The prognosis in advanced cases is poor, and more than one-third of the patients will die from progressive disease because the overall survival is about 40% (15%-65%) after 5 years<sup>[1]</sup>. The development and progression of CRC, like others cancers, are results of multiple genetic alterations, so investigation of molecular changes in tumors representing the entire disease spectrum may enhance our understanding of mechanism involved in CRC tumorigenesis. Because CRC is one of the first major epithelial cancers in which molecular alterations were

described to occur in a systematic fashion during disease progression, studies of single molecular markers have not been successful in defining the biology of this disease<sup>[2]</sup>. This has prompted investigators to explore multiple molecules regulating the tumorigenesis in an effort to identify biologically aggressive tumors and appropriately select patients for adjuvant systemic or targeted therapies. However, with the progression of molecular biology and the development of oncogene research, the cancer-related genes and genetic alterations have been found rapidly. The evaluation of the clinical utility of each of these genes would require multiple consecutive experiments with hundreds of tumors. This would be both time-consuming and labor-intensive.

As a new biological technique which allows rapid visualization of molecular targets in thousands of tissues specimens at a time, either at the DNA, RNA, or protein level, tissue microarray (TMA) can facilitate rapid translation of molecular discoveries to clinical applications<sup>[3]</sup>. So it brings us a high-throughput and rapid technique which can help us complete the time- and people-consuming work. Here, we constructed two tissue microarrays containing samples from different stages of human colon cancer, adenomatous polyps and corresponding normal para-cancerous colon tissues to survey the gene alterations that may contribute to clinical behaviors of the colon cancer. We decided to investigate the role of protein expressions which had been shown correlated with the development and progression as well as metastases of colon cancer in previous studies. In this study, 11 different proteins (p53, p21, cyclin D1, bcl-2, bax,  $\beta$ -catenin, c-myc, PTEN p-Akt1, Cox-2 and nm23-h1) expressions were assayed by using immunohistochemical (IHC) staining to consecutive formalin-fixed tissue microarray sections. The aim was to obtain a comprehensive survey of the frequency of the target molecular alterations and the relationship between the alterations and the clinicopathological features in human colon cancer.

A number of proteins have been associated with human carcinogenesis and may be relevant to CRC. Among these molecules, we chose 11 cancer-related genes (p53, p21, cyclin D1, bcl-2, bax,  $\beta$ -catenin, c-myc, PTEN p-Akt1, Cox-2 and nm23-h1) which are altered during the development and progression of CRC according to the previous study reports<sup>[4-11]</sup>. Among these molecules, p53, p21, cyclin D1, bcl-2 and bax play pivotal roles in cell cycle regulation and apoptosis. Akt/protein kinase B (PKB), which is included in phosphatidylinositol-3-OH kinase (PI3K) signaling, controls many intracellular processes, such as the suppression of apoptosis and the promotion of the cell cycle<sup>[12]</sup>. PTEN on 10q23.3 encodes a dual-specificity phosphatase that negatively regulates the phosphoinositide-3-kinase/Akt pathway and mediates cell-cycle arrest and apoptosis<sup>[13,14]</sup>.  $\beta$ -catenin is a member of the cadherin-catenin complex that mediates homotypic cell-cell adhesion<sup>[15]</sup>. It also plays a role in the *Wnt* signaling pathway through regulating target genes like *c-myc*. Cox-2 was elevated in human colon cancers, and the Cox-2 inhibitor, celecoxib, inhibited intestinal

tumor multiplicity in a mouse model and reduced the number of adenomatous polyps in a familial adenomatous polyposis patient<sup>[16,17]</sup>. The human *nm23* gene, a candidate metastatic suppressor gene, consists of two genes, *nm23-h1* and *nm23-h2*. *Nm23-h1* aberration has been shown to be correlated with the metastatic potential of colorectal cancer in some studies<sup>[9,18]</sup>. More of these molecules were studied previously by conventional pathological or molecular biological technologies and the numbers of selected target molecules were lesser, but in this study we would assay 11 proteins at a time by IHC staining on TMA.

Many investigators and clinicians consider cancer of the colon and rectum to be two distinct diseases, thus, we chose to evaluate only the patients with colon cancer treated with surgery alone in an effort to optimize the homogeneity of the study population. In addition, all the tumor specimens selected according our data were from sporadic colon cancer patients.

## MATERIALS AND METHODS

### Materials

Demographic and clinical data were collected retrospectively. None of the patients received radiotherapy or chemotherapy before surgery. Formalin-fixed and paraffin-embedded tumors, adenomatous polyps and para-cancerous tissues specimens were from the archives of the Department of Gastroenterology, the First Affiliated Hospital of Soochow University and National Engineering Center for Biochip at Shanghai. All specimens were viewed by one pathologist (Jing Fang). The specimens that were interpretable for IHC included: (1) Eighty-five cancers including different grades, such as high ( $n = 11$ ), moderate ( $n = 50$ ), low differentiated ( $n = 24$ ); (2) eighteen adenomatous polyps removed at colonoscopy; (3) nine para-cancerous colon tissues resected from colon tissues at least 5 cm apart from the corresponding cancer tissues.

### Construction and sectioning of tissue microarray

The colon cancer microarray was constructed as previously described<sup>[3]</sup>. Briefly, fresh sections were cut from the donor block and stained with hematoxylin-eosin (HE), these slides were used to guide the samplings from morphologically representative regions of the tissues. A tissue array instrument (Beecher Instruments, Silver Spring, MD) was used to create holes in a recipient paraffin block and to acquire tissue cores from the donor block by a thin-walled needle with an inner diameter of 1.0 mm or 1.5 mm, held in an X-Y precision guide. The cylindrical samples were retrieved from the selected regions in the donors and extruded directly into the recipient blocks with defined array coordinates. After the construction of the array block, multiple 4- $\mu$ m thick sections were cut with a microtome using an adhesive-coated tape sectioning system (Instrumedics, Hackensack, NJ) (Figure 1).

Tissue loss was a significant factor for tissue array-based analysis with previously reported rates of tissue damage ranging from 15% to 33%<sup>[19-21]</sup>. In our analysis the rates of lost cases attributable to tissue damage were less than 5% for the different markers and damaged tissues

**Figure 1** HE staining of 4- $\mu$ m thick section of the tissue microarray.

were excluded from clinicopathological analyses of the respective markers.

### **IHC on formalin-fixed tissue microarray sections**

IHC staining for the target genes to sections of the formalin-fixed samples on the tissue microarray was carried out by using the Envision ready-to-use methods. Slides were deparaffinized in xylene and rehydrated through graded concentrations of ethanol to distilled water, and endogenous peroxidase activity was blocked by incubation with 30 mL/L  $H_2O_2$  in methanol for 10 min at room temperature. Then sections were submitted to antigen retrieval in a pressure cooker containing 0.01 mmol/L sodium citricum buffer for 10 min. Slides were subsequently incubated in 100 mL/L normal goat serum for 20 min at room temperature. Sections were permeabilized in PBS-Triton and incubated overnight with primary antibody at 4°C. The antibodies were used in PBS-Triton with variable dilution. Mouse anti-human monoclonal antibodies to p53 (clone Do-7; 1:50 dilution; Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd.), p21 (clone DCS-60.2; 1:50 dilution; Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd.), bcl-2 (clone 100/D5; 1:50 dilution; Shanghai Chang-Do Biotechnology Co. Ltd), bax (clone 2D2; 1:50; Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd),  $\beta$ -catenin (clone CAT-5H10; 1:50 dilution; Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd), c-myc (clone 9E11; 1:50 dilution; Shanghai Chang-Do Biotechnology Co. Ltd), Cox-2 (clone COX229; 1:50 dilution; Beijing Zhongshan Golden Bridge Biotechnology Co. Ltd), nm23-h1 (1:50 dilution; Shanghai Chang-Do Biotechnology Co. Ltd) and rabbit anti-human antibody to PTEN (FL-403; 1:100 dilution; Santa Cruz Biotechnology Inc, USA), p-Akt1 (1:50 dilution; Upstate, USA), cyclin D1 (clone SP4; 1:50 dilution; Shanghai Chang-Do Biotechnology Co. Ltd) were used. Each section was then incubated with Envision<sup>+</sup>™, peroxidase, mouse or rabbit (GeneTech) for 30 min. Finally, the sections were reacted with 0.02% 3, 3'-diaminobenzidine and 0.005%  $H_2O_2$  in 0.05 mmol/L Tris-Hcl buffer and counterstained by hematoxylin.

The evaluation of the immunohistochemical staining was performed independently by two authors without knowledge of the clinicopathological information. P53, p21 and cyclin D1 immunoreactivities were observed in the nuclei of the cells, while bcl-2, bax, PTEN, p-Akt1, c-myc, Cox-2 and nm23-h1 in the cytoplasm. Only the im-

munoreactivity in the nucleus or cytoplasm of  $\beta$ -catenin was seemed as positive. The immunoreactive scores besides  $\beta$ -catenin and c-myc were determined by the sum of extension and intensity as reported previously<sup>[22]</sup> and were modified for some markers according to clinicopathological correlations. The intensity of the staining was scored using the following scale: 0, no staining of the tumor cells; +, mild staining; ++, moderate staining; and +++, marked staining. The area of staining was evaluated and recorded as a percentage: 0, less than 5%; +, 5%-25%; ++, 26%-50%; 3+, 51%-75%; and +++, more than 75%. The combined score was recorded and graded as follows: -, 0-1; +, 2; ++, 3-5; +++, 6-7. More than 10% of the cancer cells showing elevated  $\beta$ -catenin labeling in the cytoplasm was recorded as positive expression. According to the immunostaining of c-myc in our study, we considered less than 40% cells expressed c-myc as negative.

### **Statistical analysis**

Computerized statistical analyses were performed using the Statistical Package for the Social Sciences (SPSS), version 13.0. Clinical and histopathologic information and the results from the immunohistochemical studies of the tissue microarray were entered into a database. The variances of molecular expressions among different tissues and associations between molecular variables and clinicopathological data were analyzed with  $\chi^2$  test, but when the numbers of the cells in crosstables which had expected count less than 5 exceeded 25% or the minimum expected counts were less than 1, the Fisher's exact test was used. The relations among these molecules were analyzed by Spearman's bivariate correlation test. In all statistical analyses, a two-tailed  $P$  value  $\leq 0.05$  was considered statistically significant.

## **RESULTS**

### **Clinicopathological data**

Complete histological and clinical data of the patients were collected from patients' records. The median age for the study population was 58 years (range, 30-86 years). There were 24 patients with median age less than 58 years. There was a male predominance in the cancer patients (male: female ratio = 48:37). Thirty-two patients had positive lymph node metastasis, whereas 53 had negative. Fourteen patients had distant metastasis, and 71 had no distant metastasis. The clinical stages of these patients were strictly identified as A ( $n = 15$ ), B ( $n = 33$ ), C ( $n = 23$ ) and D ( $n = 14$ ) according to Dukes stage. After the second diagnostic assessment, there were 24 low, 50 moderately and 11 high differentiated tissues in these cancer tissue blocks according to the histological grades, while 18 tissues were diagnosed as adenomatous polyps and 9 were normal colon mucosa epithelium tissues.

### **Expression of p53, p21, cyclin D1, bcl-2 and bax**

Owing to the short half-life of p53 protein, and its low expression levels in normal cells, wild-type p53 levels cannot be detected by IHC. In cancer cells, most p53 mutations lead to products that accumulate in the nuclei and can easily be detected by IHC. Positive immunostaining most

**Figure 2** Immunophenotype of the investigated antigens (p53, p21, cyclin D1, bcl-2 and bax) in colon cancer (original magnification x 200). Positive stainings of p53, p21 and cyclin D1 were located in the cell nuclei, while those of bcl-2 and bax were in the cytoplasm.

<sup>1</sup>Chi-square test; <sup>2</sup>Fisher's exact test.

commonly represents accumulation of the stable protein product of a mutated *p53* gene that has lost its cell cycle-regulatory function. In this study, expression of p53 was identified in 46 of 85 (54%) colon cancer cell nuclei and 3 of 18 (16.66%) adenomas but absent in normal colon mucosa. Positive stainings of p21 and cyclin D1 were also located in the cell nuclei, while bcl-2 and bax were in the cytoplasm (Figure 2). The expression profiles of p21, cyclin D1, bcl-2 and bax are summarized in Table 1, which shows differences among these various tissues (cancer, adenomas, normal mucosa) regarding the IHC results of the cell cycle and apoptosis-associated protein. The relation between the immunohistochemical pattern and clinicopathological features is presented in details in Table 2. We found positive correlation between p53 and bcl-2 ( $r = 0.245$ ,  $P = 0.010$ ), while no significant correlation between p53 and bax ( $r = -0.081$ ,  $P = 0.395$ ).

#### Expression of Cox-2 and nm23-h1

Cox-2 and nm23-h1 were all correlated with the colon

cancer progression as previously reported<sup>[8,9]</sup>. The protein expression of Cox-2 was detected in 81 of 85 (95%) colon cancer cytoplasm and 16 of 18 (88.88%) adenomas, and 6 of 9 (66.66%) normal mucosa (Figure 3). Sixty-two colon cancer patients showed a strong positive staining of nm23-h1 (score ++~+++ in the cell cytoplasm). The details of the two genes expression profiles are shown in Table 3 and the relations with clinicopathological parameters are presented in Table 4.

#### Expression of PTEN, p-Akt1, $\beta$ -catenin, c-myc

Expressions of PTEN, p-Akt1,  $\beta$ -catenin, c-myc proteins were detected in the cell cytoplasm (Figure 4). Immunohistochemical results of PTEN, p-Akt1No showed no significant difference among the different tissues (data not shown). Significant difference in the expressions of  $\beta$ -catenin and c-myc was found among the benign mucosa, adenomas and malignant tissues (Table 5).  $\beta$ -catenin protein expression had a positive correlation with c-myc expression ( $r = 0.483$ ,  $P = 0.000$ ), thereby suggesting their

**Figure 3** Immunophenotype of the investigated antigens (Cox-2 and nm23-h1) in colon cancer (original magnification x 200). The protein expressions of Cox-2 and nm23-h1 were detected in the cytoplasm.

**Figure 4** Immunophenotype of the investigated antigens (PTEN, p-Akt1, β-catenin and c-myc) in colon cancer (original magnification x 200). Expressions of PTEN, p-Akt1, β-catenin and c-myc were detected in the cell cytoplasm.

potent roles in *Wnt* pathway during the colon carcinogenesis. Correlations of the protein expression profiles with the clinicopathological features are shown in Tables 6 and 7.

## DISCUSSION

Colon carcinogenesis is characterized by distinct morphological, genetic and cellular events. Development and progression of colon cancer to metastasis and lethal state are believed to be driven by multiple genetic alterations, the nature of which has remained poorly understood. Several pathways, such as cell cycle and apoptosis regulation, *Wnt* and PI3K/Akt pathways and so on, have been suggested to be involved in the progression<sup>[5,22,23]</sup>. However, the specific molecular alterations are largely dependent on the genetic background of the individual tumor. Therefore, investigations of molecular changes in tumors representing the entire disease spectrum may enhance our understanding of mechanisms involved in colon tumorigenesis.

To efficiently investigate the various molecules poten-

tially relevant for colon tumor biology and to determine their potential clinical significance, large-scale analysis of multiple molecules in the same tumor tissues is required. The newly evolved and recently validated tissue microarray technique allows such molecular profiling of cancer specimens by immunohistochemistry<sup>[24,25]</sup>. In 1998, Kononen *et al*<sup>[24]</sup> introduced tissue microarrays (TMAs) as a powerful technology to rapidly visualize molecular targets such as genes and gene products in thousands of tissue specimens at a time. Furthermore, the use of TMAs for immunophenotyping of malignant tumors has recently been validated by Hoos *et al*<sup>[25]</sup> who demonstrated immunohistochemical analysis to characterize the significance of alterations in the p53 pathway and other cell cycle-related molecules in a histopathologically well-characterized cohort of patients with Hurthle cell (HC) neoplasm. In this study, two tumor tissue microarrays were constructed that allowed us to investigate the pattern of protein expressions of multiple genes and the relationships between the gene alterations and biological behaviors of colon cancer. We found that

the 1.0-1.5 mm cores used to create the arrays were easy to work with, included enough tumor tissue that histological relationships were easily evaluated, and focused attention on limited regions of tumor, thus ensuring high reproducibility of scoring. Furthermore, at the same time, we could study the morphous of cells and protein expression parallelly and avoid the variance in results in different experiment conditions as seen in the conventional technology.

The cell cycle-regulatory machinery is a complex system of proteins regulating each other's activity and controlling the division of cells<sup>[26]</sup>. We selected p53, p21, cyclin D1 and bcl-2/bax for analysis as target proteins participating in the regulation of proliferation and apoptosis, which are known to be deranged in cancer cell cycles, and which have been shown to affect survival of colorectal carcinomas. The p53 tumor suppressor plays a pivotal role in cell cycle regulation and apoptosis. Mutations in the *p53* gene are among the most common mutations encountered in human malignancy. Wild-type p53 along with other cellular growth factors activate *p21* gene expression and the corresponding p21 protein triggers cell-cycle arrest in the G<sub>1</sub> phase<sup>[27]</sup>. In colorectal cancer cells, mutated p21 neither suppressed apoptosis nor affected cell survival<sup>[28]</sup>. In addition to cell-cycle control, p53 mediates programmed cell death through the bcl-2/bax apoptotic pathway<sup>[29]</sup>. In this study, we observed that p53 was undetectable in normal colon tissue and over-expressed in only three adenomas and 54% of the adenocarcinomas. When the expression of p53 with clinicopathological parameters was compared, only the significant relation with histological grade could be seen, thereby indicating that p53 may be involved in the late stage of colon carcinogenesis and in the malignant progression of colon cancer. As to the others genes, there were significant differences among the three groups (normal mucosa, adenoma and cancer)

regarding the immunohistochemical results (cyclin D1,  $P = 0.000$ ; bcl-2,  $P = 0.001$ ; bax,  $P = 0.000$ ). Comparing these markers with the clinicopathological features, we observed the correlation of histological grades with bax, and Dukes stage with cyclin D1. Thus, we can speculate that cyclin D1, bcl-2 and bax aberrations may involve in the colon cancer development and the decreased expression of bax can accelerate the cancer tissue further differentiate into advanced stage, and malignant colon tissue highly expressed cyclin D1 may acquire the invasive potent. In addition, though the difference of this protein expression between distant metastasis-positive group and -negative group was not significant ( $P = 0.052$ ) in this study, colon cancer with alteration of bcl-2 expression may facilitate to metastasize to distance sites. In our study, p21 over-expression was found in 64 of 82 (78.04%) cancers and was correlated with advanced stage colorectal cancer, which is in agreement with a previous report<sup>[30]</sup>. Furthermore, IHC revealed that some cancer cells expressed both p21 and p53, suggesting that p21 can also be activated by a p53-independent mechanism. A previous study reported that p53 can inhibit bcl-2 gene expression by transcriptional activation of the pro-apoptotic bax gene. But the relationship between p53 and bax in this cohort tissue was not established. However, our results showed that the expression of p53 had positive correlation with bcl-2. The precise mechanism of regulation of bcl-2/bax pathway through p53 needs further study.

There are two distinct Cox isoenzymes, namely constitutive Cox-1 and inducible Cox-2. It was reported that Cox-2 elevated in human esophagus, skin, and colon cancers, and the Cox-2 inhibitor, celecoxib, inhibited intestinal tumor multiplicity in a mouse model and reduced the number of adenomatous polyps in a familial adenomatous polyposis patient<sup>[16,17]</sup>. Enhanced Cox-2 expression has been related to tumor differentiation, distant metastasis and Dukes stage<sup>[31,32]</sup>. In present study, Cox-2 immunoreactivity was increased in the colon carcinoma (91%) and adenomas (88%). However, the expression of Cox-2 was correlated with less advanced grade, fewer distant metastases and lower Dukes stage in these cohort colon cancer tissues. These results indicate that Cox-2 over-expression might be an early event during the tumorigenesis in the colon and its role in progression of colon cancer deserves further investigation. Although a reduced expression of nm23-h1 has been shown to be correlated with a high metastatic potential in some human cancers, such as colorectal cancers, conflicting data have been reported<sup>[19,33]</sup>. In our study, expression of nm23-h1 was detected in 79 of 85 (92.94%) cancers, 16 of 18 (88.88%) adenomas and 4 of 8 (50%) normal tissues. The decreasing tendency of expression of nm23-h1 was found to be associated with the aggravation of differentiation, distant metastasis in the cohort patients. Therefore, the exact role of nm23-h1 in development and progression of the colon cancer needs further studies.

$\beta$ -catenin is known to complex with E-cadherin to form intercellular junctions. It also participates in the *Wnt*-signaling pathway, which frequently is disrupted in colorectal carcinomas by adenomatous polyposis

coli (APC) or  $\beta$ -catenin mutations<sup>[15]</sup>. Translocation of  $\beta$ -catenin to the nucleus with transcription start of cyclin D1 and metalloproteinase 7 could lead to more aggressive colorectal carcinomas<sup>[34]</sup>. C-myc was also found to be involved in the *Wnt* pathway and seemed as a target gene of  $\beta$ -catenin/TCF<sup>[35]</sup>. It has been extensively documented that c-myc is over-expressed at RNA and protein levels at both early and late stages of the colorectal tumorigenesis<sup>[36]</sup>. Previous immunohistochemical studies with  $\beta$ -catenin showed distinct subcellular expression patterns in the colorectal carcinomas, adenomas, and benign epithelium, whereas benign tissue almost universally expressed  $\beta$ -catenin on the plasma membrane only, adenomas and carcinomas expressed  $\beta$ -catenin to varying degrees in the cytoplasm and in the nucleus as well<sup>[6,36,37]</sup>. This finding is not surprising, given the intracellular pathway described above. However, correlations between alterations of  $\beta$ -catenin expression in colorectal cancer and outcome variables have not been consistent<sup>[38-40]</sup>. In this study, different expressions of these two molecules were found among the varying types of tissues.  $\beta$ -catenin was expressed in 70 of 85 (82.83%) cancer tissues, 13 of 18 (72.22%) adenomas and only 4 of 9 (44.44%) para-cancerous normal mucosa. Similarly, positive expression of c-myc was detected in 68 of 84 (80.95%) colon cancers, 14 of 18 (77.77%) adenomas as well as 25% benign tissues. In addition to the results which showed positive correlation between the  $\beta$ -catenin and c-myc in our study ( $r = 0.483$ ,  $P = 0.000$ ), we can assume that over-expression of  $\beta$ -catenin in the cytoplasm and c-myc might be early events during the carcinogenesis in human colon *via* involving in the *Wnt* pathway which always distorts during colon tumorigenesis. However, the cancer tissues in the cohort with over-expression of  $\beta$ -catenin or c-myc exhibited less capacity to differentiate into advanced grade and invasive potential, which are contradicted to some previous reports<sup>[40,41]</sup>. The exact roles of  $\beta$ -catenin and c-myc aberration in progression of colon cancer requires further investigations.

The phosphatidylinositol-3 kinase (PI3K)/Akt is an important survival signal pathway that has been shown to be crucial in the regulation of balance between pro-apoptotic and survival (anti-apoptotic) signal<sup>[42]</sup>. The phosphorylated Akt level can monitor cell growth and resistance to apoptosis, indicating that activation of Akt plays an important role during the progression of colorectal carcinomas by helping promote cell growth and rescue cells from apoptosis. PTEN is a phosphatase that negatively regulates the phosphoinositol-3-kinase/Akt pathway and mediates cell-cycle arrest and apoptosis<sup>[43]</sup>. One study reported that PTEN protein expression was abnormal when compared the cancer with benign tissue<sup>[44]</sup>, but same phenomenon was not found among the cohort patients including in this study. However, at the same time, PTEN expression detected by us was found to be related to tumor histological grade and p-Akt1 was related to lymph node metastasis. In this study, the expression profiles demonstrated that though did not involve in the early development of tumorigenesis, these two molecules may conduce to the lately progression of colon cancer which showed lymph node or distant metastasis. Contradiction between the results of p-Akt1 expression in

our study and a previous study<sup>[11]</sup> which reported that Akt over-expression occurred frequently during human colon carcinogenesis might be because the gene background (FAP, HNPCC or sporadic CRC) of the patients studied were not strictly identified and the antibody used which was a polyclonal antibody in our study.

In summary, tissue microarrays (TMAs) combined with immunohistochemical staining for colon cancer, adenomas and normal mucosa showed that TMAs technology with 1.0 to 1.5 mm core tissue adequately represents the immunohistochemical pattern of the colon tissue. It considerably reduces the cost and labor needed to process tissue slides and enrich the technical spectrum of histopathology. The over-expressions of p53, cyclin D1, bcl-2, Cox-2,  $\beta$ -catenin and c-myc and the low or no expression of bax might be involved in the colon tumorigenesis and PTEN, p-Akt1 may contribute to the progression of colon cancer at late stage. No or low expression of nm23-h1 in colon cancer may contribute to the cancer cells acquired the invasion and distant metastasis potential. Further study needs to investigate the precise mechanism of colon cancer development and progression.

## COMMENTS

### Background

Studies of single molecular marker have not been successful in defining the biology of the colon cancer, so we explored multiple molecules regulating the colon tumorigenesis by using tissue microarray combining with immunohistochemical staining which can help us complete the time- and people-consuming work.

### Research frontiers

In this study, the most worthwhile hotspot I think was investigating 11 molecules expressions by using the tissue microarray which allows rapid visualization of molecular targets at a time in protein level.

### Innovations and breakthroughs

Firstly I should mention that in this study, we explored 11 molecular expressions at a time during colon carcinogenesis which was seldom found in our country. In addition, the expressions of these molecules were detected by using tissue microarray which is a new high-throughput biological technique.

### Applications

Tissue microarray can facilitate rapid translation of molecular discoveries to clinical applications used, so we can speculate that the tissue microarray technology which is fast, convenient and economic may have potential dominant position in macro-scale detection of tissue specimens in cancer studies.

### Terminology

In 1998, Kononen and Kallioiniemi developed tissue microarrays (TMAs) whereby an ordered array of tissue samples are placed on a single slide. Once constructed, the TMA can be probed with a molecular target (DNA, RNA or protein) for analysis by immunohistochemistry, fluorescence *in situ* hybridization (FISH) or other molecular detection methods, enabling high-throughput *in situ* analysis of specific molecular targets in hundreds or even thousands of tissue specimens.

### Peer review

In this study, the authors investigated the expressions of 11 cancer related genes involving cell proliferation, cell cycle, apoptosis, as well as signal pathway in human colon cancer, adenoma and para-cancerous mucosa by using tissue microarray, a new biological technique, combining with immunohistochemical staining at a time. The results from this study may manifest the colon cancer situation at some level and have some reference values in our country.

## Abstract

**AIM:** To investigate the acupuncture-modulated gastric motility and its underlying neural mechanism.

**METHODS:** Intragastric pressure and/or waves of gastric contraction in rats were recorded by intrapyloric balloon and changes of gastric motility induced by acupuncture stimulation were compared with the background activity before any stimulation. Gastro-vagal or splanchnic-sympathetic nerves were recorded or cut respectively for investigating the involvement of autonomic nerve pathways. Spinalization experiment was also performed.

**RESULTS:** Acupuncture-stimulation by exciting A $\delta$  and/or C afferent fibers, could only modulate gastric motility. Acupuncture-stimulation on fore- and hind-limbs evoked a moderate gastric motility followed by increased vagus discharges with unchanged sympathetic activity, while the same stimulus to the acupoints in abdomen resulted in reversed effects on gastric motility and autonomic nervous activities. The inhibitory gastric response was completely abolished by splanchnic denervation, but the facilitative gastric response to stimulation of acupoints in limbs was not influenced, which was opposite to the effect when vagotomy was performed. The similar depressive effects were produced by the stimulation at the acupoints homo-segmental to the gastric innervation in the animals with or without spinalization. However, the facilitation induced by the stimulation at the acupoints hetero-segmental to the gastric innervation was not observed in the spinalized animals.

**CONCLUSION:** Facilitative effects of stimulating hetero-segmental acupoints are involved in the intact

preparation of vagal nerves and spinal cord, while the inhibitory response induced by stimulating homo-segmental acupoints is involved in the intact preparation of sympathetic nerves. Only the acupuncture-stimulation with intensity over the threshold of A $\delta$  and/or C afferent fibers can markedly modulate gastrointestinal motility.

## INTRODUCTION

Acupuncture, a commonly used neuromodulating technique, has been widely accepted in the treatment of pain syndromes<sup>[1]</sup>. It modulates the functions of visceral organs by inducing activation of the somato-visceral reflexes and change of the autonomic nervous system<sup>[2-4]</sup>.

Electro-acupuncture therapy is increasingly adopted in Western countries. Acupuncture involves stimulating specific somatic points on the body by puncturing the skin with a needle. Heat, pressure or impulses of electrical energy can also stimulate the points. It was reported that the nervous system, neurotransmitters and endogenous substances respond to electro-acupuncture. Abundant information is now available concerning the neurobiological mechanisms of acupuncture related with the neural pathways and neurotransmitters/hormonal factors that mediate autonomic regulation, pain relief and other therapeutics<sup>[5]</sup>. Being a kind of traditional technique with a long history, acupuncture has been used to treat a variety of diseases including pain. Electrophysiological studies showed that acupuncture might inhibit the neuron discharge induced by pain of both somatic and visceral sources at different levels of the central nervous system, which gives a good explanation for the clinic phenomena in which acupuncture produces quick effect on somatic and visceral pain and relatively slow and long post-effect. Though there are data relating the modulation of somatic afferent inputs on visceral nociception or dysfunction, evidence for the role of acupuncture in this process is not sufficient.

The Committee of NIH published a report on the indications of acupuncture in November 1997. The summary of the consensus statement indicates that there is clear evidence that needle acupuncture treatment is effective on postoperative and chemotherapy-induced nausea and vomiting during pregnancy and postoperative dental pain<sup>[6]</sup>. Recent investigations suggest that acupuncture modulations on visceral functional activities can be mediated via the autonomic nervous system<sup>[2,4,7-9]</sup>.

In the present study, therefore, we investigated the modulation of gastric motility by manual/electrical acupuncture at representative meridian-acupoints in different parts of the body and its underlying mechanism involved in different afferent fibers, autonomic nervous system and the supraspinal center.

## MATERIALS AND METHODS

### *Animal preparation*

All animal experiments were carried out in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals and approved by the Institutional Animal Care and Use Committee of China Academy of Chinese Medical Sciences. Experiments were performed on 48 adult male Sprague-Dawley rats weighing 250-300 g. The rats were fasted overnight with free access to water and anesthetized with an intraperitoneal injection of urethane (1.0-1.2 g/kg). The trachea was cannulated and a catheter was inserted into one of the jugular veins for infusion of necessary solutions or anesthetics. The abdomen was opened by midline, and then a small longitudinal incision was made in the duodenum about 2-3 cm from the pylorus. A small balloon made of condom was inserted via the incision into the pyloric area and fixed. Another catheter (1 mm in inner diameter) was also inserted into the same incision to drain digestive juices secreted from the stomach. The balloon was filled with about 0.2-0.5 mL warm water, which gave the pressure at about 80-150 mmH<sub>2</sub>O. Pressure in the balloon was measured by a transducer (TP-400T, Nihon Kohden) through a thin polyethylene tube (1.5 mm in outer diameter) and then input into a polygraph amplifier (RM-6000, Nihon Kohden) and led to a data acquisition system (Power-Lab/8 s, AD Instruments) for further analysis. Demi-fasting gastric motor activity was recorded as a control for at least 1 h before any stimulation was applied.

Changes of gastric motility induced by the stimulation were compared with the background activity in terms of intragastric pressure and/or waves of gastric contraction. If the changes of gastric motility during stimulation were 20% more or less than the background activity, the response was considered to have an excitatory or inhibitory regulation.

Blood pressure in a common carotid artery and heart rate were continuously monitored. The rectal temperature was kept constantly around 37°C by a feedback-controlled heating blanket.

### *Recording of neural activity, severance of autonomic nerves and transection of spinal cord*

To investigate whether vagal or sympathetic pathways

are involved in the stimulatory or inhibitory effects of acupuncture on gastric motility, subdiaphragmatic gastro-vagal or sympathetic postganglionic nerves coming from a celiac ganglion and innervating the gut branch were dissected under microscope. Discharges of the vagal or sympathetic nerves were put into a polygraph (RM-6000, Nihon Kohden) amplifier through bipolar platinum wire electrodes and input into a data acquisition system (Power-Lab) for further analysis. In experiments, gastro-vagal nerves were cut in subdiaphragmatic bilateral truncal vagotomy (an additional cervical bilateral vagotomy was also performed in several cases) or postganglionic nerves innervating the gut branch were cut in sympathetomy (an additional bilateral splanchnicotomy was also performed in several cases) in 24 rats.

In spinalization experiments, laminectomy was performed in C<sub>8</sub>-T<sub>1</sub> of 10 animals. Frozen physiological saline was used to produce a reversible cold block (five rats), or transected with knife to determine the involvement of supraspinal circuit in acupuncture-induced effect on gastric motility.

### *Acupuncture stimulation*

A needle (0.3 mm in diameter) was inserted into the skin and its underlying muscles at different acupoints on the body. The needle was rotated clockwise and anti-clockwise at 2 Hz for 30 s. Based on the anatomical localization in rats as compared with that in human body, the stimulated acupoints included St-13 (acupoint of Stomach-Meridian in upper-chest), Li-11 (acupoint of Large intestine-Meridian in forelimb), Cv-6 (acupoint of conception-vessel) and St-21 (acupoint of Stomach-Meridian in abdomen), Bl-21 (T<sub>12</sub> segment, acupoint of Bladder-Meridian in dorsum) and St-36 (acupoint of Stomach-Meridian in hindlimb).

In electroacupuncture experiments, acupoints were stimulated by a pair of needle-electrodes inserted 0.3 cm deep into the skin and electroacupuncture intensities were chosen as the multiples of the threshold for the activation of A $\delta$ -fiber or C-fiber, including 0.8 (0.8-T<sub>A $\delta$</sub> , non-noxious stimuli,  $1.42 \pm 0.36$  mA) and 2-times of the A $\delta$ -fiber reflex threshold (2-T<sub>A $\delta$</sub> , slight nociceptive stimuli,  $3.62 \pm 0.44$  mA), and 1.5 times (1.5-T<sub>C</sub>, strong nociceptive stimuli,  $7.68 \pm 0.53$  mA) of C-fiber reflex threshold.

The thresholds of A $\delta$ -fiber and C-fiber reflexes were decided by electrical stimulation of the sural nerve territory, which could elicit a two-component reflex response in the ipsilateral biceps femoris muscle. The first-component had a low threshold ( $1.64 \pm 0.33$  mA) response with a short latency ( $13.2 \pm 1.4$  ms) and duration ( $24.2 \pm 1.5$  ms). The second-component had a longer latency ( $158.8 \pm 10.7$  ms) and duration ( $243.8 \pm 31.5$  ms) and a higher threshold ( $4.84 \pm 0.67$  mA). These electrophysiological features clearly suggested that the two-components were produced due to the different afferent volleys activated by sural nerve stimulation. According to our previous study, it seems that the first component with a low-threshold and a short-latency could be elicited by activating the A $\delta$ -fibers, whereas the second with a higher threshold and a longer latency might result from the activation of the unmyelinated C-fiber afferents<sup>[10]</sup>.

**Figure 1** Gastric motility response to electro-acupuncture stimulation with different intensities. Gastric motility was recorded for 90 s, of which the first 20 s was the duration of spontaneous background of gastric activity, 21-50 s was the period of acupuncture stimulation at acupoints, poststimuli activity was recorded for 51-90 s. Dash line represents located abdominal acupoints.

### Experimental procedures

The rats were kept in supine position and gastric motor activity was first analyzed visually to detect the waves of contractions. A standard protocol was employed for the determination of effects of acupuncture-stimulation on gastric motility response. A background gastric activity was recorded for 5-10 min followed by a test of the responses to manual or electro-acupuncture at the acupoints for 30 s. The post-stimuli response was recorded for another 5-10 min.

After a series of experiments was finished, the rats were sacrificed under deep anesthesia (urethane, 2 g/kg ip).

### Statistical analysis

The data obtained before and after intervention between the two groups were compared statistically by independent *t*-test and paired *t*-test respectively.  $P < 0.05$  was considered statistically significant. All data were expressed as mean  $\pm$  SE.

## RESULTS

### Gastric motor characteristic

Gastric motor characteristics were observed in 42 rats. When the intrapyloric balloon pressure was increased to about 80-200 mmHgO, the rhythmic waves of contractions in pyloric area were observed. When the pressure was maintained at about 100 mmHgO by expanding the volume of the balloon with warm-water, rhythmic contractions occurred at a rate of four to six per minute and these rhythmically gastric contractions could be recorded in either the spinalized rats or the rats with intact central nervous system. The gastric contractions could also be recorded after denervation of gastric nerve branches of the vagal or splanchnic nerves.

### Gastric motility response to electro-acupuncture stimulation with different intensities

The response of gastric motility to the activation of A $\delta$ -/C-fibers was elicited by stimulating the ipsilateral sural nerve. The effects of acupuncture stimulation to Li-11 in the forelimb, St-13 in upper-breast, St-21 and Cv-6 in the abdomen and St-36 in the hindlimb on gastric motility were studied. As illustrated by an representative example in Figure 1 in combination with data in Figure 2,

**Figure 2** Quantitative analysis of gastric motility in strength-dependent response to electro-acupuncture stimulation applied to the acupoints on different parts of body. "< A $\delta$ ": the intensity of the stimulation less than the threshold for activation of A $\delta$ -fiber; "> A $\delta$  < C": the intensity of the stimulation over the threshold for activation of A $\delta$ -fiber, but less than the threshold for activation of C-fiber; "> C": the intensity of the stimulation over the threshold for activation of C-fiber.

the acupuncture stimulation with the intensity of  $0.8 \cdot T_{A\delta}$  ( $1.42 \pm 0.36$  mA) at the above five acupoints did not produce any significant influences on the gastric motility. The acupuncture stimulation with the intensity of  $2 \cdot T_{A\delta}$  ( $3.62 \pm 0.44$  mA) at the acupoints of Li-11, St-13 and St-36 elicited a mild-moderate facilitation on the gastric motility, whereas the acupuncture stimulation with the same intensity to the acupoints of St-21 and Cv-6 brought about a moderate depression of gastric motility. The acupuncture stimulation with the intensity of  $1.5 \cdot T_c$  ( $7.68 \pm 0.53$  mA) at the acupoints of Li-11, St-13 and St-36 resulted in a strong excitatory gastric motility. In contrast, a strong inhibition on the gastric motility was induced by the same acupuncture stimulation at the acupoints of St-21 and Cv-6.

Electro-acupuncture stimulation could induce regulatory effects on gastric motility. Moreover, facilitation/depression on the gastric motility induced by acupuncture stimulation was intensity-dependent. Only the stimulation with an intensity over the threshold for activation of A $\delta$ - and/or C-fibers could modulate gastric

**Figure 3** Gastric motility and autonomic nerve responses to acupuncture stimulation at different acupoints. In each acupoint stimulus, gastric motility (GM), activities of gastric vagal (vagus) and postganglionic sympathetic nerve branches to the stomach (symp), were simultaneously recorded.

motility ( $P < 0.05$ ,  $P < 0.001$ ) and the powerful effects were produced when the strongest electro-acupuncture stimulation, *i.e.* 1.5-Tc, was given ( $P < 0.05$ ,  $P < 0.001$ ).

#### Gastric motility and activity of autonomic nerves in response to acupuncture stimulation

Gastric motility in the most rats showed various responses to acupuncture stimulation at some representative acupoints on several meridians and different parts of the body. Manual acupuncture stimulation at either Li-11 in forelimb or St-36 in hindlimb led to a moderate facilitation of gastric motility with a rapid enhancement at the beginning of stimulation, followed by a tonic gastric contraction lasting throughout the period of acupuncture stimulation. The typical effects of acupuncture stimulations at Li-11 or St-36 acupoints on discharges of the branches of both gastric vagal and postganglionic sympathetic nerves to the stomach are shown in Figure 3. Acupuncture stimulation at either Li-11 ( $n = 10$ ) or St-36 ( $n = 16$ ) acupoints markedly increased vagal discharges ( $339.42 \pm 133.2$  spikes/min *vs*  $381.6 \pm 135.42$  spikes/min,  $P < 0.05$ ). The latency of increased discharges was about 2-3 s after the onset of stimulation. The facilitated response lasted for 30 s with a maximum response at about 10 s after the onset of acupuncture stimulation. In contrast to vagus response, spontaneous activity of the sympathetic nerve branch was not clearly influenced by acupuncture stimulation at either Li-11 ( $n = 12$ ) or St-36 acupoints ( $n = 12$ ) ( $P > 0.05$ ). Generally, in the animals with high spontaneous

activity of sympathetic nerves, the same acupuncture stimulation could mildly inhibit the discharges. However, the stimulation could produce a slight excitation in the animals with lower spontaneous sympathetic activity.

The same stimulus to the acupoints of either St-21 or Cv-6 in abdomen, resulted in high suppression with a rapid onset on gastric tonic motility, followed by an obvious inhibition on the rhythmic wave of contraction. The suppression maintained throughout the period of acupuncture stimulation. In the autonomic nerve participation, acupuncture stimulation at either St-21 ( $n = 12$ ) or Cv-6 ( $n = 10$ ) acupoints markedly increased sympathetic discharges ( $476.4 \pm 150.78$  spikes/min *vs*  $638.82 \pm 171.78$  spikes/min,  $P < 0.05$ ). In most cases, spontaneous vagal activity could also be inhibited slightly ( $P > 0.05$ ,  $n = 12$ ) or remained unchanged (Figure 3).

#### Effect of acupuncture stimulation on gastric motility involved in autonomic nerves

In order to discover their contribution to the facilitation/inhibition of acupoint-visceral reflex responses, denervation of the vagal or sympathetic nerves was performed in the present study.

The effect of acu-stimulation on gastric motility was examined in the rats after amputation of bilateral splanchnic nerves just beneath the diaphragm.

The inhibitory gastric response induced by acupuncture stimulation to acupoints of St-21 ( $n = 9$ ), Cv-6 ( $n = 9$ ) or Bl-21 ( $n = 9$ ) was completely abolished after sympathectomy of the bilateral splanchnic nerves, but the facilitative gastric response induced by acupuncture stimulation to acupoint of Li-11 ( $n = 9$ ) was not influenced significantly and St-36 ( $n = 9$ ) was only less influenced by splanchnic denervation (Figure 4 and Figure 5A).

Bilateral subdiaphragmatic vagotomy was performed to determine the vagal involvement in the stimulatory or inhibitory effects of acupuncture on gastric motility (in some experiments, additional vagotomy of bilateral vagal nerves was also performed at the cervical level to observe the different results from those obtained in the rats after incomplete subdiaphragmatic vagotomy). As shown in Figure 4 and the cumulative results in Figure 5B, the bilateral vagotomy did not abolish the suppressive gastric response induced by acupuncture stimulation to the acupoints of either St-21 ( $n = 9$ ), Cv-6 ( $n = 9$ ) in abdomen, or Bl-21 in middle-dorsum ( $n = 9$ ). However, the bilateral vagotomy completely depleted the facilitative gastric response provoked by acupuncture stimulation to the acupoints of Li-11 in forelimb ( $n = 9$ ) or St-36 in hindlimb ( $n = 9$ ).

#### Effect of acupuncture stimulation on gastric motility involved in supraspinal circuit

During acute spinalization at C<sub>8</sub>-T<sub>1</sub> level, steady gastric motility could still be recorded. But for avoiding the spinal shock, 30-min period of rest was necessary.

In pre-spinalized animals, as shown in Figures 6 and 7, the gastric motility was inhibited by acupoints of St-21, Cv-6 or Bl-21, and facilitated by St-36 acupoint. Acupuncture stimulation at the acupoints of St-21 ( $n =$

**Figure 4** Effect of acupuncture stimulation on gastric motility in animals with intact autonomic nervous system, after sympathectomy of bilateral splanchnic nerves just beneath the diaphragm but intact vagi and bilateral subdiaphragmatic vagotomy but intact sympathetic nerve.

**Figure 5** Analysis of the changes in gastric motility induced by acupuncture stimulation in rats after bilateral sympathectomy (A) of splanchnic nerves and vagotomy (B), respectively. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  and <sup>d</sup> $P < 0.001$  vs animals with intact autonomic nervous system.

10), Cv-6 ( $n = 10$ ) or Bl-21 ( $n = 10$ ) could inhibit gastric motility in the spinalized rats. On the contrary, gastric facilitative response induced by St-36 ( $n = 10$ ) acupuncture stimulation disappeared completely after spinalization.

## DISCUSSION

Our previous study showed that acupuncture-stimulation had facilitative or inhibitory effect on gastric motility depending on the different stimulated acupoints on different parts of the body<sup>[10]</sup>. In this study, we investigated how strong the stimulation and what autonomic nervous system can effectively modulate the gastric motility.

### Modulation of gastric motility induced by acupuncture stimulation involved in activation of fine-diameter afferent fibers

The flexion reflex is usually described as an EMG

discharge that mainly consists of two-components separated by periods of an EMG absence. The present results are very similar to those described by Falinower *et al.*<sup>[11]</sup> and by our recent observation<sup>[12]</sup> in which sural nerve stimulation evoked a two-component reflex in the flexor muscles of the ipsilateral hindlimb. Based on accumulative electrophysiological and pharmacological evidence, the first-component is triggered by activities of small diameter A $\delta$ -fibers, and the second-component is mediated by the unmyelinated C-fibers.

The present study demonstrated that electro-acupuncture stimulation with the strength below  $T_{A\delta}$  could not effectively trigger regulatory effects on gastric motility, regardless of the locations of acupoints. Only electro-acupuncture stimulation with the strength exceeding the thresholds for activation of A $\delta$  and/or C-fibers could profoundly modulate gastric motility. Moreover, the effects were strength-dependent and the powerful effects were

**Figure 6** Effects of acupuncture stimulation involving the supraspinal circuit on gastric motility in normal (A) and spinalized (B) rats.

observed when the strongest stimulation was given.

Electro-acupuncture stimulation has been known to excite various afferent fibers of rats including groups II-III<sup>[13]</sup>, groups III-IV<sup>[14]</sup> or groups II-IV<sup>[15]</sup>. Koizumi *et al*<sup>[16]</sup> performed a systematical analysis of the relationship between the magnitude of cutaneo-intestinal reflex response and groups of stimulated afferent fibers. Their results indicate that stimulation of groups II-III cutaneous fibers in the T<sub>10</sub> spinal nerve could not produce any changes in jejunal motility, while stimulation of groups II-III-IV fibers could always induce inhibitory responses. Stimulation of the sural afferent nerves of the hindlimb could elicit facilitative jejunal reflex, which was obtained when the stimulus intensity could activate group III fibers and the maximal facilitation appeared when the stimulus intensity could activate group IV afferent fibers. Noguchi *et al*<sup>[17]</sup> reported that when electro-acupuncture stimulation intensity at hindlimb was less than 1.5-mA (only activation of group II fibers), equivalently to 0.8-T<sub>Aδ</sub> (1.42 ± 0.36 mA) electro-acupuncture-stimulation in our present study, there was no significant response of duodenal motility. When the intensity of electro-acupuncture stimulation exceeded 2.0-5.0-mA (activation of groups II-III and IV fibers), equivalently to 2-T<sub>Aδ</sub> (3.62 ± 0.44 mA) electro-acupuncture-stimulation in our study, a slight increase was observed in duodenal motility. The maximal excitatory response of duodenal motility to electro-acupuncture stimulation was observed in 10-mA (activation of various afferent fibers) at hindlimb, which was equivalent to 1.5-T<sub>C</sub> (7.68 ± 0.53 mA) electro-acupuncture-stimulation in our study. These studies demonstrated that stimulating groups III-IV, particularly group IV or C afferent fibers of hindlimb, could produce an excitatory intestinal reflex response. On the other hand, stimulation of only group IV abdominal nerves produces an inhibitory intestinal reflex response.

These data suggest that only acupuncture stimulation with an intensity strong enough to excite Aδ (or group III) and/or C (or group IV) afferent fibers, can lead to markedly excitatory/inhibitory modulation of gastrointestinal motility.

**Figure 7** Effects of acupuncture stimulation at different acupoints on the regulation of gastric motility in normal and spinalized rats. Triangle-lines represent the pre-spinalized effects and square-lines indicate the post-spinalized effects. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 and <sup>d</sup>*P* < 0.001 vs the control gastric motility of pre-spinalization.

### Facilitation of gastric motility induced by acupuncture stimulation involved in vagal nerve and supraspinal circuit

The present study showed that acupuncture stimulation to the acupoints on face, neck, forelimbs, upper chest-dorsum and hindlimbs produced a facilitative response of gastric motility. These effects were involved in intact preparation of vagal nerves and the spinal cord, but did not require intact preparation of the splanchnic nerves.

Motor activity of the stomach, like other gastrointestinal organs, is modulated by the changes in vagal activity. It was reported that electro-acupuncture at acupoints of St-36 and Pc-6 (Neiguan, located in forelimb) enhances the gastric migrating myoelectrical complex in dogs by reducing the length of phase-I and increasing the length of phases II and III<sup>[18]</sup>. Ouyang *et al*<sup>[19]</sup> observed that electro-acupuncture at Pc-6 and St-36 substantially accelerates gastric emptying of liquid in dogs. The accelerating effect of electro-acupuncture on gastric emptying may be attributed to the improvement in gastric tone and antral contractile activity. Enhanced vagal activity by electro-acupuncture suggests a possible involvement of vagal pathways in its regulation of gastric motility. Xu<sup>[20]</sup> found that the regulatory effect of electro-acupuncture on gastric dysrhythmia in rabbits could be abolished after vagotomy. Sato *et al*<sup>[9]</sup> showed that acupuncture-like stimulation could elicit an excitatory gastric response when it is applied to the hindlimb. These findings suggest that acupuncture provokes a reflex that has cutaneous and muscle nerves as its afferent pathway, and the gastric vagus as its efferent pathway. In our study, acupuncture stimulation at St-36 could facilitate gastric motility by increasing the activity of gastric efferent nerves. However, this facilitation of gastric motility disappeared in spinalized rats. The facilitative duodenal response by electro-acupuncture stimulation to a hindpaw is a supraspinal reflex response involving vagal excitatory nerves, cutting the splanchnic nerve branches to the duodenal does not affect the enhanced duodenal response<sup>[17]</sup>.

Facilitation in gastric motility and increase in parasympathetic activity by (electro-) acupuncture

stimulation to all acupoints except for those of abdomen and middle-dorsum (the acupoints of homo-segmental to the innervation of stomach) are accompanied with a decrease in sympathetic activity or a breakage of possible "sympathetic dominance"<sup>[21,22]</sup>, suggesting that these effects require the participation of supraspinal center.

### ***Inhibition of gastric motility induced by acupuncture stimulation involved in sympathetic nerve and propriospinal circuit***

The present study showed that acupuncture stimulation to the acupoints on lower-chest, middle-dorsum and whole abdomen could induce an inhibitory response of gastric motility with an increase in the activities of sympathetic and/or a slight inhibition in the activity of vagal nerves innervating the stomach, suggesting that these effects are involved in intact preparation of sympathetic (splanchnic) nerves, but do not require intact preparation of bilateral vagal nerves and high spinal cord.

Sato *et al.*<sup>[9]</sup> showed that the abdominal acupuncture-like stimulation could elicit suppressive response of gastric motility, indicating that acupuncture provokes a reflex that has cutaneous and muscle nerves as its afferent pathway, and the sympathetic gastric branches as its efferent pathway. This inhibition is accompanied with an increase in the activity of efferent nerves of sympathetic gastric branches and can be observed in spinalized rats. The inhibitory duodenal response to electro-acupuncture stimulation in abdomen is a propriospinal reflex response involving splanchnic excitatory nerves, cutting the vagal nerve branches to the duodenal does not affect the suppressed duodenal response<sup>[17]</sup>. Using duplex Doppler sonography, Choi *et al.*<sup>[23]</sup> found that the frequency of intestinal motility is increased during acupuncture stimulation at St-36 acupoint. Acupuncture on the lower abdomen causes a transient relaxation of the stomach, which can be abolished by splanchnic ganglionectomy but not by truncal vagotomy<sup>[24]</sup>.

In conclusion, acupuncture stimulation to the acupoints on face, neck, forelimbs, upper chest-dorsum and hindlimbs, which are distant to the region of gastric innervation, produces a facilitative response of gastric motility with increased activities of vagus and/or a slight inhibition in the activity of sympathetic nerves. These effects are involved in the intact preparation of vagal nerves and spinal cord, but do not require intact preparation of the splanchnic nerves. Acupuncture stimulation to the acupoints on lower-chest, middle-dorsum and whole abdomen, which are homo-segmental to the region of gastric innervation, induces an inhibitory response of gastric motility with increased activities of sympathetic nerves and/or a slight inhibition in the activity of vagal nerves. These effects are involved in intact preparation of sympathetic nerves, but do not require intact preparation of bilateral vagal nerves and high spinal cord. Only the acupuncture stimulation with its intensity greater than the threshold for activation of Aδ and/or C afferent fibers can induce markedly excitatory/inhibitory modulation of gastrointestinal motility.

## Abstract

**AIM:** To observe the therapeutic efficacy of Baicalin in rats with severe acute pancreatitis (SAP) and explore its therapeutic mechanisms.

**METHODS:** The SAP rat models were randomly divided into the model control group, Baicalin treatment group, octreotide treatment group and sham operation group. All groups were randomly subdivided into 3 h, 6 h and 12 h groups with 15 rats in each group. The survival, ascites volume and pathological changes of pancreas in all rats were observed at different time points after operation. The plasma amylase content and serum TNF- $\alpha$ , IL-6, malonaldehyde (MDA) and PLA<sub>2</sub> contents were also determined.

**RESULTS:** The survival was not obviously different between the treated groups, and was significantly higher

in treated groups at 12 h compared to the model control group ( $P < 0.05$ , 15 vs 10). The ascites/body weight ratio at 3 h and 6 h was significantly lower in Baicalin treatment group compared to the model control group and octreotide treatment group ( $P < 0.05$ , 1.00 vs 2.02 and 1.43 and  $P < 0.001$ , 2.29 (1.21) vs 2.70 (0.80) and 2.08 (2.21), respectively). The contents of amylase, TNF- $\alpha$ , IL-6, MDA and PLA<sub>2</sub> were significantly lower in the treated groups than in the model control group ( $P < 0.05$ , 4342 vs 5303, 5058 vs 6272 in amylase,  $P < 0.01$ , 21.90 vs 36.30, 23.80 vs 39.70, 36 vs 54.35 in MDA and 56.25 vs 76.10 in PLA<sub>2</sub>, or  $P < 0.001$ , 65.10 and 47.60 vs 92.15 in TNF- $\alpha$ , 3.03 vs 5.44, 2.88 vs 6.82, 2.83 vs 5.36 in IL-6, respectively). The pathological scores of pancreas in the treated groups were significantly lower than that in the model control group ( $P < 0.05$ , 9.00 vs 10.05, 6.00 vs 9.00, 8.00 vs 10.05), but no marked difference was found between the treated groups.

**CONCLUSION:** The Baicalin injection has significant therapeutic effects on SAP rats, its effects are similar to those of octreotide. The Baicalin injection is also cheap and has a big application range, quite hopefully to be used in clinical treatment of SAP.

## INTRODUCTION

As one of the life-threatening severe diseases, severe acute pancreatitis (SAP) has acute onset, rapid progression, multiple complications, and its mortality has reached 20%-30%. The pathogenesis of SAP is still unknown, and no breakthrough has ever been made in its treatment. Currently, mainly somatostatin and its analog octreotide are effective drugs for SAP treatment in the clinic.

Octreotide, also named sandostatin, as an analog of

natural somatostatin plays an important role in improving the survival rate of SAP animals, inhibiting secretion of pancreatin and alleviating multiple organ injury<sup>[1-3]</sup>. However, the expensive price, short half-life and inconvenient administration of these drugs have restrained their clinical popularization, especially in remote poor areas. So, it is necessary to find some cheap and highly effective drugs.

In "Qing Yi Tang" which is a representative prescription of Chinese medicine for SAP treatment, the enormous clinical practices also suggest its sound therapeutic effects on SAP<sup>[4]</sup>. *Scutellaria baicalensis georgii* is a main material in "Qing Yi Tang" while Baicalin (monomer) is its main active constituent. The intravenous administration with very low price can overcome the shortcomings of oral administration of "Qing Yi Tang", including poor absorption and inconvenience. The *in vitro* experiments of Baicalin have proved<sup>[5-7]</sup>: it has antibacterial, anti-viral and anti-inflammatory activities. It can also inhibit platelet aggregation and eliminate oxygen-free radicals. In animal experiments, Baicalin with choleretic effect can relieve fever, inhibit the thrombin-induced transforming process from fibrinogen to fibrin, lower endotoxin generation, treat and prevent endotoxemia-induced disseminated intravascular coagulation. In addition, the initial metabolite of Baicalin in body is baicalein that can more effectively inhibit pancreatin. All these pharmacologic effects can antagonize many processes during SAP onset. Its several effects are similar to those of somatostatin and its analog such as octreotide, but it has a broader application range. It is theoretically feasible to use it for SAP treatment.

Presently, to the best of our knowledge, there has not been any study report on Baicalin treatment of SAP internationally. In this experiment, we have established the SAP rat model, discussed the effects of Baicalin in treating SAP rats, compared its effects with those of octreotide and observed the therapeutic efficacy of Baicalin and explored its therapeutic mechanisms in order to provide the reliable basis for Baicalin treatment of SAP.

## MATERIALS AND METHODS

### Experimental animals and reagents

Clean grade healthy male Sprague-Dawley (SD) rats weighing 250-300 g were purchased from the Experimental Animal Center of Medical School, Zhejiang University, China. Sodium taurocholate and sodium pentobarbital were purchased from Sigma Company, USA. Octreotide was purchased from Swiss Pharmaceutical Company Novartis, and 5% Baicalin injection (China National Invention Patent Number ZL200310122673.6) was prepared by the first author with 305 mmol/L osmotic pressure. The TNF- $\alpha$  ELISA kit was purchased from Jingmei Bioengineering Corporation (China) and the calculation unit for content is pg/mL (ng/L). The IL-6 ELISA kit was purchased from Shanghai Shenxiong Biotech Company (China) and the calculation unit for content is pg/mL (ng/L). The serum malonaldehyde (MDA) kit was purchased from Nanjing Jiancheng Bioengineering Research Institute, China. The calculation units for content are respectively nmol/mL. The serum secretory phospholipase A<sub>2</sub> enzyme assay ELA

kit (PLA<sub>2</sub>) was purchased from R&D System Ins, USA and the calculation unit for content is U/mL.

### Animal grouping

The improved Aho's method<sup>[8]</sup> was adopted to prepare SAP rat models *via* retrograde injection of 3.5% sodium taurocholate to the pancreatic duct through epidural catheter and duodenal papilla. The 135 SAP rat models were randomly divided into model control group, Baicalin treatment group and octreotide treatment group with 45 rats in each group; other 45 rats were selected as sham operation group, which only received laparotomy. All groups were then randomly subdivided into 3 h, 6 h and 12 h groups with 15 rats in each group.

### Observation index

We examined the rat mortality at 3 h, 6 h and 12 h after operation and calculated the survival, observed the gross changes of pancreas and ascites volume. Ascites/body weight ratio was measured as follows: Dry gauze was used to wipe intra-abdominal hydrops; then, a scale was used to weigh the weights of gauze before and after its soaking; the difference between weights (g) was converted into ascites volume (mL); and ascites/body weight ratio was thus obtained. After mercy killing the rats anesthetized by sodium pentobarbital in batches, the samples of pancreas were collected, fixed according to the requirements, and the pathological changes of pancreas after hematoxylin-eosin (HE) staining were observed. The contents of plasma amylase and serum TNF- $\alpha$ , IL-6, MDA and PLA<sub>2</sub> were determined *via* blood sampling from heart. The full automatic biochemical analyzer was used to determine the plasma amylase level and the calculation unit for content is U/L. The serum TNF- $\alpha$ , IL-6 and PLA<sub>2</sub> levels were determined by ELISA method.

### Pancreatic pathological score

A modified Schmidt's pathological score system was used (Table 1) and two pathologists in double-blind control condition performed the evaluation of severity of pancreatic tissue pathology. We modified the pathological score of pancreas, because the Schmidt's pathological score<sup>[9]</sup> was too difficult and complex to be used in our experiment.

### Preparation methods of animal models

Fasting but water restraint was imposed on all rat groups 12 h prior to the operation. The rats were anesthetized by intraperitoneal injection of 2% sodium pentobarbital (0.25 mL/100 g), then laid and fixed, and the routine shaving, disinfection and draping were performed. We first established the right external jugular vein transfusion passage to use the microinfusion pump for continuous transfusion (1 mL/h per 100 g) and then used 3.5% sodium taurocholate to prepare SAP model.

**Model control group:** After entering the abdomen *via* median epigastric incision, we confirmed the bile-pancreatic duct, hepatic hilus and common hepatic duct, disclosed the pancreas, identified the duodenal papilla inside the duodenum duct wall, and then used a No. 5 needle to drill a hole in the mesenteric avascular

Table 1 Improved Schmidt score of pathological changes of the pancreas

Edema	Acinar necrosis (necrotic cells/HPF)		Inflammation and perivascular infiltrate (intralobular or perivascular leukocytes/HPF)		Hemorrhage and fat necrosis (focus)	
Absent	0	Absent	0	0-1	0	Absent
Focal expansion of interlobular septae	1	1-4	1	2-10	1	1-2
Same as 1 + diffuse expansion of interlobular Septae/diffuse expansion of interlobular septae	2	5-10	2	11-20	2	3-4
Same as 2 + expansion of interacinar septae	3	11-16	3	21-30	3	5-6
Same as 3 + expansion of intercellular spaces	4	> 16	4	> 30/microabscesses	4	> 7

area. After inserting a segmental eqidural catheter into the duodenum cavity *via* the hole, we inserted the bile-pancreatic duct toward the direction of the papilla in a retrograde way, used the microvascular clamp to nip the duct head temporarily and meanwhile used another microvascular clamp to temporarily occlude the common hepatic duct at the confluence of the hepatic duct. After connecting the anesthetic tube end with the transfusion converter, we transfused 3.5% sodium taurocholate (0.1 mL/100 g) by retrograde transfusion *via* the microinjection pump (made by Zhejiang University) at a speed of 0.2 mL/min, then stayed for 4-5 min after injection and removed the microvascular clamp and eqidural catheter. After checking for bile leakage, we sutured the hole in the lateral duodenal wall, used the disinfected cotton ball to absorb up the anesthetic in the abdominal cavity and closed the abdomen. During the laparotomy in the sham operation group, we performed pancreas and duodenum turning over, observed pathological changes of multiple organs and finally closed the abdomen.

### Dosage and methods

In Baicalin treatment group, the animal experiments of 5% Baicalin injection were completed including the acute toxicity test and SAP rat treatment by small, middle and large dose. The large dose could achieve the best therapeutic effect (dose is 10 mg/h per 100 g) and the dosage referred to the result of the previous preliminary experiment. Ten minutes after successful modeling, Baicalin treatment group was first injected 5% Baicalin injection 10 mg/100 g *via* the external jugular vein passage, followed by continuous intravenous administration (10 mg/h per 100 g) by microinfusion pump; octreotide treatment group was first injected octreotide 0.2 µg/100 g *via* the external jugular vein passage, followed by continuous intravenous transfusion (10 mg/h per 100 g) by microinfusion pump at a transfusion speed of 0.2 µg/h per 100 g. All above dosages have been proved as effective dosages in the previous preliminary experiment. Both of the sham operation group and model control group were injected saline of equivalent volume at the corresponding time points after operation.

### Statistical analysis

The values were presented as mean ± SD for normal distribution variables or median and quartile range for highly skewed variables. The significance of differences among the four groups was tested using the Kruskal-

Table 2 Comparison of ascites/body weight ratio [ $\bar{M}$  (Q<sub>R</sub>)]

Groups	3 h	6 h	12 h
Sham operation	0.28 (0.23)	0.44 (0.15)	0.39 (0.22)
Model control	2.02 (0.89)	2.62 (0.97)	2.70 (0.80)
Baicalin treatment	1.00 (1.30)	1.16 (0.73)	2.29 (1.21)
Octreotide treatment	1.43 (0.62)	2.15 (0.88)	2.08 (2.21)

Wallis test for highly skewed data and analysis of variance (ANOVA) for normal distribution data. Multiple comparisons were subjected to Bonferroni correction test. The Chi-square test was used to evaluate equality of frequencies for discrete variables. Correlations were tested using the Spearman rank correlation coefficients. A *P* value less than or equal to 0.05 was considered statistically significant. All statistical analyses were conducted using SPSS version 11.5 for windows.

## RESULTS

### Survival rate

The mortality rates of the model control group were 0% (0/15), 13.33% (2/15) and 33.33% (5/15) at 3 h, 6 h and 12 h, respectively, while those of Baicalin treatment group and octreotide treatment group were 0% at different time points. The whole sham operation group survived at different time points. The survival rate of the model control group was 66.67% (10/15) at 12 h, while the survival rate of each of Baicalin treatment group and octreotide treatment group was 100% at 12 h, indicating a marked difference (*P* < 0.05).

### Comparison of ascites/body weight ratio among all groups

The ascites/body weight ratio of the model control group and treatment group significantly exceeded the sham operation group at different time points (*P* < 0.001), while there was no significant difference between the octreotide treatment group and model control group at different time points. Ascites/body weight ratio of the Baicalin treatment group was significantly less than the model control group (*P* < 0.01) and octreotide treatment group at 3 h (*P* < 0.05). Ascites/body weight ratio of the Baicalin treatment group was significantly less than the model control group and octreotide treatment group at 6 h (*P* < 0.001). However, there was no significant difference among the Baicalin treatment group, model control group and octreotide treatment group at 12 h (Table 2).

Table 3 Comparison of different indexes of blood [ $M(Q_R)$ ]

Indexes	Sham operation			Model control			Baicalin treatment			Octreotide treatment		
	3 h	6 h	12 h	3 h	6 h	12 h	3 h	6 h	12 h	3 h	6 h	12 h
Amylase (U/L)	1582 (284)	1769 (362)	1618 (302)	5303 (1373)	6276 (1029)	7538 (2934)	4342 (1496)	5130 (1591)	5571 (2307)	5419 (1670)	5058 (1314)	6531 (2280)

Table 4 Comparison of serum PLA<sub>2</sub> content (mean  $\pm$  SD)

Groups	3 h	6 h	12 h
Sham operation	14.62 $\pm$ 3.02	17.49 $\pm$ 3.82	19.02 $\pm$ 5.07
Model control	76.10 $\pm$ 16.70	101.46 $\pm$ 14.67	105.33 $\pm$ 18.10
Baicalin treatment	56.25 $\pm$ 22.43	67.91 $\pm$ 20.61	66.86 $\pm$ 22.10
Octreotide treatment	74.37 $\pm$ 19.94	63.13 $\pm$ 26.31	53.63 $\pm$ 12.28

**Comparison of plasma amylase content among all groups**

The plasma amylase content in the model control group and two treatment groups significantly exceeded that in the sham operation group at different time points ( $P < 0.001$ ). However, there was no significant difference between the Baicalin treatment group and octreotide treatment group at different time points. Although the plasma amylase content of the Baicalin treatment group was lower than that of the model control group at different time points, the difference did not reach statistical significance at 6 h and 12 h, but reached statistical significance at 3 h ( $P < 0.05$ ). Although plasma amylase content was significantly less in the octreotide treatment group compared to the model control group at 6 h ( $P < 0.05$ ), no significant difference was observed at 3 h and 12 h (Table 3).

**Comparison of serum TNF- $\alpha$  content among all groups**

Serum TNF- $\alpha$  content significantly exceeded in the model control group and treatment groups compared to the sham operation group at different time points ( $P < 0.001$ ). There was no significant difference in serum TNF- $\alpha$  content among the model control group, Baicalin treatment group and octreotide treatment group at 3 h and 12 h. However, at 6 h, both Baicalin treatment group and octreotide treatment group had significantly less serum TNF- $\alpha$  content compared to the model control group ( $P < 0.001$ ); and the octreotide treatment group had significantly less serum TNF- $\alpha$  content than the Baicalin treatment group ( $P < 0.01$ ) (Table 3).

**Comparison of serum IL-6 content among all groups**

The serum IL-6 content at 3 h and 6 h was significantly higher in the model control group and treated groups than in the sham operation group ( $P < 0.001$ ). Baicalin treatment group and octreotide treatment group had no significant difference in serum IL-6 content at all time points. The Baicalin treatment group and octreotide

treatment group had significantly lower serum IL-6 content than the model control group at all time points ( $P < 0.001$ ). However, the model control group had significantly higher serum IL-6 content than the sham operation group at 12 h ( $P < 0.001$ ), and so had the Baicalin treatment group ( $P < 0.01$ ), but no significant difference was found between the octreotide treatment group and the sham operation group (Table 3).

**Comparison of serum MDA content among all groups**

Serum MDA content significantly exceeded in the model group, Baicalin treatment group and octreotide treatment group compared to the sham operation group at different time points ( $P < 0.05$ ). Serum MDA content was significantly less in the Baicalin treatment group than the model group ( $P < 0.01$ ). Similarly, serum MDA content was significantly less in the octreotide treatment group than the model group at 6 h and 12 h ( $P < 0.05$ ). However, serum MDA content was significantly less in the Baicalin treatment group compared to the octreotide treatment group at 12 h ( $P < 0.05$ ) (Table 3).

**Comparison of serum PLA<sub>2</sub> content among all groups**

Serum PLA<sub>2</sub> content significantly exceeded in the model group and treatment groups compared to the sham operation group at different time points ( $P < 0.001$ ). At 3 h, the Baicalin treatment group had significantly less serum PLA<sub>2</sub> content than the model group ( $P < 0.01$ ), while there was no marked difference between the octreotide treatment group and the model group, and the Baicalin treatment group had significantly less serum PLA<sub>2</sub> content than the octreotide treatment group ( $P < 0.01$ ). At 6 h and 12 h, the Baicalin treatment group and octreotide treatment group had significantly less serum PLA<sub>2</sub> content than the model group ( $P < 0.001$ ). At 6 h, there was no marked difference between the Baicalin treatment group and the octreotide treatment group, whereas at 12 h, the octreotide treatment group had significantly less serum PLA<sub>2</sub> content than the Baicalin treatment group ( $P < 0.001$ ) (Table 4).

**Macroscopic and microscopic pathological changes of the pancreas**

**Sham operation group:** Macroscopically, there were only some amber ascitic fluid within the abdominal cavity, and no pathological changes visible to naked eyes in other

**Figure 1** A: Sham operation group at 12 h (normal pancreas); B: Model control group at 12 h (Interacinar edema accompanied with piecemeal necrosis of acinus, a great deal of neutrophil infiltration among acini); C: Model control group at 12 h (Massive acinus necrosis); D: Baicalin treatment group at 12 h (interlobular and interacinar edema, focal necrosis of acinus, relatively much neutrophil infiltration among acini); E: Octreotide treatment group at 12 h (Interlobular edema accompanied with focal necrosis of acinus).

organs. The overall structure of the pancreas remained intact. There were no hemorrhagic changes in the pancreas, which was yellowish without volume reduction, and no significant abnormality in the pancreas, peripancreatic and epiploon at all time points. Microscopically, most remained normal with intact gland structure, mild interstitial edema occurred in very few cases, neutrophil infiltration was occasional, and no acinar cell and fat necrosis and hemorrhage were observed (Figure 1A).

**Model control group:** Macroscopically, pathological changes of the pancreas tail were a little more obvious than those of the pancreas head; 5 min after model induction, the pancreas manifested edema, hemorrhage and necrosis. The overall severity of the pathological changes at 3 h, 6 h and 12 h increased with time after modeling. In the 3 h group, small amount of ascitic fluid mostly slightly bloody visible to naked eyes, obvious hyperemia and edema of the pancreas, partly jelly-like edema, hemor-

rhage and necrosis were observed. Most ascitic fluid after 6 h and 12 h was bloody with the larger average amount than that at 3 h. The amount and characters of ascitic fluid increased and deepened with time after modeling; the degree and range of the pancreas edema, hemorrhage and necrosis became more obvious than those at 3 h; many saponified spots on peripancreatic great epiploon and peritoneum, jelly-like change, contour vanishing, quite obvious hemorrhage and necrosis changes of the pancreatic tissue were also observed. Microscopically, in the 3 h group, obvious pancreas interstitial hyperemia and edema, small amount of inflammatory cell infiltration, sporadic focal necrosis and interstitial hemorrhage occurred among which some were hemorrhagic or lytic necrosis; in the 6 h group, pancreas interstitial edema and hemorrhage, visible focal or lamellar necrosis, comparatively large area of inflammatory cell infiltration around were observed; and in the 12 h group, obvious pancreas interstitial edema, interstitial

**Table 5** Comparison of pathological lesion score for pancreas ( $M(Q_R)$ )

Groups	3 h	6 h	12 h
Sham operation	0.00 (1.00)	0.00 (1.00)	0.00 (1.00)
Model control	8.00 (2.00)	9.00 (3.00)	10.50 (1.50)
Baicalin treatment	7.00 (1.50)	7.00 (3.00)	9.00 (4.00)
Octreotide treatment	7.00 (2.00)	6.00 (2.00)	8.00 (2.00)

hemorrhage, large area of necrosis, lobule contour damage with a large amount of inflammatory cell infiltration were observed (Figures 1B and C).

**Treatment group:** Macroscopically, in the 3 h group, the pancreatic tissue with hyperemia and edema changes, milder hemorrhage and necrosis than those of model control group were observed; in the 6 h and 12 h groups, compared with the model control group, relatively limited pancreas hemorrhage and necrosis, lighter ascitic fluid color, obviously less ascitic fluid, decreased distribution and area of saponified spot, milder pancreas hemorrhage and necrosis, and relatively integrated overall pancreas structure were observed. The pathological changes of pancreatic tissue of the octreotide treatment group resembled those of the Baicalin treatment group. Microscopically, the pathological changes of most cases in the treatment group were milder than those of the model control group at the corresponding time points, such as decreased degree of interstitial edema, reduced inflammatory cell infiltration, more clear cell structure than that of the model control group, reduced pancreas interstitial erythrocyte exudation, small amount of focal hemorrhage and necrosis with little lamellar hemorrhage and necrosis, and reduced hemorrhage and necrosis range. The pathological changes of pancreatic tissue of the octreotide treatment group resembled those of the Baicalin treatment group (Figures 1D and E).

### Comparison of pancreas pathological score among all groups

Pancreas pathological scores of the model control group, Baicalin treatment group and octreotide treatment group significantly exceeded those of the sham operation group at different time points ( $P < 0.001$ ). Pancreas pathological score of the Baicalin treatment group was significantly less than that of the model control group at 12 h ( $P < 0.01$ ). Moreover, pancreas pathological score of the octreotide treatment group was significantly less compared to the model control group at 6 h and 12 h ( $P < 0.01$ ). However, there was no significant difference between the Baicalin treatment group and the octreotide treatment group at different time points (Table 5).

## DISCUSSION

Severe acute pancreatitis (SAP) induces inflammatory reactions of pancreatic tissue itself or even systemic reactions, which is by a large portion related to excessive generation and cascade reactions of inflammatory mediators, mainly including endotoxin, oxygen-free radical, PLA<sub>2</sub>, bradyki-

**Table 6** Comparison of therapeutic efficacy of octreotide and Baicalin

Therapeutic efficacy	Curative	
	Baicalin	Octreotide
Improve survival rate	++	++

nin, complement, acute-phase protein, vasoactive amine, arachidonic acid metabolite, cytokine (lymphokine) and PAF<sup>[10-14]</sup>. This study mainly investigates the therapeutic effects of Baicalin and octreotide by observing plasma amylase content and serum TNF- $\alpha$  and IL-6 content.

TNF- $\alpha$  participates in onset and progression of early-phase inflammations of acute pancreatitis (AP), and is also related to AP severity<sup>[15,16]</sup>. Excessive generation of TNF- $\alpha$ , or imbalance between it and other cytokines will stimulate cascade reactions, induce generation of IL-1, IL-6, IL-8, *etc*, later generate inflammatory mediators, and aggravate cell damage. Current studies found serum TNF- $\alpha$  had two aspects in regulating apoptosis, namely inducing apoptosis and promoting inflammation healing when its concentration was low, while leading to necrosis of pancreatic acinar cell when its concentration was high<sup>[17]</sup>.

IL-6, mainly generated by monocyte after induction of IL-1, TNF, *etc*, has intensive inflammation-causing activity<sup>[18-21]</sup>. IL-6 can both directly increase the permeability of vascular endothelial cell, and has synergistic effect with TNF- $\alpha$ , *etc* to constitute a network of inflammatory mediators<sup>[20]</sup>. IL-6 level in serum can reflect AP severity<sup>[18,23,24]</sup>. It is generally recognized that the PLA<sub>2</sub> content or activity rises when SAP occurs<sup>[25]</sup>. The abnormal release and activation of PLA<sub>2</sub> can change lecithin into hemolytic lecithin, cause lysis and breakdown of pancreatic cell membrane, and lead to autodigestion of the pancreas<sup>[26-28]</sup>. The excessive free radicals generated in body during SAP may cause the accumulation of MDA, a lipid oxidative product. MDA content in serum can indicate the level of free radical overproduction<sup>[29,30]</sup>.

In addition, a great quantity of endotoxin can induce TNF- $\alpha$ , stimulate or promote cytokine release including IL-1 $\beta$ <sup>[31]</sup>, IL-6, TNF, and further mediate activation of leucocyte and platelet in multiple organs, such as pancreas, kidney and lung, and release lysosome, oxygen-free radical and lipid inflammatory substance. The excessive cytokines and inflammatory factors can cause waterfall-like cascade reactions, induce iNOS expression all over the body, generate a great deal of NO, damage blood vessel endothelium, and cause tissue necrosis<sup>[32-36]</sup>.

Octreotide, a medicine currently adopted in the clinic for SAP treatment, mainly achieves its therapeutic effects

by inhibiting secretion of pancreatin and other digestive enzymes, and loosening the oddi sphincter. The most important is that octreotide can block the excessive expression of inflammatory mediators and cytokines, reduce iNOS mRNA expression and NO synthesis, and then alleviate injury of multiple organs, such as pancreas and lung<sup>[37,38]</sup>. This experiment found that compared with the model control group, both the Baicalin and octreotide treatment groups could effectively reduce the generation of ascites, plasma amylase content, and serum TNF- $\alpha$ , IL-6, MDA and PLA<sub>2</sub> content, alleviate pathological changes of pancreatic tissue, and lower mortality of SAP rats.

Compared with the octreotide group, Baicalin can more significantly inhibit the generation of ascites and excessive release of IL-6 and PLA<sub>2</sub> (Table 6). In addition, Baicalin also has features, such as a broad range of pharmacological actions, low side effect, and low price<sup>[37,39]</sup>. Therefore, using Baicalin to treat SAP will be an effective and cost-effective therapy for SAP.

## Abstract

**AIM:** To investigate the effect of chitooligosaccharides on proliferation of pancreatic islet cells, release of insulin and 2 h plasma glucose in streptozotocin-induced diabetic rats.

**METHODS:** *In vitro*, the effect of chitooligosaccharides on proliferation of pancreatic islet cells and release of insulin was detected with optical microscopy, colorimetric assay, and radioimmunoassay respectively. *In vivo*, the general clinical symptoms, 2 h plasma glucose, urine glucose, oral glucose tolerance were examined after sixty days of feeding study to determine the effect of chitooligosaccharides in streptozotocin-induced diabetic rats.

**RESULTS:** Chitooligosaccharides could effectively accelerate the proliferation of pancreatic islet cells. Chitooligosaccharides (100 mg/L) had direct and prominent effect on pancreatic  $\beta$  cells and insulin release from islet cells. All concentrations of chitooligosaccharides could improve the general clinical symptoms of diabetic rats, decrease the 2 h plasma glucose and urine glucose, and normalize the disorders of glucose tolerance.

**CONCLUSION:** Chitooligosaccharides possess various biological activities and can be used in the treatment of diabetes mellitus.

## INTRODUCTION

Diabetes mellitus (DM) is a highly prevalent disease all over the world. Its long-term tissue complications that affect small and large blood vessels are directly connected with the time of patients suffering from hyperglycemia. Chitosan is a polycationic copolymer consisting of  $\beta$ -1, 4-linked 2-acetamido- D-glucose and  $\beta$ -1, 4-linked 2-amino-D-glucose units. Crab and shrimp shell wastes are currently utilized as the major industrial source of biomass for large-scale production of chitosan. Chitosan which is biodegradable, non-toxic and biocompatible has been shown to be particularly useful in many fields<sup>[1]</sup>, including food, cosmetics, biomedicine, agriculture and environmental protection. Furthermore, it can be used as a bioactive material due to its biodegradable, non-toxic and non-allergenic natures. However, chitosan shows its biological activity only in acidic medium because of its poor solubility at pH above 6.5 and low absorbability of non-digestible and high molecular polysaccharides. Therefore, recent studies on chitosan have attracted interest in converting it to chitooligosaccharides(COS), because COS not only are water-soluble but also possess versatile functional properties such as antitumor enhancing properties<sup>[2,3]</sup>, immunostimulating effects<sup>[2,4]</sup>, antimicrobial activity<sup>[5]</sup>, free radical scavenging activity<sup>[6-8]</sup>, protective effects against infections<sup>[9]</sup>, arthritis controlling activity<sup>[10]</sup>, plant disease controlling activity<sup>[11,12]</sup> and angiotensin I converting enzyme inhibitory activity<sup>[13]</sup>. However, little attention has been paid to its activity in diabetes mellitus and related mode of action.

In the present study, soluble chitooligosaccharides with low molecular weight were prepared by enzymatic hydrolysis of chitosan with chitosanase as previously described<sup>[14]</sup>. The purpose of this study was to examine the effect of chitooligosaccharides on proliferation of pancreatic islet cells and release of insulin *in vitro*.

## MATERIALS AND METHODS

### Materials

Chitosan (minimum 90% deacetylated, *Mr*: 500 000) was purchased from Jinan Haidebei Marine Bioengineering

Co., Ltd (Shangdong, China). Chitooligosaccharides were prepared by enzymatic hydrolysis of chitosan with chitosanase. NIT-1 cell line was from Institute of Medicine, Ocean University of China. Male Wistar rats (200  $\pm$  20 g) were from Laboratory Animal Centre, Institute of Medicine, Ocean University of China. Streptozotocin (STZ) was from Sigma Chemical Co. Tissue-culture medium and reagents were from Gibco. All chemicals were purchased from Sigma Chemical unless otherwise stated.

### Cell culture

Rat islets were isolated from the pancreas of male Wistar rats by collagenase digestion as previously described<sup>[15,16]</sup> and dispersed into single cells by shaking in a low calcium medium<sup>[17]</sup>. The viability of cells after isolation, determined using the fluorochrome-media-ted viability test (see below) was  $\geq$  98%. The islets were placed on glass coverslips in 35-mm petri plates and cultured in RPMI-1640 medium containing 20% fetal bovine serum (FBS), L-glutamine, and penicillin/streptomycin. NIT-1 cell line, a widely used  $\beta$  cell line for insulin secretion studies, was established from non-obese diabetic (NOD) mice transgenic for the SV40 T antigen under control of the insulin promoter, and cultured in DMEM containing 10% FBS and antibiotics (100 IU/mL of penicillin and 100  $\mu$ g/mL of streptomycin). All cultures were kept at 37°C in 950 mL/L O<sub>2</sub> and 50 mL/L CO<sub>2</sub>. The medium was changed every two days. The islet cells cultured under these conditions spread out as a monolayer within 14 d and exhibited normal responses of insulin release to glucose stimulation, as described in previous studies<sup>[18,19]</sup>.

### Effects of COS on proliferation of pancreatic islet cells and insulin release

COS were dissolved in Dulbecco's modified Eagle's medium (DMEM) without FBS and then diluted with medium to form the five degrades (10, 100, 500, 1000, and 2000 mg/L). The structure and function of cultured islet cells were observed under inverted phase contrast microscope. MTT assay was used to estimate the cell viability. Pancreatic islet cells were digested by 0.25% trypsin until appearance of unicellular suspension. Then 100  $\mu$ L suspension with the concentration of  $5.0 \times 10^4$  cells/mL was transplanted into 96-well plates. Each well had three parallels. After incubated for 24 h, the medium was changed with COS at different concentrations. Cells were incubated with 0.5 mg/mL of MTT in the last 4 h of the culture period (48 h). The medium was then decanted, 200  $\mu$ L DMSO was added to the wells, and the absorbance was determined at 492 nm using an ELISA reader. The proliferation rate was calculated ( $PR = A/A_0 \times 100\%$ ). Furthermore, the effect of COS on the viability of pancreatic islet cells was also examined at 12, 24, 36, 48, 60, 72, 96, 120, 144, 168, 192 and 216 h to study the effect of COS on the growth phase of pancreatic islet cells in 9 d. At the same time, freshly dispersed islet cells were transplanted into 24-well plates at the concentration of  $5.0 \times 10^4$  cells/mL, then divided into groups and stimulated with 100 mg/L COS for 14 d. The incubation medium was collected every 2 d and then stored at -20°C until assay. Control group was maintained in basal RPMI 1640. Each well had five parallels. At the end of the stimulation period, insulin was measured using

Figure 1 Chromatogram of chitooligosaccharids on Sephadex G-25 column.

a radio-immunoassay kit for human insulin from Linco. The experiments were performed in triplicate.

### Effect of COS on streptozotocin-induced diabetic rats

Male Wistar rats were rendered diabetic by intraperitoneal injection of STZ at 65 mg/kg. The rats whose fasting blood glucose level was above 11.11 mmol/L were used for experiments after seven days. Then the rats were randomly divided into metformin treatment group, positive control group (DM) and COS treatment groups. Test samples were given intragastrically by gavage needle for 60 successive days. COS treatment groups were given chitooligosaccharides at the concentration of 250, 500, 1500 mg/kg daily. Normal control group and DM group received an equal volume of distilled water about 10 mL/kg. Metformin treatment group was given metformin at a concentration of 200 mg/kg daily. Two-hour plasma glucose (2hPG) and urine glucose were measured every 10 d. Oral glucose tolerance was examined after 60 d of feeding study. Plasma glucose was immediately measured in duplicate using a Beckman glucose analyzer II (Beckman, Palo Alto, CA).

### Statistical analysis

ANOVA was performed with Duncan's multiple range tests. SAS was used to compare the means (SAS Institute, Inc., Cary, NC, USA).  $P < 0.05$  was considered statistically significant,  $P < 0.01$  was considered very statistically significant.

## RESULTS

### Physicochemical properties and HPLC analysis of chitooligosaccharides

Chitooligosaccharides were prepared by enzymatic hydrolysis of chitosan. Components of the hydrolysis product were separated by Sephadex G-25 (Figure 1), and component 1 analyzed by TSK-GEL G3000PWXL had an average molecular weight of 1200 u, and a degree of deacetylation of 90% by the first derivative method of UV spectrometry.

### Effects of COS on proliferation of pancreatic islet cells and insulin release

The influence of COS on pancreatic islet cell viability

**Figure 2** Effect of COS on proliferation of primary culture islet cells and  $\beta$  cell lines.

was assessed by MTT assay (Figure 2). Cell viability in the presence of different concentrations of COS was significantly higher than that in the absence of different concentrations of COS. The maximum stimulatory effect on cell viability was achieved at 100 mg/L concentration among the five samples (Figures 3A and B), the proliferation rate was 148.43% and 143.71% respectively, and had a significant difference compared with the normal control group (Figures 3C and D,  $P < 0.01$ ), suggesting that COS could accelerate the proliferation of pancreatic islet cells in 9 d, and exert direct effects on pancreatic  $\beta$  cells, promote the growth of pancreatic islet cells to maximal density in 72 h, decrease the time of latent phase and logarithm growth phase of pancreatic  $\beta$  cells (Figure 4A). The maximum stimulatory effect on cell growth phase was also achieved at 100 mg/L concentration among the five samples ( $P < 0.01$ ).

As can be seen in Figure 4B, the results showed that exposure of primary cultured pancreatic cells to COS (100 mg/L) could continuously increase the secretion of insulin from the 6<sup>th</sup> to the 14<sup>th</sup> day, and had a significant difference compared with the normal control group ( $P < 0.05$ ).

#### Effect of COS in streptozotocin-induced diabetic rats

All concentrations of chitooligosaccharides could decrease the 2hPG in 60 d (Figure 4C), the best effect was observed in the 500 mg/kg treatment group, with the 2hPG decreased to 16.14 mmol/L. The decrease rate was 47.48% compared with 2hPG before treatment.

The test of glucose tolerance was used to further evaluate the effects of different concentrations of chitooligosaccharides on improving the sensitivity of insulin. As shown in Figure 4D, if the area under the DM group curve was regarded as 100%, then AUC of the normal control group accounted for only 17.69% AUC of the DM group, while all concentrations of chitooligosaccharides could decrease AUC (Table 1). The best effect was observed in the medium dosage (500 mg/kg) treatment group, accounting for 68.69% of the area under the DM group curve ( $P < 0.01$ ).

## DISCUSSION

COS possess various biological activities and can be used in a number of industries. Unlike high molecular

**Figure 3** Photomicrograph of COS on the 48h proliferation of pancreatic islet cells and  $\beta$  cells ( $\times 100$ ) in control group (A) and 100 mg/L COS treatment group (B) of pancreatic islet cells, control group (C) and 100 mg/L COS treatment group (D) of  $\beta$  cell lines.

weight chitosan, COS which are readily soluble in water due to their shorter chain and free amino groups in D-glucosamine units and easily absorbed through the intestine, can quickly get into the blood flow and have systemic biological effects in the organism. In food industry, COS attract a greater interest as antimicrobial agents, antioxidants and enhancers of nutritional quality

**Figure 4** Effect of COS on growth phase of primary culture islet cells and  $\beta$  cell lines (A), insulin release from pancreatic islet cells (B), changes in 2 h plasma glucose (C), and in glucose tolerance test (D) after 60 d.

**Table 1** Effect of COS on changes of plasma glucose in glucose tolerance test and AUC after 60 d ( $n = 9$ , mean  $\pm$  SD)

Group	Concentration mg/kg	Plasma glucose tolerance/mmol/L				AUC mmol/L	AUC %
		0 h	0.5 h	1 h	2 h
