Extragenadal tumors can arise anywhere in the body. But, the majority are found in 3 common sites: anterior mediastinum, the retroperitoneum, and pineal gland in the brain. EGGCTs are aggressive and are usually seen in young adults. The treatment and prognosis of the disease depends on a variety of factors including the type of cancer, the tumor location, and the size of the tumor.

CASE REPORT

A 67-year-old Hispanic male presented to our institution with a complaint of epigastric pain radiating to the right upper quadrant, 8/10 in intensity, and it worsened with eating for 2 to 3 mo. The patient also complained of a weight loss of 10 pounds over the past month and vomiting for 2 d. He denied melena, hematochezia, and hematemesis. Past medical history was only significant for hyperlipidemia. The patient smoked 1 pack of cigarettes for 40 years, but denied use of alcohol. Family history was only significant for diabetes and hypertension. On physical examination, the patient felt a slight pain on deep palpation in the epigastrium with voluntary guarding. The remainder of his physical examination, including genital examination, was normal. Initial blood work obtained in the emergency room showed iron deficiency anemia, and elevated AST, ALT, and alkaline phosphatase. Tumor markers were sent and his serum alpha-fetoprotein was very high (4178; normal 0-1.8). Beta-HCG was normal. A CT scan of the abdomen showed gastric wall thickening and several 2 cm lymph nodes in mesenteric fat inferior to the stomach and liver extensively replaced with metastatic disease (Figure 1). An upper endoscopy, and endoscopic ultrasound were obtained (Figures 2 and 3). Endoscopy showed a large 8-10 cm exophytic-ulcerating lesion along the greater

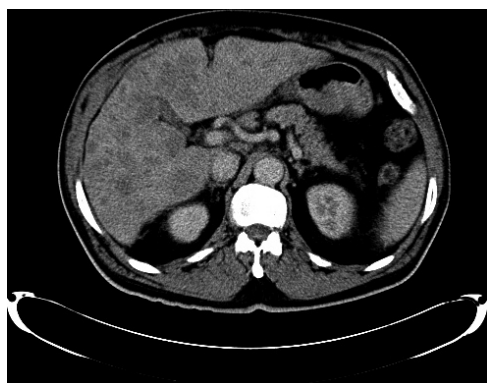

Figure 1: CT scan of the abdomen shows gastric wall thickening, several lymph nodes, and liver extensively replaced with metastatic disease.

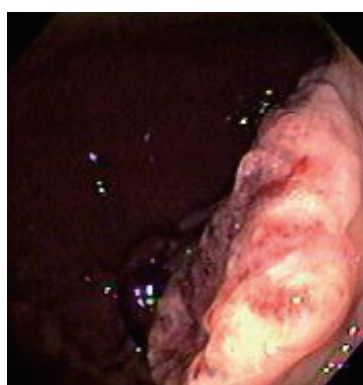

Figure 2: Upper Endoscopy shows 8-10 cm exophytic-ulcerating lesion along the greater curvature, extending from mid body to antrum

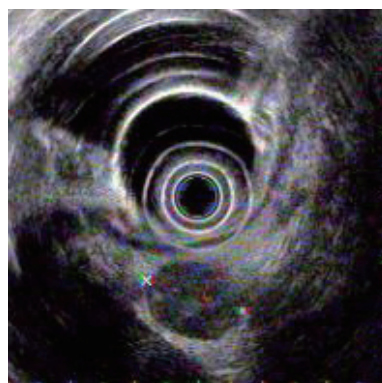

Figure 3: EUS showing a mass extending through all layers of the stomach.

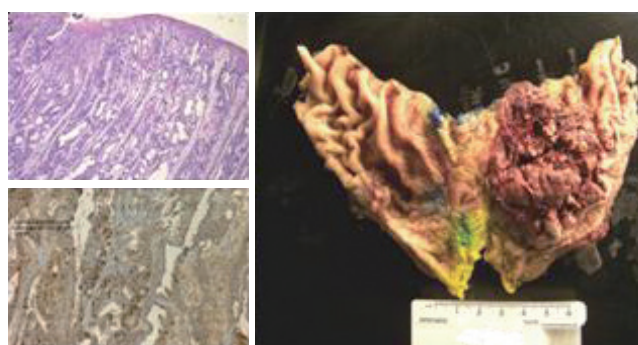

Figure 4: Immunohistochemical stains for alpha-fetoprotein strongly reactive with tumor cells.

curvature, extending from mid body to the antrum. A tissue biopsy was obtained. EUS demonstrated a mass extending through all layers of the stomach. Tissue biopsy obtained *via* EGD demonstrated invasive adenocarcinoma, which was poorly differentiated, and there were no *H Pylori* organisms. In view of the patient's very high serum alpha fetoprotein, a mixed component of extragonadal germ cell and adenocarcinoma was suspected, and the biopsy specimen was sent for special immunohistochemical staining (Figure 4). The immunohistochemical stains for alpha-fetoprotein strongly reacted with the tumor cells. Synaptophysin was focally positive and chromogranin was negative. These findings support the diagnosis of gastric adenocarcinoma, which was moderate to poorly differentiated, with features of endodermal sinus tumor and endocrine type cells.

The patient underwent exploratory laparotomy with partial gastric resection. The patient also received platinum based chemotherapy with Platinol and Taxol. He had a very eventful 2 mo of hospital course with multiple infections, upper gastrointestinal bleeding and eventual respiratory failure and death.

DISCUSSION

Extragonadal germ cell tumors are rare, representing 1% to 4% of all germ cell tumors. Seminomas account for 30% to 40% of these tumors, and non-seminomas account for 60% to 70%. The most common site of EGGCTs is the mediastinum (50%-70%) followed by the retro

peritoneum (30%-40%), the pineal gland (5%), and the sacrococcygeal area (less than 5%). In children, benign and malignant EGGCTs occur equally in males and females. In adults, only benign EGGCTs (teratomas) occur at equal frequency in both sexes; more than 90% of malignant EGGCTs occur in males^[2].

Symptoms vary depending on the site and the size of the tumor. A complete physical examination is required. Workup of EGGCTs begins with lab studies with the tumor markers alpha-fetoprotein and beta-HCG. These tumor markers provide diagnostic, staging and prognostic information. Pure seminomas and pure choriocarcinomas do not produce AFP. A CT scan of the chest, abdomen, and pelvis should be obtained. Treatment consists of surgery and chemotherapy. A classification system has been developed by the International Germ Cell Collaborative Group (IGCCG). This system categorizes tumors on the basis of histologic type, localization of metastases, and initial levels of serum AFP, beta-HCG, and LDH. Our patient who had very high levels of AFP and liver metastases expired within two months of the diagnosis^[3].

As mentioned earlier, these tumors generally present at an early age. However, few cases of EGGCTs in the elderly have been described in the literature^[4]. A case of yolk sac tumor with adenocarcinoma has been described in a 56-year-old female^[5]. On even rarer occasions, a gastric adenocarcinoma can present with a combination of these tumors. A case with such a tumor has been described in a Korean pathology journal where gastric adenocarcinoma was mixed with gastric choriocarcinoma and endodermal sinus tumor^[5].

Abstract

Celiac disease (CD) is an enteropathy with malabsorptive condition in which an allergic reaction to the cereal grain-protein (gluten) causes small intestine mucosal injury. CD is a multifactorial disorder in which both genetic and environmental factors contribute to the disease development. Mechanisms have been described to explain the pathology of CD. T cells specific for multiple gluten peptides are found in virtually all patients. Generation of such a broad T cell response may be a prerequisite for disease development. CD is associated with multiple extraintestinal presentations, including neurological deficits. Recent studies have shown a significant correlation between anti-ganglioside antibodies and neurological disorders in patients with underlying CD. Gangliosides are glycosphingolipids which are abundant in nervous system and in other tissues including gastrointestinal tract. It is not known what triggers the release of anti-ganglioside antibodies in people with gluten sensitivity. But, the mechanism is likely to involve the intestinal immune system response to ingested gliadin, a component of wheat gluten. Studies showed that mechanisms different from gluten exposure may be implicated in antibody formation, and other environmental factors may also exist. In addition, considering the fact that genetic predisposition dysregulating mucosal immune responses in the presence of certain environmental triggers like gastrointestinal infections may be strong etiological factors for developing chronic intestinal inflammation including CD, the hypothesis raised in our mind that antiganglioside antibody formation in CD may play a role not only in development of neurological complications in celiac patients, but also in development of CD itself. As presence of *Campylobacter jejuni* in other diseases with antigangliosides antibody formation has been established, we propose the possible role of *Campylobacter jejuni* in development of CD in association

with other genetic and environmental factors by the mechanism that molecular mimicry of gangliosides-like epitopes common to both lipo-polysaccharide coats of certain strains of *Campylobacter jejuni* and gangliosides in cell structure of gastrointestinal mucosa may cause an autoimmune response and consequently lead to atrophy and degeneration of mucosa possibly by apoptosis.

TO THE EDITOR

Celiac disease (CD) is an enteropathy with malabsorptive condition in which an allergic reaction to the cereal grain-protein (gluten) causes small intestine mucosal injury. CD is a multifactorial disorder in which both genetic and environmental factors contribute to the disease development^[1]. Most of CD patients carry human leukocyte antigens (HLA)-DQ2 or HLA-DQ8. But, this genetic predisposition cannot fully explain the pathogenesis of CD, as CD just develops in minority of HLA-DQ2 and HLA-DQ8 positive individuals^[2]. Several mechanisms have been described to explain the pathology of CD. Gluten proteins have several unique factors that contribute to their immunogenic properties. They are extremely rich in amino acid proline and glutamine. Due to high proline content, gluten is highly resistant to proteolytic degradation within the gastrointestinal tract. Moreover, high glutamine content makes gluten a good substrate for tissue transglutaminase (Ttg), which can convert glutamine into negatively charged glutamic acid. Such modified gluten peptides can bind to HLA-DQ8 and subsequently cause T cell response. T cells specific for multiple gluten peptides are found in virtually all patients. Generation of such a broad T cell response may be a prerequisite for disease development^[3]. CD is associated with multiple extraintestinal presentations, including bone disease, endocrine disorders and neurological deficits^[4].

Neurological disorders and CD

Limited neurological disorders are recognized in association with CD. But, their spectrum becomes wider as complications of prediagnosed CD and/or as an initial manifestation of CD. Neurological disorders include cerebellar ataxia, peripheral neuropathy, epilepsy, dementia, migraine, encephalopathy and Guillain-Barre-like syndrome. Vitamin deficiency due to malabsorption was a first described as the etiology of neurological manifestations. But, it could not explain neurological disorders in patients with normal level of vitamins or in individuals with vitamin deficiency, but without neurological syndromes^[5]. Recent studies have shown a significant correlation between anti-ganglioside antibodies, and neurological disorders in patients with underlying CD. Gangliosides are glycosphingolipids which are abundant in the nervous system and in other tissues including gastrointestinal tract^[6]. It is not known what triggers the release of anti-ganglioside antibodies in people with gluten sensitivity. But, the mechanism is likely to involve the intestinal immune system response to ingested gliadin, a component of wheat gluten. Two mechanisms have been postulated for the release of anti-ganglioside antibodies: one is the presence of ganglioside-like epitopes in gliadin and the other is the potential for complex formation between gliadin and GM1 ganglioside. One study evaluated the feasibility of these two mechanisms, and found that certain gliadin spices are glycosylated. But, they do not appear to carry GM1-like carbohydrate moieties^[7]. In contrast, *in vivo* formation of gliadin-GM1 complexes is probably feasible, since abundant GM1 is found in gut epithelial cells^[7].

It was reported that antibody titer is reversed in some patients after gluten-free diet, whereas it increases in other patents after such a diet^[8], suggesting that mechanisms different from gluten exposure may be implicated in antibody formation, and other environmental factors may exist.

Hypothesis

The above findings, and the fact that a genetic predisposition dysregulates mucosal immune responses in the presence of certain environmental factors such as gastrointestinal infections are strong etiological factors for development of chronic intestinal inflammation including CD (We can define the hypothesis in our mind that anti-ganglioside antibody formation in CD may play a role not only in developing neurological complications of celiac patients, but also in developing CD itself).

Among disorders associated with anti-ganglioside antibody formation, we focused on an autoimmune disorder with some neurological presentations like CD, and Guillain-Barre syndrome (GBS). In GBS a preceding infection may trigger an autoimmune response through

molecular mimicry in which the host generates an immune response to an infectious organism which shares ganglioside-like epitope with the host's peripheral nervous system. Among bacterial organisms which have a role in development of GBS, *Campylobacter jejuni* has been best studied, showing that about 25% of patients with GBS have a recent *Campylobacter jejuni* infection. Now, it is well established that lipo-oligosaccharide located in the wall of *Campylobacter jejuni* cross-reacts with ganglioside in axonal membrane of neurons.

We proposed a possible role of *Campylobacter jejuni* in development of CD in association with other genetic and environmental factors by the mechanism that molecular mimicry of gangliosides-like epitopes common to both lipo-polysaccharide coats of certain strains of *Campylobacter jejuni* and gangliosides in cell structure of gastrointestinal mucosa may cause an autoimmune response, and consequently lead to atrophy and degeneration of mucosa damage possibly by apoptosis in a manner similar to nerve tissue injury in GBS. The proposed mechanism can also explain the presence of neurological manifestations of CD.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Received: June 27, 2007 Revised: July 9, 2007

Abstract

Transient elastography is a recently developed non-invasive technique for the assessment of hepatic fibrosis. The technique has been subject to rigorous evaluation in a number of studies in patients with chronic liver disease of varying aetiology. Transient elastography has been compared with histological assessment of percutaneous liver biopsy, with high sensitivity and specificity for the diagnosis of cirrhosis, and has also been used to assess pre-cirrhotic disease. However, the cut-off values between different histological stages vary substantially in different studies, patient groups and aetiology of liver disease. More recent studies have examined the possible place of transient elastography in clinical practice, including risk stratification for the development of complications of cirrhosis. This review describes the technique of transient elastography and discusses the interpretation of recent studies, emphasizing its applicability in the clinical setting.

INTRODUCTION

The management and prognosis of chronic liver disease is strongly influenced by its severity. While percutaneous liver biopsy remains the gold standard, there is increasing awareness, not only of the associated morbidity and mortality of the procedure, but also its diagnostic limitations. There is considerable sampling variability, and inter- and intra-observer variation in the assessment of liver pathology. Antifibrotic therapies are in development, but it has been stated that “the lack of robust markers of fibrosis represents the single greatest factor limiting both the validation of progression or regression of fibrosis and the testing of antifibrotic therapies”^[1].

A number of approaches to non-invasive assessment of chronic liver disease have been developed. Serum markers, and serum panel markers for the assessment of chronic liver disease, such as the APRI (AST to platelet ratio index) score, Enhanced (European) Liver Fibrosis (ELFTM) test and FibroTest, have been proposed, and are the subject of several comprehensive reviews^[2-4]. Investigations based on imaging modalities, including ultrasound and magnetic resonance, are liver-specific and provide structural information related to the liver^[5]. Microbubble contrast-enhanced ultrasound to obtain hepatic vein transit times (HVTT) and phosphorus-31 magnetic resonance spectroscopy (³¹P MRS) have been shown to delineate cirrhotic and pre-cirrhotic disease stages, but require considerable operator skill and access to the relevant technology^[6-10]. Other MR techniques, such as diffusion-weighted imaging (DWI) and ultrashort echotime (UTE) have shown promise, but require further development^[11,12]. Moreover, these techniques require assessment in larger subject groups in the setting of multi-centre trials.

Liver stiffness measurement using transient elastography (TE) (FibroScan[®]) is a recently developed technique designed for the assessment of liver fibrosis, and has been extensively evaluated in several recent studies. The aim of this article is to review the current data on the use of transient elastography in clinical practice and to make recommendations for future research. A Medline search using the terms “FibroScan” and “transient elastography” was conducted. The proceedings of the 41st annual meeting of the European Association for the Study of the Liver 2006, and the 57th annual meeting of the American Association for the Study of Liver Diseases 2006 were also searched for relevant articles.

THE BASIS OF TRANSIENT ELASTOGRAPHY

Transient elastography allows liver stiffness measurement (LSM) which enables the assessment of liver disease severity, using a 1-dimensional ultrasound transducer and receiver mounted on the same axis as a vibrator, producing a low-frequency pulse or shear wave. When the probe tip is placed perpendicularly against the skin between the ribs overlying the liver and triggered, the rate of progression of the shear wave is measured.

The speed of propagation depends on the elasticity or stiffness of the tissue under examination and is measured by a series of ultrasonic pulses, which detect the transient local deformations in the liver tissue as the shear wave progresses. The elasticity of the liver is derived from the velocity of the wave approximating to the Young's modulus, E , according to the equation: $E = 3\rho V_s^2$, where V_s is the shear velocity and ρ is the mass density, assumed to be close to that of water. The deformation of tissue is plotted as a function of time and depth to create a two-dimensional "elastogram". The slope of the elastogram represents the speed of propagation and thus the liver stiffness, expressed in kPa^[13].

This technique is simple to learn, can be performed quickly by a single operator, and provides an objective measure of liver stiffness. TE has been employed in a number of clinical paradigms over the last few years, however, there is at present no consensus on its indications for use, interpretation and applicability.

ANALYSIS AND EVALUATION

Most studies carried out to evaluate the performance of transient elastography compare LSM to the histological assessment of liver biopsy. Of these, the METAVIR scoring system which is widely used in clinical practice has been employed in the majority of studies^[14]. Fibrosis is staged semi-quantitatively on a five-point scale from F0 to F4 (F0, no fibrosis; F1, portal fibrosis without septa; F2, portal fibrosis and few septa; F3 numerous septa without cirrhosis; F4, cirrhosis). Divisions of clinical significance are considered to be between F1 and F2 (from minimal to significant fibrosis) and between F3 and F4 (from fibrosis to cirrhosis). The data obtained is commonly represented by boxplots with liver stiffness (or log₁₀ liver stiffness) on the y axis and fibrosis stage on the x axis, representing the median, interquartile range and range of values for individuals at each fibrosis stage. Despite an apparently high diagnostic accuracy, there is substantial overlap between groups, especially in the pre-cirrhotic stage of liver disease. This has clinical implications since for a given liver stiffness measurement, the patient's true fibrosis score may vary from F0-1 to F4^[15].

A major criticism of liver biopsy and an important stimulus to the development of non-invasive techniques is the small portion of liver that is assessed. The specimen obtained by standard liver biopsy techniques represents just 1/50 000 of the liver, and typically only 16% of such biopsies exceed the optimal length of 25 mm required

for adequate histological assessment^[16]. This results in significant sampling variability since hepatic fibrosis, inflammation and steatosis may have a patchy spatial distribution within the liver. Added to this drawback is the presence of inter- and intra- observer variability in histological assessment, making this "gold-standard" considerably flawed. Thus, non-invasive measures such as TE are judged by liver biopsy which may be a flawed standard. Clearly, the results obtained should be regarded as a probability of correctly predicting liver fibrosis and interpreted in the context of clinical, epidemiological and biochemical data, and moreover should be correlated prospectively with robust clinical outcome measures.

ASSESSMENT OF DIAGNOSTIC ACCURACY

While the sensitivity, specificity, positive and negative predictive values describe the performance of a test with respect to a gold-standard, diagnostic accuracy provides a measure of the overall performance of a test. Diagnostic accuracy of transient elastography with respect to histology has been measured in clinical studies using the area under the receiver operator characteristic (ROC) curve, a convenient non-parametric method for the assessment of diagnostic tests, compared to a gold-standard. The sensitivity is plotted against 1- specificity for all possible cut-off values between two states. For example, this could be expressed as: positive or negative; cirrhosis or no cirrhosis; insignificant or significant fibrosis. A measure of diagnostic accuracy of the test may be derived, whereby an area near 1 represents high diagnostic accuracy. ROCs may be used to select cut-off values appropriate to different scenarios. Cut-off values may then be selected for a given situation according to the required sensitivity or specificity of a given value to distinguish the two states. This allows cut-off values to be chosen to answer clinically relevant questions. For example, to rule out cirrhosis effectively in a group of patients, a cut-off value with a specificity of 95% may be used, indicating that there is a 95% probability that patients below the cut-off value will not have cirrhosis. Alternatively, an optimum cut-off may be calculated, where the cut-off is chosen at the point where the sum of sensitivity and specificity is maximal, although this is affected by the shape of the ROC curve and therefore may vary between studies. A more inclusive measure would be obtained by using a cut-off associated with high sensitivity but lower specificity.

The largest study published to date demonstrates that different cut-off values for the diagnosis of cirrhosis exist, depending on the sensitivity and specificity required for the decision and for different aetiologies, such as chronic hepatitis B, chronic hepatitis C and alcohol-related and non-alcoholic related fatty liver disease (Table 1)^[17].

TRANSIENT ELASTOGRAPHY FOR STAGING OF HEPATIC FIBROSIS

Initial clinical studies using TE investigated the ability of

Table 1 Liver stiffness cut-off values for the diagnosis of cirrhosis according to the primary cause of liver disease

	Optimum cutoff (kPa)		
	Hepatitis C (<i>n</i> = 298)	Hepatitis B (<i>n</i> = 122)	Alcohol or NASH (<i>n</i> = 122)
Sensitivity 95%	10.0	6.0	13.2
Max. sum of sensitivity and specificity	10.4	10.3	21.5
Best diagnostic accuracy	20.2	16.9	21.5
Specificity 95%	14.1	14.3	27.7

NASH: Non-alcoholic steatohepatitis. Data obtained from Ganne-Carrie *et al* 2006^[17].

the technique to assess hepatic fibrosis when compared to the gold standard of liver biopsy. This was assessed by Sandrin and colleagues in a “proof-of-principle” study. They demonstrated a graduated increase in liver stiffness with increasing hepatic fibrosis^[13]. Chronic hepatitis C was chosen as the paradigm for many studies as the patients are numerous and the natural history of the disease and histological classification systems have been well described^[14,18]. Other workers have investigated the ability of TE to assess fibrosis compared to liver biopsy in several disease paradigms, as summarised in Table 2^[13,15,17,19-25].

Hepatic fibrosis is a complex and multistep process. Therefore, a precise description of disease severity may require assessment of more than one aspect of the disorder. TE measures liver stiffness which is thought to be due largely to the extent of fibrosis. Indeed digital image analysis demonstrates a correlation between the fibrotic area and liver stiffness^[26]. Yet, the extent of fibrosis does not provide the complete picture. Histological scoring systems are not linear and in addition to the extent, they describe the pattern of deposition of fibrous tissue^[18,14]. The effect of collagen cross-linkage on liver stiffness, associated with more severe disease, has not been clearly established. More recently, a strong relationship between liver stiffness and the hepatic venous pressure gradient (HVPG) has been described, demonstrating an association with portal hypertension^[27]. The relative contribution of fibrosis, inflammation and haemodynamic changes have yet to be determined.

A recent well-conducted study by Fraquelli and colleagues looked specifically at the reproducibility of LSM in 195 patients with liver disease of mixed aetiology (predominantly HCV)^[24]. The results obtained by two different operators working under highly regulated conditions, showed a very high degree of inter-observer agreement, with an intraclass correlation coefficient (ICC) of 0.98, representing an estimated 98% of variability due to patient characteristics, as opposed to observer variability. This agreement was substantially reduced when groups such as overweight patients, those with histological or ultrasound evidence of hepatic steatosis and especially those with mild disease (ICC 0.6 for METAVIR F0-1 *vs* 0.99 for F ≥ 2) were assessed. There were stringent inclusion criteria such as inclusion of only those patients in whom a success rate of > 65% was achieved and where the

interquartile range of the readings was less than 30% of the median. Additionally, 76% of liver biopsy specimens exceeded 20 mm in length, thus minimising sampling error. Despite the high reproducibility of LSM, there was substantial overlap in the findings between adjacent stages of hepatic fibrosis, which the authors acknowledged would limit the diagnostic accuracy of TE, particularly in intermediate fibrosis stages.

Disease activity or necro-inflammation are not directly assessed by TE, although LSM has been shown to increase with increasing necroinflammatory scores at histology^[24], and in biochemically-assessed flares of hepatitis and cirrhosis^[28]. Steatosis is a cause as well as a consequence of chronic liver disease^[29], and its effect on liver stiffness is believed to be minimal based on multivariate analyses in studies investigating other endpoints^[15,30]. However, studies assessing the severity of liver stiffness stratified by the degree of steatosis are awaited. The development of serum panel markers of hepatic fibrosis demonstrates recognition of the fact that multiple diagnostic measures are required. Castera and colleagues compared TE with FibroTest, an indirect serum panel marker, and the AST to platelet ratio index (APRI) in a cohort of patients with chronic hepatitis C, and found equivalent results with these techniques, but noted that a combination of TE and the serum panel marker provided the greatest diagnostic accuracy^[19]. On this basis, an algorithm was proposed whereby liver biopsy can be avoided in most patients with chronic hepatitis C when the tests are in agreement^[19]. Other studies have demonstrated a similar diagnostic accuracy of TE in the context of hepatitis C virus (HCV) and human immunodeficiency virus (HIV) coinfecting patients^[23], and also in the presence of biliary fibrosis in patients with primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC)^[20,23].

CIRRHOSIS AND ITS COMPLICATIONS

In view of the wide range of LSM for any single fibrosis stage, attention has turned to the use of FibroScan in the diagnosis of cirrhosis and of its complications such as varices, risk of variceal bleeding, hepatocellular carcinoma and ascites. Foucher and colleagues examined prospectively a cohort of patients with liver disease of varying aetiology^[25]. In addition to establishing the cut-off values for fibrosis of varying severity as assessed by liver biopsy, they calculated the cut-off values below which there was a 90% chance that complications such as varices (stage 2/3) (27.5 kPa), Child-Pugh score of B/C (37.5 kPa), ascites (49.1 kPa), and oesophageal bleeding (62.7 kPa) were absent. Although the number of subjects with each complication was small (between 14 and 42 cases), these cut-off values may serve to identify patients with cirrhosis at risk of such complications. However, history of ascites, hepatocellular carcinoma, and variceal bleeding may be readily obtained by direct questioning of the patient, therefore for these observations to be clinically useful, they need to be borne out in prospective studies on the development of these complications over time. Kazemi and colleagues correlated endoscopic evidence of oesophageal varices with LSM in a cohort of patients with

Table 2 Results of studies in which liver stiffness was compared with histological fibrosis stage (METAVIR system) to establish diagnostic accuracy and cut-off values

Author, yr	Patient group	Number of subjects	Cut-off for $F \geq 2$ (kPa)	AUROC $F \geq 2$	Cut-off for $F = 4$ (kPa)	AUROC $F = 4$

Ziol M <i>et al</i> 2005 ^[15]	HCV	251	8.8 (56%; 91%)	0.79	14.6 (86%; 96%)	0.97
Sandrin <i>et al</i> 2003 ^[13]	HCV	106		0.88		0.99

Cut-off values were those proposed by the authors. If more than one cut-off value was available, the value set for optimum diagnostic accuracy (i.e. cut-off at which sensitivity (se) + specificity (sp) is maximal) was used. Cut-off values are followed by the relevant sensitivity and specificity in parenthesis. HCV: Hepatitis C virus; HIV: Human immunodeficiency virus; PSC: Primary sclerosing cholangitis; PBC: Primary biliary cirrhosis.

compensated cirrhosis, and observed that a cut-off value of 19 kPa predicted varices (stage II / III) with a sensitivity of 91% and specificity of 60%^[31]. These findings suggest that endoscopic surveillance can be avoided in up to 60% patients with cirrhosis.

TOWARDS THE CLINIC

Ganne-Carrie and coworkers have published the largest series to date, but have concentrated on separation of cirrhotic from precirrhotic disease^[17]. These authors highlighted the fact that the cut-off values vary on the basis of the aetiology of liver disease as well as the level of sensitivity and specificity required for the issue under question (Table 1). There were substantial differences in the cut-off values for the prediction of cirrhosis with 95% specificity depending on the number of patients studied (775 *vs* 1007). It remains to be seen whether the cut-off values vary depending on the population of interest, for example in affluent societies with high level of co-existent type 2 diabetes and hepatic steatosis, compared to a group with few risk factors for steatosis.

Of particular interest is the question whether liver stiffness measurement affects clinical decision making. For example, a non-invasive technique, such as TE, is particularly desirable in patients with bleeding disorders, such as haemophilia. Two studies have addressed this issue. Masaki and colleagues correlated LSM with ultrasound assessment of liver disease and several serum markers in haemophiliacs coinfecting with HCV and HIV, although the findings were not linked to a clear standard or to clinical outcome measures and decisions^[32]. Posthouwer and colleagues studied a cohort of patients with haemophilia and chronic hepatitis C in whom percutaneous liver biopsy was contraindicated^[33]. Cut-off values from a previous study were applied^[19] and validated in a separate cohort of patients without a bleeding disorder. This study demonstrated the pragmatic use of TE in a specific scenario with acknowledgement that there will be inaccurate assessment in a proportion of patients. In such a scenario, a false positive test may result in a patient with mild disease receiving antiviral therapy while a patient

with a false negative test, may have severe disease and not receive treatment. It can be argued that the latter group may have a detrimental outcome, and therefore a cut-off with a higher sensitivity is indicated.

An important indication for non-invasive staging of hepatitis C-related liver disease is to determine whether antiviral treatment is appropriate in a particular patient^[15]. However, on the basis of recent studies in patients with mild hepatitis C, current UK treatment guidelines suggest that treatment is both clinically effective and cost-effective in histologically mild, moderate and severe stages of pre-cirrhotic disease^[34-36]. Increasingly, patients with functionally-compensated cirrhosis are being treated, although the likelihood of a good response to treatment is smaller in this group. Since treatment is not contraindicated in any histological group of patients with hepatitis C, the role of such non-invasive technologies should be questioned. It is possible that the evaluation of liver stiffness may provide risk assessment on the basis of which further investigations should be planned. Such a scheme may allow a period of “watchful waiting” prior to a decision on starting treatment, in addition to providing reassurance to patients with mild disease. Another area of interest is the patient’s response to treatment. Preliminary data indicates that LS decreases in patients with hepatitis C after treatment with pegylated interferon and ribavirin and that the decrease is greater in virologic responders compared to non-responders^[37]. This alteration may reflect biochemical changes associated with disease activity, as opposed to changes in fibrosis *per se*, and the long term outcome data in a large cohort of patients is awaited.

Nahon and colleagues addressed the issue of how LSM may affect clinical assessment by inviting four physicians to predict the fibrosis stage on the basis of routine history, physical examination and biochemical tests^[38]. Liver stiffness measurement was performed at the time of liver biopsy. The physicians were allowed to modify their estimate of disease severity in the light of the LSM findings, which were then compared with the biopsy results. LSM did not significantly enhance the physicians’ prediction of pre-cirrhotic disease staging compared to the assessment based on routine investigations. In the

prediction of cirrhosis, the addition of LSM improved the diagnostic accuracy by about 10% in results obtained by 3 out of the 4 physicians.

The utility of TE in routine clinical assessment of precirrhotic disease appears questionable in the light of data currently available. Routine abdominal ultrasound is carried out in nearly all patients with chronic liver disease to assess structural abnormalities, and to look for cholestasis, portal hypertension and hepatocellular carcinoma. The presence of findings such as increased heterogeneity, irregular liver outline or nodularity, caudate lobe hypertrophy, increased spleen size, and portal vein Doppler blood flow measurement all provide evidence of cirrhosis, with high specificity, but relatively low sensitivity^[39,40]. It is possible that routine ultrasound enhances the physician's assessment of whether a patient has cirrhosis, while in addition providing the additional information described above. However, it should be noted that in the study by Nahon and colleagues, of the 15 patients misclassified as cirrhosis after LSM by the senior physicians, 3 had features of cirrhosis on ultrasound or endoscopy^[38]. It is not clear how many of the patients correctly classified on the basis of LSM would have also been correctly classified had routine ultrasound information been provided. Therefore, before LSM is recommended for routine clinical use, the existing technologies should be compared by employing analogous methods of analysis.

CONCLUSION

Assessment of TE using FibroScan is a novel technique that has been evaluated in a number of well-conducted studies. It is a safe, acceptable and quick technique that provides an objective and reproducible measure of liver stiffness. LSM correlates with histological fibrosis score, but the cut-off values vary depending on the study referred to, the aetiology of the disease and the sensitivity and specificity required. LSM provides high diagnostic accuracy for the detection of cirrhosis, making it a potentially useful tool for population-based screening for cirrhosis in areas of high prevalence. However, the delineation of precirrhotic stages is less clear, although LSM compares well with serological markers of fibrosis such as the APRI score and FibroTest^[19]. LSM has a number of drawbacks which include that it is technically challenging in obese individuals, where it is associated with reduced success rate; it is not possible to perform in the presence of significant ascites; and the effect of marked steatosis has not been addressed.

Recent studies have begun to address the likely place of LSM in routine clinical practice and the impact it may have on physicians' assessment of disease severity. However, several important questions remain to be resolved including: what are the relative contributions of fibrosis and haemodynamic alterations on LSM? How does steatosis affect LSM? Which cut-off values should be used for which indication? Does LSM substantially add to the information already obtained by routine clinical assessment, abdominal ultrasound and simple blood tests such as the APRI score? Is LSM sufficiently sensitive to detect changes in fibrosis over the long term; in terms of both disease progression and response to treatment?

While such information is awaited, LSM is being performed increasingly worldwide as a result of increased awareness of the technique. The following recommendations are made for consideration when employing the technique: (1) As different cut-off values exist for different diseases, the diagnosis should always be obtained prior to interpretation of the LSM. (2) The clinical question should be defined in order that a cut-off value is used incorporating the appropriate sensitivity and specificity. (3) Criteria in terms of success rates and minimum number of readings should be defined so that assumptions are not made on the basis of inadequate data. (4) Comparison should be made with liver biopsy, if available, in order to provide continual validation. (5) The process of continuous audit should be instituted, with particular emphasis on how such measurements influence decision-making.

THE FUTURE OF IMAGING BIOMARKERS

Fibrosis and fibrogenesis is a complex multistep process. It would be surprising if a single biomarker was able to provide complete evaluation of the disease. FibroScan is an innovative and user-friendly technology but, despite strong academic and commercial promotion, its limitations have been described in a several well-conducted studies. Assessment of precirrhotic disease and the longitudinal assessment of change in fibrosis have not been fully evaluated. A comprehensive, non-invasive assessment of chronic liver disease will be very helpful for baseline assessment of disease and to evaluate the impact of new antifibrotic therapies. Serum panel markers and imaging techniques including ultrasound and magnetic resonance modalities need to be investigated longitudinally in a number of disease states in order to develop and identify the most effective combination of tests, of which TE with FibroScan may be one. The challenge is to develop and validate such a protocol, and to correlate the results with clinically meaningful outcome measures.

Abstract

Anemia is a frequent complication in patients with inflammatory bowel disease (IBD), and is associated with decreased quality of life and increased rate of hospitalization. The primary therapeutic targets of IBD-associated anemia are iron deficiency and anemia of chronic disease. An important prognostic parameter of the success or failure of therapy is the outcome of the underlying disease. Iron deficiency should be appropriately managed with iron supplementation. However, the use of oral iron therapy is limited by several problems, the most important being gastrointestinal side effects leading occasionally to disease relapse and poor iron absorption. Intravenous iron preparations are more reliable, with iron sucrose demonstrating the best efficacy and tolerability. Treatment with erythropoietin or darbepoetin has been proven to be effective in patients with anemia, who fail to respond to intravenous iron. Patients with ongoing inflammation have anemia of chronic disease and may require combination therapy comprising of intravenous iron sucrose and erythropoietin. After initiating treatment, careful monitoring of hemoglobin levels and iron parameters is needed in order to avoid recurrence of anemia. In conclusion, anemia in the setting of IBD should be aggressively diagnosed, investigated, and treated. Future studies should define the optimal dose and schedule of intravenous iron supplementation and appropriate erythropoietin therapy in these patients.

INTRODUCTION

Anemia is a frequent and serious complication in patients with inflammatory bowel disease (IBD), with reported prevalence varying from 6% to 74%^[1,2]. Anemia is associated with a decrease in the quality of life and increased rate of hospitalization^[3,4]. In the past, it was common to ascribe anemia as an unavoidable accompaniment of IBD, but recently, correction of anemia is being emphasized as a specific therapeutic objective in these patients^[5,6]. Both iron deficiency and anemia of chronic disease contribute to the development of anemia in IBD^[3]. The therapeutic targets in the treatment of IBD patients with anemia are iron deficiency and the mechanisms underlying anemia of chronic disease^[3].

Anemia is defined as "a reduction in the number of circulating RBCs, hemoglobin concentration, or the volume of packed red cells (hematocrit) in the blood"^[7]. The World Health Organization (WHO) specifies the laboratory definition of anemia as hemoglobin below 120 g/L (non-pregnant females), 110 g/L (pregnant women) and 130 g/L (men). A hemoglobin level below 100 g/L is commonly considered as severe anemia and should be aggressively treated. However, in clinical practice, the timing of therapeutic intervention is based not only on the hemoglobin level but also on the relative degree of hemoglobin reduction, the underlying comorbidities, and the presence or absence of symptoms.

Anemia is an important manifestation of IBD and patients with anemia have increased disease severity and reduced quality of life, indicating the need for effective treatment. The underlying cause of anemia in IBD is either iron deficiency, resulting from intestinal bleeding due to mucosal inflammation and ulceration, or the so-called anemia of chronic disease, resulting from inhibition or suppression of erythropoiesis and dysfunction of iron transport, mediated by inflammatory cytokines^[3,4]. Thus, the pathogenesis of IBD-associated anemia is complex and represents an example of combined iron deficiency anemia (IDA) and anemia of chronic diseases (ACD). Cobalamin or folate deficiency, drug induced anemia, and other causes of anemia such as haemolysis are seen less frequently.

Most patients with IBD-associated anemia respond to iron therapy. Oral iron supplementation appears to be effective for short periods but drug intolerance leads to discontinuation of therapy in up to 21% of patients^[8]. Moreover, the use of oral iron is associated with several limitations^[3]. By contrast, intravenous administration of iron sucrose has been found to be an effective treatment in these patients^[9,10]. Erythropoietin (EPO) administration

is associated with beneficial results in patients who are refractory to oral iron^[3]. The combination of iron sucrose and EPO has been proposed as the most efficacious treatment in IBD-associated anemia^[6,11]. The aim of the present review is to transfer our knowledge, especially the strategies for stimulating erythropoiesis, into the current clinical practice of treatment of anemia in IBD.

ANEMIA IN IBD

Iron deficiency (ID) is the most common cause of anemia in IBD. Iron, which is present in all mammalian cells, is of pivotal importance not only for oxygen transport and storage but also for many non-hematological functions. In normal subjects, the daily iron loss is 1-2 mg which needs to be replaced from the diet. The causes of iron deficiency are reduced intake, either from dietary deficiency or malabsorption, or increased losses. Chronic intestinal bleeding in IBD may exceed the quantity of iron that is absorbed from the diet, resulting in a negative iron balance^[12]. Such an imbalance occurs frequently in IBD, leading to anemia.

When the rate of iron supply to the developing erythroblast is reduced as a result of ID, red cell haemoglobinisation is impaired. The red cells emerging from the bone marrow are microcytic and hypochromic. The increase in EPO response secondary to a drop in haemoglobin levels stimulates erythropoiesis, creating an even greater demand for iron, which is unmet. As a result, there is a high degree of ineffective erythropoiesis^[13]. The most appropriate definition of iron deficiency is bone marrow proliferation in response to intravenous iron supplementation, an approach that has not been studied in IBD. Moreover, in addition to a possible iron deficiency in anemia of chronic disease, functional iron deficiency occurs because of intense erythropoiesis^[14,15] during therapy with erythropoietic agents, with a decrease in transferrin saturation and serum ferritin. Furthermore, during erythropoietin therapy, the absorption of iron increases by as much as 5 fold^[16].

After iron deficiency, anemia of chronic disease is the next important cause of anemia in these patients. There is general correlation between disease activity and the severity of anemia. Abnormal iron metabolism and improper use of iron stores are the typical features of anemia of chronic disease, characterized by low circulating iron concentration in the presence of ample reticuloendothelial iron stores. Thus, anemia of chronic disease can be easily diagnosed by the presence of hypoferraemia and increased serum levels of ferritin.

Because of differences in the therapeutic response, it is important to distinguish anemia of chronic disease from iron deficiency. Iron parameters need to be checked regularly. When both ID and ACD are present, many of the laboratory measures of iron status become unreliable. Circulating iron concentrations are subnormal in both situations. Measurement of serum ferritin reflects the level of iron in the body stores. When serum ferritin is less than 15 µg/L, iron stores are definitely depleted. When ferritin is less than 30 µg/L there is a strong suggestion of iron deficiency, whereas, a value > 200 µg/L indicates

that iron deficiency is unlikely. Moreover, diagnosis of iron deficiency in the setting of IBD is difficult and no single laboratory test is reliable. Undoubtedly, low serum ferritin levels are indicative of iron deficiency. However, in the presence of inflammation, ferritin levels may increase despite iron deficiency. Furthermore, in IBD patients the diagnostic criteria for iron deficiency depend on the level of inflammation, thus in quiescent disease a serum ferritin < 30 µg/L or TfS < 15% indicates iron deficiency, whereas, in active disease a value < 100 µg/L suggests iron deficiency. A combination of true iron deficiency and anemia of chronic disease is possible when the ferritin level is between 30 and 100 g/L. If necessary, a bone marrow aspirate can be examined, which will show absence of macrophage iron in iron-deficient subjects. The ratio of soluble transferrin receptor/log ferritin has also been proposed as a marker for differentiating ID from ACD^[17]. A ratio above 2 is suggestive of iron deficiency, whereas a ratio of less than 1 indicates anemia of chronic disease.

IRON TREATMENT

Since iron deficiency is the most prevalent cause of IBD-associated anemia, iron supplementation is the most relevant therapeutic intervention.

Oral iron preparations

Treatment of anemia in IBD with oral iron is limited by poor absorption, drug intolerance, and induction of oxidative stress at the site of bowel inflammation^[3]. Moreover, there is evidence that oral iron may increase the disease activity in IBD. Oral iron supplements commonly contain iron in the form of ferrous salts (ferrous sulphate, ferrous gluconate, and ferrous fumarate). All ferrous compounds are oxidized in the gut lumen or within the mucosa with the release of activated hydroxyl radicals, which act on the gut wall and produce a range of gastrointestinal symptoms such as nausea, bloating, diarrhea and upper abdominal pain. Absorption of iron appears to be reduced in IBD. The acute phase protein hepcidin may play a central role in this process as it is over expressed in the liver leading to reduced iron uptake by the duodenum^[18]. Moreover, oral iron enhances intestinal inflammation as well as colon carcinogenesis in animal models of colitis^[19,20].

Intravenous iron preparations

Patients with IBD and anemia respond well to intravenous iron therapy with an increase in hemoglobin levels^[9]. Administration of iron directly into the circulation requires formulations that prevent cellular toxicity of iron salts^[21]. Three different products are available: Iron dextran, iron gluconate and iron sucrose. The stability of the dextran complex allows administration of large doses at a single setting. The molecule however may cause dextran-induced anaphylactic reactions. On the other hand, iron gluconate may cause the so-called transient capillary leak syndrome. Non-transferrin bound free ionic iron may induce acute endothelial cell injury, with the development of symptoms such as nausea, hypotension, tachycardia, dyspnoea, and oedema of the hands and feet. Iron sucrose is safer

than iron dextran and is well tolerated even by patients who have previously reacted adversely to iron dextran^[22]. Single doses of up to 300 mg of iron sucrose are safe^[23]. The maximal recommended dose is 600 mg/wk^[24]. If the infusion speed is too rapid, or the single total iron dose is too high, non-transferrin bound free iron may cause transient hypotension, tachycardia and dyspnoea, as described with iron gluconate.

Recently, a new intravenous iron preparation, ferric carboxymaltose (FeCarb) has been introduced. FeCarb can be administered intravenously in single or multiple doses of up to 1000 mg within 15 min. A recent report suggests that administration of FeCarb in IBD-associated anemia provides faster hemoglobin response, a greater increase in iron stores and better patient tolerance^[25]. Intravenous iron therapy for IBD-associated anemia has been recommended since the 1970s^[26], but clinical trials were only performed in the early 1990s^[6]. During the last several years, experience in the use of intravenous iron sucrose in IBD has evolved greatly. Gasche *et al* demonstrated the efficacy of such form of iron supplementation^[6,27,28]. Moreover, intravenous iron sucrose has a good safety profile in IBD-associated anemia, with a 65%-75% response rate in 4-8 wk, associated with improvement in the quality of life^[6]. In IBD patients, high levels of serum transferrin, soluble transferrin receptor, and serum EPO predict the response to intravenous iron supplementation, while low levels indicate the need for concomitant EPO therapy^[9]. Two comparative trials (oral *vs* intravenous iron) have recently been published^[29,30], indicating better tolerability of iv iron sucrose therapy.

The current management of IBD-associated anemia with iron sucrose is based on infusing the total iron dose by multiple small infusions, since a single dose should not exceed 500 mg (or 7 mg/kg body weight). Depending on the body weight, the usual dose for single infusions varies from 200 mg to 300 mg of iron sucrose in 100 mL sodium chloride. The total iron infusion may take between 4 to 10 wk. After this period, about 25% patients will fail to show a significant hemoglobin increase, defined as an increase in hemoglobin concentration of ≥ 20 g/L at the end of the wk 4.

One limitation of intravenous iron in patients not receiving EPO therapy is that much of the administered iron is transported into the reticuloendothelial system as storage iron, where it is less readily available for erythropoiesis.

Safety issues

Intravenous iron therapy has been carefully analyzed for risks and adverse events. Iron is an essential nutrient for proliferating microorganisms, and the sequestration of iron from microorganisms into the reticuloendothelial system is a potentially effective defense strategy against pathogens^[31]. In addition, iron therapy in the setting of long-term immune activation promotes the formation of highly toxic hydroxyl radicals that can cause tissue damage and endothelial dysfunction, with increased risk of acute cardiovascular events^[31-33]. Thus, intravenous iron therapy may predispose patients to infections and unfavorable

coronary outcomes.

Iron therapy is currently not recommended for patients with anemia of chronic disease who have high or normal ferritin levels (above 100 g/L), because of the risk of possible adverse outcome.

ERYTHROPOIETIN AND ANEMIA IN IBD

Erythropoietin, a glycoprotein hormone secreted by the kidney, is the primary growth factor regulating erythropoiesis^[34]. Erythropoiesis must maintain a steady state level of circulating RBCs and in addition respond to acute challenges. The bone marrow is a highly dynamic organ that produces two to three million red cells every second. These red cells contain hemoglobin and are replaced after 75-150 d^[3]. Any imbalance in the rates of red-cell loss and production due to inadequate release of EPO, absence of co-factors required for red-cell formation (in particular iron), or an impaired ability of the erythroid progenitor cells to respond to EPO, results in anemia^[35]. Erythropoiesis is controlled by the hypoxia sensing mechanism in the kidney which responds by modulating the output of EPO^[36].

EPO acts on committed erythroid progenitor cells in the bone marrow to regulate their proliferation, to promote their differentiation and to maintain their viability as they differentiate. Thus, EPO is the major regulator of erythropoiesis^[37]. Under normal physiological conditions, EPO expression is inversely related to tissue oxygenation and hemoglobin levels, and there is a semilogarithmic relationship between the EPO response (log) and the degree of anemia (linear)^[38]. Moreover, the concentration of EPO that is normally between 5 to 29 U/L, can increase 100-fold in the presence of severe anemia. However, in some patients, EPO concentrations fail to increase despite significant anemia^[39].

Measurement of serum EPO levels is useful only in anemic patients with hemoglobin levels less than 100 g/L, since EPO levels at higher hemoglobin concentrations remain well within the normal range^[40]. Serum EPO levels that are inappropriately low for the degree of anemia, indicates blunted EPO response, and is encountered in anemia of chronic disease^[41].

Higher serum EPO levels have been reported in IBD patients compared to the normal population^[39,42,43]. The EPO levels increase with the degree of anemia^[27]. Interestingly, it has been shown that in IBD-associated anemia, EPO production is inadequate in relation to the degree of anemia^[5,9]. This finding may be of help when considering EPO therapy^[9].

Although anemia is a frequent complication of many diseases, its clinical relevance and the importance of its correction have long been neglected. Anemia was found to have a marked effect not only on the quality of life, but also on various physiological functions^[44-46]. Before the mid-1980s there was no effective therapeutic means of stimulating erythropoiesis. The clinical use of EPO began in 1986 with treatment of patients with chronic kidney disease^[47,48]. Since then, indications for the use of EPO therapy to boost erythropoiesis have broadened considerably.

ERYTHROPOIETIC AGENTS

Three erythropoietic agents are currently available in routine clinical practice: epoetin alfa, epoetin beta, and darbepoetin alfa, which differ in terms of their pharmacologic modifications, receptor-binding affinity, and serum half-life, thus allowing for alternative dosing and scheduling strategies^[49].

Recombinant Human Erythropoietin

Epoetin- α and Epoetin- β are the two available brands of recombinant human erythropoietin (rHu EPO). In 1977, small amounts of human EPO were obtained from the urine of patients with aplastic anemia^[50]. Based on limited peptide sequence information of this purified material, the gene of human EPO was isolated and cloned in 1983^[51], and the use of genetic engineering techniques allowed large-scale production of recombinant human EPO in a suitable mammalian cell line. The clinical success of this product has resulted in the use of epoetin in millions of anemic patients.

Like the endogenous hormone, epoetin binds to the dimerised EPO receptor on the surface of erythroid progenitor cells, inducing a conformational change in the receptor. This change induces phosphorylation of tyrosine residues by JAK-2 kinase on several intracellular molecules, including STAT-5, which is the major signal transducer and activator of transcription, causing gene activation in the cell nucleus^[52]. Activation of these pathways stimulates proliferation and inhibits apoptosis of the erythroid progenitor cells^[53].

Epoetin is highly effective in stimulating erythropoiesis^[5,6,54,55]. In addition there is increasing experimental evidence that EPO has a range of non-erythropoietic, pleiotropic effects, including tissue protection of the nervous system, myocardium, kidneys, intestines and the joints^[56].

Darbepoetin alfa

Despite the undoubted therapeutic efficacy of epoetin, a major limitation of this treatment is that it has to be administered parenterally two or three times a week. Much effort has therefore been directed at producing longer-acting EPO analogues that would retain their biological activity, but require less frequent dosing. The first to be synthesized was darbepoetin (DPO) alfa^[57]. DPO alfa has five N-linked glycosylation chains compared with the endogenous and recombinant EPO, both of which have three. All three molecules have, additionally, a single O-linked glycosylation chain^[58]. The molecular weight of DPO alfa is 37.1 kDa, compared with 30.4 kDa for EPO, and its elimination half-life in humans after an intravenous injection is about three-fold longer (25.3 h *vs* 8.5 h for epoetin alfa)^[59]. This allows less frequent dosing, with most patients receiving injections once weekly or once every 2-3-4 wk^[60].

Continuous erythropoietin receptor activator

Continuous EPO receptor activator (CERA) is the another erythropoietic agent, that has recently completed phase III of its clinical development program^[61,62]. CERA was developed by the integration of a single 30 kDa

polymer chain into the EPO molecule, thus, increasing the molecular weight to twice that of epoetin to about 60 kDa, and considerably increasing the elimination half-life in humans to about 130 h. The hypothesis being tested in phase III clinical studies is whether CERA can be administered safely and effectively every 3-4 wk. The preliminary data suggests that this is perhaps the case^[63,64].

Next generation erythropoietic analogues

Synthetic erythropoiesis protein, EPO fusion protein and EPO-mimetic peptides are the next generation of erythropoietic agents that exploit recent advances in drug development for stimulating erythropoiesis. These agents stimulate erythropoiesis through the activation of EPO receptors^[65-67].

ROLE OF ERYTHROPOIETIN IN IBD-ASSOCIATED ANEMIA

Hemoglobin increase

Several studies have examined the efficacy and the safety of EPO in the treatment of refractory anemia in patients with IBD^[5,6,11,68,69]. Horina *et al* first tested tEPO therapy in three patients with a long-standing history of IBD and refractory chronic anemia (Hb < 100 gr/L, plasma EPO < 100 U/L). A marked increase in hemoglobin values was noted in all three patients^[68]. Gasche *et al*^[27] reported that after 5 wk of treatment with intravenous iron alone or in combination with EPO, all anemic patients had a marked increase in hemoglobin levels. However, the mean increase in EPO-treated patients was higher compared to patients receiving iron therapy alone (50 g/L *vs* 20 gr/L respectively). Subsequently, recombinant human EPO was found to be effective in a controlled trial of patients with anemia refractory to oral iron supplementation^[5]. In this double-blind study, the superiority of combination therapy (iron + rHEPO) over iron alone was again demonstrated. In another placebo-controlled study in a patient with Crohn's disease-associated anemia that was refractory to oral iron, intravenous iron, and EPO resulted in greater and quicker hemoglobin response compared with intravenous iron alone^[6]. Concomitant EPO therapy was associated with a more rapid incline in hemoglobin levels. EPO treatment has also been shown to be safe and effective in children with iron refractory IBD-associated anemia^[11].

In a recent study^[70], Darbepoetin-alpha (DPO) was tested in patients with IBD-associated refractory anemia. This study, the first to assess DPO alfa in IBD-associated refractory anemia, demonstrated that the administration of DPO in combination with intravenous iron sucrose raised hemoglobin levels. Furthermore, the longer half-life of DPO compared to EPO allowed less frequent administration and was more convenient to the patients. Thus, all the trials have demonstrated a significant beneficial effect of erythropoietin agents in this patient population.

Improvement in quality of life

Most studies have shown that successful treatment of anemia with EPO, is accompanied with improvement in

the energy and activity level and the overall quality of life^[71]. Surprisingly, in the hemoglobin range of 80-140 g/L, the largest improvement in quality of life occurred when hemoglobin levels increased from 110 to 130 g/L^[72]. Alterations in the quality of life were also examined in anemic patients with Crohn's disease treated with iron sucrose and EPO^[6]. The sense of well being, and improvement in mood, physical ability, and social activity accounted for most of the improvement in quality of life. Moreover, avoidance of blood transfusions enhanced the improvement in quality of life^[15]. Thus, the quality of life is significantly improved in patients with IBD-associated anemia with erythropoietin therapy.

MECHANISMS OF ACTION

The therapeutic effect of EPO involves counteracting the antiproliferative effect of cytokines, along with stimulation of iron uptake and heme biosynthesis in erythroid progenitor cells. Accordingly, a poor response to treatment with erythropoietic agents is associated with increased levels of proinflammatory cytokines, and poor iron availability.

There is little data on the possible effects of therapy with erythropoietic agents and the correction of anemia, on the course of the underlying disease, particularly since epoetin can exert additional biologic effects, including interference with the signal transduction cascade of cytokines. Treatment of rats with EPO was found to reduce the degree of colitis caused by DNBS suggesting that EPO may be useful in IBD treatment^[73]. Furthermore, EPO may enhance the healing of colonic anastomosis after colonic surgery by increasing the number of fibroblasts and accelerating the maturation of new blood vessels^[74].

PREDICTIVE FACTORS OF RESPONSE TO ERYTHROPOIETIC THERAPY

The response (erythropoiesis) to a dose of EPO is not related to the patient's gender or age, suggesting that patient-specific factors such the underlying chronic disease, iron-restricted erythropoiesis, and other factors that normally result in a wide distribution of hemoglobin responses, account for the variability in erythropoietin response to EPO in different individuals^[15].

There are no baseline indices of response to erythropoietin that can be used in routine clinical practice. If functional iron deficiency and vitamin deficiency are excluded, a low serum EPO level appears to be the only established predictive factor of some importance^[75]. In IBD patients, high levels of serum transferrin, soluble transferrin receptor, and serum EPO predict the response to intravenous iron supplementation, while low levels indicate a need for concomitant EPO therapy^[9].

Further studies are needed to investigate the value of hepcidin, C-reactive protein and other measures as predictive factors. The iron-regulatory hormone hepcidin is of particular interest as it is believed to be the primary factor in anemia of chronic disease. Cytokine-mediated induction of hepcidin in inflammatory or infectious

conditions^[76] decreases duodenal absorption of iron and induces iron retention by macrophages. Likewise, CRP is also increased in inflammatory conditions, and high CRP levels are associated with reduced Hb levels and resistance to EPO treatment. Therefore, pre-treatment levels of hepcidin and CRP may provide important information on the response to erythropoietic proteins in IBD patients.

INDICATIONS FOR ERYTHROPOIETIC THERAPY IN IBD-ASSOCIATED ANEMIA

It is difficult to determine as to which patient with IBD-associated refractory anemia will require combination therapy with erythropoietic agents in view of the absence of any long-term data. However, EPO should be reserved for symptomatic patients who may otherwise require blood transfusions, who have not responded to intravenous iron, and in whom aggressive management of IBD (including immunosuppressive therapy) has not suppressed the mucosal inflammation. EPO is an adjunct and not an alternative to appropriate treatment of IBD^[77]. Several issues remain to be resolved including the use of EPO for prevention of anemia, the target hemoglobin levels, and the immunologic role of EPO in the setting of chronic bowel inflammation.

SIDE EFFECTS AND CONCERNS ABOUT EPO THERAPY

Erythropoietic therapy is highly effective in stimulating erythropoiesis and has an excellent safety profile. Apart from the rare induction of antibodies, all adverse effects of epoetin appear to be directly related to its pharmacodynamic properties i.e., the increase in red-cell number. In patients with kidney disease, such an increase may lead to a moderate rise in the blood pressure. In addition, there is a risk of thromboembolic complications with higher hemoglobin levels. Clinical trials in patients with cancer^[78] and chronic kidney disease^[79], designed to assess the effect of increasing the haemoglobin concentration to the normal range, compared with a subnormal target, have suggested no overall benefit and even the risk of potential harm. Moreover, it has recently been observed that "on the basis of available data, the maintenance of haemoglobin concentrations above 130 g/L appears to be unsafe in patients with chronic renal failure"^[80].

The success of epoetin has been clouded by the discovery in a few patients of the development of neutralizing antibodies against recombinant proteins that cross-react with native EPO, and cause pure red-cell aplasia^[81]. This problem is likely caused by the use of a new buffer (polysorbate 80), which replaced human serum albumin, and which induces the release of organic compounds with adjuvant properties from the rubber stoppers of prefilled syringes^[82].

Another issue of concern is the presence of EPO receptors on several malignant cell lines, including mammary, ovarian, uterine, prostate, hepatocellular, and renal carcinomas, as well as on the myeloid cell lines^[83]. There are contradictory reports concerning the effect of

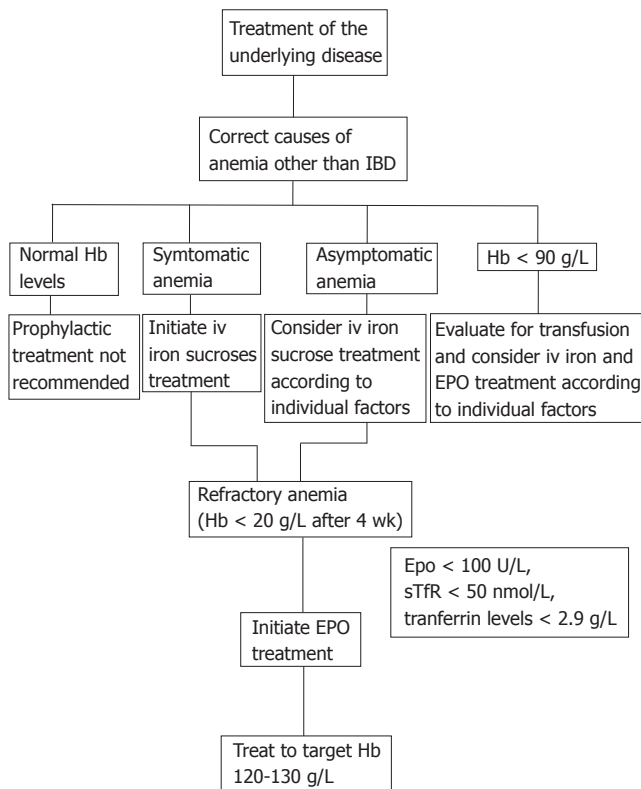

Figure 1 IBD-associated anemia. Suggested treatment algorithm for stimulating erythropoiesis in patients with IBD-associated anemia. Hb: Hemoglobin; iv: Intravenous; EPO: Erythropoietin.

epoetin on such cells. Although the use of EPO caused tumor regression in a murine model of myeloma^[84], administration to EPO-receptor-expressing human renal carcinoma cells *in vitro* stimulated their proliferation^[85]. Large amounts of EPO receptors were found in 90% of biopsy specimens of human breast carcinoma^[86]. The production of EPO receptors by cancer cells appears to be regulated by hypoxia, and in clinical cancer specimens the highest levels of EPO receptors were associated with neoangiogenesis, tumor hypoxia, and presence of infiltrating tumors. One potential adverse effect may be the induction of neoangiogenesis, since EPO increases inflammation and ischemia-induced neovascularization by enhancing the mobilization of endothelial progenitor cells^[87]. In a study in nude mice, implantation of EPO-receptor expressing cell lines and subsequent inhibition of EPO-receptor signaling resulted in inhibition of angiogenesis and destruction of the tumor mass^[83].

The effects of erythropoiesis-stimulating agents are still not fully understood. Not only do they increase haemoglobin concentration, but they may also act *via* alternative dose-dependent pathways that are harmful. Careful studies on the potential harmful effects of EPO therapy in patients with different forms of anemia of chronic disease remain to be carried out.

STRATEGIES FOR STIMULATING ERYTHROPOIESIS IN IBD

Anemia is a common complication of IBD and poses a

serious therapeutic challenge. The optimal management of IBD-associated anemia is to promote an increase in hemoglobin levels accompanied with an improvement in the quality of life. Therapy is targeted at the mechanisms underlying anemia of chronic disease and iron deficiency. The most important approach is to treat the underlying disease (Figure 1). In previous studies assessing EPO in anemic IBD patients, current or recent immunosuppressive therapy was a specific exclusion criterion^[5,6], suggesting that the patients may not be receiving optimal anti-inflammatory therapy. Moreover, as the IBD disease activity correlates with the degree of anemia, treatment of IBD should lower its incidence. Thus, as effective therapy (including immunosuppressants and anti TNF- α) induces mucosal healing^[88,89], one would expect a lower incidence of anemia.

Additionally, causes of anemia other than IBD (nutritional defects, bleeding, haemolysis, chronic kidney disease, cancer, metabolic disorders and cardiovascular disease) should be evaluated and treated. Asymptomatic anemia warrants correction, especially in patients older than 65 years of age, those with additional risk factors (such as coronary artery disease, pulmonary disease, and chronic kidney disease), or a combination of these factors.

A stepwise approach for stimulating erythropoiesis should be followed in patients with IBD. First, iron deficiency which is the most common cause of anemia should be corrected. Recent studies have demonstrated the efficacy and the safety of intravenous iron supplementation with iron sucrose. About two-thirds of patients respond to this treatment within 4-10 wk. The remaining subjects who fail to improve likely have anemia of chronic disease. Gasche *et al* suggest that serum levels of EPO, soluble transferrin receptor, and transferrin predict a positive response to iron infusion, and may identify those patients who will benefit from early treatment with EPO^[9].

EPO administration has been shown to be of benefit in patients who do not respond to iron supplementation. Several studies have demonstrated the efficacy and the safety of EPO in IBD patients with refractory anemia. EPO treatment results in a marked increase in hemoglobin values and improvement in quality of life. However, there is controversy as to whether EPO is cost-effective in treating anemia in IBD. Many physicians have employed erythropoietic agents which are not currently approved by the FDA. Thus, clinicians will have to make treatment decisions based on limited data currently available. These agents are effective in increasing hemoglobin level, and improving the quality of life for the duration they are used. However, the length of treatment, optimal dose and target hemoglobin level remain to be established. The disadvantage of these agents is that they add another drug to the patient's treatment regimen, thereby increasing the costs, inconvenience, and potential side effects. Several studies in patients with renal failure and cancer indicate that the target hemoglobin level with EPO should be 120-130 g/L. However, a normal haematocrit value may not be optimal.

IBD-associated anemia can also be managed with blood transfusions which are widely used for rapid and effective intervention. Transfusions are particularly helpful in the context of severe anemia (Hb < 90 g/L)

and life-threatening anemia (Hb < 70 g/L). However, the optimal hemoglobin threshold for red-cell transfusion in IBD patients is unknown. Recent evidence^[90,91] does not support the unrestricted use of blood transfusions, because of the risks associated with this procedure such as iron overload and sensitization of the immune system. Thus, the timing of blood transfusion in IBD-associated anemia must take into consideration not only the hemoglobin level but also the relative degree of hemoglobin decrease, any underlying comorbidities and the presence of anemia-related symptoms. It is also important that the use of blood transfusions should be followed by treatment with iron supplementation, with or without EPO.

In our clinical practice, most patients with IBD-associated anemia respond well to intravenous iron alone. It is important that the bowel inflammation is treated adequately and that sufficient iron is given. In anemic patients with active IBD, we usually start treatment with corticosteroids, in order to alleviate the clinical symptoms, followed by intravenous iron sucrose to replenish the iron stores. This strategy helps to stimulate impaired erythropoiesis and thus reduce the need for concomitant EPO injections. However, patients with ongoing inflammation have anemia of chronic disease and may require combination therapy with intravenous iron sucrose and erythropoietic agents. It has been suggested that about 25% of patients with IBD-associated anemia require combined treatment with iron sucrose and EPO^[8]. Recently, we examined the use of DPO to determine whether it is effective in refractory anemia in IBD^[70]. The administration of DPO in combination with intravenous iron sucrose was effective in these patients. Careful monitoring of hemoglobin levels and iron parameters is required to avoid recurrence of anemia in IBD patients. Additional clinical trials are warranted to establish the optimal dose and schedule of intravenous iron supplementation, and erythropoietic therapy in IBD-associated anemia.

CONCLUSION

Anemia is a frequent complication of IBD. Patients with anemia usually have greater disease severity and lower quality of life, demanding aggressive diagnosis and treatment. Iron deficiency is managed most reliably by intravenous preparations. Iron sucrose demonstrates the best efficacy and tolerability. Difficulties arise in patients with refractory anemia, who do not respond to intravenous iron. EPO administration has proven to be effective in these patients. EPO has additional beneficial effects on hemoglobin concentration. However, EPO is expensive and not without potential side effects. It is difficult to determine as to which patient with refractory anemia will require combination therapy with erythropoietic agents. The responsible use of medical resources, as well as the absence of data on long-term safety of EPO in patients with IBD, suggests that iron sucrose should be considered as the first-line therapy in IBD-associated anemia. Therefore, EPO has a secondary role, in patients who do not respond to intravenous iron alone. The long-term outcome of alleviating anemia depends on whether the bowel inflammation can be adequately treated.

Immunity to hepatitis C virus infection: Update 2007

From the editor

This 8-part topic review series, "Hepatitis C virus: virology, immunology and pathogenesis", was designed to provide expert opinion and new insights for the Journal's readership.

Hepatitis C virus (HCV) is a small single-stranded RNA virus that belongs to the *Flaviviridae* virus family. More than 120 million people are chronically HCV infected. The factors that determine the outcome and natural course of HCV infection are not completely understood. However, it is generally accepted that next to virological factors innate and adaptive immune responses play an important role in both, control of HCV infection and as disease pathogenesis (Figure 1).

In recent years, significant progress has been made in understanding basic mechanisms of viral replication, innate and adaptive immune responses, such as CD4⁺ and CD8⁺ T cells as well as neutralizing antibodies, and the possible role of regulatory T cells in orchestrating the adaptive immune response. However, the central question why HCV is able to evade the innate and adaptive immune response and to establish viral persistence in the majority of acutely infected patients is still unknown. In this review series, recent advances

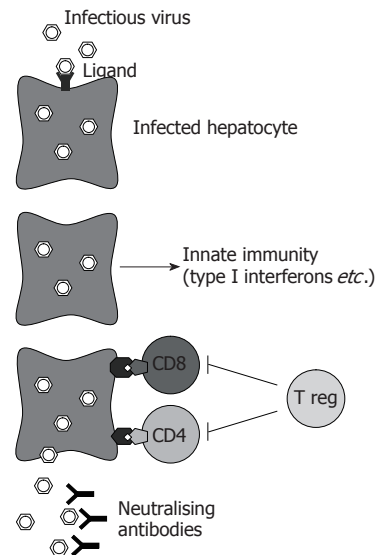

Figure 1 After HCV infection of hepatocytes, innate immune responses are induced. In addition, virally infected cells present antigens to CD4⁺ and CD8⁺ T cells. Both T cell subtypes are regulated by Tregs. Secreted virus can be bound by neutralizing antibodies. All parts of these interactions will be discussed in the following review series.

in HCV virology and immunology will be highlighted. Clearly, a better understanding of the dynamic host-virus interactions during HCV infection is crucial for the development of new prophylactic and therapeutic vaccines.

Abstract

With approximately 3% of the world's population (170 million people) infected with the hepatitis C virus (HCV), the WHO has declared HCV a global health problem. Upon acute infection about 50%-80% of subjects develop chronic hepatitis with viral persistence being at risk to develop liver cirrhosis and hepatocellular carcinoma. One characteristic of HCV is its enormous sequence diversity, which represents a significant hurdle to the development of both effective vaccines as well as to novel therapeutic interventions. Due to a polymerase that lacks a proofreading function HCV presents with a high rate of evolution, which enables rapid adaptation to a new environment including an activated immune system upon acute infection. Similarly, novel drugs designed to specifically inhibit viral proteins will face the potential problem of rapid selection of drug resistance mutations. This review focuses on the sequence diversity of HCV, the driving forces of evolution and the impact on immune control and treatment response. An important feature of any therapeutic or prophylactic intervention will be an efficient attack of a structurally or functionally important region in the viral protein. The understanding of the driving forces, but also the limits of viral evolution, will be fundamental for the design of novel therapies.

INTRODUCTION

With approximately 3% of the world's population (170 million people) infected with the hepatitis C virus (HCV), the WHO has declared HCV a global health problem^[1]. Upon acute infection about 50%-80% of subjects develop chronic hepatitis with viral persistence being at risk to develop liver cirrhosis and hepatocellular carcinoma. The current standard treatment for chronic HCV infection is based on a combination of pegylated interferon alpha and ribavirin^[2,3]. However, this combination is successful in only 50% of all subjects with response rates substantially influenced by the infecting viral genotype. Moreover, the side effects and costs of treatment further limit the use in many regions. Alternative treatment approaches including immunotherapeutic interventions are, therefore, highly warranted. One characteristic of HCV is its enormous sequence diversity, which represents a significant hurdle to the development of both effective vaccines as well as to novel therapeutic interventions. This review focuses on the sequence diversity of HCV, the driving forces of evolution and the impact on immune and control and treatment response.

GENOME STRUCTURE

The HCV genome is an RNA molecule of approximately 9600 nucleotides structured in a coding region that contains one large open reading frame and flanked by non-translated regions at the 5' and 3' ends. The polyprotein is cleaved into structural (core, envelope 1 and 2) and non-structural proteins (NS2, NS3, NS4A, NS4B, NS5A and NS5B) with one additional small protein at the junction between the structural and non-structural elements (p7 protein)^[4]. Until the recent development of an *in vitro* replication system that produces infectious viral particles^[5-7] many of the protein functions have been studied in sub-genomic replication systems or with purified protein after expression.

The 5' NTR forms a highly structured RNA element that contains an internal ribosomal entry site (IRES) that allows interaction with the 40S ribosomal subunit and initiation of cap-independent translation of the viral RNA^[8]. The polyprotein is translated as one large reading frame and subsequently cleaved by host-cellular proteases and virally encoded proteases into the individual proteins^[9]. The structural proteins core, envelope 1 and envelope 2 are cleaved

by host-cellular proteases. Processing of these proteins is believed to take place in a membrane associated complex at the endoplasmic reticulum by signal peptidases^[10]. The core protein forms the viral capsid, binds to the viral RNA and interacts with envelope proteins to form viral particles. Different receptors have been suggested for the interaction of viral particles with the hepatocyte that mediates HCV entry including CD81, scavenger receptor class-B type-I (SR-BI), low-density lipoprotein receptor (LDL), mannose binding lectins (L-SIGN and DC-SIGN) and glycosaminoglycans^[11]. E2 binds with high affinity to the extracellular loop of CD81, a tetraspanin that is expressed on different cell types including hepatocytes^[12]. Cell entry of the virus is CD81 and SR-BI dependent, suggesting that these molecules serve as receptors or co-receptors for infection^[13-16]. However, this interaction does not explain the hepatotropism as CD81 and SR-BI are not exclusively expressed on hepatocytes. Moreover, it has been shown that CD81 and SR-BI are necessary for cell entry of viral particles, but are not sufficient^[16,17]. Some cell lines that express both proteins do not support viral entry. Recently a new candidate has been suggested that may close this gap. Claudin-1, a tight junction component that is highly expressed in the liver, was recently identified as a key factor in the late entry process^[18].

These structural components of HCV are flanked by the non-structural proteins NS2 to NS5B. The function of one additional protein (p7) between these elements remains to be elucidated. It has been suggested that p7 forms an ion channel in planar lipid bilayers^[19,20]. However, it is still unclear whether it is a virion component. NS2 contains an autoprotease, which cleaves the junction between NS2 and NS3^[4]. NS3 is a multifunctional protein with a N-terminal protease domain and a C-terminal RNA helicase/NTPase domain. The NS3 protease cleaves the remaining non-structural proteins with NS4A as a cofactor for this activity. The NS3 RNA helicase/NTPase unwinds RNA and DNA^[21]; however, its role during viral replication is unclear. The integral membrane protein NS4B is sufficient to induce membranous web formation and has been proposed to serve as a scaffold for replication complex assembly. The role of NS5A is again unclear. Numerous protein-protein interactions have been suggested including a role in silencing the host's innate immune response and determining responsiveness to interferon alpha^[22]. Some of these interactions are discussed later. NS5B encodes the viral RNA-dependent RNA polymerase. In the viral replication cycle the positive-strand RNA genome serves as a template to make a negative-strand intermediate, which then again serves as a template to produce multiple nascent genomes. Recently, one additional protein resulting from frameshifted translation of the core protein has been identified (alternative reading frame protein ARFP)^[23]. However, the function of this protein is unknown.

GENOTYPES

Phylogenetic analysis of HCV genomes revealed that sequences fall into different clusters. This observation led to a classification of HCV into different genotypes and a standardized nomenclature was proposed in a consensus

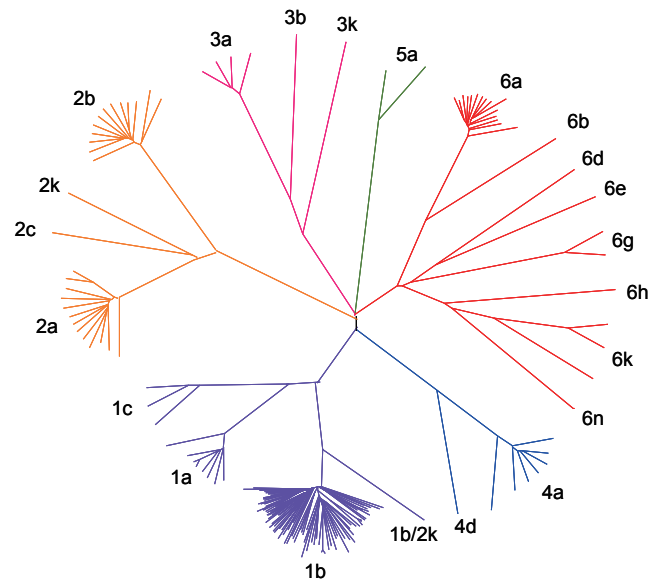

Figure 1 Published HCV Full Genomes. 169 full length HCV sequences available from the Los Alamos National Laboratory (LANL) HCV Sequence Database are illustrated in a phylogenetic tree. HCV sequences fall into six different clusters (genotype 1-6) and are further classified into subtypes. The sequence from one recombinant virus (genotype 1b/2k) is included.

paper in 1994^[24]. The global distribution of HCV genotypes is regionally specific. The predominant genotype in most areas is genotype 1. However, some areas are almost exclusively infected with other genotypes. For example, the predominant genotype in Egypt is genotype 4 and the HCV epidemic in this country could be linked to parenteral treatment of schistosomiasis in the 1950s^[25,26]. In some regions in Africa genotype 2 is more frequent^[27]. In some areas of Asia, however, genotypes 3 and 6 are predominant^[28-30]. Despite substantial sequence variation all genotypes share the same structure of linear genes of nearly identical size. The genotype specific variation of the different genes is remarkably consistent and has enabled many of the currently recognized variants of HCV to be provisionally classified based on partial sequences from subgenomic regions such as core/E1 and NS5B. The original nomenclature was recently updated further standardizing the nomenclature of existing variants^[30]. Based on phylogenetic analysis a classification into 6 major genotypes was proposed and criteria for the designation of new HCV variants were formulated. These proposals provide an HCV nomenclature scheme for the three major public HCV sequence databases (Europe^[31], USA^[32] and Japan: <http://s2as02.genes.nig.ac.jp/>) and eliminate inconsistencies of the current classification procedures. HCV genotypes differ from each other by 31%-33% on the nucleotide level^[33]. The genotypes are further divided into multiple epidemiologically distinct subtypes differing by 20%-25% from one other^[33]. A phylogenetic tree depicting all published complete HCV genomes is presented in Figure 1. For many of the HCV subtypes, particularly for the less frequent ones, complete genome sequences are not available. The lack of sequence data for rare genotypes is profound prompting a sequencing initiative supported by the NIH to improve the HCV sequence databases^[32].

SEQUENCE VARIATION

As a member of the flaviviridae, the virally encoded RNA polymerase of HCV lacks a proof reading function. Replication of this positive-stranded RNA genome is, therefore, characterized by ongoing error rates between 1 in 10000 and 1 in 100000 bp copied, which are typically found for RNA polymerases^[34]. Together with a high turnover rate of estimated 10^{12} virions per day^[35], theoretically every possible mutation in every single position of the genome will be generated in one infected host every day. This high error rate is reflected in the generation of a heterogeneous, but closely related swarm of viruses within the same host referred to as quasispecies. The quasispecies nature of HCV can be best illustrated by sequence analysis of a short, but highly polymorphic region in envelope 2 designated as the hypervariable region 1 (HVR 1). Analysis of clonal sequences reveals that sequences of the viral population from the same subject are highly variable, but still phylogenetically closely related. In public databases normally the consensus sequence, as the most predominant residue at any given position within the quasispecies population, is presented. The quasispecies nature of HCV may have important consequences during a transmission event. Depending on the transmission route the number of transmitted viral RNA copies can be limited and may not represent the true complexity of the sequence diversity of the donor. This bottleneck phenomenon has been described for sexual transmission of HCV^[36] and in the chimpanzee model^[37]. However, the bottleneck could also be interpreted as selection of the optimal strain in the new host during the earliest infection events. Different aspects about the nature of the observed HCV sequence evolution have been published. The next section gives an overview of the different mechanisms.

DRIVING FORCES OF EVOLUTION

Genetic drift

Longitudinal analysis of isolates from subjects with chronic HCV infection calculated a mutation rate on the order of $1.5\text{--}2.0 \times 10^{-3}$ nucleotide substitutions per site per genome per year^[38,39]. In the model of neutral evolution mutations are selectively neutral^[40]. The spread of these neutral mutations is mainly influenced by stochastic factors and is called genetic drift. As a consequence of this stochastic process even disadvantageous mutations can reach fixation when the virus circulates through a sufficiently small population. In turn, advantageous mutations are also affected by genetic drift when they are rare and are occasionally lost from the population. Several studies have described the rapid sequence drift of HCV over time^[33]. The model of neutral evolution and the presumption that such diversification should occur at a constant rate over time provide a framework to estimate times of spread of HCV in specific transmission networks^[41,42]. For example, a recent analysis of viral sequences obtained from an HCV and HIV outbreak in children at the Al-Fateh hospital in Libya, utilizing this molecular clock, demonstrated that the origin of the outbreak predated the year of 1998^[43]. Noteworthy, this analysis excluded the possibility that the

source virus was transmitted by foreign medical staff as suggested by local authorities.

Sequence drift has been suggested in a few studies as the major driving force of HCV evolution. An analysis by Allain *et al* suggested a dominant role in the evolution of envelope 2^[44]. They analyzed clonal sequences of six different transmission pairs years after the transmission event. In this study the ratio of non-synonymous to synonymous mutations in the analyzed region did not support the hypothesis of positive or negative selection. The author's, therefore, concluded that neutral evolution is a major component of the observed sequence diversity. Moreover, the authors did not find a correlation between the strength of the antibody response and the rate of evolution in these patients. However, in this study the strength of the humoral immune response was determined in serum collected years after the transmission event utilizing different HVR 1 peptides corresponding to autologous and heterologous sequences. Therefore, the true antibody response against the virus present during the acute phase of infection might have been underestimated. Another shortcoming of this study is that the inoculum sequence at the time of transmission was unknown and only a single time point years later was available making conclusions about the true evolutionary rate and kinetics difficult.

Positive and negative selection

In contrast to being neutral mutations may also be selected. Many mutations are probably disadvantageous or even deleterious for the virus and these variants are eliminated in a negative selection process. However, some mutations may not have an impact on replication capacity and a few may even be beneficial and confer a replication advantage. Variants harbouring these beneficial mutations will out compete for others in a dynamic process of continuous positive selection. Similar to other highly variable pathogens a complex process of continuous selection has been proposed for HCV^[45]. Theoretically, infections with persistent viruses such as HIV and HCV have time to evolve within the same host before transmission to the next host and may adapt to the specific environment in an individual. The evolution of HCV may, therefore, be substantially influenced by host factors mediating selection pressure on the virus. Even though the consensus sequence may be close to the maximum of viral replication capacity at any one time, the existence of a large and diverse viral population allows rapid, adaptive changes in response to changes in the replication environment. Many variants that are beneficial in a new environment may already be present in a low frequency in the quasispecies population and subsequently out competes the existing dominant sequence. The impact of the quasispecies complexity on the clinical outcome can be profound. Farci *et al* analyzed sequences covering HVR1 obtained during the acute phase of infection from subjects who spontaneously resolved viremia and subjects who continued to chronic infection^[46]. Spontaneous resolution of viremia was predicted by a decrease in quasispecies complexity during the first weeks of infection.

In turn patients with viral persistence had increasing viral diversity suggesting a fast adaptation process to the new environment. A similar effect of quasispecies diversity on the outcome of treatment is discussed^[47,48]. In recent years many studies have been published that aim to characterize the driving forces of this selection process.

Antibodies

The most variable region in the HCV genome is a short fragment spanning 27 amino acids of envelope 2 and is, therefore, designated the hypervariable region 1 (HVR 1). There is strong evidence that the profound sequence diversity in this region is the result of immune pressure by virus specific antibodies. Importantly, there is a close association between the observed sequence diversity in this region and the appearance of HCV specific antibodies in the sera of subjects with acute infection^[49,50]. Patients suffering from common variable immunodeficiency (CVID) who present with hypogammaglobulinemia are not able to produce high titres of HCV specific antibodies and, therefore, are not able to mount humoral immune selection pressure. Analysis of sequences of HVR1 revealed that patients with hypogammaglobulinemia had significantly less amino acid substitutions in this region over time as compared to controls^[51]. In a similar analysis, the rate of non-synonymous and synonymous mutations was compared between core and envelope in patients with and without CVID^[52]. The rate of synonymous or silent mutations was similar in the core and envelope protein. In patients without CVID, as expected, the rate of non-synonymous mutations was much higher in envelope as compared to core, a protein that is known to be highly conserved. However, this high rate of non-synonymous mutations in envelope was not observed in patients with CVID suggesting that evolution is triggered by the presence of anti-HCV antibodies. In the chimpanzee model, it was demonstrated that a high turn-over rate is not sufficient to explain HVR1 sequence diversity. Only minor sequence variation was observed in this region upon serial infection with passage of an infectious HCV clone between 8 different animals^[53]. Noteworthy, samples for the subsequent infection of the next animal were taken during the acute phase before antibodies became detectable. Again, this study indicates that this region in the envelope remains stable in the absence of antibodies despite high level viremia that was present in all animals during the acute phase of infection. Taken together, all these studies suggest that without immune selection pressure only minor sequence changes occur in HVR1.

The lack of an *in vitro* culture system has hampered direct evaluation of these putative escape mechanisms in the envelope protein. Recently, more elegant tools for this type of analysis became available by pseudotyping retroviral particles with HCV glycoproteins (HCVpp)^[54-56]. Utilizing this technique, the impact of neutralizing antibodies on the evolution of HVR1 was demonstrated in a study by von Hahn and co-workers^[57]. Here longitudinal samples were obtained over a time period of 26 years from patient H who was infected in 1977 with genotype 1a. Sera were analyzed for the presence of neutralizing

antibodies against the autologous isolate present at the time of sampling. A neutralizing antibody response could be detected as early as 8 wk after infection against the inoculum strain. Interestingly, the antibodies present in a given sample continuously failed to neutralize HCV pseudoparticles bearing the autologous sequence from the same time point. Longitudinal analyses demonstrate continuous escape from emerging antibodies over the time of infection demonstrating humoral immune pressure as the major driving force for the observed sequence diversity in HVR1.

CD8 T cells

Mutational escape from CD8 T cells targeting viral proteins has been well documented for highly variable pathogens such as HIV and SIV. Similarly, in the chimpanzee model of HCV infection selection of mutations in CD8 epitopes that inhibit recognition by specific T cells has been described by Weiner and co-workers^[58]. In a follow-up analysis the majority of targeted CD8 epitopes in chimpanzees infected with HCV evolved over time and an important role for mutational escape as a contributor for viral persistence has been suggested^[59]. However, acute infection is rarely detected in humans due to lack of specific symptoms making the design of similar longitudinal studies difficult. First evidence for selection pressure by CD8 T cells was obtained from sequence analyses of patients with chronic infection^[60]. Here the T cell response against previously defined CD8 epitopes was determined. In some cases the autologous viral sequence present in the patient differed from the described prototype sequence of the epitope and was not targeted by specific T cell lines derived from that patient. The study included a case where sequence evolution was observed in a follow-up sample suggesting that CD8 escape also plays a role during chronic HCV infection. More recently, several longitudinal studies on patients with acute HCV infection have been published providing compelling evidence for CD8 escape in humans^[61-64]. Probably the most comprehensive analysis was done by Cox *et al.*^[62]. They prospectively followed subjects with ongoing intravenous drug use and high risk behaviour for evidence of acute HCV infection. Using this approach they were able to identify eight patients with acute HCV infection. Samples from these patients were obtained during acute infection (at the time of diagnosis) and after 6 mo. Utilizing comprehensive techniques with overlapping peptides spanning the entire HCV polyprotein the breadth of the immune response was determined. At the same time, sequence evolution between the first and second sample obtained 6 mo later was analyzed. Seventeen of 25 targeted epitopes evolved over time consistent with selection of escape mutations. Of note, the single subject without selection of escape mutations cleared viremia spontaneously. In turn, 50% of the observed sequence changes outside the envelope were associated with a detectable CD8 response. In line with these findings Ray *et al.* analyzed sequences from a single source outbreak infected with HCV genotype 1b and observed reproducible selection of mutations in previously

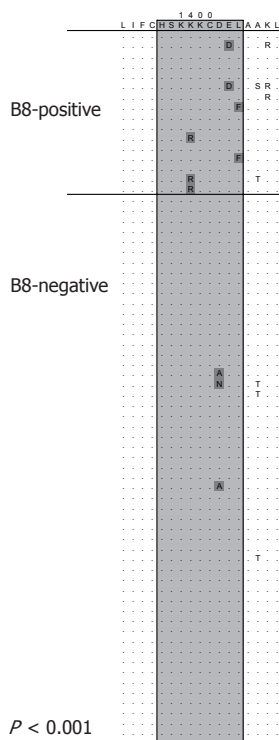

Figure 2 HLA class I-associated sequence polymorphisms in a CD8 epitope. Viral sequences are aligned to a consensus sequence and sorted into sequences derived from HLA B8-positive and HLA B8-negative subjects. Boxed is the region of a described HLA B8-restricted CD8 epitope. Differences from the consensus sequence are significantly more frequent in HLA-B8 positive subjects ($P < 0.001$). This association was reported in [68].

described CD8 epitopes in subjects expressing the restricting HLA-allele^[65]. The observation of widespread escape in individuals during acute HCV infection prompted efforts to determine whether adaptation to HLA class I-restricted selection pressure also occurs at the population level. Moore *et al* analyzed sequences spanning the reverse transcriptase protein of HIV-1 in a large HLA-diverse cohort^[66]. This study revealed accumulation of viral sequence polymorphisms at different sites of the protein in patients sharing the same HLA-allele. Many of these sequence polymorphisms were located inside previously described CD8 epitopes that are restricted by the associated HLA-class I allele. This study demonstrated that MHC class I-associated selection pressure has a major impact on the evolution of HIV-1. A similar analysis was done by the same group in a cohort chronically infected with HCV^[67]. Here, sequences spanning parts of the NS3 protein were analyzed and again a number of associations between sequence polymorphisms and particular HLA-alleles were identified. This analysis was extended to all non-structural proteins in a cohort of 70 subjects with chronic HCV genotype 1a infection with similar results^[68]. An example of an HLA class I-associated sequence polymorphism is illustrated in Figure 2. Viral sequences from all 70 subjects are aligned to a majority consensus sequence and sorted into sequences derived from HLA B8-positive and HLA B8-negative subjects. Boxed is the region of a described HLA B8-restricted CD8 epitope. Differences from the consensus sequence are significantly more frequent in HLA-B8 positive subjects compared to HLA B8-negative subjects indicating that there is reproducible selection pressure on this region in HLA B8-positive subjects. This study included a phylogenetic analysis approach for the detection of HLA-associated sequence polymorphisms highlighting the potential for

false positive detection of such associations by pure statistical approaches. However, these studies suggest that the same evolutionary forces act on HCV and HIV-1 and that selection pressure by virus specific CD8 T cells is an important driver of viral evolution.

CD4 T cells

Spontaneous resolution of viremia after acute infection with HCV has been associated with the emergence of a broad and functionally intact T cell response. There is convincing evidence that HCV specific CD4 T cells are important for viral control in the early phase. However, little is known about mutational escape in targeted CD4 T cell epitopes during HCV infection. In theory, a similar selection process as observed for CD8 T cells could be present. A quasispecies that is mutated inside an immunodominant CD4 epitope may have a selection advantage in an individual with acute HCV infection and could out compete others. Eckels *et al* found evidence for selection of mutations in CD4 epitopes in NS3^[69,70]. Analysis of a large number of clonal sequences revealed a high degree of polymorphisms in regions targeted by CD4 T cells and the ratio of synonymous versus non-synonymous mutations was consistent with positive selection. However, none of the observed variants became the dominant sequence at a second time point 16 mo later. More recently, two studies have described mutational escape from CD4 responses. The first report is part of a vaccination study in the chimpanzee model^[71]. One animal was vaccinated with DNA followed by recombinant vaccinia virus in a prime/boost strategy with HCV NS3 and NS5A/B and subsequently infected with a genotype 1a isolate. After primary infection and transient control of viremia the animal developed chronic infection. Longitudinal sequence analysis of the NS3 and NS5A/B region revealed two non-synonymous mutations. Both of them were located inside regions targeted by CD4 T cells. Additional experiments with synthetic peptides showed that the mutated sequence was not recognized by specific T cells from this animal. A second study focusing on the evolution of the envelope protein in one subject similarly identified amino acid substitutions inside targeted CD4 epitopes consistent with escape^[57]. These findings suggest that CD4 T cells may select mutations during HCV infection; however, the overall extent of CD4 escape as a contributor to the evolution of HCV remains to be clarified.

Innate immunity

Infection with HCV initiates a cascade of events within the infected cell with the goal to generate an antiviral state. The first line of defence builds the innate immune system that is triggered by engagement of pathogen-associated molecular patterns (PAMPs) to specific PAMP receptors^[72]. In case of HCV toll-like receptor 3 (TLR3) and retinoic-acid-inducible gene I (RIG-I)-receptor recognize dsRNA resulting in activation of multiple cellular factors that mediate transcription and secretion of interferon alpha and beta. Engagement of these type I interferons with their cellular receptor activates a series of interferon stimulated genes (ISG) with the goal to initiate an antiviral state with-

in the infected cell. The hepatitis C virus has developed strategies to evade this first line of host immune defence. Recently it was demonstrated that the NS3/4A protease is able to specifically cleave Cardif (CARD adaptor inducing interferon beta) and TRIF (Toll-interleukin-1 receptor domain-containing adaptor-inducing beta interferon)^[73-75]. Both proteins are involved in the activation of interferon regulatory factors (IRFs) and their inactivation, therefore, interferes with the production of interferon alpha and beta. Gale *et al.*^[76] demonstrated *in vitro* that NS5A is able to inhibit protein kinase R (PKR). PKR is activated by interferon alpha and involved in the inhibition of viral RNA translation. Its inhibition, therefore, represents a functional antagonism to the interferon alpha response. Interactions between virus and cellular host factors are sequence specific and negative selection of mutations undermining these immune evasion strategies seems reasonable. However, the underlying mechanisms of the innate immune response are highly conserved in all humans and less dependent on the genetic background of the individual. Therefore, the direction of selection pressure does not change upon transmission to the next host, which makes the observation of positive selection unlikely. Moreover, the interactions between virus and the host's innate immune response take place during the earliest phase of infection making it even more difficult to directly show that viral escape variants are selected.

Drugs

The current standard treatment regimen for patients with chronic hepatitis C is a combination of pegylated interferon alpha with ribavirin^[2,3]. Interestingly, the response rate to this treatment regimen is dependent on the infecting genotype suggesting that sequence differences between genotypes influence the susceptibility to these drugs. Patients infected with genotype 2 and 3 usually show a much faster decline in viral load after initiation of therapy associated with higher sustained response rates. The determinants of this differential responsiveness of different genotypes are poorly understood. Interferon alpha predominantly modulates the immune system^[77]. Engagement of its specific receptor turns on a cascade of IFN-stimulated genes (ISGs) resulting in a non-pathogen specific antiviral state. Different HCV sequences seem to have different capabilities to interfere with this anti-viral strategy. The response rates to treatment dramatically differ not only between different genotypes, but also between isolates of the same subtype. Comparison of sequence isolates that have been successfully treated with isolates that did not respond has put a 40 amino acid stretch of the HCV NS5A protein into the spotlight^[78]. The degree of sequence variation in this region has been associated with treatment outcome and has therefore been designated as the interferon-sensitivity determining region (ISDR). Subsequently, conflicting results have been published in similar studies; however, a meta-analysis supported the impact of this region on treatment outcome^[79]. A correlate of this observation may be the reported inhibitory action of HCV NS5A on PKR^[76]. For this interaction the ISDR and an additional 26 C-terminal amino acid stretch of NS5A are crucial. Therefore, selection of viral variants

during treatment that successfully enhance this interaction seems reasonable. However, neither was selection of mutations observed in the presence of this antiviral drug *in vitro*^[80] nor has selection of variants during treatment in longitudinal studies formally been shown. It remains, therefore, unclear how interferon alpha contributes to evolution.

The exact antiviral mechanisms of ribavirin are even less well established. Several mechanisms have been suggested including inhibition of the HCV polymerase and early chain termination during the replication process. Higher mutation rates in the presence of ribavirin have been reported potentially resulting in an 'error catastrophe'. Two recent studies analyzed the mutation rate in the presence and absence of ribavirin in patients receiving treatment. Hofmann *et al.* analyzed the NS3 and NS5B gene in 14 subjects receiving either ribavirin monotherapy or in combination with interferon alpha^[81]. Based on a comparison of clonal sequences in the quasispecies population before and after initiation of therapy they concluded that the mutation rate of HCV is higher in the presence of ribavirin. These results were reproducible in cell culture with HCV replicon bearing hepatoma cell lines. Even though the overall effect was weak, a dose dependency could be demonstrated and the inactive L-enantiomer did not show the same effect. In a similar analysis by Lutchman *et al.* the mutation rate for NS5B was calculated based on analysis of bulk and clonal sequences of the NS5B gene in 18 subjects receiving ribavirin and 13 subjects receiving placebo^[82]. A significant increase of the mutation rate in the presence of ribavirin was observed after 4 wk of treatment; however, there was no significant difference between the mutation rates after 24 wk compared to the placebo group. The authors of this latter study conclude that ribavirin unlikely acts through an increase of the mutational error rate resulting in an error catastrophe. One study demonstrated selection of a Phe to Tyr mutation in position 415 of the HCV NS5B protein in the presence of ribavirin^[83]. This mutation was associated with a less susceptible phenotype for this drug when tested in the replicon model *in vitro*. This mutation was also observed in 5 out of 16 subjects infected with genotype 1a in the study by Lutchman *et al.* However, it was not reproducible in HCV genotype 1b. It is, therefore, still unclear if specific mutations are selected in the presence of ribavirin.

Future treatment strategies will include small molecules as inhibitors of virus specific protein functions. Drugs like protease and polymerase inhibitors are very successful for the treatment of HIV. However, selection of variants that are resistant to these antiviral compounds is a major challenge in the management of patients infected with HIV. In recent years many compounds have been tested as inhibitors of the HCV protease and polymerase. Some are now available in early clinical trials. The first compound that was tested in humans was the protease inhibitor BILN 2061. In patients infected with genotype 1 the viral load was dramatically decreased after only 2 d of treatment^[84]. However, the drug was designed to inhibit the HCV protease from a genotype 1 isolate with high affinity. As expected, the efficacy was, therefore, much

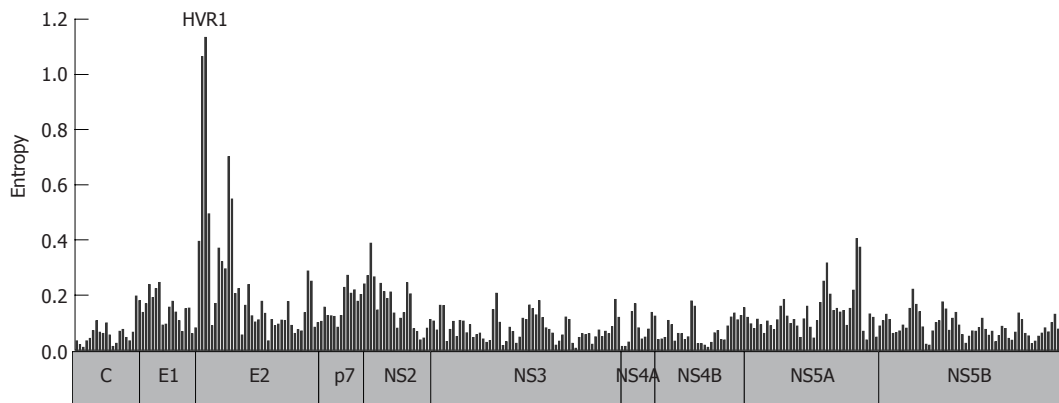

Figure 3 Entropy across the HCV polyprotein. 100 HCV genotype 1b sequences were retrieved from the Los Alamos National Laboratory (LANL) HCV Sequence Database. The entropy score was calculated for 300 windows of 20 residues overlapping by 10 residues utilizing the algorithm implemented in the database.

lower in subjects infected with HCV genotype 2 or 3^[85]. Due to observed toxic effects of this drug in high dosage in animal models further clinical trials were stopped. Other small compounds have meanwhile reached early phases of clinical testing (reviewed in^[86]) including protease inhibitors (VX-950 and SCH 503034) and polymerase inhibitors (NM283 and HCV-796). Along with their proof of excellent efficacy *in vitro* and *in vivo* several reports have been published describing resistance mutations^[87,88]. A recent study by Sarrazin *et al* analyzed clonal sequences from subjects treated with the protease inhibitor VX-950 in a clinical trial^[89]. In this analysis mutations associated with phenotypic resistance were rapidly selected during treatment and the number of resistant clones in each patient correlated well with the virologic response to the drug. The mutations were reproducibly located in only a few positions in the HCV protease gene. Interestingly, the number of resistant clones decreased after cessation of therapy indicating that some mutations are associated with fitness costs and revert back to wild type in the absence of the drug. Future studies will show if combinations of different drugs such as polymerase and protease inhibitors are beneficial to decrease the risk of resistance mutations similar to HIV.

Constraints on sequence diversity-purifying selection

Analysis of available HCV full genome sequences from public databases shows that the degree of sequence variation varies both between different proteins, but also between regions of the same protein (Figure 3). Some regions are highly conserved even across different HCV genotypes. Many of these highly conserved regions represent functionally important motifs in the viral protein in which substantial sequence variation is not tolerated. Viral evolution is clearly limited by structural constraints forcing the virus into a state in which it is able to functionally exist. Many mutations that occur during the replication process are deleterious or disadvantageous to the fitness of the virus and are, therefore, negatively selected. In contrast, as highlighted in this review multiple forces of the immune system or in some cases drugs exact positive selection pressure away from the consensus sequence in the individual. Selection of variants is, therefore, a trade-off between host pressure and functional needs. Purifying selection describes the driving force towards a sequence with optimal replication capacity

in the absence of outside pressure on the virus. Reversion of resistance mutations that have been selected in the presence of antiviral drugs back to the consensus sequence have been first described in the influenza model^[90]. For HIV, reversion of drug resistance mutations is well documented and the concept of a salvage therapy was based on this observation. In this concept treatment is re-initiated after interruption and genotypic reversion of drug resistance. However, the clinical benefit is controversial and with a wide range of antiviral drugs now available for the treatment of HIV this strategy received less attention.

In HCV reversion was first described for an escape mutation that has been selected by virus-specific CTLs^[64]. In this study a virus harbouring an escape mutation in an HLA-B8 restricted epitope in NS3 was transmitted to a host who is HLA-B8 negative and who, therefore, was not able to mount the same T cell response. In the new host the virus continued to evolve back to the prototype sequence and the variant disappeared. Similarly, Ray *et al* analyzed viral sequences from a single source outbreak years after the transmission event^[65]. Interestingly, the source of the virus again had an escape mutation in the same HLA-B8 restricted epitope in NS3. Years later the mutation has reverted back to the prototype sequence in most recipients. Of note, the mutation was stable in subjects who are HLA-B8 positive and who are theoretically able to target this region. Similar to the reversion of CTL escape mutations Sarrazin *et al*^[89] describe in their study on drug resistance to the protease inhibitor VX-960 reversion back to the wild type sequence after treatment was discontinued. These studies illustrate the main selecting forces of HCV evolution. On one side, there is positive selection pressure mainly by the immune system but also in the presence of antiviral drugs. These selection forces are not constant and vary in different hosts and different environments largely depending on the host's genetic background. On the other side, there is negative selection pressure, which presses the virus into a state of optimal replication capacity. This force is more or less constant, but largely depends on the pre-existing sequence configuration such as the genotype or presence of compensatory mutations.

CONCLUSION

The inherent sequence diversity of HCV represents a

major challenge for any treatment. HCV has the ability to rapidly adapt to a hostile environment in the acutely infected individual with an activated immune system at work. An important feature of any therapeutic or prophylactic intervention will be the efficient attack of a structurally or functionally important region in the viral protein. Ideally the attack is targeted against a region that does not tolerate substantial sequence variation in order to limit the ability to evade. Alternatively, a combination of different attacks at different sites may decrease the risk of efficient mutational escape. Recent studies in HIV have suggested that selection of escape mutations may actually be linked to control of viral replication^[91]. Indeed, many of the described CTL escape mutations particularly in the presence of protective HLA-alleles such as HLA-B27 and -B57 as well as some drug resistance mutations in HIV are associated with dramatic fitness costs for the virus. For HCV, little is known about the impact of escape and drug resistance mutations on replication capacity even though their documented reversion in the absence of the drug or immune pressure suggests similar fitness costs. With the recent development of culture systems that include the complete replication cycle we now have the tools at hand to address important questions on the interaction between different selecting forces acting on HCV. The understanding of this interaction is fundamental for the design of novel therapies.

Abstract

Hepatitis C virus (HCV) needs to tightly manipulate host defences in order to establish infection. The innate immune response slows down viral replication by activating cytokines such as the type I interferons (IFN- α / β), which trigger the synthesis of antiviral proteins and modulate the adaptive immune system. HCV has therefore developed a number of countermeasures to stay ahead of the IFN system. Here, I will attempt to summarize the current state of research regarding IFN responses against HCV and the viral escape strategies. Particular emphasis will be put on the newly discovered mechanisms HCV employs to avoid the induction of IFN in infected cells.

INTRODUCTION

The type I interferon system which mainly involves IFN- α and - β is a powerful and universal intracellular defence system against viruses. Knockout mice which are unresponsive to IFN- α / β due to targeted deletions in the type I IFN receptor quickly succumb to viral infections although they have a regular adaptive immune system^[1,2].

Likewise, humans with genetic defects in STAT-1, which is involved in the signaling cascade of the IFN system, die of viral disease at an early age^[3].

INTERFERON INDUCTION

All nucleated cells of the mammalian body are able to synthesize and secrete type I IFNs in response to virus infection. Secreted IFNs are then recognized by neighboring cells and cause them to express potent antiviral proteins^[4,5]. As a result, virus multiplication is slowed down or even stopped, and the organism buys time for the establishment of an adaptive immune response.

Type I IFNs are classified according to their amino acid sequence and comprise a large number (at least 13) of IFN- α subtypes and a single IFN- β ^[6], as well as some additional family members^[7,8]. Expression patterns, i.e. which IFNs will be synthesized at which time point, mostly depend on the particular cell type.

Fibroblasts secrete mainly IFN- β as an initial response to infection but switch to IFN- α during the subsequent amplification phase of the IFN response^[9]. By contrast, dendritic cells, which play an important role in immunosurveillance, directly secrete high levels of IFN- α subtypes^[10,11].

Induction of IFN- β gene expression in fibroblasts occurs by the intracellular, so-called "classic pathway" (Figure 1). In infected cells, a signaling chain is activated by viral RNA molecules which are generated during genome transcription and replication^[12]. Two intracellular RNA helicases, RIG-I^[13] and MDA5^[14], act as sentinels for viral RNA^[15-17]. Then, a recently discovered adaptor protein binds to RIG-I and MDA5 and mediates the signal to downstream factors. It is called either Cardif for "CARD adaptor inducing IFN- β "^[18], IPS-1 for "interferon- β -promoter stimulator 1"^[19], MAVS for "mitochondrial antiviral signaling" molecule^[20], or VISA for "virus-induced signaling adaptor"^[21]. Cardif/IPS-1/MAVS/VISA activates two I κ B kinase (IKK)-related kinases, IKK ϵ and TANK-binding kinase-1 (TBK-1), which phosphorylate the transcription factor IRF-3^[22,23]. IRF-3 is a member of the IFN regulatory factor (IRF) family and plays a central role in the activation of the IFN- β promoter^[24]. Phosphorylated IRF-3 homo-dimerizes and moves into the nucleus where it recruits the transcriptional coactivators p300 and CREB-binding protein (CBP) to

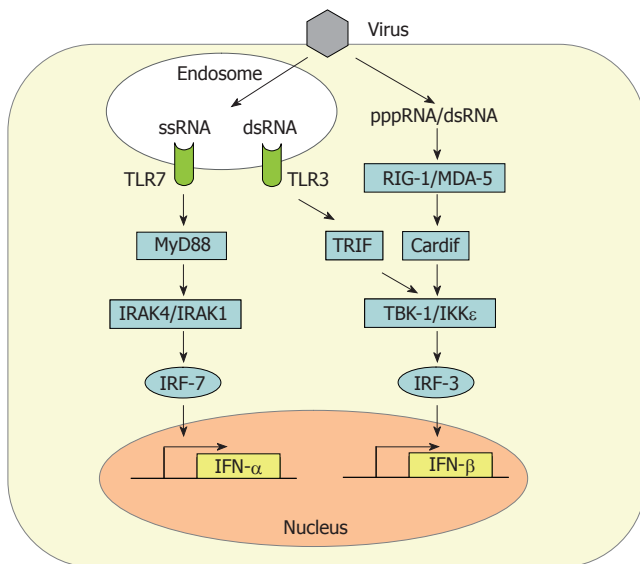

Figure 1 Type I IFN gene expression. Detection of viral ssRNA and dsRNA leads to transactivation of IFN- α and IFN- β promoters by IRF-7 and IRF-3. IRF-3 is phosphorylated by the kinases IKK ϵ and TBK-1 which in turn are activated by the intracellular RNA-sensor proteins RIG-I and MDA5. RIG-I preferentially senses 5'triphosphorylated ssRNAs (pppRNA) whereas MDA-5 recognizes dsRNA. Cardif (also termed IPS-1/MAVS/VISA) serves as an adaptor protein connecting RNA sensing and IRF-3 phosphorylation. A second dsRNA signaling pathway involves endosomal TLR-3 and the adaptor protein TRIF which also activates IKK ϵ and TBK-1. The endosomal ssRNA receptor TLR7 utilizes the adaptor protein MyD88 to stimulate IFN- α synthesis via the kinases IRAK4 and IRAK1 and the transcription factor IRF-7.

initiate IFN- β mRNA synthesis^[24,25]. This first-wave IFN triggers expression of a related factor, IRF-7, which in fibroblasts is only present in low amounts^[26]. IRF-7 can be activated the same way as IRF-3^[27-29], leading to a positive-feedback loop that initiates the synthesis of several IFN- α subtypes as the second-wave IFNs^[9,30]. In addition, NF- κ B and AP-1 are recruited in a dsRNA-dependent way^[31,32]. Together these transcription factors strongly upregulate IFN- β gene expression.

Until very recently, it was assumed that the main trigger of intracellular cytokine induction by all viruses is double-stranded RNA (dsRNA) which supposedly forms as a by-product of genome replication. However, we have recently found that some viruses do not produce substantial amounts of dsRNA^[33]. Instead, ssRNA containing a 5' triphosphate group is much more potent than dsRNA in activating RIG-I-dependent IFN induction^[34-36].

Among the cells of the lymphatic system, myeloid dendritic cells (mDCs)^[11] and, most prominently, plasmacytoid dendritic cells (pDCs)^[10] are the main IFN producers. In addition to the classical, intracellular pathway of IFN induction described above, pDCs sense the presence of viruses by the extracytoplasmic toll-like receptors (TLRs)^[37-39]. It is thought that TLRs serve as sensors for viral infection of phagocytosed cells^[40]. Human pDCs mostly express TLR7 and TLR9 which recognize viral single-stranded(ss) RNA and dsDNA, respectively^[41], whereas mDCs express TLR3 which responds to dsRNA^[42]. Upon activation, TLRs signal through different intracellular adaptor molecules such as

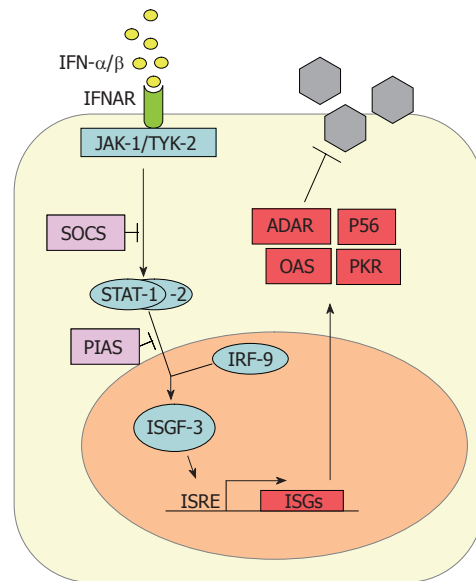

Figure 2 Cellular response to IFNs. Newly synthesized IFN- α/β binds to its cognate receptor (IFNAR) and activates the expression of numerous IFN-stimulated genes (ISGs) via the JAK/STAT pathway. ADAR, P56, OAS and PKR are IFN-stimulated gene products with antiviral properties against HCV. The SOCS and PIAS proteins negatively regulate the IFN-induced signaling pathway at different stages.

MyD88 (TLR7 and 9) or TRIF (TLR3) to induce IFN transcription^[41]. Interestingly, DCs already contain high levels of IRF-7^[43,44], thus explaining their ability to rapidly produce high amounts of alpha-IFNs. Furthermore, TLR7 and TLR9 are retained in the endosomes of pDCs to allow prolonged IFN induction signaling^[45].

INTERFERON SIGNALING

IFN- α/β subtypes all bind to and activate a common type I IFN receptor. It consists of two subunits (IFNAR-1 and IFNAR-2) and is present on virtually all host cells^[5,6]. Binding of IFN- α/β leads to heterodimerization of the IFNAR subunits and to conformational changes in the intracellular parts of the receptor which activate the so-called JAK-STAT signaling pathway (Figure 2). The signal transducer and activator of transcription (STAT) proteins are latent cytoplasmic transcription factors which become phosphorylated by the Janus kinase (JAK) family members JAK-1 and TYK-2^[46]. Phosphorylated STAT-1 and STAT-2 recruit a third factor, IRF-9 (also called p48), to form a complex known as IFN stimulated gene factor 3 (ISGF-3). The ISGF-3 heterotrimer translocates to the nucleus and binds to IFN-stimulated response elements (ISRE) in the promoter regions of IFN-stimulated genes (ISGs), thereby inducing their transcription.

Several specialized proteins serve as negative regulators and inhibitors of the JAK-STAT pathway. For example, the suppressor of cytokine signaling (SOCS) proteins specifically prevent STAT activation by binding to activated cytokine receptors, inhibiting the activity of JAKs, and targeting bound signaling proteins for proteasomal degradation^[47]. Also, the protein inhibitor of activated STAT (PIAS) family members function as small

ubiquitin-like modifier (SUMO) E3 ligases and inhibit the transcriptional activity of STATs^[48].

INTERFERON EFFECTOR PROTEINS WITH ANTIVIRAL ACTIVITY AGAINST HCV

IFN- α combined with ribavirin is the standard treatment for HCV infection, and its effect can be potentiated by co-administration of IFN- γ ^[49,50]. IFN- α/β activates the expression of more than 300 IFN-stimulated genes (ISGs) which have antiviral, antiproliferative, and immunomodulatory functions^[51,52]. IFN-induced proteins include enzymes, transcription factors, cell surface glycoproteins, cytokines, chemokines and a large number of factors that need to be further characterized. Up to now, only a few antiviral proteins have been characterized in detail. Type I IFNs are known to be effective against HCV replicon systems^[53,54], and several IFN-induced proteins have documented anti-HCV activity, namely protein kinase R (PKR)^[55], the RNA-specific adenosine deaminase 1 (ADAR 1)^[56], the 2'-5' oligoadenylate synthetases (2-5 OAS) / RNaseL system^[57], and P56^[58].

PKR, ADAR1, and 2-5 OAS are constitutively expressed in normal cells in a latent, inactive form. Basal mRNA levels are upregulated by IFN- α/β and these enzymes need to be activated by viral dsRNA. PKR is a serine-threonine kinase that phosphorylates the α subunit of the eukaryotic translation initiation factor eIF2^[59]. As a consequence, translation of cellular and viral mRNAs is blocked. ADAR 1 catalyzes the deamination of adenosine on target dsRNAs to yield inosine. As a result the secondary structure is destabilized due to a change from an AU base pair to the less stable IU base pair and mutations accumulate within the viral genome^[5]. The 2-5 OAS catalyzes the synthesis of short 2'-5' oligoadenylates that activate the latent endoribonuclease RNaseL^[60]. RNaseL, in turn, then degrades both viral and cellular RNAs, leading to viral inhibition^[61]. P56 binds the eukaryotic initiation factor 3e (eIF3e) subunit of the eukaryotic translation initiation factor eIF3. It functions as an inhibitor of translation initiation at the level of eIF3 ternary complex formation and is likely to suppress viral RNA translation^[62,63].

INTERACTION WITH INNATE IMMUNE RESPONSES

Several recent studies have clarified that the RNA of HCV is a potent trigger of IFN induction, leading to the establishment of an antiviral state. Therefore, in order to establish infection and to persist in the human host, HCV has been forced to evolve efficient counterstrategies. Intracellular IFN induction by HCV appears to be mostly mediated by RIG-I binding to viral RNA^[64]. Extracellularly, no specific TLR has been identified yet, but by deduction from data on related flaviviruses, TLR3 and TLR7 would be the most obvious candidates. The dsRNA-binding TLR3 was shown to be activated by West Nile virus^[65], and the ssRNA-binding TLR7 is activated by Dengue virus^[66]. Moreover, TLR7 can elicit HCV immunity, and a synthetic

TLR7 agonist reduced HCV mRNA and protein levels in HuH-7 hepatocytes^[67]. It is important to note that TLR7 is expressed in hepatocytes of normal as well as HCV-infected people^[67]. Thus, TLR7 may indeed play a role during natural infection.

On the other hand, HCV is capable of disturbing the IFN response at multiple levels^[68,69]. With respect to IFN induction, it was recently discovered that the NS3/4A protease specifically cleaves Cardif^[418] as well as TRIF^[70,71]. Since both these adaptor proteins are important for IFN induction via the classical intracellular pathway (Cardif) and the TLR3-driven endosomal pathway (TRIF), NS3/4A is the key factor of HCV to disturb IRF-3 activation^[72] which would otherwise result in IFN gene transcription. In addition, NS3 directly interacts with TBK1 to inhibit its association with IRF-3 and its activation^[73].

With respect to the IFN response, it was shown that expression of the full-length virus genome or the core protein suppresses IFN signal transduction^[74,75]. Most likely, this is due to an up-regulation of protein phosphatase 2A by ER stress^[76], resulting in association of STAT1 with its inhibitor PIAS1^[77]. Moreover, for the core protein it was shown that it interferes with the JAK/STAT pathway^[78] and is able to activate the JAK-STAT signaling inhibitor SOCS-3^[79], further contributing to the HCV-induced block of IFN signaling.

HCV also directly counteracts the antiviral IFN response. The NS5A protein, which confers a multitude of functions in virus replication^[80], also plays a key role in escape from the antiviral action of IFN. A stretch of 40 amino acids on NS5A, termed the IFN sensitivity region (ISDR), was correlated with responsiveness to IFN therapy^[81-83]. Moreover, NS5A was shown to directly bind to and repress PKR, and this interaction involved the ISDR^[84]. However, other groups did not find a connection between viral IFN susceptibility and a particular ISDR sequence^[85-87], and PKR activity was not affected by expression of the HCV genome^[88] or NS5A^[89], although NS5A clearly reduced the antiviral effects of IFN^[89]. A possible solution for this discrepancy could be that ISDR sequence variations affect the efficiency of HCV replication^[90,91]. Thus, the correlation between particular ISDR sequences and IFN sensitivity could be caused by differences in HCV replication strength. In addition, NS5A induces IL-8 (also termed CXCL-8), a chemokine which inhibits the antiviral actions of IFN^[92]. Elevated IL-8 levels were indeed detected in the sera of IFN non-responders^[93]. Moreover, in cell culture CXCL-8 protein levels are positively associated with chronic HCV replication and CXCL-8 removal inhibits HCV replication^[94]. Interestingly, CXCL-8 cannot only be induced by NS5A, but also by the HCV RNA-sensitive RIG-I pathway^[95].

NS5A also interferes with the 2-5 OAS/RNaseL pathway by binding to 2-5 OAS^[96]. Furthermore, the HCV genome sequences of IFN-resistant strains have fewer RNase L recognition sites than those of more IFN-sensitive ones^[97], thus allowing escape from nucleolytic cleavage^[97]. PKR activity is also modified by the internal ribosome entry site (IRES) of HCV^[98] and the E2 protein^[99].

The multiple countermeasures of HCV to avoid a

fully-fledged IFN response appear to be quite efficient, since 85% of the HCV-infected patients develop a chronic infection, and up to 60% of those patients do not respond to IFN therapy or experience a relapse when therapy is stopped^[100]. Our rapidly increasing knowledge about HCV immune escape will certainly lead to a significant improvement in both prevention and therapy for hepatitis C.

Abstract

Hepatitis C virus (HCV) is a major cause of hepatitis world-wide. The majority of infected individuals develop chronic hepatitis which can then progress to liver cirrhosis and hepatocellular carcinoma. Spontaneous viral clearance occurs in about 20%-30% of acutely infected individuals and results in resolution of infection without sequelae. Both viral and host factors appear to play an important role for resolution of acute infection. A large body of evidence suggests that a strong, multispecific and long-lasting cellular immune response appears to be important for control of viral infection in acute hepatitis C. Due to the lack of convenient neutralization assays, the impact of neutralizing responses for control of viral infection had been less defined. In recent years, the development of robust tissue culture model systems for HCV entry and infection has finally allowed study of antibody-mediated neutralization and to gain further insights into viral targets of host neutralizing responses. In addition, detailed analysis of antibody-mediated neutralization in individual patients as well as cohorts with well defined viral isolates has enabled the study of neutralizing responses in the course of HCV infection and characterization of the impact of neutralizing antibodies

for control of viral infection. This review will summarize recent progress in the understanding of the molecular mechanisms of antibody-mediated neutralization and its impact for HCV pathogenesis.

INTRODUCTION

With an estimated 170 million infected individuals, hepatitis C virus (HCV) has a major impact on public health^[1]. HCV is a major cause of hepatitis world-wide. The majority of infected individuals develop chronic hepatitis which can then progress to liver cirrhosis and hepatocellular carcinoma. Treatment options for chronic HCV infection are limited and a vaccine to prevent HCV infection is not available.

HCV is a small enveloped positive-strand RNA virus that belongs to the genus *Hepacivirus* of the *Flaviviridae* family. This virus exhibits high genetic heterogeneity and has been classified into six genotypes and several subtypes. The HCV genome encodes a single precursor polypeptide of about 3000 amino acids that is cleaved co- and post-translationally by host and viral proteases into functional structural and non-structural proteins. The virion is composed of three different structural proteins: The core protein forming the viral nucleocapsid and two envelope glycoproteins, E1 and E2.

In vivo, HCV infects only humans and chimpanzees^[2]. Each individual is infected with a mixture of distinct but closely related HCV genomes, termed quaspecies. The liver is the primary target organ of HCV, and the hepatocyte is its primary target cell. Replication of the HCV genome has been demonstrated *in vivo* and *in vitro* in liver hepatocytes, and hematopoietic cells including dendritic cells and B lymphocytes^[3,4]. HCV establishes persistent infection in the majority of infected individuals

despite the fact that it is recognized and targeted by the host's immune system^[5].

Viral proteins are recognized as non-self by the host's immune system and induce the production of antibodies. During the natural course of infection, a large number of antibodies targeting epitopes of both structural and non-structural proteins are produced. The vast majority of antibodies induced have no antiviral activity, either because they are elicited by intracellular, degraded or incompletely processed proteins released from dying cells or because they are directed against epitopes that do not play any role in the virus entry process^[6,7]. A small proportion of antibodies termed "neutralizing antibodies" are able to target exposed epitopes of the viral structural proteins and neutralize the infectious virus by preventing or controlling viral infection. This review will summarize the current knowledge about host neutralizing responses in HCV infection. It starts with a brief description of the current model systems allowing the study of neutralizing responses, followed by viral targets of neutralizing antibodies. Finally, neutralizing responses in the course of HCV infection and the impact of neutralizing antibodies for HCV pathogenesis are discussed.

MODEL SYSTEMS FOR THE STUDY OF ANTIBODY-MEDIATED VIRUS NEUTRALIZATION

For many years, studies of host neutralizing responses against HCV had been hampered by the lack of a convenient tissue culture system for HCV entry and infection. In recent years, several *in vitro* models have been developed to study defined aspects of HCV host cell interaction and antibody-mediated virus neutralization: These include recombinant HCV envelope glycoproteins^[8,9], HCV-like particles^[10], HCV pseudotyped particles^[11-13], and, more recently, cell-culture derived infectious HCV^[14-16]. Recombinant HCV envelope glycoproteins have been successfully used as a surrogate model to study virus-host cell interaction leading to the identification of putative HCV receptor candidates including CD81^[8], scavenger receptor class B type I (SR-BI)^[9] and heparan sulfate^[17] as well as antibodies inhibiting cellular binding of envelope glycoproteins^[18]. HCV-like particles (HCV-LP) generated by self-assembly of the HCV structural proteins in insect cells have been shown to exhibit morphologic, biophysical, and antigenic properties similar to putative virions isolated from HCV-infected patients^[10]. In contrast to individually expressed envelope glycoproteins E1 and E2, E1/E2 heterodimers of HCV-LPs are presumably presented in a native, virion-like conformation. HCV-LPs have been shown to bind and enter human hepatoma cells as well as primary hepatocytes and dendritic cells in a receptor-mediated manner, therefore representing a useful model system for the study of HCV-host cell interaction including the characterization of antibodies interfering with cellular binding of particles^[17,19-25].

Retroviral HCV pseudotyped particles (HCVpp) represent a convenient and elegant approach to study

viral entry and antibody-mediated neutralization^[11,12]. Infectious HCVpp consist of unmodified HCV envelope glycoproteins E1 and E2 assembled onto retroviral or lentiviral core particles^[11,12]. HCVpp are produced by transfecting cells with expression vectors encoding the full-length E1/E2 polypeptide, retroviral or lentiviral core proteins, and a packaging-competent retro- or lentiviral genome carrying a marker gene. The presence of a green fluorescent protein or luciferase reporter gene packaged within these HCVpp allows reliable and fast determination of infectivity mediated by the envelope glycoproteins. HCVpp are infectious for certain cell lines of hepatocyte origin, principally Huh-7 cells, as well as for human primary hepatocytes^[11,12]. This system has been extremely useful in identifying neutralizing antibodies as well as characterization of the molecular mechanisms of antibody-mediated neutralization^[12,25-30]. Vesicular stomatitis viruses (VSV)/HCV pseudotypes expressing HCV E1 or E2 chimeric proteins containing transmembrane and cytoplasmic domains of the VSV G glycoprotein have been developed as another HCV pseudotype model system to study HCV entry and antibody-mediated neutralization^[13,31]. VSV/HCV pseudotypes infect human hepatoma cell lines and sera from HCV-infected chimpanzees or humans neutralize the pseudotype virus infectivity^[13,32]. In contrast to retroviral HCV pseudotypes demonstrating strong tropism for liver-derived cell lines, VSV/HCV pseudotypes are generated in relatively lower titer and can infect a broad range of mammalian cell lines, including cell lines not derived from the liver.

Most recently, several laboratories succeeded in establishing the efficient production of infectious HCV particles using a unique clone derived from a viral isolate of a Japanese patient with fulminant hepatitis C (JFH-1)^[14-16]. Successful infection of naïve Huh-7 and Huh-7-derived hepatoma cells with cell-culture derived HCV (HCVcc) was demonstrated by detection of viral proteins and a highly reproducible time-dependent increase of viral RNA in infected cells^[14-16]. Virus production in Huh-7 cells was dependent on an active viral polymerase and expression of a functional viral envelope containing the HCV envelope glycoproteins E1 and E2^[14-16]. Inoculation of naïve chimpanzees with JFH-1 or chimeric J6/JFH-1-derived HCV particles synthesized *in vitro* resulted in viral infection *in vivo* demonstrating the biological significance of this model system^[14,33]. The ability to generate infectious HCVcc of different genotypes – such as the development of chimeric HCVcc or HCVcc derived from HCV genotype prototype 1a strain H77 certainly improves the scope of the cell culture system for HCV infection^[34,35]. Infection of HCVcc has been shown to be efficiently neutralized by anti-HCV antibodies derived from human sera^[14] as well as polyclonal anti-envelope antibodies^[34].

The chimpanzee remains the only natural occurring animal model for the study of HCV infection *in vivo*. The clinical course of infection is usually milder in chimpanzees than in humans. However, these animals have provided unique opportunities to study adaptive immune responses to HCV^[36]. Using the chimpanzee model, antibodies with neutralizing properties have first been described^[37,38]. These antibodies were directed against epitopes in the envelope

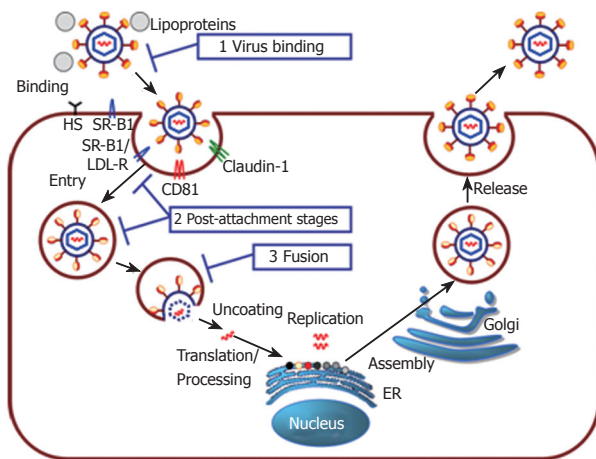

Figure 1 Potential targets for neutralizing antibodies within the HCV life cycle. A model of HCV infection with potential targets for virus neutralizing antibodies is shown. Antibodies can potentially interfere with the viral life cycle at different steps. ER: Endoplasmic reticulum; HS: Heparan sulfate; LDL-R: LDL receptor; SR-BI: Scavenger receptor class B type I.

glycoprotein E2 hypervariable region 1 (HVR-1) of HCV and appeared to be isolate-specific. The chimpanzee model has also been used to study protective immunity against re-exposure. Vaccination studies^[39] and passive immunization with rabbit anti-sera^[38] have shown some protection but infection of chimpanzees with HCV does not provide complete protective immunity against re-infection with homologous or heterologous virus^[40-44].

TARGETS OF HOST NEUTRALIZING RESPONSES

In recent years, rapid progress has been made in the understanding of the molecular mechanisms of HCV life cycle (Figure 1). Attachment of the virus to the target cell is mediated through binding of HCV envelope glycoproteins to binding factors present on the host cell surface, such as the glycosaminoglycan heparan sulfate^[17,25]. Binding and entry of HCV is believed to be a multistep process involving several attachment and entry factors, such as CD81, SR-BI and claudin-1^[45-47]. HCV is most certainly internalized in a clathrin-dependent manner and HCV genome delivery into the host cell cytosol prior to HCV replication is pH dependent^[48-51]. In analogy to other viral infections, antibodies neutralizing HCV may render virions non-infectious by interfering with different steps of the viral life cycle^[52,53]. Binding of the antibodies to the virus may directly block attachment of the virus with the host cell and thus inhibit dissemination of infection. Neutralizing antibodies may also interfere with post-binding steps such as interaction of the virus with host entry factors. If endocytosis is an obligate replicative step, internalization of the virus into the host cell by endocytosis may also cause neutralization. Neutralization of viruses by antibodies may also take place during fusion at the cell surface or in endosomes: Neutralizing antibodies may directly interfere with the fusogenic protein, hinder conformational changes necessary for the fusion process or simply obstruct contact between cellular

Table 1 HCV epitopes targeted by antibodies interfering with cellular HCV envelope glycoprotein binding, viral entry or infection

Envelope glycoprotein	Epitope (Amino acids)	Potential function	Model system
E1	192-226	Membrane fusion	HCV-LP binding ^[85]
	197-207		HCV-LP binding ^[24]
	270-284		HCVpp entry ^[63]
	313-332		HCV-LP binding ^[85]
E2	HVR-1	SR-BI/heparan sulfate binding	Chimpanzee ^[38]
	HVR-1		E2 binding, HCVpp entry ^[18,27]
	396-407		HCVpp entry ^[12]
	408-422		HCV-LP binding ^[22]
	412-419	Membrane fusion	HCVpp entry ^[55]
	412-423		HCVpp entry, HCVcc infection ^[12,57]
	416-430		HCVpp entry ^[63]
	432-443		HCVpp entry ^[12]
	436-447		HCVpp entry ^[12]
	474-494	CD81 binding	E2 binding, HCVpp entry ^[56,86]
	522-551	CD81 binding	E2 binding, HCVpp entry ^[56,86]
	600-620	Membrane fusion	HCVpp entry ^[63]
	640-653		HCV-LP binding ^[24]
	644-655		HCVpp entry ^[12]
	CD		E2 binding, HCVpp entry ^[58-61]

Envelope glycoprotein epitope (position amino acid within the HCV polypeptide) and its potential function with the viral entry process is shown. The experimental system for antibody-mediated inhibition of viral binding, entry or infection is listed together with the respective reference. CD: Conformation-dependent; E1 and E2: Envelope glycoproteins E1 and E2; HCV-LP: HCV-like particles; HVR-1: Hypervariable region-1; HCVpp: HCV pseudotyped particles; HCVcc: Cell-culture derived HCV; SR-BI: Scavenger receptor class B type I.

and viral membranes. In addition, neutralizing antibodies may also interfere with viral uncoating or the first steps necessary for viral replication (Figure 1). The identification and characterization of antibodies targeting distinct steps of viral entry is thus an important strategy for the understanding of the molecular mechanisms of antibody-mediated neutralization.

Using the above described model systems, it could be demonstrated that envelope glycoproteins E1 and E2 are critical for host cell entry and thus represent important targets for virus neutralization. Monoclonal or polyclonal antibodies targeting both linear and conformational epitopes of envelope glycoprotein E2 have been shown to inhibit cellular binding of HCV-LP binding, entry of HCVpp and infection of HCVcc (Table 1)^[10-12,14-16,19,20]. Several viral epitopes targeted by neutralizing antibodies have already been identified: epitopes of the E2 HVR-1 region (aa 384-410)^[12,18,27], two epitopes adjacent to the N-terminal HVR-1 region (aa 408-422 and aa 412-419)^[22,54,55], the E2 CD81 binding region (aa 474-494 and aa 522-551)^[12,54,56,57] and conformational epitopes within glycoprotein E2^[58-61]. These epitopes may represent potential candidate targets for antibodies in passive immunoprophylaxis. Indeed, two studies have demonstrated that monoclonal antibodies directed against

conformational epitopes^[60] or epitope aa 412-423 exhibited broad cross-neutralizing activity among all major genotypes of HCVpp entry^[54] as well as HCVcc infectivity^[62]. Most recently, at least three epitopes (aa 270-284, 416-430, 600-620) playing a role in membrane fusion processes have been identified in the envelope glycoproteins E1 and E2^[63]. Since one epitope (aa 416-430) has been shown to represent a target for monoclonal antibodies efficiently neutralizing HCV infection^[54], it is conceivable that membrane fusion may represent another target for anti-HCV antibodies with neutralizing properties.

IMPACT OF VIRUS NEUTRALIZING ANTIBODIES FOR PATHOGENESIS OF INFECTION

HCV RNA is detectable already one week following infection. Despite the rapid onset of viral replication, there is a delay in the appearance of HCV-specific T-lymphocytes and HCV-specific antibodies which only appear several weeks after infection. Patients who spontaneously clear HCV infection have been described to mount a vigorous multi-epitope-specific CD4 and CD8 T-cell response^[64,65]. Antibody-mediated neutralization occurs during HCV infection *in vivo* but the role of antibodies for the control of HCV infection has been difficult to study. Antibody-mediated neutralization has been suggested by study of patients undergoing liver transplantation for HCV- and hepatitis B virus (HBV)-related liver cirrhosis. Infusion of anti-HBs hyperimmune globulin containing anti-HCV appeared to reduce HCV infection in the transplanted liver^[66]. In addition, HCV-infected patients with primary antibody deficiencies have been reported to have accelerated rates of disease progression^[67,68]. Moreover, passive protection against HCV has been demonstrated in a cohort of patients that had been administered immunoglobulin preparations derived from HCV RNA-positive plasma but containing HCV-neutralizing antibodies^[69]. However, in the majority of patients, HCV infection is established despite the induction of an humoral immune response that targets various epitopes of the HCV envelope glycoproteins^[22,26,28,70,71].

Until recently, functional studies analyzing the neutralizing antibody response during acute and chronic HCV infection using HCV model systems demonstrated a lack of neutralizing antibodies in the majority of patients with acute HCV infection^[22,26,70,72]. These studies were limited by the fact that the viral surrogate ligand was derived from a different isolate than the virus present in the infected patient thus precluding the detection of isolate-specific antibodies. Most recently, studies using well defined nosocomial or single-source HCV outbreaks with a defined inoculum enabled to study the role of isolate-specific neutralizing antibodies for control of HCV infection in humans. Using the HCVpp model system, two studies have demonstrated that neutralizing antibodies are induced in the early phase of infection by patients who subsequently clear the virus^[29] or control viral infection^[73]. In a well characterized single-source outbreak of hepatitis C, viral clearance was associated with

a rapid induction of neutralizing antibodies in the early phase of infection. In contrast, chronic HCV infection was characterized by absent or low-titer neutralizing antibodies in the early phase of infection^[29]. In addition, patients with resolution of infection were shown to exhibit a broader cross-neutralizing activity of antibodies in the early phase of infection. An impaired ability to cross-neutralize viral variants rapidly emerging during acute infection may thus contribute to viral evasion from neutralizing responses in persistent HCV infection^[29]. These results suggest that a strong early broad neutralizing antibody response may contribute to control of HCV in the acute phase of infection and assist cellular immune responses in viral clearance. This conclusion is further supported by recent findings for HIV demonstrating that neutralizing antibodies act in concert with antiviral cellular responses for control of HIV infection^[74-76]. Furthermore, experimental data obtained in animal models have demonstrated that immune control of poorly cytopathic viruses, such as lymphocytic choriomeningitis virus (LCMV) or simian immunodeficiency virus requires a collaboration of both the cellular and humoral arms of the immune system^[77]. Indeed, gene-targeted mice expressing the immunoglobulin heavy chain of virus-neutralizing antibodies exhibit an accelerated LCMV clearance^[75]. Applying these findings to HCV infection- another prototype of persistent-prone non-cytopathic viruses- it is conceivable, that both cellular^[5,64,65,78,79] and neutralizing responses^[29,73] may contribute to control of HCV infection during the very early phase of viral infection.

Patients who do not clear the virus develop high-titer and even cross-neutralizing antibodies during the chronic phase of infection^[14,22,26,29,70,80]. Paradoxically, these antibodies are not able to control HCV infection. Viral escape from antibody-mediated neutralization in these patients may occur on several levels: (1) HCV exists as a quasispecies with distinct viral variants in infected individuals changing constantly over time and his variability has been shown to represent a mechanism of escape from antibody-mediated neutralization in the chimpanzee model^[26]; (2) the interplay of HCV glycoproteins with high-density lipoprotein and SR-BI has been shown to mediate protection from neutralizing antibodies present in sera of acute and chronic HCV-infected patients^[27,74]; (3) as shown for other viruses such as human immunodeficiency virus (HIV), escape from neutralizing antibodies may occur through a combination of different mechanisms, for instance point mutations, insertions/deletions or changes in glycosylation patterns of the viral envelope^[30,81] or conformational masking of receptor binding sites following envelope-antibody interaction^[82] preventing neutralizing antibody binding^[83].

Most recently, it has been shown for a chronic HCV patient who has been meticulously followed-up for 30 years that HCV continuously escapes the host's immune system by repeated mutational changes resulting in loss of recognition of the HCV envelope glycoproteins by antibodies^[80]. In fact, neutralization of heterologous strains does not reflect neutralization of the viral variants present in the patient's serum at the time of sampling^[80]. These data suggest that the neutralizing antibody response of

the host lags behind the rapidly evolving HCV envelope glycoprotein sequences of the quasispecies population. The fact that envelope glycoprotein sequences and neutralizing antibody specificity change over time suggest that neutralizing antibodies exert selective pressure on HCV evolution. In line with this hypothesis, it has been shown that HCV quasispecies complexity is associated with the inability to clear HCV infection and development of chronic disease^[84].

CONCLUSION

The development of robust tissue culture model systems for HCV infection within recent years has finally allowed for the study of antibody-mediated neutralization in HCV infection. Rapid progress has since then been made in determining the kinetic and targets of host neutralizing responses in the course of HCV infection. The novel model systems and patient cohorts with well defined viral isolates will now allow the identification of the molecular mechanisms of antibody-mediated neutralization as well as mechanisms of viral escape from host neutralizing responses. The elucidation of these mechanisms will be crucial for the understanding of HCV pathogenesis as well as the development of novel preventive and therapeutic strategies for control of HCV infection.

Abstract

Hepatitis C virus (HCV) infection is a major cause of liver damage, with virus-induced end-stage disease such as liver cirrhosis and hepatocellular carcinoma resulting in a high rate of morbidity and mortality worldwide. Evidence that CD4+ T cell responses to HCV play an important role in the outcome of acute infection has been shown in several studies. However, the mechanisms behind viral persistence and the failure of CD4+ T cell responses to contain virus are poorly understood. During chronic HCV infection, HCV-specific CD4+ T cell responses are relatively weak or absent whereas in resolved infection these responses are vigorous and multispecific. Persons with a T-helper type I profile, which promotes cellular effector mechanisms are thought to be more likely to experience viral clearance, but the overall role of these cells in the immunopathogenesis of chronic liver disease is not known. To define this, much more data is required on the function and specificity of virus-specific CD4+ T cells, especially in the early phases of acute disease and in the liver during chronic infection. The role and possible mechanisms of action of CD4+ T cell responses in determining the outcome of acute and chronic HCV infection will be discussed in this review.

INTRODUCTION

Hepatitis C virus (HCV) infection is a major cause of liver damage, with virus-induced end-stage disease such as liver cirrhosis and hepatocellular carcinoma resulting in a high rate of morbidity and mortality worldwide. Since the discovery of the virus, considerable evidence has emerged that CD4+ T cell responses to HCV play a key role in the outcome of infection. However many questions remain and these will be discussed in this review.

Cellular immune responses, involving both CD8+ cytotoxic T lymphocytes (CTL) and CD4+ T-helper cells, play an essential role in the control of HCV infection, as they do in other persistent viral diseases. Whereas CTLs are traditionally thought to be the main effector cells that eliminate HCV-infected cells^[1], it is clear that HCV-specific CD4+ T cells also play a critical role. These cells can potentially act in multiple ways and are central to the initiation and maintenance of adaptive immunity. Two likely major roles are in providing help for CD8+ T cells by cytokine production and activation of antigen-presenting cells, but there are multiple other mechanisms of action including direct antiviral effects, a role in B cell maturation, and regulatory functions.

A very clear example of the overall importance of HCV-specific CD4+ T cell responses *in vivo* is an experiment where the antibody-mediated depletion of CD4+ T cells before re-infection of two immune chimpanzees was performed. Such depletion resulted in persistent, low-level viraemia despite functional intra-hepatic memory CD8+ T cell responses^[2]. In this experiment incomplete control of HCV replication by memory CD8+ T cells in the absence of adequate CD4+ T cell help was associated with emergence of viral escape mutations in Class I MHC-restricted epitopes and failure to resolve HCV infection^[2]. This experiment is important in that it shows that CD4+ T cells are necessary for resolution of HCV infection. However, in this case the exact function of the CD4+ T cells was not elucidated. The fact that CD8+ T cell responses were maintained and were functional (inducing viral escape) suggests that their role is not purely in providing support for CD8+ T cell responses.

Overall, most data on CD4+ T cells comes from experiments in infected persons, particularly those

comparing chronic and resolved infection. During chronic HCV infection, HCV-specific CD4⁺ T cell responses are typically described as weak or absent whereas in resolved infection these responses are generally vigorous and multispecific. However, much of the data is derived from cross sectional studies and also based on analysis of one function-proliferation *in vitro*. There is no doubt that CD4⁺ T cell responses in resolved infection and in persistent infection look very different, but how they diverge and what the true functionality of the populations are is not yet clear. In our view, given their central importance in adaptive immunity, understanding why CD4⁺ T cell responses may fail in acute infection is the key question in HCV pathogenesis. Current data on the function and role of virus-specific CD4⁺ T-helper cells in acute and chronic HCV infection will be reviewed here and models discussed.

CD4⁺ T CELL RESPONSES IN ACUTE HCV INFECTION

Clearly, the best place to study the CD4⁺ T cell response against HCV is at the site of infection, but CD4⁺ T cell responses in the liver of acute HCV infection in humans have not been characterized to date. In chimpanzees, liver CD4⁺ T cells have been expanded with anti-CD3 and IL-2 and then tested for proliferation in response to HCV proteins^[3]. In those who failed to control the virus, no CD4⁺ T cell responses were identified whereas in those chimps who transiently or permanently controlled the virus, strong proliferative CD4⁺ T cell responses were detectable. This experiment is limited by the need to expand the cells first *in vitro*, which might exclude certain cell populations, especially at the peak of infection. What is interesting is not only the dichotomy between those animals that cleared virus and those that did not, but also the “transient” group. This group does mount an early CD4⁺ response against HCV, but it is not sustained. The clinical phenomenon of transient control is common in human infection, with “yo-yo” patterns often described, and will be discussed further below.

All human studies in acute disease have been performed on blood. In these, overall, acute resolving HCV infection has been associated with a sustained response by HCV-specific CD4⁺ T cells. In one representative study patients who failed to clear the virus were divided into two groups^[4]. Group 1 was unable to mount an HCV-specific CD4⁺ T cell response and developed chronic HCV. In Group 2, HCV RNA was cleared initially and was associated with strong HCV-specific CD4⁺ T cell responses. However, these responses diminished just before a rebound of viraemia that resulted in chronic infection. Therefore, a vigorous anti-viral CD4⁺ T cell response (as measured by proliferation assays) in the early and late phase of acute HCV seems necessary to achieve long-term viral control (CD4⁺/Th1 response). However, it is not sufficient (as in the chimpanzees), since those who mount such a response do not necessarily go on to clear virus.

Although what the Gerlach paper described is especially clear cut in relation to the “yo-yo” pattern, other groups

have also reported that the vigour of the T cell response during the early stages of infection may be a critical determinant of disease resolution and control of infection^[5]. That persistent infection can develop despite the presence of acute-phase HCV-specific CD4⁺ T cell responses has been shown in a study of healthcare workers exposed to needle-stick injuries^[6]: although two individuals had strong HCV-specific CD4⁺ T cell proliferative responses in the acute phase with significant decreases in HCV RNA initially, they subsequently became chronically infected. This was an important study since the individuals were available for analysis shortly after infection-before clinical symptoms arose. Since responses are sometimes transient, it may be that in studies where patients are only analysed after they present clinically with acute infection, early T cell responses have been missed.

Such analyses have traditionally relied on proliferation. Using alternative techniques, it has been shown that evolution of the infection to chronicity can be associated with HCV-specific CD4⁺ T cells which survive initially despite failing to proliferate or produce IFN- γ : these diminish eventually as infection persists^[7]. A study of a single patient using a novel approach with Class II MHC peptide complexes (“tetramers”) revealed the loss of functionality of cells before the final loss of detection of such populations^[8]. The failure of such responses in this patient occurred before the re-emergence of virus after transient control. This is important since it suggests that not all the failure of CD4⁺ T cell responses may occur as a consequence of prolonged viremia.

Overall, these studies suggest that a range of HCV-specific CD4⁺ T cell responses in the acute HCV phase can exist in blood and liver. In a subgroup of individuals, it may be that CD4⁺ T cell responses are not mounted initially, or are not detectable at the time of presentation. These individuals are very likely to develop chronic infection^[9]. In another group, strong responses are detected and sustained, which is typically associated with resolution of infection. An important third group (probably the majority of patients) do mount a CD4⁺ T cell response initially, but loss of such responses is associated with progression to chronicity. What the differences are in these initial responses to HCV and why certain key CD4⁺ T cell responses are not sustained remain important questions in understanding HCV persistence. To understand this further it is necessary to consider the exact targets of the CD4⁺ T cell response.

TARGETS OF THE CD4⁺ T CELL RESPONSES IN HCV INFECTION

A more effective immune response against HCV could result from targeting more epitopes, mounting larger responses or targeting a key region. There is some evidence for all three. Overall, permanent resolution of infection has been related to both the breadth (number of CD4 epitopes targeted) and the magnitude of HCV-specific CD4⁺ T cell responses. While no one target has been identified as the key determinant, a number of candidates have been proposed.

The NS3 protein has been shown to be one dominant target of CD4+ T cell responses in humans clearing HCV infection^[10]. Some epitopes in NS3 have been identified in both humans and chimps with resolved infection (see below)^[11-14]. Numerous studies indicate that CD4+ T cells targeting most HCV proteins, including non-structural (NS) proteins, are the norm in self-limited infections^[3-6,10-11,15-17]. However, some caution is needed in interpreting the exact targeting as the genomic variation between different HCV genotypes is substantial and relatively non-conserved epitopes (as might occur in envelope genes) may not always be picked up in such screens.

The number of CD4+ T cell epitopes recognised during acute HCV infection has been estimated by characterising memory CD4+ T cell populations in blood after permanent resolution of the virus: one study showed at least four, and up to 14 epitopes from the core, NS3, NS4 and NS5 proteins were recognised by CD4+ T cells in patients several months or even years after loss of HCV RNA^[11]. A recent study identified 13 CD4+ T cell epitopes within the NS3-NS4 region that were recognised by $\geq 30\%$ of patients with acute or resolved HCV^[18]. Of these, eight peptides were also recognised recurrently from different donors by specific CD4+ T cell clones in independent cloning procedures. Multispecific CD4+ T cell responses were also detectable in blood of individuals during acute HCV infection acquired by needlestick injury^[6] or IV drug use^[15]. Importantly, in some patients whose infection became chronic after the acute phase infection, responses were similar to those who spontaneously cleared the virus after acute infection^[6]. The only difference (as above) was that these responses in individuals with chronic infection were not sustained.

A recent study identified a single epitope restricted

by HLA DR1 (a common HLA molecule) in NS4, which appears to be very commonly targeted in infected individuals^[18] (Table 1). New analysis using Class II tetramers revealed that in acute infection, all DR1+ donors made a response to this peptide^[19]. This highly reproducible response is somewhat unusual, but may reflect the fact that this peptide is extremely conserved. Although the responses at presentation were indistinguishable between those who went on to resolve infection or not, early loss of tetramer+ cells was seen in those with persistent infection. The loss of such cells was not associated with mutation within the epitope and populations of such cells were not found localised in the liver only. Interestingly, when compared to controls in long term chronic infection, some very low level tetramer+ populations could be identified in the absence of proliferative responses. This suggests that specific responses were not deleted entirely, but persist at very low levels and with only limited function.

Table 1 HCV T helper epitopes mapped within a region of 21 amino acids or less. The protein, the sequence and HLA restriction elements of the T helper epitopes are provided.

ASSOCIATION BETWEEN HLA CLASS II ALLELES AND INFECTION OUTCOME

It is not yet clear whether responses to specific epitopes are clearly related to outcome. However, the T cell response to peptides derived from the virus is directed by the MHC genotype, and this could have a major influence on the quality of T cell responses. Importantly, some MHC Class II alleles in humans have been associated with persistence or resolution of HCV infection. For example, HLA-DRB1*0701 has been shown to be associated with

persistence in patients who were homogeneous in terms of gender, source of infection (genotype 1b) and ethnicity^[20]. In contrast, a number of other studies of more mixed populations have shown a strong association between other HLA Class II alleles and viral control. These alleles are HLA-DRB1*0101, HLA-DRB1*1101, and HLA-DQB1*0301^[21-23].

Although specific HLA alleles have been defined as protective, the link between the possession of a specific allele and the presentation of a specific peptide or set of peptides has not yet been made. HLA-DRB1*1101 and HLA-DQB1*0301 (these genes are in close linkage disequilibrium) have been associated with a sustained CD4⁺ T cell response in resolved HCV infection; these responses were stronger than in non-DQB1*0301+ controls^[24]. However, our understanding of this association still remains incomplete. Some of these HLA Class II restricted peptides have been identified through epitope prediction programs^[25], and the full repertoire of naturally presented peptides is not completely defined. A recent study showed that viral variation might play a role in determining the dominance of epitopes seen within a population. Here, an HLA DR11-restricted epitope (NS3 aa1248-1261) that is highly conserved within viral genotypes was found not to be the immunodominant response, despite being the most commonly recognised epitope for this HLA allele^[26]. Epitopes in viral regions that can tolerate amino acid substitutions may thus appear to be less dominant, even if they are important. This is because their capacity for increased variability means that they may not occur in the prototype viral peptide sequences often used for immunological study, or might only be represented in a fraction of the patients studied.

CD4⁺ T CELL QUALITY AND ASSOCIATION WITH ACUTE OUTCOME

It has been suggested in studies of acute disease that viral clearance is more likely to occur when HCV specific responses of patients display a Th1 profile (IFN- γ and IL-2). Those with a more typical Th2 profile (IL-4 and IL-10) were more likely to become chronic^[27] suggesting that the Th1 phenotype generates more protective immune responses in HCV. In that study, CD4⁺ T-cell proliferation and cytokine secretion in response to a panel of recombinant HCV antigens were assayed in 17 patients with acute HCV. All six patients with self-limited disease had a significant CD4⁺ T-cell proliferation to C22, E1, C100, C200, and NS5, running parallel with the antigen-stimulated secretion of IL-2 and IFN- γ , but not with IL-4 and IL-10, indicating predominant Th1 responses. Among the remaining 11 patients who developed chronicity, several cases showed specific CD4⁺ T cell responses, but their antigen-stimulated IL-2 and IFN- γ production were significantly lower than those of cases with recovery. Importantly, IL-4 and IL-10 (Th2 responses) were detectable in the group who developed chronicity. The data suggested that activation of Th2 responses in acute hepatitis C patients might play a role in the development

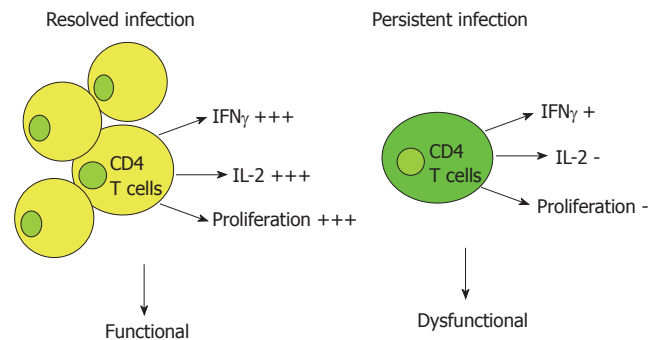

Figure 1 Cytokine secretion patterns in persistent versus resolved HCV infection.

of chronicity, but much more work needs to be done in this area, and why such responses might differ at the start of the disease needs some explanation.

HCV SPECIFIC RESPONSES IN CHRONIC INFECTION

As discussed above, once chronic HCV infection is established, cellular immune responses are rarely or barely detectable using current technology. Several groups have aimed to analyse these HCV-specific CD4⁺ T cell responses during chronic HCV infection using proliferation assays, cytokine assays and, more recently Class II tetramers.

Analysis of HCV-specific CD4⁺ T cell responses in chronic HCV infection using ELISpot or ICS showed responses at low frequency in blood and only targeted a limited number of epitopes^[4,7,11,15-17,28]. In an expanded analysis of responses to recombinant HCV proteins in persons with resolved infection, an average of 10 epitopes was targeted, whereas in persons with chronic viraemia never more than one epitope was targeted^[11].

The question of whether HCV-specific CD4⁺ T cell responses persist in chronic infection but lack function in terms of proliferation and cytokine production (IFN- γ) has been addressed by staining for expression of the IL-2 receptor α -chain (CD25), which is an early marker of activation in a study that showed that a small proportion of CD4⁺ T cells from the blood of chronically infected individuals did upregulate CD25 after stimulation with recombinant HCV proteins, but lacked the capability for proliferation and IFN- γ production^[7]. However, the use of the marker CD25, which is present normally on a fraction of CD4⁺ T cells including Tregs, limits the usefulness of this assay.

It has generally been assumed that loss of proliferation equates to loss of the specific T cell populations. Low levels of IL-2 secretion have been shown in independent studies in humans and mice to be accompanied by a loss of proliferative capacity both *in vitro* and *in vivo*^[29-32]. In HCV infection, recent data suggest that, in the presence of viraemia, HCV-specific CD4⁺ T cell populations do exist but lack proliferative capacity^[33]. This status is associated with the production of IFN- γ upon antigen stimulation, but little or no IL-2 is expressed^[34] (Figure 1).

The best approach for detecting functionally impaired

CD4⁺ T cells in chronic HCV infection is the use of MHC Class II tetramers. Using this technique, a correlation has been shown between the clinical outcome and the presence of circulating CD4⁺ T cells directed against the virus^[35]. Here, with the use of 3 HCV HLA Class II tetramers, HCV-specific CD4⁺ T cells could be detected in subjects who spontaneously resolved HCV viraemia, but not in those with chronic HCV infection, suggesting that HCV-specific CD4⁺ T cell frequencies are very low in PBMC. A further application of this technology for the analysis of intrahepatic CD4⁺ T cells could shed important light on their differentiation state and functionality.

The expansion of HCV-specific CD4⁺ T cell lines by repeated stimulation with recombinant antigens indicated that antigen-specific populations do persist^[36-38]. A note of caution should be injected here in the analysis of sustained CD4⁺ T cell responses in chronically infected patients. In many cases, these may represent a historical response to a previous viral genotype which is no longer circulating in the patient. In one case described, the response was directed against genotype 1 even though the patient carried genotype 3, with a historical genotype 1 infection^[39]. Since the peptide in the genotype 3 sequence was substantially different and not recognised by host CD4⁺ T cells, this indicates that the detected response is effectively a memory response after removal of the original virus. Since superinfection is relatively common, this issue may be a substantial one for both CD4⁺ and CD8⁺ T cells^[40].

The role of IL-10 as Th2 anti-inflammatory cytokine has been demonstrated *in vivo* in humans chronically infected with HCV^[41]. Here, individuals with advanced fibrosis were treated three times a week with IL-10 for 12 mo. Administration of IL-10 resulted in a decreased number of IFN- γ -secreting HCV-specific CD4⁺ and CD8⁺ T cells. At the same time ALT levels as a marker of inflammation were reduced, indicating the role of IL-10 as anti-inflammatory cytokine. However, with the loss of specific CD4⁺ and CD8⁺ T cells, HCV RNA levels were increased, suggesting that these same cells are responsible for viral control^[41].

One hypothesis why in chronic HCV the Th2 type may occur is that dendritic cells from patients with chronic HCV infection have defective function, possibly due to inhibition of IL-12^[42,43]. The latter cytokine is required for the induction of Th1 type cells. This dendritic cell dysfunction might result in biased T cell polarisation which could favor, for example, a Th2-type response. However, to what extent this is a major factor in pathogenesis is still controversial and the findings are not uniformly reproducible.

Overall, failure of CD4⁺ T cells is a key factor in HCV persistence and clearly in chronic disease there are relatively few functional CD4⁺ T cells to find, by whatever method. To some extent this appears to be due to loss/deletion of antigen-specific cells. On the other hand there is some evidence that a change in function also occurs in persistent infection, although whether this is cause or effect requires a great deal more study. It should be noted that although CD4⁺ T cell responses are regarded as weak in chronic HCV mono-infection, they are even weaker in HCV/HIV co-infection^[44,45]. Since co-infection is associated with an

increase of HCV load of about 0.5-1 log, this data suggests that in chronic mono-infection the remaining CD4⁺ T cell response is still playing a significant role.

MODELS FOR FAILURE OF CD4⁺ T CELL RESPONSES

If failure of the CD4⁺ T cell response against HCV is associated with virus persistence, what mechanisms could account for this? Here we outline three major contenders, escape, exhaustion and regulation.

Escape through mutation

Numerous studies in both animal and human models have documented immune escape from virus-specific CTL responses by viral mutations in CTL epitopes that lead to loss of immune control and viral persistence^[46-52]. Less information is currently available about the potential for immune escape from viral CD4⁺ T cell epitopes, although limited studies in chronic HIV and HCV infection have identified multiple autologous virus variants for specific CD4⁺ T cell epitopes^[53-56]. Peptides corresponding to viral variants were synthesised and tested in *in vitro* assays, and the majority of variants failed to stimulate proliferation or cytokine production by CD4⁺ T cells^[54-56]. That viral variants may play a role in HCV persistence has also been shown previously in a study with four HLA-DRB1*15 patients chronically infected with HCV^[57]. Here, naturally occurring single amino acid substitutions in the DRB1*15-restricted Th1 epitope (aa 358-375) in the NS3 protein failed to stimulate proliferation. This was also accompanied by a shift in cytokine secretion patterns from one characteristic of a Th1 anti-viral response to a Th2 form. These data suggest that viral immune escape from specific CD4⁺ T cell responses is possible, but clear data showing the evolution of CD4⁺ T cell escape mutants in response to T cell selection pressure are still needed.

A recent study analyzed the effects of an induced T-cell response in three immunized chimpanzees, targeting nonstructural proteins in the absence of neutralizing antibodies^[58]. The immunized animals were challenged with clonal HCV, which had the same sequence as the antigens used for immunization. Persistent control of the virus was observed in two animals, whereas in the third animal viral control was transient, followed by a resurgence concomitant with the emergence of new dominant viral populations bearing single amino acid changes in the NS3 and NS5A regions. These mutations resulted in a loss of CD4 T-cell recognition and subsequent to viral resurgence and immune escape a large fraction of NS3-specific T cells became impaired in their ability to secrete IFN- γ and proliferate.

Exhaustion

In addition to escape from virus-specific T cell responses, escape from neutralising antibody (nAb) responses is thought to be one potential mechanism leading to the persistence of some viruses with knock on effects on CD4⁺ T cells^[53,59,60]. Recent data generated in an LCMV model have provided additional insight into the relationship between

CD4⁺ T cells and immune escape from nAb responses. CD8^{-/-} mice were infected with the WE strain of LCMV to establish a long-term infection with high levels of virus production that is transiently controlled by nAbs^[60]. However, the lack of CD8⁺ CTL responses and consequently high viraemia in this model leads to escape from polyclonal nAb responses. Associated with this is the rapid induction of CD4⁺ T cell unresponsiveness^[61]. Although the molecular mechanism of CD4⁺ T cell unresponsiveness is not clear from this study, it has been postulated that the high antigenic load in this model system may have resulted in activation of all virus-specific CD4⁺ T cells, leading to exhaustion and activation-induced cell death as has been described for CTLs^[62,63]. Importantly, in the absence of LCMV-specific CD4⁺ T cells, these mice failed to generate new effective humoral responses against emerging neutralisation-escape mutants and the viral infection persisted^[61]. These data provide further evidence for the importance of interactions between the cellular and humoral immune responses for efficient control of viral infections. A similar phenomenon of exhaustion of CD4⁺ T cells could easily arise through any mechanism, which leads to long-term viremia, including escape from interferon or mutation in epitopes recognised by CD8⁺ T cells.

Regulation

Recent years have seen a revival of interest in the role of regulatory T cells—notably the CD4⁺ CD25⁺ FoxP3⁺ subset^[64]. It is plausible that in HCV infection excessive regulation is involved in the suppression of HCV specific T-cell responses. Recently, CD4⁺ CD25⁺ regulatory T-cell activity has been shown to be present in patients with chronic HCV infection, which may contribute to weak HCV-specific T-cell responses and viral persistence^[65-69]. An important question that derives from these studies is to what extent the Treg activity seen in persistent infection relates to the activity of antigen-specific cells. Treg cells may arise in the thymus (natural Tregs) but additionally virus-specific cells, which are repetitively stimulated with antigen over time, may develop regulatory characteristics. This activity may be promoted by the action of dendritic cell subsets modulated by persistent viremia. Such Treg cells might serve to downregulate both CD4⁺ and CD8⁺ T cell responses in persistent infection, particularly within the inflamed liver. A recent study revealed that approximately one in two to one in three CD4⁺ T cells in the liver of chronically infected patients are FoxP3⁺, a remarkably dominant potential Treg population^[70]. This could have a major effect on the maintenance and growth of antigen-specific CD4⁺ and CD8⁺ T cells.

CONCLUSION

HCV specific CD4⁺ T cells hold a pivotal role in disease pathogenesis. There is a consensus that there are real differences between the responses seen in resolved infection vs persistent infection, although to what extent these are cause or consequence is not clear yet. The differences include not only number, but also function, including cytokine secretion, such as the key mediator IL-2. A number of pieces of evidence point to the fact that a robust CD4⁺

T cell response is associated with a good outcome from acute infection and there is no doubt that such responses should be elicited in a vaccine. To what extent it matters which epitopes are targeted or not is not yet clear, but most observers argue that breadth is important, especially given the huge genomic variation in HCV, and that numbers are important. For those lucky enough to inherit protective HLA types, a vaccine may simply augment an already favourable response and sustain adaptive responses from CD8⁺ and B cells. For the rest, perhaps a pool of CD4⁺ T cell responses which are primed in a normal uninfected individual, and which can expand rapidly during acute infection may be sufficient to tip the balance in favour of host clearance.

Abstract

Virus-specific CD8+ T cells are thought to be the major anti-viral effector cells in hepatitis C virus (HCV) infection. Indeed, viral clearance is associated with vigorous CD8+ T cell responses targeting multiple epitopes. In the chronic phase of infection, HCV-specific CD8+ T cell responses are usually weak, narrowly focused and display often functional defects regarding cytotoxicity, cytokine production, and proliferative capacity. In the last few years, different mechanisms which might contribute to the failure of HCV-specific CD8+ T cells in chronic infection have been identified, including insufficient CD4+ help, deficient CD8+ T cell differentiation, viral escape mutations, suppression by viral factors, inhibitory cytokines, inhibitory ligands, and regulatory T cells. In addition, host genetic factors such as the host's human leukocyte antigen (HLA) background may play an important role in the efficiency of the HCV-specific CD8+ T cell response and thus outcome of infection. The growing understanding of the mechanisms contributing to T cell failure and persistence of HCV infection will contribute to the development of successful immunotherapeutical and -prophylactical strategies.

INTRODUCTION

The host immune response to pathogens involves various components of the immune system, including innate, humoral, and cellular immunity, the latter consisting of CD4+ and CD8+ T cells. All components of the immune response might have distinct roles in the outcome and pathogenesis of HCV infection and will be discussed in separate reviews in this issue of *WJG*. In this review, we will focus on the CD8+ T cell response to HCV infection. CD8+ T cells recognize viral antigen presented by HLA class I molecules on professional antigen presenting cells (CD8+ T cell priming) and on infected target cells (e.g. hepatocytes). Their antiviral activity includes cytotoxicity as well as the secretion of antiviral cytokines such as interferon-gamma (IFN- γ). In the following, successful virus-specific CD8+ T cell responses associated with viral clearance as well as ineffective CD8+ T cell responses present in persistent HCV infection will be described. The main focus of this review, however, is the multiple mechanisms that contribute to CD8+ T cell failure and viral persistence.

CD8+ T CELL RESPONSE IN ACUTE HCV INFECTION

During acute resolving HCV infection, vigorous virus-specific CD8+ T cell responses that target multiple epitopes can be detected approximately 4-8 wk after infection, and their emergence is temporally associated with the onset of liver disease^[1-4] (Figure 1A). However, the virus-specific CD8+ T cells are not able to secrete antiviral cytokines such as IFN- γ in this early phase of infection, a status referred to as 'stunned phenotype'^[2,3]. In a later phase of infection, virus-specific CD8+ T cells regain their ability to secrete antiviral cytokines, and this is temporally associated with a rapid decline of viremia and finally viral clearance. Knowledge about the intrahepatic virus-specific CD8+ T cell response during acute HCV infection was obtained from experimentally infected chimpanzees. Responses accumulate in the liver 8-14 wk after infection and coincide with liver disease as well as viral clearance^[5,6]. After resolution of infection, virus-specific CD4+ and

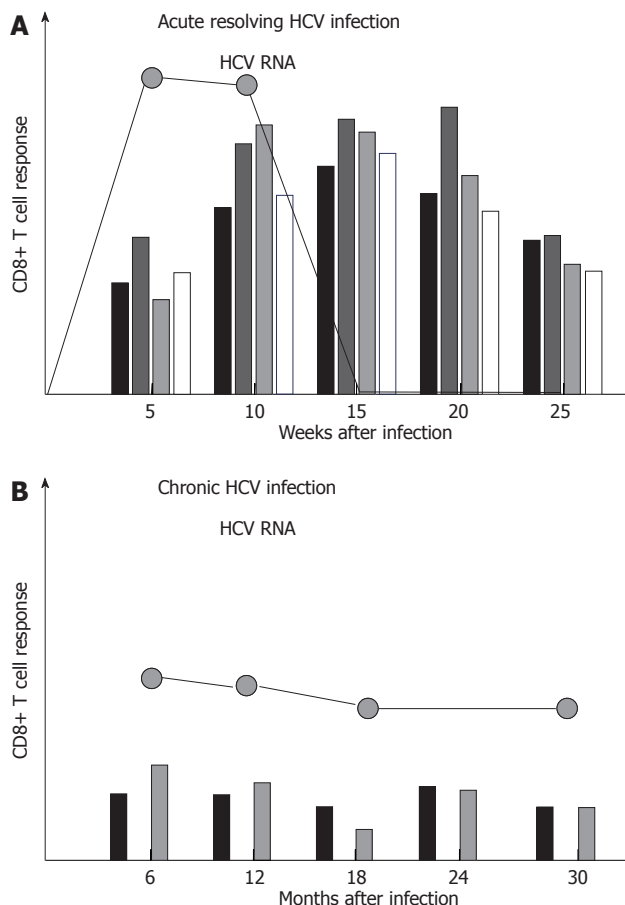

Figure 1 A: Virus-specific CD8⁺ T cell responses are strong, multi-specific, and sustained in acute resolving HCV infection; B: Virus-specific CD8⁺ T cell responses are weak and narrowly focused in chronic HCV infection.

CD8⁺ T cell responses persist for decades and can even outlast humoral responses^[7]. Virus-specific CD8⁺ T cells also play a role in mediating protective immunity. Indeed, evidence for protective immunity comes from both epidemiological studies as well as experimental studies^[8]. Chimpanzees re-challenged by HCV showed a shorter period and lower level of viremia than naïve animals^[9-11]. Sterilizing immunity against HCV, however, may not exist, since multiple episodes of heterologous or homologous re-infection have been observed in both, humans and chimpanzees.

In contrast to acute resolving HCV infection, the CD8⁺ T cell response in acute persisting HCV infection has been less defined. Previous reports comparing the CD8⁺ T cell response in acute resolving versus acute persisting HCV infection in chimpanzees and men found significantly weaker and more narrowly focused virus-specific CD8⁺ T cell responses in those subjects developing persistent infection^[1,2,5,6]. More recent studies, however, could not confirm this finding^[4,12,13]. For example, Cox *et al* performed a prospective longitudinal study in young iv drug users and analyzed the T cell response in 4 individuals with resolution of acute HCV infection and 15 individuals who progressed to chronic infection. Although all 4 individuals with resolving infection mounted virus-specific CD8⁺ T cell responses and those 4 individuals who lacked CD8⁺ T cell responses developed chronic infection, the

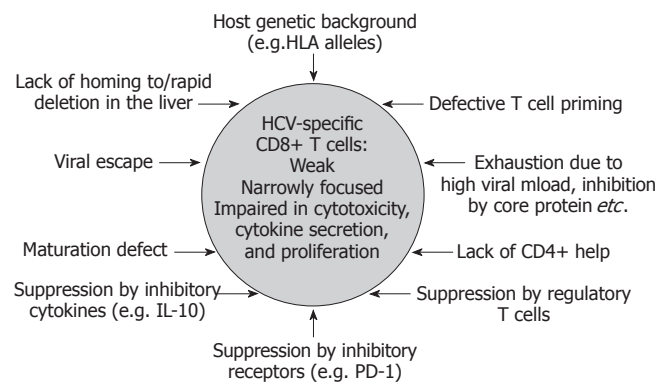

Figure 2 Possible Mechanisms of CD8⁺ T cell failure in persistent HCV infection.

CD8⁺ T cell response did not differ significantly between resolvers and persistently infected individuals^[4]. Urbani *et al* studied 6 patients with acute resolving and 11 patients with acute persisting HCV infection and found an association between strong and multispecific CD4⁺, but not CD8⁺ T cells with viral clearance. However, patients developing chronic infection displayed prolonged CD8⁺ T cell dysfunctions and maturational defects^[12]. This discordant role of CD4⁺ and CD8⁺ T cells was confirmed by Kaplan *et al*, albeit their analysis was limited to two HLA-A2 restricted CD8⁺ T cell epitopes^[13].

In sum, acute resolving HCV infection is associated with strong, broadly directed and sustained CD8⁺ T cell responses, while a universal picture of the CD8⁺ T cell response in acute persistent HCV infection has not yet been defined.

CD8 + T CELL RESPONSE IN CHRONIC HCV INFECTION

In contrast to acute resolving infection, CD8⁺ T cell responses are usually weak or even absent in chronic HCV infection, targeting only few epitopes^[14-22] (Figure 1B). In this context, it is important to point out that at least in some chronically infected patients, the CD8⁺ T cell response targets several epitopes^[17,18,22]. Importantly, however, these HCV-specific CD8⁺ T cells display functional impairments, including reduced cytotoxicity, reduced secretion of antiviral cytokines such as IFN- γ , and a reduced proliferative capacity^[23-25]. In addition, many CD8⁺ T cell responses do not target a present antigen, but rather a historical antigen due to viral escape (see below). Different mechanisms which might be involved in the failure of the HCV-specific CD8⁺ T cell response in persistent infection will be discussed in the following (Figure 2).

MECHANISMS OF CD8 + T CELL FAILURE

Primary failure and exhaustion

As discussed above, some patients with chronic HCV infection lack strong and multispecific CD8⁺ T cell responses, however, it is difficult to distinguish if virus-specific CD8⁺ T cell responses were not primed initially (primary CD8⁺ T cell failure) or responses were primed,

but vanished quickly (CD8+ T cell exhaustion). Results obtained from the early phase of acute HCV infection in chimpanzees and in health care workers infected through needle stick exposure support the hypothesis that CD8+ T cells are not primed at least in some patients with acute persisting HCV infection^[2,5,6]. In a prospective longitudinal study of young iv drug users, however, CD8+ T cell exhaustion was indeed demonstrated for at least one targeted epitope in each subject developing chronic infection^[4].

An impaired priming of HCV-specific CD8+ T cells might be mediated by numeric and functional impairments of antigen-presenting cells, e.g. macrophages and dendritic cells; however, this topic remains controversial^[26-35].

CD8+ T cell exhaustion might be explained by general as well as HCV-specific mechanisms. Of note, it has been demonstrated in the lymphocytic choriomeningitis virus (LCMV) mouse model that high viral loads lead to an unresponsive state of virus-specific CD8+ T cells, downregulation of T cell receptors, and finally physical deletion of virus-specific CD8+ T cells^[36-39]. Recent data indicate that the inhibitory receptor PD-1 might be involved in this process (see below), and it has been postulated that the detrimental effect of high viral load may not only apply in LCMV infection, but in different viral infections including HCV infection. Regarding HCV-specific mechanisms of CD8+ T cell exhaustion, the core protein has been reported to impair CD8+ T cell activation, e.g. through interaction with membrane-bound complement receptor gC1qR^[40-42].

Lack of CD4+ help

While CD8+ T cells are considered the major effector cells against viral pathogens, the successful elimination of HCV might be highly dependent on sufficient CD4+ T cell help. Indeed, it has been demonstrated in the LCMV mouse model that CD4+ T cell help is needed to sustain cytotoxic CD8+ T cell responses during chronic viral infections^[43]. In chronic HCV infection, however, CD4+ T cell responses are very weak or even absent and functionally impaired, e.g. secrete low amounts of IL-2^[44,45]. Findings in the chimpanzee model support the central role of CD4+ help in CD8+ T cell mediated viral clearance. When CD4+ T cells were depleted by neutralizing antibodies prior to viral re-challenge, HCV viremia was prolonged, CD8+ escape variants were selected and HCV finally persisted^[46]. Consistent with this concept, HCV-specific CD8+ T cell responses were seen almost exclusively in the face of a strong CD4+ T cell response in a study of acutely HCV infected patients^[1]. A recent study demonstrated that the outcome of acute HCV infection was associated with efficient virus-specific CD4+ T cell responses. In this study, however, HCV-specific CD8+ T cell responses were induced irrespective of virological outcome or HCV-specific CD4+ T cell responses^[13].

Suppression by regulatory T cells

In the last few years, the concept of regulatory T cells has undergone a comeback and different types of regulatory T cells have been characterized in different clinical settings. In HCV infection, the role of CD4+CD25+

Foxp3+ regulatory T cells as well as IL-10 producing CD8+ T cells has been defined. In chronically HCV infected patients, CD4+CD25+ T cells have been found in a higher frequency compared to individuals with resolved HCV infection or healthy controls^[47-49]. These regulatory T cells suppress the proliferation as well as interferon-gamma secretion of virus-specific CD8+ T cells *in vitro*. The suppression by CD4+CD25+ T cells was cell-cell contact dependent^[47,48], it was independent of suppressive cytokines such as IL-10 and TGF- β in some but not all studies^[47,48,50]. Interestingly, the suppression was not restricted to HCV-specific CD8+ T cells, but also included CD8+ T cells specific for other viruses, such as EBV or influenza^[47,50]. However, specificity *in vivo* might be mediated by the enrichment of CD4+CD25+ T cells in the liver^[51]. While CD4+CD25+ T cells might limit immunopathology in the chronic phase of HCV infection^[52], it has been suggested that they may facilitate viral persistence in the acute phase of infection. However, studies in larger cohorts of patients with acute HCV infection have not yet been reported. The induction of CD4+CD25+ regulatory T cells is still little characterized, however, they could be induced by certain HCV peptides from peripheral blood mononuclear cells (PBMCs) from HCV-infected, but not healthy individuals *in vitro*^[53].

Another type of regulatory T cells in HCV infection is virus-specific regulatory CD8+ T cells that express high levels of IL-10. These regulatory T cells have been detected in the liver of HCV-infected individuals; they could be expanded upon stimulation with HCV epitope peptides and their suppression of virus-specific CD8+ effector T cells could be blocked by neutralizing IL-10 antibodies^[54]. This virus-specific regulatory T cell population might have an important role in the prevention of liver damage during chronic HCV infection^[55].

The spectrum of regulatory T cells involved in HCV infection may further expand, since we recently described the induction of regulatory CD8+ T cells from the PBMC of HCV-infected patients which also expressed high levels of FoxP3 and CD25^[56]. A comprehensive review on the different types of regulatory T cells in HCV and HBV infection by Billerbeck *et al* is also included in this issue of *WJG*.

Inhibitory receptors: PD-1

The inhibitory receptor PD-1 ("programmed cell death 1") has been demonstrated to be a strong marker for exhausted virus-specific CD8+ T cells in the LCMV mouse model. The antibody-mediated blockade of the interaction between PD-1 and its ligand PD-L1 led to the restoration of cytokine secretion, proliferation, and cytotoxicity by the exhausted virus-specific CD8+ T cells and a substantial reduction in viral load^[57]. Similar roles of PD-1 have been shown in human chronic viral infections^[58] such as HIV^[59], HBV^[60,61], and HCV. In the acute phase of HCV infection, similar to LCMV infection, PD-1 is up-regulated on HCV-specific CD8+ T cells independent of outcome. However, in individuals with resolving infection PD-1 expression decreases soon, while in patients with a chronic course of infection, HCV-specific CD8+ T cells remain PD-1 positive^[62]. This finding is in parallel with

the “stunned” phenotype of HCV-specific CD8⁺ T cells in the early acute phase of infection, which is restored in resolving infection but remains in persisting infection^[2,3,24]. In chronic HCV infection, HCV-specific CD8⁺ T cells in the peripheral blood^[63] as well as liver^[64] have been shown to express high levels of PD-1. Blockade of PD-1/ PD-L1 interaction by antibodies restored cytokine production and proliferation of the exhausted CD8⁺ T cells from acute and chronic infection *in vitro*.

It is important to note, however, that the antibody-mediated blockade of the PD-1/PD-L1 pathway in chronically LCMV-infected mice did not result in viral clearance although a significant reduction of viral load was achieved. Even more importantly, PD-L1-/- mice died due to immunopathologic damage after infection with a LCMV strain usually establishing persistent infection^[57]. These findings indicate that a subtle balance in the blockade of the PD-1/PD-L1 pathway must be granted before it can be applied in the clinics.

Inhibitory cytokines: IL-10

Two recent reports on the role of IL-10 in the dysfunction of virus-specific T cells and viral persistence gained much attention in the field. These reports showed that in mice with persistent LCMV infection, IL-10 was highly up-regulated early in infection, which was associated with the dysfunction of virus-specific CD4⁺ and CD8⁺ T cells. The blockade of the IL-10/IL-10 receptor (IL-10R) pathway by a genetic approach or by an anti-IL-10R antibody early in infection, however, led to the restoration of T cell function and to clearance of infection^[65-67].

Although these reports definitely point towards an important general mechanism of T cell dysfunction, a role of IL-10 in HCV infection has been postulated before, and IL-10 therapy has even been tested in clinical trials in HCV infected patients. Indeed, many reports showed an association of IL-10 polymorphisms and outcome, disease progression, or response to antiviral therapy of HCV infection^[68-74], while other studies failed to confirm these data^[75-79]. Clinical trials with administration of recombinant IL-10 to patients with chronic HCV infection who had failed antiviral therapy with interferon-alpha led to a decrease in transaminases and histological disease progression; however, viral titers strongly increased in some IL-10 treated patients^[80,81]. This indicates that IL-10 might not only mediate viral dysfunction and thus facilitate viral persistence in acute infection, but may also reduce immunopathology in the chronic phase of infection. In this context, it is important to point out, however, that IL-10/IL-10R blockade in the LCMV mouse model did not result in severe immunopathology^[65,66].

The exact mechanism of HCV-induced up-regulation of IL-10 remains elusive. Some groups have reported induction of IL-10 production by monocytes^[82] or natural killer (NK) cells^[83] through core^[74,84], non-structural protein 3^[84], or 4^[82]. More intriguingly, HCV-specific CD8⁺ T cells with regulatory properties which produce IL-10 have been described in the liver of chronically HCV infected patients^[54]. These IL-10 producing intrahepatic CD8⁺ T cells were associated with mild inflammation and low progression of fibrosis in liver histology^[55], once more sug-

gesting that IL-10 may protect from immunopathology in chronic HCV infection. Blockade of the IL-10 pathway by anti-IL10R antibodies *in vitro* led to increased HCV-specific CD4⁺ T cell responses^[85]. In addition, antiviral therapy led to reduced production of IL-10 by virus-specific T cells in patients with chronic HCV infection^[86]. A direct inhibition of the IL-10 pathway, however, needs further careful evaluation in additional animal models before it can be transferred to men.

Viral escape

HCV is a RNA virus with an enormous replication rate (approximately 10¹² virions per day) with a RNA-dependent RNA polymerase that lacks a proofreading function. Therefore, multiple viral variants, called quasispecies, circulate in a single individual. It has been suggested that the selection of viral variants escaping from CD8⁺ T cell responses might facilitate the persistence of HCV infection. Indeed, the first evidence for viral escape in HCV infection came from chronically infected patients^[87] and experimentally infected chimpanzees^[88,89]. Chronically infected patients harbored variant viral sequences in targeted epitopes which were non-immunogenic and not cross-reactive with the prototype peptides. These viral escape mutations remained fixed over a follow-up time of up to four years, indicating that escape mutations occur early in infection^[87]. In the chimpanzee model, it could further be demonstrated that viral escape mutations occurred during the first 16 wk of infection and were associated with a chronic course of infection^[89].

Important additional information came from studies in acutely infected patients^[90-92] as well as population-based approaches^[90,93]. In these studies, viral escape from CD8⁺ T cell responses was demonstrated in patients developing persistent infection^[90-92], but not in individuals with resolving infection^[91,92]. Interestingly, many mutations outside of targeted CD8⁺ T cell epitopes represented conversion to consensus^[91], and the transmission of an HLA-B8 associated escape mutation to an HLA-B8 negative subject resulted in rapid reversion of the mutation^[90]. These results were supported by a study in a well-defined cohort of Irish women accidentally infected with HCV from a single source more than 20 years ago. In this unique cohort, amino acid substitutions in known epitopes were directed away from consensus in women having the HLA allele associated with that epitope, and toward consensus in those lacking the allele^[93]. These findings are in agreement with the concept of viral fitness cost, indicating that viral escape mutations are often associated with a reduced replicative capacity of the virus^[94]. In the absence of the T cell pressure, e.g. upon transmission to an individual negative for the restricting HLA allele, the virus reverts to consensus and thus regains its full replicative capacity. This phenomenon has been analyzed in more detail in the background of an immunodominant HLA-A2 restricted epitope, identifying that certain amino acid residue substitutions abolish HLA binding without strongly influencing viral replication, while some substitutions lead to a strong reduction of viral fitness^[95]. Importantly, there might be some CD8⁺ T cell epitopes which are not affected by viral escape

due to high functional constraints. For example, we have recently identified an HLA-A26 restricted epitope located at the NS5A/5B cleavage site which was targeted in all studied HLA-A26+ patients (3/3) with acute HCV infection and a significant number of patients with chronic HCV infection (3/15). However, the epitope sequence was highly conserved in HLA-A26 positive and negative patients, indicating that viral escape did not occur in this functionally constrained region^[96].

Based on the finding that immunodominant CD8+ T cell epitopes leave their footprint in viral sequences in chronic HCV infection^[90], viral genome sequencing studies were performed in order to identify footprints of additional potential CD8+ T cell epitopes^[97,98]. In addition to previously defined epitopes, these studies identified HLA allele dependent polymorphisms and thus candidate CD8+ T cell epitopes. Importantly, the strongest association with any HLA allele in the study by Timm *et al* was found for HLA-B27 in a region that was shown to contain an immunodominant HLA-B27 restricted CD8+ T cell epitope by an independent study in another patient cohort^[99].

There are different molecular mechanisms by which a certain mutation escapes from the CD8+ T cell response. Especially those mutations located at the HLA binding anchors, usually P2 and the C-terminal amino acid, lead to the interruption of the peptide binding to the HLA molecule. Mutations in the center of the epitope, in contrast, are more likely to interfere with T cell receptor (TCR) recognition^[95]. Mutations in the flanking region, however, prevent proteasomal epitope processing^[90,100,101].

The determinants of viral escape are less understood. In the chimpanzee model of HCV, it has been shown that upon depletion of CD4+ T cells in the acute phase of infection viral escape from the CD8+ T cell response occurs and is associated with a persistent course of infection^[46]. This finding has led to the hypothesis that viral escape is caused by insufficient CD4+ help. Other studies indicate that a limited T cell receptor (TCR) diversity might be responsible for viral escape^[102]. Of note, viral escape does not occur in the context of dysfunctional CD8+ T cell responses^[103]. The strong association between HLA-B27 and viral escape within an immunodominant HLA-B27 restricted epitope as well as the suggestion that escape variant epitopes might preferentially be restricted by HLA-B alleles indicates that the restricting HLA allele background also plays an important role in determining viral escape^[97-99].

Lack of homing to the liver

Experimentally HCV infected chimpanzees which progressed to viral persistence without temporary viral control lacked virus-specific CD8+ T cell responses in the liver despite of detectable responses in the peripheral blood^[2]. This finding led to the tempting hypothesis that the failure of the virus-specific CD8+ T cell response might be caused by an insufficient homing to the primary location of infection, the liver. However, in chronically HCV infected patients virus-specific CD8+ T cells are detectable and even enriched in the liver^[22,25,104-108]. In a comprehensive study comparing the overall breadth and

vigor of CD8+ T cell responses in the peripheral blood and liver of chronically HCV infected patients, we found that virus-specific CD8+ T cell responses were strongly enriched in the liver. Many responses were only detectable in the liver; however, few responses were limited to the peripheral blood (Neumann-Haefelin *et al*, unpublished results). Therefore, it is possible that a defective homing of HCV-specific CD8+ T cells or their rapid deletion in the liver also contributes to T cell failure and viral persistence in a subset of patients.

ROLE OF THE HOST HLA CLASS I BACKGROUND

CD8+ T cells recognize antigens presented by human leukocyte antigen (HLA) class I molecules. It has, therefore, been suggested that different HLA class I alleles are associated with differential outcomes of HCV infection, e.g. viral clearance versus persistence^[109]. Analysis of the role of HLA alleles in viral infections are hindered by multiple factors, including the wide polymorphism of HLA alleles, their association with other genetic characteristics e.g. in certain racial backgrounds (founder effect)^[110], and the variability of viral strains (genotypes, quasispecies *etc.*). However, an Irish cohort of women accidentally infected with HCV (genotype 1b) from a single source more than 20 years ago, represents a homogeneous group in which the role of HLA alleles in the outcome of HCV infection could be studied^[111]. Importantly, the HLA class I alleles A3, B27 and Cw*01 were significantly associated with viral clearance, while B8 was associated with viral persistence. Interestingly, the strongest protective effect was observed for HLA-B27: 80% (12/15) of B27 positive women were able to clear the infection spontaneously, while only a minority developed chronic infection. We recently identified an immunodominant HLA-B27 restricted HCV-specific CD8+ T cell epitope, which was targeted in the vast majority (5/6) of B27 positive Irish women who had cleared the infection^[99]. Of note, such a clear dominance of a single epitope-specific CD8+ T cell response has not been described for any other HLA allele in HCV infection. In chronically infected patients, still a remarkable percentage of patients (3/8) recognized the epitope. However, most B27 positive chronically infected patients had evidence of viral escape within the otherwise conserved viral region containing this epitope. Thus, a single immunodominant HLA-B27 restricted CD8+ T cell epitopes might mediate both, clearance of HCV infection in the majority of B27 positive individuals, and viral evolution associated with viral persistence in a minority of individuals.

Strikingly, a very similar frequency of viral escape variation was demonstrated within an immunodominant HLA-B8 restricted CD8+ T cell epitopes^[90]. This indicates that in the background of both, a protective HLA allele (B27) as well as a detrimental HLA allele (B8) the principle mechanisms of CD8+ T cell failure might be the same. More precise details such as viral fitness cost associated with the respective escape variation^[94,95], T cell receptor (TCR) diversity^[102] or heterologous immunity^[112,113]

may play an additional critical role in the definition of a protective HLA allele.

Two other population studies in more heterogeneous cohorts showed an association between HLA-B57 and HCV clearance in Caucasian as well as African Americans and West Africans^[114,115]. Interestingly, HLA-B27 and HLA-B57 have also been shown to be protective in HIV infection, being strongly associated with low viral titers, low CD4+ T cell decline, and long-term non-progression of the disease^[116]. Thus, a picture emerges that the same HLA alleles may confer protection in different clinical infections, indicating that similar mechanisms of viral control and disease progression apply in these infections. A better understanding of the host-virus interactions leading to different clinical outcomes of HCV infection will be important not only to understand the mechanisms of viral clearance and persistence, but also for the development of new antiviral vaccine strategies.

CONCLUSION

CD8+ T cells are generally thought to be the major effectors in viral infections; however, multiple host and viral mechanisms contribute to the failure of antiviral CD8+ T cell responses and viral persistence in the majority of HCV infected patients. In the last few years compelling progress has been achieved in the understanding of these mechanisms (compare with^[117]). These findings are not only important for the development of successful immunoprophylactic approaches, but may also be more directly adopted for immunotherapeutic interventions.

Abstract

Chronic viral infections such as hepatitis B virus (HBV), hepatitis C virus (HCV) and human immunodeficiency virus (HIV) are major global health problems affecting more than 500 million people worldwide. Virus-specific CD8+ T cells play an important role in the course and outcome of these viral infections and it is hypothesized that altered or impaired differentiation of virus-specific CD8+ T cells contributes to the development of persistence and/or disease progression. A deeper understanding of the mechanisms responsible for functional differentiation of CD8+ T cells is essential for the generation of successful therapies aiming to strengthen the adaptive component of the immune system.

INTRODUCTION

The adaptive immune response is characterized by the

ability to respond specifically and quickly to antigens that the host has encountered previously. Virus-specific CD8+ T cells critical in this response can be divided into naïve, effector and memory CD8+ T cells. In the strictest sense, the memory response should be maintained in the absence of antigen, poised to respond quickly, specifically, and with sufficient amplitude to protect the host from repeated infection by a previously encountered pathogen^[1,2]. The ability to survive in the absence of antigen differentiates memory T cells from effector cells that exist at the peak of the immune response, while antigen is present. However, in the context of viral infection, differentiation from effector T cells into memory cells may differ depending on the nature of the pathogen.

Many viral infections are acutely cleared by the immune response, whereas others result in persistent infection and are associated with altered differentiation of host T cells. For example, antigen-specific CD8+ T cells isolated from persons with resolved infections such as influenza (Flu) or respiratory syncytial virus (RSV) clearly represent functional memory. With “latent” infections such as Epstein-Barr virus (EBV) or cytomegalovirus (CMV) where low level of virus may still be intermittently present, a strict definition of memory may not be appropriate for these antigen-specific CD8+ T cells^[2]. In fact, van Leeuwen *et al*^[3] proposed to classify these cells as “resting vigilant effector cells” due to their ability to continuously control the latent virus. Currently, neither the frequency nor mechanism of re-encounter with antigen after resolved, primary EBV or CMV infection is well understood. For chronic viral infections such as HIV, hepatitis B virus (HBV) and hepatitis C virus (HCV), isolated antigen-specific CD8+ T cells also may not represent true memory T cells, but rather effector-type cells, or perhaps a population comprising effector and memory cells.

The criteria used to define the differentiation of virus-specific T cells are complicated. In mouse models of viral infection, time after experimental infection is often used to delineate effector T cells from memory T cells. For example, after experimental LCMV infection and clearance, d 40+ has been set as a time at which stable memory CD8+ T cells can be isolated, with many memory qualities being acquired between d 8 and 21 post infection^[4,5]. In addition to time-after-infection, a number of surface antigen markers have been used to differentiate effector CD8+ T cells from memory CD8+ T cells, and to differentiate subsets of memory cells that possess varied levels of differentiation and function. Activation markers

such as CD38 and HLA-DR are often used to identify effector cells which up-regulate these markers during an immune response and which are generally not expressed on quiescent memory cells. Memory cells that re-encounter antigen re-express these activation markers^[6]. Surface expression of the IL-7 receptor- α (CD127) is also used to differentiate effector from memory cells. Naïve and memory cells require an ability to survive and proliferate in the absence of antigen, a process called “homeostatic proliferation”. Cytokines, such as IL-7, and signaling through CD127 are critical in this process^[7]. Naïve cells exposed to antigen decrease expression of CD127 on their cell surface (effector phenotype). Once antigen is cleared, CD127 is re-expressed on memory cells and enables their maintenance. This re-expression characterizes them as memory cells. However, CD127 expression may not be a fool-proof marker of memory, since some subsets of CD8+ T cells identified as memory CD8+ T cells express only low levels of CD127, particularly in latent/chronic viral infections. Whether these cells represent true memory in the strict sense of the definition, or rather represent a population of effectors amidst memory cells is not yet fully elucidated. Finally, immediate cytolytic activity may be the best way to differentiate effector from memory T cells, though some memory cell types also possess immediate cytolytic activity albeit at lower levels^[8].

Improved understanding of functional memory CD8+ T cell development and the identification of unique phenotypic markers of memory CD8+ T cells could be helpful in vaccine development for viral infections where adaptive immune responses play an important role in control and/or clearance (HIV, HBV, HCV). In theory, if efficient memory T cell responses could be induced by vaccination, protective immunity could be achieved. Additionally, further enlightenment into the transition from effector CD8+ T cell into memory CD8+ T cell could aid in the discovery and use of immune modulating therapies that might heighten the response to vaccination. As an example, adoptive transfer studies in mice of antigen-specific CD8+ CD127+ T cells taken during the effector phase of the immune response to LCMV infection have identified CD127 as a marker of CD8+ T cells able to control virus upon re-infection^[5,9]. Therefore, it can be hypothesized that vaccine induction of CD127 expression on CD8+ T cells may be beneficial and should be a goal of any effective vaccine for chronic viral infections. In this review, we will summarize current knowledge of antiviral CD8+ T cell differentiation with a focus on persistent infections such as HCV.

MODELS OF MEMORY CD8+ T CELL DIFFERENTIATION

Several models have been proposed to describe the differentiation of CD8+ T cells from naïve cells to memory cells^[10,11]. In the “linear” or “progressive” model, naïve cells undergo an effector T cell phase prior to developing into memory cells, and all memory T cells are direct descendents of effector cells. This model posits that memory T cells do not develop until antigen is

markedly reduced or eliminated. In the “divergent model”, a stimulated naïve T cell gives rise to either an effector or memory T cell. In this model, naïve T cells can directly give rise to memory T cells without going first through an effector phase. The “decreasing-potential” model accounts for scenarios where antigen persists after primary infection and posits that naïve T cells differentiate into effector cells first. If antigen is cleared early after infection, functional memory T cells develop. If antigen persists, the function of the effectors is sequentially impaired and memory CD8+ T cell development is compromised. Eventually, persistent antigen leads to a non-functional effector cell and eventual cell death by apoptosis. As in the linear model, functional memory cells do not develop until antigen is cleared.

Subsets within the memory CD8+ T cell compartment have been segregated based on markers other than CD127. Sallusto *et al.*^[12] utilized the expression of the lymph node homing receptor, CCR7, and a transmembrane phosphatase involved in T cell signaling, CD45RA, to distinguish central memory (CCR7+ CD45RA-) and effector memory (CCR7-CD45RA- and CCR7-CD45RA+) CD8+ T cell populations^[12]. Central memory cells were characterized by rapid proliferation after antigenic stimulation, while effector memory cells were more capable of immediate effector functions^[12]. In theory, central memory cells are most capable of surveying lymph nodes and responding to antigen with enhanced proliferative capacity, while effector memory cells are more capable of migrating into tissues and exacting immediate effector functions. Appay *et al.*^[13] have proposed another model of CD8+ T cell differentiation during chronic or persistent infection. Studying antigen-specific CD8+ T cells during several different viral infections, they hypothesized that there is a progressive memory differentiation based on differential expression of CD27 and CD28 co-stimulatory molecules^[13]. They defined early (CD27+, CD28+), intermediate (CD27+, CD28-) and late memory CD8+ T cell subsets of virus-specific cells^[13]. The early subset had the greatest proliferative capacity while the intermediate and late subsets had progressively greater cytotoxic potential^[13]. Furthermore, the late subset also expressed CD57, a marker of replicative senescence^[13].

Recently, Romero *et al.*^[14] combined the phenotypic markers used by Sallusto *et al.*^[12] and Appay *et al.*^[13] to further dissect the memory CD8+ T cell pool. They identified four subsets within the effector memory (CD45RA-, CCR7-) pool based on differential staining of CD27 and CD28. Interestingly, the different subgroups differed not only phenotypically, but showed a progressive reduction in telomere length coinciding with a progressive increase in cytotoxic molecules (granzyme B, perforin). Their model lends support to the idea that there is a progressive up-regulation of cytolytic activity and a stepwise loss of CCR7, CD28 and CD27 during the differentiation process. They showed that CD8+ T cells specific for a resolved infection (Flu) consisted of both a central memory (CCR7+, CD45RA-, CD27+ and CD28+) population and a sub-population of effector memory cells termed EM1 (CCR7-, CD45RA-, CD27+ and CD28+).

They hypothesized that this effector memory population, which has only a low expression of the lymphocyte homing receptor, CCR7, confers memory functions and provides surveillance in peripheral tissues^[14].

ACUTE VIRAL INFECTION

Effector phase

In the classic understanding of an adaptive T cell immune response, there is an initial massive expansion of antigen-specific T cells, followed by a period of marked contraction as the pathogen is cleared. This period of expansion and contraction can be referred to as the “acute” or “effector” phase of the immune response. Exceptions to this paradigm likely exist following chronic or latent infections, for example, in CMV infection of humans, where the contraction phase may be more limited^[3]. During this process of expansion and contraction, functional memory cells are formed and persist to protect the host from future infection. Upon infection of mice with LCMV, rare naïve T cells specific for cognate antigen increase exponentially within secondary lymphoid tissues^[15,16]. The responding T cells in this “clonal burst” clear the infection *via* dissemination to non-lymphoid tissues (common sites of infection), the secretion of anti-microbial cytokines such as interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α), and direct lysis of infected host cells^[17-19]. Interestingly, no antigenic stimulation is needed after the initial clonal stimulation, meaning that daughter-cell expansion and differentiation into a memory population occurs in an antigen-independent manner^[20-22]. However, mediation of effector functions, such as cytokine production and killing, is dependent upon contact with antigen bearing targets. In situations where virus is successfully eliminated, > 90% of effector T-cells undergo apoptosis (contraction), and a small population of CD127+ surviving cells undergo further differentiation from an activated phenotype to a resting phenotype to generate a long-lived memory pool that is ready to respond more rapidly upon secondary infection^[5,10]. This pool is maintained in the absence of antigen, and is characterized by IL-7 and IL-15-dependent homeostatic proliferation resulting in relatively constant numbers of CD8+ T cells^[23-25]. During the progression from naïve to effector to memory cells, the homing potential of these cells changes. Upon differentiation to effectors, CD8+ T cells down-regulate lymphoid homing molecules such as CD62L and CCR7, and begin to migrate to nonlymphoid effector sites. Eventually, these lymphoid homing molecules are gradually up-regulated, giving cells the ability to home to lymphoid tissues. This dichotomy of homing potential has prompted researchers to further define memory cells into effector memory or central memory subsets, with the latter having lymphoid homing potential^[26,27].

Much of what we know about memory T cell differentiation is from murine models of infection since identifying humans in the acute phase of viral infection is often difficult, and time from acquisition of infection is rarely precisely known (exceptions described below for accidental infection). Additionally, for some viral infections the acute phase of infection may be relatively

short in duration, while for other infections the “acute” phase may last for weeks to months (HCV). Nevertheless, studying the phenotype of antigen-specific CD8+ T cells during different human acute viral infections has shown that there is a remarkable similarity in terms of surface marker expression and function. During acute infectious mononucleosis, EBV-specific CD8+ T cells show massive expansion (up to 44% of total CD8+ T cells in peripheral blood), and the majority express the activation markers, HLA-DR and CD38, and the memory marker CD45RO (also CD45RA low), but have down-regulated the lymphocyte homing molecule CD62L^[28]. CD28 expression on EBV-specific cells has been shown to range from 9% to 86% depending on the donor, with CD57 expression ranging from 2% to 37%. Appay *et al*^[13] have also shown that during acute infection, some EBV-specific CD8+ T cells express the proliferation marker Ki67. Additionally, these cells were prone to apoptosis since they expressed minimal levels of the anti-apoptotic factor Bcl-2^[13].

In an individual with acute CMV infection, Carmichael *et al*^[29] showed that at the peak of clinical symptoms (3 wk after symptom onset), 80% of CMV-specific CD8+ T cells were CD45RO high, CD28 negative, and CCR7 negative. Studying primary CMV infection after kidney transplantation in humans, Gamadia *et al*^[30] showed that CMV-specific CD8+ T cells evaluated at wk 31 after first positive CMV PCR, were nearly all CD27 positive, but with mixed expression of CD28 (54%). Nearly all expressed CD45RO (minimal CD45RA), and most were CCR7 negative (91%)^[30]. They expressed significant levels of Ki67 (78%), granzyme B (93%) and perforin (100%)^[30]. Few of these acute CMV-specific CD8+ T cells expressed CD127 (1%)^[30].

Other viruses known to cause more persistent infections including HIV, HBV, and HCV, still show characteristic effector T cell development in the early stages after acute infection. For example, in primary HIV infection, nearly all HIV-specific CD8+ T cells expressed CD38 and approximately 11%-41% were Ki67 positive^[13,31]. There was minimal Bcl-2 expression, which correlated inversely with CD38 expression^[13]. Very early after HIV infection, the majority of HIV-specific CD8+ T cells also expressed CD27 and approximately 40% expressed CD28^[31].

Evaluation of 5 persons with acute HBV infection showed that the majority of HBV-specific CD8+ T cells were HLA-DR positive (92%-98%) and CD45RO positive (95%-100%), and most were CCR7 and CD45RA negative, again consistent with an effector phenotype^[32]. The majority expressed CD27, and similar to HIV, 40%-50% expressed CD28^[32]. The frequency of CD127 expression on these antigen-specific cells was also very low^[33].

The phenotype of HCV-specific CD8+ T cells from the peripheral blood of patients evaluated during the acute phase of HCV infection also showed the characteristic expression patterns of effector T cells^[13,34]. Studying 9 patients with acute HCV infection, Lechner *et al*^[34] demonstrated that during acute infection, the activation marker CD38 was up-regulated on HCV specific CD8+ lymphocytes from all patients irrespective of their clinical outcome. By wk 20 after the acute phase, there was a loss

of expression of this activation marker on HCV-specific CD8+ T cells^[34]. Similarly, HLA class II was elevated early during infection and decreased over time^[34]. Studying five health care workers exposed to HCV via accidental needle stick, Thimme *et al.*^[35] demonstrated that HCV-specific CD8+ T cells detectable from a patient with spontaneous viral clearance expressed CD38 on wk 8 and 10 after infection, but by wk 12 and thereafter they were CD38 negative^[35]. CD38 expression correlated with hepatitis, as measured by ALT level^[35]. Interestingly, these activated cells were unable to produce IFN- γ when stimulated by cognate peptide *in vitro*, and the appearance of HCV-specific, IFN- γ producing CD8+ T cells coincided with the disappearance of CD38 expression^[35]. Lechner *et al.*^[36] studied acute infection in one patient, and noted that in addition to increased expression of CD38 and HLA class II on HCV-specific CD8+ T cells early during infection, CCR5 expression was also maximal during the first 20 wk. During the acute phase, CD127 expression was minimal on HCV-specific CD8+ T cells^[37,38].

In summary, for the majority of these viral infections, during the acute phase, there is an increase in expression on antigen-specific CD8+ T cells of activation and proliferation markers, and a decrease in lymph node homing molecules and CD127 expression. Cytolytic molecules are increased but anti-apoptotic factors are decreased. In general, CD27 expression remains present and there are intermediate levels of CD28 expression.

VIRAL PERSISTENCE OR CLEARANCE

Memory phase

While acute models of infection in mice have provided much phenotypic and functional insight into memory CD8+ T cell generation, chronic models of infection have shed light on the inadequacies of cellular responses, and how the resulting persistence of antigen load can affect the differentiation and function of these antigen-specific cells. Indeed, the course of memory CD8+ T cell differentiation during chronic infections can vary greatly from that which is seen in acute infections, including unique tissue distribution of antigen-specific T cells, dominance of T cell populations that normally have subdominant specificities, and even gradual exhaustion or deletion of entire T cell populations from the repertoire^[25]. The hallmark of differentiation in chronic infection is a stepwise loss of T cell effector functions that becomes more severe as time progresses, as opposed to the gain of effector functions that is seen in acute infections^[39]. This “exhaustion” can be broken into several categories, corresponding to the severity of impairment of effector function and proliferative potential. Initial antigen stimulation leads to CD8+ T cells that are functionally competent in that they can produce IFN- γ , TNF- α , IL-2, are cytolytic, and have robust proliferative capacity. However, if virus persists, these cells become partially exhausted, losing their ability to lyse target cells and produce IL-2 first, followed by decreased TNF- α production^[40,41]. Interestingly, cells that are partially exhausted may still have the ability to proliferate and produce IFN- γ , albeit with reduced efficiency. As antigen persists, cells may become fully

exhausted, completely losing both effector functions and the ability to proliferate^[39,41,42]. It has also been shown in chronic LCMV infection that deletion of antigen-specific CD8+ T cells can occur if antigen load is both extremely high and persistent^[41,43]. Additionally, CD4+ T cells play an important role in the chronic exhaustion of CD8+ T cell responses, both throughout infection and in the priming of cells during the acute phase of infection. Unlike antigen load, CD4+ T cell help is directly related to the functionality of the CD8+ T cell effector response: the absence of this help leads to a more rapid and severe progression to the exhausted phenotype^[25].

Unlike the similarities in the range of phenotype of antigen-specific cells seen during the acute phase of different viral infections in humans, the phenotype of antigen-specific cells isolated during different latent/chronic viral infections is more diverse. In the chronic phase of HCV infection, Lechner *et al.*^[36] were unable to detect the activation markers CD38 or HLA class II expression on any HCV-specific CD8+ T cells. This is different from HIV infection, where during chronic infection a proportion of HIV-specific CD8+ T cells in the blood expressed CD38 and HLA-DR^[44]. Appay *et al.*^[13] compared HIV, CMV, EBV and HCV-antigen specific CD8+ T cells taken from blood during the latent/chronic stage of infection. Though the majority of antigen-specific CD8+ T cells for these viral infections had all lost evidence for activation (minimal CD38 expression) and proliferation (minimal Ki67 expression), and had up-regulated the survival factor, Bcl-2, the expression of CD27 and CD28 differed^[13]. The majority of HCV-specific CD8+ T cells expressed both CD27 (90%) and CD28 (90%), while EBV-specific CD8+ T cells had comparable levels of CD27 expression but lower CD28 expression (60%). HIV-specific CD8+ T cells had relatively high levels of CD27 expression (80%), but very low levels of CD28 expression (10%). Finally, the majority of CMV-specific CD8+ T cells had relatively low expression of both CD27 (30%) and CD28 (20%). This comparison of differentiation in the chronic/latent phase of multiple infections prompted the authors to label EBV- and HCV-specific CD8+ T cells “early”, HIV-specific CD8+ T cells “intermediate” and CMV-specific CD8+ T cells as “late” differentiated. CCR7 expression was low on HIV-, CMV- and EBV-specific CD8+ T cells^[13], whereas others have shown that peripheral HCV-specific CD8+ T cells are largely CCR7+^[45,46]. Others have shown that EBV-specific CD8+ T cells may be better represented as a mixture of effector memory and central memory cells (or early and late differentiation states) as delineated by differential staining of CCR7 and CD45RA^[47].

For cleared viral infections such as influenza and RSV, antigen-specific CD8+ T cells resembled these HCV and EBV-specific cells in that they were mostly CD27+ and CD28+^[48,49]. RSV-specific CD8+ T cells were mostly CCR7 negative (92%)^[49] in contrast with influenza, where a greater frequency of specific CD8+ T cells were CCR7 positive^[49]. The range of CCR7 expression on both RSV and Flu, however, were broad among different patients in this study (0%-71% for RSV and 0%-57% for Flu)^[49].

Similar to the mouse, CD127 expression appears to be

Table 1 Phenotype of antigen-specific CD8⁺ T cells found in blood and tissue during different viral infections

Virus	Peripheral blood phenotype	Tissue	Tissue phenotype
Flu	CD27 ⁺ CD28 ⁺ CCR7 ⁺ CD127 ⁺	Lung	CD27 ⁻ CD28 ⁻
RSV	CD27 ⁺ CD28 ⁺ CCR7 ⁻ CD127 ⁺	Lung	CD27 ⁻ CD28 ⁻
EBV	CD27 ⁺ CD28 ⁺ CCR7 ⁻ CD127 ⁻	Tonsil	↑ CD38 ↑ CCR7 ↑ CD127
CMV	CD27 ⁻ CD28 ⁻ CCR7 ⁻ CD127 ⁻ CD45RA ⁺	Tonsil	↑ CD127
HIV	CD27 ⁺ CD28 ⁻ CCR7 ⁻ CD127 ⁻	Rectum	CCR7 ⁻ CD127 ⁻ ↓ perforin
HCV	CD27 ⁺ CD28 ⁺ CCR7 ⁺ CD127 ⁺	Liver	↑ CD69 CCR7 ⁻ CD127 ⁻
HBV	CCR7 ⁺ CD127 ⁺	Liver	↑ HLA-DR

Arrows indicate increase or decrease relative to expression in blood.

associated with memory phenotype and viral clearance of some infections in humans. CD8⁺ T cells isolated from persons with resolved viral infections such as influenza or RSV expressed high levels of CD127^[50]. Similarly, longitudinal analysis of 6 patients with acute resolving HBV infection showed that after viral clearance, CD127 expression increased markedly and correlated with the loss of CD38 and PD-1 expression, acquisition of CCR7 expression and enhanced proliferative capacity^[33]. In contrast, for latent infections (EBV, CMV) and persistent viral infections (HIV) low levels of CD127 have been noted on virus-specific CD8⁺ T cells^[50-52]. However, in EBV infection CD127 expression was higher on cells specific for latent epitopes compared with lytic epitopes^[47]. When we evaluated CD127 expression on peripheral HCV-specific CD8⁺ T cells from patients with chronic HCV infection, we were surprised to find that in the majority of patients, nearly all expressed high CD127 expression despite the high level of antigen present^[53]. This phenotype is reminiscent of resolved infection such as influenza. However, Bengsch *et al*^[37] identified two subsets of patients with chronic HCV: One with HCV-specific CD8⁺ T cells predominantly expressing low levels of CD127 and the other expressing higher levels of CD127. Interestingly, the CD127 low group also had higher level of CD38⁺ frequencies and lower level of CCR7 expression hinting that in this group, re-activation of these cells may have induced the down-regulation of CD127.

Table 1 summarizes the phenotype of antigen-specific cells from the peripheral blood of persons with resolved, latent and chronic viral infections. There is substantial heterogeneity between the different viral infections, as noted in the table.

MECHANISMS OF VARIED MEMORY DIFFERENTIATION IN PERSISTENT OR LATENT INFECTION

Currently, the explanation for the variation in differentiation phenotype seen in the setting of different viral infections is not completely understood, but a number

of hypotheses exist. Clonal expansion, effector functions and memory formation require three signals during the immune response: antigen (signal 1), co-stimulation (signal 2) and cytokine (signal 3)^[54]. Alterations in these signals could contribute to alterations in CD8⁺ T cell phenotype and function. Optimal expansion and function of naïve CD8⁺ T cells required antigen and co-stimulation to be present for approximately 36 h and cytokine (IL-12) present from about h 12 to h 60^[54,55]. These signals launch a complex program of proliferation and differentiation. Given this “autopilot” response^[56], the quality and context of the original signal may have a critical impact on subsequent T cell differentiation^[57]. Differing numbers of naïve precursor cells, antigen loads, cytokine milieu and primary location of infection (lymph node, gut, lung, liver) seen with the different viral infections would offer additional possible explanations for the diversity of these CD8⁺ T cells. In line with this hypothesis, Marzo *et al*^[58] have shown that initial precursor frequency is critical in determining effector and central memory CD8⁺ T cell differentiation. Increasing the input number of antigen-specific CD8⁺ T cells during the primary immune response resulted in increasingly larger populations of central memory cells. Furthermore, effector memory CD8⁺ T cells generated from high or low numbers were fundamentally different, in that cells generated from low initial naïve T cell precursor frequency were unable to interconvert and re-express CD62L^[58].

Even after establishment of persistent viral infection, initial events in naïve T cell proliferation and differentiation likely continue to play a critical role in the varied CD8⁺ T cell differentiation phenotypes that are seen in different viral infections. Vezys *et al*^[59] have recently shown that during persistent viral infection, there is a continuous recruitment of naïve T cells that contributes to the heterogeneity of antiviral CD8⁺ T cells. In their model, antigen-specific memory T cells were not maintained in the presence of antigen without replenishment from thymic emigrants. By induction of a partial hematopoietic chimerism in persistently infected mice using busulfan and congenic bone marrow, they showed that there were variations in the expression of CD27, CD62L, CD127 and bcl-2 between cell populations primed at different times^[59], and that heterogeneity in the memory population was related to this. Their study certainly complicates the current models of T cell differentiation described above, and highlights the dynamic nature of chronic viral infections, even despite relatively stable levels of viral load measured in the peripheral blood of patients with chronic HBV, HCV or HIV.

After initial viral infection and programming of naïve CD8⁺ T cells, downstream events may also impact on CD8⁺ T cell differentiation. Wherry *et al*^[60] have recently shown that in the setting of chronic infection, it is viral antigen and extensive division of virus-specific CD8⁺ T cells that maintains cell numbers, in marked contrast to the slow turnover seen during homeostatic proliferation of memory T cells from cleared viral infection. These cells, in the context of persistent infection, would be expected to display a different phenotype from those isolated from cleared infection, given differences in cell turnover. After

naïve CD8+ T cells are activated and become effector cells, they shortly lose the ability to produce IL-2 upon re-encounter with antigen and co-stimulation, a condition referred to as activation induced non-responsiveness (AINR)^[54]. IL-2 (provided by CD4+ T cells) is able to reverse this state. Co-stimulation via molecules other than CD28, such as OX40 (CD134), and 4-1BB (CD137) may also be critical in providing a stimulation for continued expansion once AINR develops^[54]. Interestingly, we have shown in chronic HCV infection that the co-inhibitory molecule, PD-1, is highly expressed on HCV-specific CD8+ T cells and on total CD8+ T cells at the site of infection in the liver^[53]. It is possible, that a lack of adequate co-stimulation and/or vigorous co-inhibitory signals prevent reversion of AINR and explains the exhaustion and CD8+ T cell deletion seen during this chronic viral infection. In addition to loss of IL-2 production, chronic antigen stimulation eventually also leads to characteristic progressive loss of TNF- α and finally IFN- γ production by cytotoxic CD8+ T cells^[39,57,61]. Since cytokines alone have been shown to induce T cell differentiation^[62] a lack of available cytokine during persistent infection may also explain altered differentiation patterns seen with different viral infections. In a transgenic mouse model, HBV-specific CD8+ T cells are rapidly induced to produce IFN- γ when they enter the liver, but are then rapidly suppressed despite continued antigen^[63]. Suppression of cytokine production was mediated by the co-inhibitor, PD-1, since blockade of PD-1 led to a delay in the suppression of IFN- γ producing cells^[63].

The potency of the pathogen and the antigen load may also influence memory differentiation. In a mouse model of infection, reducing the stimulation of CD8+ T cells by using an attenuated pathogen led to primarily a central memory subset, while infection with a more virulent pathogen led to effector cell development^[64]. Tussey *et al*^[65] compared the phenotype of HIV-specific CD8+ T cells in the setting of viral control (using anti-retroviral medication) and in the setting of uncontrolled viremia. They showed that the phenotype of these antigen-specific cells differed based on the level of viremia, and hypothesized that the level of antigen burden determined the differentiation state. Similarly, Papagno *et al*^[66] showed that in HIV infection excessive levels of antigen stimulation as determined by level of HIV disease progression lead to a progressive differentiation toward a state of replicative senescence. Given these studies, the importance of the quantity and duration of persistent antigen would seem to be very important factors leading to varied differentiation programs. However, in chronic HCV infection, antigen burden is large, with viral loads often on the order of 10^6 - 10^7 , yet as previously described, differentiation of HCV-specific CD8+ T cells is more limited and these cells have been termed “early”. Viral escape is one possibility for the lack of progressive differentiation, yet when we sequenced HCV isolated from the peripheral blood at the epitope specific for the tetramer used to identify these “early” differentiated HCV-specific CD8+ T cells, no mutations were seen^[53]. Another possibility to explain variation in differentiation phenotype is differences in innate signals among different infections,

and differences in these signals occurring at early and late time-points during persistent infection^[67]. This could be particularly relevant for HCV infection, since it has been shown that the NS3-4A serine protease of HCV degrades the adapter molecule, Cardif^[68], and thereby interferes with the RIG-I mediated process of innate recognition of dsRNA. The “early” differentiated phenotype of HCV-specific CD8+ T cells during chronic infection could be a reflection of this impairment in innate signaling. Pulendran *et al*^[67] has also speculated that during the early stages of an immune response, highly stimulatory DC subsets might deliver strong TCR signals favoring effector T cell differentiation, while at later stages, a milder form of T cell stimulation by less stimulatory DC subsets could favor the development of central memory T cells.

Location, location, location

Finally, a perhaps somewhat overlooked cause for differences in memory phenotype in different viral infections may be related to the anatomic location of the different viral infections, and to discrepancies between the active site of infection (liver, lung, *etc.*) and the site from which cells were obtained for study. Mice infected with vesicular stomatitis virus (VSV) developed memory cells with functional differences in cytolytic activity based on their location in either tissue (lung, liver, small intestine) or secondary lymphoid organs, highlighting the importance of anatomic location in type of isolated memory cell subset^[69]. Masopust *et al*^[70] have also shown that virus specific intraepithelial lymphocytes in the gut resemble neither central nor effector memory CD8+ T cells isolated from spleen or blood by almost all properties examined, including effector function, differentiation, homing receptors and cell cycle. In fact, memory CD8+ T cells changed phenotype upon change of location^[70].

As noted above, we were surprised to find a phenotype of HCV-specific CD8+ T cells that resembled the phenotype of a resolved infection (Flu) in terms of high expression of CD127, CCR7, CD28 and CD27. However, analysis of antigen-specific cells at the site of active infection, the liver, revealed that nearly all of the antigen-specific CD8+ T cells displayed a different phenotype, with low CD127 expression^[37,53]. Similarly, Accapezzato *et al*^[71] have shown that HCV-specific CD8+ T cells isolated from liver express markedly lower CCR7 expression in comparison with peripheral blood. HCV-specific CD8+ T cells in the liver also displayed an activated phenotype with elevation of expression of the early activation marker CD69^[72]. We hypothesize that a lack of exposure to antigen by the peripheral CD8+ T cells enabled up-regulation of CD127 and CD62L and memory formation, since exposure to cognate peptide *in vitro* induced a down-regulation of CD127 on these same cells. The effector-like cells isolated from the liver were likely actively involved in the immune response occurring at the site of infection. Similar to our findings with chronic HCV infection, peripheral blood HBV-specific CD8+ T cells expressed high levels of CD127 during chronic HBV infection despite high levels of antigen load^[73]. Analysis of HBV-specific CD8+ T cells in the liver of patients with resolving HBV infection showed that a greater frequency

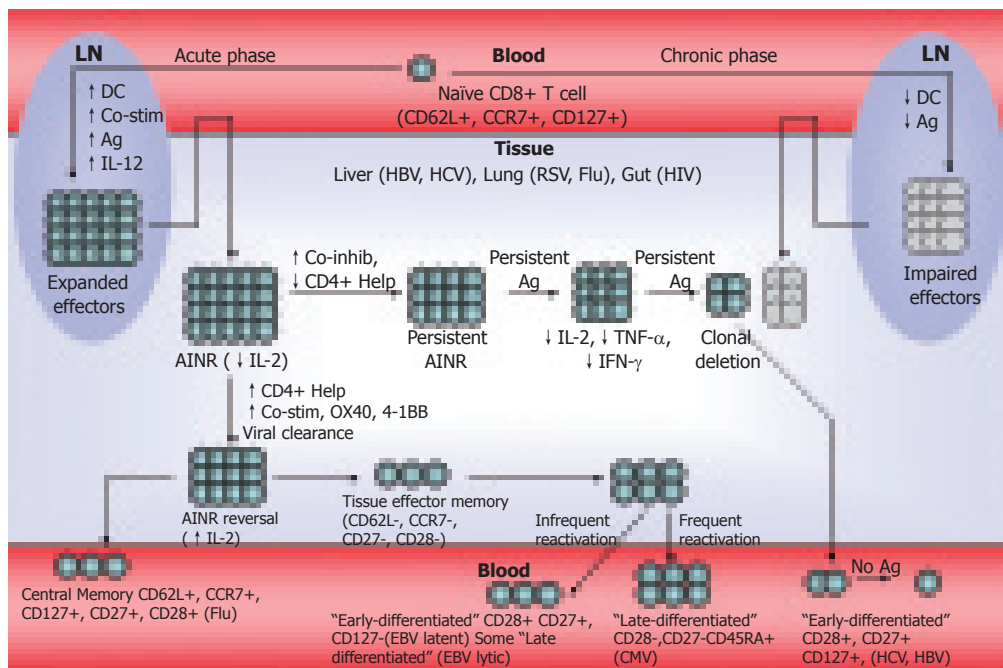

Figure 1 Tissue-specific model of antigen-specific memory CD8+ T cell differentiation.

were activated, as demonstrated by HLA-DR expression, in comparison with the peripheral blood^[74]. It will be interesting to further analyze the phenotype of these HBV-specific cells at the site of infection.

In addition to the liver, human memory CD8+ T cells at other locations are clearly influenced by the anatomic site where they reside. De Bree *et al*^[75] have compared Flu and RSV-specific CD8+ T cells in the lungs and peripheral blood. They found that the lung contained markedly higher frequencies of Flu- and RSV-specific cells compared with the peripheral blood^[75]. A substantial percentage of these lung residing antigen-specific CD8+ T cells had progressed to a relatively late differentiation phenotype with low expression of CD28 and CD27^[75]. EBV-specific CD8+ T cells isolated from the tonsils of long-term carriers were more likely to express the activation marker CD38 and CD103, an integrin induced by epithelium-derived cytokine TGF- β ^[76]. Both EBV (lytic)- and CMV-specific CD8+ T cells in the tonsils were shown to have increased CD127 expression in comparison with peripheral blood^[47]. In HIV infection, rectal HIV-specific CD8+ T cells expressed a similar effector memory phenotype as in the peripheral blood (CCR7-), but expressed minimal perforin, unlike in the peripheral blood where as many as 23% of Gag-specific CD8+ T cells expressed perforin^[77]. Table 1 summarizes the phenotype differences of viral-specific CD8+ T cells between peripheral blood and tissue (liver, lung, tonsil, gut). Clearly, there is much to be learned about memory T cell differentiation by further evaluation of T cells residing in tissues other than peripheral blood.

A MODEL OF TISSUE DEPENDENT MEMORY DIFFERENTIATION

So, how might the variation in differentiation phenotypes of antigen-specific CD8+ T cells from different viral infections and from different anatomic locations look? A

schematic is shown in Figure 1. During the acute phase of infection, naïve CD8+ T cells surveying the lymph node (LN) may encounter antigen presented by activated dendritic cells (\uparrow DC) in the context of high antigen concentration (\uparrow Ag), significant co-stimulatory signal (\uparrow Co-stim), and cytokine (IL-12 or type I interferon) (\uparrow IL-12). This leads to an expansion of competent effectors that have decreased lymph node homing receptors (CD62L, CCR7) and migrate to sites of infection (e.g. liver, lung, gut). These cells lose the ability to produce IL-2 (activation induced non-responsiveness, AINR)^[54]. With proper CD4+ T cell help (\uparrow CD4+ Help) or other co-stimulatory signals, such as via 4-1BB (\uparrow Co-stim, OX40, 4-1BB), these cells maintain function and succeed in clearing virus. One population of cells forms central memory cells (CD62L+, CCR7+, CD127+, CD45RA-) that have up-regulated lymph node homing molecules and are easily detected in the peripheral blood. A second population of effector memory cells is maintained in the tissue (perhaps by homeostatic mechanisms) (CD62L-, CCR7-, CD27-, CD28-). For the latent viruses, EBV and CMV, we hypothesize that differences in the frequency and/or location of re-activation offers an explanation for the "early" vs "late" phenotype. Perhaps CMV reactivation or even low-level persistence occurs at peripheral sites, and sampling of antigen-specific CD8+ T cells from the peripheral blood reflects this (late differentiation). EBV reactivation may be less frequent (and not persistent) and, therefore, a phenotype similar to a resolved infection such as Flu or RSV is sometimes seen (though CD127 expression is diminished). EBV reactivation may also lead to a population of more differentiated cells specific for the lytic epitope. If AINR cannot be reversed, as might be the case with a lack of CD4+ T cell help (\downarrow CD4+ Help) or via enhanced co-inhibitory signals (\downarrow Co-inhib), there is a progressive loss of function of virus-specific CD8+ T cells (\downarrow IL-2, \downarrow TNF- α , \downarrow IFN- γ) eventually leading to clonal deletion. For HCV and HBV infections,

perhaps at the site of infection in the liver, where antigen is present and concentrated, persistent antigen maintains a population of effector-like cells. As Wherry *et al.*^[78] have described in chronic LCMV infection, this cell population would not be maintained without antigen present. These effector cells would be expected to express low levels of CD127 and lymph node homing molecules. Additionally, naïve cells encounter antigen during the chronic phase; however in this setting, DCs are less stimulatory (\downarrow DC) and antigen is lower (\downarrow Ag) than what is seen during acute infection. The resulting impaired effectors contribute to the pool of antigen-specific cells. In the periphery, HCV- and HBV-specific CD8⁺ T cells are not maintained by persistent antigen, but rather proceed to form functional memory T cells and are maintained via homeostatic signals. We and others have found that peripheral blood HCV-specific CD8⁺ T cells expressing CD127 have a capacity for proliferation upon ex vivo antigen encounter similar to other functional memory T cells. For HIV infection (and persistent LCMV infection), where antigen is located in the periphery, these cells are maintained only by the presence of antigen and thereby, display the phenotype of an effector-like cell in the periphery.

CONCLUSION

The phenotype of antigen-specific CD8⁺ T cells persisting during different viral infections is quite varied. This variation may be related to a number of factors including level of antigen persistence, strength of antigen presenting cell interactions, balance of co-stimulatory/co-inhibitory signals, and the influence of the anatomic location of infection. The requirement of continued antigen in the maintenance of virus-specific CD8⁺ T cells during chronic viral infection and continued recruitment of naïve CD8⁺ T cells into the population of antigen-specific cells highlight the dynamic nature of these infections and the cells responding to them. Improved understanding of the relative contribution of each of these factors in the formation of functional memory cells may aid in the development of virus-specific treatments to enhance the immune response to infection or vaccines.

Abstract

The pathogenesis and outcome of viral infections are significantly influenced by the host immune response. The immune system is able to eliminate many viruses in the acute phase of infection. However, some viruses, like hepatitis C virus (HCV) and hepatitis B virus (HBV), can evade the host immune responses and establish a persistent infection. HCV and HBV persistence is caused by various mechanisms, like subversion of innate immune responses by viral factors, the emergence of T cell escape mutations, or T cell dysfunction and suppression. Recently, it has become evident that regulatory T cells may contribute to the pathogenesis and outcome of viral infections by suppressing antiviral immune responses. Indeed, the control of HCV and HBV specific immune responses mediated by regulatory T cells may be one mechanism that favors viral persistence, but it may also prevent the host from overwhelming T cell activity and liver damage. This review will focus on the role of regulatory T cells in viral hepatitis.

INTRODUCTION

An infection with HCV or HBV activates the immune system to defend the host with a broad range of innate and adaptive immune responses. Macrophages, natural killer cells and neutrophils are an important part of the innate immune response that produces inflammatory and antiviral cytokines. Activated dendritic cells induce the differentiation of naïve T cells into virus specific CD4+

and CD8+ T cells for adaptive immunity. CD4+ T cells Type 2 induce B cells to produce antiviral antibodies; CD4+ T cells Type 1 cells secrete IFN- γ and activate the massive proliferation of cytotoxic CD8+ cells that destroy infected cells or secrete proinflammatory cytokines^[1-3].

These complex molecular and cellular mechanisms help to control and, in the best case, to eliminate the virus in the acute phase of infection. However, in the majority of HCV and a significant amount of HBV infections the immune system fails to eliminate the virus and viral persistence is established. Although essential for successful virus elimination, the virus specific T cell responses of the host may also cause tissue damage and autoimmune reactions in the liver, especially in the setting of chronic viral infection. Therefore, many regulatory mechanisms of the immune system control the virus specific immune responses in order to prevent massive tissue damage or autoimmune disease.

Over the last few years, it has become evident that regulatory T cells (T_{reg} cells) may play an important role in the suppression of virus specific immune responses^[4-6]. Indeed, several studies suggest a role of diverse populations of T_{reg} cells in the natural course of HCV and HBV infections. In this review, we will summarize the current knowledge about the role of regulatory T cells in HCV and HBV infection.

REGULATORY T CELL SUBSETS

A regulatory phenotype of a T cell population was first described for a CD4+ T cell subset that constitutively expresses the interleukin 2 receptor α -chain (CD25). In 1995 Sakaguchi *et al* showed that the transfer of lymphocytes depleted of CD4+CD25+ T cells into athymic mice caused the development of various autoimmune diseases in the recipient mice. Interestingly, the reconstitution with CD4+CD25+ T cells prevented autoimmune reactions in these mice, indicating a function of this T cell subpopulation in the control of self tolerance^[7]. In the last decade numerous studies in mice and men showed that diverse T cell populations exhibit regulatory capacity and play an important role in the suppression of immune responses to self as well as foreign antigens^[8]. Regulatory T cells are divided into a natural CD4+CD25+ T_{reg} cell population and diverse populations of induced or adaptive T_{reg} cells^[9]. Natural T_{reg} cells develop in the thymus under strong TCR engagement with self peptides and play an important role in the maintenance of self-tolerance and immune homeostasis.

About 5%-10% of CD4⁺ T cells in mice and humans are natural T_{reg} cells^[10]. Natural CD4⁺CD25⁺ T_{reg} cells constitutively express cytotoxic T-lymphocyte antigen 4 (CTLA4), glucocorticoid-induced TNF receptor family related protein (GITR)^[11,12] and the forkhead family transcription factor FoxP3^[13,14]. Of note, mutations in the gene *foxP3* cause the absence of natural T_{reg} cells and a loss of self tolerance. Indeed, it has been shown that FoxP3 expression is the essential factor for the induction of the natural T_{reg} cell population. FoxP3 is the best marker for the identification of natural T_{reg} cells in mice and men, thus far^[15]. However, it has recently been shown that FoxP3 may also be transiently induced in activated human T cells^[16,17].

In contrast to natural T_{reg} cells, induced T_{reg} cells develop from non regulatory T cells in the periphery and not in the thymus. Diverse populations of induced regulatory T cells have been identified, thus far. Among those, CD4⁺ cells secreting IL-10 or TGF- β , named TR1- or TH3 cells, as well as CD4⁺CD25⁺FoxP3⁺ T cells and CD8⁺ T cells with various phenotypes have been shown to have a regulatory capacity^[8,18]. The extrathymically conversion of non-regulatory T cells into regulatory T cells requires special immunological conditions. In many respects, the cytokine TGF- β and a distinct mode of antigen exposure have been shown to play an important role in the development of induced T_{reg} cells^[8,19]. Indeed, several studies in both mice and humans demonstrated that naïve and memory CD4⁺ T cells can be converted into CD4⁺CD25⁺FoxP3⁺ regulatory T cells in the presence of TGF- β ^[20-23]. In addition, it has been shown in several mouse models that a specific way of antigen presentation, e.g. continuous exposure to low dose antigen or to a systemic peripheral antigen, can lead to the expansion of induced CD4⁺CD25⁺FoxP3⁺ regulatory T cells^[24-26].

Overall, these results and the phenotypical diversity of induced T_{reg} cell subpopulations indicate that several different mechanisms of T_{reg} cell development may exist in the periphery that still need to be defined for each subpopulation of induced T_{reg} cells. Furthermore, lineage relationship and functional overlap of induced T_{reg} cells and natural T_{reg} cells still need to be characterized in detail.

FUNCTIONAL CHARACTERISTICS OF REGULATORY T CELLS

The major function of natural and induced T_{reg} cells is the suppression of immune responses to self or foreign antigens. Indeed, numerous studies in mice and humans showed that regulatory T cells suppress the proliferation, cytokine-production (IFN- γ , IL-2) and cytolytic activity of naïve and antigen specific CD4⁺ and CD8⁺ cells. In addition, T_{reg} cells are able to suppress the functions of antigen presenting cells and B cells^[27]. T_{reg} cells may mediate their suppressive activity either through the secretion of anti-inflammatory cytokines like IL-10 or TGF- β , direct killing of the target cells or distinct cell-cell contact dependent mechanisms^[27]. The surface molecules CTLA4 and GITR have been suggested to play a role in direct cell-cell contact mediated suppression. CTLA-4

expressed on T_{reg} cells may bind to CD80/CD86 expressed on antigen presenting cells to activate the IDO (indoleamine 2,3-dioxygenase) dependent generation of tryptophan. A decrease of free tryptophan reduces T cell activation^[28,29]. The transfer of cAMP from T_{reg} to effector cells via gap junction contact has recently been proposed to be another possible mode of cell-cell contact mediated suppression. cAMP inhibits the proliferation and IL-2 secretion of T cells^[30]. In addition, T_{reg} cells have also been shown to generate extracellular adenosine that suppresses T cells responses^[31]. However, the mechanisms and the antigen-specificity of T_{reg} cell mediated immunosuppression are still largely unknown.

In addition to the ability to control immune responses, at least those T_{reg} cell populations that express FoxP3 share other functional characteristics that distinguish them from effector T cells. Indeed, the expression of the transcription factor FoxP3 significantly influences the phenotype and function of T_{reg} cells^[32]. FoxP3⁺ T cells show different TCR signaling patterns from effector T cells, do not proliferate well, when cultured *in vitro* and do not produce IL-2 or other inflammatory cytokines^[32]. Recently, genome wide analysis of FoxP3 target genes in mouse natural T_{reg} cells revealed that FoxP3 regulates those genes involved into TCR signaling pathways and cytokine-production as well as genes encoding for T_{reg} cell associated surface molecules like CD25 or GITR^[33,34]. In conclusion, the functional as well as the phenotypical differences between T_{reg} cells and effector T cells are largely dependent on the expression of FoxP3 in regulatory T cells.

REGULATORY T CELLS IN VIRAL INFECTION

Many viruses, like HCV and HBV, are able to evade the host immune response and to establish chronic infection. Efficient virus specific T cell responses are critical to eliminate the virus in the acute phase of infection. Importantly however, viruses have evolved strategies of immune evasion to subvert innate and adaptive immune responses and to facilitate viral persistence^[35].

Growing evidence suggests that regulatory T cells may play an important role in the suppression of antiviral T cell responses in the acute and chronic phase of infection. Indeed, the virus specific induction of regulatory T cells may have two very different consequences: first, it may help the virus to establish viral persistence and second, it may be an important process that occurs to prevent excessive immunopathological damage^[4,5].

First evidence that regulatory T cells may play a role in viral infection was forthcoming from a study by Souvas *et al* who showed that the depletion of CD4⁺CD25⁺ T cells in mice infected with herpes simplex virus (HSV) enhanced virus specific CD8⁺ T cell activity in the acute phase of infection as well as after viral clearance. Furthermore, HSV infection appeared to have a direct effect on natural T_{reg} cells, since regulatory T cells from HSV infected mice showed an increased suppressive capacity towards HSV specific and unspecific CD8⁺ T cell responses^[36]. While these findings indicate a detrimental role of natural T_{reg} in the host-virus immune balance, another study with HSV infected mice proposed a

protective role of natural T_{reg} cells in viral infection. Mice suffering from blinding keratitis, caused by HSV infection, showed much more severe lesions in the eyes when depleted of natural CD4+CD25+ regulatory T cells^[37].

Regulatory T cells have also been shown to play a role in chronic retroviral infections, indicated by studies with mice infected with Friend virus (FV). CD8+ T cells are critical for clearance of FV in the acute phase of infection, while insufficient CD8+ T cell effector functions are associated with viral persistence. A study by Dittmer *et al* showed that immunosuppression and CD8+ T cell impairment in chronic FV infection is a result of induced T_{reg} cell activity. Indeed, adoptive transfer experiments revealed that IL-10 secreting CD4+ cells from persistently infected mice suppressed antigen specific IFN- γ secretion of CD8+ cells^[38]. Furthermore, a kinetic analysis of T cell responses in acute FV infection demonstrated that the onset CD8+ T cell dysfunction as early as 2 wk after infection was associated with the expansion of induced T_{reg} cells^[39].

Taken together, these *in vivo* results from different mouse models suggest the important role of regulatory T cells in the suppression of virus specific T cell responses. In the following, recent human studies indicating the role of regulatory T cells in viral hepatitis will be discussed in more detail.

REGULATORY T CELLS IN HCV INFECTION

About 170 million people worldwide suffer from chronic hepatitis C virus infection. HCV is able to persist in up to 70% of those infected and may cause chronic hepatitis, liver cirrhosis and hepatocellular carcinoma. HCV is a positive-stranded RNA virus that belongs to the Flaviviruses^[1].

HCV clearance is associated with a vigorous HCV specific CD4+ and CD8+ T cell response in the acute phase of infection. In contrast, viral persistence is associated with a weak and dysfunctional virus specific T cell response^[40]. Several possible mechanisms of T cell failure and HCV immune evasion have been proposed, like T cell deletion, T cell dysfunction and the emergence of viral escape mutations^[2,41]. Recently, the possible role of different regulatory T cell populations in HCV persistence has also been suggested.

Indeed, several groups have shown a higher frequency of CD4+CD25+ regulatory T cells in the blood of chronically HCV infected persons versus recovered or healthy persons^[42-45] and the presence of CD4+FoxP3+ T cells in the liver of chronically HCV infected patients^[45,46]. However, whether these cells are natural T_{reg} cells that originate from the thymus or whether these cells are induced T_{regs} that developed from conventional CD4+ T cells upon HCV antigen contact in the periphery, remains to be determined. Of note, CD4+CD25+ regulatory T cells from chronically HCV infected patients are capable of suppressing HCV specific CD8 T cell and CD4+ T cell proliferation as well as CD8+ T cell IFN- γ secretion in a dose-dependent manner that requires direct cell-cell contact. However, CD4+CD25+ T_{reg} cells of infected subjects did not only suppress HCV specific T

cell proliferation, but also Influenza-, CMV-, and EBV specific T cell responses, suggesting an antigen unspecific inhibition of CD8+ T cells^[42,45].

The role of immunosuppressive cytokines, such as IL-10 and TGF- β , in the CD4+CD25+ T_{reg} cells dependent suppression remains controversial. Some studies reported that T_{reg} cells secrete IL-10 and TGF- β after HCV antigen stimulation and that TGF- β neutralization reverses T_{reg} cell mediated suppression of virus specific T cell responses^[43,47], while others did not observe this effect^[42,45].

It is important to note that CD4+CD25+ T_{reg} cells obtained from chronically HCV infected patients had an increased suppressive activity against HCV specific CD8+ T cells compared to natural T_{reg} cells isolated from subjects that had recovered from acute HCV infection, suggesting that chronic HCV infection leads to the expansion and activation of CD4+CD25+ T_{reg} cells. However the suppressive effect observed in patients who successfully cleared the virus was still significant^[42]. Furthermore, a recent study with HCV infected chimpanzees, the only animal model for HCV infection, showed that the frequency of CD4+CD25+FoxP3+ T_{reg} cells and the suppressive capacity of those cells against virus specific T cell responses were as high in HCV recovered chimpanzees as in persistently HCV infected chimpanzees^[48]. These results suggest that CD4+CD25+ T_{reg} cells do not only suppress virus specific T cell responses in chronic infection but may also control memory T cells after virus recovery. Of note, further analysis of CD4+CD25+ T_{reg} cells in chimpanzees revealed that T_{reg} cells from chronically HCV infected and recovered chimpanzees displayed fewer T cell receptor excision cycles and a better proliferative capacity *in vitro* compared to T_{reg} cells from HCV naïve chimpanzees. These data may indicate HCV specific proliferation of T_{reg} cells in HCV infected chimpanzees.

First evidence that T_{reg} cells may be induced by HCV antigens was provided by a study that examined the CD4+ T cell response to the HCV core protein. Interestingly, HCV specific IL-10 secreting T cells were detected in the blood of chronic HCV infected persons^[49]. These regulatory Tr1 cells recognized the same epitopes on the core protein as IFN- γ producing Th1 cells. However, HCV specific IL-10 secretion is not limited to the CD4+ T cell subset, since IL-10 producing HCV specific CD8+ T cells were identified that suppressed IFN- γ secretion of CD8+ T cells targeting the same epitope as the IL-10 secreting cells^[50]. Of note, both cell subsets were predominantly present in the liver, suggesting a compartmentalization of effector and regulatory T cells to the site of infection. In addition, another study also reported the accumulation of HCV specific IL-10 producing CD8+ T cells in the liver of chronically infected patients. *In situ* staining of liver biopsies revealed that IL-10+ HCV specific CD8+ T cells are located in liver areas with low hepatocellular apoptosis and low liver fibrosis, further supporting a potential role of these cells in the prevention of liver damage^[51]. However, these studies did not determine the FoxP3 expression of these CD8+ T cells.

The conclusion, that regulatory CD8+ T cells may play an important role in chronic HCV infection is further underlined by the observation that HCV specific CD8+

Table 1 Regulatory T cell subsets in HCV and HBV infection

Regulatory T cell phenotype	Virus	Compartment	Suppression	Cytokines
CD4+CD25+ (FoxP3+) ^[42-46,48,54,56,58,61,62]	HCV	Blood/Liver	Cell-cell contact dependent suppression of antigen specific and unspecific T cell proliferation and cytokine production	In part IL-10/ TGF-β
CD4+ (T _H 1 cells) ^[49]	HCV	Blood		IL-10
CD8+ (FoxP3+) ^[50-52]	HCV	Blood/Liver	Suppression of antigen specific T cell proliferation and INF-γ secretion	IL-10/TGF-β
CD8+FoxP3+ CTLA-4+GITR ⁺ ^[53]	HCV	Blood	Cell-cell contact suppression of antigen unspecific T cell proliferation	IFN-γ

CD25⁺FoxP3⁺ T cells from the blood of chronically infected patients suppress HCV specific T cell responses *via* TGF-β secretion. Of note, the blockade of TGF-β markedly enhanced the HCV specific IFN-γ secretion by CD4⁺ and CD8⁺ T cells^[52].

A population of HCV specific FoxP3⁺CD8⁺ T cells that suppressed CD4⁺ and CD8⁺ T cell proliferation in a cell-cell contact dependent manner has also been described^[53]. Indeed, these cells expanded simultaneously with FoxP3⁺CD8⁺ effector T cells after *in vitro* HCV specific peptide stimulation of peripheral blood mononuclear cells (PBMC) from chronically HCV infected patients. These results suggest that stimulation with a defined viral antigen leads to the expansion of two distinct CD8⁺ T cell populations: FoxP3⁺ effector as well as FoxP3⁺ regulatory T cells. FoxP3 expression on virus-specific CD8⁺ T cells *ex vivo* has not been shown, however. Of note, *in vitro* stimulation of PBMC from chronically HCV infected patients with HCV specific antigens also resulted in an expansion of HCV specific CD4⁺CD25⁺FoxP3⁺ regulatory T cells^[54]. However, at least for the CD8⁺ T cell compartment this is not a HCV specific effect since the expansion of virus specific FoxP3⁺ regulatory CD8⁺ T cells after *in vitro* peptide stimulation was also detected in influenza specific CD8⁺ T cells.

In summary, all these studies suggest a role of different regulatory T cell populations in the pathogenesis of HCV infection (Table 1). The elevated frequency of CD4⁺CD25⁺ regulatory T cells in the blood of chronically HCV infected patients, the ability of these cells to suppress HCV specific T cell responses, the accumulation of FoxP3⁺ T cells in the liver as well as the existence of different HCV specific regulatory T cell populations, strongly indicate that HCV infection induces virus-specific regulatory T cells that may contribute to viral persistence by suppressing HCV specific T cell responses. The presence of T_{reg} cells, especially in the liver, may also protect the host from tissue damage. In this context, it is interesting to note, that one study showed that HCV infected patients with normal alanine transaminase (ALT) levels have an increased frequency of HCV specific TGF-β secreting CD4⁺CD25⁺ regulatory T cells combined with decreased liver inflammation compared to patients with elevated ALT levels^[47].

REGULATORY T CELLS IN HBV INFECTION

Hepatitis B virus is a hepatotropic DNA virus infecting

about 300 million people worldwide. About 5%-10% of acutely infected patients develop a persistent HBV infection that is associated with T cell hyporesponsiveness and dysfunctions^[55]. Thus, T_{reg} cells may also play a role in HBV infection. Indeed, one study reported a high frequency of CD4⁺ CD25⁺ T_{reg} cells in the blood of chronically HBV infected subjects and an increase of HBV specific T cell proliferation after depletion of CD4⁺CD25⁺ T cells^[56]. Although these data suggest a potential role of T_{reg} cells in mediating T cell dysfunction during chronic HBV infection, another study reported discrepant results^[57]. In fact, neither a higher frequency nor an elevated suppressive capacity of CD4⁺CD25⁺ T_{reg} cells isolated from the blood of chronically infected patients compared to CD4⁺CD25⁺ T_{reg} cells from persons recovered from HBV infection, were observed in this study^[57].

However, recent studies shed more light on these controversial results about the role of T_{reg} cells in HBV infection. Indeed, a broad analysis of the frequency and function of CD4⁺CD25⁺ T_{reg} cells in the blood and liver of patients with acute HBV, chronic HBV, chronic severe HBV and healthy controls revealed that only patients with a chronic severe HBV infection showed a significant higher level of CD4⁺CD25⁺ T_{reg} cells in the blood compared to patients with mild course of chronic HCV and acute HCV infection^[58]. A significant accumulation of CD4⁺CD25⁺FoxP3⁺ T_{reg} cells in the liver was found in patients with chronic HBV and chronic severe HBV infection^[58,59]. A positive correlation between HBeAg level, HBV DNA level and the frequency of CD4⁺CD25⁺ T_{reg} cells in the blood of chronically infected patients further supports the role of T_{reg} cells in HBV infection^[58-60]. Finally, two studies showed the presence of HBeAg-specific CD4⁺CD25⁺FoxP3⁺ T_{reg} cells in chronically HBV infected patients^[61,62]. Interestingly, HBeAg specific CD4⁺CD25⁺ T_{reg} cells declined in the blood of patients during acute exacerbation of hepatitis in the immunoactive phase in chronic HBV infection while the HBeAg specific CD8⁺ T cell frequency increased at the same time. These data indicate that HBV specific T_{reg} cells may suppress HBV specific CD8⁺ T cells responses during flares in chronic HBV infection and may thus contribute to protection from severe hepatitis^[61].

The analysis of T_{reg} cells during acute HBV infection showed that T_{reg} cells may also play a role in this state of the infection. Indeed, the frequency of CD4⁺CD25⁺ T_{reg} cells was normal in the early acute phase of infection, increased during the convalescent phase and decreased

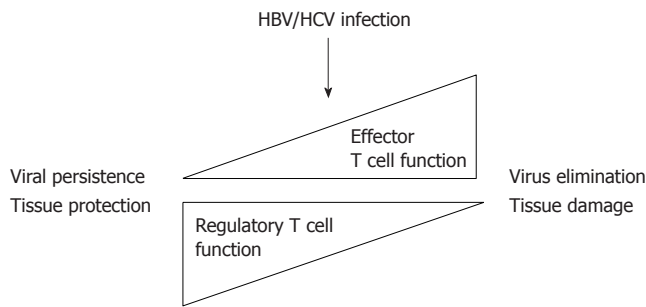

Figure 1 Regulatory T cells may contribute to viral persistence but they may also prevent tissue damage.

again to normal after virus resolution^[58]. Of note, CD4+CD25+ T_{reg} cells isolated from the blood of acutely HBV infected patients had an increased suppressive activity against HBV specific T cell responses compared to antigen unspecific T cell responses, suggesting the generation of HBV antigen specific T_{reg} cells during acute HBV infection^[58]. In summary, as in HCV infection, recent studies suggest that regulatory T cells do also play a role in HBV infection (Table 1).

FUTURE PERSPECTIVES

Taken together, there is strong evidence that different regulatory T cell populations mediate virus-specific T cell suppression in HCV and HBV infection. This immune suppression may contribute to viral persistence, but also to protection from overwhelming liver damage (Figure 1). Although, the studies discussed in this review give important first insights into the role of regulatory T cells in viral hepatitis, they also raise many questions. In fact, HCV infection in particular seems to induce a striking number of distinct HCV specific regulatory T cell populations. However, the lineage relationship between these T_{reg} cell populations as well as their relationship with HCV specific effector T cells remains elusive. It is unclear whether the CD4+CD25+ T_{reg} cells analyzed in HCV infected patients natural T_{reg} cells derive from the thymus develop from CD4+ T cells upon HCV antigen encounter in the periphery. The latter is most likely for HCV specific regulatory CD8+ T cells. However, if HCV specific T_{reg} cells are induced in the periphery, do they develop from naïve T cells as distinct induced CD4+ or CD8+ regulatory T cell lineages or do they generate from HCV specific effector memory T cells in a certain immunological context of the virus infection?

Other important questions that need to be addressed are the place and time point of regulatory T cell induction in HCV and HBV infection, as well as the mode and antigen specificity of T_{reg} cell mediated suppression in both viral infections. In addition, the presence and action of regulatory T cells in the liver, the site of virus replication and chronic inflammation should be analyzed in more detail. Furthermore, it will be important to determine if virus specific regulatory T cells do only play a role in the progression of a chronic infection or if they are already activated during the acute phase of infection and contribute to the development of viral persistence, as has

already been indicated in the case of HBV infection.

Of note, T_{reg} cells may serve as a potential target for therapeutic interventions. The depletion of regulatory T cells during an acute viral infection may have the therapeutic potential to prevent viral persistence. Furthermore, a manipulation of regulatory T cells may also improve vaccine efficiency. Studies with mouse models already suggest that depletion of CD4+ CD25+ T cells can help to resolve an infection^[36] or to enhance the effect of a virus DNA vaccination^[63,64]. However, a depletion of regulatory T cells in the setting of a chronic viral infection could also lead to massive tissue damage, if virus specific CD8+ T cells are no longer suppressed. Therefore, an application of these approaches in humans requires a more detailed knowledge about the exact interplay of regulatory T cells, viruses and virus specific immune responses. Otherwise, the overall function of regulatory T cells in the maintenance of immune homeostasis and self tolerance could be dangerously disturbed.

Abstract

Apoptosis is central for the control and elimination of viral infections. In chronic hepatitis C virus (HCV) infection, enhanced hepatocyte apoptosis and upregulation of the death inducing ligands CD95/Fas, TRAIL and TNF α occur. Nevertheless, HCV infection persists in the majority of patients. The impact of apoptosis in chronic HCV infection is not well understood. It may be harmful by triggering liver fibrosis, or essential in interferon (IFN) induced HCV elimination. For virtually all HCV proteins, pro- and anti-apoptotic effects have been described, especially for the core and NS5A protein. To date, it is not known which HCV protein affects apoptosis *in vivo* and whether the infectious virions act pro- or anti-apoptotic. With the availability of an infectious tissue culture system, we now can address pathophysiologically relevant issues. This review focuses on the effect of HCV infection and different HCV proteins on apoptosis and of the corresponding signaling cascades.

INTRODUCTION

Hepatitis C virus (HCV) infection persists in approximately. Eighty percent of patients and is a leading cause of liver

cirrhosis and hepatocellular carcinoma^[1-4]. Worldwide, about 300 million individuals are HCV infected. The only antiviral treatment available to date with PEG-INF and ribavirin does not eliminate HCV infection in a large proportion of patients, especially in HCV genotype 1 infection, and, at the same time, has multiple severe side effects. With the availability of an infectious tissue culture system, we now can address pathophysiologically relevant issues for new treatment options^[1-3]. HCV belongs to the flaviviridae. It has an enveloped, positive strand RNA genome of 9.6 kb length containing one open reading frame translated into a single polypeptide. Posttranslational cleavage yields 4 structural (E1, E2, core, p7 (probably) and 6 nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, NS5B). Six different genotypes (1 [a, b, c], 2 [a, b, c], 3 [a, b], 4a, 5a, 6a) and 52 subtypes have been described. Due to the lack of proofreading function of the RNA-dependent RNA-polymerase (NS5B), HCV has a high mutation rate and exists as genetically heterogeneous quasispecies in individual patients^[5-7]. The different genotypes differ genetically from one another by at least 30%, and the different subtypes within a genotype by more than 20%. This genetic heterogeneity makes it difficult to compare apoptotic pathways obtained with different HCV genotypes. In general, apoptosis is central to viral clearance. In HCV-infected liver, however, despite enhanced hepatocyte apoptosis, viral persistence is observed.

APOPTOSIS IN HCV-INFECTED LIVER

Immune cell deficiency

The immune response to viral infections includes different components of the innate and the acquired immune system. They induce apoptosis as a host defense against viral infections. The innate immune system as the first line of defense directly activates inflammatory cells, such as macrophages (e.g., granulocytes, Kupffer cells in the liver) and natural killer (NK) cells which may directly cause death of the infected cells. On the other hand, viral RNA or proteins can bind to intracellular molecules that modulate or directly induce cell death^[8]. In this immune cell-independent, virus-induced apoptosis of the host cell protein kinase R (PKR)^[9,10] and the cytoplasmic RNA helicase RIG-I^[11] play central roles. RIG-I activates Cardif, a cytosolic protein that localizes to the mitochondrial membrane where it acts pro-apoptotic^[12,13]. PKR is also activated by interferons

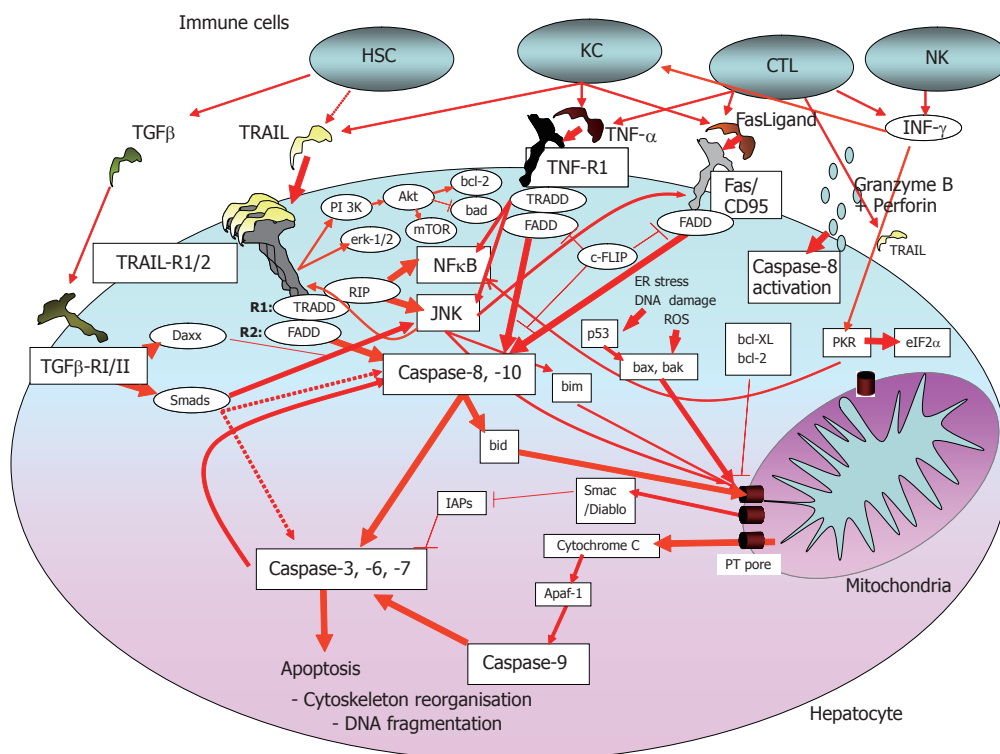

Figure 1 Signal transduction pathway of apoptosis in hepatocytes. Immune cells induce apoptosis in hepatocytes by death receptor ligands (TRAIL, TNF α , CD95Ligand, TGF- β) and granzyme B/perforin. Ligand-induced apoptosis activates caspase-8, whereas intrinsic apoptosis occurs via the mitochondrial permeability transition (PT) pore and activation of caspase-9. Caspase-9 and -8 activation converge in activation of the effector caspases-3, -6 and -7, resulting in irreversible apoptosis induction. HSC: Hepatic stellate cells; KC: Kupffer cells; CTL: Cytotoxic T-lymphocytes; NK: Natural killer cells.

(Figure 1) and acts *via* the downstream transcription factor eIF-2 α ^[14,15]. In HCV infection, the activated innate immune system alone is obviously insufficient to eliminate the virus^[16]. The acquired immune system consists of the humoral (antibody-secreting B-lymphocytes/plasma cells) and the cellular immune system (CD4+- and CD8+-T-lymphocytes). This system is essential for the clearance of most viral infections and depends on complex intercellular interactions and the recognition of viral antigens presented by specific cells (e.g., dendritic cells). CD4+-T-lymphocytes activate CD8+-T-lymphocytes, cytotoxic T lymphocytes (CTLs), macrophages and B-lymphocytes^[16]. The antigen-primed CD8+-T-lymphocytes/CTLs directly kill infected cells *via* direct cell-cell-contact, and release of cytotoxic and/or antiviral cytokines (e.g., IFN γ , TNF α), whereas IFN γ and IFN α are also able to eliminate the virus without killing the host cell^[17,18]. In chronic HCV infection, the acquired immune system is, among others, impaired by T cell failure, dysfunction and exhaustion^[19]. This failure includes CD4+- as well as CD8+-T-lymphocytes.

ENHANCED HEPATOCYTE APOPTOSIS IN HCV INFECTION *IN VIVO*

Most of the cytotoxic effects mentioned above occur *via* programmed cell death, with activation of the intracellular suicide program through specific signals. Because chronic viral infection may reflect a failure of the immune system, specific apoptosis induction may not occur. In chronic HCV infection, however, enhanced hepatocyte apoptosis has been described, independent from the HCV genotype^[20]. Apoptosis varies between 0.54%^[20] and 20.00% of hepatocytes^[21], depending on the methods used. Typical pathomorphological features

of apoptosis (e.g., nuclear fragmentation, cell shrinkage) may be seen only in a minority of hepatocytes. The close physical proximity of apoptotic hepatocytes and infiltrating lymphocytes suggests an immune cell-mediated apoptosis^[20,22]. Apoptosis correlates with liver pathology^[20,21] and may contribute to fibrogenesis^[23]. Due to the difficulty to identify HCV infected hepatocytes, it is unknown whether apoptotic hepatocytes are indeed HCV infected. The number of HCV infected hepatocytes is in the range between 1% and 10%^[24]. Therefore, we actually do not know whether apoptosis is indeed related to HCV clearance. In an animal model of cholestasis, inhibition of hepatocyte apoptosis reduced fibrogenesis^[25] and excessive apoptosis lead to fulminant hepatitis^[26,27]. Therefore, anti-apoptotic therapy to prevent HCV-related liver damage has been suggested^[28,29]. By contrast, in a chimeric mouse-human model, pro-apoptotic gene therapy with proapoptotic Bid, engineered to contain a specific cleavage site for NS3/NS4A protease, results in a considerable decline of HCV RNA in serum^[30]. The relation between PEG-IFN/ribavirin-induced viral clearance and apoptosis of infected hepatocytes is largely unknown. INFs induce apoptosis in hepatoma cells, activate pro-apoptotic PKR^[10] and upregulate death receptor ligands. However, anti-apoptotic effects have also been described^[17,31-33].

LIGAND-INDUCED HEPATOCYTE APOPTOSIS IN HCV INFECTION

Hepatocytes most likely represent so-called type-II cells, for which external activation of the death signaling pathway often is insufficient to induce apoptosis. Here, apoptosis requires in addition amplification by the mitochondrial pathway (intrinsic apoptosis pathway). The

latter is affected by oxidative stress, DNA damage, and viral proteins (Figure 1).

Targeted apoptosis induction *via* CTLs and macrophages largely occurs *via* the ligands and receptors of the TNF α family: TNF α /TNF-receptor 1, CD95/CD95Ligand and TRAIL/Trail receptor-1 and -2, respectively (Figure 1). Ligand binding induces the formation of a death-inducing signaling complex, resulting in the activation of caspase-8 (caspases are the proteases involved in the apoptosis signaling cascade^[34]). Active caspase-8 can trigger two signaling pathways. The first pathway involves cleavage of bid, followed by mitochondria-dependent activation of caspase-9 *via* cytochrome C release and apaf-1^[35] (Figure 1). Mitochondria-dependent apoptosis is amplified by pro-apoptotic bax, bad, bak and others, while molecules like bcl-2 or bcl-XL act anti-apoptotic. These proteins converge at the mitochondrial permeability transition (PT) pore that regulates release of apoptotic regulatory proteins, e.g., procaspase-9, cytochrome C, apoptosis inducing factor (AIF) or Smac/Diablo^[36-38]. The second pathway involves caspase-8 activation that may bypass mitochondria resulting in the direct activation of effector caspases (caspase-3, -6, -7). Cellular inhibitors of apoptosis (IAPs, survivin, c-FLIP) are able to block caspase activation and apoptosis^[39] (Figure 1).

Growth-factor activated MAP-kinases Erk-1/2 and PKB/Akt inhibit apoptosis directly (e.g., through inactivation of pro-apoptotic bad) or *via* upregulation of anti-apoptotic proteins (e.g., bcl-2). By contrast, sustained stress activation of c-jun kinase (JNK) enhances death ligand-induced apoptosis *via* bim activation and consecutive mitochondrial apoptosis or *via* enhanced death-receptor membrane trafficking^[40-42]. Most death ligands, especially TNF α and TRAIL, activate NF κ B, which has anti-apoptotic effects in hepatocytes by upregulation of anti-apoptotic proteins, e.g., c-FLIP and bcl-XL^[43].

Death receptor ligands may be secreted by immune cells (e.g., macrophages) or may be membrane-bound. The latter form induces apoptosis more efficiently^[44]. In the normal liver, INF γ -activated Kupffer cells can kill neighbouring cells *via* TRAIL and CD95Ligand^[37,44]. By contrast, in injured liver, activated hepatic stellate cells release TGF- β that may induce apoptosis of hepatocytes^[45,46]. While TGF- β 1 expression is increased in the HCV-infected liver^[22], the impact of TGF- β on hepatocyte apoptosis in HCV-infected patients remains elusive. Apart from apoptosis induction, TGF- β is a key molecule in the pathogenesis of liver fibrosis^[47].

Hepatocytes undergo apoptosis in response to CD95Ligand and TNF α , whereas TRAIL presumably only induces apoptosis in infected or malignantly transformed hepatocytes/hepatoma cells, but not in normal liver cells. For all three death ligands, in chronic HCV infection, upregulation has been described^[20,48-51]. Further, HCV-specific CTL clones induced CD95Ligand-, TNF α - and perforin-dependent hepatocyte apoptosis^[52,53]. In HCV-infected liver, CD8+ T cells express CD95Ligand^[49] and TRAIL^[54] (Fischer, Blum Schmitt-Gräff *et al.*, unpublished data). Interestingly, CD95Ligand-induced apoptosis did not depend on HCV infection/antigen presentation, because bystander killing of non-HCV infected hepatocytes was

observed. TRAIL-induced apoptosis seems especially important in viral defense. Adenoviral-infected murine and human hepatocytes are sensitized to TRAIL-induced apoptosis, while CD95Ligand-induced cell death is not affected^[50,55]. In TRAIL knock-out mice resolution of pulmonary influenza infection is TRAIL-dependent^[56], and CMV infected colon epithelial cells or skin fibroblasts become sensitive to TRAIL-induced apoptosis^[57]. Further, in mice infected with encephalomyocarditis virus, blocking of TRAIL resulted in higher viral titers and early death^[58]. In concanamycin- and listeria-induced hepatitis, liver cell apoptosis is TRAIL-dependent^[59]. PEG-INF/ribavirin therapy of patients with chronic HCV infection results in a rapid and sustained TRAIL elevation, suggesting a role of TRAIL in viral clearance^[60]. Similar observations have been made for soluble CD95Ligand^[61,33]. Therefore, TRAIL-induced apoptosis may play a major role in HCV defense and elimination.

Another mechanism of apoptosis involves the release of granzyme B and perforin by CTLs^[62,63]. Exocytosed perforins form transmembrane channels in the target cell that allow the entry of granzyme B. Similar to death-ligand induced apoptosis, granzyme B-mediated apoptosis largely depends on caspase activation and the sensitivity of the target cell. Hepatocytes seem resistant to granzyme B mediated cell death, and CTL killing of infected hepatocytes is perforin/granzyme B- independent^[29,64]. Therefore, a contribution of this apoptosis mechanism in patients with viral hepatitis is very unlikely.

MODIFIED HEPATOCYTE APOPTOSIS *IN VITRO*

Viral proteins interfere with the cellular apoptotic signaling pathway and block key cellular elements of the host cell. Until recently, the lack of an infectious HCV tissue culture system did not allow to study the impact of HCV infection on hepatocyte apoptosis. Overall, the data regarding the role of different HCV proteins are controversial and ascribe to a given viral protein pro- and anti-apoptotic effects, depending on the experimental system used. Since in most models viral proteins are overexpressed by non-viral promoters, for virtually all HCV proteins a pro-apoptotic effect has been described. Apart from the unphysiological expression of viral proteins, these models further lack the balance of intracellular viral expression of the different HCV proteins and their interactions. Especially in HCV infection, intracellular viral protein expression is very low.

Further, HCV is genetically highly variable and exists as quasispecies in a given patient. Different pro- and anti-apoptotic effects of the HCV core protein from an individual patient have been described^[65], suggesting special properties of different quasispecies proteins. These protein differences may explain in part the different effects of viral proteins on apoptosis. Studies of the contribution of genotypes or quasispecies to the effects on apoptosis are largely missing. Further, experiments designed to study the impact of HCV infection on hepatocyte apoptosis must also consider the interactions between the different

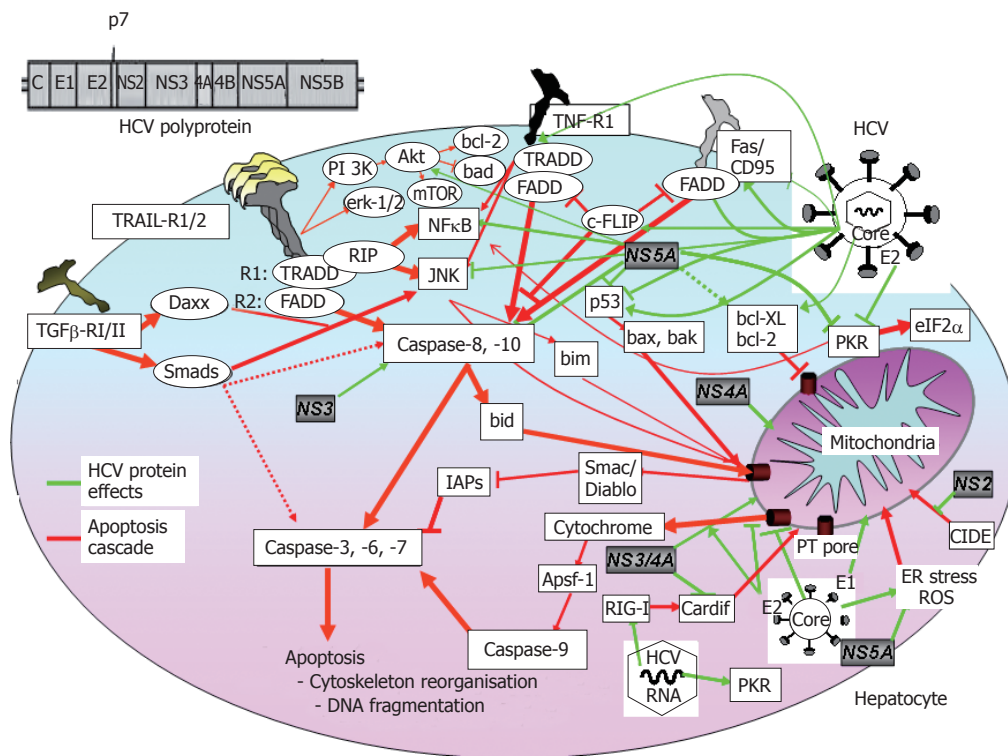

Figure 2 Interference of HCV proteins with the apoptosis cascade. Pro- and anti-apoptotic effects of HCV proteins converge at the mitochondria (e.g., NS2, NS3/4A, NS5A, E2, core), partly indirectly via p53 (NS5A, core) and activation of PKB/Akt, c-Jun kinase JNK (core) or NFκB (NS5A). HCV interacts directly with death receptors (core), the corresponding death receptor domains (FADD) and caspase-8 (NS5A). HCV double-strand RNA-activated protein-kinase R (PKR) induced signaling via RIG-I (retinoic acid inducible gene-I) and Cardif is directly (E2, NS5A) and indirectly (NS3/4A) disturbed.

HCV proteins. Therefore, only models based on the complete and infectious virus may reflect to some extent the *in vivo* situation.

HCV core protein

The structural HCV core protein makes up the virion nucleocapsid^[1,5,66]. The core protein has been shown to affect various cellular signaling pathways^[67] and to activate different promoters, e.g., c-myc, c-fos^[68-70]. It has further been shown to have pro- and anti-apoptotic effects in death ligand-mediated hepatocyte apoptosis. Core-dependent inhibition of TNF-α^[71] and CD95Ligand-induced apoptosis^[72] has been described in a hepatoma cell line. In other models, overexpressed HCV core protein did not prevent CD95Ligand-induced apoptosis in hepatoma cells^[73] or transgenic mice expressing HCV core protein, E1, E2 and NS2, respectively. HCV core protein inhibits CD95Ligand-mediated apoptosis by prevention of cytochrome C release from mitochondria and consecutive activation of caspase-9, -3 and -7^[74]. Direct physical and pro-apoptotic interaction of the core protein with the cytoplasmatic domains of CD95, TNF-R1^[75] and lymphotoxin-β^[76] receptors have been reported. Further, direct binding to the downstream death domain of FADD and c-FLIP^[77] has been shown to result in anti-apoptotic effects. Recently, inhibition of the TGF-β-pathway by direct interaction of the core protein with the DNA-binding domain of Smad3, important apoptosis mediators of TGF-β-receptor-I/II, has been demonstrated^[65].

Several studies demonstrated binding of the HCV core protein to p53, either inhibiting or activating p53^[69,78-80] with consecutive anti- or pro-apoptotic effects. In some studies apoptosis was inhibited in hepatoma through core-dependent phosphorylation and activation of STAT3 that induces the anti-apoptotic bcl-XL^[81,82]. Other studies

showed core-induced apoptosis through mitochondrial cytochrome C release and indirect activation of bax^[83,84]. TRAIL-induced apoptosis in hepatoma cells seems enhanced by core-dependent bid-cleavage^[83]. Mitochondrial functions are altered by core-induced oxidative stress, making cells more susceptible to apoptosis^[85]. Machida *et al*^[86] showed HCV-dependent production of reactive oxygen species (ROS), lowering of the mitochondrial transmembrane potential and consecutive caspase-independent cell death.

Taken together, it remains unclear whether HCV core protein inhibits or induces death receptor-mediated apoptosis of hepatocytes (Figure 2).

HCV envelope proteins E1 and E2

HCV proteins E1 and E2 are envelope proteins, that mediate viral binding and entry^[7,87]. In a transgenic mouse model expressing HCV proteins, CD95Ligand-mediated hepatocyte apoptosis is inhibited by E1, E2, NS2 and core, respectively. The activation of mitochondrial apoptosis (intrinsic pathway) is involved, because release of cytochrome C and caspase-9, but not caspase-8 activation are inhibited. To date, the contribution of the individual HCV proteins was not investigated^[74]. In E1-expressing hepatoma cells, apoptosis depends on the presence of the C-terminal transmembrane domain of E1, presumably altering membrane permeability of E1^[88,89].

Inhibition of TRAIL-induced apoptosis in hepatoma cells by E2, presumably through inhibition of mitochondrial cytochrome C release has been demonstrated^[90], while E1 had no effect and core did not counteract the anti-apoptotic effect of E2. Comparable results were obtained in core-E1-E2 transfected hepatoma cells or transgenic mice. In both models, core-E1-E2 induced less apoptosis than core-transfected

cells/transgenic mice and controls, respectively^[91]. By contrast, E2 induces mitochondria-related and caspase-dependent apoptosis in the same hepatoma cell line^[92]. These controversial data may reflect the use of different promoters that overexpress E2, while at the same time, the HCV genotype or the individual sequence of E2 have not been considered. Therefore, it still remains unclear whether HCV E1 has apoptosis-modulating activity *in vivo*, and whether HCV E2 acts anti- or pro-apoptotic (Figure 2).

HCV nonstructural proteins

The non-structural HCV proteins NS2 and NS3 are the two viral proteases required for posttranslational cleavage of non-structural proteins. NS2 is a transmembrane protein localized in the endoplasmic reticulum (ER) that directly binds and inhibits CIDE-B-induced apoptosis (cell death-inducing DFF45 (DNA-fragmentation-factor)-like effector^[93]). CIDE-B-induced apoptosis is assumed to occur *via* the mitochondrial pathway^[94,95]. Its role in hepatocyte apoptosis and viral hepatitis remain to be determined, however.

NS3 has a helicase and NTPase activity that are involved in RNA replication^[7]. Importantly, NS3 prevents viral RNA-induced pro-apoptotic RIG-I effects by specific cleavage of downstream Cardif, a protein that translocates to the mitochondrial membrane when activated^[13]. The precise role of Cardif in hepatocyte apoptosis and viral hepatitis is unknown, however. In contrast, NS3 induces caspase-8 dependent apoptosis in hepatocytes^[96] and in dendritic cells^[97]; the underlying mechanism remains unknown.

HCV NS4A is a cofactor that binds to NS3. NS4A alone and complexed with NS3 is localized in mitochondria and induces the release of cytochrome C and caspase-8 independent apoptosis^[98]. NS4B is an integral ER membrane protein that may play a role in anchoring the replication complex^[6,7]. A role in the apoptotic signaling pathway has not yet been described.

The function of NS5A is not yet well defined. NS5A interferes with the response to IFN and seems to play an important role in viral replication^[5,7]. NS5A has sequence homologies with bcl-2 and binds to FKBP38, thereby augmenting the anti-apoptotic effect of bcl-2^[99] and inhibiting the pro-apoptotic action of bax in hepatoma cells^[100]. Anti-apoptotic effects of NS5A are further mediated by cytoplasmatic sequestering of p53^[101], activation of PI3-kinase-Akt/PKB survival pathway^[102], activation of STAT3 with enhanced expression of bcl-XL and p21^[103] and activation of NFκB^[104]. By contrast, the direct inhibition of pro-apoptotic bin1, a tumor suppressor protein with a SH3 domain, has been described in hepatoma cells^[105], and a direct NS5A-induced apoptosis has also been shown^[97,106]. NS5B is the viral RNA-dependent RNA polymerase^[5-7]. There are no studies demonstrating a role of NS5B in apoptosis of hepatocytes/hepatoma cells, while a pro-apoptotic effect of NS5B has been demonstrated in dendritic cells^[97].

In conclusion, similar to HCV structural proteins, the effect of non-structural proteins on hepatocyte apoptosis *in vivo* remains unclear.

CONCLUSION

The role of apoptosis in HCV infection is not well defined. Kinetics and extent of hepatocyte apoptosis as well as the pro- and anti-apoptotic mechanisms involved remain unclear. It remains further unclear whether enhanced hepatocyte apoptosis in HCV infection is related to viral clearance, and whether it has a therapeutic benefit.

Most experimental models have fundamental shortcomings and there are no data from primary hepatocytes, tissue cultures or animal models. The majority of the data were obtained with different tumor cell lines that may in themselves be inhomogeneous. Different HCV genotypes and quasispecies may induce different effects, and most studies employ nonphysiologically overexpressed viral proteins. In HCV infected patients, by comparison, only very low quantities of HCV proteins are detectable, and the balanced expression of these proteins may be essential. Therefore, the results obtained to date have to be interpreted with great caution. The now available infectious tissue culture systems^[1-3] as well as future *in vivo* model systems may give answers to these questions, may better reflect the *in vivo* situation and may help to clarify the interference of HCV with apoptotic pathways and its role in the pathogenesis of HCV infection and clearance.

Abstract

AIM: To investigate the effects of electroacupuncture (EA) at neiguan (PC6) on gastric distention-induced transient lower esophageal sphincter relaxations (TLESRs) and discuss the mechanisms of this treatment.

METHODS: Protocol I: Twelve healthy cats underwent gastric distention for 60 min on the first day. Electrical acupoint stimulation was applied at the neiguan or a sham point on the hip in randomized order before gastric distention, on the third day and fifth day. Those cats that underwent EA at neiguan on the fifth day were named "Neiguan Group" and the cats that underwent EA at a sham acupoint on the fifth day were named "Sham Group" (control group). During the experiment the frequency of TLESRs and lower esophageal sphincter (LES) pressure were observed by a perfused sleeve assembly. Plasma levels of gastrin (GAS) and motilin (MTL) were determined by radioimmunoassay. Nitrite/nitrate concentration in plasma and tissues were measured by Griess reagent. The nuclei in the brain stem were observed by immunohistochemistry method of c-Fos and NADPH-d dyeing. Protocol II: Thirty six healthy cats were divided into 6 groups randomly. We gave saline (2 mL iv. control group), phaclofen (5 mg/kg iv. GABA-B antagonist), cholecystokinin octapeptide (CCK-8) (1 µg/kg per hour iv.), L-Arginine (200 mg/kg iv.), naloxone (2.5 µmol/kg iv.) and tacrine (5.6 mg/kg ip. cholinesterase inhibitor) respectively before EA at Neiguan and gastric distention. And the frequencies of TLESRs in experimental groups were compared with the control group.

RESULTS: Protocol I: Not only the frequency of gastric distention-induced TLESR in 60 min but also the rate of common cavity during TLESRs were significantly

decreased by EA at neiguan compared to that of sham acupoint stimulation. C-Fos immunoreactivity and NOS reactivity in the solitarius (NTS) and dorsal motor nucleus of the vagus (DMV) were significantly decreased by EA at neiguan compared to that of the sham group. However, the positive nuclei of C-Fos and NOS in reticular formation of the medulla (RFM) were increased by EA at neiguan. Protocol II: The inhibited effect of EA at neiguan on TLESRs frequency was completely restored by pretreatment with CCK (23.5/h vs 4.5/h, $P < 0.05$), L-arginine (17.5/h vs 4.5/h, $P < 0.05$) and naloxone (12/h vs 4.5/h, $P < 0.05$). On the contrary, phaclofen (6/h vs 4.5/h, $P > 0.05$) and tacrine (9.5/h vs 4.5/h, $P > 0.05$) did not influence it.

CONCLUSION: Electric acupoint stimulation at Neiguan significantly inhibits the frequency of TLESR and the rate of common cavity during TLESR in cats. This effect appears to act on the brain stem, and may be mediated through nitric oxide (NO), CCK-A receptor and mu-opioid receptors. But the GABAB receptor and acetylcholine may not be involved in it.

Wang C, Zhou DF, Shuai XW, Liu JX, Xie PY. Effects and mechanisms of electroacupuncture at PC6 on frequency of transient lower esophageal sphincter relaxation in cats. *World J Gastroenterol* 2007; 13(36): 4873-4880

<http://www.wjgnet.com/1007-9327/13/4873.asp>

INTRODUCTION

Transient lower esophageal sphincter relaxations (TLESRs) is the most important mechanism of gastroesophageal reflux (GER) either in the patients of gastroesophageal reflux disease (GERD)^[1] or in normal subjects^[2]. Distention of the proximal stomach is a major stimulus for triggering TLESRs^[3]. The stimulus passes through vago-vagal reflex and is integrated in the brain stem. There is ongoing interest in developing drugs that can decrease GER by interfering with TLESRs, including

GABA-B receptor agonist^[4], Cholecystokinin-A receptor antagonist^[5], nitric oxide synthase (NOS) inhibitor^[5,6], morphine^[7] and atropine (act through central cholinergic blockade)^[8-10]. The aim of our study is to explore new approaches (EA at Neiguan acupoint) to decrease the rate of TLESRs during gastric distention, and discuss the mechanisms of this treatment.

Acupuncture has been used to treat functional gastrointestinal disorders in eastern countries for centuries. It can modulate visceral sensation as well as function through stimulation at selected acupoints along the meridians (channels of acupoints)^[11]. EA at zusanli (ST-36) can increase the basal LES pressure^[12]. Transcutaneous electric nerve stimulation (TENS) at Hukou acupoint increased the degree of LES relaxation in volunteers^[13] and reduced basal LES pressure in patients with achalasia^[14,15]. Previous studies have suggested that TENS at neiguan may inhibit the rate of TLESRs triggered by gastric distention^[16] and reduce the perception to gastric distention^[17] in human beings. But the precise mechanisms for this phenomenon have not been extensively investigated and are not fully understood.

MATERIALS AND METHODS

Materials

Protocol I was performed on 12 adult cats weighing 3.7 ± 0.2 kg (M/F: 8/4), and 36 adult cats weighing 3.6 ± 0.5 kg (M/F: 25/11) were studied for protocol II. Cats were provided by the Animal Center of the First Hospital of Peking University. They were kept in individual cages in a controlled environment with a temperature of 22-26°C, 12/12-h light/dark cycles, and fed with standard cat diet. The animals were deprived of food 10 h before each experiment. All procedures were approved by the Committee for Animal Care and Usage for Research and Education of the Peking University. Anesthesia was initially induced with katamine (30 mg/kg im). Supplementary doses of katamine (15 mg/kg ip) were given whenever necessary to maintain an appropriate depth of anesthesia, as assessed they remained motionless yet still had cornea reflex. They were euthanized with pentobarbital sodium (0.5 mL/kg ip) at the end of the protocol.

Phaclofen, CCK octapeptide and tacrine were obtained from Sigma Chemical Co. (St. Louis, Missouri, USA). Naloxone was provided from Beijing Shuanghe Chemical Company. L-arginine was offered by Beijing Dingguo Chemical Company.

The GAS Radioimmunoassay kit was purchased from the China Institute of Atomic Energy, Beijing, China. The MTL Radioimmunoassay kit was purchased from the Neurobiological Technique Center of the Second Military Medical University, Shanghai, China. The Griess reagent for testing nitrite/nitrate concentration was purchased from Promega Corporation, USA. The reduced form nicotinamide adenine dinucleotide phosphate (NADPH) of and NBT (nitro blue tetrazolium) were obtained from Biomol Corporation, London, UK. The antibody of C-Fos was obtained from Santa Cruz Biotechnology, California, USA.

Recording methods

The manometry catheter (outer diameter 0.5 cm) consisted of a multilumen silicone tube with five side holes located at 9, 6, 3, 0 and -6 cm from the upper margin of the 6 cm-long Dent sleeve sensor (Dentsleeve, Belair, Australia). The catheter was continuously perfused with distilled water by a low compliance pneumohydraulic capillary infusion system (UPS-2020, Holland) at a rate of 0.2 mL/min. The external pressures transducers were connected via an analog/digital converter to a personal computer system. The data were displayed continuously on a monitor and stored on the personal computer system (MMS B.V. the Netherlands).

After anesthesia the cat was set in a supine position. A manometry catheter was placed through the mouth into the esophagus and positioned so that the sleeve sensor straddled the LES to register LES pressure. The distal side hole was used as a reference point for intragastric pressure. And the upper LES side holes were used to measure esophageal body pressure.

A mylohyoid electromyography (MMS B.V. the Netherlands) was used to record swallowing^[11,18]. The pinhead electrode was inserted in the mylohyoid muscle, and the reference electrode was fixed to the interscapular region of the back.

Electroacupuncture

Two acupuncture needles of 0.22 mm in diameter (Suzhou global acupuncture instrument Co. Ltd, Suzhou, China) were inserted perpendicularly at the bilateral Neiguan acupoint (PC6, located 1.5-2.0 cm above the wrist between the ligaments of the flexor carpi radialis and the palmaris longus^[19]) overlying the median nerve to a depth of 5 mm. An electrical stimulator (Model LH202H Hans, Beijing Huawei Medical Instrument Co. Ltd, Beijing, China) provided current to the needles. Wave patterns were sparse with dense pulse intervals ranging from 2 to 100 Hz (2/100 Hz), with constant amplitude and current flow (3-4 mA). The duration was 60 min. Correct positioning was confirmed by observing slight repetitive paw flexion during stimulation^[20].

Control stimulation on a sham acupoint was conducted at the hip, a point away from the traditional meridians and dermatomes.

Gastric distention

Air was insufflated (at a rate of 15 mL/s) into the stomach through a 2.0-mm diameter tube intubated through mouth to stomach. It's depth equal to 5 cm plus the esophageal body length. 30 mL air into the stomach every 6 min amount to 300 mL were insufflated in the 1 h period of gastric distention.

Study protocol I : Effects of EA on LES motor function

Twelve adult cats were divided into Neiguan group and Sham group randomly. Each cat was studied for three sessions, and an interval of each session is 2 d (Figure 1). In the first session, the basal rate of TLESRs triggered by gastric distention was observed for one hour. In session 2 and session 3, the influence of EA at neiguan or sham

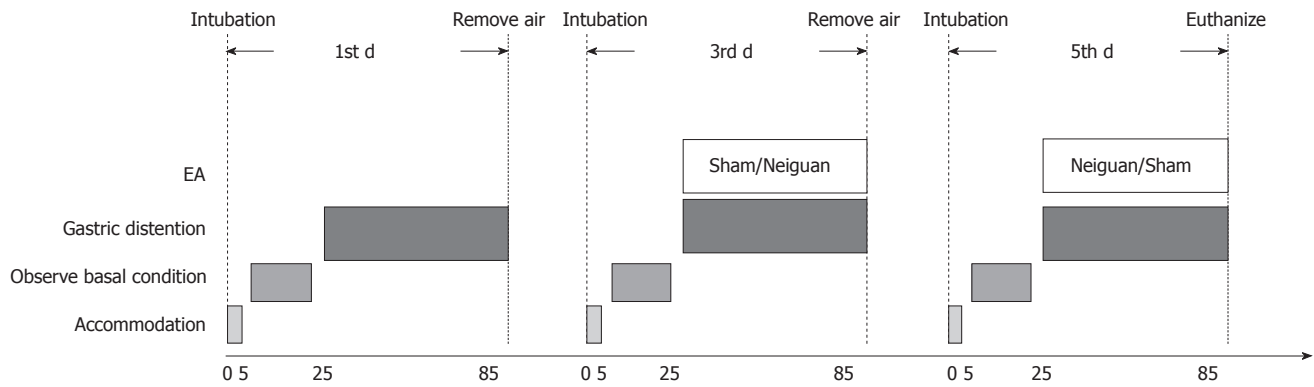

Figure 1 The flow chart of protocol I.

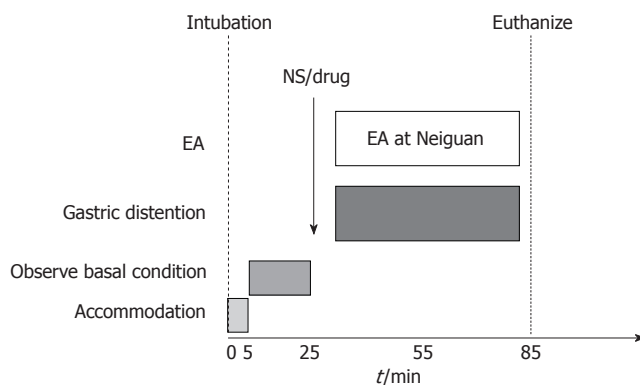

Figure 2 The process of protocol II.

acupoint to the rate of gastric distention induced TLESRs was observed in a random order.

After 5min of accommodation, the basal conditions were observed for 20 min (including basal rate of TLESRs and basal LES pressure). And then the gastric distention was applied in session 1. In session 2 and 3, gastric distention and electroacupuncture were applied at the same time. The remaining air was removed at the end of each session. At the end of session 3, the cats were euthanized and the blood, gastric fundus and brain stem were obtained for further research.

Study protocol I : Effects of drugs (phaclofen, CCK octapeptide, L-arginine, naloxone and tacrine) on inhibition of TLESRs by electric acupoint stimulation

Thirty six healthy cats were divided into 6 groups randomly. We gave normal saline(NS) (2 mL iv.), GABA-B antagonist phaclofen^[21] (5 mg/kg iv.), CCK octapeptide^[5] (1 µg/kg per hour iv.), L-arginine^[5] (200 mg/kg iv.), naloxone^[22] (2.5 µmol/kg iv.) and tacrine^[23] (5.6 mg/kg ip. cholinesterase inhibitor in central nerve system) respectively before EA at Neiguan and gastric distention, and observed the frequency of TLESR and LES pressure (Figure 2). At the end of this study, the cats were euthanized and the blood, gastric fundus and brain stem were obtained for further research.

Data analysis

TLESRs were defined according to established methods^[9].

Basal LES pressure was measured at the end of expiration relative to gastric pressure. The LES pressure during gastric distention was measured for 1 min every 6 min, and an overall mean for each period of the study was calculated. Common cavities were defined as abrupt simultaneous and sustained rises of basal esophageal pressure to intragastric pressure in at least the two lower esophageal body manometry recording sites^[24]. Common cavities are considered as markers of gas or liquid reflux from the stomach into the esophagus.

Assay of gastrointestinal hormones and nitrite concentration

When the cats were euthanized, 15 mL venous blood was collected into a test tube containing 400 µL of 10% EDTA-Na₂ (an anticoagulant) and 200 µL of trasylol. The blood samples were centrifuged at 4°C at 3500 r/min for 20 min. The serum was separated and stored at -70°C before analysis. The tissue of gastric fundus is about 2 cm × 2 cm. After weighting, tissues were added to 1 mL of 1 mol/L acetic acid and mixed evenly in a homogenizer to obtain a homogenate and were refrigerated at 4°C for 100 min. The extracted homogenates were added to 1 mL of 1 mmol/L NaOH and centrifuged at 3500 r/min 4°C for 20 min. The supernatant fluid was collected and stored at -70°C.

Gastrin (GAS) and motilin (MTL) levels were measured with commercial radioimmunoassay kits. Nitrite/nitrate levels were tested by Griess reagent.

c-Fos immunohistochemistry and NADPH-d histochemistry

After 60 min of gastric distention on the fifth day, the animal was transcardially perfused with 9 g/L saline followed by 40 g/L paraformaldehyde in 0.1 mol/L phosphate buffer saline (PBS, pH 7.3). The brain stem was removed and postfixed in the same fixative overnight and cryoprotected by immersion in 200 g/L sucrose for 72 h.

Coronal sections (40 µm) of the brain were cut in a cryostat. Every fourth section was used to reveal c-Fos immunoreactivity and the second set of sections was used to reveal NADPH-diaphorase (NADPH-d) staining.

The first set of sections were placed into a 50 g/L goat serum for 30 min at room temperature (RT), and incubated overnight at RT in primary antibody c-Fos (1:200). After washing for 15 min with PBST, the sections were incubated in biotinylated anti-rabbit IgG

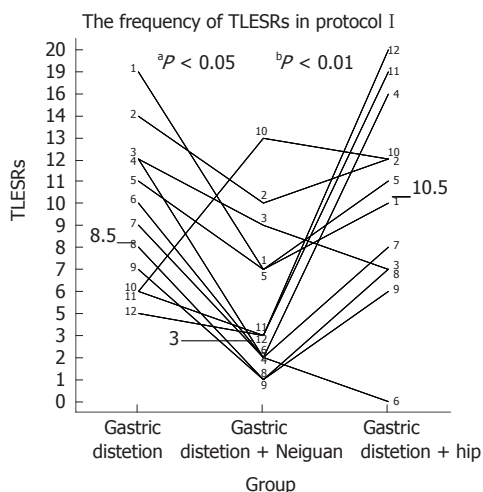

Figure 3 EA at neiguan decreased the rate of TLESRs induced by gastric distention, compared with EA at sham acupoint ($^aP < 0.01$) and baseline distention ($^bP < 0.05$). Each number represents one cat.

(Zymed, South San Francisco, Canada) diluted 1:300 in PBST at RT for 2 h, and then incubated in peroxidase-conjugated streptavidin (1:300 dilution, Zymed) for 2 h at RT. The immunoreactivity was visualized by incubating with 0.05 mol/L Tris-HCl buffer containing 0.1 g/L 3, 3'-diaminobenzidine, and 0.3 mL/L H_2O_2 for 10-20 min at RT. The stained sections were mounted on APES-coated glass slides, dehydrated and coverslipped.

The second set of sections were incubated at 37°C for 2 h in a solution containing 1 mmol/L NADPH, 0.5 mmol/L NBT, Tris-HCl 50 mmol/L, and Triton X-100 2 g/L. After a rinse in PBST, sections were mounted on APES-coated glass slides, dehydrated and coverslipped.

The distribution of c-Fos and NADPH-d positive cells was detected under a microscope (Olympus, Tokyo, Japan), and the cells were counted on LEICA Q550CW system (Leica Microsystems Imaging Solutions Ltd, Wetzlar, Germany), 10 sections for NTS/DMV, 8 sections for RFM. The average number of c-Fos or NADPH-d positive neurons per section for each cat was calculated, respectively.

Statistical analysis

The number of TLESRs was compared using Wilcoxon signedrank test and expressed as median (interquartile range). Basal LES pressure and intragastric pressure were presented as means \pm SD and were compared using repeated-measures. The rate of common cavity is compared using paired sample χ^2 . Nitrate concentrations, plasma hormone levels and the average number of c-Fos or NADPH-d positive nucleus of respective brain areas per section were expressed as mean \pm SD and was compared using independent t .

SPSS 11.0 was used for statistical analysis, and $P < 0.05$ was considered statistically significant.

RESULTS

Study protocol I: Effects of EA on LES motor function

Transient LES relaxations: The frequency of TLESRs

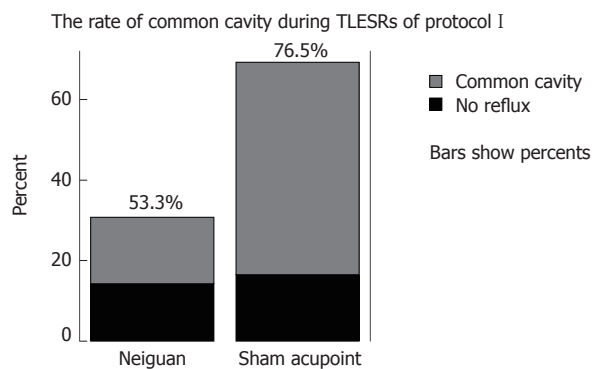

Figure 4 EA at Neiguan decreased the rate of common cavity during TLESRs compared with EA at sham acupoint ($P < 0.05$).

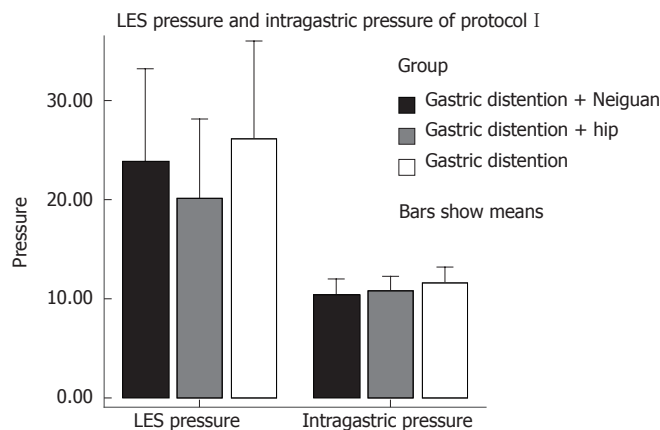

Figure 5 Electric stimulation at Neiguan didn't influence the LES pressure and intragastric pressure.

during acupoint stimulation at neiguan [3 per hour (range, 1-13)] was significantly lower than that during both the baseline period without any stimulation [8.5 per hour (range, 5-19), $P < 0.05$] and the period of sham stimulation at the hip [10.5 per hour (range, 0-20), $P < 0.01$] (Figure 3).

Common cavities during TLESRs: During EA at neiguan, a total of 60 TLESRs induced by gastric distention were observed in one hour, from it 32 were associated with common cavity, and its rate was 53.3%. During EA at sham acupoint, there are 136 gastric distention induced TLESRs in all, and 104 were associated with common cavity. The rate was 76.5%. Between-group comparisons showed that the rate of common cavity during EA at Neiguan was significantly lower than that occurring during EA at Sham acupoint ($P < 0.05$) (Figure 4).

LES pressure: EA at neiguan (PC6) had no effect on LES pressure. Overall mean LES pressure during electrical acupoint stimulation at neiguan (34.33 ± 18.16 mmHg) was similar to that during stimulation at the sham acupoint (30.97 ± 15.72 mmHg, $P > 0.05$) and during the baseline period without any acupoint stimulation (37.74 ± 18.69 mmHg, $P > 0.05$) (Figure 5).

Intragastric pressure: EA at neiguan (PC6) had no effect on gastric pressure during gastric distention. Overall

Table 1 Nitrite concentration in plasma and gastric fundus of protocol I (mean \pm SD)

Group	Serum (mmol/mL)	Gastric fundus (mmol/mg)
Neiguan	0.85 \pm 0.62	3.50 \pm 0.87
Sham	0.66 \pm 0.59	4.18 \pm 1.09

No significant difference was found between the two groups.

Table 2 Plasma GAS and MTL in each group of protocol I (mean \pm SD)

Group	GAS (pg/mL)	MTL (pg/mL)
Neiguan group	79.43 \pm 28.84	82.23 \pm 43.79
Sham group	156.30 \pm 72.53	103.6 \pm 68.16

GAS: gastrin; MTL: motilin. No significant difference was found between the two groups.

Table 3 c-Fos and NADPH-d staining in CNS

group	C-Fos		NOS	
	NTS and DMV	RFM	NTS and DMV	RFM
Neiguan group	21.9 \pm 6.9 ^a	96.6 \pm 16.5 ^a	23.6 \pm 4.6 ^a	75.6 \pm 17.0 ^a
Sham group	45.3 \pm 10.1	61.0 \pm 13.8	43.9 \pm 11.0	30.6 \pm 8.5

NADPH: nicotinamide adenine dinucleotide phosphate; CNS: central nerve system; NOS: nitric oxide synthase; NTS: nucleus tractus solitarius; DMV: dorsal motor nucleus of vagus; RFM: reticular formation of medulla. ^a $P < 0.05$ vs Sham group.

mean gastric pressure during EA at neiguan (10.37 ± 3.17 mmHg) was similar to that during stimulation at the sham acupoint (10.81 ± 2.89 mmHg, $P > 0.05$) and during the baseline period without any acupoint stimulation (11.58 ± 3.16 mmHg, $P > 0.05$) (Figure 5).

Nitrite concentration: EA at neiguan (PC6) did not influence the nitrite levels in plasma and gastric fundus tissues compared with Sham group ($P > 0.05$) (Table 1).

Gastrin (GAS) and motilin (MTL) levels: EA at neiguan (PC6) did not influence the GAS and MTL levels in plasma (Table 2).

C-Fos and NADPH-d staining in the central nerve system (CNS)

The c-Fos positive cell nuclei of activated cells showed the characteristic dark brown staining of oxidized DAB. Compared with the Sham group, electroacupuncture at neiguan significantly inhibited the number of C-Fos-labeled neurons in nucleus tractus solitarius/dorsal motor nucleus of vagus (NTS/DMV) (Figure 6A and B). However, it stimulated a significantly greater number of C-Fos positive nuclei in areas of reticular formation of the medulla (RFM) (Figure 7A and B).

NADPH-d activity was visualized as a vibrant blue color within perikarya, dendrites and axons. Electroacupuncture at neiguan significantly decreased the number of

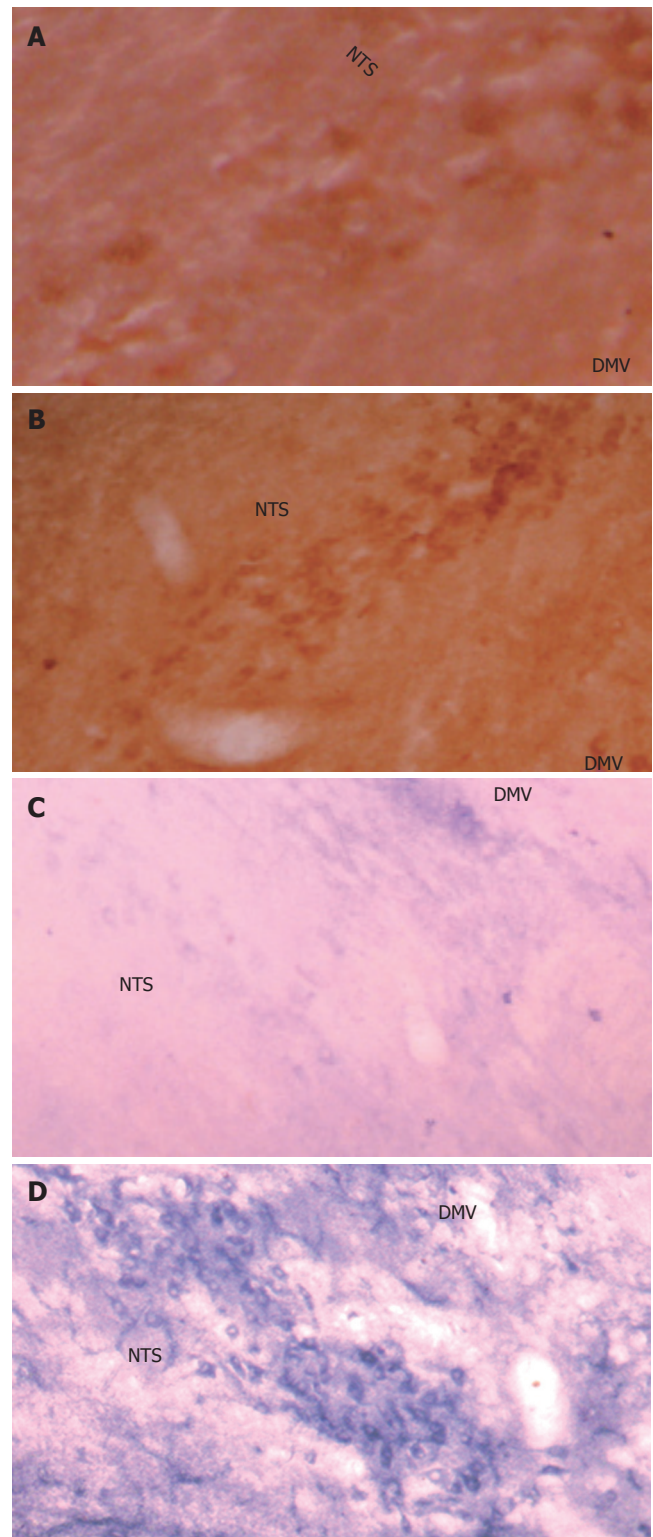

Figure 6 Photomicrographs showing C-Fos and NOS positive neurons in nucleus tractus solitarius/dorsal motor nucleus of vagus (NTS/DMV). A: C-Fos immunohistochemistry of neiguan group; B: C-Fos immunohistochemistry of sham acupoint group; C: NADPH-d histochemistry of neiguan group; D: NADPH-d histochemistry of sham acupoint group ($\times 10$).

NADPH-d stained cells in NTS/DMV (Figure 6C and D), but increased the number of positive cells in RFM (Figure 7C and D).

The number of positive nuclei in each group is listed in Table 3.

Study Protocol II : Effects of Drugs (phaclofen, CCK octapeptide, L-arginine, naloxone and tacrine) on inhibition of TLESRs by Electric Acupoint Stimulation

Transient LES relaxations: After saline infusion, the frequency of TLESRs during acupoint stimulation at neiguan [4.5 per hour (range, 1-11)] was still significantly

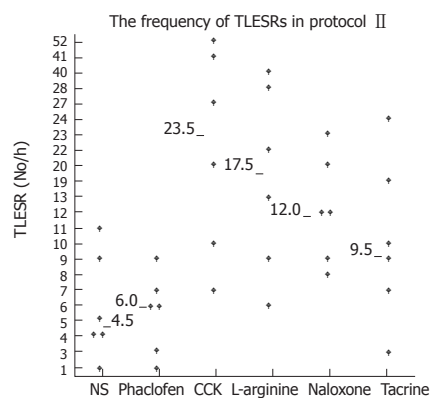

Figure 8 CCK, L-arginine and naloxone significantly increase the frequency of TLESRs compared with control group ($^{\circ}P < 0.05$). But phaclofen and tacrine did not change the frequency of TLESRs compared with control group ($P > 0.05$). It was indicated that the inhibited effects of EA at neiguan were completely restored by pretreatment with CCK-A, L-arginine and naloxone. But it was not influenced by phaclofen and tacrine.

lower than that during sham stimulation at the hip in protocol I [10.5 per hour (range, 0-20), $P < 0.05$].

Infusion of Phaclofen and tacrine did not influence the rate of TLESRs during acupoint stimulation at neiguan. They were [6 per hour (range 1-9) *vs* 4.5 per hours (range 1-11), $P > 0.05$] and [9.5 per hour (range 3-24) *vs* 4.5 per hour (range, 1-11), $P > 0.05$] respectively. However, during infusion of CCK octapeptide, L-arginine and naloxone, the inhibited effect of EA at neiguan had been completely restored. The rate of TLESRs were CCK [23.5 per hour (range 7-52) *vs* 4.5 per hours (range 1-11), $P < 0.05$], L-arginine [17.5 per hour (range 6-40) *vs* 4.5 per hours (range 1-11), $P < 0.05$] and naloxone [12 per hour (range 8-23) *vs* 4.5 per hours (range 1-11), $P < 0.05$] respectively (Figure 8).

DISCUSSION

Acupuncture has been used to treat functional gastrointestinal disorders in the eastern countries for centuries. A large amount of clinical evidence supports the effectiveness of acupuncture for treating functional disorders of the gastrointestinal tract, and the most commonly used acupoints in treating gastrointestinal symptoms are Neiguan (PC6) and Zusanli (ST-36). In the present study, we found electric acupoint stimulation at the neiguan acupoint resulted in a significant reduction of the rate of TLESRs induced by gastric distention. This result was consistent with previous investigations on human beings [12]. Furthermore, the present work also demonstrated the action site and neurotransmitters of this effect.

Speculation on the action site of electroacupuncture at neiguan

We postulate that the site at which electric acupuncture stimulation acts to inhibit the occurrence of TLESRs may be as follows: First, it may increase the proximal gastric motility or increase the gastric fundus tone, so that to decrease the volume of gastric fundus, and inhibit

the stretch receptors localized in the gastric fundus (As we know, the stretch receptors were the major receptor in triggering TLESRs^[25,26]) and then reduce the sensory input from gastric distention. Second, it may inhibit the integration of TLESRs in some area of the brain stem, such as NTS (nucleus tractus solitarius) and DMV (dorsomotor nucleus of the vagus nerve). Third, electric acupoint stimulation at Neiguan may exert its action primarily on the efferent motor pathway.

With present research, electric stimulation at Neiguan did not change the intragastric pressure and nitrite levels in the tissue of gastric fundus compared with EA at sham acupoint. Nitric oxide is well accepted as an inhibitory neurotransmitter in the gastrointestinal tract, and may exert a tonic inhibition on the proximal stomach^[27]. So the result of our study suggested that EA at neiguan cannot change the tone of gastric fundus. And it is consistent with previous research^[12,28].

In the current research, electric stimulation at neiguan had no effect on the residual LES pressure, so it is unlikely that it exerts action primarily on the efferent motor pathway.

The dorsal vagal complex (DVC) comprising nucleus tractus solitarius (NTS) and dorsomotor nucleus of the vagus nerve (DMV) is the center of the integration of TLESRs^[9]. The brain stem dyeing shows that when compared with sham group EA at neiguan significantly decreases the C-Fos and NOS positive nucleus in NTS/DMV. However, it stimulated a significantly greater number of C-Fos and NOS positive nucleus in areas of reticular formation of the medulla (RFM). And RFM may be one of the acupuncture action sites^[29].

Consequently, the action site of EA at neiguan may be localized within the brain stem. It may increase NOS in the nucleus of RFM, so that it inhibits NOS in NTS/DMV, and then decreases the frequency of TLESRs.

Speculation on the neurotransmitter of electroacupuncture at neiguan

In the second part of this research, the inhibited effect of EA at neiguan on TLESR's rate was completely restored by pretreatment with CCK, L-arginine and naloxone. On the contrary, phaclofen and tacrine did not influence it. So this effect appeared to be mediated through nitric oxide (NO), CCK-A receptor and mu-opioid receptors. But the GABAB receptor and acetylcholine may not be involved in it.

In our study, electric stimulation at Neiguan also did not influence the gastrin and motilin levels in plasma. It suggested that the inhibited effects of electric stimulation were not through these two neuropeptides.

The variance between previous research

Endogenous opioid peptides (EOPs) are considered as major candidates for a role in acupuncture action because numerous investigations have clearly demonstrated that electroacupuncture effect is antagonized by the opioid receptor antagonist naloxone^[30]. And in our research, the naloxone can reverse the inhibited effect of electroacupuncture on TLESRs. In contrast to our results in cats, Zou *et al.*^[12] found the inhibited effect of

acupoint stimulation was not inhibited by naloxone. In that study, the frequency of electrical stimulation is 100 Hz. However, our wave patterns were sparse and dense pulse intervals ranging from 2 Hz to 100 Hz (2/100 Hz). Previous studies have demonstrated that low-frequency (2 Hz) electroacupuncture analgesia (EAA) is induced by the activation of μ - and δ -opioid receptors *via* the release of enkephalin, β -endorphin, and endomorphin; and high-frequency (100 Hz) EAA is caused by activation of κ opioid receptors *via* release of dynorphin^[31]. So it may be the reason of the variance between our findings and Zou's research.

In conclusion, electric acupoint stimulation at the Neiguan result in a significant reduction of the rate of TLESRs induced by gastric distention. This effect appears to act at the brain stem, and may be mediated through NO, CCK-A receptor and mu-opioid receptor.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a disorder characterized by an increased exposure of the esophagus to the intragastric contents. Recent studies have suggested that transient lower esophageal sphincter relaxation is the main mechanism underlying gastroesophageal reflux. It involves a prolonged relaxation of the lower esophageal sphincter, mediated by a vago-vagal neural pathway, synapsing in the brainstem. Acupuncture has been used to treat functional gastrointestinal disorders in the eastern countries for centuries. It can modulate visceral sensation as well as function through stimulation at selected acupoints along the meridians (channels of acupoints).

Research frontiers

Transient lower esophageal sphincter relaxation (TLESR) is the most important mechanism of gastroesophageal reflux (GER) in the patients of GERD. So it had become an important target in dealing with gastroesophageal reflux disease.

Innovations and breakthroughs

Although there have one article indicated that electroacupuncture at neiguan (PC6) may decrease the frequency of TLESRs, our research is the first paper to observe the mechanisms carefully.

Applications

Our research observed the relationship between electroacupuncture at neiguan (PC6) and TLESRs. And there may be a significant clinical impact in the future.

Terminology

TLESR: It is a spontaneous relaxation of LES without swallow induced. Its definition included: (1) absence of swallowing for 4 s before to 2 s after the onset of LES relaxation. (2) relaxation rate of $> \text{or} = 1 \text{ mmHg/s}$. (3) time from onset to complete relaxation of $< \text{or} = 10 \text{ s}$. (4) nadir pressure of $< \text{or} = 2 \text{ mmHg}$. Exception: a markedly prolonged LES relaxation $> \text{or} = 10 \text{ s}$, and nadir pressure $< \text{or} = 2 \text{ mmHg}$ can also be classified as TLESR, irrespective of the relation with swallow; Common Cavity: It was defined as abrupt simultaneous and sustained rises of basal esophageal pressure to intragastric pressure in at least the two lower esophageal body manometry recording sites.

Peer review

This manuscript it is well written and the experimental design is sound. In addition, there may be a significant clinical impact if these results will be confirmed in the future.

Abstract

AIM: To investigate that both the neuronal function of the contractile system and structural apparatus of the gastrointestinal tract are affected in patients with longstanding diabetes and autonomic neuropathy.

METHODS: The evoked esophageal and duodenal contractile activity to standardized bag distension was assessed using a specialized ultrasound-based probe. Twelve type-1 diabetic patients with autonomic neuropathy and severe gastrointestinal symptoms and 12 healthy controls were studied. The geometry and biomechanical parameters (strain, tension/stress, and stiffness) were assessed.

RESULTS: The diabetic patients had increased frequency of distension-induced contractions (6.0 ± 0.6 vs 3.3 ± 0.5 , $P < 0.001$). This increased reactivity was correlated with the duration of the disease ($P = 0.009$). Impaired coordination of the contractile activity in diabetic patients was demonstrated as imbalance between the time required to evoke the first contraction at the distension site and proximal to it (1.5 ± 0.6 vs 0.5 ± 0.1 , $P = 0.03$). The esophageal wall and especially the mucosa-submucosa layer had increased thickness in the patients ($P < 0.001$), and the longitudinal and radial compressive stretch was less in diabetics ($P <$

0.001). The esophageal and duodenal wall stiffness and circumferential deformation induced by the distensions were not affected in the patients (all $P > 0.14$).

CONCLUSION: The impaired contractile activity with an imbalance in the distension-induced contractions likely reflects neuronal abnormalities due to autonomic neuropathy. However, structural changes and remodeling of the gastrointestinal tract are also evident and may add to the neuronal changes. This may contribute to the pathophysiology of diabetic gut dysfunction and impact on future management of diabetic patients with gastrointestinal symptoms.

INTRODUCTION

Gastrointestinal (GI) symptoms (nausea, vomiting, bloating, abdominal pain, diarrhea, etc.) are frequent in patients with diabetes mellitus^[1-4]. The symptoms are often severe and substantially compromise quality of life. Abnormal GI function in diabetic patients has been demonstrated with methods such as manometry, scintigraphy, radiography, and breath tests. For example, the esophagus is characterized by dysmotility with fewer contractions having decreased amplitudes and abnormal wave forms^[5]. The pathogenesis of the GI symptoms in diabetes is complex in nature, multi-factorial and not well-understood^[5]. Dysmotility and delayed emptying of the stomach have been demonstrated, and in the small and large intestine dysmotility, delayed transit, and bacterial overgrowth have been observed^[5]. The GI dysfunction and symptoms may be caused by autonomic neuropathy being one of the most prevalent complications affecting

up to 40% of patients with long-standing diabetes^[6,7], and several clinical studies have demonstrated neuropathy of the autonomic nervous system (especially vagal but also sympathetic), as well of enteric nerves^[8]. Impaired visceral sensory function, glycemic control and psychological factors may also be contributing factors^[9-13]. Finally, mechanical factors may also contribute to the symptoms. Hence, studies in animals with experimental diabetes have shown structural remodeling and protein cross-linking in the GI wall layers compared to control animals^[14-18]. Structural remodeling caused by diabetes in animals is known to cause changes in the biomechanical properties, resulting in increase of both stiffness and thickness of the GI wall^[19-22].

The impact of the structural changes in the human GI wall on the function and on biomechanical properties has not been studied in detail due to inaccessibility of the organs and lack of suitable methodology. Such studies are needed since it is still generally assumed that the contractile (and structural) apparatus of the GI tract is normal, and that the disordered function and abnormal contractile activity predominantly reflects neuronal abnormalities^[23,24]. Better ways of studying the GI tract may impact on the future management of diabetic patients with GI symptoms. Cross-sectional ultrasound imaging have recently been developed to study the biomechanical properties of the GI tract during distension in animals^[25,26] and humans^[27-29]. The deformation pattern, the radial distributions of strain, stress and stiffness, and the distension-induced sensation have been assessed in the human esophagus^[30]. The technique has also been applied to assess the biomechanical properties of the human duodenum^[31]. Ultrasound has no known short or long term hazards and provides excellent soft tissue imaging with a good temporal and spatial resolution and is a valuable tool for studying GI function *in vivo*.

The hypotheses in the present study were that (1) the biomechanical properties of the esophageal and duodenal wall were changed due to diabetes-induced tissue remodeling and that (2) the contractile activity of the esophagus and duodenum was affected by the neuronal dysfunction related to diabetic autonomic neuropathy. Hence, the aims were to apply the new ultrasound based testing approach to (1) assess the distension-induced contractile activity in the human upper gut in healthy controls and in patients affected by gastrointestinal dysfunction due to diabetic autonomic neuropathy, and (2) to look into the mechanism of the findings by assessing the GI remodeling including the wall thickness and distension-induced deformation patterns.

MATERIALS AND METHODS

Study subjects

Data were obtained from 15 diabetic patients recruited at the Department of Endocrinology M, Aarhus University Hospital (13 males, 2 females, mean age 43 years, range 25-62 years) and 12 healthy controls (7 males, 5 females, mean age 37 years, range 29-50 years) recruited among the hospital staff and at the university. The local Ethical Committee approved the study protocol (VN

2003/120mch) which also conforms to the Declaration of Helsinki. Oral and written informed consent was obtained from all subjects.

All of the 12 patients who completed the study (Table 1) had type 1 diabetes lasting 12 to 46 years (average 23 years) and all suffered from debilitating symptomatic diabetic autonomic neuropathy (shown by a minimum of two symptoms from different organ systems) and verified by abnormal cardiovascular reflexes (heart rate variability and blood pressure changes during deep breathing and going from lying to standing). All suffered from peripheral neuropathy as demonstrated by absent or diminished patellar reflexes and abnormal biotensimetry values. The patients underwent examinations that were justified by their symptoms to exclude any organic diseases affecting the GI tract. Clinical data from the 12 patients who completed the study are presented below and in Table 1. All patients had severe GI symptoms: nausea (12 of 12), vomiting (10 of 12), abdominal pain (4 of 12), diarrhea (9 of 12), and constipation (2 of 12). Five of the 12 patients were taking medication known to affect gastrointestinal function (erythromycin, metoclopramide and proton pump inhibitors) while the rest were not treated because of previous insufficient response to various drugs. Four patients suffered from neuropathic pain and were treated with analgesics (oxycodone, gabapentin, pregabalin and paracetamol). None of the patients had prior abdominal surgery or suffered from psychiatric diseases or had any suspicion of psychological abnormalities. The control subjects did not take medications, had no prior abdominal surgery and did not suffer from any GI symptoms or pain-related diseases. They all had normal physical examination and blood tests.

Experimental probe design

The probe consisted of a 120 cm catheter (Ditens A/S, Aalborg, Denmark) with a 6.2 mm outer diameter and eight lumens of different sizes (Figure 1 top)^[30]. A 50 μ m thick polyurethane bag (Ditens A/S, Aalborg, Denmark) was attached to the catheter with 5 cm between the attachment points and with its centre positioned corresponding to the crystal of the ultrasound probe. The bag could be inflated to a maximum diameter of 50 mm (cross-sectional area (CSA) of 2000 mm²) with a constant bag length without stretching the bag wall. The size of the bag was chosen on the basis of previous studies of the duodenum where the CSA never exceeded 2000 mm² when the bag was inflated to the point where moderate pain was reported^[32].

The largest lumen in the probe contained a 20 MHz endoscopic 360 degrees ultrasound probe (UM-3R, Olympus Corporation, Tokyo, Japan). The signal from the endoscopic ultrasound unit (EU-M30, Olympus Corporation, Tokyo, Japan) was directly captured and stored digitally (AVI MPEG4 format) by frame grabber software (Studio 8, Pinnacle Systems Inc., CA, USA) for later analysis. Another large lumen was for infusion and withdrawal of fluid to the bag. The lumen was connected to a roller pump (Type 110, Ole Dich, Hvidovre, Denmark) for inflation and deflation of the bag with 37°C sterile water at a constant rate^[30,33].

Two small lumens (< 1 mm in diameter) were used for

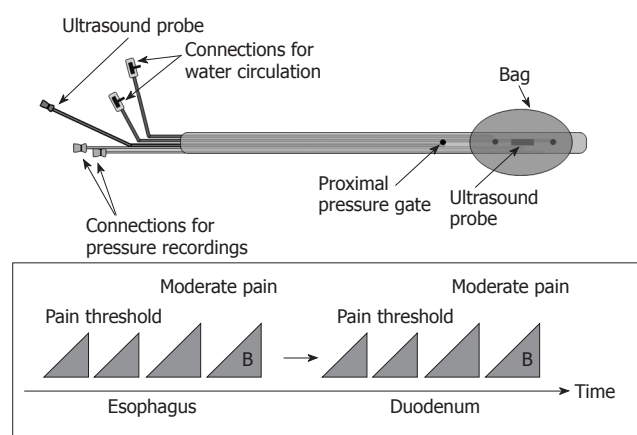

Figure 1 The probe design allows bag distension of the esophagus and duodenum together with cross-sectional ultrasound imaging and recording of the bag and proximal pressures (top). The distension protocol is shown at the bottom. The first distensions to the pain threshold were preconditioning stimuli also used for learning. They were followed by a distension (15 mL/min in the esophagus and 25 mL/min in the duodenum) to the perception of moderate pain. Finally, a bolus of 20 mg of butylscopolamine (B) was given intravenously in order to diminish distension-evoked smooth muscle contractions and a final distension to the perception of moderate pain was done.

recording of pressures inside the bag and 6 cm proximal to the center of the bag. The channels were continuously perfused at a rate of 0.1 mL/min with sterile water by a low-compliance perfusion system. The pressure channels were attached to external pressure transducers (Baxter,

Deerfield, IL, United States). The signals were amplified, analogue-to-digital converted and stored on a computer for later analysis (Openlab, Ditens A/S, Aalborg, Denmark).

Study protocol

The patients were fasting for 12 h prior to the experiment due to the well known delayed gastric emptying in this patient group (Table 1). During the fasting period the blood glucose concentrations were monitored every hour and adjusted to approximate the normal range (below 6 mmol/L) using intravenous glucose infusions and subcutaneous injection of fast-acting insulin (Actrapid, Novo, Bagsværd, Denmark). The healthy controls were fasting for six hours (Figure 1, bottom).

The probe was swallowed and the subject was positioned supine with the upper part of the body 30 degrees tilted. The lower esophageal sphincter was identified guided by the pressure recordings and the ultrasound image. The bag was positioned 10 cm above the lower esophageal sphincter. Distension was done by inflating the bag at a rate of 15 mL/min. Several preconditioning distensions to the pain threshold were done prior to experimental distensions to the perception of moderate pain^[34,35]. The preconditioning distensions were repeated until the obtained data were reproducible. The bag was deflated between distensions at a rate of 15 mL/min. Then 20 mg of butylscopolamine (Buscopan, Boehringer, Ingelheim, Germany) was administrated intravenously to abolish esophageal contractility followed

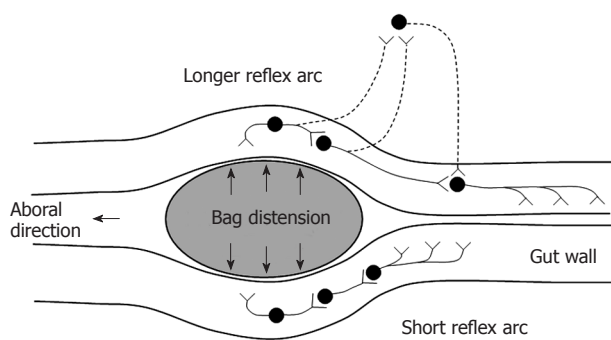

Figure 2 Schematic illustration of the neural pathways involved in distension-induced contraction. The primary afferent neurons, the excitatory interneurons and efferent neurons are shown. The dotted neurons illustrate extrinsic pathways. The induction of contraction on the bag depends on the local reflex arc (bottom). The measurement 6 cm proximal to the bag depends on a longer reflex arc including extrinsic pathways (top).

by one distension to the perception of moderate pain.

The probe was then advanced into the horizontal part of the duodenum guided by transabdominal ultrasound (SonoSite 180, SonoSite Inc, Bothell, WA, USA), endoscopic ultrasound and by the motility pattern observed. Approximately 30 min after the esophageal testing, and when duodenal phase II activity was observed, duodenal distensions were performed before and after administration of butylscopolamine as described above but at an inflation rate of 25 mL/min.

The total examination time was approximately two hours and the blood glucose concentrations in all patients and controls were measured before, after one hour, and at the end of the study. The blood glucose level was adjusted to approximate the normal range if it deviated during the study.

Analysis of the distension-induced contractile activity

Contractions were defined as having amplitude ≥ 10 cm H₂O and duration ≥ 3 s. Contractile activity at the distension site and proximal to it were analyzed for the filling phase of all distensions. The time from start of the distension to induction of the first contraction during the distension procedure was noted. The time to induce the first contraction at the distension site is generally thought to be dependent on a local short enteric reflex arc. The time to induce the first contraction 6 cm proximal to the bag depends on a longer reflex arc that is more likely affected by extrinsic pathways (Figure 2). Hence, the ratio between these contractile responses serves as a proxy of the function of the neural pathway between the bag and proximal pressure measurement site. The number of contractions during the first minute and the frequency of all contractions were also noted. Furthermore, the pressure amplitude and duration of the strongest contraction were calculated. A proxy of the contractile work was computed by multiplying the amplitude and the duration of the strongest contraction. In the duodenum the frequency of contractions at the proximal pressure measurement site was also calculated before and after the distension procedure.

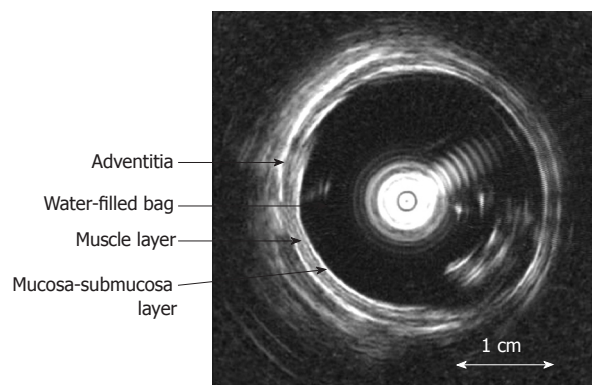

Figure 3 The cross-sectional ultrasound image of the distended distal esophagus allows identification of the esophageal layers, i.e. mucosa-submucosa, muscle and adventitia layers. The white round shadow in the centre is caused by the intraluminal ultrasound probe.

Biomechanical analysis of esophageal and duodenal distensions

The biomechanical properties including stress-strain and tension-strain relations, esophageal wall thickness and multidirectional deformation were measured and calculated from the intraluminal ultrasound images (Figure 3) and pressure recordings (see Appendix).

Statistical analysis

Data are given as mean \pm SE unless otherwise stated. The contractile activity of the patients and controls was analyzed using one-way analysis of variance (ANOVA). The contraction frequencies in the duodenum in relation to the distension and the duodenal wall stiffness were analyzed using two-way ANOVA, which was also used for the esophageal stress, strain, stress-strain ratio, multidirectional deformation and wall thickness, and duodenal tension, strain and tension-strain ratio at maximum perception. The esophageal wall stiffness was analyzed using three-way ANOVA with the factors: (1) controls *vs* patients, (2) before *vs* after butylscopolamine, and (3) mucosal surface *vs* submucosa-muscle interface *vs* outer surface. The association between the clinical data and the contractile activity and biomechanical properties was analyzed using Spearman correlation test. *P*-values less than 0.05 were considered significant. If the data were not normal-distributed they were logarithmically transformed before the parametric tests were performed. SPSS version 11.0 was used for the statistical analysis.

RESULTS

The study was completed in 12 (10 males, 2 females, mean age 40 years, range 25-62 years) of the 15 diabetic patients. Three patients interrupted the study in its initial phase due to severe throat irritation, nausea and vomiting. All healthy controls completed the study.

Blood glucose levels

At the beginning of the 12 h fasting period the diabetic patients had a mean blood glucose level of 10.6 (range

7.0-16.5) mmol/L with fluctuations during the first hours. The glucose level was adjusted and stabilized to a mean level of 8.1 (range 5.2-10.5) mmol/L during the study period. The controls had a mean blood glucose level (after 6 h fasting) of 4.6 (range 3.5-5.2) mmol/L during the study period.

Distension-induced contractile activity

Data on the contractile activity induced by the bag distensions are provided in Table 2.

Esophagus: The diabetic patients had shorter time to the first contraction on the bag (borderline), increased number of bag contractions during the first minute, increased frequency of contractions, reduced pressure amplitudes and reduced contractile work of the bag contractions. Similar findings were found 6 cm proximal to the bag where the diabetic patients had shorter time to the first contraction, increased number of contractions during the first minute, and reduced contractile work of the contractions. The ratio between the time until the first contraction on the bag and the time until the first contraction 6 cm proximal to the bag was increased in the diabetic patients. This likely reflects dysfunction of local intestinal neural pathways.

Duodenum: The contractile activity between the diabetic patients and controls did not differ in the duodenum. The ratio between the time until the first contraction on the bag and the time until the first proximal contraction tended to increase in the diabetic patients. Furthermore, the frequency of contractions in the diabetic duodenum was 2.3 ± 1.0 min⁻¹ before, 2.1 ± 0.8 min⁻¹ during and 2.8 ± 0.6 min⁻¹ after the distension and in the controls the numbers were 1.5 ± 0.4 min⁻¹, 1.6 ± 0.6 min⁻¹ and 1.9 ± 0.8 min⁻¹, respectively. Hence, no difference between the patients and controls (*F* = 0.8, *P* = 0.4) and in relation to the distension (*F* = 0.5, *P* = 0.6) were found.

Esophageal wall thickness

The thickness of the entire esophageal wall, the muscle

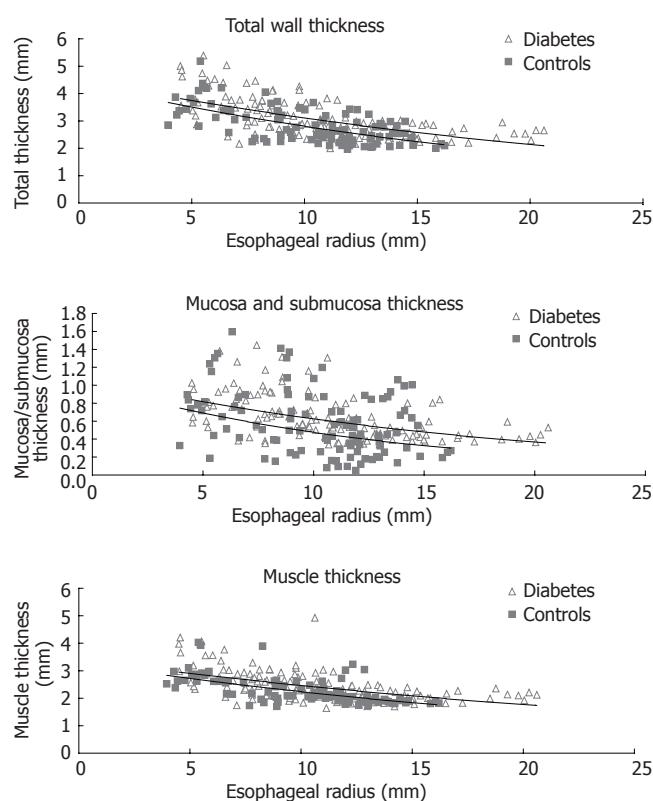

Figure 4 The distension-induced change in thicknesses of the total esophageal wall structure, the muscle layer, and mucosa-submucosa layer during smooth muscle relaxation with butylscopolamine are illustrated as function of the esophageal radius. The data points represent the multiple measuring points during each distension of the patients and controls. Exponential trend lines (solid lines) of the patients and controls are shown. The total wall thickness and the mucosa-submucosa layer were increased in the diabetic patients.

layer and mucosa-submucosa layer obtained during the distensions (after administration of butylscopolamine) are illustrated in Figure 4. The wall and the mucosa-submucosa layer were thicker (0.2-0.3 mm) in the diabetic patients compared to the control subjects (*F* = 13, *P* < 0.001, and *F* = 13, *P* < 0.001). The muscle layer thickness showed a borderline increase (*F* = 3.7, *P* = 0.055).

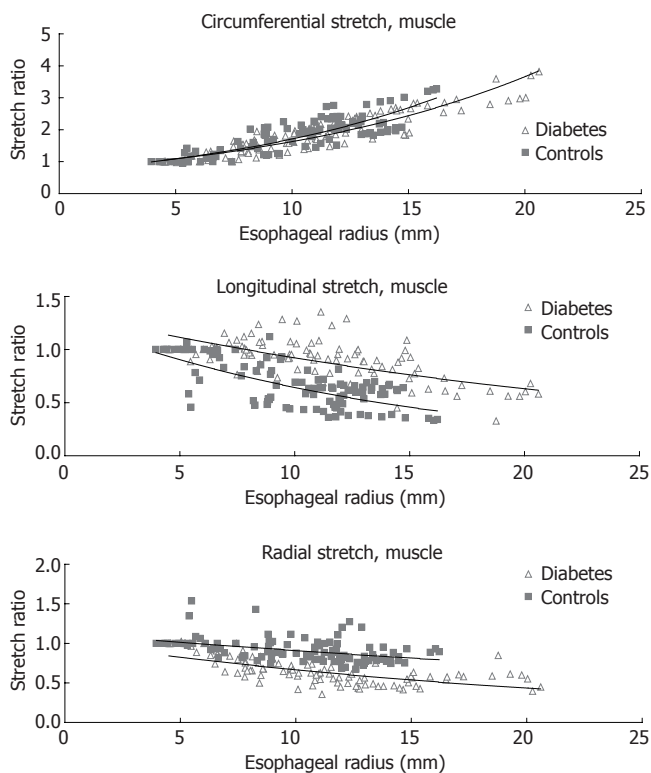

Figure 5 The distension-induced change in circumferential, longitudinal and radial stretch ratios are illustrated as function of the esophageal radius. The curves were obtained during smooth muscle relaxation with butylscopolamine. The data points represent the multiple measuring points during each distension of the patients and controls. Exponential trend lines (solid lines) of the patients and controls are shown. The shortening during distension was clearly reduced in the diabetic patients while the radial stretch was decreased.

Multidirectional deformation of the esophagus

The circumferential, longitudinal and radial stretch ratios during distension in both the diabetic patients and control subjects are shown in Figure 5. The curves were obtained from the muscle layer and after administration of butylscopolamine. The same pattern was seen in all sub-layers both before and after administration of butylscopolamine. During distensions the patients tended to stretch less in the circumferential direction ($F = 0.007$, $P = 0.1$). The compressive deformation (shortening) in the longitudinal and radial directions during distension was clearly reduced in the diabetic patients ($F = 150$, $P < 0.001$ for longitudinal direction and $F = 180$, $P < 0.001$ for the radial direction). Thus, the esophageal wall appeared to be deformed less in all normal directions in diabetics compared to healthy volunteers.

Stress-strain and tension-strain relations

The tissue stiffness (approximated by the mechanical alpha-constant, see Appendix) in circumferential direction of the different esophageal layers and the duodenum are provided in Figure 6.

Esophagus: The circumferential stiffness increased throughout the esophageal wall ($F = 14$, $P < 0.001$). The difference in tissue stiffness between the patients and the control subjects was non-significant ($F = 0.3$, $P = 0.6$) and unaffected by butylscopolamine ($F = 2.2$, $P = 0.15$).

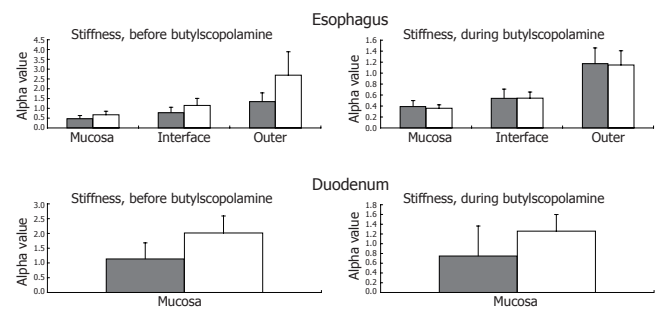

Figure 6 The computed esophageal stiffness (circumferential [alpha] constant) of the mucosa, submucosa-muscle interface and outer surface are illustrated. The solid grey bars represent the controls, while the grey-white bars represent the diabetic patients. The stiffness tends to be higher in the diabetic patients and is normalized during smooth muscle relaxation with butylscopolamine. This indicates an increased esophageal resting tone in diabetes. The computed duodenal stiffness is also illustrated. Mean and SEM values are shown.

At moderate induced pain, the circumferential stress, the circumferential strain and the ratio between them (which also indicates the wall stiffness) obtained in the patients were not significantly different from those obtained in the control subjects ($F = 0.7$, $P = 0.4$; and $F = 1.3$, $P = 0.3$; and $F = 0.7$, $P = 0.4$), and unaffected by butylscopolamine (all $P > 0.4$).

Duodenum: The difference in tissue stiffness (Figure 6) between the patients and the controls was non-significant ($F = 2.2$, $P = 0.14$). The stiffness was not changed by butylscopolamine ($F = 1.1$, $P = 0.3$). At moderate pain the circumferential tension, the circumferential strain and the ratio between them (indicating the wall stiffness) did not differ between patients and control subjects ($F = 1.0$, $P = 0.3$; and $F = 0.02$, $P = 0.9$; and $F = 2.3$, $P = 0.14$), and was unaffected by butylscopolamine (all $P > 0.5$).

Correlation to clinical data

The distension induced contractile activity in the diabetic patients was not affected by the mean glucose level during the study ($P > 0.2$ for all comparisons). The disease duration was clearly associated with the distension-induced contractile activity. Thus, the disease duration correlated with increased frequency of the contractions and with the number of contractions during the first minute proximal to the esophageal bag (correlation coefficient $r_s = 0.71$, $P = 0.009$ and $r_s = 0.69$, $P = 0.01$), and to increased duration of the strongest contraction on the esophageal bag ($r_s = 0.71$, $P = 0.009$). In the duodenum the disease duration correlated with increased frequency (bag: $r_s = 0.58$, $P = 0.04$; proximal: $r_s = 0.68$, $P = 0.01$), increased number of contractions during the first minute (bag: $r_s = 0.57$, $P = 0.04$; proximal: $r_s = 0.68$, $P = 0.04$), increased pressure amplitude (bag: $r_s = 0.59$, $P = 0.04$; proximal: $r_s = 0.70$, $P = 0.01$), duration (bag: $r_s = 0.62$, $P = 0.03$; proximal: $r_s = 0.69$, $P = 0.01$) and contractile work (bag: $r_s = 0.63$, $P = 0.03$; proximal: $r_s = 0.72$, $P = 0.01$) of the strongest contraction both at and proximal to the bag.

DISCUSSION

An ultrasound based testing approach was applied to

assess the contractile activity, geometry and biomechanical properties of the esophagus and duodenum in patients affected by gastrointestinal symptoms and diabetic autonomic neuropathy. Overall, this study illustrates that the patients had increased reactivity to standardized esophageal distension including dyscoordination and reduced contractile work of the contractions. The disease duration was associated with increased contractile reactivity. Finally, the esophageal wall thickness and the pattern of deformation in longitudinal and radial directions were affected in diabetic patients indicating remodeling.

Both acute and chronic hyperglycemia is known to impair the GI motor responses to stimulation^[12,36] and to reduce the perceived sensation^[37]. This study was designed to minimize the influence of the blood glucose level on the contractile activity. However, the patients in the present study typically suffered from severe fluctuating glucose levels and fluctuations in GI symptoms with intermittent nausea and vomiting which makes glycemic control very challenging. Even though the mean blood glucose level during the study was higher in the diabetic patients, the glucose level itself did not seem to affect the contractile activity. Hence, the differences found in this study are more likely due to neuromuscular changes. However, comparison of data obtained in different studies of diabetic patients must be done with caution.

The present study utilizes a *cross-sectional imaging technique*. Conventional methods based on *pressure-volume measurements* obtained during bag distension do not directly measure variables used in analysis of tissue deformation and stiffness^[38]. Since the esophagus is thick-walled, only cross-sectional ultrasound imaging with good temporal and spatial resolution provides data for computation of the circumferential stress, wall thickness and multi-directional deformation^[30].

All patients included in the study had, as per inclusion criteria, severe and long-lasting upper GI symptoms (nausea, vomiting, bloating and pain). The observed esophageal contractile hyperreactivity may be explained by both primary neuropathic changes of the gut nerves and secondary changes due to reflex mechanisms caused by increased sensitivity to the distensions (central sensitization)^[39]. However, esophageal motor abnormalities in terms of decreased contraction amplitude, decreased number of esophageal peristaltic contractions^[13,23,24,40] and impaired coordination^[41,42] have also been recorded in diabetic patients without GI symptoms. Disordered esophageal motility and acid reflux may be related to diabetic neuropathy^[43]. Such changes correspond to the changes observed during distension in the present study. The observed reduction in time until the first contraction on the bag in the diabetic patients suggests that a local neuronal dysfunction is responsible for the hyperreactivity. This is consistent with the finding that the hyperreactivity is associated with the disease duration. A neuronal dysfunction can theoretically be addressed to the mechanoreceptor, afferent fibers, interneurons, or efferent fibers located in the gut wall. Impaired balance of the inhibitory and excitatory pathways from the central nervous system can potentially also affect the motor response. The time until the first contraction 6 cm proximal to the bag was also reduced in the diabetic

patients, which may indicate hyperactivity and dysfunction of local intestinal neural pathways (a long reflex arc which may also include extra-intestinal pathways, Figure 2). Since this long reflex arc is more affected than the short arc (evidenced in Table 2 and by the computed ratio), the neuronal pathways rather than the mechanoreceptors seem to be affected. Even though neuropathic damage to the nerve fibers is expected, central (and peripheral) neuronal hyperexcitability in response to the distensions may counteract the response. Such hyperreactivity and hyperexcitability have for example been shown in patients with non-cardiac chest pain^[44]. In contrast, in structural GI disorders such as systemic sclerosis, the local mechanoreceptors in the gut wall seem to be affected (resetting) more than the neuronal pathways^[45]. However, the present study cannot definitively distinguish between neuronal changes restricted to the enteric nervous system and the effect of changes in the central inhibitory and excitatory neuronal pathways. Advanced methods using evoked brain potentials and functional magnetic resonance imaging may shed more light on this important aspect. Also one should take into consideration that the neuronal changes observed could be due to both diabetes-induced autonomic neuropathy and changes in the afferent visceral nervous system (sensitization and hypersensitivity) evoked by the long-standing GI symptoms^[39]. Finally, the vagal innervation of different organs and central *vs* peripheral levels can easily be affected to different degrees^[46]. As an indicator of dysfunction of the esophageal neuromuscular apparatus, the diabetic patients also seem to have an increased resting tone of the muscle component in the esophagus. This is indicated by the mechanical constants in Figure 6 where smooth muscle relaxation is shown to abolish/normalize the increased stiffness observed in the diabetic patients.

Studies of the small intestinal contractile activity in diabetes have revealed a wide spectrum of motor patterns ranging from normal to grossly abnormal^[5]. The distension-induced duodenal contractile activity recorded in this study was not clearly affected in diabetes compared to the control subjects. However, the duodenal reactivity increased with the disease duration.

The question is if the disordered contractile activities observed in these studies are only due to the neuronal changes and dysfunction (diabetes-induced autonomic neuropathy) or if primary diabetes-induced remodeling in the GI tract may also play a role. Animal studies have shown that diabetes may induce crypt hyperplasia, change in the villous microvasculature and increase in the mucosal and muscle mass^[14,17,19,47]. A histopathological study of the human stomach in diabetic patients with severe gastroparesis showed prominent collagenization and smooth muscle atrophy of the muscle layer^[48]. Studies on diabetes and aging show that advanced glycation end-products are causing cross linking of collagen molecules responsible for basement membrane thickening and loss of matrix elasticity^[15,16,49]. Animal studies support the presence of structural and biomechanical changes with increased stiffness, weight per unit length and wall thickness (i.e. increased stiffness and thickness of the GI wall)^[19-22]. Even though the wall stiffness and circumferential deformation induced by the circumferential distensions

in the present study were not significantly affected in diabetes, the esophageal deformations in longitudinal and radial directions and the wall thickness were abnormal with reduced deformation. The fact that the deformation is reduced but the stiffness appears unchanged can be attributed to the stress-dependent growth law for soft tissues stating that tissue remodeling is determined by the stress and remodels towards a tissue-specific stress level^[35]. The esophageal wall and the mucosa-submucosa layer were thickened in diabetes, which indicates growth processes of the intestinal wall. The observed increase in esophageal wall thickness can theoretically be caused by increased muscle tone, even though an attempt to abolish smooth muscle contractions was done and repeated if contractions were still present. Butylscopolamine diminishes cholinergic mediated tone and from the tracings it appeared that relaxation was obtained. Also the decreased ability of esophageal shortening during distension and the change in radial deformation supports that structural changes occur in diabetic esophagus. The contractile work of the esophageal contractions was decreased in spite of increased neuronal activity, increased muscle thickness and the increased esophageal resting tone. This indicates that the ability of the muscle to contract could be restricted by structural remodeling (accumulation of connective tissue). The fact that the esophageal wall deformed less in diabetic patients supports this hypothesis. Alternatively, myopathic abnormalities with diabetes-induced reduced action of the muscle fibers may also be important^[48].

The present study shows that both the neuronal function of the contractile system and structural apparatus of the GI tract are affected in patients with long-standing diabetes and autonomic neuropathy. This may contribute to the understanding of the pathophysiology of diabetic gut dysfunction and may have impact on future management of these patients.

APPENDIX

Analysis of esophageal distensions

Ultrasound images were captured corresponding to the start of the distension (the zero-pressure state) and between contractions during the distensions (tonic state) by a video converter (jpg format, 787 × 576 pixels, A4 Video Converter v. 2.3, www.a4video.com)^[35]. The mucosal surface (bag-mucosa interface), the submucosa-muscle interface, and the outer surface (muscle-adventitia interface) contours of the esophageal wall were identified by visual inspection by an experienced radiologist using image measurement software (SigmaScan Pro v. 5.0.0, SPSS Inc., Chicago, IL, USA) (Figure 3). This allowed computation of the cross-sections encircled by the mucosal surface (CSA_{muc}), submucosa-muscle interface (CSA_{in}) and outer surface (CSA_{out}), and the corresponding

circumferences (C_{muc}, C_{in} and C_{out}).

For each of the three sur- and interfaces the *circumferential stretch ratio* (a deformation measure) was computed as the relative elongation of each circumference: $\lambda_\theta = c/c_{\text{zero-pressure}}$, where $c_{\text{zero-pressure}}$ denotes the circumference of the unloaded segment. The $c_{\text{zero-pressure}}$ was measured directly from ultrasound images at the start of the butylscopolamine distension. The *circumferential strain* at each circumference (mucosa, submucosa-muscle and outer, respectively) was represented by the Green strain:

$$\varepsilon_\theta = \frac{c^2 - c_{\text{zero-pressure}}^2}{2c_{\text{zero-pressure}}^2} \quad (1)$$

The radial deformation of the mucosal and muscle layers were computed as *radial stretch ratio*: $\lambda_r = h/h_{\text{zero-pressure}}$, where h and $h_{\text{zero-pressure}}$ represents the thickness of the distended and butylscopolamine relaxed layers.

Assuming a circular shape, the wall thicknesses were calculated as:

$$h_{\text{total}} = r_{\text{out}} - r_{\text{muc}} = \sqrt{\text{CSA}_{\text{out}}/\pi} - \sqrt{\text{CSA}_{\text{muc}}/\pi}, \quad (2a)$$

$$h_{\text{muc}} = r_{\text{in}} - r_{\text{muc}} = \sqrt{\text{CSA}_{\text{in}}/\pi} - \sqrt{\text{CSA}_{\text{muc}}/\pi}, \text{ and} \quad (2b)$$

$$h_{\text{muscle}} = r_{\text{out}} - r_{\text{in}} = \sqrt{\text{CSA}_{\text{out}}/\pi} - \sqrt{\text{CSA}_{\text{in}}/\pi}. \quad (2c)$$

The *longitudinal stretch ratio* of each layer which indicate the degree of longitudinal deformation was calculated as $\lambda_z = \frac{1}{\lambda_\theta \lambda_r}$ assuming incompressibility ($\lambda_\theta \lambda_r \lambda_z = 1$) of the tissue^[35].

Since the esophagus is thick-walled the pressure and stress decay through the wall is expected to be non-linear^[50]. Hence, the distribution of the circumferential stress through the wall was computed as:

$$\tau_{\theta,r} = \frac{r_{\text{out}}^2 r_{\text{muc}}^2 \Delta p}{r^2 (r_{\text{out}}^2 - r_{\text{muc}}^2)} + \frac{\Delta p r_{\text{muc}}^2}{r_{\text{out}}^2 - r_{\text{muc}}^2} \quad (3)$$

where r denotes the radial location inside the wall^[30,50]. The radii r_{out} and r_{muc} was calculated as: $r_{\text{out}} = \sqrt{\text{CSA}_{\text{out}}/\pi}$ and $r_{\text{muc}} = \sqrt{\text{CSA}_{\text{muc}}/\pi}$. Δp represents the bag pressure corrected for the baseline pressure (representing the mediastinal resting pressure) before the butylscopolamine distensions.

To obtain mechanical constants of each layer the circumferential stress-strain relationship of the mucosal surface, the interface between submucosa and muscle layer, and the outer surface layers for each subject were plotted. α and β constants were obtained using non-linear curve fitting (Microcal Origin 6.0, Microcal Software Inc., Northampton, MA, USA) approximating the equation^[51]:

$$\tau_\theta = \beta(e^{\alpha \varepsilon_\theta} - 1) \quad (4)$$

The computed stiffness parameter is dependent on passive stretch and the contribution from active muscle contraction or tone. Administration of butylscopolamine abolishes smooth muscle contractions whereby the passive properties can be assessed.

Analysis of duodenal distensions

The duodenal ultrasound images were captured as

described at the start of each distension and between the distension-induced contractions (see above). This allowed computation of the luminal duodenal *CSA* and mucosal circumference *c*. The *circumferential stretch ratio* was computed as the relative elongation of the mucosal surface (circumference *c*) during distension:

$$\lambda_\theta = c / c_{\text{zero-pressure}} \quad (5)$$

Since the ultrasound imaging not always allowed measurements at the start of the distension (artifacts due to air), $c_{\text{zero-pressure}}$ was in some cases approximated by a double logarithmic fitting of the circumference-pressure data. The validity of the fitting procedure was verified from the experiments with good imaging quality. A good agreement between fitted and measured values was found^[51]. The *circumferential strain* was computed as the Green strain, see Eq. 1.

As an approximation the wall thickness was not taken into account^[35] and consequently the *circumferential tension* was computed using Laplace's law:

$$T_\theta = \Delta p r \quad (7)$$

where *r* denotes the inner duodenal radius assuming circular shape: $r = \sqrt{CSA/\pi}$. The wall tension is the integration of the stresses through the wall (the stress moment).

The circumferential tension-strain relationships for each subject were plotted to obtain the curve fitting constants. The α and β constants were obtained using non-linear curve fitting (Microcal Origin 6.0, Microcal Software Inc., Northampton, MA, USA) using a modification of Fung's approach^[51]:

$$T_\theta = \beta(e^{\alpha\lambda_\theta} - 1) \quad (8)$$

Limitation of the ultrasound technique

The ultrasound technique suffers from limitations too. At low degrees of distension convolutions of the plastic bag resulted in artifacts (air and plastic folds) and in many cases only the bag-mucosa, submucosa-muscle and muscle-adventitia interfaces could be clearly identified. At low degrees of distension it was difficult to clearly identify the inner circumference of the duodenum. This was due to small amounts of air outside the bag and folds in the bag resulting in artifacts and the fact that the bag might not always be in contact with the wall in the entire circumference at low degrees of distension. To compensate for this problem, the mucosal circumference at low degrees of distension was approximated using double-logarithmic curve fitting. Other limitations were that the ultrasound system used in this study did not provide sufficient image quality for accurate measurement of the wall thickness in the entire duodenal circumference, especially at high degrees of distension.

Abstract

AIM: To evaluate the efficacy of ferucarbotran-enhanced MR imaging in the detection of focal hepatic lesions compared to plain and Gd-DTPA-enhanced MR imaging.

METHODS: Fifty-nine patients with suspected focal hepatic lesions were admitted to the study. Plain MR imaging (FSE T₂WI with fat suppression and GRE T₁WI sequences) and Gd-DTPA dynamic enhanced MR of the liver were initially performed followed by ferucarbotran-enhanced MR imaging 48 h later (including GRE T₁WI, FSE T₂WI with fat suppression, and GRE T₂*WI sequences). Images were reviewed independently by three observers. Results were correlated with surgery and pathologic examination or reference examination, and sensitivity was statistically calculated for the different MR imaging sequences.

RESULTS: Among all confirmed lesions ($n = 133$), ferucarbotran-enhanced MR imaging revealed 130 lesions on FSE T₂WI with fat suppression, 115 lesions on dynamic T₁WI GRE, and 127 lesions on GRE T₂*WI. Pre-contrast MR imaging revealed only 84 lesions on GRE T₁WI and 106 lesions on FSE T₂WI with fat suppression, while Gd-DTPA dynamic enhanced GRE T₁WI revealed 123 lesions. For 44 micro-lesions (< 1.0 cm) in all patients the detection rates were as follows: ferucarbotran-enhanced FSE T₂WI with fat suppression, 93.2% (41/44); ferucarbotran-enhanced GRE T₂*WI, 88.6% (39/44); Gd-DTPA dynamic-enhanced GRE T₁WI, 79.5% (35/44); pre-contrast FSE T₂WI with fat suppression, 54.5% (24/44); and pre-contrast GRE T₁WI, 34.1% (15/44). In detecting micro-lesions, statistically significant difference was found for Ferucarbotran-enhanced FSE T₂WI with fat suppression and GRE T₂*WI sequences compared to the other sequences ($P < 0.05$).

CONCLUSION: Ferucarbotran-enhanced FSE T₂WI with fat suppression and GRE T₂*WI sequences are superior in detecting micro-lesions (< 1 cm) in comparison with plain and Gd-DTPA dynamic-enhanced MR imaging.

INTRODUCTION

The detection of focal liver lesions in patients with liver cancer is a very important challenge because failure to detect cancerous lesions can have major clinical consequences. High accuracy in liver cancer detection can improve the efficacy of treatment, including partial hepatectomy, liver transplantation, radiofrequency ablation, percutaneous ethanol injection, transarterial chemoembolization, or (commonly) a combination of these methods^[1-5]. Currently, magnetic resonance (MR) is increasingly used in the detection of hepatic lesions^[6]. With the use of conventional extracellular contrast agents such as gadolinium chelates, analysis of enhancement patterns on T₁-weighted dynamic imaging during the different vascular phases is an important tool in the detection and characterization of focal hepatic lesions. Post-contrast imaging has been shown to be superior to conventional plain MR imaging in detecting hepatic lesions^[7]. It is known, however, that 40%-60% of cancer nodules, especially those in cirrhotic liver that are smaller than 10 mm, are missed at ultrasonography (US), computed tomography (CT)^[8], and MR^[9]. Given this background, a possible solution to this problem is the use of liver-specific MR contrast materials: that is, agents that are targeted to either the hepatocytes or the Kupffer cells. Ferucarbotran is available as a new superparamagnetic iron oxide (SPIO) agent for liver imaging in most European countries and some Asian countries^[10,11]. The present study was designed

as an open-label, within-patient comparison of the diagnostic performance of non-enhanced, gadolinium-enhanced, and ferucarbotran-enhanced MR imaging, in terms of lesion detection and characterization according to the Phase III clinical trial of ferucarbotran in China. This article is mainly concerned with evaluating efficacy in the detection of hepatic lesions.

MATERIALS AND METHODS

Patients

The study protocol was approved by the Zhongshan Hospital Ethics Committee. A total of 59 patients (40 men, 19 women; mean age, 48.9 year; age range, 26-68 year) with at least one suspected focal hepatic lesion were enrolled in the study and received test contrast material between December 2003 and July 2004. Each patient gave written or witnessed informed consent and was evaluated for eligibility. Each patient underwent a reference-standard examination. The best method to confirm imaging findings—that is, pathologic confirmation—was unavailable for every patient in this study.

Contrast material

Ferucarbotran (Resovist, Schering, Berlin, Germany) was preloaded into a 2.25 mL connecting intravenous tube (Connection Tubing; Clinico, Bad Hersfeld, Germany) and manually injected as a bolus through a filter with 5- μ m pore size; the connecting catheter was flushed with 10 mL of saline solution within 3 s of injection (injection rate, approximately 2-3 mL/s). Patients with a body weight of 60 kg or more received 1.4 mL of ferucarbotran, while those with a body weight of less than 60 kg received 0.9 mL (range, 7.0-12.9 μ mol iron/kg); 1 mL ferucarbotran contains 28 mg of iron. Gd-DTPA (Magnevist, Schering, Erlangen, Germany) was manually administered as an intravenous bolus injection at a dose of 0.2 mL/kg (corresponding to 0.1 mmol/kg) with a flow rate of 2-3 mL/s.

MR imaging protocol

MR imaging was performed with a superconducting magnet operating at 1.5T (Signa, GE Medical Systems, Milwaukee, USA). The imaging protocol consisted of pre- and post-contrast imaging at 25, 60, 180, and 480 s after the administration of each contrast material, with an interval of 48 h between the injection of each. Every examination consisted of T2-weighted fast spin-echo (FSE) with fat suppression, T1-weighted fast multiplanar spoiled gradient-recalled (SPGR), and T2* GRE sequences (Table 1). The imaging factors were the same for all patients, and all sequences were performed before and after Gd-DTPA contrast agent and ferucarbotran administration.

Imaging assessment

According to the surgical and pathologic confirmation or reference examination, all images from the MR imaging sequences were interpreted independently by three radiologists; the number of lesions was then calculated, excluding cysts. Consensus reading was necessary to ensure

that both observers assessed the same lesion. Lesions were divided into three groups according to lesion size (< 1 cm, 1-3 cm, > 3 cm).

Statistical analysis

The detection rates for the different sequences (FSE T2WI with fat suppression, GRE T1WI, and GRE T2*WI) were compared using Pearson's chi-square test and the Fisher exact probability test. $P < 0.05$ was considered to indicate statistical significance.

RESULTS

According to pathologic confirmation and the reference examinations, a total of 133 lesions were present among the subjects (85 lesions were confirmed by pathology; 75 hepatocellular carcinoma lesions, 35 metastatic lesions, 7 dysplastic nodules, 6 hemangiomas, 5 cases of focal nodular hyperplasia, 2 tuberculomas, 1 inflammatory pseudotumor, 2 angioleiomyolipomas). Twenty-one lesions were larger than 3.0 cm, 68 were 1-3 cm, and 44 were smaller than 1 cm. On ferucarbotran-enhanced MR imaging, FSE T2WI with fat suppression revealed 130 lesions, dynamic T1WI GRE revealed 115 lesions, and GRE T2*WI revealed 127 lesions (Figure 1 A-H). On pre-contrast MR imaging, GRE T1WI revealed only 84 lesions and FSE T2WI with fat suppression revealed 106 lesions. Gd-DTPA dynamic-enhanced GRE T1WI revealed 123 lesions (Table 2). Three lesions were not found by any observer on any sequence: All were smaller than 0.8 mm in diameter and were metastases from mammary adenocarcinoma and colorectal cancer. In another patient, a 0.3 mm-diameter subcapsular metastasis was detected only by ferucarbotran-enhanced FSE (Figure 2A-F).

Table 2 shows the detectability among 44 micro-lesions (< 1.0 cm) for all patients as follows: ferucarbotran-enhanced FSE T2WI with fat suppression, 93.2% (41/44); ferucarbotran-enhanced GRE T2*WI, 88.6% (39/44); Gd-DTPA dynamic-enhanced GRE T1WI, 79.5% (35/44); pre-contrast FSE T2WI with fat suppression, 54.5% (24/44); and pre-contrast GRE T1WI, 34.1% (15/44). The detectability of ferucarbotran-enhanced FSE T2WI with fat suppression and ferucarbotran-enhanced GRE T2*WI sequences was significantly greater than that of the other sequences ($P < 0.01$).

DISCUSSION

Ferucarbotran contains superparamagnetic iron oxide nanoparticles (maghemite [γ -Fe₂O₃] and magnetite [γ -Fe₃O₄]) coated with a carboxydextran shell, and was developed as a new intravenous liver-specific contrast agent. Its T1 relaxivity is 25.4 mmol/L per second, with T2 relaxivity of 151.0 mmol/L. second. The blood half-life is similar to that of ferumoxides (another SPIO agent), but the mean particle size is smaller (60 nm)^[10,11]. Ferucarbotran is taken up by reticuloendothelial system (RES) cells in the liver, spleen, bone marrow, and lymph nodes. Hydrolytic enzymes degrade intracellular SPIO particles causing a loss of R2 relaxivity as the iron loses its

Table 1 MR sequences and parameters

Sequence	TR	TE	NEX	Matrix	FOV (cm)	Thickness	Intersection gap (mm)	Flip angle (mm)
T2-FSE/TSE with fat suppression	3333-4000	98	2	256 × 160	36 × 36	8	2	-
GRE T1WI	150	2	1	256 × 128	36 × 36	8	2	90°
GRE T2*WI	150	11.5	1	256 × 160	36 × 36	8	2	10°

Table 2 Comparative analysis of lesion detection for 133 lesions in 59 patients using pre-contrast, ferucarbotran-enhanced, and Gd-DTPA-enhanced sequences

Sequence	n (%)		
	< 1 cm (n = 44)	1-3 cm (n = 68)	> 3 cm (n = 21)
1 Pre-contrast T1WI GRE	15 (34.1) ^b	48 (70.6) ^b	21 (100.0)
2 Pre-contrast FSE T2WI with fat suppression	24 (54.5) ^b	61 (89.7)	21 (100.0)
3 Dynamic Gd-DTPA-enhanced T1WI GRE	35 (79.5) ^a	67 (98.5)	21 (100.0)

crystalline structure^[12]. Within minutes of administration, 80% of the injected dose of SPIO agent efficiently accumulates in the liver, while approximately 5%-10% of the injected dose accumulates in the spleen^[13-15]. On T2-weighted sequences there is a marked decrease in the signal intensity of normal liver and spleen; because malignant tumor tissue typically lacks a substantial number of Kupffer cells or has a lower activity of phagocytic cells, it appears as hyperintense/bright lesions that are contrasted against the hypointense/black liver^[11,16].

In the detection of micro-lesions (< 1.0 cm) in the present study, delayed T2-weighted ferucarbotran-enhanced FSE with fat suppression and T2*-weighted ferucarbotran-enhanced GRE provided higher sensitivity in MR imaging than pre-contrast (T1-weighted GRE) images (93.2% and 88.6%, respectively, *vs* 34.1%). More lesions were detected on T2-weighted ferucarbotran-enhanced FSE than on dynamic Gd-DTPA-enhanced images in 16%-20% of our patients. It had statistically significant difference in detecting micro-lesions ($P = 0.021$), which is in agreement with previous studies^[11,16-18]. In the present study, even a 0.3 mm-diameter metastasis was detected by T2-weighted ferucarbotran-enhanced FSE with fat suppression. The loss of liver parenchyma signal intensity after ferucarbotran administration improves lesion-to-liver contrast, which in turn improves detection (especially in micro-lesions), visualization, delineation, and overall diagnostic confidence^[19] (Figure 3A-D). Although diagnostic confidence is a subjective parameter, it is relevant in the clinical situation because a radiologist must determine the confidence with which findings observed on images are correct. Evaluation of diagnostic certainty was also recommended by Thornbury in his six-tier model

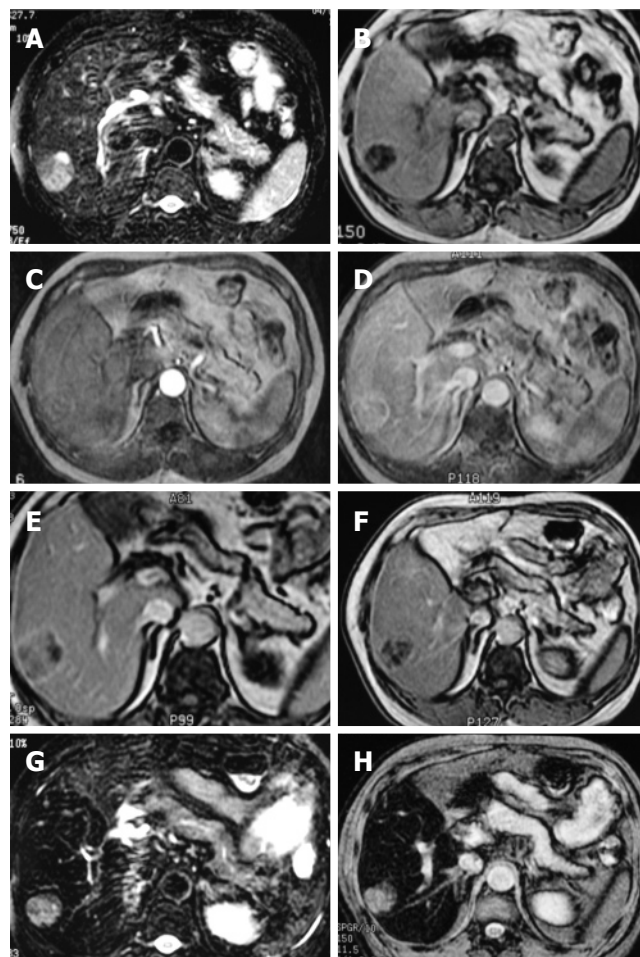

Figure 1 Images of HCC. **A:** The lesion appears hyperintense on the pre-contrast T2WI FSE image; **B:** The lesion appears hypointense on the pre-contrast T1WI GRE image; **C:** The lesion enhances inhomogeneously during the hepatic arterial phase; **D:** Ring-enhancement is observed during the portal venous phase; **E, F:** Dynamic T1WI GRE images obtained after administration of ferucarbotran show ring-enhancement of an asymmetric moderately hyperintense lesion; **G, H:** A markedly hyperintense lesion with surrounding hypointense liver parenchyma is shown during the accumulation phase on ferucarbotran-enhanced T2WI and T2*WI images.

of efficacy^[20]. Diagnostic confidence conceptualizes the diagnostic thinking efficacy (one tier of the Thornbury model) and links the technical and diagnostic efficacy of a contrast agent to the therapy of the patient. Higher accuracy in liver cancer detection potentially changes the clinical treatment of patients with liver cancer. The report of Ros *et al* states that the proportionate change in clinical treatment was as high as 59% after examination using SPIO-enhanced MR^[21]. For detection of lesions larger than 1 cm, there was no significant difference among the findings of the different sequences (excluding pre-

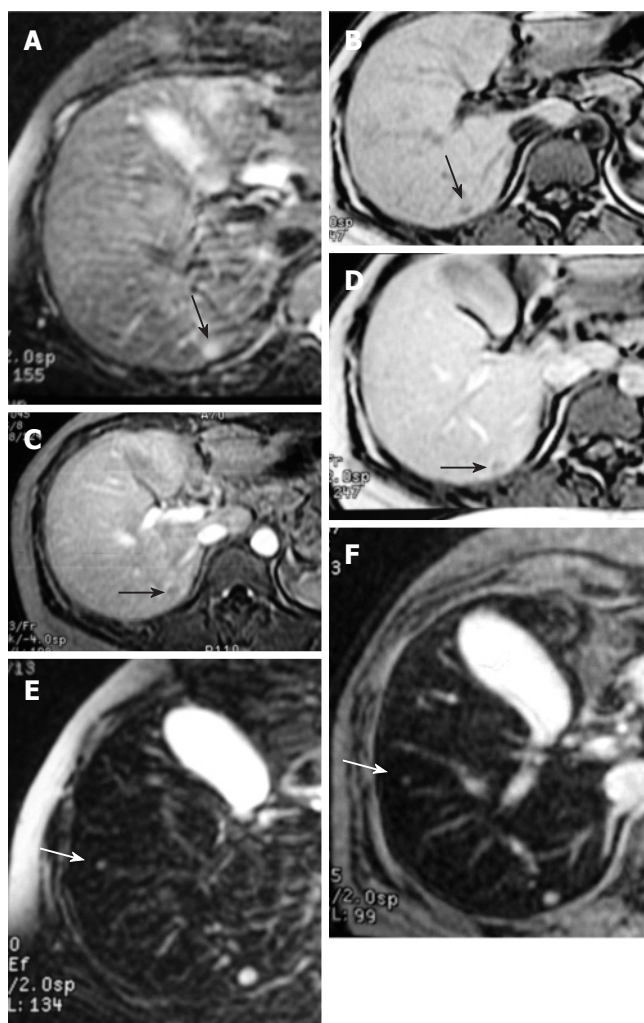

Figure 2 Liver metastasis from mammary adenocarcinoma. **A, B:** Only one lesion (black arrow) was found on the pre-contrast T2WI and T1WI GRE images; **C, D:** Only one lesion (black arrow) was found on dynamic T1WI GRE images obtained after administration of Gd-DTPA; **E, F:** An additional small metastasis (0.3 mm, white arrow) was detected on T2WI and T2*WI images during the accumulation phase.

contrast sequences); however, diagnostic confidence was determined for the same reason as that described above.

Ferucarbotran is an SPIO agent that can be injected as a bolus^[10]. It contains particles with smaller mean hydrodynamic diameter than that of the stock solution, which has a stronger T1-effect and longer blood half-life because of slower uptake into the RES. Previous studies using animals found that iron particles begin attaching to the Kupffer cells 3 min after administration^[22]. The R1 relaxivity of ferucarbotran varies considerably within the range of diagnostically applied proton Larmor frequency (i.e., field strength); however, R1 relaxivity at 40 MHz with 12.3 mmol/L per second is still four times higher than the R1 relaxivity of low molecular gadolinium chelates. The very high R2/R1 ratio is characteristic of superparamagnetic colloids of the SPIO type. This ratio varies from 6 to 15 as the Larmor frequency increases from 10 to 40 MHz, a fact which might be in favor of the use of lower imaging fields to better utilize the T1 effect of these materials^[12]. In fact, this subfraction contributes

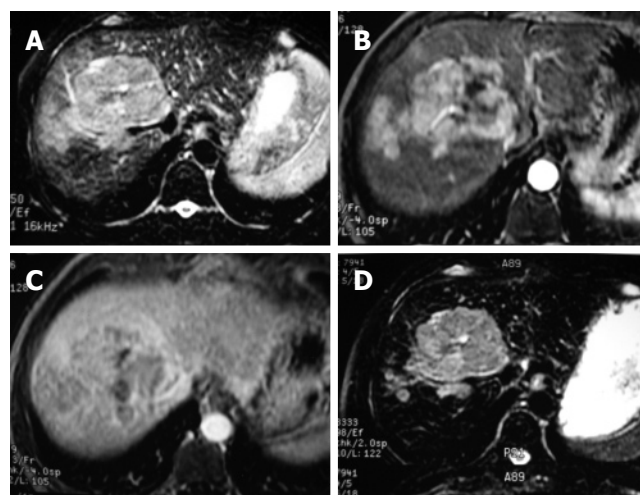

Figure 3 HCC image. **A:** The lesion appears hyperintense on the pre-contrast T2WI FSE image, but is not clearly delineated; **B:** The lesion is markedly enhanced during the hepatic arterial phase; **C:** The lesion appears hypointense during the portal venous phase, but is not clearly delineated; **D:** The main lesion and satellite nodules are clearly delineated from the surrounding hypointense liver parenchyma on the ferucarbotran-enhanced T2WI image during the accumulation phase.

to the signal change on T1-weighted images and is the reason why the signal characteristics are comparable to those of angiographic agents with a blood-pool effect. This subfraction also explains the biexponential blood half-life of ferucarbotran, which has also been tested for its capability in contrast-enhanced MRA^[23]. Enhancement increased with the degree of T1-weighting and shifted towards higher concentrations with shorter echo times. The T1 effect of ferucarbotran is a function of dose and concentration in plasma, and can be monitored during a time window in which the plasma concentration stays below a certain level depending on pulse sequence parameters. Nevertheless, in the present study, dynamic ferucarbotran-enhanced T1-weighted GRE/FLASH showed no superiority over dynamic Gd-DTPA-enhanced T1-weighted GRE/FLASH in the detection of lesions. The benefit of dynamic T1-weighted MR imaging techniques is in the characterization of lesions; however, in many respects dynamic imaging with ferucarbotran is different from that with Gd-DTPA. In dynamic T1-weighted images obtained with ferucarbotran, the signal increase is observed to be lower but longer lasting, as described by Amelie *et al*^[24].

Ferucarbotran has an advantage over ferumoxides (Feridex, Advanced Magnetix; Guerbet), which is the only marketed SPIO in most countries. Although it is well known that ferumoxides have relatively high R1 values (up to four or five times higher than those of gadolinium-based contrast agents)^[10,25,26], these T1 effects cannot be readily exploited for dynamic T1-weighted MR imaging. Bolus administration of ferumoxides has not been recommended because of the possible side effects (lumbar pain and cardiovascular problems, including dose-dependent hypotensive reactions) that positively correlate to the rate of injection; therefore, this compound must be administered as a slow drip infusion^[13]. Ferucarbotran used in this study has few side effects^[10,11] and can be given as a

rapid bolus injection. No adverse reactions were observed in any of the patients in the present study; however, as for any SPIO contrast agent, the efficacy of ferucarbotran depends on the number of Kupffer cells or their activity. For example, some well-differentiated hepatocellular carcinoma lesions still contain a certain amount of Kupffer cells and which could confuse us to make the correct diagnosis^[27,28].

In conclusion, ferucarbotran is a safe contrast material for MR imaging of local liver lesions. The use of ferucarbotran-enhanced images improves diagnostic confidence and lesion detection, especially in the detection of micro lesions (< 1 cm). Ferucarbotran can be rapidly injected without clinically important adverse events, enabling dynamic MR imaging to be performed. As a dual-function and complementary MR imaging agent, ferucarbotran-enhanced images in combination with dynamic Gd-DTPA-enhanced images are helpful in improving the accuracy of differential diagnoses for focal hepatic lesions.

COMMENTS

Background

In patients with liver cancer, the detection of focal liver lesions is one of the most important challenges. High accuracy in liver cancer detection can improve the efficacy of treatment. It is known, however, that 40%-60% of cancer nodules, especially those that are smaller than 10 mm in cirrhotic liver, are missed on ultrasonography (US), computed tomography (CT) and magnetic resonance (MR).

Research frontiers

Ferucarbotran, a liver-specific MR contrast material targeted to the Kupffer cells, is available as a new superparamagnetic iron oxide (SPIO) agent for liver imaging. A current research hotspot involves the evaluation of two contrast media for their efficacy in detecting hepatic lesions.

Innovations and breakthroughs

Ferucarbotran is a safe contrast material for MR imaging of focal liver lesions. The use of ferucarbotran-enhanced images improves diagnostic confidence and lesion detection, especially in the detection of micro lesions.

Applications

Ferucarbotran-enhanced images combined with dynamic Gd-DTPA-enhanced images aid in improving the accuracy of differential diagnosis for focal hepatic lesions.

Terminology

SPIO agent is a liver-specific contrast agent that contains superparamagnetic iron oxide nanoparticles coated with a carboxydextran shell. Ferucarbotran is taken up by reticuloendothelial system (RES) cells in the liver, spleen, bone marrow, and lymph nodes.

Peer review

The effectiveness of ferucarbotran-enhanced MR imaging in the detection of hepatic lesions is known. The present study compares the diagnostic efficiency of three MR imaging sequences in patients with focal hepatic lesions. The scientific value of this manuscript is demonstrated.

Abstract

AIM: To systematically evaluate the efficacy and safety of endoscopic resection of gastrointestinal smooth muscle tumors (SMTs, including leiomyoma and leiomyosarcoma) and to review our preliminary experiences on endoscopic diagnosis of gastrointestinal SMTs.

METHODS: A total of 69 patients with gastrointestinal SMT underwent routine endoscopy in our department. Endoscopic ultrasonography (EUS) was also performed in 9 cases of gastrointestinal SMT. The sessile submucosal gastrointestinal SMTs with the base smaller than 2 cm in diameter were resected by "pushing" technique or "grasping and pushing" technique while the pedunculated SMTs were resected by polypectomy. For those SMTs originating from muscularis propria or with the base size ≥ 2 cm, ordinary biopsy technique was performed in tumors with ulcers while the "Digging" technique was performed in those without ulcers.

RESULTS: 54 cases of leiomyoma and 15 cases of leiomyosarcoma were identified. In them, 19 cases of submucosal leiomyoma were resected by "pushing" technique and 10 cases were removed by "grasping and pushing" technique. Three cases pedunculated submucosal leiomyoma were resected by polypectomy. No severe complications developed during or after the procedure. No recurrence was observed. The diagnostic accuracy of ordinary and the "Digging" biopsy technique was 90.0% and 94.1%, respectively.

CONCLUSION: Endoscopic resection is a safe and effective treatment for leiomyomas with the base size \leq

INTRODUCTION

Gastrointestinal smooth muscle tumors (SMTs, including leiomyoma and leiomyosarcoma) represent relatively common lesions that are thought to originate from a muscular layer of gastrointestinal tract. They can be found in the esophagus, stomach, small intestine, and colon^[1-3]. The most common symptoms of gastrointestinal SMTs are gastrointestinal bleeding, as a result of overlaying mucosa ulceration, and pain. Other symptoms may include anorexia, dysphagia, obstruction, perforation, or fever^[4-6].

Gastrointestinal SMTs are difficult-to-cure gastrointestinal tumors when compared with polyps and the complete surgical resection is still considered to be the most definitive therapy for gastrointestinal SMTs. In recent years, several reports^[7-10] suggest that endoscopic treatment of GI submucosal leiomyoma is a valid alternative to invasion surgery. However, these reports cannot provide enough convincing evidence for the efficiency and safety of the treatment they used because lack of enough cases (majority of these reports include only one single case). Meanwhile, the endoscopic resection is inappropriate for leiomyosarcoma and those leiomyomas with either the base ≥ 2 cm in diameter or originating from muscularis propria because of the risk of hemorrhage and perforation^[7-10]. Therefore, a safe and efficient therapeutic strategy for endoscopic resection of leiomyoma is worth being explored.

From 1986-2006, more than 100 cases of gastrointestinal submucosal tumors (including leiomyoma) were found and successfully resected under endoscopy in our unit. Enlightened by these cases, we prospectively explored the feasibility, efficacy, and safety for endoscopic removal of

leiomyoma. During the last fifteen years, 69 cases of SMTs have undergone the endoscopic examinations and finally proven pathologically at our hospital. Within these, 32 cases of submucosal leiomyoma were successfully removed under endoscopy. The present study evaluated the efficacy and safety of our technique for endoscopic resection of submucosal leiomyoma. Meanwhile, our preliminary experience on diagnosis of SMT based on endoscopy and endoscopic ultrasonography (EUS) was also reviewed in this study.

MATERIALS AND METHODS

Patients

From January 1992 to January 2006, 69 cases of SMT were found under endoscopy and identified by further pathological examination at First Affiliated Hospital of Nanchang University (Nanchang, China). Of these, 39 were male and 30 were female. The age range was 15-74 (average 45.6) years. All the patients complained of at least one of the GI symptoms such as gastrointestinal bleeding, abdominal pain, anorexia, and dysphagia, which could be attributed to the SMT. Written informed consent was obtained from every patient. The locations and types of these SMTs are presented in Table 1. Under immunohistochemical staining, all these SMTs were positive for smooth muscle actin (SMA) but negative for CD117 (C-kit).

All the patients underwent routine gastrointestinal endoscopy (Olympus GF/CF 230 or 240I; PENTAX-2901) to assess the location, appearance, extent, and overlaying mucosa integrity of the SMTs. After February 2005, endoscopic ultrasonography (EUS, Olympus GF-UM20) was utilized to detect the size and shape, echodensity, and the originating layer of tumor in the wall structure. Interpretation was based on the five-layer structure of the wall. For those SMTs with overlaying mucosa ulcerations, the biopsy specimens were obtained from the bottom of the ulcer. The "digging" biopsy technique was employed for those protrusive lesions without overlaying mucosa ulceration but with the base ≥ 2 cm in diameter or originating from muscularis propria.

The criterion for choice of therapy was: (1) the pedunculated submucosal SMTs with the base smaller than 2 cm in diameter were resected by polypectomy; (2) the sessile submucosal SMTs with the base smaller than 2 cm in diameter were removed using a "pushing" technique or "grasping and pushing" technique; (3) those SMTs pathologically identified malignant, originated from muscularis propria, or with the base size ≥ 2 cm were surgically resected. Histopathologic features of both endoscopically and surgically removed SMTs were reviewed by two experienced histopathologists. In addition, all specimens underwent immunostaining of SMA and CD117 (C-kit). Histological examination was also used to determine whether the tumor was removed completely.

After endoscopic removal of SMT, patients were required to remain in the hospital for at least 2 d. Bed rest was necessary for the patients with colonic SMT. Patients with upper gastrointestinal SMTs fasted for 2 d. Endoscopy was performed one week after resection to

Table 1 The sites of the GI SMT identified by endoscopy and histological examination

assess healing and examine hemorrhagic signs such as exposed vessels. Follow-up endoscopic examination was performed every six months for the first year and annually thereafter. Each case was followed up by endoscopic examination for 1-2 years.

Polypectomy

The technique for the resection of pedunculated SMTs was the same as initiated for epithelial polyps. In brief, the snare was placed around the stalk of the SMT, tightened and lifted toward the cavity of the GI tract. The snare was tightened gradually and the SMT was resected by coagulation current.

"Pushing" technique

For a sessile SMT, the snare was placed around the lesion (Figure 1). The head (gastroscopy) or anal (colonoscopy) side of the lesion was pushed by the insulated cannula of snare to form a semipedunculation. The snare was tightened gradually at the top of the semipedunculation and total SMT was captured and then resected completely by a high-frequency electrosurgical current.

"Grasping and pushing" technique

This technique was performed with a double channel endoscopy. In brief, a polypectomy snare inserted through the accessory channel was first placed around the submucosal tumor. The body of the tumor was lifted by a grasping forceps inserted from the other channel to form a semipedunculation. The submucosal tumor was then captured by tightening the snare gradually at the top of the semipedunculation. Finally, the tumor was resected by a high-frequency electrosurgical current.

"Digging" biopsy technique

Initially, a biopsy forceps was used to open a hole in the overlaying mucosa leaving the SMT exposed. At least 4 biopsy specimens were then obtained from the exposed SMT.

RESULTS

During the last 15 years, 54 cases of leiomyoma were

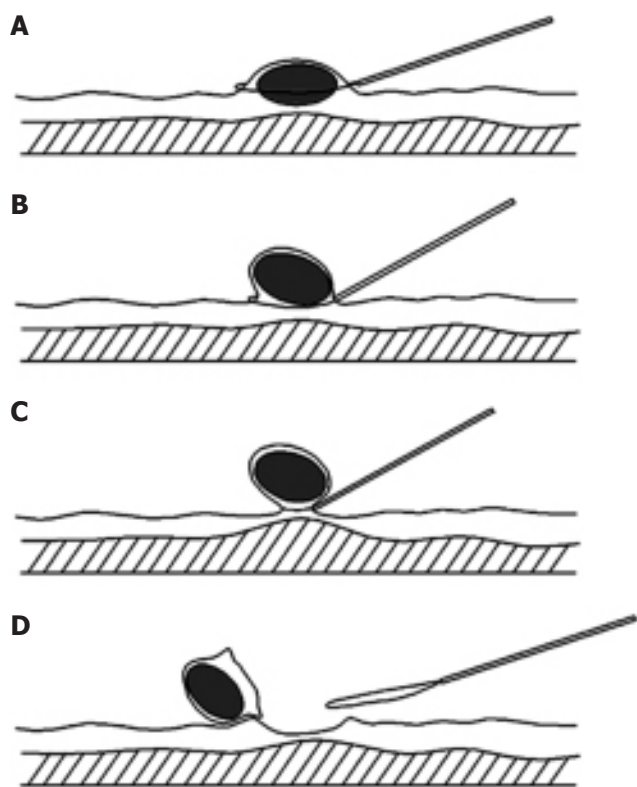

Figure 1 Schematic diagram for “pushing” technique. **A:** The snare was placed around the leiomyoma; **B:** The head (gastroscope) or anal (colonoscopy) side of leiomyoma was pushed by the insulated cannula of snare to form a semipedunculation; **C:** The snare was tightened gradually and total leiomyoma was captured; **D:** The leiomyoma was resected completely.

identified at our hospital. Under endoscopy, most leiomyomas appeared as a red and smooth sessile protrusions with normal overlying mucosa. Only 3 cases of leiomyoma were shown as pedunculated lesions. The esophagus was the most frequent site (51.8%) for leiomyoma (Table 1), followed by stomach (35.2%), colon (7.4%), and duodena (5.6%). No correlation was found between the occurrence and either age or gender in this study. The average base size of leiomyomas measured under endoscopy was 1.2 ± 0.2 cm (standard deviation, SD). The smallest one was 0.8 cm in diameter while the largest was 3.4 cm in diameter. From February 2005 to January 2006, EUS was performed in 6 cases of leiomyoma. All these leiomyoma were shown as an echolucent mass with sharp margin and originating from muscularis mucosa (3 cases) or muscularis propria (3 cases) of gastrointestinal tract. Average size of these 6 cases of leiomyomas measured under EUS was 1.1 ± 0.3 cm (SD).

Among the above-mentioned 54 cases of leiomyoma, 19 cases of submucosal leiomyoma were resected by “pushing” technique (Figure 2) while 10 cases were removed by “grasping and pushing” technique (Table 2). Only 3 cases pedunculated submucosal leiomyoma were resected by polypectomy (Table 2). All these resected leiomyomas were confirmed by the following histopathologic examination. Immediate endoscopic observation after all these resections showed a 1.2–1.5 cm cauterization burn without other abnormalities. No complications such as perforation and hemorrhage

Table 2 The amount and location of the GI leiomyomas resected by “pushing” technique, “grasping and pushing” technique, and polypectomy, respectively

Total		19	10	3

developed during or after the procedure in most of these patients. Oozy bleeding occurred in 4 patients and easily controlled after epinephrine or thrombin spraying. After a follow-up period of one to two years with repeated endoscopy, no recurrence was found.

Among the remaining 22 cases of leiomyoma with the base size ≥ 2 cm or originating in muscularis propria, 9 cases were observed with occurrence of overlying mucosa ulceration. Of these, 8 cases (88.9%) were confirmed pathologically by obtaining biopsy specimens from the bottom of the ulcer while one case failed to report by this method. For those leiomyomas without ulcer, 12 cases (92.3%) were confirmed by “digging” biopsy while only one case (7.7%) failed to report by this method. All 22 cases of leiomyoma were successfully removed by surgery.

In this study, 15 cases of leiomyosarcoma were surgically resected and confirmed by following histopathologic examination. No correlation was found between the occurrence and either age or gender in this study. Of these, endoscopy revealed the lesion as an intraluminal protuberant tumour with ulcer (Figure 3A) in 7 cases and without ulcer in 4 cases. Another 4 cases appeared as an ulcer alone. The occurrence frequency of ulcer in leiomyosarcoma is 73.3% (11/15), which is obviously higher than that in leiomyoma (16.7%, 9/54). Leiomyosarcoma were observed in stomach (80.0%) and duodena (20.0%). The average base size of leiomyosarcoma measured under endoscopy was 6.8 ± 2.3 cm (SD). A significant difference was found between the base size of leiomyoma and leiomyosarcoma ($P < 0.001$, non-paired *t* test). From February 2005 to January 2006, three cases of leiomyosarcoma underwent EUS examination. All three tumours were found to arise from the fourth echo poor layer (muscularis propria); EUS showed that one gastric tumour disrupted all the wall layers. The tumour echostructure and margins were inhomogeneous and irregular in all three cases (Figure 3B).

In those 11 cases of leiomyosarcoma with occurrence of ulcer, 10 cases (90.9%) were confirmed pathologically by obtained biopsy at the bottom of the ulcer. One case failed to report by this technique and finally confirmed

after surgical resection. The remaining 4 cases of leiomyosarcoma without ulcer were confirmed by "digging" biopsy.

DISCUSSION

To resect submucosal SMT by endoscopy, it is crucial to determine the originating layer of the lesion. If the tumor arises from muscularis propria, complete resection should be avoided because of the risk of perforation^[7-12]. Recently, EUS was considered to be very helpful in determining the size, consistency, extension of submucosal tumors, and the layer from which tumors originate^[12-15].

Therefore, the assistance of EUS greatly increases the safety of endoscopic resection of submucosal SMTs^[9,12,13]. In our unit, EUS were employed in evaluating 6 cases of leiomyoma. Of these, three cases were found originating from muscularis mucosa, and then were resected completely under endoscopy. Another 3 cases, originating from muscularis propria, were successfully performed via surgical resection. However, the EUS were equipped in our department only after January 2005. Before 2005, we determined the location of submucosal tumor through detecting the mobility of tumor by closed biopsy forceps. In brief, if the forceps pushed the tumor to slide under mucosa, it suggested that the tumor originated superficially

in muscularis mucosa and was resectable by means of endoscopy. Whereas, an immobile tumor revealed that the tumor had its roots in muscularis propria and could not be removed by endoscopic resection. Although we admit that this criterion is somewhat imprecise, all submucosal leiomyomas (26 cases) determined by this method were successfully performed endoscopic resections, no perforations or severe bleeding occurred after resection. In addition, in those 6 cases examined by EUS, the conclusions drawn by this method fit well with those by EUS. All these were enough to prove the reliability of our method.

The “Pushing” technique has been employed by our group for resection for various gastrointestinal submucosal tumors including leiomyoma, fibroma, lipoma, carcinoid. All these submucosal tumors were successfully resected, with the exception of one case of fibroma, which underwent severe bleeding after resection. In the present study, 19 cases of leiomyoma were successfully and safely removed by the “pushing” technique. No recurrence was observed after 1-2 years follow-up. The crucial step for this technique is the movement of pushing. Because of the pushing by insulated cannula of snare, a semipedunculation forms and then the whole body of the tumor is easily captured by pre-placed snare. This ensures that the tumor can be resected completely. Meanwhile, because the tumor body is lifted toward cavity before cauterization and the line of resection is at the bottom of the tumor body and the top of the semipedunculation, the muscularis propria has already separated from the place of cauterization and then will not be injured by the high-frequency electrosurgical current. Additionally, to minimize potential severe hemorrhage and perforation, we avoid undergoing endoscopic resection of those lesions with the base ≥ 2 cm. All these fully demonstrate the efficiency and safety of the “pushing” technique utilized. When compared with other techniques such as En Bloc^[9,15-17], the pushing technique is much easier to be operated and takes less time.

The En bloc technique has been used by several groups for endoscopic resection of submucosal SMTs^[9,15-17]. By our understanding, there are at least two advantages for this technique. First, this technique contains an important step-injection of the saline solution into the submucosa, which is to separate the line of resection from muscularis propria and then prevent the injury of muscle layer. This step greatly increases the safety of the operation. Second, the removed tumors can be easily captured for further histological examination. However, we consider that this technique also has the shortcomings of complicated operation and time-consuming. In fact, it is a tough job for an endoscopist to inject the solution exactly into the base of the leiomyoma without injuring the wall of the gastrointestinal tract. Furthermore, injection of saline may make the margin of the lesion unclear. To overcome these problems, we tried to explore the possibility of deleting the procedure of saline injection. Normally, 19.4 mm grasping forceps can easily grasp the body of tumor and lift it up towards the cavity of the gastrointestinal tract to form a pseudo-pedunculation. In fact, this step has already separated the tumor from muscularis propria and then is

enough to prevent the injury of muscle layer when the captured tumor is removed by pre-placed snare. In some cases, the surface of the tumor is too slippery and difficult to grasp. To solve this problem, we first grasped the overlaying mucosa, and then pushed the tumor by insulated cannula of snare to form a semipedunculation, which also prevented the injury of muscularis propria when captured tumors were removed by high-frequency electrosurgical current. In the last 15 years, 10 cases of leiomyoma have been safely removed in our department by using this “grasping and pushing” technique. No recurrence was observed after 1-2 years follow-up. All these fully support the efficiency and safety of the grasping and pushing technique we utilized.

For those SMTs with the base size ≥ 2 cm and/or originating in muscularis propria, to differentiate malignant from benign is crucial for further treatment. Histological diagnosis is necessary not only to ascertain whether a lesion is benign or malignant (usually larger lesions with irregular borders, inhomogeneous areas, or eroded surfaces), but also to detect smaller lesions without malignant morphologic features. In recent years, several methods have been developed for this histological diagnosis. Matsui *et al.*^[18] have described a biopsy technique-endoscopic ultrasonography-guided fine needle aspiration biopsy (EUS-FNAB). In this technique, the biopsy materials are obtained from a needle, which is inserted into the lesions guided by EUS. Open biopsy, developed by Kojima *et al.*^[9], is another effective biopsy technique for gastrointestinal submucosal lesions. In this technique, the covering mucosa is resected to expose the tumor and then several tissues are obtained by ordinary forceps at the bottom of the artificial ulcer. The techniques we used in this study were the “digging” and ordinary biopsy techniques. In order to evaluate the diagnostic accuracy of these two techniques, we selected those cases which were finally removed by surgery. In our series, the diagnostic accuracy of “digging” biopsy is 94.1% for those SMTs without ulcer (leiomyoma: 92.3%; leiomyosarcoma: 100%). This result is very close to the above-mentioned two techniques, but the “digging” biopsy is much easier and cheaper than EUS-FNAB and open biopsy. In this series, no severe hemorrhage developed after the “digging” biopsy. In addition, the diagnostic accuracy of ordinary biopsy in the SMTs with ulcer is 90.0%, similar to that of “digging” biopsy.

Although EUS is very helpful in deciding the technique for endoscopic resection of submucosal SMTs, it is difficult to differentiate the malignant from benign SMTs by means of EUS unless there is local extension or metastasis, because no significant difference has been found between malignant and benign lesions with regard to homogeneity of internal echo pattern or marginal echo pattern^[3,19,20]. However, EUS is considered to be reliable in predicting the potential malignancy of SCTs^[3]. The three most predictive EUS features described by Palazzo *et al.*^[3] are irregular margins, cystic spaces, and lymph nodes with a malignant patterns. Palazzo *et al.*^[3] concluded that (1) the presence of at least one of these criteria had a sensitivity of 91%, a specificity of 88%, a positive predictive value of 83%, and a negative predictive value of 94% for

potential malignancy; (2) a combination of two of these three criteria had a positive predictive value and specificity of 100%; (3) tumors of 30 mm or less, with regular extraluminal margins and a homogeneous pattern, are likely to be benign. Our series also support predictive EUS features although only 6 cases of leiomyoma and 3 cases of leiomyosarcoma were investigated.

In conclusion, endoscopic resection is a safe and effective therapy for submucosal leiomyoma with the base size ≤ 2 cm. The guidance of EUS greatly increases the safety of endoscopic resection of submucosal leiomyoma. The “digging” biopsy technique would be a good option for the histologic diagnosis of SMT.

COMMENTS

Background

Gastrointestinal smooth muscle tumors (SMTs, including leiomyoma and leiomyosarcoma) represent relatively common lesions. The complete surgical resection was considered to be the most definitive therapy for SMTs in the past. In recent years, some researchers reported that endoscopic treatment of GI submucosal leiomyoma is a valid alternative to invasion surgery. However, they failed to provide enough convincing evidences for the efficiency and safety of the treatment they used because lack of enough cases.

Research frontiers

In the last few decades, gastrointestinal endoscopy has been widely used in the treatment of gastrointestinal diseases, it is very important to elucidate the efficiency and safety of endoscopic treatment of SMTs.

Innovations and breakthroughs

The authors revealed that endoscopic treatment of SMTs is efficient and safe through a prospective research with many cases. Meanwhile, the “Pushing” technique and “Grasping and pushing” technique were put forward and analyzed.

Applications

The current study will guide the clinical application of endoscopic treatment of SMTs.

Peer review

This paper may show us endoscopic management of smooth muscle tumor in a single hospital for more than 10 years. However, this study is only a descriptive study of the experienced cases. The authors should consider again the novel findings obtained from the experienced cases.

Abstract

AIM: To study the outcomes of patients with compensated hepatitis C virus-related cirrhosis.

METHODS: Twenty-four grade A5 and 11 grade A6 of Child-Pugh classification cirrhotic patients with active virus replication, treated for a mean period of 31.3 ± 5.1 mo with moderate doses of interferon-alpha and ribavirin, were compared to a cohort of 36 patients with similar characteristics, without antiviral treatment. Salivary caffeine concentration, a liver test of microsomal function, was determined at the starting and thrice in course of therapy after a mean period of 11 ± 1.6 mo, meanwhile the resistive index of splenic artery at ultra sound Doppler, an indirect index of portal hypertension, was only measured at the beginning and the end of study.

RESULTS: Eight out of the 24 A5- (33.3%) and 5 out of the 11 A6- (45.45%) treated-cirrhotic patients showed a significant improvement in the total overnight salivary caffeine assessment. A reduction up to 20% of the resistive index of splenic artery was obtained in 3 out of the 8 A5- (37.5%) and in 2 out of the 5 A6- (40%) cirrhotic patients with an improved liver function, which showed a clear tendency to decrease at the end of therapy. The hepatitis C virus clearance was achieved in 3 out of the 24 (12.5%) A5- and 1 out of the 11 (0.091%) A6-patients after a median period of 8.5 mo combined therapy. In the cohort of non-treated cirrhotic patients, not only the considered parameters remained unchanged, but 3 patients (8.3%) had a worsening of

the Child-Pugh score ($P = 0.001$).

CONCLUSION: A prolonged antiviral therapy with moderate dosages of interferon-alpha and ribavirin shows a trend to stable liver function or to ameliorate the residual liver function, the entity of portal hypertension and the compensation status at acceptable costs.

INTRODUCTION

Hepatitis C virus (HCV) infection is a leading cause of liver disease worldwide. Infected patients usually develop chronic hepatitis, which may progress producing diffuse disorganization of normal hepatic structure, to liver cirrhosis over a long period. Approximately 10%-20% of patients with chronic HCV infection have cirrhosis at the first clinical presentation, and near 20%-30% of those who do not present liver cirrhosis will eventually develop this illness and its complications^[1-3].

To date, the most effective treatment to prevent disease progression and eventually cure chronic hepatitis C (CHC) virus infection is the combined therapy of pegylated (PEG) interferon (IFN) alpha and ribavirin (RBV). The rate of sustained viral response (SVR) in immunocompetent patients undergoing this antiviral regimen ranges from 42% to approximately 80%, depending on the HCV genotype, with an acceptable safety profile^[6,7]. Thus, PEG-IFN alpha has substituted standard IFN alpha in the regimens used to treat CHC. However, the advantage of such an approach, with the additional cost it entails, still remains to be demonstrated^[8]. In patients with compensated HCV-related cirrhosis, standard IFN alpha or combination therapy offers an interesting SVR^[9]. Neither substantial difference has been reported between PEG-IFN alpha and standard IFN alpha in combination with

RBV, nor PEG-IFN has a higher risk of complications^[10]. Indeed, also in the decompensated form of liver cirrhosis, favourable results have been achieved after a 24 wk-course of combined therapy^[11]. Since liver cirrhosis progression is related to other factors beyond the viral infection, the therapeutic efficacy should be evaluated under a wider perspective. Actually, data on the liver residual function and hepatic hemodynamics assessment, following the route of compensated liver cirrhosis after antiviral therapy, are limited, having prevalently studied the survival rate and hepato-carcinoma appearance.

Expecting a modification of the liver parenchymal structure and vascular bed (as partial gain following the reduced cellular damage, fibrosis and nodular regeneration) after a long-term antiviral treatment at a moderate-dosage, our principal aim was to investigate the impact of this schedule on eventually modifying the progression of liver cirrhosis. Then, we started weighing three characteristic prognostic aspects of the illness, i.e., the residual liver function (index of intact cellular mass) by a quantitative liver function test (QLFT), the presence of liver decompensation by regular assessment of Child-Pugh (C-P) severity class, and the altered hemodynamics (consequence of a cyto-architectural alteration) by a non-invasive parameter reflecting the portal hypertension entity.

MATERIALS AND METHODS

Population

Among the 121 patients (regularly followed up at our out-patient clinic) suffering from HCV-related liver cirrhosis, with HCV load > 800 000 IU/mL and genotype 1, 71 were enrolled in the study, well matched for sex, age and severity of the disease. These 71 patients were divided into treated group (35) and non-treated group (36) (Table 1). Of the patients (including 13 females) in the first group, 24 (mean age 58.9 ± 5.7 years) belonged to C-P grade A5 cirrhotics and 11 (mean age 61 ± 5.0 years, 7F) to C-P grade A6 cirrhotics. A further characteristic was that 18 underwent previous antiviral therapy during the past years (14 non-responders and 4 relapsers). These patients were treated for a mean period of 31.3 ± 5.1 mo with moderate doses of IFN alpha (8 with 1.5 MU daily, 13 with 3 MU on alternate days and 14 with 1 mcg/kg body weight of Peg-IFN alpha 2b weekly) in combination with oral RBV (400 or 600 mg per day for body weight < or > 75 kg). One was excluded from the study because he spontaneously ended the therapy and two had a suspension period of more than six weeks. Collaterally, a cohort (without antiviral treatment) of 36 initially compensated cirrhotics (25, A5 C-P patients including 12 females, and 11 including 6 females, A6 C-P patients) was studied for the same period (9 patients were suffering from various grades of mood disorders, 4 were affected by microcythemia, 6 presented with thyroid laboratory abnormalities, 17 refused the treatment by choice. Of these patients, 15 were non-responders and 2 relapsers to previous antiviral therapy).

No patient in the two groups received mono- or combined treatment in the last two years.

The diagnosis of liver cirrhosis was made by histology

(25 patients), laboratory data (34 patients), and combined clinical and laboratory parameters plus ultra sound (US) findings (12 patients).

Main outcome measures

As QLFT, we chose to probe the microsomal activity of enzymes, e.g., cytochrome P450 1A2, with the total overnight salivary caffeine assessment (TOSCA), comparable to the well-known caffeine clearance according to a recent study^[12] and with the normal values set at ≤ 1 mcg/mL. Briefly, patients were allowed to drink coffee in late afternoon and on the day after overnight intake-washout, a sample of saliva, was collected in the morning, roughly centrifuged, frozen and stored until analysis. TOSCA was performed at first and then thrice during the course of therapy, at a mean interval period of 11 ± 1.6 mo. Caffeine was determined by an enzyme multiplied immunoassay technique (Dade Behring Liederbach, Germany) at the end of the follow-up period. Clinical assessment combined with other laboratory parameters, i.e., serum albumin, prothrombin time and bilirubin levels, was performed between periods of TOSCA evaluation. Occult blood in stools was detected to exclude gastrointestinal haemorrhage due to portal hypertension, as a possible cause of decompensation.

The resistive index of the splenic artery (SARI) at US Doppler was used to indirectly ascertain the entity of portal hypertension as previously described^[13]. SARI was taken at the beginning and the end of the observation period using a 3.5 convex probe of an ESAOTE (Genoa, Italy), by two operators who were blind to each other and the laboratory results.

A slightly modified C-P classification was adopted to define the severity of liver cirrhosis (Table 2). A worsening total score was set at three points when patients belonged to the A5 class and two points in case of the A6 class.

Exclusion criteria

The exclusion criteria included: (a) alcohol abuse screening according to recent recommendation^[8], (b) metabolic syndrome following the adult treatment panel III classification^[9], (c) detection of iron overload, (d) serum positivity for HBsAg, (e) previous chronic use of potentially toxic drugs as amiodarone, methotrexate and high doses of vitamin A.

Statistical analysis

Chi square test was used to study the frequencies. Differences between means were studied by unpaired T test or Mann-Whitney test. Wilcoxon signed ranks test was carried out for paired observations. ANCOVA (repeated measure analysis of variance corrected for the basal values) was carried out to analyze the differences in TOSCA data at various time intervals. Association was evaluated by applying Pearson correlation. Logistic regression was used to verify if the IFN formulation and the schedule of antiviral therapy affected the severity of liver cirrhosis, based on C-P classification. The inter-observer agreement at US was appraised by the Cohen's Kappa. Kaplan-Meier (K-M) survival curves were used for comparing

Table 1 Laboratory and sonographic parameters of the population at entry

	Treated									
	Not (36 patients)					Yes (35 patients)				
	Mean	SD	Median	Minimum	Maximum	Mean	SD	Median	Minimum	Maximum
ALT ¹	61.25	9.7				61.3	13.6			
Chol ²			133.5	59	190			132	89	200

SLD at US ⁴			134	122	151			133	120	146

ALT: alanine aminotransferase; Chol: total cholesterol; Plts: platelets; SLD: splenic longitudinal diameter; US: ultra sound; SD: standard deviation. ¹*P* = 0.97 at unpaired T test; ²*P* = 0.72 at Mann-Whitney (M-W) test; ³*P* = 0.15, at M-W test; ⁴*P* = 0.65 at M-W test.

Table 2 Child-Pugh classification (slightly modified)

Clinical and laboratory data	Points for increasing abnormality ¹		
	1	2	3
HE (grade ²)	None	(SHE)0-1-2	3-4
Ascites	None at US	Mild or controlled by diuretics	Present despite diuretics
PT (% of activity) ³	> 70	70-40	< 40
Albumin (g/dL)	> 3.5	2.8-3.5	< 2.8
Bilirubin (mg/dL)	< 2	2-3	> 3

¹Scoring system: 5-6 points, grade A; 7-9 points, grade B; 10-15 points, grade C. ²HE: hepatic encephalopathy; Grade 0: sub-clinical hepatic encephalopathy, SHE, unravelled by retain tests A or B; Grade 1: anxiety, irritability, depression, impaired concentration, sleep disturbances; Grade 2: disorientation, poor short-term memory, disinhibited behaviour, drowsiness; Grade 3: somnolence, bizarre behaviour, confusion, amnesia, paranoia; Grade 4: Coma. ³PT, prothrombin time, also expressed in seconds prolonged < 4; 4-6; > 6, or as INR < 1.7; 1.7-2.3; > 2.3. US: ultra sound.

C-P classification worsening probability curves in the two groups of patients. Cox proportional-hazards regression was employed to analyze the effect of non treatment (risk factor) on the C-P score aggravation. MedCalc version 9.0.2.1. and SYSTAT version 11.00.01 were used.

The study was conducted following the International Conference on Harmonization for Good Clinical Practice, in accordance with the Code of Ethics of the World Medical Association (Declaration of Helsinki).

RESULTS

Whenever neutrophil count was < 750 cells/ μ L or haemoglobin < 10 g/dL, granulocyte colony-stimulating factor (filgrastim, Neupogen, Amgen Inc., California, 300 μ g to eight patients, weekly) or erythropoietin analog (Eprex, Janssen-Cilag, 10 000 units to seven patients, twice/thrice weekly) was administered (after the blood count increased, the growth factor administration was prolonged for at least two weeks). In the treated group, six out of the 24 A5 C-P (25%) and four out of the 11 A6 C-P (36.4%) cirrhotic patients showed an improvement (> 20% in respect to the base-line determination) in TOSCA (Figure 1). A clear association was found between the post-treatment TOSCA values and the prothrombin time ($r = -0.76$, *P* = 0.0001). No patient showed a worsening liver function. In the comparative cohort of initially

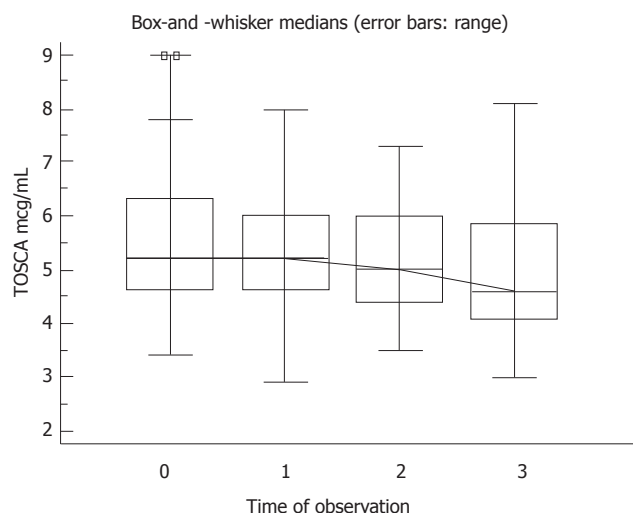

Figure 1 Behaviour of the applied quantitative liver function test in 35 patients treated with combined antiviral therapy. TOSCA: total overnight salivary caffeine assessment. The knurled line shows which groups are significantly different in the values of TOSCA, in respect to the basal ones; ANCOVA (repeated measure) test, *P* = 0.0001.

compensated cirrhotic patients without antiviral treatment, five out of the 36 patients (13.9%) had an exacerbation in respect to previous TOSCA values. A higher C-P score was found in non-treated than with treated patients (8/36 versus 1/35, *P* = 0.04).

Taking the US operator-dependent variability into consideration (although our inter-observer agreement was high, i.e., 89%), an appreciable reduction (> 20% compared with the pre-treatment measurements) in the SARI was obtained in 3 of 6 A5 C-P and 2 of 4 A6 C-P cirrhotic patients, showing an improvement in liver function. Furthermore, a significant decrease in the median SARI was present in the whole population compared to the pre- and post-treatment values.

HCV viral clearance was achieved in 3 out of the 24 (12.5%) A5 C-P and 1 out of the 11 (.91%) A6 C-P patients after a median (range) period of 8.5 (8-10) mo combined therapy.

No independent risk factor for C-P worsening was highlighted among the type of IFN, doses and period of treatment.

In our series during the entire period of study, no liver failure, hepato-cellular carcinoma and non-Hodgkin's lymphoma were discovered. There was a significant difference in the K-M curves of liver cirrhosis during

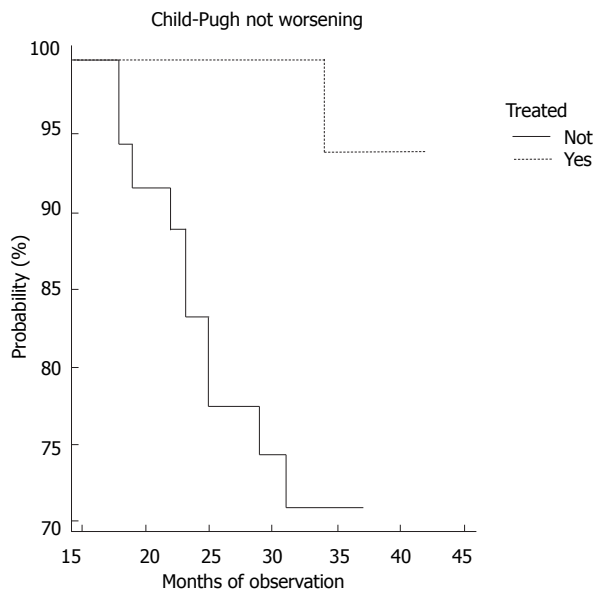

Figure 2 Behaviour of Child-Pugh classification in patients on (n 35) or not on (n 36) combined antiviral therapy. Comparison of the probability curves between treated and non-treated patients was made (Log-rank test). Chi-square test = 8.3, $P = 0.004$; Hazard ratio = 10.9; 95% CI = 1.75-18.9.

the four year-observation period between the two groups. About 30% of patients in the non-treated group experienced a worsening C-P score than the opposite cohort (Figure 2).

A small percentage of side-effects was registered in the treated group, e.g., two patients showed onset or enlargement of psoriatic plaques, three asthenia, one repeated low urinary tract infection, six anorexia, two low-grade fever, seven local erythema, one mild alopecia.

The cost of combined therapy plus growth factors per patient was estimated to be approximately 6000 US\$ for standard IFN and 15 000 US\$ for Peg-IFN, respectively.

The final values of TOSCA in samples were assessed for each group of patients ($\alpha = 0.05$, $\beta = 0.01$).

DISCUSSION

The main outcomes of antiviral therapy for chronic hepatitis C detected are the viral clearance and its lasting time. Actually, IFN therapy seems also be able to determine a decrease in the rate of functional disease progression in patients with the same disease, even in non-responders and relapsers^[14].

On the other hand, previous data have emphasised the scarce response to IFN therapy when dealing with advanced chronic liver diseases. This finding has not been further supported by a recent study^[11]. However, an uncertainty still exists, because it is not clear if a reduction in viral load or its clearance is of some benefit for any of the main processes, i.e., fibrosis and nodular regeneration, the extent of which determines the severity of liver cirrhosis. Variation exists among individuals regarding the rate and time of the progression of fibrosis to cirrhosis. There is evidence that the Ito cells are activated in response to HCV-induced hepatocellular

damage initiating fibrosis^[15]. These cells proliferate and become myofibroblasts, enhancing degradation of the normal matrix and producing excess abnormal matrix. Reactive oxygen species (ROS)^[16] and inflammatory cytokines (mainly transforming growth factor and platelet-derived growth factor) speed up fibrosis. These cells play a key role in the alteration of metalloproteinase enzymes that regulate matrix collagen metabolism^[17]. Fibrous tracts join branches of afferent portal veins and efferent hepatic veins, bypassing the hepatocytes and limiting their blood supply. Since the same myofibroblasts stimulated by endothelin-1, contribute to the increased portal vein resistance, fibrosis leads to "hepatocyte ischemia" with successive hepatocellular dysfunction and portal hypertension. Cirrhosis resulting from HCV infection has a slowly progressing course. Then, using the classic ones as therapeutic end-points^[18], could result in the short-medium ones. Furthermore, an eventual change in some prognostic aspects of liver cirrhosis has not been reported, especially if long-term, moderate-dosage schedules were used.

Having this in mind, we tracked the progression of liver cirrhosis, using three combined parameters, all indices of the severity of the illness.

We found an improvement in residual liver function as assessed by TOSCA, a lack of C-P classification variation and a concomitant constancy of the indirect assessment of portal hypertension grade. All of them showed a stable severity of the illness in treated patients. Antiviral therapy could affect the ongoing liver cirrhosis by influencing the inflammation- or apoptosis-mediated fibrosis process, working on HCV viral replication, lessening ROS formation. The last mechanism is of paramount importance because it alters reparative processes. Interestingly, a reduced cellular damage could also justify the improvement in QLFT following therapy. Obviously, SARI is a surrogate marker, reflecting the hyper-dynamic, high-flow circulatory state as a consequence of splanchnic vasodilatation caused by portal hypertension. Actually, the only supra-hepatic vein catheterization could ultimately give valid information on hypertensive status. In any case, this non-invasive tool offers its best resources for serial measurements of hypertension and it has not yet been criticized as other Doppler US parameters^[19]. In our study, a stable sonographic parameter or a slightly-reduced sonographic parameter which non invasively weighs the portal hypertension, was evidenced. Furthermore, the present study has other limitations in its methodology. The first is that it was not a randomized study, but a pilot study. In fact, only patients who accepted the treatment or had no contra-indications were enrolled. The second is that a four-year-interval was not representative of the natural history of this chronic disease, although it could foresee a certain trend. The third is that even if we tried to exclude the presence of co-factors, we were not sure that occult causes such as low intake of alcohol or episodic drug toxicity could have influenced the progression of liver cirrhosis in the non-treated patients. Moreover, we could have measured a serum fibrosis marker, a procollagen-III peptide, even if a consolidated study has failed to assess its utility^[20]. We stress that the follow-up and work-up

intervals were similar in the two groups. The fourth is that the quality of life was not opportunely evaluated, which is very important for the patient, although the non-standard dosage plays a key role in reducing side-effects. One positive aspect of this approach could be the health-care-cost in light of a likely procrastination of the need for hospitalization and liver transplantation.

In conclusion, our results favour the hypothesis that a stability (lack of fatal progression) or a trend to improve the severity of liver cirrhosis based on the clinical status and laboratory-instrumental profile is a reliable end-point after antiviral therapy. A prolonged combined antiviral course at reduced doses may slow down the progression of liver disease to cirrhosis. Further well-designed studies are needed to corroborate the present observations.

COMMENTS

Background

Hepatitis C virus (HCV) infection is a major health care problem. Recently combined antiviral therapy has been ascertained to improve the non-progressive form of chronic liver disease, eliminating the viral load and reducing fibrosis. However, whether HCV-related-liver cirrhosis characterized by a reduced hepatocellular mass and an increased pressure of portal vein can be cured still remains a challenge.

Research frontiers

The hot spots discussed in the article are the main outcomes of this controlled study, i.e., the assessment of real liver function with a simple and repeatable test (TOSCA) that probes the microsomal enzymatic activity and the evaluation of an Ultrasonographic index of portal hypertension.

Innovations and breakthroughs

The differences from the other related or similar studies relay on the particular schedule of combined antiviral therapy for the treatment of HCV-related liver cirrhosis (low long-protracted doses).

Applications

The perspectives of future application of this research could be expanded by larger and double-blinded studies to validate the good cost/benefit ratio.

Terminology

Total overnight salivary caffeine assessment (TOSCA) is comparable to the well-known caffeine clearance. Briefly, patients were allowed to drink coffee up to late afternoon and after overnight intake-washout, a sample of saliva, was collected in the morning of the next day, roughly centrifuged, frozen and stored until analysis.

Peer review

The manuscript describes that antiviral therapy in patients with hepatitis C-related cirrhosis shows a trend to stabilize or even to ameliorate residual liver function. Although the number of patients was rather small, the study provides evidence for how to treat these patients.

Abstract

Diffuse large B-cell lymphoma is the most common type of non-Hodgkin's lymphoma. More than 50% of patients have some site of extra-nodal involvement at diagnosis, including the gastrointestinal tract and bone marrow. However, a diffuse large B-cell lymphoma presenting as acute pancreatitis is rare. A 57-year-old female presented with abdominal pain and matted lymph nodes in her axilla. She was admitted with a diagnosis of acute pancreatitis. Abdominal computed tomography (CT) scan showed diffusely enlarged pancreas due to infiltrative neoplasm and peripancreatic lymphadenopathy. Biopsy of the axillary mass revealed a large B-cell lymphoma. The patient was classified as stage IV, based on the Ann Arbor Classification, and as having a high-risk lymphoma, based on the International Prognostic Index. She was started on chemotherapy with CHOP (cyclophosphamide, doxorubicin, vincristine and prednisone). Within a week after chemotherapy, the patient's abdominal pain resolved. Follow-up CT scan of the abdomen revealed a marked decrease in the size of the pancreas and peripancreatic lymphadenopathy. A literature search revealed only seven cases of primary involvement of the pancreas in B-cell lymphoma presenting as acute pancreatitis. However, only one case of secondary pancreatic involvement by B-cell lymphoma presenting as acute pancreatitis has been published. Our case appears to be the second report of such a manifestation. Both cases responded well to chemotherapy.

Saif MW, Khubchandani S, Walczak M. Secondary pancreatic involvement by a diffuse large B-cell lymphoma presenting as acute pancreatitis. *World J Gastroenterol* 2007; 13(36): 4909-4911

INTRODUCTION

Non Hodgkin's lymphoma (NHL) frequently arises in extra-nodal sites, with about 50% of patients having extra-nodal involvement^[1]. The gastrointestinal tract is the most frequent site of involvement, with the stomach and intestines being involved in most cases^[2]. Involvement of the pancreas by NHL has been infrequently reported^[3,4]. Only about 0.2%-2% of patients with NHL have pancreatic involvement at the time of presentation^[1,4,5]. The present report describes a unique case of NHL with secondary pancreatic involvement presenting as acute pancreatitis. A literature search has revealed seven cases of primary involvement of the pancreas by B-cell lymphoma presenting as acute pancreatitis^[6,7]. However, only one case of secondary pancreatic involvement by B-cell lymphoma presenting as acute pancreatitis has been reported^[8].

CASE REPORT

A 57-year-old Caucasian female presented to her primary medical doctor with complaints of abdominal pain. Pain was located in the epigastrium, was dull in character, constant, and grade 3-4/10 in severity. On examination, the patient was also found to have a painful right axillary mass, which appeared to be matted lymph nodes. A biopsy of the matted lymph nodes was undertaken.

However, 4 d later, the patient presented to our emergency department because of worsening abdominal pain. Pain had increased to a severity of 9-10/10 and was associated with nausea and bilious vomiting. On physical examination, she was found to have extreme epigastric tenderness. Laboratory investigations showed an elevated serum amylase level of 623 U/L (normal range 30-110 U/L) and a serum lipase level of 4963 U/L (normal range 23-300 U/L). The patient was initially diagnosed with acute pancreatitis and admitted to the hospital. Past medical history was negative for alcohol consumption or medication use. Abdominal ultrasound done at the time of admission did not reveal any gallstones. Electrolytes and lipid panel were completely normal.

A subsequent abdominal computed tomography (CT) scan showed a diffusely enlarged pancreas due to an infiltrative neoplasm, along with bulky retroperitoneal lymphadenopathy, bulky peripancreatic, mesenteric adenopathy, ascites and peritoneal carcinomatosis

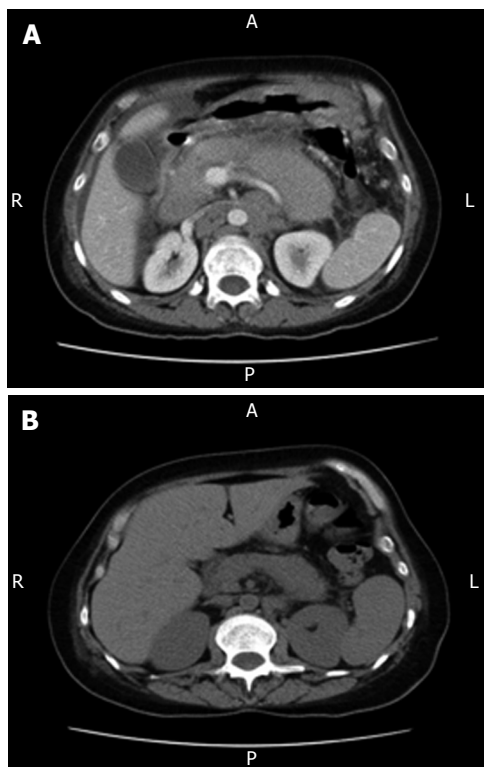

Figure 1 A: Baseline CT scan (pre-therapy). Abdominal CT scan shows diffusely enlarged pancreas due to infiltrative neoplasm, along with bulky retroperitoneal lymphadenopathy, bulky peripancreatic, mesenteric adenopathy, ascites and peritoneal carcinomatosis; B: Post-therapy CT Scan (non-enhanced). A follow-up CT scan of the abdomen reveals a marked decrease in size of the pancreas and retroperitoneal lymph nodes.

(Figure 1A). A report of the biopsy of the axillary mass was available the day after admission, and showed fragments of mononuclear cells with features consistent with lymphocytes, predominantly large in size, with frequent mitotic figures and focal necrosis (Figure 2). Immunohistochemical analysis showed features consistent with a large B-cell lymphoma. Eleven immunohistochemical stains were performed, including CD20, which was positive. Serum lactic dehydrogenase level was elevated to 1227 IU/L (normal range 300-600 U/L) at the time of admission.

Bone marrow biopsy showed evidence of bone marrow involvement by the diffuse large B-cell lymphoma. The patient was classified as stage IV A, based on the Ann Arbor classification designed for Hodgkin's and non-Hodgkin's lymphoma. She was classified as high risk on the International Prognostic Index for diffuse large B-cell lymphoma.

The patient received one cycle of chemotherapy with cyclophosphamide (750 mg/m² Intravenous), doxorubicin (50 mg/m² intravenous), vincristine (1.4 mg/m² intravenous) and prednisone (100 mg/m² orally daily for 5 consecutive days) (CHOP regimen). Within a week after chemotherapy, the patient's abdominal pain had resolved and nausea and vomiting had significantly decreased. Her serum amylase and lipase levels returned to normal (Table 1). A follow-up CT scan of the abdomen revealed a marked decrease in the size of the pancreas and retroperitoneal lymph nodes (Figure 1B).

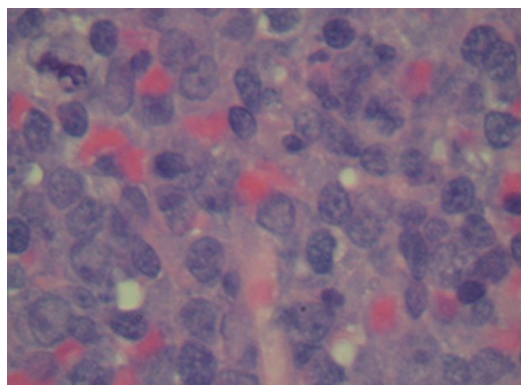

Figure 2 Biopsy of the axillary mass reveals a diffuse large B-cell lymphoma.

Table 1 Differences in serum amylase and lipase levels before and after treatment

	Serum amylase level (U/L)	Serum lipase (U/L)
Before chemotherapy	623	4963
Two days after chemotherapy	72	122
Four days after chemotherapy	45	97

DISCUSSION

Malignant lymphoma infrequently involves the pancreas. The estimated frequency of primary NHL of the pancreas is about 2.2%^[4]. Secondary involvement of the pancreas by NHL is rare. Approximately 0.2%-2% of patients with NHL have pancreatic involvement at presentation^[1,4,5]. An autopsy series of 1269 cases of NHL found pancreatic involvement in 28.9% of the cases^[8]. A literature search of the PubMed database has revealed seven cases of primary involvement of the pancreas by B-cell lymphoma, presenting as acute pancreatitis^[6]. However, only one case of secondary involvement of the pancreas by B-cell lymphoma presenting as acute pancreatitis has been described^[6]. As in our case of secondary pancreatic involvement, that previous patient also presented with acute abdominal pain radiating to the back. He was found to have elevated serum amylase and serum lipase. A CT scan showed diffuse swelling of the pancreas with two masses, one in the corpus and one in the tail. There was also lymphadenopathy near the pancreas. CT of the thorax showed a large lymph node in the mid mediastinum. This lymph node was biopsied and revealed a large B-cell lymphoma. This case of secondary pancreatic involvement also responded well to chemotherapy. A standard regimen of chemotherapy led to normalization of serum lipase and amylase levels, as well as a decrease in the size of the pancreas and the peripancreatic and retroperitoneal lymph nodes.

Diffuse large B-cell lymphoma is the most common NHL, and makes up 30% of newly diagnosed cases. The lymphoma can present with enlarged lymph nodes at either the primary or extra-nodal sites. More than 50% of patients have some extra-nodal involvement at diagnosis^[1]. The most common sites are the gastrointestinal tract and

bone marrow, each being involved in 15%-20% of cases.

The presenting symptoms of pancreatic lymphoma are usually non-specific and include abdominal pain (83%), abdominal mass (58%), weight loss (50%), jaundice (37%), acute pancreatitis (12%), small bowel obstruction (12%) and diarrhea (12%). These symptoms help distinguish pancreatic lymphoma from pancreatic carcinoma^[2]. Imaging plays an important role in the diagnosis and staging of pancreatic masses^[5,9,12]. This is particularly true for pancreatic lymphoma, as treatment and prognosis are significantly different from those for pancreatic adenocarcinoma^[9]. A CT scan is the modality commonly used for the detection of pancreatic lymphoma. Two types of morphological presentation have been reported on CT; one is a tumor-like, localized, well-circumscribed mass presenting as a hypoechogenic mass, and the second is a diffuse enlargement infiltrating the pancreas^[9,10]. The well-circumscribed tumoral form is distinguished from pancreatic adenocarcinoma by the absence of pancreatic duct involvement and the presence of surrounding lymphadenopathy^[9,10]. The imaging findings in the second type are similar to those in acute pancreatitis. Ultrasound- or CT-guided fine needle biopsy of the pancreatic mass can also help distinguish pancreatic lymphoma from pancreatic adenocarcinoma^[4]. In the present case, pancreas biopsy was not necessary to diagnose the lymphoma because sufficient tissue was obtained from the axillary mass.

Anthracycline-based chemotherapy is the standard treatment for NHL, and includes six to eight cycles of R-CHOP for patients of all ages^[11]. High-grade pancreatic lymphoma generally responds well to standard chemotherapy^[11].

Our patient presented with acute abdominal pain and was in the high-risk category of the International Prognostic Index, and was therefore treated as an emergency with high-dose inductive chemotherapy. She responded very well to the chemotherapy and following the first cycle, there was a decrease in the size of the pancreas, as well as the peripancreatic and retroperitoneal lymph nodes. The patient's abdominal pain resolved and her serum amylase and lipase levels normalized.

Secondary involvement of the pancreas by B-cell lymphoma is a rare occurrence. It is important to include such secondary involvement in the differential diagnosis of patients that present with acute pancreatitis. Pathologic

diagnosis is important in distinguishing pancreatic lymphoma from pancreatic carcinoma. Most cases of pancreatic lymphoma respond very well to chemotherapy.

ACKNOWLEDGMENTS

We thank Haswell James E, MD and Soldano Lucille, MD for helping us prepare the manuscript and for their input. A special thanks to the American Cancer Society for their support.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by WJG

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of WJG, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submission

Online submission is strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
<http://www.wjgnet.com>
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Received: June 2, 2007 Revised: July 26, 2007

Abstract

There is a general consensus in re-interpreting the so-called liver function tests in the light of novel discoveries. At the same time, recent evidence favours the use of different laboratory data to assess liver damage, fibrosis or regenerative process, but this point is not always shared. Actually, balancing the need for diagnosis, prognostic evaluation and therapy response of liver disease with a good cost/benefit ratio is very difficult. New tests are probably not needed but the aim should be for better utilization of existing tests to contain the increasing cost of health care.

Key words: Laboratory liver tests; Alanine aminotransferase; Aspartate aminotransferase; Quantitative testing of liver function; Alcoholic liver disease; Non-alcoholic steatohepatitis; Hepatitis C virus

Tarantino G. From bed to bench: Which attitude towards the laboratory liver tests should health care practitioners strike? *World J Gastroenterol* 2007; 13(37): 4917-4923

<http://www.wjgnet.com/1007-9327/13/4917.asp>

SCENARIO

The liver being a multifunctional organ (specialized in detoxification, metabolism and defence), the reliability of a single laboratory test is relatively limited (obviously, chemistry is the first approach followed by imaging and histology, not necessarily in this order). So far, the hepatic diagnostic evaluation is based on several contextual or in sequence analyses. Different algorithms have been proposed to improve the detection, the differentiation and the severity of liver diseases. Actually,

the favourable relationship between hepatologists and the clinical chemistry experts is jeopardized by an overuse of laboratory services. This attitude does not reduce mortality, does not shorten hospital stays, nor contribute to the quality of medical care. Actually, balancing the need for diagnosis, prognostic evaluation and therapy response of liver disease with a good cost/benefit ratio is quite difficult. But, is it true that those never ending reports that advice the practitioners about the clinical utility of various diagnostic tools greatly broaden the health care costs?

Until now, physicians evaluate the type and the entity of hepato-cellular damage. Generally, it is considered to appear as inflammation and colliquative necrosis. In this direction the laboratory liver tests (LLTs) moved since the discovery of the transaminases usefulness in diagnosing acute hepatitis, anciently known as “icterus catharralis”, in the mid 1950s, and published some years later^[1].

These tests are erroneously named as liver function tests, and alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are considered the most important. They are present in high concentration in hepatocytes, where they catalyse the transfer of amino groups from alanine and aspartate to the α -keto group of ketoglutaric acid in order to produce pyruvic acid and oxaloacetic acid, respectively. These enzymes leak into the blood when the hepatocytes cell membranes are damaged.

IS THE ROLE OF APOPTOSIS DEFINITELY UNDERESTIMATED IN EVALUATING THE ENTITY OF LIVER INJURY?

As previously stated, the hepatic damage evaluation is abundantly unbalanced toward the inflammation/necrosis process. Apoptosis may occur in the absence of significant transaminases increase as happens in hepatocellular necrosis. Apoptosis describes the process by which damaged or senescent cells are eliminated from the organism. The expression “the falling of old leaves from trees in the autumn” clearly explains the apoptosis meaning. Apoptosis occurs by two mechanisms: death receptor or extrinsic mechanism and mitochondrial or intrinsic mechanism. Hepatocytes express different death receptors, i.e., Fas, tumor necrosis factor-receptor 1 (TNF-R1), TNF-related apoptosis-inducing ligand receptor 1 (TRAIL-R1), and receptor 2 (TRAIL-R2); stellate cells express Fas and TRAIL when are activated into myofibroblast-like phenotype and undergo apoptosis during resolution of liver injury *in vivo*. Cholangiocytes seem to be a type of

cells in which the mitochondrial mechanism to apoptotic is essential. Apoptosis has a major role in hepatic injury and subsequent progression to fibrosis as it has been well established in different hepatic diseases. In fact, apoptosis is one of the most important mechanisms leading to hepatocyte elimination in non-alcoholic fatty liver disease (NAFLD) and contribute to intensify inflammation in the same disease inducing proapoptotic protein p53 with the inhibition of antiapoptotic Bcl-2^[2].

Apoptosis results in the extracellular release of a limited number of proteins including: cytochrome c, some caspases and cleaved cytokeratin-18 and possibly a few other proteins. Mitochondrial cytochrome c release is the key event, which is critical for the initiation of the formation of the apoptosome complex that is essential for the activation of caspase-9 and initiation of the mitochondria-dependent apoptotic cascade^[3,4]. Following this pattern of speculation, a new (not completely!) marker in detecting Non-Alcoholic Steato Hepatitis (NASH)^[5], has been studied.

MORE SUBTLE TESTS OF LIVER CELL DAMAGE WILL PROBABLY BECOME AVAILABLE IN THE FUTURE, BUT IN THE MEANTIME, DOES MEASUREMENT OF SERUM AMINOTRANSFERASE CONCENTRATIONS FULFILL THE PRECISION PURPOSE?

ALT is the more specific marker of hepatocellular injury because it occurs exclusively in the liver, whereas AST occurs to some extent also in heart, skeletal muscle, kidney and pancreas. AST is prevalently found in mitochondria (near 80%) and to a lesser extend in cytoplasm (20%). Meanwhile, ALT is bound to cytoplasm. It is necessary to stress that, although transaminases are sensitive indicators of hepatocyte damage, they could not be considered reliable markers. The likelihood that abnormal aminotransferase levels reflect liver disease is exponentially increased by the presence superior to six months; the association with signs or symptoms of liver disease; the high enzyme levels; the plurality of abnormal liver enzymes.

Serum ALT/AST concentrations are raised in almost all forms of liver disease, but to different degrees. Very high concentrations ($> 10 \times$ Upper limit of normality, ULN) are typical of acute viral, drug-induced hepatitis, ischemic injury to the liver. ALT/AST levels may be unexpectedly high in the early stage of biliary obstruction and, rarely, in flares of autoimmune chronic hepatitis. Those levels do not necessarily mirror the severity of hepatocyte necrosis or the patients' prognosis. This point is evident in massive hepatic necrosis, when a decreasing serum concentration signifies not recovery, but a fewness of hepatocytes from which the enzymes can leak. In the patient in state of shock, serum ALT and AST concentrations typically rise abruptly and return to normal within days after haemodynamic stability is restored. Return to previous

normal values may be sufficiently rapid in drug-induced hepatitis. These laboratory abnormalities patterns contrast with those in acute viral hepatitis, in which the decrease is far more gradual. Serum ALT and AST concentrations are moderately raised ($2-10 \times$ ULN) in chronic and asymptomatic cases of acute viral or drug-induced hepatitis, autoimmune hepatitis, and alcoholic liver disease. In these disorders the enzyme concentrations generally correlate with the activity of the disease. Post-viral cirrhosis, the whole spectrum of NAFLD, cholestatic liver disease, and hepato-cellular carcinoma are characterised by slightly raised serum aminotransferase levels ($< 2-3 \times$ ULN). The serum AST/ALT ratio may help diagnose some liver diseases. In most patients with acute liver injury the ratio is 1 or less, whereas in alcoholic hepatitis it is generally about 2. Deficiency of pyridoxal-5'-phosphate, a necessary coenzyme for both aminotransferases, is common in alcoholic liver disease. This deficiency decreases hepatic ALT to a greater extent than AST, ending up in changes in serum concentrations. Although diagnostic laboratories scarcely offer measurement of AST isoenzymes, a high ratio in the serum of mitochondrial to total AST indicates mitochondrial damage and provides further evidence of alcoholic liver disease. Paradoxically, in patients suffering from liver cirrhosis of any etiology without ongoing liver injury the values may be normal.

COULD THE "MEASUREMENT LOCATION" AFFECT THE ALT AND AST ELEVATION DEGREE?

This point is clearly supported by some evidence. The causes of very high serum aminotransferase concentrations in a particular centre are influenced by its location, as noted in Swansea, Wales, where viral hepatitis accounts for only 3.5% of AST concentrations of over 400 U/L. Ischaemic/hypoxic liver injury accounts for a half, extrahepatic biliary obstruction for a quarter, and drug toxicity for 8.5% of the cases. This pattern reflects a highly developed community. In developing countries viral hepatitis is still prevalent, and toxic hepatitis is more likely and biliary obstruction from gallstones less likely to be encountered than they are in Swansea^[6].

ARE CLUES IN THE HISTORY AND CLINICAL EXAMINATION NECESSARY TO ASSESS ALT/AST LEVELS?

A recent study sought for identifying any benefit of routine LLTs, i.e., AST, ALT, total bilirubin, or alkaline phosphatase, in 268 consecutive, chronically ill, geriatric patients presenting for acute care from a long-term care facility. All were without jaundice, right upper quadrant pain, pruritus, bruising, or evident signs of chronic liver disease. The degree of LLTs abnormality during admission was compared to the clinical diagnosis at the time of discharge. The levels normalized within two days in 26 of these patients, 25 of whom had a history of vascular disease (96%). All but one of the 268 patients were

discharged without further evaluation. Over one year of follow-up, no patient returned for a liver-related problem. Based on these findings, only those patients with LLTs levels that are twice normal and which do not normalize within two days warrant further evaluation. Authors concluded that transient LLTs abnormalities may be due to decreased liver perfusion^[7].

CARDIOVASCULAR DISEASE EVALUATED BY A VINTAGE TEST

ALT is a marker of NAFLD presence (be aware of silent NASH) and predicts incident type 2 diabetes mellitus. Lately, ALT was shown to be also associated with endothelial dysfunction and carotid atherosclerosis^[8].

SHOULD NEW PERSPECTIVES BE APPLIED TO THE PROGNOSIS EVALUATION OF LIVER DISEASES?

In westernized countries metabolic, alcoholic and chronic viral disease represent the major part of hepatic illnesses. The search for markers of alcohol abuse has been dynamic for the past years. Several laboratory abnormalities based on liver enzymes, metabolic substances, hormone levels and haematological characteristics have been observed to be associated with the problem of drinking.

Due to its short half life, breath, urine or blood ethanol analyses provide scarce information about the entity of alcohol drinking, being an increased tolerance possibly identified. Blood or breath alcohol levels > 1.5% without great evidence of intoxication or > 3% at any time have been reported to be the first-level criterion of alcoholism.

An elevated serum level of membrane-bound enzyme, gamma-glutamyl transpeptidase (GGT) has been widely used as a marker of alcohol abuse. The half life of elevated GGT is between two and three weeks. Unfortunately, the sensitivity of GGT in detecting alcohol abuse has been reported to greatly vary (34%-85%).

GGT does not increase after acute alcohol intake, but needs continuous alcohol consumption of 80-200 g/d for several weeks. In addition to alcohol abuse, increased GGT is frequently found in NAFLD, heart failure and in subjects using antiepileptics, anticoagulants or barbiturates.

Mean corpuscular volume (MCV) is an index of red blood cell size. Increased MCV values have been observed in 34%-89% of alcohol abusers. Increased MCV values are also found in cases of vitamin B₁₂ and folic acid deficiency, chronic liver diseases, hypothyroidism, haematological disorders as well as among smokers. MCV responds slowly to abstinence and up to 40% may have an elevated MCV value even after three months of abstinence.

Other generally used markers are serum amino-transferase. These enzymes are more indicative of liver damage than of alcohol abuse. The overall sensitivity of AST has been estimated to be 35% as a marker of alcohol abuse^[9]. The sensitivity for ALT is even lower. One of the modern laboratory tests for alcohol abuse is serum carbohydrate deficient transferrin (CDT). The marker consists of the asialo, mono-sialo and di-sialo isoforms of

transferrin that are deficient in their terminal trisaccharides. False-positives have been reported in patients with severe liver diseases (primary biliary cirrhosis, chronic hepatitis C, hepato-cellular carcinoma) and in patients with genetic D-variant of transferrin. During abstinence, the CDT values normalize with a mean half-life of 15 d. CDT values seem to increase after one week of drinking at a level of at least 80 g ethanol per day. Obviously, the diagnosis of alcoholic liver disease (ALD) is based on alcohol consumption, physical signs and symptoms, and laboratory tests. In a recent study, the sensitivity and specificity of CDT for ALD was 93.4% and 71.9%, respectively^[10].

Alcoholism plays a key role in worsening any other liver disease! An up-to-date research using population-based mortality data to investigate whether heavy drinking affected the age of death among individuals with HCV was analyzed a total of 7263163 death records in the United States between 2000 and 2002. This study provided evidence to establish heavy alcohol consumption as one of the key risk factors contributing to premature deaths from HCV in the United States. Still, it pointed out that alcohol consumption affects men and women differently in HCV mortality^[11].

From a similar point-of-view, laboratory tests reflecting the "metabolic co-factor" linked to HCV-related chronic hepatitis should not be neglected.

WHICH LIVER DISEASE IS UNRAVELLED BY CHRONIC ABNORMAL ALT LEVELS?

Near 10% of the patients with chronically abnormal ALT levels show no evident relationship with any illness. The prognosis of this finding, the link with liver fibrosis and the need for a liver biopsy are largely unknown. The aim of a recent retrospective study in 67 patients with accidentally detected chronically elevated ALT levels, who had a liver biopsy, was to evaluate the prevalence of NASH, and the biological factors associated with this entity. Fibrosis scores were: F0, 37.3%; F1, 32.8%; F2, 26.9%; F3, 1.5%; and F4, 1.5%. NASH was absent in 59.7% and present in 40.3%. Significant differences were observed between F < 2 and F ≥ 2 fibrosis patients for AST and ALT and between patients with NASH or without for body mass index. The prevalence of F ≥ 2 fibrosis and NASH in patients with unexplained chronic abnormal ALT were 30% and 40%, respectively. Since the risk of F ≥ 2 fibrosis was significantly increased in patients with AST > N and/or ALT > 2N, liver biopsy, concluded the Authors, should be performed only in patients with AST > N or ALT > 2N^[12].

WHICH IS THE NORMAL RANGE OF ALANINE-AMINOTRANSFERASE?

The ULN of serum ALT was in these years challenged, because patients diagnosed with liver diseases may have 'normal' or near-'normal' ALT levels, and because possible modulators are often ignored in determining normal range. Some researchers reviewed medical records of subjects aged 15-90, who underwent standard panels of laboratory tests, including serum ALT, over 6 mo at a

central laboratory. Three groups were defined: Group 1, comprised total study population ($n = 272$). Group 2 ($n = 87$) comprised total study population, excluding those receiving potentially hepatotoxic drugs, or diagnosed with liver disease, or had any abnormal laboratory test results other than for triglycerides, cholesterol, glucose, or HbA1c. Group 3 ($n = 17$) the 'healthy' population, from whose ALT values we established the new ULN, comprised Group 2 subjects with normal triglycerides, cholesterol, glucose, and HbA1c levels. The results were intriguing. The 95th percentile ALT values, corresponding to the ULN, in groups 1, 2, and 3 were 50.1, 40, and 37.5 U/L, respectively. 6.2% of subjects whose ALT was below ULN listed by the test manufacturer (52 U/L), had ALT level above in their new ULN. Linear and logistic-regression analyses showed that ALT levels were significantly modified by gender, age, glucose, cholesterol, triglycerides, and overweight/obesity diagnosis^[13].

Elevated liver enzymes are infrequent in patients with Hepatitis C virus (HCV) infection undergoing chronic hemodialysis (HD), suggesting that ALT is a poor predictor of hepatocellular damage in this population. The objective of this research was to establish a more appropriate cut-off value of ALT to identify biochemical activity due to HCV infection in HD patients. A total of 217 patients, with an average age of 51.2 years, were evaluated in a single year; 130 were males (60%). Serum ALT was measured by a kinetic method in five consecutive monthly blood samples, from which an average was obtained and divided by ULN. The cut-off value of ALT was obtained from a ROC curve. Within the 217 patients, 18 (8.3%) were anti-HCV-positive, 17 (7.8%) of whom were also HCV-RNA-positive. Genotype distribution was: 1a = 47%; 1b = 18%; 3a = 35%. Mean ALT/ULN (0.77 ± 0.57) of the 18 anti-HCV-positive cases was higher than the negative group (0.38 ± 0.23). The mean ALT/ULN (0.81 ± 0.57) of the 17 HCV-RNA-positive cases was also higher than the negative cases (0.37 ± 0.23). The cut-off value of ALT to distinguish the anti-HCV-positive from negative patients was 0.50% or 50% of the ULN (sensitivity = 67%; specificity = 83%). According to the HCV-RNA, the cut-off value of ALT was 0.45% or 45% of the ULN (sensitivity = 71%; specificity = 80%). The Authors concluded that reducing the cut-off of ALT by half, enabled a better identification of biochemical activity in patients with HCV infection on chronic HD^[14].

ALT activity is the most widely used laboratory test for the recognition of liver disease. As aforementioned, normality limits for values of serum ALT activity have been questioned lately. One reason for this recent uncertainty may be an unrecognized decline in aminotransferase levels in the aging population. To verify such hypothesis a cross-sectional evaluation of the association between age and ALT activity was performed. Laboratory data of residents in single home for the aged and of adult subjects in three general practice clinics in Israel were reviewed, excluding subjects with known liver disease. One hundred and twenty-eight individuals from the home for the aged and 207 individuals from three family practices were included. The study ended up in finding out that ALT activity regressed with age creating

an inverted U curve with a peak at 40-55 years, (polynomial regression). According to age groups, serum ALT level was 19 ± 13 U/L in those under 40 year, 25 ± 19 U/L in 40-55 year olds, 22 ± 10 U/L in 56-72 year olds, 17 ± 9 U/L in 73-83 year olds, and 13 ± 5 U/L in 83-100 year olds. Gender also showed different levels for ALT, i.e., 22 ± 15 U/L in men, and 17 ± 11 U/L in women. Multiple regression analysis including age, gender revealed that age and gender retained association with ALT activity but not interestingly BMI. No such associations were noted for AST activity. These data suggest a significant inverted-U-like association between age and serum ALT activity. Thus, when interpreting the laboratory results of a subject suspected of liver disease, age should probably be taken into account^[15].

Despite the association between elevated ALT levels and liver diseases, the entity of the ALT elevation does not always correlate with the extent of liver cell damage. Accordingly, the ALT levels are of scarce prognostic value. It is noteworthy to stress that, currently, measurement of serum ALT levels is the most frequently used test to identify patients with liver diseases.

Other reports have questioned whether established values to define normal ALT/AST range are accurate and have suggested that the upper limit of normal should be revised. A study by Prati^[16], screening 6835 first-time blood donor candidates, demonstrates that ALT activity was independently related to body mass index (BMI) and to laboratory indicators of abnormal lipid or carbohydrate metabolism, as well as to sex. Still, the authors calculated "healthy" ranges for serum ALT level in 3927 donors who had a normal BMI and normal levels of serum glucose, cholesterol, triglyceride, and who were not taking medications. The upper limit of normal for ALT level decreased from 40 U/L to 30 U/L in men and from 30 U/L to 19 U/L in women. The new normal ranges increased the sensitivity for detection of patients with liver injury from 55% to 76% but decreased the specificity from 97% to 88%. But, should these more realistic values for normal ALT levels be widely adopted? Probably yes, because this would sensibly increase the number of asymptomatic patients with abnormal ALT values and would identify far more patients with NAFLD and clinically mild or occult HCV infection^[17].

The normal range for ALT/AST levels was set a half century ago and has never changed since then!

PROFILING THE OLD CUMBERSOME TESTS ON A NEW LIGHT: A RIGHT CHOICE?

An occurrence could be by the following study implanted to investigate if and to what extent antiviral therapy influenced a broad panel of quantitative testing of liver function (QTLF). Fifty patients with chronic hepatitis C were either treated with interferon, interferon/ribavirin or peg-interferon/ribavirin. QTLF, including aminopyrine breath test (ABT), galactose elimination capacity (GEC), sorbitol clearance (SCI) and indocyanine green clearance

(ICG) was performed before and 3 mo after initiation of antiviral therapy. After three months of antiviral treatment, 36 patients showed normal transaminases and were negative for HCV-RNA, 14 patients did not respond to therapy. ABT and GEC as parameters of microsomal and cytosolic liver function were reduced in all patients before therapy initiation and returned to normal values in the 36 therapy responders. Parameters of liver perfusion (SCI and ICG) were not affected by antiviral therapy. In the 14 non-responders, no changes in QTLF values were observed during the treatment period. Early determination of ABT and GEC may differentiate responders from non-responders to antiviral treatment in hepatitis C^[18].

An effort to simplify the “real” liver function tests, favouring their application on a large scale, at least in advanced forms, was present-day made by evaluating the TOSCA^[19].

SHOULD LABORATORY LIVER TESTS BE PERFORMED AFTER THE IMAGING RESULTS?

Some Authors speculated about the association between the severity of liver steatosis and MS in apparently healthy Korean adults. They examined 1022 men and women, aged 30-79 years, who participated in a health screening test. A standard interview, anthropometrics, biochemical studies, and abdominal UltraSonography (US) were conducted for each participant. Metabolic syndrome (MS) was defined according to the National Cholesterol Education Program Adult Treatment Panel III, lightly modified. The severity of liver steatosis was evaluated using liver US, and AST, ALT, and GGT levels were determined. The results clearly evidenced that the MS showed a stronger association with the severity of US steatosis than with the serum liver enzyme levels. The researchers advised that the degree of fatty infiltration detected on US could be used as an indicator of liver dysfunction attributable to metabolic abnormalities^[20].

IS GAMMA-GLUTAMYL TRANSPEPTIDASE A SERUM MARKER OF CHOLESTASIS/ALCOHOL-INDUCED DAMAGE/ ENZYMATIC INDUCTION ONLY?

Oxidative stress plays a crucial role in a variety of clinical settings including atherogenesis, and mediates many pathways linked to inflammation. GGT, an enzyme responsible for the extracellular catabolism of antioxidant glutathione, may directly take part in atherogenesis and evolve as a potential biochemical risk indicator of cardiovascular morbidity and mortality. Classically, GGT has been thought of as a diagnostic tool for hepatobiliary disorders and alcohol abuse. More recently, growing body of data points out that serum GGT levels can aid detection of individuals at high risk for subsequent cardiovascular events, and thus have an application in primary and secondary prevention of cardiovascular disease. Although

several investigations have shown that some drugs are effective in decreasing both serum lipids and GGT, and concomitantly the incidence of subsequent cardiovascular disease (CVD). Based on current experimental and epidemiological studies, Turgut postulates that GGT present in the serum, even within its laboratory reference intervals regarded as physiologically normal, is a promising biomarker for cardiovascular risk^[21].

An increase in serum GGT predicts onset of MS, incident CVD, and death suggesting that GGT is a marker of metabolic and cardiovascular risk^[22]. An unchanged or increased GGT level over time, even when GGT is in the normal range, is correlated with increasing insulin resistance and is associated with a risk of incident type 2 diabetes in both sexes, independently of baseline GGT, which is itself a diabetes risk factor^[23]. Also for other Authors, the role of GGT is different. In fact, it has been proposed that elevated serum GGT is an independent marker of the activation of systemic inflammation and increased oxidative stress, independent of their relationship to MS, and that the presence of MS and elevations of this liver enzyme may additively worsen the atherogenic state^[24].

ARE THERE ANY INTERESTING MARKERS ON THE EDGE?

A recent study, zeroing in on novel parameters, assessed the role of transforming growth factor-beta1 (TGF-beta1, as anti-apoptotic marker) and vascular endothelial growth factor (VEGF, as angiogenetic factor) in the pathogenesis of fibrosis associated with HCV-related chronic hepatitis and evaluated the influence of the antiviral therapy on above parameter levels depending on the treatment results^[25]. This research showed that a complete response in these patients is associated with significant changes in TGF-beta1 and VEGF.

FIBROSIS MARKERS: ARE THEY REALLY USEFUL?

Liver fibrosis is the excessive deposition and redistribution of extracellular matrix (ECM) in this organ induced by chronic injury. It leads to ultimately cirrhosis, characterized by progressive liver insufficiency/portal hypertension, and hepato-cellular carcinoma. There is a certain need for reliable, non-invasive, repeatable markers of fibrosis and fibrogenesis to substitute the invasive method (liver biopsy, which is burdened by a high degree of sampling error). A systematic literature search, using relevant papers, was timely performed to weigh the usefulness of non-invasive biomarkers of liver fibrosis^[26].

Serum biomarkers are differentiated in those reflecting ECM turnover (fibrogenesis and fibrolysis) and/or fibrogenic cell changes, mainly of Ito cells. They are procollagen peptides, hyaluronan, and laminin. The remainders are based on algorithmic evaluation of commonly observed liver alterations that do not necessarily reflect ECM metabolism or fibrogenic cell changes. Several numerical scores or indices are reported for parameters,

which are mostly routine laboratory tests and frequently multiparametric, e.g., panels. In good substance, although several serum markers and panels offer the opportunity to noninvasively assess the extent of liver fibrosis and spare some patients the risks associated with percutaneous liver biopsy, only a few of them allow the determination of different stages of fibrosis on a continuum similar to that achieved with liver biopsy^[27].

Indeed, hyaluronic acid is considered an accurate variable for the severity of hepatic inflammation and fibrosis^[28].

Conclusively, the impact of both classes of biomarkers for diagnosis and monitoring of fibrosis, fibrogenesis, and fibrolysis is limited. They cannot replace needle biopsy even though some of them, generally expensive, might be complementary in follow-up studies. Transient elastography could be a valid alternative choice.

FINAL CONSIDERATION

Unfortunately, it is true that new reports that advice the practitioners about the clinical utility of various diagnostic tools, when embraced, make the health care costs increase without expanding the diagnostic-prognostic horizon, with very few exceptions.

To make the hepatologists' life a little more complicated, some computations have been advanced. For example, the model of end-stage liver disease (MELD) score has gained acceptance over the Child-Pugh (C-P) score in predicting survival in patients with decompensated cirrhosis, although it is more sophisticated. A suggestive research compared the predictive values of MELD, C-P and creatinine-modified C-P scores in decompensated cirrhosis. The areas under the receiver operating characteristic curves did not differ significantly among the four scores. In Cox regression analysis, all four scores were significantly associated with survival, while MELD and creatinine-modified C-P scores had better predictive values than C-P score. Adjustment for GGT (*de novo*) levels increased the predictive values of all systems. Thus, MELD compared to the C-P classification does not appear to offer a clear advantage in predicting survival in patients with decompensated cirrhosis in daily clinical practice^[29].

Still, the MELD model is only slightly superior to the Child-Pugh classification for the prediction of long-term survival in TIPS patients^[30].

The "ancient" serum total bilirubin, present in MELD as well as in C-P scores, offers the best single prognostic factor in evaluating liver cirrhosis progression, except for patients suffering from Gilbert syndrome.

Prothrombin activity (expressed in time or percentage or as INR) should be regarded as a clue of disseminated intravascular coagulation.

Alcoholic liver injury: Pathological features and models

From the editor

In this 9-topic review series, we will provide an insight into the pathogenesis of alcohol-mediated liver damage. The aspects addressed in the reviews cover the most important pathological features induced by ethanol/or ethanol metabolism: dysregulation of cell cycle progression, immune response, impaired protein hydrolysis by proteasome and steatosis and apoptosis induction. The mechanisms of ethanol-elicited liver injury are related to compromised transmethylation, involvement of ethanol in iron metabolism and emerging roles of mitochondria and free radicals in establishment and progression of liver damage. These events are observed not only in hepatocytes, but also in some other liver cells, including the sinusoidal endothelial cells and immune cells. At the molecular level, these pathological symptoms are progressing due to the altered signal transduction processes, which further impair cell functions. To study the alcohol-induced cell damage, certain adequate cell models, including polarized hepatic cells, are developed. The following reviews written by well-established scientists with a long-term expertise in the field of alcohol-induced liver injury.

Abstract

Patients with alcoholic liver disease frequently exhibit increased body iron stores, as reflected by elevated serum iron indices (transferrin saturation, ferritin) and hepatic iron concentration. Even mild to moderate alcohol consumption has been shown to increase the prevalence of iron overload. Moreover, increased hepatic iron content is associated with greater mortality from alcoholic cirrhosis, suggesting a pathogenic role for iron in alcoholic liver disease. Alcohol increases the severity of disease in patients with genetic hemochromatosis, an iron overload disorder common in the Caucasian population. Both iron and alcohol individually cause oxidative stress and lipid peroxidation, which culminates in liver injury. Despite these observations, the underlying mechanisms of iron accumulation and the source of the excess iron observed in alcoholic liver disease remain unclear. Over the last decade, several novel iron-regulatory proteins have been identified and these have greatly enhanced our understanding of iron metabolism. For example, hepcidin, a circulatory antimicrobial peptide synthesized by the hepatocytes of the liver is now known to play a central role in the regulation of iron homeostasis. This review attempts to describe the interaction of alcohol and iron-regulatory molecules. Understanding these molecular mechanisms is of considerable clinical importance because both alcoholic liver disease and genetic hemochromatosis are common diseases, in which alcohol and iron appear to act synergistically to cause liver injury.

INTRODUCTION

Iron is essential for an array of key biological processes including erythrocyte production, DNA synthesis and cellular respiration^[1-3]. The normal iron content of the body in an adult male is 35 to 45 mg of iron per kilogram of body weight^[2]. The majority of the iron is bound to hemoglobin in erythrocytes. The rest is incorporated into myoglobin in the muscle, the tissue enzymes and plasma transferrin^[2]. Parenchymal cells of the liver and reticuloendothelial macrophages serve as depots for excess iron storage^[2,4]. However, due to its potential to take part in the Fenton reaction as a transition metal, iron can also be toxic to the cell^[5,6]. Hepatic iron overload is common in many liver diseases, where iron is a risk factor in disease progression^[7-13].

IRON AND ALCOHOL

Alcoholic liver disease (ALD) patients frequently display evidence of iron overload^[14-18]. Recently, even mild to moderate alcohol consumption has been shown to elevate the indices of iron stores^[19]. Suzuki *et al*^[20] have demonstrated elevated expression of transferrin receptor-1 in ALD patients by immunohistochemical analysis of liver biopsy samples. Moreover, Kupffer cells isolated from experimental animal models of ALD also display increased iron content^[21,22]. It is a well established fact, that both iron and alcohol individually cause oxidative stress and lipid peroxidation^[6,23-26]. Hence, alcohol induced iron overload enhances the production of free radicals and proinflammatory cytokines, thereby leading to liver injury^[11,12,27]. Elegant studies with experimental animal models of ALD have demonstrated, that increased iron content in Kupffer cells leads to the activation of the transcription factor, nuclear factor-kappa (NF- κ B), and increased expression of the proinflammatory cytokine, tumor necrosis factor-alpha (TNF- α)^[21,22,28]. These effects were abolished by iron chelation^[29], thereby indicating a role for iron-mediated cell signaling in the pathogenesis of experimental alcoholic liver disease.

The iron overload disorder, genetic hemochromatosis (GH), is one of the most prevalent genetic diseases in

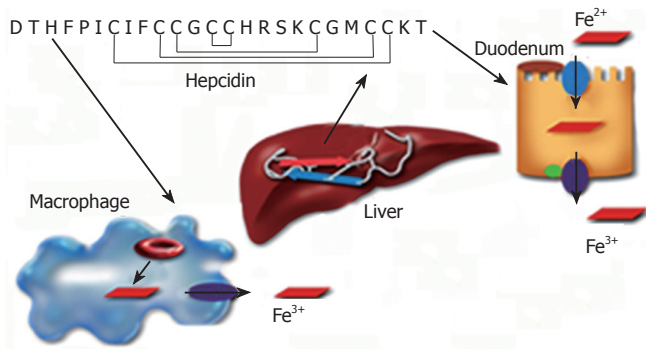

Figure 1 Regulation of iron metabolism by hepcidin. Hepcidin peptide, which is synthesized by the liver and released into the circulation, regulates iron homeostasis by inhibiting duodenal iron transport and the release of iron from macrophages.

individuals of Caucasian origin^[30-32]. The majority of GH patients are homozygous for a C282Y mutation in their Hfe gene^[33,34]. Excessive alcohol consumption has been reported to exacerbate liver injury in GH patients homozygous for the C282Y mutation of Hfe gene^[35]. However, despite all these findings, the underlying mechanisms of iron accumulation observed in alcoholic liver disease, and the source of the excess iron remain elusive. *In vivo* whole-body retention studies have demonstrated a two-fold increase in intestinal iron absorption in chronic alcoholics^[36]. Changes in intestinal permeability are thought to be the underlying mechanism of enhanced intestinal iron absorption^[36]. Of note, hepatocytes are the primary site of iron storage in the liver, and iron may also leak out of injured hepatocytes. However, it is also feasible that the iron stores in alcoholic patients are increased through recognized regulatory mechanism(s). Significant advances have been made with the discovery of novel iron-regulatory molecules in recent years, which have improved our understanding of iron metabolism. Studying the regulation of these molecules by alcohol is important for understanding the underlying mechanisms of iron overload in alcoholic liver disease.

IRON-REGULATORY MOLECULES

Since there is no physiological pathway of excretion for excess iron in the body, the uptake, transport and storage of iron must be tightly regulated^[37-41]. A series of novel iron-regulatory molecules including iron transporters and soluble mediators have recently been identified. Divalent metal transporter 1 (DMT1, also known as Nramp2) is a multi-transmembrane protein^[42], responsible for importing dietary non-heme iron through the apical site of absorptive enterocytes in the duodenum^[42]. Studies employing mice with the targeted deletion of DMT1 in the duodenum have confirmed the role of DMT1 in intestinal iron absorption^[43]. Conversely, ferroportin (also known as MTP1, Ireg1) exports iron into the bloodstream^[44-46]. As a transition metal, iron undergoes reduction and oxidation reactions during these cellular uptake and export processes. Understanding the mechanisms involved in these reactions and identifying the candidate enzymes will require further investigation^[47-49]. Iron circulates in the plasma by binding

to the glycoprotein, transferrin (Tf). Iron-laden Tf is taken up into the cell by forming complexes with transferrin receptor-1, TrfR1^[2,50]. Recently, another homologous receptor, TrfR2 has been identified^[51]. Unlike TrfR1, which is ubiquitously expressed, TrfR2 is mainly expressed in the liver^[51].

The regulation of iron metabolism involves multiple organs including the duodenum, liver and bone marrow. Hence, the presence of soluble mediators has long been suspected. The discovery of hepcidin peptide has not only confirmed these notions but also highlighted the importance of the liver in the regulation of iron homeostasis. Hepcidin is an antimicrobial peptide, which was first isolated from human urine and blood^[52,53]. It is synthesized in the hepatocytes of the liver as an 84 amino acid precursor protein, which is subsequently cleaved into the 25 amino-acid disulphide-bridged active peptide form^[54,55]. Mice express two copies of the hepcidin gene, Hpc1 and Hpc2, resulting from a tandem duplication of the hepcidin gene^[54,56,57]. Transgenic mice studies have confirmed a role for hepcidin in the regulation of iron metabolism. Hepcidin knockout mice develop iron overload in the liver, pancreas and heart^[58], whereas mice overexpressing hepcidin display severe iron deficiency and anemia^[59]. Hepcidin synthesis in the liver is sensitive to body iron levels; increasing with iron overload and decreasing in the case of iron deficiency^[54,60,61]. Interestingly, hepcidin is also regulated by inflammatory signals, and the inflammatory cytokines, IL-1 and IL-6^[62-65]. However, the role of Kupffer cells in the regulation of hepcidin expression by inflammation is controversial^[66,67].

Hepcidin plays a central role in the regulation of iron metabolism by inhibiting intestinal iron transport and the release of iron from macrophages (Figure 1)^[60,61]. Hepcidin achieves this by binding to the iron exporter ferroportin and inducing its internalization and degradation^[68,69]. Studies with both hemochromatosis patients and transgenic mouse models have identified candidate proteins, which modulate hepcidin synthesis in the liver (Figure 2A)^[70-74]. Hemochromatosis patients, homozygous for the expression of TrfR2 mutations display increased transferrin saturation but reduced urinary hepcidin levels^[70]. Despite the iron overload phenotype, expression of hepcidin in the livers of TrfR2 knockout mice is similar to that of control littermates^[72,75]. Similarly, both genetic hemochromatosis patients with Hfe mutations and Hfe transgenic mice display significantly reduced hepcidin expression in the liver^[73,74]. Taken together, these studies demonstrate a role for both TrfR2 and Hfe in the regulation of hepcidin expression in the liver. However, the underlying mechanisms are unknown. Recently, the juvenile hemochromatosis gene hemojuvelin, has been shown to regulate hepcidin expression via the bone morphogenetic protein (BMP) signaling pathway in the liver (Figure 2A)^[76,77].

The promoter of the hepcidin gene harbors consensus binding sites for several transcription factors including C/EBP- α , HNF4- α , Stat3 and Smad4^[78-81]. CCAAT/enhancer-binding protein alpha (C/EBP- α) plays a role in the iron-mediated regulation of hepcidin gene transcription^[78].

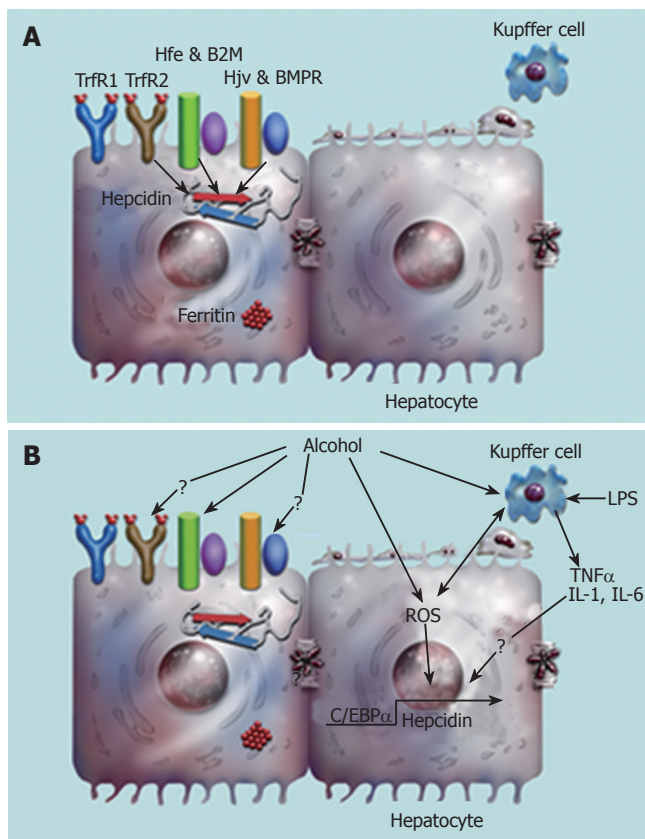

Figure 2 A: Modulators of hepcidin synthesis in the liver. Transferrin receptor 2 (TrfR2), Hfe and beta-2 microglobulin (B2M) complex; hemojuvelin (HJV) and bone morphogenetic protein receptor (BMPR) complex. B: Alcohol-mediated regulation of hepcidin transcription in the liver may involve both parenchymal and non-parenchymal cells of the liver.

ALCOHOL AND HEPCIDIN

Alcohol consumption increases the transfer of both iron and endotoxin from the intestine into the circulation^[36,82]. Hepcidin synthesis in the liver is regulated by iron and inflammation, with hepcidin playing a central role in iron homeostasis^[54,58,59,62,63,69,83]. Hence, a role for alcohol is implicated in the regulation of hepcidin expression in the liver. Indeed, alcohol was found to down-regulate hepcidin expression both *in vitro* with alcohol metabolizing hepatoma cells, and *in vivo* with mice subjected to short-term alcohol exposure^[84]. The effect of alcohol on hepcidin expression in hepatoma cells was abolished by 4-methylpyrazole, a specific inhibitor of the alcohol metabolizing enzymes^[84]. Furthermore, alcohol did not alter the expression of transferrin receptor-1 and the iron storage protein, ferritin, or the activation of iron regulatory RNA-binding proteins, IRP1 and IRP2^[84]. These findings demonstrate that alcohol does not regulate hepcidin expression by altering the iron status of the cell but rather acts on hepcidin directly. Short-term alcohol exposure down-regulated hepcidin 1, but not hepcidin 2 mRNA expression in mice^[84]. Similarly, iron has also been shown to up-regulate hepcidin 1 gene expression in mice^[57]. Furthermore, rats with chronic alcohol exposure also display reduced hepcidin expression^[85,86]. Collectively, these studies demonstrate a role for alcohol in the regulation of hepcidin expression in the liver.

Alcohol-mediated down-regulation of hepcidin expression in the liver leads to elevated expression of the iron transporter proteins, DMT1 and ferroportin in the duodenum^[84]. This effect is abolished by injecting mice with the hepcidin peptide confirming a role for hepcidin in the alcohol-mediated increase in duodenal iron transporter protein expression^[84]. The increase in intestinal iron transporter expression leads to increased intestinal iron absorption, and hence to increased body iron indices. A recent study has also reported increased serum iron in mice exposed to alcohol^[87]. We have observed an increased expression of the iron storage protein, ferritin in the livers of rats with chronic alcohol exposure^[86]. Taken together, these findings suggest that iron overload observed in patients with alcoholic liver disease is mediated by regulatory mechanisms, and that the alcohol-mediated down-regulation of hepcidin synthesis in the liver may be one of the underlying mechanisms of iron overload.

Hepcidin synthesis in the liver responds to body iron levels, and is up-regulated by iron overload *in vivo*^[54,61,83]. This raises the question of whether the alcohol-induced decrease in liver hepcidin expression would be sustained while the body iron levels progressively increase through continued alcohol consumption. It is feasible that the decrease in liver hepcidin expression may only be an initial response to alcohol, which may eventually be negated by elevated iron levels. On the other hand, it is also possible, that hepcidin expression in the liver is continuously suppressed by alcohol despite the iron overload state, which will eventually lead to liver injury. Thus, we investigated the combined effect of iron and alcohol in the regulation of hepcidin expression. Despite iron overload, alcohol down-regulated the expression of hepcidin in the liver^[86] demonstrating that alcohol renders liver hepcidin synthesis insensitive to body iron levels. A further decrease in hepcidin expression was also observed in Hfe knockout mice exposed to alcohol^[86]. It is worth noting that hepcidin protects the body from iron overload by inhibiting duodenal iron uptake and iron release from macrophages (Figure 1)^[60,61,69]. These findings suggest that the mechanisms which protect the body from the harmful effects of iron overload (e.g. increased hepcidin expression and decreased iron uptake and storage) are compromised by alcohol^[86].

Both iron and alcohol induce oxidative stress and oxidative stress plays an important role in alcoholic liver disease^[23-25,88-90]. Treatment with antioxidants abolished the effect of alcohol on hepcidin expression in the liver and on duodenal iron transporter expression in the duodenum^[84]. These findings strongly suggest a role for acute alcohol-induced oxidative stress in the regulation of hepcidin expression. Alcohol down-regulated both hepcidin promoter activity and the DNA-binding activity of the transcription factor, C/EBP alpha. This effect was abolished by treating mice with antioxidants^[84]. Furthermore, alcohol also inhibited the iron-mediated up-regulation of C/EBP activity in the liver^[86]. These findings demonstrate that redox changes and oxidative stress associated with alcohol metabolism regulate hepcidin gene transcription by altering C/EBP alpha activity. Oxidative stress is therefore one of the mechanisms by which

moderate alcohol consumption regulates liver hepcidin expression and hence iron homeostasis, without causing steatosis or apparent liver injury (Figure 2B)^[84].

Hepcidin is expressed in hepatocytes of the liver^[54]. However, we observed a more prominent down-regulation of hepcidin expression *in vivo* compared to *in vitro* in hepatoma cells suggesting a role for non-parenchymal cells of the liver in the regulation of hepcidin expression^[84]. Kupffer cells play an important role in the progression of alcoholic liver disease^[13,91]. Since alcohol down-regulates, and inflammation up-regulates hepcidin expression^[62,63,84,85], this raises the question of whether Kupffer cells and inflammation play a role in alcohol-mediated regulation of hepcidin expression. Recently, we have shown a role for oxidative stress in the regulation of hepcidin transcription by alcohol^[84]. Alcohol metabolism induces oxidative stress in the hepatocytes and Kupffer cells of the liver^[13,90,91]. Oxidative stress leads to the release of the pro-inflammatory cytokine, TNF- α from activated Kupffer cells^[12,13,92,93]. TNF- α has been reported to down-regulate hepcidin expression *in vitro*^[62]. Thus, alcohol-mediated regulation of hepcidin expression may involve both the hepatocytes and Kupffer cells of the liver (Figure 2B). The role of parenchymal and non-parenchymal cells of the liver, and the proinflammatory cytokines in the regulation of hepcidin expression by alcohol requires further investigation.

CONCLUSION

A role has been established for alcohol in the regulation of hepcidin expression in the liver. Alcohol-mediated oxidative stress inhibits C/EBP- α DNA-binding activity and down-regulates hepcidin transcription in the liver. Increased down-regulation of hepcidin expression by alcohol may play a role in the disease severity of genetic hemochromatosis patients in combination with alcohol intake. Down-regulation of hepcidin expression in the liver leads to increased intestinal iron transporter expression. Moreover, alcohol also abrogates the protective effect of hepcidin in iron overload by rendering the synthesis of hepcidin in the liver insensitive to body iron levels. Deregulation of hepcidin synthesis in the liver may be one of the underlying mechanisms by which alcohol consumption leads to iron overload. Ultimately, iron acts as a secondary risk factor in alcoholic liver disease. A better understanding of the molecular mechanisms underlying the regulation of iron homeostasis by alcohol may help us to develop therapeutic strategies or diagnostic tools to detect alcohol-induced liver injury at earlier stages before it develops into a chronic disease with irreversible liver damage.

Abstract

The proteasome is a major protein-degrading enzyme, which catalyzes degradation of oxidized and aged proteins, signal transduction factors and cleaves peptides for antigen presentation. Proteasome exists in the equilibrium of 26S and 20S particles. Proteasome function is altered by ethanol metabolism, depending on oxidative stress levels: low oxidative stress induces proteasome activity, while high oxidative stress reduces it. The proposed mechanisms for modulation of proteasome activity are related to oxidative modification of proteasomal proteins with primary and secondary products derived from ethanol oxidation. Decreased proteolysis by the proteasome results in the accumulation of insoluble protein aggregates, which cannot be degraded by proteasome and which further inhibit proteasome function. Mallory bodies, a common signature of alcoholic liver diseases, are formed by liver cells, when proteasome is unable to remove cytokeratins. Proteasome inhibition by ethanol also promotes the accumulation of pro-apoptotic factors in mitochondria of ethanol-metabolizing liver cells that are normally degraded by proteasome. In addition, decreased proteasome function also induces accumulation of the negative regulators of cytokine signaling (I- κ B and SOCS), thereby blocking cytokine signal transduction. Finally, ethanol-elicited blockade of interferon type 1 and 2 signaling and decreased proteasome function impairs generation of peptides for MHC class I-restricted antigen presentation.

INTRODUCTION

The steady state level of proteins depends on their rates of synthesis and degradation. The proteasome is a major protein-degrading enzyme, which has a predominant role in intracellular protein catabolism. This enzyme influences various cell functions, as the enzyme not only hydrolyzes obsolete and oxidized proteins, thereby preventing cellular toxicity, but also regulates signaling events by destroying short-lived signal transduction factors and by controlling apoptotic cell death. Another important function of the proteasome is the generation of peptides for MHC class I-restricted antigen presentation. Recently, the proteasome has been shown as a potent regulator of the circadian cycle^[1] by its role in degradation of Cryptochrome and Period proteins. Besides proteolysis, the proteasome has non-proteolytic functions, regulating transcription, DNA repair and chromatin remodeling^[2].

PROTEASOME STRUCTURE AND FUNCTIONS

In mammalian cells, proteasome is localized mainly in the cytosol and the nucleus^[3]. It plays an important role in proteolytic centers within the cells, such as the centrosome, a perinuclear structure. Targeted proteins are transported to the centrosome for degradation, which is carried out by two proteasome structures, the 26S and 20S proteasomes. The 26S proteasome consists of core proteasome (20S proteasome) and two 19S (PA700) regulatory particles^[4]. The 20S proteasome is a large complex, which has four stacks containing 14 different gene products and is organized as outer alpha (α) subunits that "shape" 20S proteasome and beta (β) subunits that constitute the 20S catalytic core subunits (β 1, β 2 and β 5, or Y, Z and X). β subunits have various activities, based on the ability to cleave either hydrophobic bonds (chymotrypsin-like

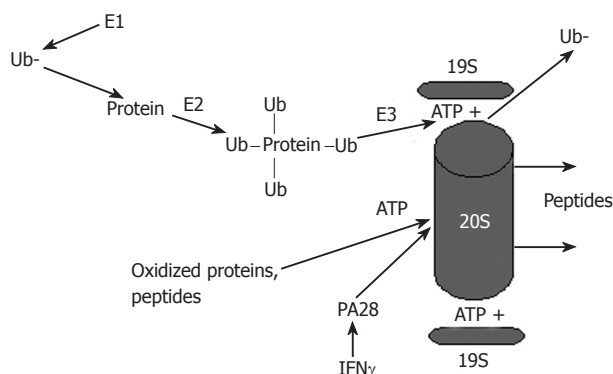

Figure 1 Proteasome-dependent degradation of proteins by the 26S and the 20S proteasome. Proteins undergo ubiquitylation and are degraded in an ATP-dependent manner by the 26S proteasome, which activity is regulated by the 19S particle. Alternatively, oxidized proteins can be degraded by the 20S proteasome. This degradation is ATP-independent and is regulated by the 20S proteasome activator, PA28.

activity), basic bonds (trypsin-like activity), or acidic bonds (caspase-like activity). The 20S proteasome exists in two forms: constitutive proteasome and immunoproteasome. The immunoproteasome subunits, LMP2, LMP7 and MECL-1, replace the constitutive subunits, usually under the influence of IFN γ ^[2]. The immunoproteasome is involved in generation of MHC class I-restricted peptides for antigen presentation. The efficiency of peptide cleavage by the immunoproteasome is higher than by the constitutive proteasome^[5]. Mice lacking the LMP7 subunit have reduced antigen presentation^[6]. Recently, interferon type 1 (IFN α) has been reported as an effective inducer of immunoproteasome in liver cells^[7]. Unpublished results from our laboratory confirmed this finding in hepatoma cell lines stimulated with IFN α .

ATP-DEPENDENT AND INDEPENDENT HYDROLYSIS OF PROTEINS BY PROTEASOME

Degradation of proteins by proteasome may or may not require ATP. The 26S proteasome catalyses protein degradation in an ATP-dependent manner, while the 20S proteasome does it ATP-independently. The most important question is how the proteasome “senses” the proteins, which are to be degraded. 26S proteasome usually recognizes proteins, which are marked with ubiquitin, a small 8.5-kDa protein that is covalently attached to protein substrate. To be attached, ubiquitin is activated by E1, the ubiquitin-activating enzyme (Figure 1). Activated ubiquitin is transferred *via* a high-energy thiol ester intermediate, E2-ubiquitin-conjugating enzyme, to the protein substrate destined for degradation. Protein covalently attaches multiple ubiquitin molecules that generate polyubiquitin chain binding to internal lysine (lysine 48) residue. If the substrate protein binds to monoubiquitin (i.e. one ubiquitin molecule per residue) instead of polyubiquitin (K48), it is targeted for degradation by the lysosome. Linkage through Lys 48, is associated with the ubiquitin-proteasome pathway, while Lys 63 linkage has a role in the

inflammatory response, endocytic pathway, and ribosomal protein synthesis^[8]. The ubiquitin-conjugated protein is subjected for degradation by the 26S proteasome with a help of E3 ligase. To be ubiquitylated and recognized by proteasome, the substrates usually undergo post-translational modification, such as phosphorylation and oxidation. For recognition by E3, in certain cases proteins may require association with molecular chaperones^[9].

The important functions of the 19S particle in 26S proteasome are to recognize ubiquitylated proteins and to open the aperture of the 20S proteasome α -rings to allow substrate entry into the catalytic core. The 19S particle unfolds ubiquitylated substrates, dissociates from ubiquitin with the help of de-ubiquitylating enzymes for further ubiquitin recycling and inserts the proteins into the 20S proteasome for degradation. This insertion needs ATP hydrolysis and is controlled by ATPases, which forms 19S sub-complexes known as the base and the lid.

Alternatively, degradation of non-ubiquitylated proteasome substrates can be carried out in an ATP- and ubiquitin-independent manner by the 20S proteasome, which requires the gate opening by the activators, PA28 α , β and γ (Figure 1). PA28 α and β are predominantly located in the cytosol, whereas PA28 γ has a nuclear localization. PA28 enhances hydrolysis of short peptides. In mice, disruption of PA28 α and β genes leads to defective generation of MHC class-restricted peptides^[10], while mice with disrupted PA28 γ gene have slower cell proliferation and enhanced susceptibility to apoptosis. Functions of the PA28 are antagonized by proline-rich proteins, PI31 and Pr39, which, *in vitro*, block proteasome activity^[11,12].

20S proteasome can be simultaneously activated by both 19S and PA28 *via* the two outer rings. This structure is called a hybrid proteasome, which displays the catalytic properties of both the 26S and 20S forms of the proteasome. These hybrid proteasomes generate a unique spectrum of antigenic peptides for presentation in an ubiquitin-dependent as well as ubiquitin-independent ways^[13].

ETHANOL METABOLISM AND LIVER PROTEASOME FUNCTION

The liver is the main site of ethanol metabolism. Hepatocytes express the major ethanol metabolizing enzymes, alcohol dehydrogenase (ADH) and cytochrome P450E1 (CYP2E1), which catalyze the generation of acetaldehyde and reactive oxygen/nitrogen species when liver cells are exposed to ethanol. The level of intracellular oxidative stress depends on the balance between oxidative and protective (antioxidant systems) factors. The level of oxidative stress differentially regulates proteasome function (i.e. low oxidative stress enhances proteasome activity, while high oxidative stress suppresses it).

There is a reciprocal relationship between CYP2E1 and the proteasome. Studies on HepG2 cells that overexpress CYP2E1 showed that ethanol and other CYP2E1 ligands increase the content and activity of CYP2E1 without affecting CYP2E1 mRNA^[14,15]. Pulse-chase experiments demonstrated that ethanol and other ligands stabilize the

enzyme against proteolysis. The proteasome is responsible for CYP2E1 degradation since treatment with the proteasome inhibitor, PSI, which blocks its chymotrypsin-like activity, caused a dose-dependent increase in the CYP2E1 apoprotein. Heat shock proteins 70 and 90 provide the communication between CYP2E1 and the proteasome^[16,17].

Stabilization of CYP2E1 by ethanol, in turn, results in increased production of ethanol metabolites, which block proteasome function. *In vitro* treatment of VL-17A cells (ADH/CYP2E1-positive HepG2 cells) with 100 mmol/L ethanol significantly reduces proteasome activity^[18,19] as well as the ability of crude proteasome preparations (cytosols) from VL-17A cells to hydrolyze HBV peptide cleavage^[20]. The effects of ethanol exposure are blocked by treatment with inhibitors of ethanol metabolism and CYP2E1 activity. *In vivo*, proteasome inhibition is common in rodents intragastrically fed with ethanol^[21,22]. The proteasomal chymotrypsin-like activity reduction in intragastrically fed rats was blunted in animals treated with a CYP2E1 inhibitor, chlormethazole^[23]. Furthermore, suppression of proteasome activity by ethanol was established in wild-type mice, but not in ethanol-fed CYP2E1 knockout mice^[24]. In orally fed mice, the effect on the proteasome depends on blood ethanol levels achieved after chronic ethanol feeding: usually when blood ethanol exceeds 40 mmol/L, there is a suppression of proteasome function. However, lower blood ethanol levels sometimes result in proteasome activation^[21].

The proposed mechanisms for modulation of proteasome activity are related to oxidative modification of proteasomal proteins with primary and secondary products derived from ethanol oxidation. Thus, CYP2E1 activation, reactive oxygen species formation and subsequent adduction of proteasome with protein carbonyls in E47 cells (CYP2E1⁺ HepG2 cells) caused a decline in the trypsin-like, proteasome activity^[25]. Furthermore, *in vivo* ethanol studies on intragastrically fed rats demonstrated significant induction of CYP2E1 and an increase in 4-hydroxynonenal (4-NHE) concentrations after one month of ethanol feeding, which resulted in decreased proteasome activities^[26]. While a 3.5-fold CYP2E1 induction occurred after 15 d of feeding, there was no loss in proteasome activity, indicating that modulation of proteasome activity is a delayed response to CYP2E1-induced proteasome oxidation. Proteasome suppression was attributed to 4-HNE adducts of the 19S (PA700) proteasome regulator specifically an ATPase Rpt4 subunit. It was postulated that this adduction caused disrupted association between the 19S and 20S proteasome particles. In addition, our laboratory discovered the regulating effects of nitration on proteasome function. Nitration is caused by peroxynitrite, a reaction product of superoxide (generated by CYP2E1) and nitric oxide (generated by nitric oxide synthase), which is released as a result of ethanol metabolism and is involved in alcohol-induced liver injury^[27]. Massive nitration of 20S proteasome with subsequent 3-NT adduct formation caused a reduction of chymotrypsin-like proteasome activity, primarily due to reduced interaction between

PA28 and the 20S proteasome. Interestingly, low levels of nitration activated proteasome function and enhanced proteasome activation by PA28^[28]. Similar effects of the peroxynitrite donor, SIN-1, were observed using highly purified proteasome, cultured hepatoma cells and rodent livers. Immunoproteasome has been shown to be more sensitive to the effects of peroxynitrite than the constitutive form of the enzyme^[29]. Studies on the 26S proteasome (4-HNE adducts) and on the 20S proteasome (3-NT adducts) revealed that in oxidatively modified proteasome, the ability of 20S proteasome to respond to activating stimuli of its regulators, 19S proteasome and PA28 is limited, which impedes proteasome function. The 26S proteasome is more susceptible to oxidative stress than 20S proteasome^[30].

Another potent oxidant generated by ethanol metabolism, acetaldehyde, which is produced by ADH and CYP2E1 has also been shown to affect proteasome function. *In vitro* adduction of acetaldehyde to cytosolic proteins inhibits proteasome function in a dose-dependent manner^[31]. We also observed suppression of proteasome activity in hepatoma cells treated with 400 mmol/L acetaldehyde (Osna, unpublished observation). Thus, not only CYP2E1, but also ADH by generating ethanol metabolites can contribute to proteasome inhibition.

OXIDATIVE MODIFICATION OF PROTEINS: AGGREGATION AND PROTEASOME FUNCTION

The inability for ubiquitylated proteins to be degraded by proteasome is based not only on impaired proteasome activity but also on the relative susceptibility of substrates to degradation. Proteasomal substrates (proteins) can be modified by oxidation of amino acid residues by intracellular oxidants, such as H₂O₂ or by covalent binding to reactive species, such as peroxynitrite. Depending on their degree of modification, these substrates become either more or less susceptible to proteasome-catalyzed hydrolysis. Thus, when aconitase was treated with peroxynitrite and hydrogen peroxide, low concentrations of oxidants (up to 2 mmol/L for hydrogen peroxide and up to 1 mmol/L for peroxynitrite) enhanced susceptibility of aconitase to degradation, while higher concentrations of oxidants decreased proteolysis^[32].

Ubiquitin is essential for ATP-dependent protein degradation by the proteasome. Under certain pathological conditions or due to genetic predisposition, defective ubiquitin + 1 (Ub + 1) is generated by a dinucleotide deletion in Ub mRNA. Proteins ubiquitylated with Ub + 1 are the substrates for proteasomal degradation, but at high concentrations of Ub + 1, the degradation is inhibited^[33]. Ub + 1 forms tight noncovalent interactions with target proteins and cannot be removed from the substrate (Luders *et al.*^[34], 2003). The accumulation of Ub + 1-labeled undegraded proteins is observed in neurological disorders (e.g. Huntington's Disease, Alzheimer's Disease and Down's Syndrome).

Decreased proteolysis by the proteasome also results in the accumulation of insoluble protein aggregates, which

cannot be degraded by proteasome and which further inhibit proteasome function. In patients with alcoholic cirrhosis, the aggregates are known as Mallory bodies or so-called alcoholic hyaline^[35,36] and are a common signature of alcoholic liver diseases. Mallory bodies are formed by liver cells when proteasomes are unable to remove cytokeratins, mainly cytokeratins 7 and 19^[37]. Experimental studies revealed that the blockade of proteasome with specific inhibitors or by ethanol metabolism induces overexpression of heat shock proteins and Mallory body formation, which was observed both *in vivo* and *in vitro*^[38,39]. Ub + 1 has also been detected in Mallory bodies, which is a common histological signature of alcoholic liver disease. *In vitro* delivery of Ub + 1 to mouse hepatocytes caused formation of aggresomes and Mallory body formation^[38].

THE UBIQUITIN-PROTEASOME SYSTEM AND ETHANOL-INDUCED CELL DEATH

Proteasome function controls cell death and survival under the normal and pathological conditions. Thus, suppression of proteasome function with specific proteasome inhibitors results in increased cell death. The link between the proteasome function and cell survival is supported by the fact of degradation of certain cell cycle controlling and pro- or anti-apoptotic factors by the 26S proteasome. Because apoptotic events are downstream from proteasome function and ethanol suppresses proteasome activity, it may be possible that proteasome inhibition would promote the accumulation of pro-apoptotic factors in mitochondria of ethanol-metabolizing liver cells. Ultimately, it might stimulate liver cell apoptosis.

Inhibition of the 26S proteasome causes hepatotoxicity *in vitro* and *in vivo*. In Hep G2 cells transfected with CYP2E1, the amount of cell death by apoptotic mechanism depended on actual CYP2E1 activity^[40]. We also observed elevation of caspase 3 activity in VL-17A cells exposed to 100 mmol/L ethanol^[19]. In addition, a proteasome inhibitor, MG132, injected to mice 4 h prior to TNF α injection, sensitized liver cells to TNF α -induced apoptosis^[41]. In ethanol non-metabolizing cells, there is a negative feedback between chemotrypsin-like activity of proteasome and caspase-3 activation, when cells were treated with staurosporin. Furthermore, thymocytes, which normally are rich with proteasome, have declined proteasome activity when they underwent apoptosis after dexamethasone treatment^[42].

Ethanol promotes cell death by inducing both apoptotic and necrotic events. Mitochondria, the primary site of energy (ATP) generation, are critical for induction of cell death by ethanol. Ethanol metabolism causes mitochondrial dysfunction, including impairment of fatty acid β -oxidation, inhibition of mitochondrial respiration and damage of mitochondrial DNA. The opening of mitochondrial pores (mitochondria permeability transition, MPT), normally blocked by anti-apoptotic factor, Bcl-2, results in release of cytochrome C that initiates the further death events. The scenario of the death events depends on ATP levels. In the case of ATP depletion, cells die *via* necrosis. However, if ATP levels are not changed,

cytochrome C release causes activation of the mediators of apoptosis, caspases, and subsequent DNA fragmentation. Certain pro-apoptotic factors (Bid, Bax) closely associated with the mitochondrial membrane are degraded by the proteasome^[43]. Thus, ethanol plays a dual role in regulating cell death: on one hand, it has a tendency to deplete ATP and facilitates necrosis; on the other hand, due to the proteasome suppression, it promotes the accumulation of pro-apoptotic factors in mitochondria of ethanol metabolizing liver cells and initiates apoptosis.

UBIQUITIN-PROTEASOME INVOLVEMENT IN ALCOHOL-INDUCED TISSUE INFLAMMATION

The outcome of acute inflammation depends on the balance of pro- and anti-inflammatory events initiated by mediators of inflammation, which can be “turned on or off” *via* certain signal transduction pathways. To be effective and non-toxic, the signals must be short enough to allow switching to the next stage of the process (such as the transition from inflammation to regeneration). These changes in gene activation repertoire occur with the help of transduction factors, which, after their job is done, are ubiquitinated and degraded by the proteasome. Alcohol consumption seems to interfere with the transduction of pro-inflammatory signals.

Many important pro-inflammatory and proliferative signals are regulated *via* the NF- κ B pathway. Activation of this pathway occurs by cytokines (such as tumor necrosis factor α , TNF α), phosphorylation of cytoplasmic inhibitory protein I κ B and subsequent translocation of NF- κ B to nucleus to initiate gene transcription. I κ B can be “marked” by ubiquitin upon phosphorylation and then is degraded by proteasome; alternatively, non-phosphorylated I κ B is modified by small ubiquitin-like modifier (SUMO) and is not targeted for degradation^[44]. In ethanol non-metabolizing cells, ethanol enhances NF- κ B activation; however, in ethanol metabolizing cells, I κ B dissociation is blocked and NF- κ B activation does not happen. Acetaldehyde, a product of ethanol metabolism, is responsible for I κ B stabilization and non-degradation by the proteasome^[45]. Acetaldehyde combines with the product of lipid peroxidation, malondialdehyde, and form the adducts with numerous proteins (malondialdehyde-acetaldehyde adducts, MAA). The MAA adducts reduce the susceptibility of lysozyme to proteasome degradation. MAA-modified proteins can serve as the targets of autoimmune reactions, enhancing liver injury^[46].

In liver, ethanol treatment modulates activity of various signal transduction pathways and induces certain downstream events. Thus, feeding of animals for 16 wk with ethanol diet causes up-regulation of chemokines and neutrophil infiltration in the liver. It also induces elevation of IL-8 levels, which results in suppression of the 26S proteasome, due to activated JNK/AP1 pathways^[41].

The Jak-STAT pathway, which plays a critical role in inflammation, proliferation, repair, and antiviral defense and usually supports proteasome activation, is also

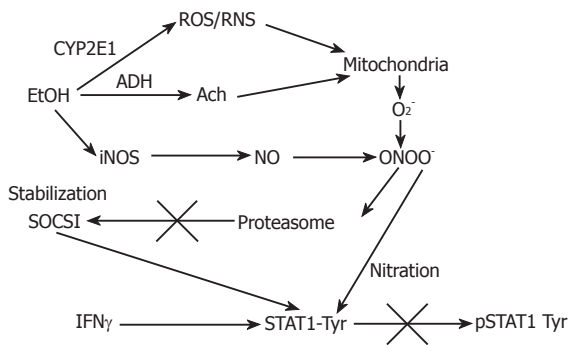

Figure 2 The proposed effects of EtOH metabolism on IFN γ -induced STAT1 phosphorylation in VL-17A cells. EtOH is metabolized by ADH and CYP2E1 to Ach and ROS/RNS and increase a formation of PN (peroxynitrite, ONOO \cdot), a reaction product of O $_2^{\cdot-}$ and NO, which at high concentrations blocks proteasome function. This causes stabilization of SOCS1, a negative regulator of Jak-STAT1 signaling as well as prevents STAT1 phosphorylation on tyrosine residues.

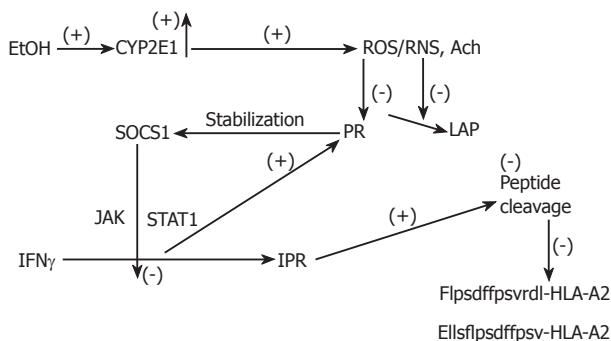

Figure 3 The proposed mechanism of regulation of peptide cleavage by ethanol metabolism. Ethanol (EtOH) treatment induces CYP2E1 activity, which catalyzes production of oxidants. These products block proteasome (Pr) and leucine aminopeptidase (LAP) activities, stabilizing SOCS1 and preventing IFN γ -dependent activation of PA28 and immunoproteasome (I Pr). Finally, generation of C- and N-extended peptides for MHC class I-restricted antigen presentation is blocked.

regulated by ethanol metabolism. Thus, acute ethanol exposure inhibited STAT3 activation by leptin in human Huh7 hepatoma cells^[47]. Inhibition of MAP kinase, protein kinase A and protein kinase C partially enhance IFN γ -induced STAT1 phosphorylation reduced by ethanol^[48]. We also reported inhibition of STAT1 phosphorylation in VL-17A hepatoma cells^[49], which was attributed to ethanol-mediated induction of SOCS1, due to the limited degradation of SOCS1 by suppressed proteasome (Figure 2). Peroxynitrite formation with subsequent nitration of tyrosine residues seems to play a critical role in this process. Similarly, inhibition of proteasome has also been shown to inhibit IL-6 signaling *via* stabilization of SOCS3^[50], which is supposed to be proteasome dependent as well.

Except liver tissue, some other types of tissues (brain, heart) induce the inflammation in response to ethanol and its metabolism. In these tissues, ethanol metabolism occurs predominantly *via* CYP2E1 and catalase, a peroxisomal enzyme, which catalyze ethanol oxidation by using H $_2$ O $_2$ as a hydrogen acceptor. Hepatocytes transfected with catalase, are also protected from lipid peroxidation after glutathione

depletion^[51]. In all ethanol-affected tissues, ethanol can also undergo non-oxidative metabolism and form fatty acid ethyl esters, which also induce mitochondrial dysfunction, inhibit protein synthesis and toxically affect cultured cells^[52].

ETHANOL-ELICITED IMPAIRMENT OF PROTEASOME FUNCTION AND MHC CLASS I -RESTRICTED ANTIGEN PRESENTATION

Processing of peptides for MHC class I-restricted antigen presentation is necessary for elimination of liver cells that express viral and other non-self proteins. At the most downstream level, these non-self proteins are cleaved by the proteasome in the cytoplasm^[10,53]. Further N-terminal cleavage is carried by aminopeptidases^[54]. These cleavages are regulated by IFN γ *via* the Jak-STAT1 pathway. Generated 8-10 amino acid peptides are presented on the cell surface, for recognition by cytotoxic T-lymphocytes (CTLs) and elimination. Escaping surveillance of infected cells by CTLs ultimately causes chronic persistence of viral infection in the liver, as is often observed in case of viral hepatitis B and C. Recently, we have shown that ethanol treatment of VL-17A cells suppresses proteasome and leucine aminopeptidase functions, which results in a partial blockade of HBV peptide hydrolysis and suppression of IFN γ -induced expression of PA28 and immunoproteasome^[20] (Figure 3). Ethanol-elicited impairment in IFN γ signaling is partially responsible for the latter event. This situation might be observed in chronically HBV-infected alcohol consumers, who are unable to clear viral infection in the liver.

CONCLUSION

Ethanol exposure creates oxidative stress in liver cells and that bi-phasically affects proteasome activity: low oxidative stress up-regulates proteasome function, while high oxidative stress suppresses it. Both acetaldehyde and CYP2E1-induced ROS and RNS contribute to this inhibition. Suppression of proteasome function results in enhanced cell death, mainly due to increased apoptosis. It also induces inflammation, by modulating various signal transduction pathways. Low proteasome activity interferes with efficient MHC class I-restricted presentation of antigenic peptides, which lowers antiviral defense.

Abstract

The development of alcoholic liver disease (ALD) can be attributed to many factors that cause damage to the liver and alter its functions. Data collected over the last 30 years strongly suggests that an immune component may be involved in the onset of this disease. This is best evidenced by the detection of circulating autoantibodies, infiltration of immune cells in the liver, and the detection of hepatic aldehyde modified proteins in patients with ALD. Experimentally, there are numerous immune responses that occur when proteins are modified with the metabolites of ethanol. These products are formed in response to the high oxidative state of the liver during ethanol metabolism, causing the release of many inflammatory processes and potential of necrosis or apoptosis of liver cells. Should cellular proteins become modified with these reactive alcohol metabolites and be recognized by the immune system, then immune responses may be initiated. Therefore, it was the purpose of this article to shed some insight into how the immune system is involved in the development and/or progression of ALD.

INTRODUCTION

It has become commonly accepted that immune mechanisms are partially responsible for the onset and/or progression of alcoholic liver disease (ALD). This is demonstrated by alcohol abuse increasing the immune deficiency in numerous diseases including: pneumonia, tuberculosis, human immunodeficiency virus (HIV), hepatitis C virus (HCV), hepatitis B virus (HBV), and many other less common infections^[1]. This observation is often overlooked because of the many other complications of alcohol abuse such as: malnutrition, ingestion of high saturated fats, vitamin deficiency, drug abuse, and smoking^[2]. The immune system has been suggested as playing a role in ALD because of the many clinical manifestations that have been observed and are thought to contribute to the damage of liver tissue^[3,4]. However, the combination of immune function, metabolism, genetics, nutrition, and environmental factors most likely together play a role in the development of ALD. This review will begin to digest some of the potential hypothesis as to how the immune system, in combination with other factors contribute to the onset or progression of alcoholic liver disease.

LIVER TOXICITY DUE TO ETHANOL AND ITS METABOLITES

General byproducts

After ethanol is ingested, it is absorbed in the gut and transported to the liver by the bloodstream where it is metabolized by either the alcohol dehydrogenase or cytochrome-P450 pathways. The first and most important pathway is alcohol dehydrogenase, which is isolated in the mitochondria and oxidizes ethanol to acetaldehyde. Acetaldehyde is further oxidized to acetate by acetaldehyde dehydrogenase. These reactions help form NADH and NAD, which alter the redox state of the cell, causing harmful effects on lipid and carbohydrate metabolism when the normal ratio is altered^[5]. Elevated levels of NADH inhibits fatty acid metabolism leading to the possible formation of acute fatty liver^[6] or they may play a role in the formation of scar tissue in the liver (i.e. fibrosis)^[7]. In the second method of ethanol metabolism, CYP2E1 (an isoenzyme of the cytochrome-P450 system) is involved. However, it is very limited at low doses, but can be induced by continuous exposure to higher levels of ethanol when the need arises^[8]. As a general rule,

alcoholics tend to have higher levels of this enzyme than non alcoholics^[9].

Studies have found that CYP2E1 can metabolize certain fatty acids to exacerbate the CYP2E1 pathway causing a build-up of fatty infiltrate into the liver^[10]. During CYP2E1 breakdown of alcohol, there is a release of highly reactive oxygen species (ROS). These ROS molecules damage the liver by altering the degradation of fat molecules, resulting in oxidative stress and free radical build up^[11]. Therefore, both ethanol metabolism pathways contribute to the build-up of fats and oxidative stress in the liver, providing a source for highly reactive molecules capable of modifying or altering proteins in the liver.

Metabolite adducts

In the livers of chronic alcoholics, a number of metabolites are produced that could potentially become reactive to form stable protein adducts. Previous findings have demonstrated that acetaldehyde (AA) protein adducts form during the metabolism of ethanol to acetaldehyde^[12-15]. These acetaldehyde adducts are immunogenic and have been found in the serum of both alcohol fed rats^[16] and alcoholic patients^[17]. Researchers have found that these AA-adducts interact with specific amino acids, particularly lysine, during their formation^[18,19], as lysine residues on proteins tend to be highly reactive when protonated, and the level of modification depends on the concentration of acetaldehyde.

One AA-adduct that was investigated for a number of years is the N-ethyl lysine adduct that can be formed when AA is incubated under reducing conditions. However, the development of monoclonal and affinity purified polyclonal antibodies to this adduct have shown that it is not present in the tissue of rats chronically consuming ethanol or human alcoholics. This now makes sense, since the levels of reduction necessary to form this product do not occur in the liver during alcohol metabolism (which is an oxidative mechanism)^[20,21].

As mentioned above, the metabolism of ethanol occurs through two pathways, both of which are oxidative and induce oxidative stress. Lipid peroxidation metabolizes fats to form malondialdehyde (MDA) and 4-hydroxy-2-nonenal (HNE), which can react with proteins to generate still other adducts^[19,22]. Both of these adducts have been suggested to be detected in patients with alcoholic liver disease, with their concentrations possibly correlating with the severity of the disease^[23,24].

The increased concentration of acetaldehyde levels and the oxidation of the fats in the liver due to chronic ethanol intake, increase the oxidative state of the liver, providing a key component in the formation of another adduct that "molds" these two observations. Recent studies have shown that both malondialdehyde (from lipid peroxidation) and acetaldehyde (from ethanol metabolism) react with lysines on proteins in a synergistic manner to form hybrid adducts different from either of these two aldehydes alone^[25]. This adduct has been called Malondialdehyde-Acetaldehyde adduct (MAA) and has been shown to form two different components on the lysine residue. The first is a relatively stable compound formed on lysine with two molecules of MDA and 1 molecule of AA. This 2:1 adduct

is extremely stable and fluorescent due to its characteristic ring structure. The second compound is formed on lysine with one molecule of MDA and one molecule of AA. This 1:1 adduct is very unstable and most likely serves at the precursor to the 2:1 adduct^[26]. The MAA-adduct has been found in both rats^[27] and human subjects^[28] chronically consuming alcohol and in human studies, it has been shown that increased levels of adducts in the serum correlated with severity of liver disease^[28].

Immune response to MAA-adducts

The MAA-adduct has been the focus of numerous studies to determine its role in the onset of alcoholic liver disease. One thing that is clear is that these MAA-protein adducts, when injected into animals (in the absence of adjuvant), produce strong antibodies to the adduct, carrier protein, and the protein carrier conjugate^[21]. Studies performed in our laboratory have demonstrated that MAA-adducts initiate the immune system to respond. These responses are achieved by binding to scavenger receptors, up-regulating adhesion molecules, inducing pro-inflammatory cytokines, producing antibody and T-cell responses, and increasing the pro-fibrotic response.

Clearance of MAA-adducts

Recent evidence has shown that MAA-adducts bind to cells expressing scavenger receptors on their surface^[29,30]. Chronic ethanol feeding studies with rats has shown that ethanol impairs the receptor(s) on liver endothelial cells impairing their ability to clear acetaldehyde and MAA adducts^[31-33]. The inability to clear these molecules out of the circulation leaves them available to other cells of the immune system. These immune cells bind modified adducts and induce inflammatory responses.

MAA-adducts upregulate adhesion molecules

In alcoholic liver disease, there is an increase in the infiltration of immune cells, which accounts for the necrosis of hepatocytes^[34]. The recruitment of these cells occurs by the increase in adhesion molecule expression on liver sinusoidal endothelial cell (SECs) surface^[35]. This action occurs when expression of selectins on SECs mediate loose attachment of leukocytes to the vessel walls. Chemoattractants cause the activation of integrins on leukocytes and these integrins bind to intercellular adhesion molecules (ICAMs) on the surfaces wall of the SECs. The leukocytes then respond to the amount of chemoattractant and diapedese through the SECs cell junction^[36]. It has been shown that metabolites of alcohol can increase the expression of these adhesion molecules on the surface of SECs^[37-41].

The ability of these adducts to increase chemoattractants (TNF-Alpha, MCP-1, and MIP-2) and adhesion molecules (ICAM, p-selectin, and L-selectin) provide evidence for the recruitment of immune cells into the liver. Damage to the liver results from the movement of these cells into the liver parenchyma subsequently, causing an increase in cell death.

MAA-adducts induce pro-inflammatory cytokines

Aldehyde adducts have also been shown to induce the release of pro-inflammatory cytokines and chemokines in

kupffer, endothelial, and stellate cells^[42-45]. These adducts most likely bind to scavenger receptors located on these cells and signal the release of cytokines. Since these adducts are not cleared efficiently, they are able to be re-circulated and induce pro-inflammatory responses. Also, T-cells and antibody can be elicited to exacerbate this response.

It has been determined that levels of the cytokines TNF-alpha, IL-1 and IL-6 are elevated in alcohol liver disease patients^[46-48]. One possible mechanism for the increased levels of TNF-alpha is that increased gut permeability due the ethanol (leaky gut), causes the translocation of lipopolysaccharide (LPS) from the lumen into the blood stream^[49]. LPS generated from bacterial cell walls has been shown to stimulate macrophages to release TNF-alpha and other cytokines^[50-53]. Data generated from our laboratory has shown that LPS (in extremely small amounts) in conjunction with MAA-modified proteins actually increases the release of TNF-alpha, MCP-1, and MIP-1 by rat liver kupffer and endothelial cells^[42]. One could postulate that both the metabolites of ethanol (adduct formation on proteins) and the increased levels of LPS in the blood stream (gut derived) provide the necessary components for endothelial and kupffer cells to begin releasing pro-inflammatory cytokines. Stellate cells have also been shown to increase the release of these pro-inflammatory cytokines in response to aldehyde adducts^[45,54,55].

Increase in antibody and T-cell responses to MAA-adducts

Immune responses to MAA-adducts have been shown to be induced in the absence of adjuvants^[19,21]. This response may represent an important mechanism by which T and B-cells respond to soluble proteins. It has been shown that with as little as 25 micrograms of MAA-modified protein, a tremendous antibody response is demonstrated; both to the MAA-adduct and the protein carrier conjugate^[21].

Involvements of T-cells in these responses are shown by the strong expansion of T-cells to the MAA-adduct in *in vitro* studies^[56]. These responses were determined to be to the adduct and protein carrier conjugate. It was also determined that scavenger receptors were involved in the uptake of the MAA-adduct and presentation to T-cells^[30]. Recent studies in our laboratory have shown that MAA-modified self proteins can become immunogenic, potentially modifying liver proteins, and increasing the risk of specific organ damage.

Pro-fibrotic response to MAA-adducts

Hepatic fibrosis is the start of the wound-healing process resulting from the injury to the liver caused by years of alcohol consumption. This process can be reversed should ethanol consumption be eliminated. However, if ethanol consumption continues, fibrosis will occur, followed by scarring and finally the development of cirrhosis^[57,58]. Fibrosis is the build up of excessive depositions of extracellular matrix (ECM) proteins, which consists of collagen and fibronectin^[59]. These ECM proteins may cause the characteristic scar tissue formed in the liver after an injury has occurred. Byproducts of ethanol

metabolism have been shown to increase the release of these products. Hepatic stellate cells up-regulate collagen genes in response to stimulation with acetaldehyde^[60,61]. Also of interest is the finding that SECs secrete the isoform (EIII A) of fibronectin in response to MAA-adducts, which are capable of causing stellate cells to release collagen^[62]. Activation of the stellate cells is the key component in the fibrogenic process, providing the main production of fibrillar collagen. The build up of modified protein adducts causes disability of effective clearance, thereby increasing the activation of SECs and stellate cells, resulting in a fibrogenic response. The only way to intervene in the continual response from fibrosis to cirrhosis is to remove the ethanol from the system. Some anti-fibrotic drugs have been experimentally tested, yet there are still problems concerning delivery and concentration^[63-65].

IMMUNE FUNCTION AND ALCOHOL

Innate immune response

Ethanol affects many functions of the innate immune system. The cell types involved in this early response include: macrophage, neutrophils, and natural killer cells. One of the most active cells, the macrophage, is designed to respond to bacterial cell wall antigens by releasing cytokines, and engulfing foreign agents. In alcoholic liver disease, kupffer cells in the liver are activated by lipopolysaccharide (LPS) caused from a breakdown in the intestinal wall permeability. This phenomenon has been called "leaky gut" and occurs when alcohol increases gut permeability, causing bacteria from the intestinal tract to escape into the blood stream^[66,67]. When LPS is present, it activates kupffer cells to release TNF-alpha and superoxides that result in an inflammatory response. Recent studies in our laboratory have shown that adducts and very small amounts of LPS can stimulate kupffer cells and SECs to release these pro-inflammatory cytokines^[42]. Once these cytokines are initiated, inflammation and necrosis occurs to hepatocytes and other cell types of the liver.

Neutrophils are the cell type that is predominantly recruited to the liver in response to the increase in cytokine concentrations. When these cells infiltrate into the site of infection, they phagocytose antigens and release proteolytic enzymes capable of destroying cell walls. They also release more chemoattractants to expedite the inflammatory process^[68]. In alcoholic liver disease, these cells play a role in the propagation of the disease by infiltrating and cleaning up dead or dying cells. In fact, it has been shown that IL-8, a known neutrophil chemoattractant, is elevated in patients with alcoholic liver damage^[69,70]. These cell types can be seen microscopically infiltrating the liver in patients with alcoholic hepatitis^[1].

Adaptive immune system

The adaptive immune system consists of cells types designed to induce memory to specific antigens. It is characterized by the presentation of antigen to T-cells and clonal expansion of these cells to increase specificity to proteins, further increasing disposal of foreign agents.

More importantly, there is a tolerance to self antigens, protecting the organism from self elimination^[71]. When a breakdown in the adaptive immune response occurs, autoimmune diseases are sometimes initiated.

T-cells and NK T-cells have been implicated in the development of alcoholic liver disease by the increased numbers found in human livers following ethanol injury^[72]. Studies have demonstrated that co-culturing lymphocytes (from alcoholic cirrhotic patients) with ethanol increased the expression of adhesion molecules and TNF-alpha as compared to control patients^[38]. In this same study, the control patient lymphocytes when cultured with ethanol had a suppressive effect on the release of these molecules. The T-cells in the liver help drive the inflammatory process by releasing more cytokines including: TNF-alpha and INF-gamma. Another study implicating lymphocytes in ALD was done by transferring T cells from ethanol-fed rats to control recipient rats. In this experiment, damage to the naive livers was shown using reactive T-cells from alcohol-fed animals^[73]. Cytotoxic T cells can be generated in response to acetaldehyde-modified spleen cells^[74], giving aldehyde-modified proteins a role in the activation of these cells. Additionally, we have shown that aldehyde-modified proteins at high levels (non-physiological) can cause cell death and apoptosis to these cells^[75]. Therefore, the build up of these adducts in the liver could potentially increase the level of cell death/apoptosis, increase cytokine production in all immune cell types, and cause increased inflammation in the liver leading to cirrhosis.

Alcoholic liver disease has often been associated with circulating antibodies and lymphocytes specific to hepatic antigens^[76,77]. Circulating antibodies specific to acetaldehyde adducts and hydroxyethyl-free radicals have also been found to correlate with ALD^[78,79]. Malondialdehyde-acetaldehyde (MAA-adducts) have been found to be significantly increased in patients with ALD, which correlated with the severity of liver damage^[28]. Work done in animals has shown that MAA-adducted proteins are immunogenic without the use of adjuvants^[21]. Antibodies directed against these proteins were specific for both the MAA-adduct and the carrier protein. When hen egg lysozyme (HEL) was used as the carrier antigen, an antibody response to the carrier protein and not the adduct was observed^[56]. This provides a possible mechanism of autoantibody production wherein metabolites of ethanol modify hepatic self antigens and induce an autoimmune response against the liver.

In order to induce an autoimmune response, the right set of circumstance must be present to override the fail-safe mechanism(s) put in place by immune cells of the organism. In the adaptive immune response, this means that tolerance must be broken. How is tolerance broken in alcoholic liver disease? When metabolites of alcohol are present in the liver (as described above), the immune response is tremendously increased in the liver. Toxicity due to the chemical breakdown of these metabolites and the inflammation of immune cells increase the number of hepatocyte damage. Spilling of cellular material into the liver is cleaned up by macrophage and neutrophils. Self proteins from hepatocytes could become modified with acetaldehyde, malondialdehyde, or both. These self

proteins could bind to and be taken up by macrophage, endothelial cells, or dendritic cells and presented to T-cells. If this occurs, reactive cytotoxic T-cells or the production of antibody could aid in damaging the liver. Experimental evidence to support this hypothesis has been demonstrated in animal models^[80,81].

Previous studies with maleylated mouse serum albumin (MSA) have shown the breaking of tolerance by inducing an antibody response to the carrier protein (MSA)^[82]. These proteins were found to bind to scavenger receptors on the surface of macrophage and presented to T-cells from the spleen. In fact, many different aldehyde-modified proteins have been shown to bind to scavenger receptors^[29,83-85]. Studies performed in our laboratory have demonstrated similar findings when MSA was modified with acetaldehyde and malondialdehyde^[21]. These MAA-modified self proteins appear to bind scavenger receptors, are processed and presented in the cell, and increase the proliferative response in T-cells^[30]. Further proof for these observations is the increase in the co-stimulatory molecules B7-1 and B7-2 by splenocytes stimulated with MAA-modified proteins^[86]. These co-stimulatory molecules are the key component in autoimmune regulation and the breaking of tolerance^[87]. When the T-cell binds an antigen presenting cell, the T-cell receptor binds to the matching peptide presented in the groove of the MHC molecule. If co-stimulatory molecules are ligated, then the cell is signaled to respond and the T-cells begin to proliferate. Specificity is to the peptide in the groove, and if this is a self protein, the immune system sees these proteins (liver specific) as a foreign invader and eliminates the threat. This threat is eliminated with cytotoxic T-cells destroying the cell with their powerful enzymes^[71]. If these proteins happen to be presented to multiple B-cells and crosslinking of receptors occurs, antibody production specific for the self-protein is initiated with the help of T-helper cells. Antibodies would then bind to the self proteins and be taken up by Fc receptors located on NK cells and attacking the liver cells^[71]. See Figure 1 for a description of this hypothesis.

INTERACTION OF DIET, ETHANOL, AND IMMUNE FUNCTION

Diet and ethanol intake

Alcoholics have always been considered to be malnourished due to the exchange of food calories for alcohol, leaving a reduction in valuable nutrients. One explanation for this is that increased alcohol intake interferes with absorption of these nutrients from the intestine, making them unavailable to the body^[8]. Thus, a decrease in body fat is the case for a number of individual alcoholics. However, metabolic syndrome in individuals has become a risk factor with the increase in high fat diets^[88]. Metabolic syndrome is a chronic inflammatory condition that promotes insulin resistance and fat accumulation in the liver^[89]. This disease, known as fatty liver, is quickly becoming an epidemic in our society as a result of increased dietary fat intake^[90]. Taken into account the chronic inflammatory condition in alcoholic liver disease alone, one could assume that the two

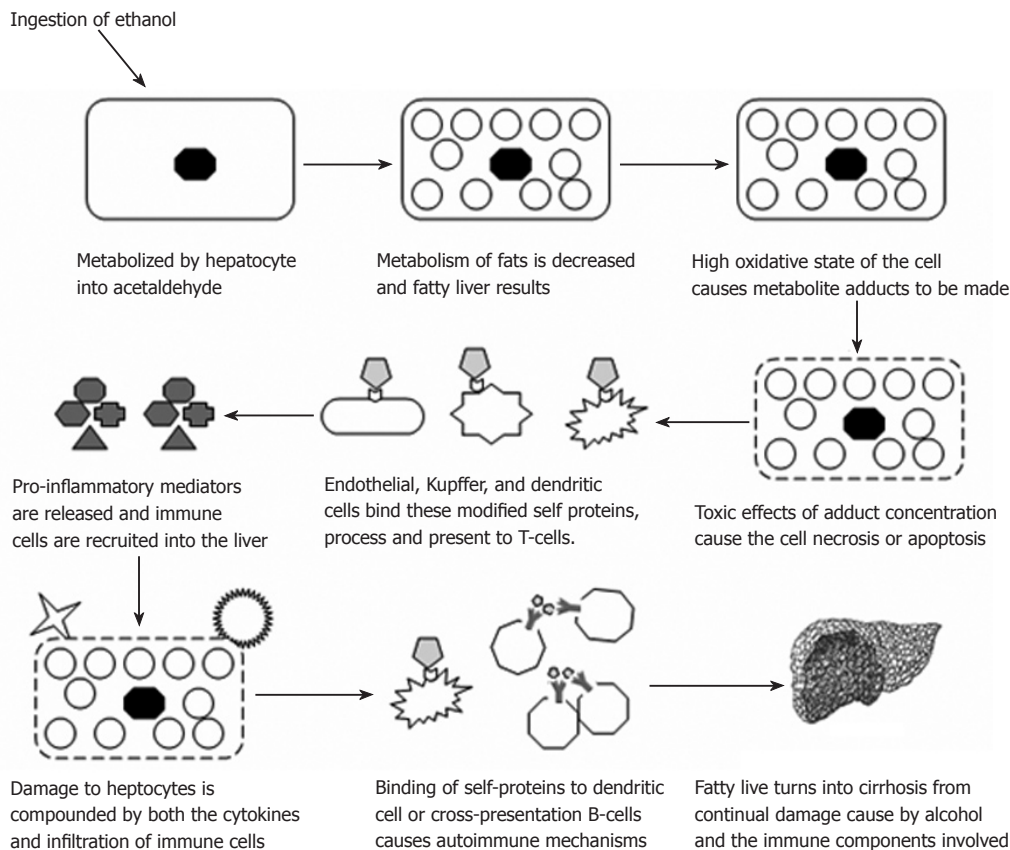

Figure 1 The proposed involvement of immune mechanisms in the development and/or progression of alcoholic liver disease. A schematic depicting the involvement of the immune system in the progress of fatty liver to end stage cirrhosis.

diseases together would greatly increase the severity of the disease. To support this claim experimentally, investigators have shown in a rat model that incorporates an ethanol diet with polyunsaturated fats, there is an increase in the severity of liver damage^[91].

As mentioned above, alcohol metabolism increases the accumulation of fats in the liver. This is caused by suppression in lipid oxidation as a result of the increased production of acetate produced from the metabolism of ethanol^[92]. Fatty liver can also occur when levels of NADH are increased. This enzyme is increased when alcohol is broken down by alcohol dehydrogenase and accounts for a number of metabolic conditions including: hyperlipemia, hypoglycemia, hyperlactacidemia, hyperuricemia, and gout attacks^[8]. In looking at the increased inflammatory state and oxidative stress of the liver under these conditions, one could speculate that lipoproteins and other proteins are modified by the metabolites of ethanol.

Lipoproteins are oxidized under certain conditions. These lipoproteins are under investigation for contributing to coronary heart disease^[93]. However, there is some indication that these modified lipoproteins may play a role in damage to the liver. They have been shown to bind to scavenger receptors on stellate cells and stimulate extracellular matrix proteins^[94]. Aldehyde-modified proteins are similar in nature to these modified LDL proteins, in that they bind to some of the same receptors^[95]. Interestingly, in other studies, MAA-adducted proteins were found in atherosclerotic aortas, implicating a similar connection between MAA-modified proteins and oxidized LDL^[96]. These data indicate that modified proteins may not be limited to the liver and may reach the blood stream

and travel throughout the body. Since these modified proteins bind to scavenger receptors on endothelial cells, it seems likely that excess presence of these adducts could be harmful.

Malondialdehyde, one of the breakdown products of lipid metabolism, has been implicated in autoimmune disease^[97]. Anti-MDA adducts have been found in patients with systemic lupus erythematosus (SLE) and correlated with antibody markers specific for this disease. MDA-adducts have also been found to correlate with atherosclerosis and many other diseases by their ability to form lipofuscin^[98,99]. MDA-adducts in our laboratory has been found in atherosclerotic plaques using immunohistochemical techniques^[96].

These adducts formed from the metabolism of fats or alcohol and have been shown experimentally in human subjects to have many harmful effects. The fact that they can be toxic to cells at high levels increases the cell death or apoptotic numbers in the organ^[75,100,101]. This increases the amount of pro-inflammatory cytokines in the organ and calls immune cells in to clean up the debris. If aldehyde adducts bind to the cellular debris, and this material is picked up by an antigen-presenting cell, the risk for an increased immune response is prevalent. If these molecules happen to be presented to an activated dendritic cell, the immune response is generated that is specific for the self protein.

Taken altogether, the observation that many individuals are overweight or already have fatty liver without the consumption of alcohol^[102], there is an increased risk of liver damage when alcohol is consumed in large quantities. Metabolism of fats and ethanol together constitute a fine balance between clearance and build

up of reactive metabolites. Acetaldehyde from alcohol and malondialdehyde from lipids increase in number until the product is eliminated from the body. If and when individuals continue to consume either ethanol, fats, or both in large quantities, they run a risk of adduct formation. As discussed above, adduct formation can lead to a number of diseases including: autoimmunity, atherosclerosis, alcoholic liver disease, non-alcoholic liver disease, and many others.

Management or treatment options

In looking at treatment options for alcohol abuse and obesity, the fastest way to resolve these diseases is to eliminate the source. Alcoholic steatosis can be reversed if withdrawal from ethanol is accomplished. In fact, abstinence from ethanol can improve cirrhosis and/or fibrosis within only several weeks if eliminated from the diet^[103]. As for obesity, any loss in weight has large implications in improving disease state of any kind. However, individuals will continue to consume fats and ethanol so treatment using other methods could help in the quest for improved disease state.

Nutrition of patients with alcoholic liver disease has been a key component, as many of these individuals are malnourished. This puts pressure on the immune system in its ability to clear infections and aid in liver regeneration^[103]. Increasing proteins, vitamins, essential amino acids, and decreasing saturated fat intake can aid in the recovery of many liver disease patients^[91,104]. However, diet change is hard for individuals so administration of certain vitamins has been somewhat successful. These include injections of vitamin B1, supplements of vitamins B2 and B6, and increasing folic acid levels^[8].

When nutritional changes are not working for these patients, various compounds have had some success. These include: steroids, anti-TNF, S-adenosylmethionine, betaine, antibiotics, and possibly statins. Corticosteroids have been able to reduce the inflammatory response in numerous diseases. In alcoholic liver disease, steroids have been shown to reduce cytokine production, suppress acetaldehyde adducts, and inhibit the production of collagen^[105]. Studies have demonstrated that TNF-alpha levels are greatly increased in the liver following chronic alcohol consumption^[106]. This cytokine is toxic to cells and is the major source of inflammation in the liver. Treating with anti-TNF antibodies immobilizes the effects of TNF-alpha on hepatocytes and other cells in the liver^[107].

Treatment with anti-oxidants has been somewhat successful in the quest for alcoholic liver disease therapy. S-adenosylmethionine (SAM) and betaine have been shown to restore glutathione levels, which increase the ability of the liver to metabolize fats^[108-110]. SAM and betaine work by correcting alterations in methionine metabolic pathways, restoring methylation reactions in the oxidative liver. Use of antibiotics for treatment of liver cirrhosis in individuals with bacterial infections is also beneficial^[111,112]. Bacterial infections in these patients are due in part to the increase in gut permeability, where by alcohol cause the release of normal flora into the blood stream. Lipopolysaccharide from the cell walls of these bacteria increase levels of

cytokines greatly enhancing toxicity to cells in the liver^[48]. By decreasing the level of bacteria in the system, activation of the immune system by these cytokines can be reduced.

Statins are commonly used to lower harmful cholesterol in the blood stream^[113]. These drugs are mainly used to prevent atherosclerosis and heart disease. However, recent evidence for preventing other diseases has become available. For example, statins have been postulated to have an anti-inflammatory and immunomodulatory role in protecting the body against endotoxin from bacteria^[114]. Evidence has also shown that these drugs may have implications in the treatment or prevention of metabolic syndrome^[115]. The cholesterol lowering and anti-inflammatory properties of these drugs might be helpful in the future to lower the fatty liver associated with alcoholic liver disease. Studies will need to be performed to determine the efficacy of statins.

There is some suggestion that ethanol in moderation might have some beneficial effects to certain individuals. Decreased risk of coronary heart disease has been associated with individuals who drink as little as one to six alcoholic beverages per week^[116]. Experts think that small doses of alcohol may increase the level of good cholesterol (HDL) in the blood stream regardless of the beverage consumed^[117]. However, the overall benefit of alcohol does not outweigh the risk of the toxic effects of this drug. Like all things in life, moderation is the key to living a healthy lifestyle.

CONCLUSION

While there are a number of contributing factors resulting in the development and/or progression of alcoholic liver disease, the immune system appears to be a major player. Immune function in alcoholics has shown circulating autoantibodies, hypergammaglobulinemia^[3,118], antibodies to metabolite adducts^[24,28,79], and the infiltration of immune cells into the liver^[34,37,72]. One other factor to support the immune system is seen in alcoholic patients who have received a liver transplant. If these individuals start consuming ethanol, hepatic fibrosis or cirrhosis occurs much more quickly than the years it took to develop prior to transplant^[119]. This quick memory response to the liver suggests that the adaptive immune system is involved.

Other factors that contribute to the development of ALD include: metabolism, toxicity, genetics, and nutritional factors. The metabolism of excess ethanol causes many harmful effects that could contribute to the formation of metabolite adducts. If these adducts form while cells are dying from the toxic effects of ethanol, self-proteins could become modified, providing the necessary mechanism for autoimmune disease. If you figure in the susceptibility of certain individuals and their genetic make up, the risk for liver disease becomes higher. Also factored into to this is the observation that many alcoholics are malnourished, consuming many of their calories from alcohol^[8]. It has been shown that the immune system works better when a healthy balanced diet is followed^[120]. One other common issue is the consumption of high levels of fatty foods in the diets of most individuals. Alcohol metabolism already

contributes to the build-up of fats in the liver (fatty liver); compound that with the addition of more fats in the diet and the potential exists for a double-edged sword of damage and oxidative stress.

The fact remains that alcohol consumption has many harmful effects on the body. However, getting people to stop drinking completely is an unrealistic expectation. The need for understanding the mechanisms of alcoholic liver disease remains necessary for determining better therapy and intervention strategies.

Abstract

Alcoholic liver disease is a major health care problem worldwide. Findings from many laboratories, including ours, have demonstrated that ethanol feeding impairs several of the many steps involved in methionine metabolism. Ethanol consumption predominantly results in a decrease in the hepatocyte level of S-adenosylmethionine and the increases in two toxic metabolites, homocysteine and S-adenosylhomocysteine. These changes, in turn, result in serious functional consequences which include decreases in essential methylation reactions *via* inhibition of various methyltransferases. Of particular interest to our laboratory is the inhibition of three important enzymes, phosphatidylethanolamine methyltransferase, isoprenylcysteine carboxyl methyltransferase and protein L-isoaspartate methyltransferase. Decreased activity of these enzymes results in increased fat deposition, increased apoptosis and increased accumulation of damaged proteins—all of which are hallmark features of alcoholic liver injury. Of all the therapeutic modalities available, betaine has been shown to be the safest, least expensive and most effective in attenuating ethanol-induced liver injury. Betaine, by virtue of aiding in the remethylation of homocysteine, removes both toxic metabolites (homocysteine and S-adenosylhomocysteine), restores S-adenosylmethionine level, and reverses steatosis, apoptosis and damaged proteins accumulation. In conclusion, betaine appears to be a promising therapeutic agent in relieving the methylation and other defects associated with alcoholic abuse.

INTRODUCTION

Biological transmethylation reactions utilize methyl groups derived from dietary methyl donors and from cofactors carrying 1-carbon units. A pathway that is central to many of these reactions is the metabolic cycling of methionine (Figure 1).

The significant role of methionine metabolism in liver is underscored by the fact that nearly half of the daily intake of methionine in humans and rats is metabolized there *via* methionine adenosyltransferase (MAT)-catalyzed reaction to generate S-adenosylmethionine (SAM), the principal methylating agent in the body. Under normal conditions, most of the 6-8 g SAM generated per day serves as a methyl donor for many transmethylation reactions. The normal estimated rate of these reactions, corrected to 70 kg body weight, is 16.7-23.4 mmol/d in young normal adults and 15.5-21.7 mmol/d in elderly subjects^[1]. At least 50 of such SAM-dependent methylation reactions have been identified in mammals^[2]. These reactions catalyzed by diverse methyltransferases result in the production of methylated biomolecules, such as phospholipids, proteins, nucleic acids and small molecules that have vital biological roles in biosynthesis, regulation, repair and detoxification. The other product is S-adenosylhomocysteine (SAH), which is hydrolyzed to adenosine and homocysteine by S-adenosylhomocysteine hydrolase (SAHH). This series of reactions is referred to as transmethylation. The methionine cycle is completed when homocysteine is remethylated back to methionine. The biochemical step between homocysteine and methionine occurs through two reactions, both of which are equally important in converting homocysteine to methionine in the liver^[3]. In the first, a methyl group is transferred from betaine (which in turn, is derived from the oxidation of choline) to homocysteine to form methionine and dimethylglycine (DMG) *via* betaine-homocysteine methyltransferase (BHMT). The second reaction utilizes folate and through the action of methionine synthetase (MS), a methyl group is transferred from 5-methyltetrahydrofolate (MTHF) to vitamin B₁₂ to form

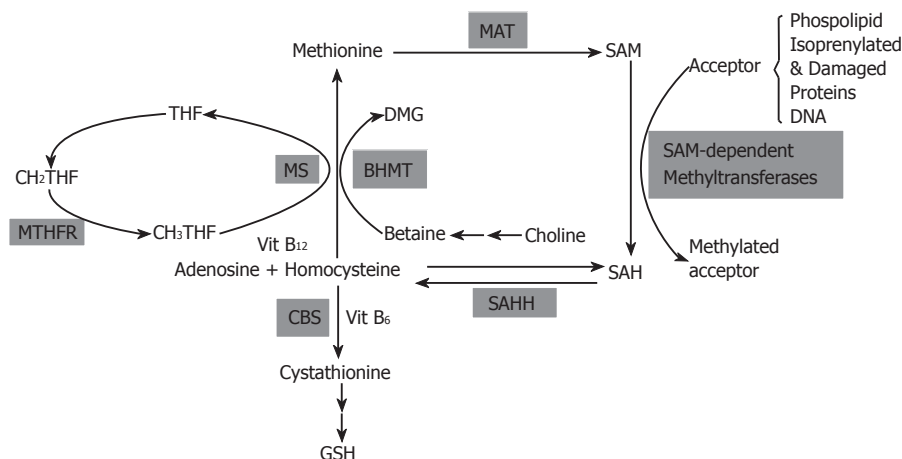

Figure 1 Methionine metabolic pathway in the liver highlighting the importance of the methyltransferase-catalyzed reactions maintained by the cycling of the main participants, methionine, S-adenosylmethionine (SAM), S-adenosylhomocysteine (SAH) and homocysteine. The hepatocellular ratio of SAM to SAH is critical in controlling many transmethylation reactions.

methylcobalamine. The methylcobalamine in turn transfers the methyl group to homocysteine to produce methionine. The remethylation of homocysteine by the folate pathway is ubiquitously distributed but the BHMT-mediated pathway is tissue-specific existing primarily in the liver and kidney^[14]. Another enzyme that links the one-carbon pool and methionine metabolic pathway is 5, 10 methylene tetrahydrofolate reductase (MTHFR) that is involved in the production of MTHF. Folate also functions to transfer one carbon units for the synthesis of thymidylate, a key step in DNA synthesis.

Homocysteine can also be irreversibly catabolized through the transsulfuration pathway by the action of cystathionine β -synthase (CBS). The transsulfuration pathway superimposes on the methionine pathway and is important for the synthesis of cysteine and glutathione (GSH) as well as the removal of homocysteine. The transsulfuration occurs in a restricted number of mammalian tissues—liver, kidney, pancreas and the intestine, because the rest of the organs lack expression of one or more enzymes of this pathway.

Effects of alcohol on liver methionine metabolism

Many laboratories have shown that alcohol consumption induces alterations in methionine metabolic pathways. A major defect elicited by ethanol consumption appears to be inhibition of liver MS activity, which results in impaired remethylation of homocysteine to form methionine^[5-8]. Concomitantly, to compensate for the decreased MS activity, the activity of BHMT, an alternate enzyme for homocysteine remethylation, is induced after ethanol ingestion. A major outcome of this increase is a marked lowering in liver betaine levels in an effort to maintain SAM levels for transmethylation reactions^[9]. However, SAM levels diminish upon prolonged ethanol exposure^[10]. This does not appear to be due to a loss in liver-specific MAT level or activity since no decrease was observed despite 9 wk of intragastric feeding with ethanol and high fat^[11]. Similar results were also reported for micropigs fed chronic ethanol for up to a year^[7]. However, subsequent studies done by the same group have revealed decreased liver SAM levels in micropigs fed ethanol for 14 wk^[12]. Data from human studies also demonstrates subnormal

MAT function in liver biopsies from alcoholic patients^[13,14].

Our laboratory and others have further reported that despite the compensatory increase in BHMT, alcohol-induced impairment of liver MS activity results in an enhanced generation of the potentially toxic agent homocysteine^[12,15,16]. This in turn results in an increased intracellular level of SAH^[7,8,12,17,18] as the equilibrium of the SAH hydrolase reaction energetically favors SAH generation over SAH hydrolysis. We further reported that the intracellular ratio of SAM:SAH levels was significantly lower (2.5) in freshly isolated hepatocytes and livers of ethanol-fed rats as compared to the ratio of 5 observed in hepatocytes and livers of control-fed rats^[17, 19]. Although many laboratories have shown comparable ratio values and decreases with ethanol as we report^[20,21], studies with mice and micropigs reveal a similar trend of ratio decrease but lower absolute ratio values^[22,23].

It is very crucial to maintain SAM:SAH ratios because SAH is a competitive inhibitor for many SAM-dependent methyltransferases. The K_i value for SAH is in the submicromolar to low micromolar range and is often less than the K_m value for SAM for many of the methyltransferases^[24]. Therefore, any significant decrease in the ratio negatively affects many transmethylation reactions.

Betaine maintains normal SAM:SAH ratios after ethanol consumption

Ours and other laboratories have also shown that betaine (a naturally occurring tertiary amine, trimethylglycine) can enhance the remethylation of homocysteine *via* BHMT-catalyzed reaction^[15,16] to alleviate ethanol-induced changes in intracellular SAH levels^[17] as well as cause elevations in SAM levels^[19,25]. Similar increases in hepatic SAM levels have also been reported in mice fed intragastrically an ethanol diet supplemented with betaine^[26]. Betaine, by modulating SAM and SAH levels, results in normalization of the alcohol-induced alterations in the hepatocellular SAM:SAH ratios^[17,19].

We have further observed that while ethanol treatment resulted in a 2-fold elevation of hepatic BHMT activity, this increase was further elevated in the livers of rats fed ethanol diet supplemented with 1% betaine. This increase in activity correlates with the enzyme level of BHMT

quantified by western blot analysis using an antibody to rat BHMT as well as with quantitative RT-PCR studies^[19]. These results imply that the inclusion of betaine in the diet promotes the alternate remethylation pathway to ultimately maintain hepatocellular SAM:SAH ratios by not only providing the substrate, betaine, for the BHMT-catalyzed reactions, but also further inducing BHMT at the gene and protein level. Further studies indicate an interplay between ethanol and not only the diet composition, but also its presentation^[27].

Effects of ethanol and betaine on transmethylation reactions

Researchers over the years have attempted to determine which transmethylation reactions are affected by acute or chronic ethanol consumption as well as to understand how these altered reactions in turn, contribute to alcohol-induced liver injury. Further attempts have been made to determine the therapeutic effects of some participants of the methionine cycle, such as betaine and SAM, in minimizing the adverse effects.

Our laboratories and others have shown that there are many SAM-dependent methylation reactions that are adversely affected by ethanol consumption and normalized by co-administration by betaine. Of particular interest to us is three such reactions that clearly demonstrates a close relationship between the activities of methyltransferases with hallmark features of alcoholic liver injury. These three liver methyltransferases are: (1) Phosphatidylethanolamine methyltransferase (PEMT), the methyltransferase involved in the generation of phosphatidylcholine (PC); (2) isoprenylcysteine carboxyl methyltransferase (ICMT), the methyltransferase that carboxyl methylates isoprenylated proteins; (3) Protein L-isoaspartate methyltransferase (PIMT), the methyltransferase that catalyzes the repair of isoaspartyl sites of spontaneously damaged proteins.

Association between PEMT activity and steatosis

PEMT catalyzes three successive methyl group transfers from SAM to phosphatidylethanolamine (PE) to generate PC. This pathway has been reported to be responsible for about 50% of total SAM utilized^[28]. Although PC can also be synthesized by the Kennedy Pathway in the liver^[29], it has recently been shown that the PC derived *via* the PEMT pathway is preferentially used in the assembly of very low density lipoproteins (VLDL) and is necessary for its normal secretion^[30]. As the liver exports triglycerides and cholesterol only as constituents of VLDL particles, any impairment in the processes of either the synthesis or export of VLDL particles could lead to fat accumulation within the hepatocyte. Indeed, experimentally inhibiting PC synthesis *via* the PE methylation pathway or targeted PEMT gene disruption has been shown to impair the incorporation of triglycerides into VLDL and reduce its secretion by hepatocytes^[30,31]. Conversely, stable expression of PEMT has been shown to enhance this secretion^[31]. The ultimate substantiation of the critical role of methylation reactions catalyzed by PEMT in the prevention of fat accumulation in hepatocytes is provided

by the observations that homozygous PEMT knockout mice spontaneously develop hepatic steatosis despite adequate choline in the diet^[32].

PEMT and alcoholic steatosis

While earlier studies have implicated decreased hepatic VLDL secretion to play a role in the development of alcoholic steatosis^[33], the association of PEMT activity with alcoholic liver injury was suggested by reports that identified decreased PEMT activities in livers of cirrhotics and a modulation of PEMT activities by altered SAM:SAH ratios^[14,34,35]. However, the relationship between PEMT activity, SAM:SAH ratios and alcoholic steatosis became apparent after our observations that the SAM:SAH ratios in livers and hepatocytes of ethanol-fed rats is much lower than the ratios in livers and isolated hepatocytes of control diet fed rats^[17,19]. Our further understanding of the relationship between ratios, PEMT activities and steatosis became evident from experiments conducted in our laboratory using liver microsomal fractions, isolated hepatocytes and in an *in vivo* rat model of ethanol abuse.

Using microsomal fractions isolated from liver of Purina-fed rats, PEMT activities measured in the presence of varying amounts of SAH (such that the ratio of SAM:SAH in the incubation mixture varied to mimic ratios seen in hepatocytes from ethanol, control or *in vitro* betaine-supplemented conditions) revealed increasing inhibitions of PEMT activity with decreases in the SAM:SAH ratio. A 30-40% inhibition of PEMT activity was observed when the SAM:SAH ratio was 2.5 (which corresponds to the intracellular ratio observed in isolated hepatocytes from ethanol-fed rats) as compared to the activity observed at the ratio of 5.0 (the ratio observed in the controls). A ratio as seen in the betaine-supplemented hepatocytes essentially resulted in restored enzyme activity^[17]. Identical experiments were also performed on fractions prepared of hepatocytes obtained from both control and ethanol-fed rats. While similar activities were noticed in isolated microsomal fractions obtained from both cell types under basal conditions^[36], the PEMT activities were also equally impaired by the decreasing SAM:SAH ratios. These results implied: (1) that the PEMT enzyme level appears to be unaffected by alcohol consumption, but it is the alcohol-induced decrease in the hepatocellular SAM to SAH content ratio that causes impaired PEMT activity, and (2) betaine, by virtue of its ability to increase the ratio, would restore (increase) the activity of PEMT.

To examine the physiological relevance of the direct inhibition of PEMT activity in isolated microsomal fractions by increasing SAH amounts, the influence of ethanol on PC generation *via* the PEMT pathway was also analyzed. It was observed that ethanol feeding resulted in decreased PC production by a PEMT catalyzed reaction. Betaine either as *in vitro* supplementation to isolated hepatocytes obtained from ethanol-fed rats or fed to rats on ethanol diet corrected the ethanol-induced decrease in SAM:SAH ratios^[19] and by normalizing the PC production *via* the PEMT-catalyzed reaction, significantly reduced fatty infiltration associated with ethanol consumption^[19,36]. It has

also been shown that the PC to PE ratio is a key regulator of cell membrane integrity and plays a role in progression of steatosis to steatohepatitis^[37].

ICMT-catalyzed transmethylation reactions and apoptosis

The substrates of ICMT are proteins that terminate with the CAAX motif (where C = cysteine, A = aliphatic amino acid, and X = undefined). Such proteins first undergo prenylation of the cysteine residues, followed by proteolytic cleavage of the AAX sequence. ICMT subsequently catalyzes the reversible carboxyl methylation of the newly exposed isoprenylcysteine using SAM as the methyl donor. This post-translational modification is required for the normal activity of proteins such as GTPases that play a crucial role in the signaling of many complex biological processes, including the prevention of apoptosis^[38,39].

The functional importance of normal ICMT in preventing apoptosis is demonstrated in many studies. Apoptosis in cultured cells can be induced by inhibiting the carboxyl methylation of endogenous physiological substrates of ICMT^[40-42] or by elevated intracellular SAH levels^[43,44]. That SAH-induced apoptosis could be prevented by over-expression of ICMT emphasizes an involvement of impaired ICMT in the apoptotic cascade^[41]. The physiological importance of ICMT is further reiterated by studies on homozygous ICMT knockout mice. These mice present with developmental defects of the liver that are so severe that virtually all of the knockout embryos die by mid-gestation^[45], possibly due to liver agenesis/apoptosis^[46]. Subsequent studies revealed that ICMT-catalyzed carboxyl methylation of its substrates, Ras and Rho GTPases, are very critical for prevention of caspase activation and programmed cell death^[41].

ICMT, alcoholic apoptosis and betaine

It has been demonstrated that ethanol administration is linked to increased hepatocyte apoptosis in both clinical and experimental alcohol-induced liver injury in a variety of species of animals including rats, mice and minipigs^[7,16,47-52]. Compelling evidence from our laboratory implicates altered hepatocellular SAM:SAH ratios and subsequent decreased ICMT activity to be responsible for alcoholic apoptosis. The first supporting data for this conjecture is that betaine supplementation (which normalizes homocysteine and hepatocellular SAM:SAH ratios) is effective in preventing hepatocyte apoptosis^[53]. While Ji *et al*^[16,26], using the mouse model of intragastric ethanol feeding, have also shown the protective effect of betaine on alcoholic apoptosis, their focus has been in pursuing a link of homocysteine-induced ER stress to apoptosis. But further studies in our laboratories using biochemical approaches have confirmed that indeed it is the increased intracellular SAH levels (that were achieved by using adenosine or tubercidin to specifically increase SAH levels without a change in homocysteine levels) that cause increases in apoptosis of hepatocytes. Further, these induced increases in apoptosis and increased SAH levels could both be significantly attenuated (40%-50%) by simultaneous betaine exposure^[53]. Verification that

the protective effect of betaine was primarily *via* the BHMT-catalyzed methyl group transfer, and not due to osmoregulation^[54], was illustrated by using DMG^[53], a product feedback inhibitor of BHMT^[55].

We have also shown increasing inhibitions of ICMT activity with decreases in the SAM:SAH ratio similar to our observations with PEMT. Almost 30% less ICMT activity was observed when the SAM:SAH ratio was 2.5 (intracellular ratio in hepatocytes from ethanol-fed rats) as compared to the activity observed at the ratio of 5.0 (the ratio observed in the controls or betaine-fed ethanol rats). We have also shown that hepatocellular ICMT enzyme levels are not affected by ethanol consumption (Kharbanda and Tuma, unpublished observations). There is evidence that the ICMT activity may be enhanced in non-parenchymal hepatic cells after ethanol consumption^[56,57], which suggests that the alterations in methylation reactions may be limited to alcohol-metabolizing cells.

Final support for a role of normal ICMT in preventing apoptosis has been derived from experiments using inhibitors of ICMT such as cysmethynil^[58], N-acetyl-L-farnesyl cysteine (AFC) and N-acetyl-geranylgeranyl cysteine (AGGC). Data shows that exposure to cysmethynil, AFC or AGGC induce hepatocytes to undergo apoptosis (Kharbanda and Tuma, unpublished observations). These observations clearly implicate a role of normal carboxyl methylation of endogenous ICMT substrate(s) in hepatocytes to play crucial roles in the prevention of apoptosis as has been shown for other cell types^[40-42]. Efforts are in progress to determine the downstream effector(s) of ICMT-catalyzed transmethylation reactions associated with inhibition of apoptosis of hepatocytes.

There are also reports that caspase-8 gene expression is sensitive to intracellular methylation status^[59]. Alcohol-induced increased SAH levels could directly increase caspase-8 expression/activity to result in enhanced apoptosis^[18].

PIMT and damaged proteins

Proteins undergo spontaneous thermodynamically driven changes over time that can result in decreased functionality. A common form of such damage is the spontaneous and non-enzymatic modification of aspartate and asparagine (which are among the most unstable residues in proteins and peptides) to form atypical isoaspartyl residues. The enzyme PIMT catalyzes the transfer of the methyl group of SAM to these isoaspartyl sites, allowing reisoimerization and restoration of the original alpha peptide linkage after repeated rounds of methylation^[60]. This physiological repair reaction helps prevent the accumulation of the protein molecules containing these abnormal aspartyl residues. In mammals, PIMT is expressed in all tissues with the highest level in the brain and blood tissues^[61]. Homozygous PIMT knockout mice accumulate damaged proteins in their tissues and organs, including the liver^[61].

Isoaspartate residues have been identified in a variety of cellular structural and functional proteins such as tubulin, calmodulin, histone 2B and collagen type-I. Evidence has been accumulating that the modified

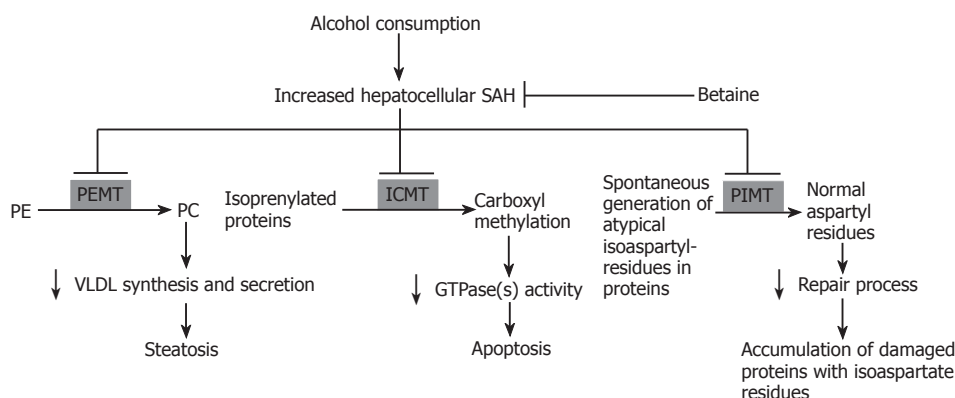

Figure 2 Schematic of the effects of ethanol and betaine on transmethylation reactions. Overall, it had been determined the deleterious effects of ethanol on impaired transmethylation reactions can be prevented by betaine supplementation.

proteins have impaired biological activity that can be substantially restored *via* methylation by PIMT^[62]. The physiological relevance of this repair by PIMT has also been demonstrated *in vivo* by studies using PIMT-deficient mice. These animals show aberrant vesicular transport which is caused by microtubule disorganization resulting from increased amounts of isoaspartyl residues in β -tubulin, a major substrate of PIMT and a component of microtubules^[63].

Environmental factors such as heat shock, photochemical stress and oxidative stress have been reported to result in an enhanced accumulation of damaged proteins with isoaspartate residues^[64,65].

Alcohol, PIMT, accumulation of damaged proteins and betaine

Our recent data shows that in addition to the above mentioned factors, chronic alcohol ingestion results in the accumulation of isoaspartyl-bearing damaged proteins in rat liver homogenates, particularly in the cytosol and microsomal fractions. This accumulation correlates to the lower SAM:SAH ratios and consequent impaired PIMT activity in livers of these rats as no change in the PIMT enzyme level by alcohol was observed. Furthermore, rats fed the betaine-supplemented ethanol diet showed similar isoaspartyl residue quantities per unit protein as controls. This restoration of the protein repair process was related to the effect of betaine to normalize the SAM:SAH ratios, which in turn, normalizes the PIMT-catalyzed protein repair methylation reaction^[66].

We also determined the effect of varying SAM:SAH ratios on the activity of purified PIMT. We observed 30% less PIMT activity at a ratio of 2.5 (which corresponds to the ratio in livers of ethanol-fed rats) as compared to a ratio of 5 as seen in livers of control or betaine-supplemented fed ethanol rats^[66]. These results were similar to those obtained with PEMT and ICMT activity measurements.

We are currently focusing on identifying some of the unique cellular structural and functional proteins susceptible to isoaspartyl damage following ethanol consumption by a proteomic approach and in understanding their role in altering the hepatocellular dynamics that could contribute to the progression of alcoholic liver injury.

Effects on other methyltransferases

DNA Methyltransferases and Alcohol: Modulation of

gene expression by alterations in DNA methylation can result in epigenetic changes and functional consequences. Current investigations are focused in understanding the molecular steps involved in the effects of ethanol on epigenetic modifications in relation to pathological changes in the liver. The inhibition of SAM-dependent DNA methyltransferase activities by ethanol-induced decreased SAM:SAH ratio could be responsible for the impaired DNA methylation reported in rats fed intragastrically with ethanol and a high fat diet^[11]. The reduced hepatic DNA methylation patterns by ethanol consumption has been reported to be associated with increased expression of c-myc and increased genome-wide DNA strand break accumulation^[11]. Other studies have shown no effects of alcohol consumption on O⁶-methylguanine DNA methyltransferase levels in the liver of cirrhotic^[67], however its activity may be affected by altered SAM:SAH ratios. More information can be obtained from an excellent editorial of the epigenetic effects of ethanol on liver injury that was recently published^[68].

Glycine-N-Methyltransferase and Alcohol: This is an abundant cytosolic SAM-dependent methyltransferase involved in the synthesis of sarcosine. But GNMT, unlike PEMT, ICMT, PEMT and the DNA methyltransferases, is less sensitive to inhibition by SAH^[24]. However, it is allosterically inhibited by MTHF^[69] and plays a role in regulating SAM:SAH ratios^[70]. Ethanol has been shown to decrease GNMT transcript levels, however an increase in its activity was observed after alcohol consumption, possibly related to decreased MTHF levels^[71].

CONCLUSION

Alcohol-induced elevation of intracellular SAH levels can impair the methylation reactions catalyzed by three enzymes, PIMT, PEMT and ICMT, which consequently contribute to the accumulation of damaged proteins with isoaspartyl residues and the induction of hepatic steatosis and apoptosis, respectively. We further provide data to support that these pathologies can be significantly attenuated by betaine administration. We believe that this protection is *via* remethylation of homocysteine that leads to normalized intracellular SAH levels and maintenance of normal methylation reactions of these three and other methyltransferases. A schematic of this working scheme is

depicted as Figure 2. Overall, we have identified that the increased hepatocellular SAH levels generated by chronic ethanol exposure can negatively affect the activities of the three methyltransferases, PEMT, ICMT and PIMT. These methylation defects, in turn, cause decreased synthesis and secretion of VLDL, impaired activation of GTPases and diminished protein repair process on molecules such as tubulin. These deficiencies ultimately contribute to the induction of steatosis, apoptosis and the accumulation of damaged proteins which could exaggerate hepatocellular injury by disrupting normal cellular function including trafficking events. Betaine administration can prevent the increase in SAH and thereby prevent these ethanol-induced pathologies.

In addition to its effects in ameliorating alcoholic liver injury, betaine has also been shown to prevent carbon tetrachloride-induced liver injury^[72] as well as to considerably decrease indices of steatosis in nonalcoholic steatohepatitis (NASH) patients^[73-75]. These properties along with the low cost and easy use and availability of betaine underscore the advantages of choosing this metabolite for the treatment of liver injury.

Abstract

Ethanol is a hepatotoxin. It appears that the liver is the target of ethanol induced toxicity primarily because it is the major site of ethanol metabolism. Metabolism of ethanol results in a number of biochemical changes that are thought to mediate the toxicity associated with ethanol abuse. These include the production of acetaldehyde and reactive oxygen species, as well as an accumulation of nicotinamide adenine dinucleotide (NADH). These biochemical changes are associated with the accumulation of fat and mitochondrial dysfunction in the liver. If these changes are severe enough they can themselves cause hepatotoxicity, or they can sensitize the liver to more severe damage by other hepatotoxins. Whether liver damage is the result of ethanol metabolism or some other hepatotoxin, recovery of the liver from damage requires replacement of cells that have been destroyed. It is now apparent that ethanol metabolism not only causes hepatotoxicity but also impairs the replication of normal hepatocytes. This impairment has been shown to occur at both the G1/S, and the G2/M transitions of the cell cycle. These impairments may be the result of activation of the checkpoint kinases, which can mediate cell cycle arrest at both of these transitions. Conversely, because ethanol metabolism results in a number of biochemical changes, there may be a number of mechanisms by which ethanol metabolism impairs cellular replication. It is the goal of this article to review the mechanisms by which ethanol metabolism mediates impairment of hepatic replication.

INTRODUCTION

The association between alcohol consumption and liver disease has been recognized for centuries. It is now well established that ethanol is a hepatotoxin. It is thought that the liver is a target of ethanol-induced toxicity because the hepatocytes of the liver are the primary ethanol metabolizing cells in the human body. The metabolism of ethanol results in many biochemical changes that have been proposed to contribute to liver disease. Among these changes are the generation of the reactive intermediate acetaldehyde, increased generation of reactive oxygen species, anoxia, changes in mitochondrial functions and bioenergetics, as well as an increase in the redox-state of hepatocytes.

There are two major ethanol-metabolizing pathways in hepatocytes; the first is mediated by the cytosolic enzyme alcohol dehydrogenase. This enzyme is responsible for the vast majority of the ethanol metabolism by hepatocytes^[1]. The second major pathway is mediated by the membrane bound enzyme cytochrome P450 2E1. The activity of this enzyme has been shown to be induced by ethanol and therefore, it has a greater contribution to the metabolism of ethanol in cases of chronic ethanol abuse^[2]. Even though there is a tremendous amount of evidence indicating that ethanol metabolism is required for many ethanol-induced dysfunctions, the mechanism(s) by which ethanol metabolism causes hepatic damage are not entirely clear. Although the mechanisms of ethanol-induced liver damage are equivocal, it is obvious that recovery from ethanol-induced liver injury is dependent on the ability of cells to replicate, replacing those damaged or killed as a consequence of ethanol metabolism.

Cellular replication is a process in which a tightly orchestrated series of sequential events must occur for successful completion. This series of events is collectively referred to as the cell cycle. The ultimate goals of the cell cycle are accurate replication of DNA and cell division.

The cell cycle can be broadly divided into five stages or phases. G0 is a stage in which cells are metabolically active but are not actively involved in the replication process (hepatocytes are normally in this stage). G1 is the initial stage of the replicative cycle, this is the stage in which enzymes and substances required for DNA synthesis are produced. S is the stage where DNA synthesis occurs. G2 is the stage in which the enzymes and substances required for mitosis are synthesized or activated. M phase is the stage in which cells divide and cellular replication is completed.

Tissue repair is a balance between damage and repair. Tissue damage occurs when injury dominates the ability of the tissue to replace cells lost to injury. In the case of ethanol-induced liver damage, it appears that ethanol metabolism is not only responsible for tissue damage but also impairs the ability of hepatocytes to respond normally and replace dead or damaged cells. Whether cellular injury to the liver has been caused by the effects of ethanol metabolism or by some other means, recovery is dependent, at least in part, on the capacity of the liver to replace cells lost to toxic insult. It is the focus of this article to review the evidence and potential mechanisms by which ethanol metabolism impairs the replication of hepatic cells and initiates or enhances alcoholic liver disease.

G1 phase inhibition

The liver has a tremendous capacity to replace cells that are lost or damaged by cytotoxic injury. In fact, if part of the liver is surgically removed, the remaining portion of the liver will increase in size to replace the mass of the original organ. This surgical procedure, performed with experimental animals has been termed partial hepatectomy and has become a standard model to investigate hepatic regeneration. Following partial hepatectomy, a synchronized wave of cellular replication occurs; thus, this model of liver damage is extremely amenable to the study of individual aspects of the cell cycle.

Much of what we have learned about the effects of ethanol on the cell cycle and hepatic replication has been derived through the use of the partial hepatectomy model of liver injury. In early studies using this model of liver injury, Wands *et al*^[3] found that the timing of ethanol administration after partial hepatectomy was important in determining the effects of ethanol on hepatic regeneration.^[12] If the animals were administered a single dose of ethanol 4 h before, or up to 8 h after partial hepatectomy, no effect of ethanol was detected on DNA synthesis 24 h after the surgical procedure. Conversely, if ethanol was administered 12-16 h after partial hepatectomy, DNA synthesis at 24-h post surgery was significantly impaired. If the animals received multiple doses of ethanol 0-8 h after partial hepatectomy, the effects of ethanol were altered and more severe inhibition of DNA synthesis was observed. These results led the authors to suggest that the inhibitory effects of ethanol on liver regeneration were cell cycle dependent; hepatocytes appeared to be most sensitive to the effects of ethanol early in G1, prior to the initiation of DNA synthesis. Once DNA synthesis was initiated, hepatocytes appeared to be relatively resistant to the effects of ethanol^[3]. It has also been shown that chronically feeding

ethanol to experimental animals impairs the regenerative capacity of the liver^[3,4]. This impairment was characterized by a delay in the peak, as well as a reduction in the magnitude of DNA synthesis, after partial hepatectomy^[4].

Although these initial *in vivo* investigations established the fact that ethanol affected the regenerative capacity of the liver, they did not address the possible mechanisms involved in this impairment. Higgins and Borenfreund, using the rat liver tumor cell line 32 II A6/2d, showed that addition of pharmacological concentrations of ethanol (10-100 mmol/L) for up to three days resulted in a concentration-dependent reduction in the final population density of the culture^[5]. Additionally, these authors demonstrated that substitution of acetaldehyde, the reactive byproduct of ethanol metabolism, for ethanol in the growth medium reproduced the ethanol-mediated impairments. This indicated that ethanol metabolism was responsible for the observed impairments and that acetaldehyde had a role in this dysfunction. To further implicate the role of ethanol metabolism, addition of the alcohol dehydrogenase inhibitor, pyrazole, ameliorated the ethanol-mediated impairments^[5]. Extending these findings, Higgins and Borenfreund analyzed 32 II A6/2d cells exposed to ethanol by flow cytometry and found an increase in the percentage of cells in the G1 phase of the cell cycle. The authors concluded that the inhibition of cellular proliferation associated with acute ethanol exposure in these cells was a result of this accumulation of cells in the G1 phase of the cell cycle^[6].

In the normal liver, the vast majority of hepatocytes are arrested in the G0 phase of the cell cycle. Hepatocytes require stimulation of hormones and growth factors to traverse G1 and begin cellular replication^[7]. Using isolated rat hepatocytes, Carter *et al*^[8] demonstrated that inclusion of ethanol to the growth medium dampened the proliferative response induced by hormonal and growth factor stimulation. These results indicated that the signals required to induce completion of G1 are also affected by ethanol.

Ethanol metabolism results in the production of reactive oxygen species; accumulation of reactive oxygen species results in oxidative stress^[9,10]. After partial hepatectomy there is an increase in the expression of TNF α and a number of mitogens^[7]. Interestingly, TNF α (which is necessary for induction of hepatocyte DNA synthesis) and mitogens both cause transient increases of H₂O₂ (a species of reactive oxygen). Transient increases in reactive oxygen species induce the expression of three important mediators of hepatocyte replication, the mitogen activated protein kinase (MAPK), extracellular regulated kinases (ERK) 1 and 2, and cyclin D1. Prolonged exposure to reactive oxygen species not only induces ERK 1 and 2, but also induces the cyclin dependent kinase inhibitor p21, and p38 MAPK, an inhibitor of cyclin D1. The combined effects of reduced cyclin D1 and expression of p21 efficiently inhibits the proliferation of cells^[11].

Investigating the effect of chronic ethanol administration on liver regeneration after partial hepatectomy, Koteish *et al*^[12] demonstrated that p38 MAPK and p21 were significantly increased in the livers of animals chronically fed ethanol, compared to controls after partial hepatectomy. These increases were accompanied by decreased expression

of cyclin D1, increased expression and activity of the cyclin dependent kinase inhibitor p27, and an increase in the activity of the transcriptional activator signal transducer and activator of transcription-3 (STAT-3). STAT-3 can be involved in cell cycle progression or growth arrest^[13] and is capable of inducing the expression of the cyclin-dependent kinase inhibitors p21 and p27. Normally, cyclin D1 binds to and sequesters p21, effectively nullifying its inhibitory affects. When cyclin D1 is deficient, as it is after partial hepatectomy in ethanol-fed animals, the activity of p21 as a cyclin-dependent kinase inhibitor is favored and cells can be arrested at the G1/S transition. Because ethanol metabolism produces reactive oxygen species in hepatocytes, the authors suggested that the increased activity of STAT-3, induction of p21, and cell cycle arrest at the G1 stage of the cell cycle may be a form of cytoprotection, protecting the cells from the acute increases in reactive oxygen species resulting from partial hepatectomy or other oxidative injury^[12].

Fat accumulation and impaired hepatic replication

The first pathologic change that occurs to the liver as a result of ethanol consumption is the appearance of fat in the liver, a condition known as steatosis. The accumulation of fat in the liver was once thought to be benign, but is now recognized as a factor that can be involved in more serious liver injury^[14]. It has been proposed that ethanol sensitizes the liver to a “second hit”, and that this “second hit” then induces the damage associated with alcoholic liver disease^[15]. In the model proposed above, fat accumulation in the liver, as a result of ethanol consumption, sensitizes the liver to additional oxidative injury.

To determine if the accumulation of fat in the liver was sufficient to sensitize the liver to oxidative damage, Torbenson *et al*^[16] investigated the effects of fatty liver on liver regeneration after partial hepatectomy. Mice with mutations in their leptin genes (leptin deficient ob/ob mice) spontaneously develop fatty livers. Using ob/ob mice, Torbenson *et al*^[16] found that liver regeneration was delayed in the ob/ob mice compared with lean littermates. The authors also found that the accumulation of the activated, phosphorylated form of STAT-3 (pSTAT-3) was increased in the livers of ob/ob mice compared with lean littermates. Additionally, an inverse correlation between the nuclear location of pSTAT-3 and DNA synthesis was observed, as well as decreased percentages of nuclei labeled with the DNA analog 5-bromo deoxyuridine (BrdU), increased expression of the cyclin-dependent kinase inhibitors p21 and p27, and expression of cyclin D1^[16]. These authors also suggested that this cell cycle arrest could act as a cytoprotective mechanism to protect hepatocytes from reactive oxygen species.

These results were very reminiscent of those observed in ethanol-fed animals, and leads one to speculate whether the induction of fatty liver by ethanol consumption is a causative agent of cell cycle impairment and aberrant cellular replication.

Mitochondrial dysfunction

Mitochondrial dysfunction has also been implicated as a mechanism by which ethanol metabolism mediates

hepatocyte injury. The mitochondria are the sites where oxidative phosphorylation occurs and ATP is produced. The process of oxidative phosphorylation inherently generates the reactive oxygen species, superoxide anion, and therefore, is a major source for the production of reactive oxygen species. Interestingly, mitochondrial dysfunction has also been shown to have a role in impaired hepatic regeneration.

Mice deficient in the inner mitochondrial anion carrier uncoupling protein-2 (UCP2), a negative regulator of superoxide production^[17], show impairment in their hepatic regenerative response after partial hepatectomy^[18]. The characteristics associated with this impairment in liver regeneration are reminiscent of those observed in ethanol-fed and leptin deficient ob/ob animals, and include elevated levels of reactive oxygen species, as well as increased and sustained expression of p21 and p38 MAPK.

UCP2 is induced by fatty acids and its expression is upregulated in the livers of ethanol-fed and ob/ob animals^[19,20]. Although one would expect that increased UCP2 would inhibit reactive oxygen-mediated impairment of liver regeneration, this does not appear to be the case^[18]. It has been suggested that the excess fuel supply present in the fatty liver promotes increased production of superoxide to levels beyond the capacity of the increased UCP2. This results in a net increase in reactive oxygen production that leads to the reactive oxygen species-mediated activation of signals, cell cycle inhibition, and impaired hepatic regeneration^[18].

G2/M transition

Using cells based on the well-differentiated hepatoblastoma cell line, Hep G2, that were genetically engineered to express alcohol dehydrogenase, our group investigated the effects of ethanol on cellular replication. Initially, it was shown that culturing these cells, termed VA-13 cells, in the presence of 25 mmol/L ethanol resulted in a decrease in the accumulation of the number of cells in the culture, and that this effect could be ameliorated by inhibiting alcohol dehydrogenase activity^[21]. Additionally, it was shown that inclusion of cyanamide, an inhibitor of aldehyde dehydrogenase, accentuated this impairment and that culturing the VA-13 cells in the presence of isopropanol, had no effect on cell accumulation. Alcohol dehydrogenase-mediated metabolism of isopropanol results in the production of acetone, not acetaldehyde. These results led to the proposal that acetaldehyde was responsible for the impairment in cell accumulation^[21].

Further investigation of the mechanisms of this impairment revealed an increase in the percentage of cells at the G2/M transition of the cell cycle in cultures of VA-13 cells maintained in ethanol^[22]. The activity of the cyclin-dependent kinase, CDK1, is required for mitosis to occur^[23]. Catalytic activity of CDK1 is negatively regulated by phosphorylation at threonine 14 (Thr 14) and tyrosine 15 (Tyr 15) and positively regulated by its interaction with cyclin B1. It was shown that the inactive phosphorylated form of CDK1 was increased by ethanol metabolism. Additionally, it was shown that there was no impairment in the ability of CDK1 to associate with cyclin B1. These findings indicated

that the G2/M cell cycle arrest was, at least in part, the result of an increase in the phosphorylated form of CDK1 and decreased activity of this cyclin-dependent kinase, the activity of which is required for mitosis^[22].

Recently we have begun studies investigating the mechanisms by which ethanol metabolism results in increased phosphorylation of CDK1, and have found that ethanol metabolism activated the checkpoint kinases Chk1 and Chk2. A number of stages or transitions at which the cell cycle is delayed or arrested have been described and have been termed checkpoints^[24]. These checkpoints are highly conserved evolutionarily. It is generally thought that the checkpoints have been conserved because of the importance of repairing damaged or inaccurately replicated DNA, thereby ensuring genomic integrity.

Cell cycle checkpoints result from the activation of signal transduction pathways that are mediated by ataxia telangiectasia mutated (ATM) and ATM-and Rad3-related (ATR), two closely related, highly conserved kinases with catalytic domains related to the phosphatidylinositol 3-kinase^[25]. ATM and ATR are thought to share the responsibility as the apical protein kinases of all cell cycle checkpoints with the possible exception of the mitotic spindle checkpoint^[25]. A variety of stimuli can initiate activation of the ATM/ATR regulated signal transduction pathways these include: DNA damage, delayed or incomplete DNA replication, viral infection, or oxidative stress^[25,26]. In cells of human origin, ATM and ATR primarily mediate their actions through two downstream effector kinases Chk1 and Chk2^[27]. One of the cell cycle transitions that can be regulated by this signal transduction cascade is the transition from the G2 to the M phase of the cell cycle. Although Chk1 and Chk2 are structurally unrelated serine/threonine protein kinases that are activated through phosphorylation by either ATM or ATR^[28], functionally they exhibit significant overlap with respect to substrate specificity, which appears in some circumstances to function redundantly.

Chk1 and Chk2 react with a variety of substrates involved in the G2/M cell cycle arrest. Among the more important are the phosphatase Cdc25c, and the tumor suppressor p53^[29-31]. Cdc25c is a phosphatase that removes the inhibitory phosphates at Tyr 15 and Thr 14 of CDK1^[32]. Both Chk1 and Chk2 phosphorylate Cdc25c at Ser 216. This phosphorylation creates a 14-3-3 protein-binding site; binding of 14-3-3 to Cdc25c results in Cdc25c being sequestered in the cytoplasm, inhibiting its transport to the nucleus where it is required to dephosphorylate CDK1^[32]. Using the VA-13 cells we have found that ethanol metabolism results in activation of both Chk1 and Chk2 and an increase in the phosphorylation of Cdc25c at serine 216. This may inhibit the dephosphorylation of CDK1, and contribute to the cell cycle arrest at the G2/M transition.

The tumor suppressor p53 is a transcriptional activator and therefore, binds specific DNA sites and modulates the transcriptional activity of target genes. The activity of p53 is primarily regulated by post-translational modification^[33]. Chk1 and Chk2, as well as ATM and ATR, phosphorylate p53. Phosphorylation and acetylation of p53 enhances p53 activity by increasing its stability, making it a less

desirable substrate for Mdm2-mediated degradation, and increasing its affinity to its target sites^[34-36]. Therefore, p53 mediates its actions by modulating the expression of its downstream targets. Among the cell cycle transcriptional targets that are up-regulated by p53 are p21 and 14-3-3^[37]. Additionally, expression of cyclin B1, the cyclin required for the G2/M activity of CDK1, is repressed^[38]. We have shown that the phosphorylation of p53 is increased in VA-13 cells exposed to ethanol, and that there is an increase in the expression of the cyclin dependent-kinase inhibitor p21 indicating that p53 may also be involved in the ethanol metabolism-mediated G2/M cell cycle arrest. Thus, multiple p53-dependent and-independent pathways regulate the G2/M transition.

Cell cycle arrest and liver disease

There is little doubt that ethanol impairs the replication of hepatocytes by a number of mechanisms, and that this impairment may have detrimental consequences not only in terms of inhibiting cellular replication, but also perhaps by aberrant cellular replication. The replacement of damaged or injured hepatocytes lost from the liver parenchyma normally occurs by the replication of mature hepatocytes^[39]. The normal replication of mature hepatocytes can be inhibited by cell cycle delay or arrest^[11,12,40,41]. Under conditions where normal mature hepatocyte replication is inhibited, the replication of the bipotential progenitor cells known as oval cells is increased to compensate for the inhibition of normal hepatocyte replication^[40,42,43]. Because oval cells are bipotential and can differentiate into either hepatocytes or bile ductular epithelium, it has been proposed that impairment of the primary pathway of hepatocyte replacement not only leads to regeneration of hepatocytes but also to increased proliferation of ductals^[44]. Importantly, it has been shown that there is a very strong correlation between the increased proliferation of bile ducts and liver fibrosis in patients suffering from alcoholic liver disease^[42,45]. This has led to the suggestion that impairment of mature hepatocyte replication and increased replication of oval cells contributes to portal fibrogenesis^[44].

CONCLUSION

Alcoholic live disease is a complex multifactorial disease. It appears that the biochemical changes that occur in the liver as a result of ethanol are primarily responsible for the ethanol-induced toxicity to this organ. The liver has a tremendous capacity to replace cells lost to toxic insult. It is clear that the biochemical changes that occur as a result of ethanol metabolism can affect the replication of hepatic cells and potentially the recovery of the liver. The impairment in cellular replication may initiate or potentate liver damage by impairing the regeneration of cells lost to ethanol metabolism-mediated toxic injury or induction of aberrant replicative pathways. Further investigation of these dysfunctions is required to fully delineate the role of impaired cellular replication in alcoholic liver disease.

Abstract

Chronic ethanol consumption is associated with serious and potentially fatal alcohol-related liver injuries such as hepatomegaly, alcoholic hepatitis and cirrhosis. Moreover, it has been documented that the clinical progression of alcohol-induced liver damage may be associated with an increase in hepatocellular death that involves apoptotic mechanisms. Although much information has been learned about the clinical manifestations associated with alcohol-related diseases, the search continues for a better understanding of the molecular and/or cellular mechanisms by which ethanol exerts its deleterious effects such as the induction of pro-apoptotic mechanisms and related cell damaging events. As part of the effort to enhance our understanding of those particular cellular pathways and mechanisms associated with ethanol toxicity, researchers over the years have utilized a variety of model systems. Recently, work has come forth demonstrating the utility of a hybrid cell line (WIF-B) as a cell culture model system for the study of alcohol-associated alterations in hepatocellular mechanisms. Success with such emerging model systems could aid in the development of potential therapeutic treatments for the prevention of alcohol-induced apoptotic cell death that may ultimately serve as a significant target in delaying the onset and/or progression of clinical symptoms of alcohol-mediated liver disease. This review article summarizes the current understanding of ethanol-mediated modifications in cell survival and thus the promotion of pro-apoptotic events with emphasis on analyses made in various experimental model systems, particularly the more recently characterized WIF-B cell system.

INTRODUCTION

It has been well established that chronic ethanol consumption can lead to a variety of pathological consequences (ethanol-related liver injuries such as hepatomegaly, fatty liver, alcoholic hepatitis and cirrhosis)^[1,2], yet the mechanism(s) by which ethanol causes hepatotoxicity requires further clarification. From several years of investigation, certain factors have been identified as having a role in ethanol-induced toxicity, such as changes in redox status (NAD⁺/NADH ratio), the accumulation of acetaldehyde (a product of ethanol oxidation), depletion of antioxidants such as glutathione, and the generation of reactive oxygen species (ROS)^[3-8]. As a consequence, it has been demonstrated that amongst the various deleterious effects that can result from ethanol administration, it has been shown that alcohol-induced diseases are accompanied by morphological liver changes that include the increased production of apoptotic cells^[9-11]. More specifically, it has been demonstrated that ethanol administration is linked to hepatocyte apoptosis^[12-14] and that the number of apoptotic cells detected in the liver correlates with the development of ethanol-induced pathological liver injury^[15].

Apoptosis is a regulated mode of cell death, which is characterized by specific biochemical and morphological changes in the cell. Morphologically, during induction of apoptosis, the affected cells shrink, lose cytoskeletal contacts and undergo chromatin condensation. During the terminal phase of the apoptotic process, the nucleus collapses followed by fragmentation of the entire cell into apoptotic bodies which are recognized and eliminated through phagocytosis by neighboring cells^[16-18]. The search for the biochemical and signal transduction pathways involved in producing the characteristic apoptotic morphological cellular changes has been underway for several years. The current dogma is that apoptosis is

thought to occur by two main pathways involving either an extrinsic route (which utilizes death receptors), and/or an intrinsic pathway that involves mitochondrial intracellular stress signals^[19]. Once triggered, the apoptotic machinery is set into motion through the activation of a family of intracellular cysteine proteases known as caspases, which amplify appropriate signals by acting as initiators as well as executioners in the death program. For instance, there are downstream executioner enzymes (caspases 3, 6, and 7) that are activated by upstream initiator caspases (caspases 8, 2, 9, and 10) that are in turn regulated by specific protein-protein interactions. As an example, caspases may be activated in an extrinsic manner by membrane signaling events (death domain transmembrane receptors) and/or by intracellular intrinsic changes resulting in the release of specific proteins from the mitochondria. Intertwined in these pathways are the proteins that control the intrinsic or extrinsic routes of apoptosis that often belong to families that have specific domains that mediate their action. Some of the regulatory proteins that have been identified include those of the Bcl-2 family, which possess anti-apoptotic as well as pro-apoptotic activity *via* the *Bcl-2* and *Bax* genes respectively.

Normally, in a healthy individual, the highly regulated apoptotic system is counterbalanced by cytoprotective signals that maintain tissue homeostasis. However, when an organism is subjected to repeated or exacerbated insults of a pathological stimulus such as alcohol, pro-apoptotic death factors can be inappropriately expressed shifting the balance towards enhancement of the apoptotic machinery and subsequent deleterious effects. Hence, it has become clinically relevant that a better understanding of the mechanisms and factors involved in apoptosis be ascertained which has lead to an emergence of studies concerning the role of apoptosis in the initiation and progression of alcohol-induced liver injury.

ETHANOL-MEDIATED PATHOLOGICAL FACTORS AND APOPTOSIS

Over the past decade, significant progress has been made concerning the identification of contributing factors that are involved in the initiation and progression of apoptosis in both clinical and experimental alcoholic liver disease states. In general, it has been shown that alcohol-mediated apoptosis is a multi-factorial process that could involve: (1) oxidative stress mechanisms^[20]; (2) the effects of various cytokines, particularly TNF- α and TGF- β ^[21,22]; (3) the involvement of death receptor pathways (TNF-receptor 1 and Fas/CD95)^[7,23]. How and when these factors elicit hepatotoxic effects is not completely understood, however it has been noted that a direct correlation exists between the ethanol concentration and time of exposure in the ability of these factors to promote apoptotic and/or necrotic cell death. For instance, it has been shown that higher amounts of alcohol resulted in a decline in apoptosis with an increase in promotion of necrotic cell death, presumably from the induction of microsomal cytochrome components, specifically cytochrome P450 2E1 (CYP2E1). Conversely, at lower concentrations of

ethanol, apoptosis is the preferential mode of injury as death was found to be triggered by the Fas receptor system^[24]. Thus, ethanol administration is related to cellular injury mechanisms, yet a complete understanding of the presumably intertwined factors that can be involved in hepatotoxicity is still sought. The following is a brief review of current knowledge concerning the factors identified in alcohol-mediated apoptotic liver damage.

Oxidative stress and alcohol-induced liver apoptosis

Following the recognition that ethanol and its metabolites induce the formation of reactive oxygen species (ROS) in liver cells; studies were able to link the ethanol-mediated induction of oxidative stress to the observed enhancement of apoptosis. Specifically, it has been demonstrated that one of the mechanisms responsible for ethanol-induced hepatotoxicity appears to involve the induction of intracellular enzymes, such as alcohol dehydrogenase (ADH) and the induction of CYP2E1, that oxidize ethanol to reactive metabolites, producing reactive oxygen species and lipid peroxides^[20]. In linking the ethanol-induced oxidative stress with liver cell apoptosis, it was determined that ROS cause damage to the mitochondria by altering mitochondrial membrane potential and/or membrane permeability. This in turn can initiate the release of pro-apoptotic factors, such as cytochrome c, thus activating the caspase cascade^[25-27]. Identified targets in this process include mitochondrial DNA and specific proteins that are promoters of apoptosis (Bax, Bad, and Bid), which are related to the Bcl-2 oncogene family^[7].

Ethanol treatment was also shown to impair antioxidant levels in hepatocytes, resulting in ROS generation and increased oxidative stress. For example, the balance of glutathione is impaired by ethanol treatment and was found to be involved in the regulation of mitochondrial function in alcohol-associated apoptosis^[28]. In particular, it was determined that the mitochondrial glutathione (mGSH) pool itself is depleted after ethanol administration, leading to the induction of the apoptotic cell death program^[29-31].

Overall, in reviewing the data, it is clear that ethanol administration results in enhanced oxidative stress; that mitochondria are intimately involved in the survival of the cell as both a producer and target of ROS; and that apoptotic death can be the consequential end of these changes.

The role of cytokines in ethanol-induced apoptosis

Cytokines are produced by multiple cell types in the liver and are integral in cellular signaling processes. Normally, liver cells use well-developed defense mechanisms as protection against cytokine-mediated damage. However, when toxins such as ethanol stress the cells, they lose their survival protection and become susceptible to the effects of the various cytokines^[21].

This scenario has been shown as the ethanol-related release of cytokines [e.g. tumor necrosis factor- α (TNF- α), interleukin-1 beta (IL-1 β), IL-6, IL-8, IL-10, and transforming growth factor-beta 1, TGF- β 1] is associated with the promotion of pro-apoptotic mechanisms^[22,32]. Furthermore, TNF- α and TGF- β in particular have

been strongly implicated in ethanol-induced apoptosis. Specifically, it has been well documented that the chronic exposure of ethanol can result in an elevation of hepatic TNF- α , which in turn has been related to the activation of caspases and the apoptotic program^[8,33,34]. One pathway in which TNF- α -associated apoptosis occurs is through the interaction with the death receptor family, Fas ligand/Fas, and TNF/TNF receptor (TNFR) systems. Within this family are three characterized receptors (TNFR1, TNFR2, and the Fas antigen, which are structurally related with shared homology for a death domain sequence, a C-terminal intracellular domain that is involved in apoptosis pathways. In another mechanism of TNF- α -induced cell death, the role of TNF- α and mitochondrial GSH depletion in ethanol-related apoptosis was further defined. As mentioned above, ethanol impairs the transport of cellular glutathione (particularly mGSH) resulting in its depletion and the subsequent sensitization of the cell to undergo an apoptotic death. This ethanol-related depletion of mGSH was also found to be associated with TNF-mediated cell death in hepatocytes, as the cells became apoptotic as a result of TNF-related events (such as the generation of hydrogen peroxide). Validation of this association came through studies demonstrating that TNF- α -induced oxidative stress and subsequent apoptosis could be prevented by incubating hepatocytes with antioxidants as well as S-adenosyl-L-methionine, a substance that increases mGSH levels^[35]. Overall, the data obtained from numerous studies has demonstrated that ethanol exacerbates TNF-related hepatotoxicity, in part, through the induction and perpetuation of apoptotic cell death pathways.

Participation of TGF- β 1 in ethanol-induced apoptosis has also been widely studied. TGF- β 1 is the prototype member of the TGF- β family that is involved in a diverse array of biological activities including development, differentiation, tissue remodeling, and apoptosis^[36,37]. Several liver cells (including hepatocytes and hepatic stellate cells) can produce TGF- β 1 in response to alcohol toxicity, and this production is considered to have a significant impact in the initiation and progression of alcoholic liver disease^[38,39]. Researchers have identified some of the pro-apoptotic pathways that have been induced by the up-regulation of TGF- β 1 in response to ethanol treatment. It has been demonstrated utilizing a fetal hepatocyte model that TGF- β 1 induces apoptosis by producing oxidative stress in the cells by increasing ROS production and decreasing the level of a natural antioxidant, glutathione^[40,41]. In addition, the increase in TGF- β 1-mediated signaling, resulting in caspase activation, can be associated with the enhanced cleavage of the caspase substrate PARP [poly (ADP)-ribose polymerase]^[42]. It has also been identified that TGF- β 1 can activate the caspase cascade by either of the two primary pro-apoptotic mechanisms (death receptor-mediated pathway or intracellular stress-signaled pathway involving mitochondrial changes and the release of cytochrome c), and either pathway can involve the formation of an apoptosome complex that activates the proteolysis of the cell^[43].

Involvement of the Fas/Fas ligand system in ethanol-induced liver cell apoptosis

Of the death receptor-mediated pathways, the involvement of the Fas/Fas ligand system has proven to play a significant role in alcohol-related apoptosis in the liver. The pro-apoptotic signaling of Fas (a glycosylated cell-surface protein) is similar to other death receptors in that a specific interaction of the oligomerized receptor with an associated ligand (i.e. Fas ligand) or antibody stimulates the recruitment of the cytoplasmic adapter protein (Fas associated death domain, FADD) that mediates caspase activation and the signaling of the apoptotic death program^[44]. In the liver, increases in the expression of membrane-bound Fas as well as the levels of soluble Fas and Fas ligand have been associated with pathological conditions associated with alcoholic hepatitis^[13,45]. Also, the up-regulation of Fas ligand in hepatocytes following ethanol treatment is thought to induce apoptotic death of neighboring cells by interacting with the Fas receptor on the surface of those cells^[45]. Overall, it is thought that the activation of Fas results in the promotion of the apoptotic program that can include the induction of the caspase cascade and permeabilization of the mitochondrial membrane^[46,11]. Moreover, the importance of the Fas/Fas ligand system in caspase 3 activation and apoptosis in the liver following ethanol treatment was substantiated as the administration of a caspase 3 inhibitor was shown to block ethanol-induced caspase 3 activity along with apoptosis^[47]. Thus, there is a growing amount of evidence that the Fas/Fas ligand system is a critical element in the activation of the caspase cascade and the subsequent demise of liver cells following chronic ethanol abuse.

MECHANISMS OF ALCOHOL-INDUCED APOPTOSIS

The enhancement of our understanding of the mechanisms involved in the apoptotic cascade is becoming exceedingly important and relevant to disease states such as ALD. However, studies concerning the effect of ethanol on cellular processes such as apoptosis are often limited due to the applicability of the model system. As an example, the dose required for ethanol-induced hepatotoxicity *in vitro* has been found to vary between cell strains presumably due to the differences in the metabolism of ethanol by ADH and CYP2E1^[25]. Also, the use of freshly isolated hepatocyte models were found to produce confounding results when searching for mechanistic parameters as the cells dedifferentiate (i.e. lose cell polarity and many liver-specific characteristics such as the ability to metabolize ethanol) within a few hours after isolation, making the cells useful for short-term culture conditions only. Despite these limitations, many studies have been performed yielding useful information concerning pro-apoptotic mechanisms that are induced following ethanol administration.

Around fifteen years ago, interest began to develop concerning the relevance of apoptotic cell death in liver pathology with particular interest in hepatocellular injury associated with ethanol toxicity^[48]. Since the

acceptance that apoptosis may play a significant role in the development of liver injury, studies have searched for the potential mechanisms and pathways that are involved. In animal models, it was demonstrated that ethanol feeding resulted in an increase in apoptotic cells in the liver^[11,49] that was subsequently shown to be related to the induction of reactive oxygen species (ROS) as a result of ethanol metabolism and the generation of acetaldehyde^[50]. Furthermore, it was concluded that the ethanol-induced ROS production was driven by redox changes that ultimately lead to mitochondrial dysfunction and caspase activation. These intrinsic events were not, however, the only mechanism by which ethanol was found to induce apoptosis. Specifically, it was determined that ethanol can also induce apoptosis through the involvement of the extrinsic death receptor pathway via the Fas/CD95 receptor system^[50].

In other works, acute studies involving ethanol treatment to cells isolated from animals also demonstrated that oxidative stress was involved in mitochondrial membrane changes that were found to result in cytochrome c release and caspase activation^[51,52]. Additionally, studies using developed recombinant cell lines demonstrated the role ethanol-inducible CYP2E1 has in alcohol-mediated apoptosis. Particularly, it was shown that ethanol-induced apoptosis was related to oxidative stress and subsequent lipid peroxidation in CYP2E1 over expressing cells^[53], confirming the central role ROS and CYP2E1 have in ethanol-mediated cell death as hypothesized in previous works^[25,54-56]. Additional evaluations demonstrated that such activation of intrinsic apoptotic pathways could be related to alcohol-mediated glutathione depletion which enhances the sensitivity of the cell to succumb to death, especially when faced with additional insults (e.g. increases in TGF- β expression or the presence of Hepatitis virus)^[52,57-59]. Furthermore, continued searches for pro-apoptotic mechanisms involved in ethanol-mediated cell injury have provided additional information regarding the potential contribution regulatory mechanisms have in hepatocellular apoptosis, such as the role of NF- κ B and ethanol-mediated alterations in proteasome function^[60,61], whether the processes are p53 dependent^[62,63], and what role pro-apoptotic Bcl-2 family proteins have in mediating mitochondrial permeability and apoptosis during alcohol cytotoxicity^[59].

Overall, substantial information has been gained linking oxidative stress from alcohol metabolism *via* ADH and CYP2E1 to the induction of several pro-apoptotic mechanisms involving both intrinsic and extrinsic apoptosis pathways. However, the development and use of additional model systems, such as a recently described polarized hepatic cell line, may significantly contribute to our understanding of pro-apoptotic mechanisms induced as a consequence of ethanol administration.

ETHANOL-INDUCED APOPTOSIS IN A POLARIZED LIVER CELL MODEL

Many of the studies performed previously concerning the effect of ethanol on cellular processes have used alcohol-

fed animal models as sources of isolated hepatocytes in order to provide more compatible models to human pathology than most cell culture systems provide. However, limitations were often observed in the model systems used. For example, the study of protein trafficking events in cultured systems has been hampered by the lack of a well-polarized cell that adequately mimics the complexity of *in vivo* hepatocyte protein delivery systems (i.e. the indirect transport of apical membrane proteins). Recently, our laboratory has demonstrated that the use of the WIF-B hepatoma hybrid cell line (in which polarity is a stable and dominant trait)^[64,65] is an ideal *in vitro* model for studying the effects of ethanol on cellular processes^[66]. Specifically, the WIF-B cells were found to exhibit alcohol dehydrogenase (ADH) activity allowing for the efficient metabolism of ethanol. Also, increases were observed in cellular triglyceride levels in the WIF-B cells following ethanol treatment, similar to the reported fat accumulation that is observed in human alcoholic liver injury. In addition, treatment of the WIF-B cells with alcohol resulted in morphological changes in the cells as demonstrated by decreases in bile canaliculi formation and cell-cell contacts^[66]. Thus, the use of the WIF-B cell line to study ethanol-induced cellular mechanisms is quite appropriate since the cells present a unique culture system that has the ability to metabolize ethanol and is a system that more closely resembles human morphology than other known cell lines.

The WIF-B hybrid cell is a cross between a human fibroblast (WI 38) and a Fao rat hepatoma cell line^[64,67]. This clone represents a polarized and differentiated cell of hepatic origin that exhibits long-term viability in culture, develops a hepatocellular-polarized phenotype and expresses human genes coding for liver-specific proteins (albumin, fibrinogen, and ADH)^[68]. One of the unique characteristics of the WIF-B clone is that the cells grow in monolayers and acquire a polarized phenotype as the cells form bile canaliculi-like spaces (BC) that have concentrated apical membrane proteins. Therefore, these cells are useful for the functional studies of hepatocyte-specific properties such as the transport of membrane proteins. Indeed, several studies have utilized the advantages of the maintained polarized cell to study intercellular communication, bile acid transport systems, and membrane trafficking pathways^[69-71].

In recent studies using this hepatic model, it was demonstrated that ethanol treatment induces apoptosis via signals emanating from the pro-apoptotic death receptor systems (i.e. Fas/CD95) as well as from intrinsic signals that resulted in mitochondrial changes^[72]. Specifically, it was demonstrated that ethanol treatment of WIF-B cells resulted in a significant increase in apoptotic-related morphological changes (cells that contained condensed chromatin) that were also associated with pro-apoptotic biochemical features (indicated by the induction of caspase-3 activity). Also, it was shown that caspase-3 activation in ethanol-treated WIF-B cells was related to mitochondrial permeability transition (MPT) as ethanol treatment resulted in cytochrome c release that was found to be sensitive to cyclosporine A (an inhibitor of MPT). Additionally, it was determined that in the ethanol-induced

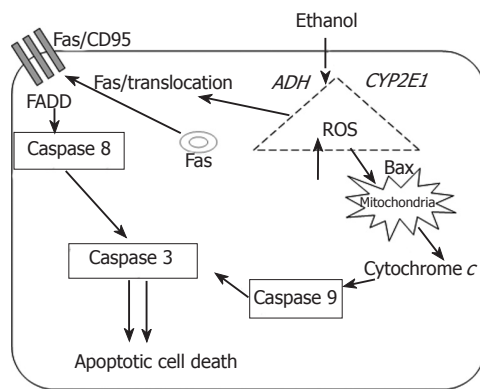

Figure 1 Schematic representation of the potential pathways involved in the initiation and propagation of ethanol-induced apoptosis. Ethanol metabolism and the consequential generation of reactive oxygen species are implicated in the activation of pro-apoptotic mechanisms via death receptor (i.e. Fas/CD95) as well as as intrinsic apoptotic pathways.

apoptosis in WIF-B cells, the activities of upstream initiator caspases (caspase-2 and caspase-8), that are directly related to membrane signaling events of death receptors such as Fas, were increased. Concurrently, it was determined that Fas protein levels in the membrane fraction of the cell were found to be enhanced without a corresponding change in mRNA levels.

Overall, it was shown that ethanol treated WIF-B cells were induced to undergo apoptosis via protease activation and this was found to be related to death receptor signaling as well as mitochondrial stress events (Figure 1). These results are consistent with those reported in other model systems, especially the work by Minana *et al*^[60]. In those studies, the investigators demonstrated that ROS (produced as a consequence of ethanol metabolism) induced apoptosis by two different mechanisms that involved MPT and the Fas receptor system. However, characterization of CYP2E1-mediated events in ethanol-mediated apoptosis in WIF-B cells has not been completed. In preliminary work, it has become evident that the WIF-B model system may be quite useful as CYP2E1 activity and protein levels can be reproducibly evaluated in these cells by ethanol as well as pyrazole treatment (unpublished data). Therefore, the utilization of WIF-B cells, a model which allows manipulation of the ethanol metabolizing systems, may significantly increase the potential of acquiring novel and clinically relevant information. Thus, further studies using WIF-B cells aim to enhance our understanding of crosstalk mechanisms that may exist between the major apoptotic-inducing pathways (extrinsic and intrinsic). Also, a more complete understanding of how apoptotic signals are favored and triggered over survival or compensatory signals is sought. Additionally, information as to how necrotic cell death mechanisms overcome apoptotic signals as the duration and amount of ethanol consumption is increased could potentially be determined using the WIF-B model system.

CONCLUSION

Apoptotic hepatotoxicity has been implicated in the pathogenesis of several liver diseases including that

involving ethanol abuse. Insights into the cellular mechanisms involved in the initiation and propagation of apoptosis will significantly impact our understanding of alcohol-induced liver disease and may lead to the potential development of therapeutic interventions. The use of an emerging model system, polarized hepatic WIF-B cells, could significantly impact the study of alcohol-related hepatocellular injury, especially concerning the delineation of mechanisms involved in ethanol-induced cell death. In addition, polarized hepatic cell cultures may aid in the acquisition of translational information as the WIF-B cells offer a more compatible model system that better correlates to human pathology for analysis of potential therapeutic targets that could modulate apoptotic mechanisms induced by ethanol.

Abstract

Mitochondrial dysfunction is known to be a contributing factor to a number of diseases including chronic alcohol induced liver injury. While there is a detailed understanding of the metabolic pathways and proteins of the liver mitochondrion, little is known regarding how changes in the mitochondrial proteome may contribute to the development of hepatic pathologies. Emerging evidence indicates that reactive oxygen and nitrogen species disrupt mitochondrial function through post-translational modifications to the mitochondrial proteome. Indeed, various new affinity labeling reagents are available to test the hypothesis that post-translational modification of proteins by reactive species contributes to mitochondrial dysfunction and alcoholic fatty liver disease. Specialized proteomic techniques are also now available, which allow for identification of defects in the assembly of multi-protein complexes in mitochondria and the resolution of the highly hydrophobic proteins of the inner membrane. In this review knowledge gained from the study of changes to the mitochondrial proteome in alcoholic hepatotoxicity will be described and placed into a mechanistic framework to increase understanding of the role of mitochondrial dysfunction in liver disease.

INTRODUCTION

Long term heavy alcohol consumption is the most prevalent cause of liver-related morbidity and mortality in the United States. Excessive alcohol consumption is estimated to be the third leading cause of preventable death in the United States with up to 12 000 deaths each year attributed to alcoholic liver disease^[1]. While it has long been held that the severity of alcoholic liver disease is dependent on the dose and duration of alcohol consumption, it has become increasingly clear that other factors may play a significant role in the development of liver disease^[2]. Studies show that only 25% of heavy drinkers will develop alcoholic steatohepatitis and even less than 10% will progress to cirrhosis^[3]. These observations have led to the general hypothesis that environmental, genetic, metabolic and/or viral factors, also referred to as "hits", may influence the progression from simple fatty liver (steatosis) to more serious liver diseases^[2].

Evidence supports a "multi-hit" hypothesis in the pathophysiologic sequelae of alcoholic liver disease wherein the "first-hit" involves lipid accumulation in hepatocytes (steatosis), followed by "second-hits" that lead to more serious conditions such as alcoholic steatohepatitis, fibrosis, cirrhosis, and cancer. Examples of "second-hits" include metabolic stressors such as obesity, hypercholesterolemia, and hyperglycemia, which are components of the cardiometabolic syndrome, and environmental stressors, which may include dietary factors and pollutants such as tobacco smoke. Recent epidemiologic and clinical studies indicate that environmental tobacco smoke, a widespread toxicant, may accelerate fibrogenesis and increase the severity of a number of chronic liver diseases including hepatocellular carcinoma, hepatitis C-mediated liver injury, and primary biliary cirrhosis^[4-8]. Moreover, alcohol, tobacco smoke, and obesity have been shown to be synergistic risk factors for hepatocellular carcinoma in patients^[9]. Taken together,

these studies clearly highlight the need to identify the molecular targets and mechanisms through which these potential stressors or "hits" interact to accelerate and worsen alcoholic liver disease.

Studies suggest a potential mechanistic link among chronic alcohol consumption and many of the proposed secondary stressors, which include increased oxidative damage, hypoxic stress, and disrupted redox cellular signaling. Interestingly, the mitochondrion is a primary target for many of these metabolic derangements, which can also differentially exacerbate hepatic pro-inflammatory responses. Furthermore, the mitochondrial proteome is exquisitely sensitive to modifications by reactive oxygen and nitrogen species (ROS/RNS) and thus offers a unique opportunity to investigate the molecular mechanisms underlying hepatic pathobiology from chronic alcohol consumption. Accordingly, this review article will present an overview of the emerging new roles of mitochondria and reactive species in the development of alcoholic liver disease.

MITOCHONDRIAL DYSFUNCTION IN ALCOHOLIC LIVER DISEASE: BIOENERGETIC DEFECTS AND OXIDANT PRODUCTION

The effects of chronic alcohol consumption on liver have been extensively studied and have advanced our understanding of the molecular mechanisms responsible for alcohol hepatotoxicity. In general, chronic consumption of alcohol causes liver disease *via* oxidative stress, hypoxia, upregulation of pro-inflammatory cytokines, and bioenergetic defects involving the interactions of multiple liver cell types. Early in the disease process gut-derived endotoxin^[10] activates Kupffer cells, which release a variety of potentially toxic substances including cytokines and ROS/RNS that negatively affect hepatic stellate cells and hepatocyte functions^[11]. Consequently, a number of responses occur in hepatocytes including increased ROS/RNS production, mitochondrial damage, and altered nitric oxide (NO)-dependent control of respiration^[12-14]. This profound disruption in mitochondrial metabolism contributes, in part, to liver disease by placing hepatocytes under bioenergetic stress. This is important because the inability to maintain hepatic ATP levels will predispose the liver to permanent damage due to a depression in the ATP requiring anabolic pathways responsible for replacing damaged and/or lost cellular macromolecules.

One critical change to hepatic mitochondria after chronic consumption of alcohol is a decrease in the rate of ATP synthesis. Conclusive evidence shows that chronic alcohol exposure depresses the activities of all the oxidative phosphorylation complexes by approximately 30%-50%, except Complex II^[15,16]. Inhibition of mitochondrial protein synthesis due to alcohol-mediated damage to the mitochondrial DNA^[13,17] and ribosomes^[18,19] is proposed to contribute to decreased functioning of the oxidative phosphorylation system and depressed rates of ATP synthesis^[20,21]. Recently, studies by Cunningham and colleagues have shown that both hepatic energy charge and

NADH-linked respiration are decreased in mitochondria isolated from liver of non-human primates allowed to consume alcohol for 18 mo^[22]; thus recapitulating the findings observed in rodent studies. This alcohol-dependent loss of mitochondrial function is also predicted to cause further increases in ROS/RNS production and oxidative damage to the organelle and liver.

During electron transport in the respiratory chain, electrons can "leak" from the respiratory complexes and be passed one at a time to molecular oxygen (O_2) to form low amounts of superoxide anion ($O_2^{\bullet-}$), which is proposed to be increased in hepatocytes due to alcohol-dependent alterations in mitochondria. Mitochondria contribute to the production of ROS in hepatocytes when alcohol is consumed through the metabolism of alcohol *via* distinct oxidative mechanisms and chronic alcohol-related alterations to the oxidative phosphorylation system^[23,24]. First, ethanol metabolism increases the availability of reducing equivalents (i.e. NADH) to the mitochondrion, which results in the redox active semiquinone intermediates within Complexes I and III to be in a more "reduced" state, thereby facilitating the reduction of O_2 to $O_2^{\bullet-}$ ^[25,26] (Figure 1). Moreover, in the chronic alcohol consumer, it is postulated that mitochondrial production of ROS is elevated not only due to increased NADH delivery to the respiratory chain, but also as a consequence of molecular defects to the respiratory complexes caused by chronic alcohol consumption^[13,27-29].

The mechanism of $O_2^{\bullet-}$ production by Complex III (ubiquinone cytochrome *c* reductase) is well understood, as it is linked to the reactions of the ubiquinone or "Q"-cycle^[30]. As the levels of cytochrome *b* are decreased by chronic alcohol consumption^[27,29] this defect is postulated to decrease the rate of re-oxidation of the ubisemiquinone anion ($Q^{\bullet-}$). This resulting increase in the steady-state levels of $Q^{\bullet-}$ would subsequently lead to increased $O_2^{\bullet-}$ in mitochondria from alcohol exposed subjects (Figure 1A). In contrast, the mechanism responsible for increased $O_2^{\bullet-}$ production by Complex I (NADH dehydrogenase) in response to chronic alcohol consumption remains undefined because the sites responsible for generating $O_2^{\bullet-}$ are not known. For example, the semiquinone in the flavin mononucleotide and the various iron-sulfur centers of Complex I have all been implicated as potential sites of $O_2^{\bullet-}$ production (Figure 1B). Recent studies have demonstrated that the majority of $O_2^{\bullet-}$ generated in mitochondria respiring on the Complex II-linked substrate succinate occurs *via* reverse electron transport into Complex I^[31-33]. This mechanism involves reverse electron flow from succinate to NAD^+ providing reducing equivalents to the redox carriers of Complex I, which then function as sites of $O_2^{\bullet-}$ production (Figure 1C). The contribution of reverse electron flow through Complex I may be enhanced as a consequence of alcohol-dependent defects to the complex^[27,28]. Similarly, mitochondrial levels of ROS may be increased by chronic alcohol consumption as a consequence of increased mitochondrial CYP450 2E1 levels^[34] and as a by-product from matrix enzymes such as α -ketoglutarate dehydrogenase^[35,36]. These higher rates of ROS production in the alcohol-damaged mitochondria

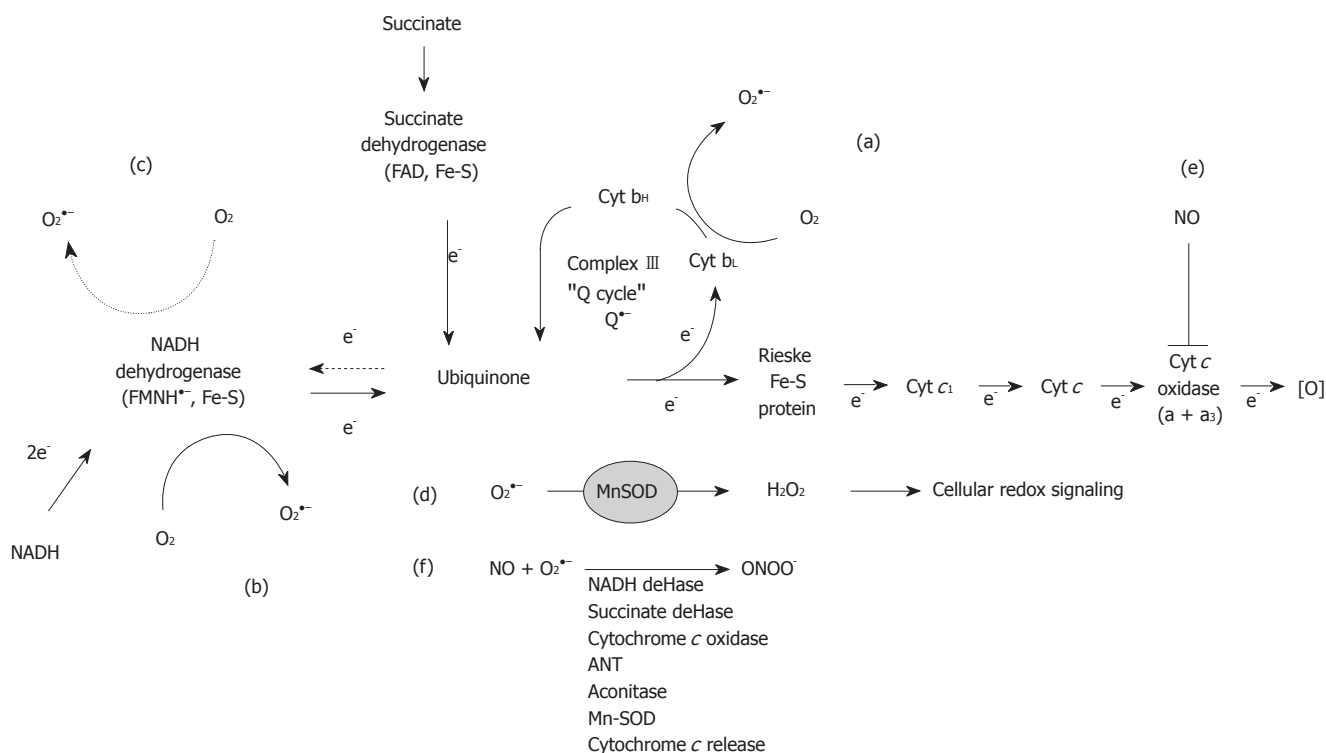

Figure 1 Superoxide production and reactive nitrogen species reactions in mitochondria. During electron transfer superoxide ($O_2^{\bullet-}$) is generated within Complexes I (b, c) and III (a) due to the presence of stable semiquinone anion species. Solid arrows illustrate forward electron flow, whereas dashed arrows indicate reverse electron flow through Complex II to increase $O_2^{\bullet-}$ production in Complex I (c). $O_2^{\bullet-}$ dismutation to hydrogen peroxide (H_2O_2) by manganese superoxide dismutase (MnSOD) affects cellular redox signaling pathways (d). Increased iNOS expression leads to diffusion of nitric oxide (NO) into mitochondria where it inhibits cytochrome c oxidase (e), which increases $O_2^{\bullet-}$ generation.

are predicted to negatively affect mitochondrial function through oxidative damage to mitochondrial macromolecules and cellular function through modulation of cellular redox signaling pathways (Figure 1D).

NITRIC OXIDE, REACTIVE NITROGEN SPECIES, AND MITOCHONDRIA PHYSIOLOGY: IMPACT ON ALCOHOL HEPATOTOXICITY

In this section some of the key characteristics by which nitric oxide (NO) and RNS affect mitochondrial function in the context of alcoholic liver injury will be presented. As discussed above, several studies have demonstrated that chronic alcohol consumption increases hepatocyte ROS production presumably from the mitochondrial respiratory chain^[12,25,37]. As these increased levels of ROS exceed those required for signal transduction and detoxification *via* antioxidant systems, mitochondrial DNA, protein, and lipid damage is predicted to be enhanced as a consequence of chronic alcohol exposure. In addition, NO production is increased in response to chronic alcohol *via* induction of inducible nitric oxide synthase (iNOS)^[12,38]. This has important ramifications for toxicity because NO and its metabolite peroxynitrite (ONOO⁻) have been implicated as key mediators of mitochondrial dysfunction^[39,40]. Indeed, the detrimental effects of NO largely stem from excess NO diffusing into the mitochondrion and reacting

with $O_2^{\bullet-}$ to produce ONOO⁻, a reactive metabolite that can directly or indirectly participate in reactions leading to inactivation of mitochondrial proteins *via* post-translational modifications^[41]. Moreover, it is known that NO can regulate mitochondrial function through reversible binding at the heme site in cytochrome c oxidase, which inhibits oxygen consumption^[42,43] and through cross-talk mechanisms with soluble guanylate cyclase^[44]. Potential impacts of NO and ONOO⁻ on mitochondria are illustrated in Figure 1E and F.

Exposure of mitochondria to low concentrations of NO results in the reversible inhibition of cytochrome c oxidase activity due to the competition of NO with O_2 at the binuclear center of the enzyme^[45-48]. Thus, NO has the effect to inhibit mitochondrial respiration. Studies from our laboratories have shown a novel role of NO in the pathogenesis of alcohol hepatotoxicity. We have demonstrated that the response of respiration to NO is altered by chronic alcohol consumption such that mitochondria from alcohol-fed animals are more sensitive to NO-dependent inhibition of respiration^[14,38]. It is proposed that this loss of control of NO signaling per se, results in excessive inhibition of the respiratory chain leading to bioenergetic dysfunction (i.e. decreased ATP synthesis) and increased ROS production^[49], which contribute to the development of alcoholic liver injury. The critical role of NO in alcohol hepatotoxicity is further supported because the increased sensitivity of mitochondrial respiration to inhibition by NO is absent in iNOS knockout mice fed alcohol chronically^[38]. Therefore,

this finding supports the hypothesis that the early induction of iNOS modifies the control of NO-dependent respiration, which contributes to the development of alcohol-dependent steatosis and inflammation^[38,50].

It has been shown that NO-mediated inhibition of respiration alters activation of hypoxia responsive targets in cells such that increased NO interferes with the upregulation of molecules required by cells to adapt to hypoxic stress^[51,52]. This may also have the effect of changing oxygen gradients in tissues. Indeed, this is precisely the series of events that we propose occurs with NO in alcohol hepatotoxicity^[49], which has been shown to be associated with tissue hypoxia^[53,54]. Several studies have clearly demonstrated that acute alcohol exposure "steepens" the hepatic oxygen gradient as a consequence of ethanol oxidation^[55,56], thus rendering the pericentral regions of the liver lobule hypoxic^[53]. Thus, the effect of acute hypoxia in an individual actively drinking is proposed to be exaggerated in the chronic alcohol consumer as a consequence of the alcohol dependent increase in inhibition of mitochondrial respiration by NO^[14]. In fact, studies by Arteel and colleagues demonstrate that chronic alcohol consumption increases liver hypoxia^[54]. This concept is important to consider because it suggests that the interaction of hypoxia and disrupted NO signaling in mitochondria may accelerate the progression from steatosis to more severe liver pathologies. Moreover, it is these conditions that will lead to the irreversible post-translational modification and inactivation of mitochondrial proteins, which are proposed to contribute to alcohol-mediated mitochondrial dysfunction and hepatic pathobiology.

MODIFICATION TO THE LIVER MITOCHONDRIAL PROTEOME IN RESPONSE TO CHRONIC ALCOHOL CONSUMPTION

From the discussion above it is clear that increased NO and altered control of respiration by NO can lead to excessive ROS/RNS formation and the post-translational modification of mitochondrial proteins. Specifically, it has been shown that ROS, RNS, and reactive lipid species can modify critical amino acid residues thereby disrupting the catalytic function of proteins. As stated above, these toxic effects on proteins largely stem from the diffusion of NO into mitochondria and its reaction with $O_2^{\bullet-}$ to generate more reactive species, such as ONOO⁻, other secondary RNS, and reactive lipid products. Because alterations in the redox state of protein thiols are important in regulating mitochondrial function such as respiration and oxidant production^[57,58], the identification of proteins with oxidized and/or modified thiol groups is critical for elucidating the mitochondrial defects that contribute to alcoholic liver disease.

A number of reversible and irreversible modifications to cysteine residues are known to occur upon interaction of free sulfhydryl groups (-SH) with ROS, RNS, and reactive lipids. Reversible modifications to thiols include the formation of nitrosothiols (P-SNO), sulfenic acids (P-SOH) and mixed disulfides (P-SSG). Cysteine residues can also be irreversibly oxidized to higher oxidation states such as sulfinic (P-SO₂H) and sulfonic (P-SO₃H)

acids by ROS and RNS. Each of these modifications has the potential to elicit a unique biological response that may disrupt normal mitochondrial functions. Studies have linked the oxidation and modification of protein thiols with induction of the mitochondrial permeability transition, alterations in energy metabolism, and oxidant production^[59]. Our laboratories have shown an alcohol-dependent loss of function of the mitochondrial low K_m aldehyde dehydrogenase (ALDH) as a consequence of oxidative modification of thiols^[60]. This is significant because inactivation of this important detoxification enzyme could potentially lead to increased levels of acetaldehyde and other reactive aldehyde species, which themselves have been shown to inactivate proteins through cysteine modifications^[61,62]. Recently, Song and colleagues also demonstrated alcohol-dependent inactivation of ALDH and several β -oxidation enzymes *via* oxidation and nitrosation of thiols^[63]. Taken together, these findings are consistent with the concept that modification of protein thiols may contribute to alcoholic steatosis and mitochondrial dysfunction through inactivation of proteins critical to the energy conservation pathways in liver.

While changes in the redox status of cysteine residues are known to affect mitochondrial activities, other types of post-translational modification should be considered as well. Tyrosine nitration (P-NO₂) is generally thought to induce permanent loss of protein function^[64] however recent studies suggest that tyrosine nitration may be oxygen-regulated, target-selective, and reversible such that it may function as a "nitrative signaling" process controlling mitochondrial energy metabolism^[65,66]. Studies have also established that 4-hydroxynonenal (4-HNE), a reactive lipid, may play an important role in alcohol hepatotoxicity *via* modification of key signaling proteins^[67,68] and inhibition of cytochrome *c* oxidase activity^[69,70]. 4-HNE has also been shown to inhibit several of the matrix dehydrogenase enzymes^[71,72] and proteins of the β -oxidation system^[73]. Moreover, electrophilic lipids like 4-HNE and the cyclopentenone 15-deoxy- $\Delta^{12,14}$ -prostaglandin J₂ have been shown to co-localize to mitochondria and induce mitochondrial ROS production^[74]. These results provide strong evidence suggesting that reactive lipids may disrupt mitochondrial function through selective targeting of mitochondrial enzymes.

In addition to post-translational modifications, it is also proposed that changes in the levels (i.e. abundances) of proteins that comprise the mitochondrial proteome may also negatively affect mitochondrial bioenergetics leading to liver injury. Early studies by Coleman and Cunningham established a key link between the chronic alcohol-related defects in Complexes I, III, IV, and V and losses in the 13 mitochondrial encoded polypeptides and redox centers that comprise the oxidative phosphorylation system complexes^[27,75,76]. Similarly, using a variety of proteomics approaches our laboratories have extended these findings to demonstrate a coordinated decrease in both mitochondrial and nuclear encoded subunits of the respiratory complexes, particularly those that comprise cytochrome *c* oxidase^[12,13]. Moreover, proteomic analyses revealed that 40 additional mitochondrial proteins had altered levels in response

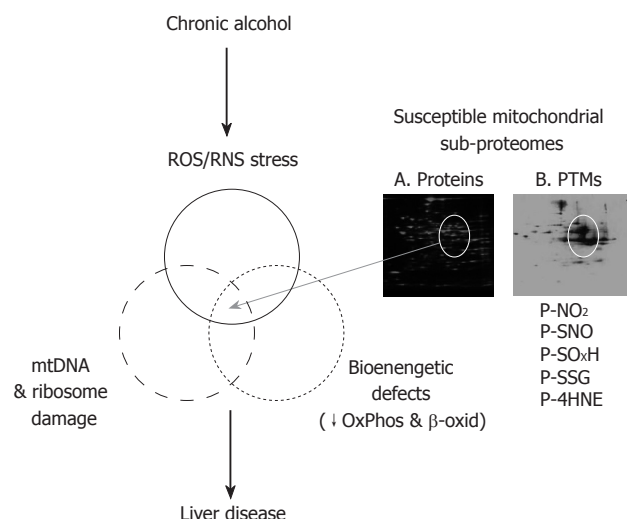

Figure 2 Overlapping alterations to the liver mitochondrial proteome contribute to the development of alcohol-induced liver disease. This figure illustrates the concept that there is a unique mitochondrial sub-proteome that when altered by chronic alcohol mediated mtDNA/ribosome damage, increased ROS/RNS production, and energy deficits contribute to the development of alcohol hepatotoxicity. These alterations involve changes in both protein levels (panel A) and post-translational modifications (PTMs, panel B) to this susceptible population of mitochondrial proteins.

to chronic alcohol consumption^[13]. These studies are interesting in that, previously unidentified alterations in several key energy metabolism enzymes of β -oxidation, the TCA cycle, and amino acid metabolism, as well as several mitochondrial chaperones were found to be altered by chronic alcohol exposure. Importantly, these changes can also be linked to pathways with a clear impact on one of the primary pathologies of alcoholic liver disease, i.e. steatosis. These findings highlight the power of proteomics to detect previously unidentified alterations to "vulnerable" mitochondrial sub-proteomes following chronic alcohol consumption that contribute, in part, to the development of alcoholic liver disease (Figure 2). These alterations may include changes in protein levels as well as post-translational modifications to this susceptible sub-set of mitochondrial proteins.

In summary, mitochondria play a variety of roles in a number of essential cellular functions including energy production and homeostasis, redox cell signaling, and apoptosis. Disruption of mitochondrial function, manifested by the inability to maintain cellular ATP levels is critical to the development of chronic alcohol-induced liver injury. Moreover, as a primary source for the formation of ROS and RNS, the mitochondrion is recognized as a critical component involved in cellular stress responses. While the sequence of events leading to alcohol induced mitochondrial dysfunction and liver injury remains undefined, emerging evidence suggests that: (1) interaction of NO with the respiratory chain may predispose hepatocytes to hypoxic injury and (2) post-translational modifications of critical residues within mitochondrial proteins by reactive species may alter cellular functions including energy metabolism and redox signaling. Similarly, an alcohol-mediated increase in ROS/RNS can damage mitochondrial DNA and ribosomes

resulting in decreased mitochondrial protein synthesis, which ultimately translates into a severe mitochondrial dysfunction. Investigations have provided novel mechanistic information regarding the impact of chronic alcohol consumption on the mitochondrial proteome; providing unique insight into the molecular mechanisms responsible for disease. This knowledge will clearly advance the design and testing of novel mitochondria-specific therapeutics in the treatment of alcoholic liver disease.

Abstract

Alcohol-induced fatty liver (steatosis) was believed to result from excessive generation of reducing equivalents from ethanol metabolism, thereby enhancing fat accumulation. Recent findings have revealed a more complex picture in which ethanol oxidation is still required, but specific transcription as well as humoral factors also have important roles. Transcription factors involved include the sterol regulatory element binding protein 1 (SREBP-1) which is activated to induce genes that regulate lipid biosynthesis. Conversely, ethanol consumption causes a general down-regulation of lipid (fatty acid) oxidation, a reflection of inactivation of the peroxisome proliferator-activated receptor- α (PPAR- α) that regulates genes involved in fatty acid oxidation. A third transcription factor is the early growth response-1 (Egr-1), which is strongly induced prior to the onset of steatosis. The activities of all these factors are governed by that of the principal regulatory enzyme, AMP kinase. Important humoral factors, including adiponectin, and tumor necrosis factor- α (TNF- α), also regulate alcohol-induced steatosis. Their levels are affected by alcohol consumption and by each other. This review will summarize the actions of these proteins in ethanol-elicited fatty liver. Because steatosis is now regarded as a significant risk factor for advanced liver pathology, an understanding of the molecular mechanisms in its etiology is essential for development of effective therapies.

INTRODUCTION

Fatty liver (steatosis) is the earliest, most common response of the liver to moderate or large doses (i.e. binge drinking) of alcohol as well as to chronic ethanol consumption^[1]. Steatosis was previously considered a relatively harmless side effect of heavy alcohol use. However, recent evidence now indicates that alcohol-induced fatty liver enhances susceptibility of the liver to more advanced pathology if drinking continues. Individuals with alcohol-induced steatosis are vulnerable to developing alcoholic steatohepatitis (ASH), hepatic fibrosis, cirrhosis and even hepatocellular carcinoma. Obesity, which may potentiate alcoholic fatty liver, is also considered an additional risk factor for alcoholic cirrhosis^[2] and for advanced liver disease in obese nondrinkers^[3]. The latter is most often presented clinically as nonalcoholic steatohepatitis (NASH). The reason(s) why some individuals progress from fatty liver to the more advanced stages of liver disease is not clear. The current concept adopted by many investigators is the two hit hypothesis in which the first hit is steatosis. This is followed by a second "hit" in the form of cytokine (e.g. TNF- α) production, mitochondrial dysfunction and/or oxidative stress. All three of these "hits" are widely believed to be major contributors to alcohol-induced liver injury and may compound the initial steatosis. An evolving concept that is gaining acceptance is that certain accumulated fatty acids are toxic to the liver, but that their toxicity is blunted by esterification with glycerol to form triacylglycerols (triglycerides). Thus ethanol-elicited hepatic lipid accumulation as well as that caused by dietary sources, has prompted renewed interest as a cornerstone of liver toxicity, as it may not only initiate but enhance the progression of alcoholic liver disease. This review will discuss both the metabolic and the molecular factors that contribute to ethanol induced steatosis. It will also consider the possible mechanism(s) by which liver injury is initiated to produce advanced liver pathology.

ETHANOL METABOLISM AND FATTY LIVER

The liver is the primary site of ethanol metabolism, as hepatocytes express the major ethanol metabolizing enzymes, alcohol dehydrogenase (ADH), and cytochrome P450 2E1 (CYP2E1) at higher levels than any other tissue^[4-6]. ADH, with a Michaelis constant of 1 to 2 mmol/L, catalyzes ethanol oxidation, using NAD as a coenzyme in a reaction that forms acetaldehyde and reduced NAD (i.e. NADH⁺) in reaction (1) below. This and the subsequent oxidation of acetaldehyde to acetate with the formation of another reducing equivalent of NADH⁺ in a reaction catalyzed by aldehyde dehydrogenase (ALDH) in reaction (2) below were shown to cause significant changes in cellular redox potential and provide more substrate availability for fatty acid synthesis.

Enhanced generation of reduced NAD also disrupts mitochondrial β -oxidation of fatty acids thereby diminishing the rate of lipid oxidation. This metabolic explanation for fatty liver was the prevailing concept for a number of years, but it was not sufficient to explain the rapid formation of fatty liver after acute ethanol administration. In addition, the degree of change in liver redox potential that occurs *in vivo* after chronic ethanol administration to rodents was significant but rather modest. Thus, the metabolic explanation for alcohol-induced fatty liver became insufficient to account for all changes that occurred in hepatic lipids after ethanol consumption. Later discoveries in cell signaling and characterization of specific transcription factors prompted investigations of specific factors that are operative in the pathophysiology of ethanol-induced steatosis.

UPDATED MECHANISMS OF ETHANOL-INDUCED FATTY LIVER

Enhancement of lipid synthesis by ethanol consumption

Hepatic fatty acid triglyceride and phospholipid synthesis are accelerated after acute and chronic ethanol consumption^[7]. Enhanced lipogenesis is a reflection of higher expression of lipogenic enzymes including fatty acid synthase, acyl CoA carboxylase (ACC), ATP citrate lyase (ACL), stearoyl CoA desaturase and malic enzyme.^[8,9] These enzymes are encoded by genes regulated by the transcription factor, sterol regulatory element binding protein-1 or SREBP-1.

Activation of SREBP-1 and enhanced expression of lipogenic enzymes

By activating SREBP, a member of a family of transcription factors that target genes encoding enzymes involved in cholesterol metabolism, ethanol consumption can short circuit normal hepatic lipid metabolism,

converting the liver from a lipid burning to a lipid storing organ. There are three isoforms of SREBP: SREBP-1a, 1c and 2. SREBP 1a and 1c are alternative forms of the protein encoded by the same exon. Forms 1c and 2 are principally involved in regulating fatty acid and cholesterol synthesis, respectively. All SREBP proteins reside in the endoplasmic reticulum. To function as a transcription factor, the amino terminal domain of SREBP is proteolytically cleaved from the carboxy terminal domain in the Golgi apparatus and the fragment translocates to the cell nucleus. This is accomplished by proteolytic cleavage through the action of two proteases; site-1 protease (S1P) and site-2 protease (S2P), both located in the Golgi apparatus. SREBP is initially translocated from its site in the ER to the Golgi by SREBP activating protein (SCAP). SCAP activity is sensitive to intracellular cholesterol levels and possesses a cholesterol sensing domain in its primary structure. When cholesterol levels are low, SCAP translocates SREBP from the ER to the Golgi where S1P cleaves the precursor form of SREBP, producing a membrane-bound intermediate. The intermediate is then cleaved by S2P to release the active transcription factor domain from the membrane, enabling it to bind to specific promoter elements on the DNA. Under normal circumstances, when intracellular cholesterol levels rise, SCAP activity is suppressed, thereby preventing transport and activation of SREBP by S1P and S2P. Ethanol metabolism, on the other hand, disturbs the regulatory loop of SREBP activation and causes increased cleavage of SREBP-1c, even when intracellular levels of cholesterol and/or fatty acids are high. Active SREBP-1c is detected experimentally in nuclear fractions as a -65 kDa protein, derived originally from a -125 kDa precursor. Thus, SREBP-1c has an essential function in the development of ethanol-elicited fatty liver. Nuclear fractions from livers of ethanol-fed rodents or from cultured cells that are capable of ethanol metabolism have elevated levels of the active form of SREBP-1c. A requirement for ethanol metabolism in SREBP induction has been reported using cultured cells and there is considerable evidence that the activating factor is acetaldehyde^[10]. The mechanism of ethanol-elicited SREBP-1 activation is also partly due to inhibition of the AMP-activated protein kinase (AMPK), described in greater detail below. AMPK catalyzes the phosphorylation of target enzymes, some of which are important rate-limiting enzymes in hepatic lipid metabolism. By inhibiting the activity of AMPK, ethanol relieves suppression of SREBP-1, causing its activation and increasing its levels in the nucleus.

Ethanol-elicited decline in fatty acid oxidation: Regulation of the peroxisome proliferator activated receptor alpha

Ethanol-elicited decline in fatty acid oxidation: Regulation of the peroxisome proliferator activated receptor alpha is a nuclear receptor that regulates expression of genes that possess peroxisome proliferator response elements in their promoter regions. Several such genes are those that encode fatty acid transporters, including carnitine palmitoyl transferase I, proteins involved in export,

such as apolipoprotein B, the microsomal triglyceride transfer protein, fatty acid binding protein, and acyl CoA dehydrogenase. PPAR- α interacts with the retinoid X receptor (RXR). The protein complex is activated by binding to fatty acids, thereby enhancing expression of proteins involved in the fatty acid transport and oxidation.

Ethanol administration to rodents or ethanol exposure to ethanol-metabolizing cultured cells causes a general down-regulation of PPAR- α , as reflected by reduced binding by the RXR-PPAR- α complex to a PPAR- α -specific promoter sequence^[11]. This effect of ethanol is enhanced by exposure of ethanol-treated hepatoma cells to the aldehyde dehydrogenase inhibitor, cyanamide and is abolished by the alcohol dehydrogenase inhibitor, 4-methylpyrazole. Further, RXR-PPAR- α extracted from hepatoma cells previously exposed to ethanol or acetaldehyde binds poorly to an oligonucleotide containing peroxisome proliferator response elements, indicating that acetaldehyde is responsible for the action of ethanol. It is possible that acetaldehyde, because of its ability to covalently bind proteins^[12] can form adducts with the PPAR- α transcription complex, thereby preventing its ability to bind the promoter element(s). It is noteworthy; however, that the effect at the level of transcription does not universally down-regulate all PPAR- α -regulated enzymes. *In vivo* studies have shown that the steady state level of mRNA encoding medium chain acyl CoA dehydrogenase is decreased by ethanol, but mRNAs encoding other PPAR- α -sensitive enzymes, including those mentioned above are minimally affected, unaffected, and in the case of fatty acid binding protein, actually induced by ethanol. An explanation for this, as described by You and Crabb^[13] is that the regulation of fatty acid oxidation is not solely controlled by the activities of the fatty acid oxidative enzymes. There is additional allosteric regulation of fatty acid transport into the mitochondrion by the intramitochondrial levels of malonyl CoA, which inhibits the carnitine palmitoyltransferase I (CPT I), thereby preventing transport of fatty acyl CoA derivatives into this organelle. With the concomitant up-regulation of fatty acid biosynthesis by ethanol, this is an important step in the down-regulation of fatty acid oxidation. An additional natural regulatory factor is the adipocyte hormone adiponectin. Chronic ethanol administration causes a significant reduction in circulating adiponectin, which is associated with the ethanol-elicited reduction in fatty acid oxidation^[14]. Restoration of adiponectin to ethanol-fed animals by treatment with the recombinant form of the hormone restores fatty acid oxidation to normal. Moreover, such treatment decreases the levels of TNF- α in these animals, as the hormone and the cytokine are known to regulate each other's production^[15].

It is also noteworthy that ethanol-elicited inhibition of fatty acid oxidation can be reversed, as demonstrated by experiments in which ethanol-fed animals were co-treated with the PPAR- α agonist, WY14,643. Fatty liver was blocked in these animals due to induction of PPAR- α , which, in turn, accelerated fatty acid oxidation thereby preventing ethanol-elicited fatty liver^[15]. These findings underscore the metabolic importance of fatty acid oxidation in the elimination of steatosis and emphasize

the therapeutic potential of this agent and other PPAR- α agonists as adjuncts to the natural hormone, adiponectin.

Adenosine monophosphate-activated protein kinase and alcohol-induced fatty liver

Hepatic lipid metabolism has been shown to be tightly regulated by adenosine monophosphate-activated protein kinase (AMPK). This enzyme, a heterotrimeric protein, is, itself, activated by AMP as well as by phosphorylation by another kinase, LKB-1. Elevated AMP levels are indicators of low intracellular energy charge. Therefore, when AMP activates the AMPK it down-regulates energy requiring pathways, presumably as a means of energy (ATP) conservation. Such ATP-utilizing pathways are generally biosynthetic and include lipid, RNA and protein synthesis. Conversely, AMPK activates ATP-generating catabolic pathways, such as fatty acid oxidation, the TCA cycle and glycolysis. The rate-limiting enzyme in lipid biosynthesis is the acetyl CoA carboxylase (ACC), the activity of which is down-regulated *via* phosphorylation by AMPK^[16]. ACC catalyzes the carboxylation of acetyl CoA to malonyl CoA. The latter is a potent inhibitor of lipid oxidation and its declining levels potentiate mitochondrial transport and fatty acid oxidation.

When ethanol is added to cultured hepatoma cells that oxidize ethanol, it induces transcription of an SREBP-regulated promoter and increases the levels of the mature form of SREBP-1. Both these effects are blocked by the inclusion in the culture medium of 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR) or metformin, both AMPK activators^[17]. Furthermore, overexpression of AMPK in these cells blocks the ethanol-induced increase in promoter activity and SREBP protein. Exposure of cells to ethanol reduces the activity of AMPK. *In vivo* studies confirm these findings. Feeding mice an ethanol diet significantly reduces hepatic AMPK activity, while increasing the activity of the rate-limiting enzyme, ACC^[17]. At the same time, fatty acid oxidation is reduced. These findings demonstrate that AMPK regulates the ethanol-elicited SREBP-1 activation and the development of steatosis. They also demonstrate the therapeutic value of AICAR and of metformin in preventing and/or reversing fatty liver caused not only by ethanol but also by dietary induction. The latter has been demonstrated in metformin-treated leptin-deficient experimental animals^[18]. Thus the central role of AMPK in regulating these activities is well illustrated by ethanol's effect in the genesis of fatty liver.

Role of Egr-1 in ethanol-induced steatosis

Another transcription factor, early growth response-1 (Egr-1) also appears to have a role in ethanol-elicited steatosis. Egr-1, also known as nerve growth factor 1-A (NGF1-A), is an immediate early gene and transcription factor that regulates genes involved in response to cellular stress. Early work demonstrated that Egr-1 is induced in response to growth factors^[19,20]. Several genes relevant to alcohol-induced liver injury have promoter regions that bind Egr-1. Among these genes are those that encode platelet-derived growth factor (PDGF), transforming growth factor beta (TGF- β), and intercellular adhesion molecule-1 (ICAM-1)^[21]. Specifically, with regard to ethanol-induced fatty liver, Egr-1

also binds the gene encoding tumor necrosis factor alpha (TNF- α)^[22]. This latter finding is noteworthy as this cytokine is considered lipogenic, causing the activation of SREBP-1, thereby enhancing lipid biosynthesis^[23]. Perhaps the most compelling evidence for the essentiality of Egr-1 in ethanol-elicited steatosis is that reported by McMullen *et al*^[24], who showed that, in contrast to wild type mice, which develop fatty liver in response to chronic ethanol administration, that Egr-1 null mice exhibit neither hepatic steatosis nor elevated TNF- α , after four weeks of chronic ethanol feeding. These workers also reported enhanced production of Egr-1 in ethanol-fed mice treated with lipopolysaccharide (LPS), compared with similarly-treated pair-fed control mice. The data suggest that the absence of Egr-1 prevents ethanol-elicited fatty liver and reduces sensitivity to LPS. Studies by Zhou *et al*^[1] demonstrated that 90 min after an acute dose of ethanol (6 g/kg body wt), hepatic TNF- α levels rise three-fold, followed by elevated levels of hepatic triglycerides. While these investigators did not measure Egr-1, they showed a close association between elevated levels of plasma endotoxin, oxidative stress, and TNF- α in ethanol-fed mice, suggesting that endotoxin, *via* oxidative stress, stimulates the production of TNF- α . This latter may result from enhanced transcription by Egr-1.

While Egr-1 is rapidly synthesized, its levels are also regulated through degradation by the proteasome^[25]. It has been postulated that inhibition of proteasome activity by ethanol administration has a distinct role in the increase in SREBP-1 protein, which is also a proteasome substrate^[17]. Similarly, PPAR- α and RXR levels are controlled by the ubiquitin-proteasome pathway^[26,27]. So, too proteasome inhibition may also contribute to the ethanol-induced rise in Egr-1. Recent experiments in our laboratory have demonstrated that acute ethanol administration to wild type mice causes enhancement of both Egr-1 mRNA and protein levels in livers of these animals one hr after ethanol administration. These increases precede the ethanol-elicited rise in triglycerides, detected after 3 h. In cultured hepatoma cells that metabolize ethanol, overexpression of Egr-1 following transfection with an adenoviral Egr-1 expression vector, enhances triglyceride accumulation in these cells over those of control cells. Furthermore, exposure of transfected cells to ethanol causes a further rise in the level of Egr-1 with a concomitant rise in cellular triglycerides (Donohue, unpublished). These findings provide further evidence for an essential role of Egr-1 in ethanol-induced fatty liver and the possibility that it may initiate downstream events. They also suggest that in cultured cells, there may be post-translational regulation of Egr-1 *via* ethanol-elicited suppression of proteasome activity. While Egr-1 regulates the expression of TNF- α , it also binds to promoter regions of other genes, including that encoding transforming growth factor- β (TGF- β), which has a major role in hepatic fibrosis^[28]. Thus, Egr-1 may not only be a major factor in steatosis, but also in the more advanced stages of alcohol-induced liver injury, as suggested by Pritchard and Nagy^[20].

Alcohol-elicited steatosis: What is the actual toxin?

The preceding sections have described the molecular

mechanisms by which ethanol consumption disrupts hepatic lipid metabolism, resulting in fatty liver. As stated earlier, an evolving concept that is gaining acceptance is that certain accumulated fatty acids are toxic to the liver, but that their toxicity is blunted by esterification with glycerol to form triacylglycerols (triglycerides). Ironically, triglyceride accumulation is the principal means by which fatty liver is quantified. Thus the question of whether there is a generalized toxicity of accumulated fatty acids or that specific fatty acids are hepatotoxic is important in determining whether alcoholics are at risk for more advanced disease. Recent work by Yamaguchi *et al*^[30,31] used antisense oligonucleotide (ASO) to block the synthesis of diacylglycerol acyltransferase (DAG), thereby inhibiting triglyceride synthesis. Blockade of DAG, which catalyzes the final step in triglyceride synthesis, reduced hepatic steatosis in these animals when they were fed a methionine-choline-deficient diet to induce NASH. However, such treatment with the ASO exacerbated liver injury to cause fibrosis, despite the fact that TNF- α levels were decreased, adiponectin levels were increased, and insulin sensitivity was improved. The explanation for these findings is that the prevention of triglyceride synthesis enhanced the intracellular levels of free fatty acids in the liver. While the specific fatty acids were not identified, the fact that enhanced lipid peroxidation occurred in liver-injured animals suggests that accumulation of unsaturated fatty acids would most likely be incriminated in causing further liver damage. With regard to ethanol-elicited steatosis, there is a substantial body of evidence that unsaturated fatty acids from corn oil or fish oil cause greater liver damage than saturated fatty acids when either of these are fed in combination with alcohol.

CONCLUSION

The foregoing review has summarized both the formerly and currently accepted models of alcohol-induced fatty liver. In summary, ethanol consumption causes activation of SREBP-1, which induces genes involved in lipid biosynthesis. Conversely, ethanol consumption down-regulates the PPAR- α transcription factor, which regulates enzymes involved in fatty acid oxidation, and simultaneously prevents the import of fatty acids into the mitochondrion for oxidation. The regulation of Egr-1 by ethanol is a less well characterized but an important area of investigation, as its rapid induction may well be upstream of the latter two factors or it may exert coordinate regulation along with SREBP-1 and PPAR- α . Finally, it should be emphasized that in sections of this review, comparisons of ASH were made to other fatty liver diseases, including NASH. The latter was used simply as an analogous disorder, but there was no intent to imply that the two (ASH and NASH) are the same. Clearly, further investigations are warranted into the pathophysiology of ethanol-induced steatosis, but recent investigations have demonstrated considerable progress toward therapeutic measures. These latter discoveries will most certainly prompt further ones in preventing or abating liver damage caused by alcohol abuse.

Abstract

Alcoholic liver injury comprises of interactions of various intracellular signaling events in the liver. Innate immune responses in the resident Kupffer cells of the liver, oxidative stress-induced activation of hepatocytes, fibrotic events in liver stellate cells and activation of liver sinusoidal endothelial cells all contribute to alcoholic liver injury. The signaling mechanisms associated with alcoholic liver injury vary based on the cell type involved and the extent of alcohol consumption. In this review we will elucidate the oxidative stress and signaling pathways affected by alcohol in hepatocytes and Kupffer cells in the liver by alcohol. The toll-like receptors and their down-stream signaling events that play an important role in alcohol-induced inflammation will be discussed. Alcohol-induced alterations of various intracellular transcription factors such as NF κ B, PPARs and AP-1, as well as MAPK kinases in hepatocytes and macrophages leading to induction of target genes that contribute to liver injury will be reviewed. Finally, we will discuss the significance of heat shock proteins as chaperones and their functional regulation in the liver that could provide new mechanistic insights into the contributions of stress-induced signaling mechanisms in alcoholic liver injury.

Key words: TNF α ; Toll-like receptors; NF κ B; Heat shock proteins; Mitogen-activated protein kinases

INTRODUCTION

Alcohol induced liver injury is marked by pathological changes in the liver ranging from steatosis, steatohepatitis to cirrhosis and sometimes hepatocellular carcinoma. The complex pathogenesis of acute and chronic alcohol consumption is multifactorial with diverse consequences in different tissues and cell types. Alcohol consumption leads to elevated endotoxin in the blood and liver leading to activation of immune cells that produce inflammatory mediators (i.e. cytokines). Abnormal cytokine production is a major feature of alcoholic liver disease. Elevated serum concentrations of TNF α , IL-6 and IL-8 have been reported in alcoholic patients and correlated with liver injury and clinical outcome^[1]. Among inflammatory cytokines, TNF α is a critical factor in alcoholic liver injury, a hypothesis that has been confirmed in animal models and human studies^[2,3]. Resident macrophages/Kupffer cells in the liver increase their production of cytokines in patients with alcoholic liver disease. Cultured monocyte/macrophages from alcoholic hepatitis patients produce TNF α spontaneously that is enhanced further in response to lipopolysaccharide (LPS)^[1]. In alcoholic liver injury, studies have shown that it is TNF α that is responsible for hepatocyte killing resulting from increased sensitivity of otherwise resistant cells to TNF-induced killing/apoptosis^[4]. It appears that early alcoholic liver injury involves interactions of cytokine over-production due to induction of the "hyper-inflammatory" state in monocytes/macrophages and sensitization of hepatocytes to cell death. The intracellular molecular mechanisms in response to alcohol exposure leading to inflammatory gene expression in the innate immune cell compartment and its down-stream effect on parenchymal cells of the liver are of considerable current interest.

In this article we will review the key components involved in alcohol-induced sensitization to TLR-signaling pathways and the pivotal role of transcription factors and mitogen-activated protein kinases (MAPK) contributing to alcohol-induced inflammation and hepatocyte injury. Furthermore, we will highlight the possible role of stress-induced heat shock proteins as chaperones in alcoholic liver injury.

CELL TYPES INVOLVED IN ALCOHOLIC LIVER INJURY

The currently accepted model of alcoholic liver injury

is characterized by increased gut permeability due to prolonged alcohol consumption resulting in increased endotoxin levels in portal circulation^[5]. Endotoxin is recognized by the resident macrophages/Kupffer cells in the liver via the toll-like receptor-4 (TLR4) leading to activation of intracellular signaling pathways in the macrophages and production of pro-inflammatory cytokines (TNF α , IL-1), chemokines (IL-8, MCP-1) and TGF β ^[6,7]. Kupffer cell-derived mediators then activate the other cell types in the liver resulting in damage. Chemokines recruit polymorphonuclear neutrophils and other inflammatory cells such as macrophages and T cells which contribute to amplification of the inflammatory response. Hepatocytes undergoing oxidative stress due to ROS generation and CYP2E1 induction are sensitized to TNF α induced apoptosis and necrosis^[3,8]. Furthermore, mediators such as TGF β and LPS activate stellate cells to proliferate and produce collagen leading to fibrosis and progression of liver injury^[9]. Alcohol-related injury of liver sinusoidal endothelial cells and their role in progression of disease has not been well studied. Some studies suggest that liver sinusoidal endothelial cells can be activated to produce cytokines and chemokines by malondialdehyde-acetaldehyde adduct proteins, generated by alcohol metabolism and thus could further contribute to amplification of alcohol-induced inflammation^[10]. Collectively, alcoholic liver injury involves various liver cell types during progression of disease.

ALCOHOL, OXIDATIVE STRESS AND INFLAMMATION

Chronic alcohol induced inflammatory responses in the liver are thought to be central to alcoholic liver injury. Excessive generation of reactive oxygen species (ROS) called free radicals plays an important role in alcohol-induced cellular damage^[8]. A number of studies have shown that alcohol increases generation of ROS *in vitro*^[11-13]. However, to determine the *in vivo* generation of ROS by alcohol has been rather challenging. Nevertheless, ROS-induced cellular responses are critical in alcohol-induced inflammation as well as TNF-induced hepatocyte killing^[2,13]. The ROS-related intracellular mechanisms leading to the sensitization of cellular injury by alcohol are underway in various laboratories. In the liver, Kupffer cells produce ROS in response to chronic alcohol exposure as well as endotoxin^[13]. Recent evidence shows that direct interaction of NADPH oxidase isozyme 4 with TLR4 is involved in LPS-mediated ROS generation and NF κ B activation^[14]. In alcohol fed rats, pretreatment with diphenyliodonium (DPI), which inhibits NADPH oxidase and normalizes ROS production, decreased LPS-induced ERK1/2 phosphorylation and inhibited increased TNF α production in Kupffer cells^[13]. Thurman and his group have shown that p47 phox-/- mice are resistant to alcohol-induced liver injury, indicating an important role for NADPH oxidase in not only inflammatory responses but also liver injury^[15]. Furthermore, dilinoleoylphosphatidylcholine (DPC) also prevented LPS induced NF κ B and ERK1/2 activation and TNF α production

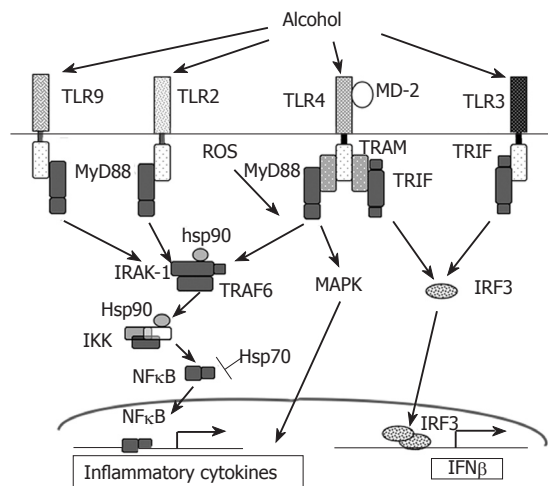

Figure 1 TLR signaling pathways affected by alcohol.

in Kupffer cells of chronic alcohol fed rats^[16]. It is now widely accepted that ROS not only plays a critical role in direct hepatocyte injury but also contributes to increased inflammatory responses further enhancing liver injury. Hence, the mechanisms affecting interaction of ROS and inflammatory responses as well as alcohol-induced sensitization mechanisms leading to hepatocyte death by alcohol need further elucidation.

ALTERATION OF TLR INDUCED SIGNALING PATHWAYS BY ALCOHOL

A major role for TLR mediated signaling, via endotoxin, in alcoholic liver disease (ALD) (Figure 1) was established by studies of Thurman and colleagues^[7,17]. Innate immune responses activated *via* the Kupffer cells, the primary effector cell in the liver, play a key role in the early pathogenesis of alcohol-induced liver injury^[18]. Increased levels of circulating lipopolysaccharide (LPS) in alcoholic patients have been shown^[19]. The currently accepted model of alcoholic liver injury elucidates that LPS promotes hepatic injury *via* induction of Kupffer cell activation resulting in production of TNF α and other inflammatory mediators. The Kupffer cells respond to stimulation by gut-derived endotoxins and apoptotic dead cells in the tissue resulting in increased inflammatory responses. Studies in knock out mouse models have shown that chronic alcohol feeding in CD14, TLR4 and LPS-binding protein (LBP) deficient mice results in alleviation of alcohol-induced liver injury indicating an important role for the TLR4 pathway^[7,20]. Furthermore, LPS recognition by TLR4 expressed on hepatic stellate cells and sinusoidal epithelial cells may also contribute to the progression of ALD^[21,22].

Circulating TNF α is increased in chronic alcoholics as well as in mouse chronic alcohol feeding models^[1,23]. Alcohol sensitizes Kupffer cells and monocytes/macrophages to produce increased TNF α in response to endotoxin^[24]. Although studies on effects of alcohol on membrane proximal events using mutant and knock out mice have shown an important role for CD14^[20]

and TLR4^[7], recent studies show hepatic expression of TLR2 or TLR4 mRNA was not changed by chronic alcohol feeding or by acute alcohol administration^[25]. Upon activation of TLR4, IRAK is recruited to the TLR4 complex *via* interaction with MyD88 (Figure 1). Acute and chronic alcohol exposure affects activation and recruitment of the IRAK-1 and IKK kinase activation^[28] Mandrekar *et al*^[26-28] unpublished. In contrast to chronic alcohol consumption, acute alcohol exposure inhibits TLR4 signaling in monocytes and macrophages after *in vitro* as well as *in vivo* alcohol treatment in mice leading to decreased LPS-induced TNF α production. Acute alcohol administration also suppressed TLR3 downstream signaling^[29]. *In vitro* acute alcohol exposure of human monocytes or macrophages suppresses LPS-induced IRAK-1 phosphorylation^[28] and inhibits poly I:C induced IRAK-1 degradation^[29] (Figure 1). Furthermore, acute alcohol exposure of murine macrophages inhibits TLR2, TLR4 and TLR9 ligand-induced IL-6 and TNF α production^[30]. Thus, it is evident that TLR-associated molecules such as CD14, TLR4 and LPS-binding protein (LBP) as well as their intra-cytoplasmic mediators TLR receptor associated kinases (IRAKs), I κ B kinase (IKK) and NF κ B are altered by alcohol and contribute to alcoholic liver injury.

TRANSCRIPTION FACTORS INDUCED BY ALCOHOL

In response to alcohol exposure, multiple signaling transduction pathways are activated in the liver. Receptors such as TLRs, TNF α , *etc.* in various liver cell types culminating in nuclear events involving binding of transcription factors to the promoter elements of target genes. The progression of alcoholic liver disease is characterized by initial appearance of fatty liver and inflammation, necrosis and apoptosis followed by fibrosis. It is generally accepted that the molecular mechanisms regulating the different stages of alcoholic liver disease from fatty liver and inflammation to fibrosis and cirrhosis are diverse. Since early alcoholic liver injury, a reversible condition, which comprises of development of fatty liver and inflammation, research on intracellular mechanisms has been focused primarily on these early stages. Chronic alcohol exposure increases expression of genes regulating fatty acid synthesis and suppresses genes involved in fatty acid oxidation resulting in increased fatty acid accumulation or steatosis. Transcription factors regulating fatty acid metabolism including sterol regulatory element binding protein (SREBP) and peroxisomal proliferating factor α (PPAR α) that is involved in fatty acid oxidation play a pivotal role in early alcoholic liver injury. Liver specific overexpression of SREBP1 α or SREBP1c results in fatty liver with significantly increased hepatic triglyceride content^[31]. In hepatoma cultures and ethanol-consuming mice, SREBP mRNA and active SREBP1 protein levels were significantly increased^[32,33] and accompanied by hepatic triglyceride accumulation. PPAR α , an essential regulatory factor up-regulating fatty acid oxidation also plays an important role in alcoholic fatty liver induction.

French and colleagues reported that chronic alcohol feeding decreased PPAR α mRNA^[34]. Further, exposure of primary hepatocytes and hepatoma cells to chronic alcohol resulted in impaired PPAR α DNA binding activity that was prevented by 4-methylpyrazole, an inhibitor of alcohol dehydrogenase^[35]. Although chronic alcohol decreased PPAR α activity, treatment of mice with WY14643, a PPAR α agonist restored DNA binding activity without affecting quantities of PPAR α , indicating additional mechanisms affected by alcohol to regulate fatty acid oxidation.

Similar to the effects of chronic alcohol on transcription factors involved in lipid homeostasis, alcohol-induced inflammatory mediators that play an important role in disease progression, are induced by key transcription factors. The most well studied example is the activation of NF κ B in monocytes and macrophages controlling pro-inflammatory cytokine induction. Studies have shown increased LPS-induced NF κ B DNA binding activity in monocytes of patients with alcoholic hepatitis compared to controls^[36]. While chronic alcohol exposure increases LPS-induced NF κ B binding in monocytes and macrophages, acute alcohol exposure decreases LPS-induced NF κ B binding resulting in different regulation of pro-inflammatory cytokine genes based on duration of alcohol exposure. While several animal models have shown increased hepatic LPS-induced NF κ B DNA binding activity, some studies have failed to observe any effect of chronic alcohol feeding on NF κ B activity^[37-39]. Many studies have described a positive effect of ROS in the regulation of NF κ B activation^[38,40,41]. Recent studies have shown that alcohol-induced TNF α production due to activation of the NADPH oxidase system and interaction with adapters of the TLR4 signaling pathway influence NF κ B DNA binding and promote pro-inflammatory cytokine production^[14]. It is likely that chronic alcohol exposure may activate NF κ B *via* ROS-dependent mechanisms since treatment of liver macrophages with dilinoleoylphosphatidylcholine (DPC) protects liver injury and prevents NF κ B activation^[16].

Activator protein-1 (AP-1) another transcription factor is also regulated by acute and chronic alcohol exposure in monocyte/macrophages and hepatocytes. Acute and chronic alcohol exposure increases AP-1 DNA binding activity^[28,42,43] in monocytes/macrophages whereas isolated Kupffer cells do not show any effect on AP-1 activity after chronic ethanol feeding^[44]. Furthermore, chronic alcohol increases AP-1 expression and induces activation in livers of chronic alcohol fed mice and in isolated primary hepatocytes^[42,45]. Increased activation of AP-1 could influence pro-inflammatory and anti-inflammatory cytokine gene induction and hence could contribute to the amplification of the inflammatory response after chronic alcohol exposure. Since AP-1 regulates collagen synthesis, increased AP-1 activation could also be implicated in alcohol-induced fibrotic changes in the liver^[46].

PPAR γ , another transcription factor known to inhibit inflammatory responses is also regulated by chronic alcohol exposure in macrophages. PPAR γ expression was increased in Kupffer cells and hepatocytes during chronic alcohol exposure^[47]. Treatment with PPAR γ agonists prevented development of chronic alcohol induced

steatosis and inflammation^[48]. The exact mechanism by which PPAR γ exerts its effect to resolve alcohol-induced liver injury remains to be studied.

Early growth response factor-1 (Egr-1), a zinc finger transcription factor induced in response to environmental stress and shown to regulate cellular growth and proliferation is up-regulated during chronic alcohol exposure in Kupffer cells^[44,49]. Increased LPS-stimulated Egr-1 expression is dependent on ERK1/2 activation in Kupffer cells of chronic alcohol fed mice compared to pair-fed controls^[44]. Furthermore, recent data show that chronic alcohol feeding induced liver injury is blocked in Egr-1 knock out mice, indicating a role for the ERK1/2-Egr-1 pathway in the pathogenesis of alcoholic liver injury^[50]. These studies illustrate that based on the cell type involved and duration of alcohol exposure, regulation of transcription factors is highly complex and requires further evaluation. Future investigations on regulation of transcription factors during the different stages of alcoholic liver injury will aid in designing effective therapeutic strategies.

ALCOHOL AND MAP KINASES

LPS recognition also activates MAPK family members including extracellular receptor activated kinases 1/2 (ERK1/2), p38 and c-jun-N-terminal kinase (JNK) resulting in TNF α production^[51]. Chronic alcohol increases LPS-induced ERK1/2 activation which contributes to TNF α expression in macrophages^[44]. Similarly, LPS stimulation of Kupffer cells exposed to chronic alcohol showed increased p38 activity whereas decreased JNK activity was observed in livers after chronic alcohol feeding^[39]. Activation of p38 MAPK by LPS has been shown to contribute to TNF α mRNA stability via interaction with tristetraprolin (TTP)^[52]. Inhibition of p38 activation completely abrogated alcohol-mediated stabilization of TNF α mRNA^[39]. On the other hand, ERK1/2 inhibition did not affect TNF α mRNA stability but affected its transcription^[44]. LPS stimulation of JNK leads to phosphorylation of c-jun and subsequent binding of c-jun to the CRE/AP-1 site in the TNF α promoter^[51]. Although chronic alcohol feeding decreased JNK activity without any effect on TNF α mRNA, acute alcohol exposure increased JNK phosphorylation as well as AP-1 binding in the presence of combined TLR4 plus TLR2 stimulation^[28] in human monocytes. Furthermore, LPS-induced ERK1/2 phosphorylation was decreased in acute alcohol exposed monocytes^[28], whereas p38 MAPK activity was increased contributing to anti-inflammatory mediators such as IL-10 after acute alcohol exposure in monocytes^[43]. Increased oxidative stress in chronic alcohol exposed rats promotes hepatocyte apoptosis and necrosis and is implicated in the alcohol-induced sensitization to the pro-apoptotic action of TNF α ^[2]. Besides modulation of MAPK activity in macrophages, potentiation of alcohol induced hepatocyte death has been attributed to increased mitochondrial permeability transition and caspase-3 activation in hepatocytes and depends on p38 MAPK activation but is independent of caspase-8^[4,53].

ALCOHOL AND CHAPERONES: ROLE OF HSP70 AND HSP90

Mammalian heat shock proteins (hsps) induced in response to cellular oxidative stress serves as chaperones in refolding, disaggregation and degradation of damaged polypeptides^[54,55]. Amongst the family of heat shock proteins, Hsp70, Hsp60, Hsp90 and Hsp32 (also termed HO-1) have been implicated in protective mechanisms against increased oxidative stress in liver injuries. Upregulation of hsps in liver cells in culture has been shown to diminish the toxicity of a number of hepatotoxicants. Immunohistochemical detection revealed elevated Hsp70 in livers of alcoholic patients^[56]. Male Wistar rats fed with acute as well as chronic ethanol for 12 wk showed induction of Hsp70 in various regions of the brain and to a small extent in the liver^[57,58]. However, the intensity of induction of Hsp70 in the liver, the principal organ of ethanol oxidation was much less pronounced than the hippocampus or striatal areas of the brain^[57,58]. Recent studies also reveal that acutely and chronically ethanol-treated primary astrocyte cultures showed increased Hsp70 expression at 50 mmol/L, but not at 200 mmol/L ethanol concentration suggesting that severe toxicity of a 200 mmol/L ethanol concentration seems to exceed the power of inducible protective mechanisms elicited by heat shock proteins in astrocytes^[59]. The mechanism by which Hsp70 exerts its protective role is not clear. Oxidative stress due to depletion of glutathione (GSH) and induction of Hsp70 has been closely linked^[60]. Antisense-Hsp70 experiments in rat astrocyte cultures resulted in moderate oxidative damage in control astrocytes and a consequent drastic decrease in the viability of ethanol-treated cells, with mitochondrial functionality being affected^[59]. Thus, heat shock proteins confer a survival advantage to the cells preventing oxidative damage. Hsp70 induction using geranylgeranylacetone showed subsequent inhibition of alcohol-induced apoptosis of hepatocytes^[61]. Induction of hsp72 by hyperthermia pre-conditioning increased hsp70 and reduced TNF α responses in CCl₄-induced cirrhotic rats^[62]. Use of drugs that elevate intracellular hsp70 may serve to exert a cytoprotective effect in alcoholic liver disease. In addition to its role in cytoprotection, hsp70 also inhibits inflammatory responses in immune cells^[63]. Hsp70 interacts with various components of the NF κ B signaling pathway (Figure 1). Overexpression of Hsp70 leads to repression of NF κ B mediated gene expression^[63]. Further, nuclear translocation of NF κ B is also affected in cells transfected with the Hsp70 gene^[64]. Hsp70-induced NF κ B inhibition is attributed to both increased I κ B α expression and attenuated I κ B α degradation^[65]. In addition, Hsp70 can directly interact with NF κ B p65 and NF κ B p50 to influence NF κ B mediated responses^[66].

Hsp90 also plays an important role in regulating the TLR signaling pathway and can thus influence inflammatory responses (Figure 1) by chaperoning key signaling molecules. Inhibition of Hsp90 impairs function of its client signaling proteins and thus alters cell function^[67]. Treatment of cells with inhibitors of Hsp90 such as the

benzoquinone ansamycin, geldanamycin activates a heat shock response without the stress^[68]. Geldanamycin also inhibits LPS-induced NF κ B activity and TNF α production in macrophages^[69,70]. Hsp90 is crucial for biogenesis and activity of IKK α and IKK β , kinases responsible in I κ B α phosphorylation and activation of NF κ B, and inhibition of Hsp90 results in IKK α and IKK β depletion^[71]. Thus Hsp90 can play a crucial role in maintaining the activity of various components of the NF κ B signaling pathway. In alcoholic liver disease, ethanol induced oxidative stress using the intragastric feeding model induces thiol modification of Hsp90 in the liver^[72]. Whether the thiol modification of Hsp90 contributes to progression of alcoholic liver disease needs further evaluation. Studies have shown that chronic alcohol exposure modulates endothelial cell function by increasing NO production *via* PI3 K-dependent up-regulation of eNOS and its interaction with Hsp90^[73]. Furthermore, Hsp90 and Hsp70 have been shown to form insoluble aggregates with cytokeratins to form Mallory bodies^[74] in alcoholic liver disease. Selective enhancement of cytochrome P450 activity in rat hepatocytes can be achieved by heat shock treatment^[75]. Alcohol inducible cytochrome P450 2E1 (CYP2E1) is also shown to be a Hsp90 “client” protein and regulation of Hsp90 can profoundly affect enzyme turnover^[76]. Thus, taken together, it is tempting to speculate that chaperoning activity of Hsp90 and Hsp70 could be modulated using pharmacological inhibitors to alleviate alcohol-induced oxidative stress and inflammation and reversal of liver injury.

CONCLUSION

In conclusion, the biological effects of acute and chronic alcohol exposure and the net result on intracellular signaling pathways in liver cell types are complex. It is evident that the innate immune response plays a significant role in the development of alcoholic liver injury. A wealth of information is available on the contribution of pro-inflammatory responses in alcohol-induced liver damage. Studies on interactions of various signaling mechanisms in the different cell types of the liver and their outcomes in the liver microenvironment will provide a better understanding of the pathogenesis of alcoholic liver disease. Future studies performed to delineate novel molecular pathways are necessary and will provide a better understanding of liver injury induced by chronic alcohol consumption.

Abstract

AIM: To define NGF (nerve growth factor) and its high-affinity receptor $trkA^{NGF}$ presence and distribution in fibrotic liver and in HCC, and to verify if NGF might have a role in fibrosis and HCC.

METHODS: Intracellular distribution of NGF and $trkA^{NGF}$ were assessed by immunohistochemistry and immunoelectron microscopy in liver specimens from HCC, cirrhosis or both. ELISA was used to measure circulating NGF levels.

RESULTS: NGF and $trkA^{NGF}$ were highly expressed in HCC tissue, mainly localized in hepatocytes, endothelial and some Kupffer cells. In the cirrhotic part of the liver they were also markedly expressed in bile ducts epithelial and spindle-shaped cells. Surprisingly, in cirrhotic tissue from patients without HCC, both NGF and $trkA^{NGF}$ were negative. NGF serum levels in cirrhotic and/or HCC patient were up to 25-fold higher than in controls.

CONCLUSION: NGF was only detected in liver tissue with HCC present. Intracellular distribution suggests paracrine and autocrine mechanisms of action. Better definition of mechanisms may allow for therapeutic and diagnostic/prognostic use of NGF.

INTRODUCTION

NGF (nerve growth factor) is a prototypical member of the neurotrophin family essential for survival, differentiation, and maintenance of neuronal cells in the central and peripheral nervous system^[1]. In recent years, many findings have indicated that NGF could also have a role outside the central and peripheral nervous system. In particular, it may be involved in lung and skin tissue repair^[2] as well as in allergic inflammation and fibrosis^[3]. Increased levels of circulating NGF were observed in several autoimmune, chronic inflammatory and fibrotic disorders^[4,5]. Numerous data also indicate that NGF is involved in tumour growth, invasion and metastasis^[6-14].

Two types of receptors mediate NGF effects: $trkA^{NGF}$, the high-affinity receptor with protein kinase activity, specific for NGF, and $p75^{NTR}$, the low-affinity glycoprotein receptor, also binding other neurotrophins^[15,16]. Most of the biological activities elicited by NGF are mediated by binding to $trkA^{NGF}$ receptor^[17,18]. $trkA^{NGF}$, $p75^{NTR}$ receptors or both, together with NGF, are expressed in various cancers, including lung^[7], breast^[12] and prostate cancer^[10,11,13], suggesting that the NGF autocrine or paracrine pathway may have a role in tumorigenesis. NGF is also shown to be over expressed in lung and skin fibrotic process^[2] as well as in liver during experimental fibrotic injury^[19]. However, the role of NGF in tissue remodelling, fibrotic process and cancer progression is still controversial.

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world, showing a rapid progressive clinical course, poor response to pharmacological

treatment and a severe prognosis^[20,21]. A major risk factor for HCC is hepatitis C virus (HCV)-related cirrhosis^[22-25]; many chronically infected patients remain asymptomatic for a long period, with liver cirrhosis developing after approximately 30 years^[26,27]. The lack of predictive markers that can detect the beginning of liver cirrhosis in chronic HCV patients may also contribute to the late diagnosis of HCC, its progression and the poor prognosis.

The expression of NGF and its receptors in liver tissue during fibrotic injury and HCC has been previously investigated mostly in animal models with contradictory results. Some authors demonstrated that hepatocytes expressed NGF but not trkA^{NGF} during profibrotic liver injury, or in early preneoplastic lesions and HCCs. TrkA^{NGF} was only expressed in the walls of arteries associated with tumors^[28,29]. These data suggest that in hepatocytes NGF may not be an autocrine factor, but may rather act in a paracrine fashion. On the contrary, other authors^[19] reported the presence of trkA^{NGF} mRNA, but not of NGF mRNA in hepatocytes of fibrotic rat liver. It is not clear from the literature which cell types (apart the hepatic stellate cells) constituting the whole liver tissue are actually involved in the cross-talk mediated by NGF during liver tissue remodelling processes and HCC progression.

In this study we investigated the expression of NGF and its high-affinity receptor trkA^{NGF} in patients suffering from HCC, cirrhosis or both. This was performed to verify if the expression of this neurotrophin may be correlated with tissue remodelling processes and HCC progression. We also studied the expression of NGF and trkA^{NGF} in the different cell types inside the fibrotic and HCC tissues, analyzing the intracellular distribution in each cell type at an ultrastructural level, attempting to clarify their involvement in the hepatic damage. Circulating NGF levels were also measured.

MATERIALS AND METHODS

Human liver specimens

20 human liver specimens, taken for diagnostic purposes or resected before transplantation, were used in this study: 5 near normal liver biopsy specimens, 4 with cirrhosis without HCC from transplanted patients (Child-Pugh A), 11 with cirrhosis and HCC post-hepatitis C [Child-Pugh A ($n = 4$); Child-Pugh C ($n = 7$)]. All the patients had voluntarily signed a written consent to participate the study. The diagnosis was based on histopathologic examination of routinely processed tissue together with clinical and laboratory data. Each specimen was received fresh, and fixed in part in 10% buffered formalin solution for immunohistochemistry, and the other part in 1% or 2.5% glutaraldehyde for immunogold labelling or morphological analysis by transmission electron microscopy observation, as described below.

Criteria used for identification of immuno-positive cell types in liver tissues

Cell types in liver tissues from cirrhotic and HCC patients have been identified on the basis of microscopic and ultramicroscopic morphological feature. In particular:

(1) Endothelial cells: elongated narrow cells composing the wall of sinusoids; (2) Kupffer cells: macrophage cells, exhibiting considerable phagocytic ability, bulging into sinusoidal lumen; (3) Biliary epithelial cells: tightly arranged cuboid or columnar cells, constituting the wall of bile ducts, lying on a basement membrane and bearing microvilli on the luminal surface; (4) Spindle-shaped cells: elongated fibroblast-like cells embedded in fibrous tissue, possessing characteristics of myofibroblast, as shown by positive staining for smooth muscle actin (SMA).

Immunohistochemistry and Confocal Laser Scanning Microscopy (CLSM)

Expression of NGF and trkA^{NGF} in normal liver, cirrhotic and HCC tissues, obtained as described above, was investigated by Confocal Laser Scanning Microscopy (CLSM) using an indirect immunofluorescence technique. Immuno labelling was performed on sections obtained from paraffin embedded tissues using rabbit polyclonal antibodies against NGF (Chemicon Int., Temecula, CA, USA) or trkA^{NGF} (Santa Cruz Biothech., Santa Cruz, USA). Primary antibodies detection was obtained by a reaction with TRITC-conjugated goat anti-rabbit IgG. To test the specificity of the immunoreaction, for each liver specimen examined and on a section close to that used for NGF or trkA^{NGF} staining, negative controls were performed by substitution of primary antisera with non-immune rabbit serum. Fluorescently labelled samples were imaged by the confocal microscope LEICA TCS 4D (Leica, Heidelberg, Germany) supplemented with an Argon/Krypton laser and equipped with 40×1.00 -0.5 and 100×1.3 -0.6 oil immersion lenses. The excitation/emission wavelengths employed were 488 nm/510 nm, for green auto-fluorescence (used to visualize liver tissue morphology), and 568 nm/590 nm for TRITC-labelling. During the observation, both fluorescent signals were obtained simultaneously. To better visualize the intracellular distribution of NGF or trkA^{NGF} along the thickness of tissue sections, confocal sections were taken at intervals of 0.5 μm , a 3D reconstruction image for each fluorescent signal was recorded, and merged images of the two signals were obtained using the confocal microscope software.

To determine the nature of spindle-shaped cells, double staining using rabbit polyclonal antibodies against NGF (Chemicon Int.) and mouse monoclonal antibody against smooth muscle actin (SMA, Sigma-Aldrich Co., St. Louis, Mo, USA) was performed. Anti-SMA detection was obtained by a reaction with Alexa Fluor 488-conjugated rabbit anti-mouse IgG (Molecular Probes Inc., Eugene, OR).

For the assessment of staining intensity, a minimum of three section for each sample were examined and the different level of positive immunoreaction was evaluated on the basis of number of positive cells and fluorescence intensity. The following criteria were used for evaluation of staining: (-), same as the background obtained in control performed by substitution of specific anti-NGF or trkA^{NGF} antibodies with non-immune rabbit serum; (\pm), moderately higher than the background; (+), higher than the background; (++), much higher than the background.

na: not available (HCC tissue without cirrhosis).

For histological observation, sections obtained from paraffin embedded tissues and close to that used for immunohistochemistry were stained with haematoxylin-eosin (HE) and observed by an optical microscope.

Transmission Electron Microscopy (TEM)

For ultrastructural observation, samples of normal liver, cirrhotic and HCC tissues were fixed with 2.5% glutaraldehyde in 0.1 mol/L Millonig's phosphate buffer (MPB), and then post-fixed with 1% OsO_4 in the same buffer. Samples were dehydrated in increasing concentrations of ethanol and embedded in Spurr epoxy resin (Agar Scientific LTD, Stansted, Essex, UK). For immuno-electron microscopy, tissue samples were fixed with 1% glutaraldehyde in 0.1 mol/L MPB, dehydrated in increasing ethanol concentrations and embedded in LR White acrylic resin (Agar Scientific LTD). Immunogold labelling was performed on ultrathin sections using the same rabbit polyclonal antibodies against NGF or trkA^{NGF} used for immunohistochemistry. Negative controls were performed by substitution of primary antisera with non-immune rabbit serum. Detection of primary antibodies was obtained by the reaction with 10 nm gold particles-conjugated goat anti-rabbit IgG. For morphological and immunogold labelling observation, ultrathin sections were stained with uranyl acetate and lead citrate and observed under a Philips CM12 transmission electron microscope operating at 80 kV.

NGF determination

Circulating NGF levels were measured in sera from 27 patients with a documented cirrhosis, HCC or both, by

a modified highly sensitive two-site immunoenzymatic assay (ELISA), using anti-NGF antibodies (clone 27/21, Chemicon Int.)^[30,31]. This assay specifically identifies human NGF but not brain-derived neurotrophic factor, with a detection limit of 0.5 pg/mL.

RESULTS

Expression of NGF in liver biopsies

The results of NGF and trkA^{NGF} immunostaining in all the human liver specimens examined are summarized in Table 1.

Analysis of NGF distribution by immunohistochemistry and CLSM observation indicated that all 11 patients with cirrhosis and HCC were positive, while the 5 normal liver biopsy specimens as well as the 4 samples from transplanted patients with cirrhosis without HCC, were negative. In HCC tissues NGF was detectable in a high number of cells at different levels of intensities, depending on the patient (Table 1, Figure 2) but never in normal liver tissue (Table 1, Figure 1). Interestingly, in liver from patients with cirrhosis (Child-Pugh C, undergoing transplantation) but without HCC, NGF and trkA^{NGF} were negative (Table 1 and Figure 3A₂ and 3A₃). Conversely NGF and trkA^{NGF} were markedly positive in patients with cirrhosis that had evolved into HCC, already at early staging (Child-Pugh A; Table 1 and Figure 3B₂ and 3B₃).

Furthermore, both the number of positive cells and the intensity of immunoreaction were significantly elevated in cirrhotic tissues with respect to the HCC tissues obtained from the same liver (Table 1 and Figure 4). Moreover in HCC tissues, NGF was mainly localized in the cytoplasm and on the nuclei of hepatocytes, and

to a lesser extent on endothelial and Kupffer cells and some lymphocytes (Figure 2). However, in cirrhotic tissue, it was also markedly expressed on biliary epithelial cells constituting the wall of bile ducts, and on spindle-shaped cells embedded in fibrous tissue (Figure 4). Double staining using anti-NGF and antibody against SMA (Figure 4J and K) indicated that these spindle-shaped cells presumably correspond to the hepatic stellate cells described by other authors^[19].

Ultrastructural observation by transmission electron microscopy after immunogold labelling showed that in hepatocytes of HCC tissue (Figure 5), positive reaction for NGF mainly localized on cytoplasmic vesicles (Figure 5B and C) and on endoplasmic reticulum (Figure 5E), suggesting that synthesis and accumulation of this molecule may occur. In some cases, immunogold labelling was also present on nuclei, beneath the nuclear membrane (Figure 5D). Furthermore, in cirrhotic tissue (Figure 6) a more intense immunoreaction, with respect to HCC tissue, was observed on cytoplasmic vesicles (Figure 6B), free in the cytoplasm (Figure 6B) and along endoplasmic reticulum (Figure 6B) of hepatocytes, indicating that in cirrhotic tissue NGF may be actively produced by hepatocytes. Positive immunogold reaction was also observed on cytoplasmic vesicles of endothelial cells (Figure 6C) and of spindle-shaped cells (Figure 6D). In biliary epithelial cells NGF localized in large cytoplasmic vacuoles that were present in the portion of cells near the ductal lumen (Figure 6E).

Expression of TrkA^{NGF} in liver biopsies

Immunohistochemical staining and CLSM observation showed that in HCC tissue trkA^{NGF} localized on the cell membrane of few hepatocytes (Figure 7A₂), while in cirrhotic tissue an intense immunoreactivity was also observed on biliary epithelial cells (Figure 7B₃ and 7B₆). This was particularly evident beneath the cell membrane near the ductal lumen (Figure 7B₃), and on spindle-shaped cells scattered throughout fibrotic tissue surrounding reactive bile ducts (Figure 7B₆). Positive immunoreaction was also observed on endothelial cells constituting the wall of blood vessels (Figure 7B₆).

Furthermore, in cirrhotic tissue, immunogold labelling showed that in biliary epithelial cells (Figure 8A) trkA^{NGF} localized on cell membrane and on cytoplasmic vesicles beneath it (Figure 8A₁), suggesting a possible receptor recycling after receptor-ligand reaction. Immunoreactivity was also observed in the cytoplasm of some endothelial cells (Figure 8B₁) and on cell membrane of some lymphocytes (Figure 8B₂).

NGF detection in sera

NGF levels were measured in sera obtained from 27 patients with documented cirrhosis, HCC, or both by immunoenzymatic assay. All patients disclosed with circulating NGF levels elevated 25-fold over the normal with (range 73-520 pg/mL, compared to a mean of 20 pg/mL in healthy donors, Figure 9).

DISCUSSION

The expression of NGF and its receptors in human and

rodent liver cells has been investigated for some time in previous studies with contradictory results. Oakley *et al.*^[29] demonstrated for example, that hepatocytes expressed NGF, but not trkA^{NGF} during profibrotic liver injury, in early preneoplastic lesions and HCCs, suggesting that in the hepatocytes NGF may not be an autocrine factor but may rather act in a paracrine manner. Other studies^[28] reported that in HCC tissue from male B6C3F1 mice, trkA^{NGF} is expressed exclusively in the walls of arteries associated with tumors, presumably in smooth muscle cells, whereas it is negative in other cell types including tumor cells. The same authors also demonstrated that NGF was expressed not only in HCCs but also in early preneoplastic lesions, possibly representing a very early change during mouse hepatic carcinogenesis. On the contrary, Cassiman *et al.*^[19] provided evidence that in human and rat cirrhotic tissues, NGF and other neurotrophins, as well as their receptors, were expressed not only in hepatic stellate cells, but also in regenerating bile ducts and in some hepatocytes with a cytoplasmic or nuclear staining patterns. Recently it has been reported that NGF is over expressed in approximately 60% of human HCC tissues compared to the surrounding liver tissue with cirrhosis and chronic hepatitis, suggesting a role for NGF in the progression of HCC^[32]. Also, until now, to our knowledge, it has not yet been clarified what role NGF plays and which cell types in the liver tissue are actually involved in the NGF mediated cross-talk during liver fibrosis and HCC progression. In addition, even if increased levels of circulating NGF have been reported in several autoimmune, chronic inflammatory and fibrotic disorders^[4,5], meanwhile data concerning circulating NGF levels in HCC or cirrhotic patients are not known.

In this study we provide immunohistochemical evidence that NGF and its high-affinity receptor trkA^{NGF} are over expressed in patients suffering from HCC and to a greater extent from HCC with cirrhosis. Surprisingly, NGF and trkA^{NGF} were negative in liver specimens from patients with cirrhosis undergoing transplantation but without HCC, supporting the hypothesis of an active role for NGF in HCC insurgence and progression. The elevated circulating NGF levels recorded in sera from patients with documented cirrhosis, HCC or both, as well as the tissue distribution of NGF and its receptor further support the correlation between NGF activity and the progression of liver fibrosis towards HCC. We also have been able to identify the NGF and trkA^{NGF} immuno positive cell types in liver tissues from cirrhotic and HCC patients, comparing the results obtained by immunohistochemistry and immuno-electron microscopy, as summarized in Table 2.

The evidence that hepatocytes in HCC and cirrhotic tissues from the same liver produce NGF (as suggested by the localization on cytoplasmic vesicles and on endoplasmic reticulum) and express its receptor strongly support the hypothesis that NGF may act by both autocrine and paracrine mechanisms, rather than a prevalent paracrine one, as previously suggested^[29].

NGF and trkA^{NGF} have been reported over expressed *in vivo* in proliferating cholangiocytes after bile duct ligation. NGF also stimulates rat cholangiocyte proliferation *in vitro*^[33]. We observed that in cirrhotic tissue both NGF and its receptor are over expressed on proliferating biliary

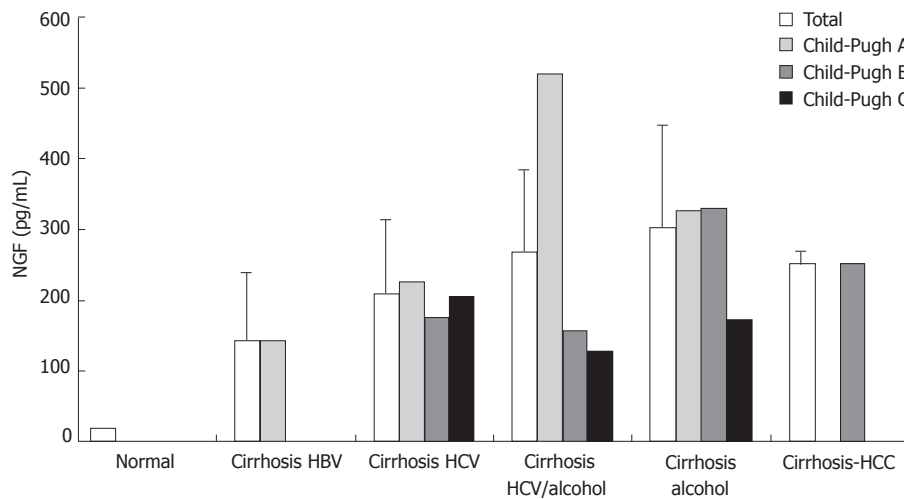

Figure 9 Bar diagram illustrating the circulating NGF levels, determined by test ELISA, in patients with documented cirrhosis/HCC. NGF amounts, reported with regard to the etiology, is calculated either as mean \pm SD (all patients examined) or as mean values for Child-Pugh class A (score = 5-6), for Child-Pugh class B (score = 7-9) and for Child-Pugh class C (score = 10-15). As a control, mean \pm SD of circulating NGF levels from some healthy individuals is also reported.

epithelial cells, mainly localized on large cytoplasmic vacuoles in the ductal lumen portion of cells suggesting an intraductal lumen secretion during the progression from cirrhosis to HCC. Other studies^[34,35] have shown that binding of NGF to its cognate receptor trkA^{NGF} induces formation of signalling endosomes containing both the NGF and activated trkA^{NGF} receptor, with the latter exhibiting very high dynamic trafficking between the cell surface and internal cell compartments. Therefore, the predominant staining on cytoplasmic vacuoles observed for trkA^{NGF} on biliary epithelial cells in cirrhotic tissue may represent the receptor endocellular trafficking. Taken together, these findings indicate that NGF and its related receptor play an important role also in modulating the physiopathology of the intrahepatic biliary epithelium in the course of liver tissue remodelling processes and HCC progression.

The mechanism of NGF involvement in liver tissue remodelling processes and HCC progression remain unclear. However, our observation, defining NGF distribution both inside the liver and in the intracellular compartments, indicate that it may function, in a paracrine and an autocrine manner, as a messenger molecule in the cross-talk between different cell types. This, in addition to the reported lack of NGF expression in cirrhotic tissue without concomitant HCC even if present at high level in serum, strongly support the need to further clarify the mechanism and to define the role of this neurotrophin.

This opens up an interesting perspective for the possible use of NGF, not only as a marker of progression

and transformation, but also as an attractive target for a new therapeutic approach.

Abstract

AIM: To investigate the expression profile of IL-8 in inflammatory and malignant colorectal diseases to evaluate its potential role in the regulation of colorectal cancer (CRC) and the development of colorectal liver metastases (CRLM).

METHODS: IL-8 expression was assessed by quantitative real-time PCR (Q-RT-PCR) and the enzyme-linked immunosorbent assay (ELISA) in resected specimens from patients with ulcerative colitis (UC, $n = 6$) colorectal adenomas (CRA, $n = 8$), different stages of colorectal cancer ($n = 48$) as well as synchronous and metachronous CRLM along with their corresponding primary colorectal tumors ($n = 16$).

RESULTS: IL-8 mRNA and protein expression was significantly up-regulated in all pathological colorectal entities investigated compared with the corresponding neighboring tissues. However, in the CRC specimens IL-8 revealed a significantly more pronounced overexpression in relation to the CRA and UC tissues with an average 30-fold IL-8 protein up-regulation in the CRC specimens in comparison to the CRA tissues. Moreover, IL-8 expression revealed a close correlation with tumor grading. Most interestingly, IL-8 up-regulation was most enhanced in synchronous and metachronous CRLM, if compared with the corresponding primary CRC tissues. Herein, an up to 80-fold IL-8 overexpression in individual metachronous metastases compared to normal tumor neighbor tissues was found.

CONCLUSION: Our results strongly suggest an

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers, with nearly one million estimated new patients per year world wide in 2006. Despite continuous improvements in diagnosis and therapy, approximately 60% of colon cancer patients develop metastases. While there is a good survival rate for patients diagnosed with localized disease, the CRC prognosis worsens dramatically with advancing stages and distant metastases and only 5% of patients diagnosed with distant metastases survive 5 years^[1,2]. Colorectal specimens and cell lines derived from them have been shown to express a variety of chemokines, including the multifunctional cytokine Interleukin (IL)-8, a member of the CXC chemokine superfamily of structurally and functionally related inflammatory cytokines that stimulate the migration of distinct subsets of cells^[3,4]. IL-8 and other anti-inflammatory cytokines have been shown to act as potent chemoattractants for leucocytes, such as neutrophils and natural killer cells, thus contributing to healing processes but also stimulating inflammatory diseases such as rheumatoid arthritis, sepsis and inflammatory bowel disease^[5-7]. Subsequent studies revealed that IL-8 also promotes the movement of cells of different lineages, such as fibroblasts and keratinocytes^[8,9]. In recent years, IL-8 was reported to induce the migration of tumor cells and its expression was correlated with tumor growth, angiogenesis and metastatic potential in various human carcinomas and animal models^[10-16].

Yet, up to now, the pathophysiological role of IL-8 in

tumor development and metastasis is not fully understood and still a matter of debate. For example, various recent studies point out that IL-8 expression correlates with disease progression in human melanoma^[17-19]. On the other hand, IL-8 expression in melanoma is only associated with early malignancy, whereas metastatic melanoma as well as dysplastic naevi specimens showed little or no IL-8 up-regulation as shown by immunohistochemical staining^[20]. Although constitutive IL-8 expression was determined in melanoma cells from surgical specimens, no correlation was found between the degree of cytokine expression and the clinical tumor stage^[21]. Accordingly, there is no distinct relationship between IL-8 expression and metastatic potential in various cell lines representing different clinical stages^[22,23] and some studies have even reported on antitumoral IL-8 effects^[24].

However, increasing data suggest that constitutive expression of IL-8 in colon carcinoma cell lines is associated with the metastatic potential and that IL-8 might act as an autocrine/paracrine growth factor in colon cancer progression and metastasis^[25,26]. Still it remains unclear, whether IL-8 expression is related to cancer progression and the metastatic potential in colorectal carcinoma tissues. Therefore, the purpose of this study was to examine the expression profile of IL-8 in inflammatory as well as non-malignant and malignant colorectal diseases and colorectal liver metastases (CRLM) to evaluate its role in the regulation of colorectal cancer (CRC) and the development of CRLM.

MATERIALS AND METHODS

Patients

Surgical specimens and corresponding normal tissue from the same samples were collected from patients with ulcerative colitis (UC, $n = 6$), colorectal adenomas (CRA, $n = 8$), colorectal carcinomas of different cancer stages ($n = 48$) and synchronous or metachronous CRLM ($n = 16$) who underwent surgical resection at our department between 2003 and 2006. Informed consent for tissue procurement was obtained from all patients. The study was approved by the ethics commission of the Ärztekammer of the Saarland. The clinical variables were obtained prospectively from the clinical and pathological records and are in accordance with the UICC/TNM classification^[27] (Tables 1 and 2).

Tissue preparation

Tissue samples were collected immediately after resection, snap frozen in liquid nitrogen and then stored at -80°C until they were processed under nucleic acid sterile conditions for RNA and protein extraction. Tumor samples were taken from vital areas of histopathologically confirmed (M.W.) adenocarcinomas and liver metastases, respectively. As corresponding normal tissue we used adjacent unaffected mucosa, 2-3 cm distal to the resection margin from the same resected adenocarcinoma or liver specimen, respectively. All tissues obtained were reviewed by a minimum of two experienced pathologists (M.W. *et al*) and examined for the presence of tumor cells. As

minimum criteria for usefulness for our studies we only chose tumor tissues in which tumor cells occupied a major component ($> 80\%$) of the tumor sample.

Single-strand cDNA synthesis

Total RNA was isolated using RNeasy columns from Qiagen (Hilden, Germany) according to the manufacturer's instructions. RNA integrity was confirmed spectrophotometrically and by electrophoresis on 1 g/L agarose gels. For cDNA synthesis 5 μg of each patient total RNA sample were reverse-transcribed in a final reaction volume of 50 μL containing 1 \times TaqMan RT buffer, 2.5 $\mu\text{mol/L}$ random hexamers, 500 $\mu\text{mol/L}$ each dNTP, 5.5 mmol/L MgCl_2 , 0.4 nakt/L RNase inhibitor, and 1.25 nakt/L Multiscribe RT. All RT-PCR reagents were purchased from Applied Biosystems (Foster City, CA). The reaction conditions were 10 min at 25°C , 30 min at 48°C , and 5 min at 95°C .

Real-time PCR

All Q-RT PCR assays containing the primer and probe mix were purchased from Applied Biosystems, (Applied Biosystems, Foster City, CA) and utilized according to the manufacturer's instructions. PCR reactions were carried out using 10 μL 2 \times Taqman PCR Universal Master Mix No AmpErase[®] UNG and 1 μL gene assay (Applied Biosystems, Foster City, CA), 8 μL Rnase-free water and 1 μL cDNA template (50 mg/L). The theoretical basis of the qRT assays is described in detail elsewhere^[28]. All reactions were run in duplicates along with no template controls and an additional reaction in which reverse transcriptase was omitted to assure absence of genomic DNA contamination in each RNA sample. For the signal detection, ABI Prism 7900 sequence detector was programmed to an initial step of 10 min at 95°C , followed by 40 thermal cycles of 15 s at 95°C and 10 min at 60°C and the log-linear phase of amplification was monitored to obtain C_T values for each RNA sample.

Gene expression of IL-8 was analyzed in relation to the levels of the slope matched housekeeping gene Cyclophilin C (CycC)^[29]. Since reporting of data obtained from raw C_T values falsely represent the variations, we converted the individual C_T values to the linear form as follows:

$$\text{Fold difference} = 2^{-(\text{mean } C_{T, \text{pathological tissue}} - \text{mean } C_{T, \text{calibrator}})} = 2^{-\Delta C_T}$$

Hence, the normal tissue became the 1 \times sample, and all other quantities were expressed as an n-fold difference relative to this tissue.

Isolation of total protein

Protein lysates from frozen tissues were extracted with the radioimmunoprecipitation (RIPA) cell lysis and extraction buffer from Pierce (Pierce, Rockford, USA). Total protein content was assessed by using the Pierce BCA protein assay reagent kit (Pierce, Rockford, USA).

Enzyme-linked immunosorbant assay

IL-8 tissue concentrations in the lysates were determined by sandwich-type Enzyme-linked immunosorbant assay (ELISA) according to the manufacturer's protocol: R&D systems (R&D Systems Inc. Minneapolis, Minnesota, USA)

for the quantification of IL-8. The absorbance was read at 450 nm.

Laser Capture Microdissection

Laser microbeam microdissection (LMM) was employed for obtaining pure tumor cell and pure normal cell samples for subsequent genetic analysis. LMM was performed on three samples for each tissue type for IL-8. Histochemical staining was used on cryo sections before microdissection. Specimen preparation, microdissection and catapulting were performed following a laser pressure catapulting protocol according to the manufacturer's instructions (P.A.L.M. Microlaser Technologies, Bernried, Germany). RNA was extracted using the P.A.L.M. RNA extraction kit and for reverse transcription the invitrogen reverse transcription kit (Invitrogen Life Technologies, Karlsruhe, Germany) was applied. Subsequently quantitative PCR analysis was performed.

Statistical analysis

IL-8 expression profiles in the different groups are presented as mean and standard error of the mean (SEM). Statistical calculations were done with the MedCalc

RESULTS

IL-8 expression in colorectal carcinomas related to tumor stage

Recently, we demonstrated the involvement of the murine macrophage inflammatory protein (MIP)-2, a functional murine analogue of the human IL8, in angiogenesis and tumor growth^[16]. Here, we analysed IL-8 expression in human tissue specimens of various colorectal diseases and cancer stages using Q-RT-PCR and ELISA. Our tissue specimens descended from 6 patients with UC, 8 patients with CRA and 48 patients with CRC of various cancer stages with different metastatic potentials (Tables 1 and 2). Adjacent, disease and tumor free tissue samples of the UC, CRA and CRC patients served as control groups, respectively.

Q-RT-PCR analysis revealed significant up-regulation of IL-8 mRNA expression in all pathological tissue specimens analysed, if compared with the unaffected corresponding UC-, CRA- and CRC neighbor tissues, as presented in Figure 1A. In UC- and CRA tissue specimens IL-8 mRNA expression was on average 11- and 10-fold up-regulated ($P < 0.05$, respectively). Yet, in the different T- stages of the CRC specimens IL-8 expression was more than 25-fold up-regulated ($P < 0.05$). The results shown in Figure 1A represent the pooled mean expression levels and the SEMs from 6 UC-, 8 CRA-, 8 T1-, 15 T2-, 15 T3- and 10 T4 stage CRC patients, respectively. Since averaging out the C_t values or ratios could mask significant differences between individual paired samples, we also analysed the differences between gene expression from matched normal/cancer samples. The results obtained from this level of analysis corresponded widely with the results presented in Figure 1A thus confirming the correlation between the degree of IL-8 expression and advanced tumor stage. Sections of tumor and normal cells have been microdissected in three specimens of each tissue type, followed by subsequent RT-PCR gene expression analysis

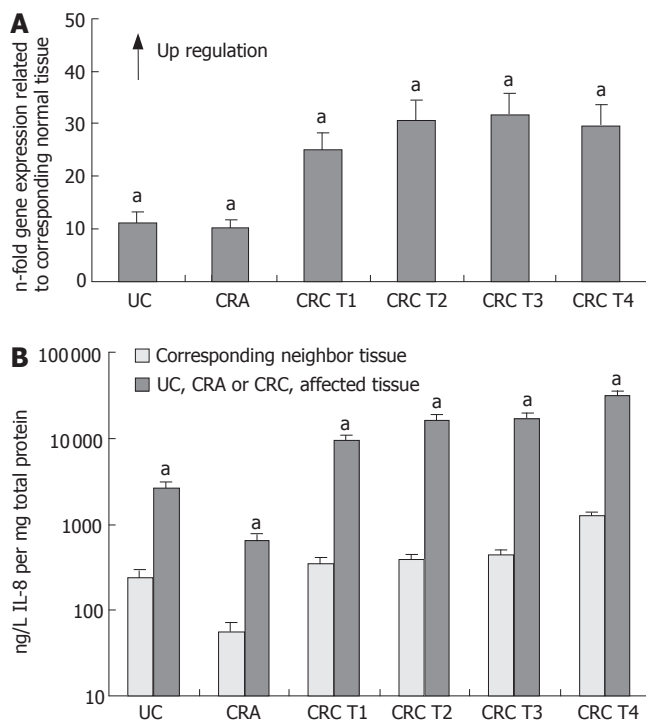

Figure 1 IL-8 expression in ulcerative colitis (UC), colorectal adenoma (CRA) and colorectal carcinomas (CRC). **A:** Q-RT-PCR; **B:** ELISA (mean \pm SE, $^aP < 0.05$, $n = 6, 8, 8, 15, 15$ and 10 , respectively).

to ensure that the expression data corresponded well with the results presented in Figure 1A.

In consistence with our results obtained at the RNA level, IL-8 protein expression, as assessed by ELISA, revealed also significant up-regulation of IL-8 protein expression in all pathological tissue specimens in comparison to the unaffected corresponding UC-, CRA- and CRC mucosa tissues, respectively (Figure 1B). Analysis of IL-8 tissue protein concentrations showed a similar profile with an average 12- and 11-fold overexpression in the UC- and CRA tissue specimens in relation to normal mucosa tissues ($P < 0.05$), and on average 30-fold higher IL-8 expression in the different T- stages of the CRC specimens, if compared with the respective tumor neighboring mucosa tissues ($P < 0.05$). Moreover, absolute expression on the protein level revealed a distinct increase in IL-8 expression levels in tumor- and tumor-free neighbor tissues of CRC patients with T-stage 4 in comparison to CRC patients with T-stages 1-3 ($P < 0.05$). However, most notably, we observed that IL-8 protein concentrations were significantly higher expressed in all CRC specimens compared to non-malignant and inflammatory tissue samples ($P < 0.05$, Figure 1B), showing on average 30-fold IL-8 protein up-regulation in the CRC specimens in comparison to the CRA tissues. For example, comparative analysis of the absolute protein levels between the CRC specimens and the CRA tissues revealed a significantly higher IL-8 expression of almost 30000 ng/L IL-8 in the CRC tissues of tumor- stage 4 compared to approximately 600 ng/L IL-8 in the CRA tissues ($P < 0.05$, Figure 1B).

IL-8 expression in colorectal liver metastases

In the next set of experiments, we analysed IL-8 mRNA

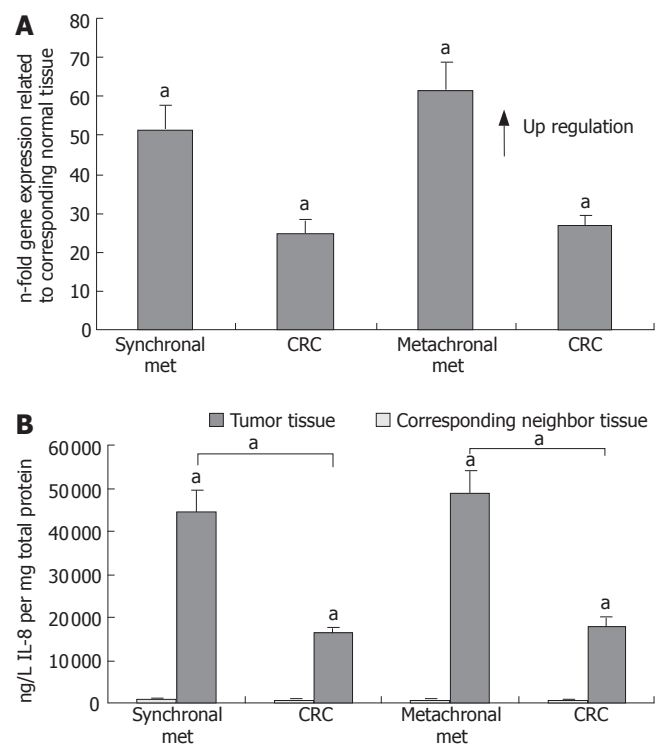

Figure 2 IL-8 expression in colorectal liver metastases of synchronous (Synchronous Met) and metachronal (Metachronal Met) origin and corresponding colorectal carcinomas (CRC). **A:** Q-RT-PCR; **B:** ELISA (mean \pm SE, $^aP < 0.05$, $n = 9$ and 7 , respectively).

and protein expression in 16 CRLM of synchronous and metachronous origin and the corresponding colorectal cancer tissues where the metastases originated from (Table 1). Healthy tumor neighbor tissues of the CRLM and corresponding CRC tissues served again as control groups. On the RNA level we found on average a 52-fold increase in IL-8 expression in the synchronous metastases compared with the corresponding tumor neighbor tissues and a 62-fold increase in IL-8 expression in the metachronous metastases ($P < 0.05$, respectively, Figure 2A). These findings were well in line with the results obtained on the protein level, which showed a 47-fold increase in IL-8 expression in synchronous metastases and a 60-fold increase in metachronous metastases ($P < 0.05$, respectively) with up to 80-fold IL-8 overexpression in individual metastases, when compared to the corresponding tumor-free hepatic neighbor tissues, respectively (Figure 2B). In our survey, neither gender nor the specific tumor localization (colon versus rectum) influenced IL-8 expression profiles in our CRC patient series. However, CRC patients with synchronous or metachronous metastases beyond the age of 60 expressed significantly more IL-8 than CRC patients younger than 60 years ($P < 0.05$). Most interestingly, the highest IL-8 overexpression was detected in synchronous and metachronous colorectal metastases, if compared to their corresponding primary CRC tissues ($P < 0.05$, respectively Figure 2B). For example, comparative analysis of the absolute protein quantities between the CRLM specimens and their corresponding CRC tissues revealed an IL-8 expression of almost 50000 ng/L in the CRLM tissues of metachronous metastases compared to approximately

18000 ng/L in the corresponding CRC primary tumor tissues ($P < 0.05$, Figure 2B).

DISCUSSION

In this study, we present an unprecedented complete and comparative analysis of the IL-8 RNA and protein expression profile of various inflammatory, non-malignant and malignant histopathological colorectal entities comprising ulcerative colitis and colorectal adenomas, both representing known premalignant conditions often preceding the development of colorectal malignancies. We further included colorectal carcinomas of different tumor stages as well as synchronous and metachronous colorectal liver metastases along with their related primary colorectal tumors.

The major findings of this study demonstrate that the magnitude of IL-8 expression in surgical CRC tissue specimens correlates with colorectal cancer progression and the development of synchronous and metachronous liver metastases. Moreover, to our knowledge we could demonstrate for the first time that irrespective of the tumor stage IL-8 is significantly higher expressed in CRC tissues compared to inflammatory colorectal conditions and adenomas of the colon/rectum. Since such conditions often constitute prevalent pre-existing disease states in the etiopathogenesis of colorectal cancer, our results strongly suggest a close association of IL-8 up-regulation and the development of CRC. In line with this conclusion is the concept that inflammation is a critical component of tumor progression. Chronic inflammation can activate cell actions that increase the induction of irreversible DNA damage and the risk of cancer and it is now becoming clear that tumor cells have co-opted some of the signalling molecules of the innate immune system, such as chemokines and their receptors for invasion, migration and metastasis^[31]. In addition, we demonstrated significant IL-8 overexpression in CRLM in comparison to the related primary colorectal tumors, indicating a correlation between IL-8 expression and the malignant status of colorectal cancer cells. Thus, our results not only suggest an association between IL-8 expression and the induction and progression of colorectal carcinoma, but also clearly point to a correlation between IL-8 expression and the development of CRLM. As our results are based on expression data, they will need further evaluation. Therefore, the next step in our investigations will comprise the functional analysis in cell culture assays. However, even at this point, the clinical significance of our findings has meaningful consequences. Examining the IL-8 expression profile in CRC patients may potentially help to assess more precisely the course of the cancerous condition. In this respect it is conceivable to monitor the IL-8 expression level in CRC patients that show no diagnosable symptoms of CRLM at the time of presentation, but may still carry a high risk for developing such metastases. A significantly up-regulated level of IL-8 might thus be a useful tool to evaluate the prognosis of patients with CRC with an important impact on future treatment strategies. Thus, patients with a higher risk of developing CRLM may receive a different treatment from patients with a lower

risk of developing CRLM.

Our findings are supported by previous studies^[32], exploiting the potential clinical significance of serum IL-8 measurements in untreated CRC patients in comparison to healthy volunteers. Circulating IL-8 serum concentrations revealed a significant correlation with the clinical stage of CRC, bowel wall invasion and liver metastasis^[32,33]. Our results are also well in line with the outcome of recent surveys which compared the expression of a number of different chemokines and growth factors in a panel of arbitrarily chosen CRC specimens with normal mucosa by use of ELISA. The authors also found significant IL-8 over-expression in the malignant tissues that correlated with tumor size, depth of infiltration, Dukes stage and shorter overall survival times^[34,35]. Accordingly, Li and colleagues^[25] studied IL-8 expression in vitro in human colon carcinoma cells with different metastatic potentials and found an association between constitutive IL-8 expression and aggressiveness of human colon carcinoma cells, which was assigned to autocrine growth and angiogenic properties of IL-8 in the regulation of multiple biological activities in endothelial cells^[36,37]. In animal studies inhibition of IL-8 reduced tumorigenesis of human non-small cell lung cancer in SCID mice^[38], and our group^[16,39] reported that MIP-2 dose-dependently promotes angiogenesis as well as hepatic engraftment and tumor growth of colon cancer cells. In other tumor types a direct role of IL-8 was demonstrated, e.g. by enhancing proliferation and invasive potential of metastatic melanoma cells^[19]. Although several authors investigated possible pathways^[40,41], the precise molecular mechanisms underlying the IL-8 mediated regulation of tumor cells still remain obscure. Recently, IL-8 was reported to promote cell proliferation and migration through metalloproteinase-cleavage in human colon carcinoma cells^[42], and other studies indicated that IL-8 mediated tumor progression may be regulated by tumor-associated stress factors^[43].

In spite of the increasing number of studies that outlined an important role and potential mechanisms of IL-8 contributing to cancer progression in various cancer types through its regulative, autocrine and paracrine functions, its interference with respect to the development of malignancies, metastasis and angiogenesis still remains controversial. For example, Kassim and colleagues demonstrated an association between IL-8 expression and a dismal prognosis in epithelial ovarian cancer patients^[44], while other studies demonstrated that IL-8 reduced tumorigenicity of human ovarian cancer *in vivo* due to neutrophil infiltration^[45]. Accordingly, in a model of colon cancer in rats, IL-8 was found to have a highly reproducible antitumoral effect that was associated with a systemic activation of T lymphocytes^[24,46]. Likewise, various metastatic tumor cell lines were shown to produce IL-8 constitutively^[19,25], while other cell lines like some metastatic prostate tumor cell lines do not express IL-8 at detectable levels^[22]. Finally, in some studies no correlation between IL-8 secretion and tumor growth kinetics or metastatic potential was found at all^[47].

Despite still ongoing controversies regarding the biological relevance of IL-8 in cancer biology, our clinical and experimental findings strongly support

a multifunctional role for IL-8 in tumor induction, progression and metastasis. Taken together, our data outline a significant correlation between IL-8 expression and the induction and progression of CRC as well as the development of CRLM. The predominance of high IL-8 expression levels in surgical colorectal carcinoma specimens might thus be a useful indicator of poor prognosis. In addition to its prognostic significance we therefore propose IL-8 as a putative target for the development of novel treatment concepts in the therapy of CRC. Herein, neutralization of IL-8 or inhibition of its production and activity might be a future basic treatment strategy in the management of CRC.

COMMENTS

Background

In recent years, an increasing number of studies suggested an involvement of IL-8 in the migration of tumor cells and correlated its expression with tumor growth, angiogenesis and metastatic potential in various human carcinomas and animal models. Yet, up to now, the pathophysiological role of IL-8 in tumor development and metastasis is not fully understood and discussed controversially. Moreover, it remains unclear, whether IL-8 expression is related to cancer progression and the metastatic potential in colorectal carcinoma tissues.

Research frontiers

The research hotspot is to elucidate a potential pathophysiological role of IL-8 in CRC development and metastatic spread and to clarify the precise molecular mechanisms underlying the IL-8 mediated regulation of colorectal carcinoma (CRC) cells.

Innovations and breakthroughs

In recent years, IL-8 expression was reported to be associated with colon cancer cell proliferation and the metastatic potential in colon carcinoma cell lines. Moreover, IL-8 was suggested to act as an autocrine/paracrine growth factor in colon cancer progression. In order to further evaluate the role of IL-8 in the regulation of CRC and the development of colorectal liver metastases (CRLM), we examined the expression profile of IL-8 in ulcerative colitis (UC) and colorectal adenoma (CRA) as conditions often preceding the development of colorectal malignancies, and moreover, in CRC tissues of different tumor stages as well as in synchronous and metachronous CRLM along with their related primary colorectal tumors. We demonstrated a significant correlation between IL-8 expression and the induction and progression of CRC as well as the development of CRLM.

Applications

Our findings suggest that monitoring the IL-8 expression level in CRC patients may potentially help to assess the course of the cancerous condition and the prognosis of patients with respect to the development of CRLM. Thus, we propose IL-8 as a useful indicator of poor prognosis and a putative target for the development of drugs in the therapy of CRC.

Terminology

UC is a disease that causes ulcers in the lining of the rectum and colon. It is one of a group of diseases called inflammatory bowel disease. CRA means a benign epithelial neoplasm of the colon or rectum, which extends from the ileocecal junction to the sigmoid colon. CRC develops as a locally invasive cancer in the colon and rectum often evolving from polyps with a very high incidence of metastatic spread.

Peer review

This is very nice work looking at IL-8 and the correlation with induction, progression and metastatic potential colorectal cancer. The scientific and innovative contents

as well as readability can reflect the advanced levels of the clinical and basic researches in gastroenterology.

Abstract

AIM: To investigate the effects of ursodeoxycholic acid (UDCA) on chenodeoxycholic acid (CDCA)-induced liver injury in hamsters, and to elucidate a correlation between liver injury and bile acid profiles in the liver.

METHODS: Liver injury was induced in hamsters by administration of 0.5% (w/w) CDCA in their feed for 7 d. UDCA (50 mg/kg and 150 mg/kg) was administered for the last 3 d of the experiment.

RESULTS: At the end of the experiment, serum alanine aminotransferase (ALT) increased more than 10 times and the presence of liver injury was confirmed histologically. Marked increase in bile acids was observed in the liver. The amount of total bile acids increased approximately three-fold and was accompanied by the increase in hydrophobic bile acids, CDCA and lithocholic acid (LCA). UDCA (50 mg/kg and 150 mg/kg) improved liver histology, with a significant decrease (679.3 ± 77.5 U/L vs 333.6 ± 50.4 U/L and 254.3 ± 35.5 U/L, respectively, $P < 0.01$) in serum ALT level. UDCA decreased the concentrations of the hydrophobic bile acids, and as a result, a decrease in the total bile acid level in the liver was achieved.

CONCLUSION: The results show that UDCA improves oral CDCA-induced liver damage in hamsters. The protective effects of UDCA appear to result from a decrease in the concentration of hydrophobic bile acids, CDCA and LCA, which accumulate and show the cytotoxicity in the liver.

INTRODUCTION

It is generally accepted that ursodeoxycholic acid (UDCA) can improve values for clinical and biochemical indices in patients with cholestatic liver disease, such as primary biliary cirrhosis (PBC)^[1-4], primary sclerosing cholangitis (PSC)^[5,6] and viral hepatitis^[7,8]. UDCA exerts its choleretic action on the cholestatic liver and consequently decreases the values for serum indices of hepatotoxicity, such as alanine aminotransferase (ALT).

Cholestasis, defined as impairment of bile flow in hepatobiliary circulation, is accompanied by the retention of bile acids in the liver^[9]. As mentioned above, cholestasis is observed widely not only in cholestatic liver diseases such as PBC and PSC, but also in viral hepatitis such as hepatitis C^[10]. It is necessary to determine the changes in the bile acid amounts in the liver in liver diseases and how UDCA affects the bile acid pool changes. Such studies are limited clinically and interpretation of the data from experimental animals is required. In studies using mice and rats, however, care should be taken in interpreting the data because bile acids have different metabolic profiles^[11,12]. For example, β -muricholic acid is one of the major bile acids, which is not produced in humans. On the other hand, hamsters have the advantage that their profile of the bile acid metabolism resembles that in humans^[13,14].

In this study, we fed CDCA, a hydrophobic bile acid, to hamsters to induce liver injury, and to investigate the efficacy of UDCA administration using the model for the first time. We also evaluated the correlation between bile acid concentration in the liver and the protective effects of UDCA in the liver.

MATERIALS AND METHODS

Materials

Ursodeoxycholic acid (UDCA) was synthesized at

Mitsubishi Pharma Corporation (Osaka, Japan), and its purity was confirmed to be higher than 99%. Chenodeoxycholic acid was purchased from CALBIOCHEM (San Diego, California).

Animals

Six-week-old Syrian golden hamsters (weighing 89-117 g) were purchased from Japan SLC Inc. (Hamamatsu, Japan). The animals were maintained in a 12-h day/night cycle, with standard powder chow (MF, Oriental Yeast Co., Ltd. Tokyo, Japan) and tap water given *ad libitum*. All animal experiments were approved by the Animal Ethical Committee of Mitsubishi Pharma Corporation and performed in accordance with guidelines of the Japanese Pharmacological Society.

Experimental protocol

After acclimation for 5 d, the hamsters were randomly allocated to four groups, 10 animals each. For 7 d, the animals in each group were fed a standard powder chow (MF) with or without 0.5% (w/w) CDCA as follows: chow without 0.5% (w/w) CDCA (normal group); chow with 0.5% (w/w) CDCA (control group and UDCA-treated groups). UDCA was orally administered (50 or 150 mg/kg) to the CDCA-fed hamsters at a volume of 5 mL/kg between 3 pm and 5 pm, once a day for the last 3 d of the experiment. Purified water was administered to hamsters in the normal group and control groups.

All animals were fasted for 18 h before sacrifice. The animals were weighed, and then anesthetized with diethyl ether. Blood was collected by cardiac puncture for the determination of serum ALT which was analyzed with an autoanalyzer (FUJI DRI-CHEM 7000, FUJIFILM, Tokyo). Then the liver was rapidly removed, weighed and rinsed with saline. The liver was processed for histopathological examination and for bile acid analysis (other than the UDCA 50 mg/kg group).

Histopathological examination

Part of the rinsed liver tissue was fixed in 100 mL/L formalin and embedded in a paraffin block. The paraffin section was stained with hematoxylin-eosin (HE) and examined microscopically. Histological findings were assessed blindly and independently by two pathologists and graded from (-) to (+++) for the severity of vacuolation, cell infiltration and focal necrosis as follows: -: no change, ±: slight change, +: mild change, ++: marked change, and +++: severe change.

Bile acid analysis

Bile acids in the liver were analyzed according to a method described elsewhere^[15]. Briefly, 100 µL each of methanol and 23-nordeoxycholic acid (the internal standard), and 1 mL of 0.2 mol/L NaOH (maintained at 80°C) were added to about 50 mg of liver tissue homogenate. The mixture was immediately heated at 80°C for 20 min to dissolve the liver tissue, then mixed with 3 mL of water, and left to cool to room temperature. A 3-mL n-hexane extraction was performed three times to remove neutral lipids. Bile acids were then extracted from the remaining aqueous phase with a BondElut C18 cartridge. The methanol

Table 1 Body weight changes and food intake during the experiment (mean ± SE)

Group	Body weight (g)		Weight gain (g)	Food intake (g/d)
	Before the experiment	End of the experiment		
Normal	104.8 ± 2.5	110.6 ± 3.3	5.8 ± 1.8	7.1 ± 0.2
Control	103.7 ± 2.5	106.9 ± 1.9	3.2 ± 1.2	6.5 ± 0.3
UDCA 50 mg/kg	103.1 ± 2.9	104.7 ± 3.1	1.6 ± 1.3	6.2 ± 0.4
UDCA 150 mg/kg	104.7 ± 2.1	107.2 ± 1.9	2.5 ± 1.6	6.2 ± 0.2

UDCA: Ursodeoxycholic acid. There was no significant difference between normal and control groups (Student's *t*-test). There was no significant difference between the control group and UDCA groups (Dunnett's multiple comparison test).

eluate was evaporated and the bile acids were analyzed by HPLC (Inertsil ODS-2 column). Examined bile acids were as follows: cholic acid (CA), CDCA, deoxycholic acid (DCA), LCA and UDCA. Concentrations of these 5 bile acids were calculated with summations of the 3 different types of conjugates (i.e., unconjugated, glycine and taurine conjugated bile acid) and expressed per gram of tissue weight. They were also expressed as composition percentages of total bile acids detected.

Statistical analysis

During the experiment, data on one out of every ten animals of each group were removed due to experimental treatment failures. Data on 9 animals of each group were processed as results in this study. Results were expressed as mean ± SE except the case for the bile acid analyses, which were expressed as mean ± SD. Differences among the group means were tested using Student's *t*-test or Dunnett's multiple comparison test. *P* < 0.05 was considered statistically significant.

RESULTS

Body weight and food intake changes during the experiment

The results of body weight and food intake are shown in Table 1. No significant differences were found in those parameters among the hamsters in the four groups during the experiment.

Effect of UDCA on serum ALT in CDCA-induced liver injury in hamsters

As shown in Figure 1, feeding of CDCA for 7 d induced liver injury, and the serum ALT level (679.3 ± 77.5 U/L) in the CDCA-fed group (control group) was significantly (*P* < 0.01) elevated as compared with that of the normal group (61.4 ± 8.7 U/L). UDCA administration for the last 3 d of the experiment significantly (*P* < 0.01) reduced the serum ALT values (50 mg/kg: 333.6 ± 50.4 U/L, 150 mg/kg: 254.3 ± 35.5 U/L) as compared to the control group (679.3 ± 77.5 U/L).

Effect of UDCA on hepatic pathology

Induction of hepatic injury was confirmed histopathologically. Slight to mild vacuolation in a broad area was

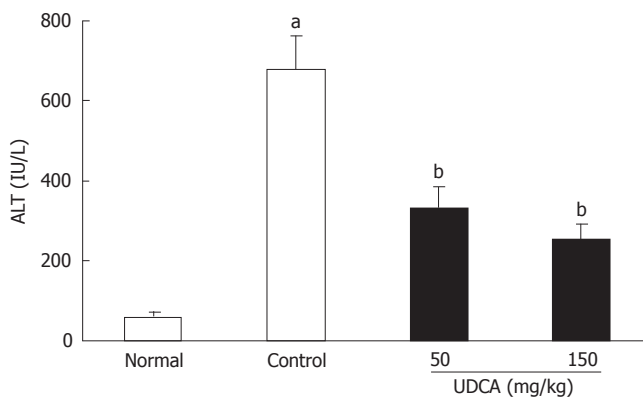

Figure 1 Effect of UDCA on serum ALT in hamsters fed CDCA. Data are expressed as mean \pm SE ($n = 9$). ^a $P < 0.01$ vs normal group (Student's *t*-test); ^b $P < 0.01$ vs control group (Dunnett's multiple comparison test).

observed in the livers in the CDCA-fed group (control group), which was not observed in the normal group (Table 2, Figure 2A and B). UDCA treatment (150 mg/kg) led to a significant reduction in the grades of vacuolation observed in the control group (Table 2, Figure 2C). No changes were observed in cell infiltration and focal necrosis by CDCA feeding.

Bile acid concentration and composition in the liver

Concentrations and compositions of 5 major bile acids in the liver in each group are shown in Table 3. Livers from the normal group contained CA 102.0 ± 41.7 nmol/g ($68.2\% \pm 3.2\%$ of total bile acids), CDCA 36.0 ± 17.1 nmol/g ($23.8\% \pm 3.6\%$), DCA 10.3 ± 4.4 nmol/g ($6.8\% \pm 1.3\%$), and UDCA 1.9 ± 2.2 nmol/g ($1.2\% \pm 1.3\%$). The concentration of LCA was less than 1.0 nmol/g. In CDCA-fed hamsters, the total bile acids level was increased more than three-fold (484.7 ± 189.7 nmol/g). Analysis of each bile acid concentration revealed that CDCA concentration increased ten-fold (364.9 ± 141.5 nmol/g), and LCA concentration also markedly increased (89.4 ± 32.4 nmol/g). Compositions of the two hydrophobic bile acids were increased to $75.3\% \pm 2.7\%$ and $18.7\% \pm 2.0\%$, respectively. The concentration of UDCA was increased to 4.0 ± 0.9 nmol/g, whereas its composition did not change ($0.9\% \pm 0.3\%$) by CDCA feeding. On the other hand, concentrations and compositions of CA and DCA were

decreased significantly (CA: 20.9 ± 13.8 nmol/g and $4.0\% \pm 1.1\%$; DCA: 5.6 ± 3.2 nmol/g and $1.1\% \pm 0.3\%$).

When 150 mg/kg of UDCA was administered, the total bile acids level was significantly decreased ($P < 0.01$) to 296.0 ± 88.0 nmol/g, which suggests the improvement of cholestasis. Increase of UDCA (27.4 ± 12.8 nmol/g) level was observed accompanied by decrease of CDCA (196.4 ± 65.3 nmol/g) and LCA (56.0 ± 15.7 nmol/g) level. Concentrations of CA (12.8 ± 3.8 nmol/g) and DCA (3.3 ± 2.2 nmol/g) did not change statistically from those of the control group by the administration of UDCA.

DISCUSSION

The liver injury model was produced by a 7-d diet of 0.5% (w/w) CDCA administered to hamsters, which have a similar metabolic profile of bile acids as in humans. An increase in serum ALT was observed and the appearance of liver injury was confirmed histopathologically, which was assessed (Figures 1 and 2, Table 2). These phenomena were in accordance with the results of previous studies^[16,17] which showed the toxicity of CDCA in hamsters. First of all, we determined the change in concentrations of major bile acids in liver of the hamsters to clarify the correlation of those bile acids and the liver injuries. We also administered UDCA in the hamsters to examine the improvement of liver damage caused by CDCA feeding,

using the changes in the concentrations of bile acids.

In terms of bile acid concentration, CDCA feeding increased the amounts of CDCA and LCA in the hamster liver; on the other hand, it decreased the amounts of CA and DCA (Table 3). This might be explained as follows: At first, CDCA feeding itself increases CDCA in the liver. The increased CDCA is transported from the liver to the digestive tract through the bile duct. CDCA is metabolized to LCA by the enterobacteria there. LCA, which is a potent hydrophobic bile acid^[18], migrates to the liver by enterohepatic circulation. In contrast, a decrease in CA and DCA would be explained as follows: Oda *et al*^[16] showed that CDCA was a potent inhibitor of cholesterol-7 α -hydroxylase. Based on this inhibition of the enzyme activity, feeding of CDCA inhibited biosynthesis of CA which is synthesized from cholesterol, and DCA which is formed by the bacterial 7 α -hydroxylation of CA in the intestine and migrates to the liver by enterohepatic circulation, resulting in decreased proportions of these bile acids in the liver.

It is reported that cholestasis is believed to be an impairment of bile transport or the molecular mechanism from the liver to intestine, consequently leading to intrahepatic accumulation of hydrophobic bile acids, such as CDCA, DCA and LCA. Increase in the hydrophobic bile acids is reported to induce cytotoxicity in hepatocytes^[16,19]. The mechanism of hepatic damage by these bile acids has not been clarified completely; however, several possibilities have been presented. It has been reported that some bile acids induce mitochondrial perturbation^[20,21]. More recently hydrophobic bile acids have been shown to regulate the expression of several genes by acting as ligands of some nuclear receptors in the liver. Through these mechanisms, they affect bile salt synthesis^[22,23], detoxification^[24,25], and transporting molecules^[26,27].

UDCA is widely used for the treatment of liver dysfunction in patients with primary biliary cirrhosis and acute and chronic intrahepatic cholestatic disorders^[1-8]. The powerful choleric effect of the drug was also confirmed in this hamster model. Improvement of liver histology associated with a significant decrease in serum ALT level was observed. The 150 mg/kg UDCA-administered group showed a significant decrease in the concentrations of total bile acids in the liver as comparison with the control group. The concentration of UDCA in the liver became 27.4 \pm 12.8 nmol/g liver by the administration of 150 mg/kg UDCA. Setchell *et al*^[28] have shown that concentration of UDCA became 40.1 \pm 9.0 nmol/g liver when clinical

dosage of the drug (600 mg/d) was administered for 4 d in patients suffering chronic hepatitis C. These findings suggested that liver UDCA concentration after UDCA administration in hamster was not extremely different from that in human.

In the liver of this group, the concentration of UDCA was raised, whereas that of the hydrophobic bile acids, CDCA and LCA was significantly decreased. UDCA is more hydrophilic compared to CDCA and LCA^[12]. It was confirmed that the reduction in the concentration of hydrophobic bile acids and the replacement with hydrophilic bile acids in liver might be the mechanism of UDCA.

In recent years, several studies have been conducted to determine the mechanisms of action for UDCA at the molecular level. Schuetz *et al*^[29] showed that UDCA activated the pregnane X receptor (PXR), and the reversal of cholestasis in humans by UDCA might include PXR-mediated activation of CYP3A4 and perhaps drug transporter targets that lead to enhanced metabolism and efflux of hepatotoxic bile acids. Rost *et al*^[30] showed that UDCA might prevent impairment of hepatic function by restoring the expression of the hepatic transporter. Our next study will be the simultaneous investigation of the transporter expression and the bile acid concentration in this hamster model.

In conclusion, this study showed that the liver injury model was successfully produced by a 7-d diet of 0.5% (w/w) CDCA administered to hamsters. In this model, liver accumulations of two hydrophobic bile acids, CDCA and LCA, were observed. UDCA improved liver damages, which was confirmed with the decrease in serum ALT, and improvement of the liver histology. The protective effects of UDCA seem to result from a decrease in the concentration of the hydrophobic bile acids which accumulate in the liver.

The authors thank Mr. Akihiro Fujii for helpful advice and discussion and Ms. Hiroko Sato and Ms. Yoshie Anabuki for excellent technical assistance.

COMMENTS

Background

Ursodeoxycholic acid (UDCA) is widely used for the therapy of liver dysfunction in many types of liver disease. The mechanisms of this drug, however, have not

been fully clarified yet. Abnormal retention of bile acids in the liver is a common finding when hepatic function is impaired. In this study we investigated the hepatoprotective effects of UDCA, using chenodeoxycholic acid (CDCA)-induced liver injury in hamsters to elucidate a correlation between liver injury and bile acid profiles in the liver.

Research frontiers

It has been reported that the profile of bile acid metabolism in hamsters resembles that in humans. Administration of CDCA is known to cause liver injury in hamsters. Thus, we considered that it was possible to evaluate the relationship between hepatoprotective action of UDCA and liver bile acid profiles in hamsters.

Innovations and breakthroughs

There are some reports that the rate of UDCA increased and those of CDCA and DCA decreased in serum and bile by UDCA treatment. One of the mechanisms of action of UDCA for improvement of liver dysfunction is replacement hydrophobic bile acids [CDCA, deoxycholic acid (DCA) and lithocholic acid (LCA)] with hydrophilic bile acids including UDCA. Because the liver is thought to be the major target organ of UDCA, changes of bile acid concentrations in the liver must be very important. There have been, however, few reports to study the correlation between liver bile acids concentrations and the hepatoprotective effects of UDCA.

Applications

UDCA is widely used for the therapy of liver dysfunction in many types of liver disease, especially those with the accumulation of bile acids. Cholestasis is one of the typical diseases accompanied by the phenomenon. The results obtained in this study have shown that decrease of hydrophobic bile acids in the liver are correlate with the hepatoprotective action of UDCA and it may be one of the mechanisms of the drug.

Terminology

Individual bile acids differ in hydrophobicity and hepatotoxicity. CDCA, DCA and LCA are more hydrophobic and hepatotoxic than UDCA.

Peer review

The manuscript written by Iwaki *et al* describes the protective effect of UDCA on liver injury induced by CDCA. Although UDCA is clinically used for many liver diseases, the mechanisms for actions have not been fully understood. Therefore, their study is important, and the results are interesting.

Abstract

AIM: To evaluate the predictive value of hepatocyte proliferation and hepatic angiogenesis for the occurrence of Hepatocellular carcinoma (HCC) in hepatitis C virus (HCV) cirrhotic patients.

METHODS: One hundred-five patients (69 males, 36 females; age range, 51-90 year; median 66 year) with biopsy proven HCV cirrhosis were prospectively monitored for HCC occurrence for a median time of 64 mo. Angiogenesis was assessed by using microvessel density (MVD), hepatocyte turnover by MIB1 and PCNA indexes at inclusion in liver biopsies.

RESULTS: Forty six patients (43.8%) developed HCC after a median time of 55 (6-120) mo while 59 (56.2%) did not. Patients were divided into two groups according to the median value of each index. The difference between patients with low (median MVD = 3; range 0-20) and high (median MVD = 7; range 1-24) MVD was statistically significant ($\chi^2 = 22.06$; $P < 0.0001$) which was not the case for MIB1 or PCNA (MIB-1: $\chi^2 = 1.41$; $P = 0.2351$; PCNA: $\chi^2 = 1.27$; $P = 0.2589$). The median MVD was higher in patients who developed HCC than in those who did not. HCC-free interval was significantly longer in patients with the MVD ≤ 4 ($P = 0.0006$). No relationship was found between MIB1 or PCNA and MVD (MIB-1 $r^2 = 0.00007116$, $P = 0.9281$; PCNA: $r^2 =$

INTRODUCTION

Hepatocellular carcinoma (HCC) is nowadays the leading cause of death in patients with cirrhosis and its incidence is continuously increasing in the west^[1]. Although cirrhosis is present in about 80%-90% of cases in western countries, other risk factors have been well defined such as age, sex, platelet count, alpha-fetoprotein (AFP) level and the cause of the underlying liver disease^[2]. Cirrhosis is considered to cause HCC independently of etiology and HCC from different individuals may have different phenotypes^[3]. This could be due to individual host response to etiologic agent, but there are features that unify HCC occurring in a background of a specific etiologic agent^[3]. HCC is the result of a multi step process that proceeds from the initiation of one or more hepatocytes to a diffuse disease^[4]. HCC due to chronic viral infection may be an indirect result of hepatocyte proliferation that occurs during chronic hepatitis in an effort to replace infected cells that have been immunologically attacked^[5]. Changes due to viral factors may also play a more direct role in liver oncogenesis^[6,7]. Most cases of HCC in the West occur in patients with cirrhosis mainly due to hepatitis C virus (HCV) infection which is the second cause of HCC in the world^[8]. HCV-infected patients have a high risk for developing HCC but mechanisms leading to the increased

risk for liver cancer are still matter of debate.

Chronic HCV infection may lead to a high hepatocyte turnover, resulting in replicative senescence of liver cells, accumulation of DNA alterations^[9,10] and cancer. This phenomenon appears to be hardly specific to HCV infection^[3].

Angiogenesis is known to play a pivotal role in almost every kind of malignancy favoring growth and metastasis of several types of cancer including HCC^[11]. Many angiogenesis-related factors such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), platelet-derived endothelial cell growth factor (PD-ECGF), thrombospondin (TSP), angiogenin, pleiotrophin and endostatin levels have been evaluated and shown to be of prognostic significance in various types of cancer. Quantification of microvessel density (MVD) inside the tumour has been widely demonstrated to be a reliable tool of evaluating angiogenesis^[12]. The exact role of these factors is still unclear although the crucial importance of VEGF, cyclooxygenase-2 (COX-2) and inducible nitric oxide synthase (iNOS) overexpression are widely recognized^[13].

The prognostic significance of MVD independently of other pathologic predictors was demonstrated in several malignancies, i.e. breast, gastric, colorectal, pancreatic carcinoma, testicular germ tumour, malignant melanoma and even hematological malignancies^[14-17].

HCC is a highly vascular tumour characterized by a propensity for vascular invasion. Angiogenesis increases in the early phases of HCC development^[18]. MVD is reported to be correlated to the size of the tumour and may predict early recurrence after resection^[19,20]. Therefore, it is conceivable that the high density of new vessels observed in the liver of patients with chronic HCV infection may contribute to the early development of cancer cells and may explain the high incidence of HCC in these patients^[18].

In a previous study, we demonstrated that liver angiogenesis as measured by MVD was significantly more common and intense in patients with chronic HCV infection in comparison to matched patients with chronic HBV infection or controls^[21]. Experiments *in vitro* using endothelial cells exposed to liver homogenates and sera of patients with different hepatic diseases confirmed that HCV positive biologic tissues stimulated in a greater extent migration and proliferation of endothelial cells^[21]. Based on these results, liver angiogenesis due to chronic HCV infection was argued to be independent of inflammation. These observations indicated that liver angiogenesis is most intense in HCV infected patients, suggesting a possible mechanism linking HCV infection to the increased risk of developing HCC.

The present study aimed at investigating whether increased liver angiogenesis as estimated by the MVD in liver biopsies could be predictive of the future occurrence of HCC in patients with HCV related cirrhosis. Furthermore, since PCNA staining, a marker of hepatocyte proliferation, was previously reported to be predictive of HCC, in this study also two proliferative indexes, PCNA and MIB₁ and their correlation to MVD were studied together other known risk factors for HCC.

MATERIALS AND METHODS

Patients

One hundred and five cirrhotic patients (69 males and 36 females; age range, 51-90 year; mean 62.5 ± 8.3 year) were included and monitored (120 mo) from January 1993 to January 2003. All enrolled patients met the following criteria: (1) chronic HCV infection documented by the presence of anti-HCV antibodies and HCV RNA in the serum; (2) histologically proven HCV related cirrhosis; (3) absence of other causes of viral or non-viral liver disease including alcohol abuse or any kind of genetic disease; (4) absence of contemporary or previous antiviral treatment. All patients were investigated at the beginning of the study by routine liver function test assessment, liver ultrasound scan, and determination of serological markers of viral infections and autoimmune diseases. All patients had a homogenous liver at ultrasound (US) examination and serum alfafetoprotein (AFP) level under 20 µg/L. All patients were affected by Child-Pugh A well compensated liver cirrhosis according to international criteria^[22,23]. They were thereafter included in a screening program for HCC consisting in periodic US examination and determination of serum AFP levels at least every 6 mo.

This study was approved by the local Ethical Committees of both Azienda Ospedaliero-Universitaria Careggi, Firenze, Italy and Hopital Jean Verdier, Assistance Publique-Hopitaux de Paris et UFR SMBH-Universite Paris XIII, Bondy, France. All enrolled subjects gave their informed consent to undergo liver biopsy for diagnostic purposes and to participate in the study.

Virological assessment

All patients were tested for anti-HCV antibodies by a second generation enzyme-linked immunosorbant assay (Ortho Diagnostic Systems, Inc., Raritan, NJ) and radio immunoblotting assay (Chiron Corporation, Emeryville, CA). Confirmation of the presence of serum viral HCV-RNA in anti-HCV positive patients was performed by a standard polymerase chain reaction technique. Serum hepatitis B markers and HBV DNA (Abbott Laboratories, North Chicago, IL) were performed in addition.

Immunohistochemistry

Liver biopsies were coded, formaldehyde-fixed, paraffin-embedded, cut into 4 µm thick sections, and stained with standard techniques. Immunohistochemical stainings were performed on 4 µm thick formaldehyde-fixed paraffin embedded sections, using the streptavidin-biotin immunoperoxidase technique. Antigen retrieval with microwave treatment with citrate buffer, pH 6.0, for 10 min was used. After blocking endogenous peroxidase the primary antibodies were applied.

Monoclonal antibody anti-CD34 (Immunotech, Mar-siglia, Fr) was used at a 1:100 dilution at 4°C for 12 h. Sections were incubated for 12 h at room temperature with MIB-1 monoclonal antibody (Immunotech, Marseille, Fr) at 1:50 dilution or were incubated for 2 h at room temperature with PCNA monoclonal antibody (Dako, Carpinteria CA) at 1:200 dilution. For negative controls, sections were treated the same way except they were incubated with Tris-

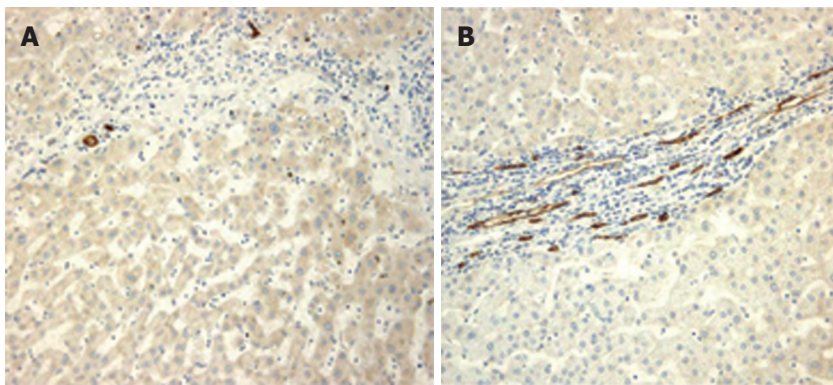

Figure 1 Immunohistochemical staining for CD 34 expression, assessed by QB-END/10 monoclonal antibody. A: Low panel (MVD ≤ 4); B: High panel (MVD > 4).

Table 1 The 105 patients divided in two groups according to the MIB-1 or PCNA score

	HCC incidence during follow-up	No HCC during follow-up	Total
MIB-1 > 1	40	46	86
MIB-1 ≤ 1	6	13	19
PCNA > 4	23	23	46
PCNA ≤ 4	23	36	59
Total	46	59	105

buffered saline instead of the primary antibody.

The percentage of tumor cells positive for MIB-1 as well as PCNA was determined semiquantitatively by assessing the whole tumor section, and each sample was scored by 0.1 points for every 1% of positive cells.

MVD evaluation

MVD was assessed by light microscopy using the counting method introduced by Weidner *et al.*^[24], CD34 was used to identify newly formed microvessels. As explained elsewhere^[21] liver tissue sections were scanned at low magnification ($\times 40$ and $\times 100$) to find the areas that showed the most intense vascularization (hot spots). Individual microvessels were counted in three fields at $200\times$ magnification ($20\times$ objective lens and $10\times$ ocular lens; 0.7386 mm^2 per field). The final MVD was the mean value obtained from counts of the 3 fields. MVD was expressed as mean \pm standard deviation (vessels per mm^2). Any immunostained endothelial cell or endothelial cell cluster that was clearly separated from hepatocytes and other connective tissue elements was considered a single and countable microvessel. Vessel lumens were not necessary for a structure to be defined as a microvessel, and red cells were not used to define a vessel lumen. Evaluation of MVD was performed without knowledge of any clinical and pathological data.

Statistical analysis

Statistical analysis was performed using Yates' corrected analysis to compare proportions. Correlation between continuous variables was performed with linear regression analysis. Disease-free survival rates were computed by the Kaplan-Meier method and were compared by the log-rank test. Student's *t*-test, one-way ANOVA, χ^2 analysis were also used where indicated. $P \leq 0.05$ was considered

significant. Cox regression method was used to analyze the effect of single risk factors on HCC occurrence risk. SPSS 10.0 software (SPSS, USA) was used to analyze the data.

RESULTS

Serum AFP levels of patients were $7.55 \pm 4.87\text{ }\mu\text{g/L}$, and their platelets levels of patients were $113 \pm 25 \times 10^8/\text{L}$ (mean \pm SD). The median time of follow-up in the whole group of patients was 64 months. Forty-six out of the 105 (43.8%) patients developed HCC during the follow-up. The median time to HCC occurrence was 55 (range 6-120) mo. Fifty-nine patients (56.2%) did not develop HCC the observation time. Year incidence of HCC was 4.4 %. CD 34 staining as a marker of newly formed microvessels was observed within hepatic tissue along vascular channels, in groups of cells that apparently did not border vascular lumina and in groups of cells located in portal tracts and septa. Figure 1 shows examples of low (MVD ≤ 4 , Panel A) and high (MVD > 4 , Panel B) CD 34 expression, assessed by QB-END/10 monoclonal antibody. The highest number of newly formed microvessels observed in one single microscopic field ($250\times$) was 24. A microvessel density score less than or equal to 4 was considered to be low angiogenesis expression while one greater than 4 as high. The cut-off score of 4 was chosen as it was the median of the MVD scores in our study group.

When considering the whole group of 105 patients, 32 out of the 46 patients who developed HCC showed a high (> 4) MVD score while only 14 patients of the 59 patients who did not develop HCC showed a high MVD score ($\chi^2 = 22.26$; $P < 0.0001$).

The median MVD score of those patients developing HCC was 7 (range 1-24) while the median score of those who remained HCC-free was 3 (range 0-20). Proliferating cells were identified by immunohistochemistry for monoclonal antibodies, MIB-1 and PCNA. No difference was observed when comparing immunostaining for Ki-67 (MIB-1 high score: > 1 and low score: ≤ 1 and PCNA: high score: > 4 and low score: ≤ 4 as score 1 and 4 were the medians of the MIB-1 and PCNA scores in our study group, respectively) in the group of patients which developed HCC during the study as compared to other patients who did not develop HCC (MIB-1: $\chi^2 = 1.24$; $P = 0.2351$; PCNA: $\chi^2 = 1.27$; $P = 0.2589$) (Table 1).

No correlation was found between the MVD score and MIB-1 (Panel A, MIB-1: $r^2 = 0.00007116$; $P = 0.9281$) or

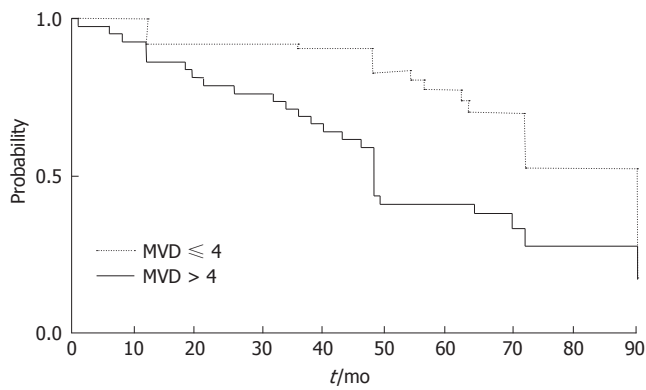

Figure 2 HCC-free time during follow-up of patients.

PCNA score (Panel B; PCNA: $r^2 = 0.001950$; $P = 0.6692$). As previously shown, the presence of cirrhosis had no significant effect on immunostaining results for either QB-END/10 or MIB-1 or PCNA antibodies (data not shown)^[21].

The HCC-free interval during follow-up turned out to be significantly longer in the group of patients having an MVD score < 4 ($P = 0.0006$) (Figure 2). On the contrary, no difference was shown by chi-squared analysis of the 105 patients who were divided in two groups according to the PCNA score ($\chi^2 = 1.27$; $P = 0.2589$). Among known risk factors for HCC such as sex, age, platelets and AFP only male sex was a risk factor for HCC development ($\chi^2 = 3.91$; $P = 0.048$).

DISCUSSION

HCC is a lethal malignancy and its incidence ranks fifth but fourth in terms of mortality^[2,4]. It is well known that the growth of tumours and metastatization depend on adequate angiogenesis. HCC is a hyper-vascular tumour and neo-vascularization is a hallmark of HCC. At least two studies demonstrated that angiogenesis, as assessed by counting of microvessels, should be considered as an important prognostic factor in HCC surgical therapy (resection) outcome^[25,26]. Intense angiogenesis expressed as high microvessel count is associated with neoplastic disease spread and poor survival. The present study is the first one that analyzes the predictive value of MVD for occurrence of HCC in patients with HCV cirrhosis. Results shown here suggest that HCV positive cirrhotic patients with more intense hepatic angiogenesis are at higher risk for HCC occurrence. This data contribute to a more accurate definition of risk factors in HCV positive cirrhotic patients together with other simple epidemiological parameters such as sex and age. According to this findings, hepatic MVD could be added to other of histologic parameters such as large cell dysplasia that could help to a more accurate definition of high risk groups of patients for HCC. Furthermore, it gives a contribute to our understanding of liver cancerogenesis in HCV positive patients.

Several studies considered angiogenesis in HCC patients, even in early stages, but none provided evidence of a relationship between angiogenesis and the probability

of HCC developing during chronic HCV infection. Although a relationship between MVD and HCC free survival time and prognosis in patient surgically treated for HCC was already proven, this is the first study that analyze the prognostic value of MVD in patients with chronic HCV infection and liver cirrhosis. Many angiogenesis-related immunohistochemical markers, such as VEGF, b-FGF, PD-ECGF, TSP, pleiotrophin and endostatin levels as well as the identification of angiogenesis measured as MVD have been found to be of prognostic significance in cancer disease. Particularly, MVD has been widely demonstrated to be a suitable assay to evaluate cancer related angiogenesis^[12,15].

A prognostic value of MVD independently from conventional pathologic predictors was demonstrated in many types of cancer. It was shown that angiogenesis as measured by MVD correlates significantly with tumour size in patients undergoing HCC resection and may predict early recurrence after liver resection. Increased angiogenesis assessed by MVD can be considered as an hallmark of HCV chronic hepatitis as we emphasized years ago^[21]. In that study, it was shown that MVD was 14 fold increased in patients with chronic HCV hepatitis compared to controls and 5 fold compared to patients with matched chronic HBV hepatitis. Patients with non viral liver diseases such as primary biliary cirrhosis and inflammatory pseudo tumour were considered as controls and had a mild and non significant increase in MVD. Studies performed in vitro confirmed those findings showing enhanced HUVEC migration and proliferation when endothelial cells were exposed to sera or liver homogenates from HCV infected patients.

In the present study we used the MVD count to quantify angiogenesis in the liver of 105 patients with HCV related cirrhosis. Forty-six of them have developed HCC after a median time of 55 mo whilst 59 patients did not develop HCC. The whole group of patients was divided in two groups according to the MVD count. Patients with a MVD count higher than 4 were exposed to a higher risk of developing HCC during follow-up. A high MVD score in fact, was associated with a significantly higher probability to develop HCC during follow-up. It is noteworthy that the median time of follow-up of those who remained free from HCC was significantly longer than that of the group of patients that would have developed HCC during follow-up. The mean annual incidence of HCC occurrence was 4.4% corresponding to what is usually observed in this type of patients.

Among other known risk factors for HCC, only male sex was associated with a higher risk to develop HCC. The difference between male and female in the occurrence of HCC was statistically significant (69 males *vs* 36 females; $P = 0.048$). However, it must be said that to establish risk factors for multifactorial diseases as is cancer are usually needed a much larger number of subjects included in a survey study than what included in the present study. In addition, in the present study only patients with histology proven HCV related liver cirrhosis with a mean age older than what is commonly reported in the literature as mean age of HCC occurrence were considered. We think that these facts played a big role in explaining why

some of other known risk factors for HCC did not appear statistically related to liver cancer in the present study. Interestingly, different geographic areas did not play any role in affecting HCC risk in the present work, in fact French and Italian patients who developed HCC did not show a significant difference in mean age (68.5 years *vs* 65.3 years, French *vs* Italian, respectively) at the moment of diagnosis. In addition, dividing French from Italian patients the MVD score remained predictive for HCC development ($\chi^2 = 13.18$; $P < 0.0001$; and 5.60; $P < 0.0179$ French and Italians, respectively).

In this study, besides the MVD counts, we considered the predictive value of 2 proliferative indexes, PCNA and MIB-1, that have been proposed as risk factors for the occurrence of HCC^[12]. In our hands, PCNA and MIB-1 staining were not predictive of the occurrence of HCC.

No one of patients included in the present study had had treatment with antiviral drugs before entering the study neither had during it. After that it was shown^[27,28] that antiviral treatment resulted in a reduction of HCC risk the study could not go on for ethical reasons. These findings, although have brought to the end our study, on the same time, they indirectly confirmed the validity of the observation we did in the present study. In fact, lymphoblastoid IFN alpha has antiangiogenic activity in addition to its antiviral activity and therefore our findings support the role of IFN alpha treatment in patients with HCV positive liver cirrhosis.

Recent epidemiological studies have showed that the annual incidence of HCC is greater in HCV related cirrhosis than in other types of liver diseases due to non viral agents but also HBV liver disease at least in Western countries and in Japan^[29]. In geographic areas such as Africa and South-East Asia the occurrence of HCC is greatly influenced by aflatoxin exposure and p53 mutations in addition to HBV and HCV infection. In Western countries and in Japan where exposure to aflatoxin is negligible the incidence of HCC in patients with HBV cirrhosis has always been found lower than in patients with HCV cirrhosis leading to endless speculations about the oncogenic role of a RNA virus unable to integrate in the hepatocyte genome^[29]. We think that intense liver angiogenesis might provide a plausible explanation of this phenomenon and explains why patients with mixed causes of chronic liver diseases such as alcoholic or HBV liver disease are at very high risk of HCC when super-HCV infection occurs. The mechanism by which increased angiogenesis in HCV patients is unknown but COX-2 expression in hepatocytes might play a role as it is correlated to the degree of angiogenesis in liver tumours and is up-regulated by viral core and NS5A protein in patients with chronic hepatitis^[30]. This hypothesis is consistent with data where cancer related angiogenesis was evaluated. In particular, it was demonstrated the association between HCC vascularity and COX-2 and iNOS expression^[31]. The Authors concluded that higher COX-2 and iNOS expression in HCC was correlated to angiogenesis and to a worst prognosis of patients^[31].

Novel therapies have been proposed for HCC^[32-34]. Based on *in vitro* data, chemoprevention of HCC by COX-2 inhibitors has been recently proposed although further studies should be carried out.

In conclusion, the increased hepatic angiogenesis assessed by the MVD counting is a hallmark of HCV liver disease, it can play a role in liver carcinogenesis and, most importantly, can be considered as a risk factor for HCC occurrence in patients with HCV cirrhosis. If confirmed, this observation could help to make a better definition of high risk patients, giving a clue to understand the mechanism leading to high incidence of cancer in these patients and a potential therapeutic target in the future.

COMMENTS

Background

Chronic HCV infection is one of the most important causes for HCC, however hepatic oncogenic mechanisms related to HCV infection are still not fully elucidated. Since it was shown that HCV is angiogenic, we hypothesised that HCV related angiogenesis is a risk factor for HCC development.

Research frontiers

Years ago we showed that patients with chronic HCV hepatitis had more common and intense liver angiogenesis as compared to matched patients with chronic HBV hepatitis and patients such as those with PBC or pseudo-inflammatory tumor who were used as controls for inflammation (1). Angiogenesis is a well recognized risk factor for cancer, at least for its growth and diffusion (2). Patients with chronic HCV infection show expression of COX-2 an inducible enzyme that is angiogenic and anti apoptotic. Thus, the goal of our manuscript was to show that in cirrhotic patients, with chronic HCV infection, those with the most intense hepatic angiogenesis were at greater risk for HCC development.

Innovations and breakthroughs

The manuscript improves our understanding on how chronic HCV infection may be responsible for the higher incidence of HCC as compared to other patients with chronic liver diseases. In fact, the demonstration that active liver angiogenesis increases the risk for HCC not only can explain why interferon treatment reduce the risk of HCC acting directly on angiogenesis (interferons are compounds with substantial anti angiogenic activity), but it also opens new perspectives for designing new therapeutic strategies to prevent HCC in cirrhotic HCV patients. With regards this point, for instance, the recent demonstration that sorafenib (ASCO 2007, abstract book), a new anti tyrosine kinase agent whose main action is antiangiogenic, can be very active and helpful in the treatment of advanced HCC, support data of the present manuscript.

Terminology

Angiogenesis is the phenomenon that occurs in several physiological and pathological conditions in the body and it is characterized by the production of new vessels starting from pre-existing endothelial cells. The micro vessel density counting (MVD) is a quite diffuse manner to measure angiogenic activity and it correlates quite well with bad prognosis of cancer patients. PCNA and MIB-1 are two indexes used to measure proliferative activity in a tissue.

Peer review

The manuscript deals with an important issue in clinical oncology and gastroenterology: To improve our understanding on how chronic HCV infection increases the risk of HCC in addition to the fact to cause chronic inflammation and liver cirrhosis.

Abstract

AIM: To screen for the co-infection of hepatitis B (HBV) and hepatitis C virus (HCV) in human immunodeficiency virus (HIV) infected patients in southern India.

METHODS: Five hundred consecutive HIV infected patients were screened for Hepatitis B Virus (HBsAg and HBV-DNA) and Hepatitis C virus (anti-HCV and HCV-RNA) using commercially available ELISA kits; HBsAg, HBeAg/anti-HBe (Biorad laboratories, USA) and anti-HCV (Murex Diagnostics, UK). The HBV-DNA PCR was performed to detect the surface antigen region (pre S-S). HCV-RNA was detected by RT-PCR for the detection of the constant 5' putative non-coding region of HCV.

RESULTS: HBV co-infection was detected in 45/500 (9%) patients and HCV co-infection in 11/500 (2.2%) subjects. Among the 45 co-infected patients only 40 patients could be studied, where the detection rates of HBe was 55% (22/40), antiHBe was 45% (18/40) and HBV-DNA was 56% (23/40). Among 11 HCV co-infected subjects, 6 (54.5%) were anti-HCV and HCV RNA positive, while 3 (27.2%) were positive for anti-HCV alone and 2 (18%) were positive for HCV RNA alone.

CONCLUSION: Since the principal routes for HIV transmission are similar to that followed by the

INTRODUCTION

Human immunodeficiency virus (HIV) and Hepatitis B and C viruses (HBV and HCV) are the three most common chronic viral infections documented world-wide^[1,2]. These viruses have similar routes of transmission, namely through blood and blood products, sharing of needles to inject drugs and sexual activity, enabling co-infection with these viruses a common event^[3-5]. HBV and HCV co-infections in HIV positive individuals is of utmost importance due to the underlying consequences such as the hepatological problems associated with these viruses, which have been shown to decrease the life expectancy in the HIV-infected patients^[5].

Given the epidemiological similarities of HBV and HIV infections, it is not surprising that markers of past HBV infections namely hepatitis B surface antibody (anti-HBs) or hepatitis B surface antigen (HBsAg) positivity, as the reported evidence of past HBV infection among people living with AIDS is about 10%^[6,7]. HIV accounts for 38.6 million infections world-wide at the end of 2005^[8] while HBV and HCV account for 400 million and 170 million chronic infections respectively^[9,10]. Moreover, among the HIV-infected patients, 2-4 million are estimated to have chronic HBV co-infection while 4-5 million are co-infect-

ed with HCV^[9]. Hepatitis B is a significant public health hazard in the subcontinent, where the average carrier rates in the general population is estimated to be 4%^[11,12]. Further, reports on the prevalence of HCV infection in the Indian subcontinent are scarce. A community-based Indian study indicated a seroprevalence of 0.87%^[13] and that the rate reportedly increased from 0.31% for children < 10 years to 1.85% among subjects > 60 years of age^[13]. In addition, the rate of HBV and/or HCV co-infection in HIV patients have been variably reported depending on the geographic regions, risk groups and the type of exposure involved^[14-20]. The literature regarding the prevalence of HIV co-infection with HBV and/or HCV in India is sparse. Hence, we investigated the co-infection pattern of HBV and HCV among HIV infected south Indian subjects with various risk factors and analyzed the association of viral markers of HBV and HCV infection among subjects with various stages of HIV disease.

MATERIALS AND METHODS

Study population

Patients attending clinics at YRG Centre for AIDS Research and Education (YRG CARE) were screened for HIV based on suspicion on clinical grounds after performing pre-test counseling and informed consent. Only the confirmed HIV positive serum samples (as per World Health Organization testing strategies) were included in this study and were anonymously tested for hepatitis B and C virus markers.

Virological assays

The patients were screened for HBV and HCV using ELISA kits; Hepatitis B surface antigen (HBsAg), Hepatitis B envelop antigen (HBeAg), antibody to envelop antigen (anti-HBe) using Biorad laboratories, USA and antibody to hepatitis C virus (anti-HCV) using Murex Diagnostics, UK. The HBV-DNA PCR was performed as per the methods of Shih *et al*^[21]. Primers specific for the surface antigen region (pre S-S) were used for the molecular diagnosis of HBV infection. For the diagnosis of HCV RNA, extracted RNA was subjected to reverse transcriptase-nested polymerase chain reaction assays (RT-PCR) for the constant HCV 5' untranslated region (5'UTR)^[22].

Statistical analysis

Descriptive statistics are presented with mean \pm standard deviation (SD) or proportions, for continuous or categorical variables, respectively. The Mann-Whitney test was used to compare continuous variables between groups. Statistical package for social sciences (SPSS, Version 13.0) software was used for analyzing the data. A *P* value < 0.05 was considered statistically significant.

RESULTS

Epidemiological characteristics

Of the 500 HIV infected participants investigated, 56 (11.1%) were co-infected with hepatitis viruses [45 (9%) HBV and 11 (2.2%) HCV positive]. Male gender predominance was observed (86%), (48 males and 8

females) and the median age was 37 years (95% CI \pm 3.6) (range from 20-55 years). The main clinical, virological and epidemiological characteristics are presented in Table 1. Data on the risk factors for HIV seroconversion were available for all patients; 359 (72%) were heterosexual, 38 (8%) were intra venous drug users (IVDs), 46 (9%) were blood transfusion recipients and 57 (11%) were unnoticed. Among the co-infected patients the predominant risk factor observed was heterosexual (70%) rather than parental risk (14%) as shown in Table 1.

Majority of the HIV-infected patients were from the 31-40 years age group (39 %) followed by the 41-50 years age group (27%). Mean age of the HIV positive patients was 35 years (95% CI \pm 6.8 years), 37 years (95% CI \pm 3.6 years) among the co-infected patients. HBV-HIV co-infection was high in the 31-40 years age group (58%) while HCV-HIV co-infection was predominant among subjects with > 51 years of age (55%) (Figure 1).

Immunological characteristics

The stage of HIV infection according to the revised 1993 Centers for Disease Control and Prevention (CDC) classification was determined in all patients. Among 45 HIV/HBV co-infected patients only 40 patients were classified according to HIV disease groups namely Group A 4 (10%), Group-B 19 (48%) and Group-C 17 (42%) whereas all the 11 HIV/HCV co-infected subjects could be classified as Group-A, 1 (9%), Group-B, 3 (27%) and Group-C, 7 (64%). Nonetheless, the CD4 lymphocyte profile between HIV and hepatotropic virus co-infected patients was not significant (Table 1, Table 2, Table 3).

HBV and HIV co-infection

Of the 45 HIV/HBV co-infected patients, only 40 could be classified under the various HIV disease groups. The HBeAg positivity was seen in 25%, 47% and 71% whereas antiHBe positivity was seen in 75%, 53% and 29% in the HIV disease groups A, B, and C respectively (Table 2). The HBV DNA positivity was seen in 25%, 47% and 76% of the patients in groups A, B and C respectively (Table 2). The HBe/antiHBe was inversely proportional to each other and significantly associated with the stage of HIV disease progression (*P* < 0.01). Out of 23 total HBV-DNA positive cases, significantly higher level of HBV-DNA positivity (87%) was observed in HBe positive cases compared to HBe seroconverted patients (13%). In the overall HBV-DNA positivity among HIV/HBV co-infected patients, the stage of HIV disease progression was significantly associated the positivity pattern of HBV DNA (*P* < 0.01). Randomly selected 250 HBsAg seronegative cases were also tested for qualitative HBV-DNA by PCR and none of the patients revealed "occult" HBV infection.

HCV and HIV co-infection

Of the 11 HIV/HCV coinfecting patients (i.e. either positive for anti-HCV or HCV RNA or both) (Table 1), 6 were anti-HCV and HCV RNA positive, 3 were anti-HCV alone positive and 2 were HCV RNA alone positive. The HCV-RNA positivity was 100%, 66%, and 71% in group-A, group-B, and group-C respectively (Table 3).

Table 1 Baseline characteristics of HIV and hepatitis coinfected patients

Groups	Total	Age	Sex		Probable route of transmission				Mean CD4 counts (cells/mm ³)	CDC status		
			Male	Female	Sexual	IVDs	Blood	Not known		A	B	C
HIV alone	444	36 ± 9	298	146	320	35	41	48	334 ± 199 ¹ 294 ± 173 ²	26 ¹	17 ¹	20 ¹
HIV + HBV	45	32 ± 6	39	6	35	-	2	8		4 ²	19 ²	17 ²
HIV + HCV	11	38 ± 8	9	2	4	3	3	1	231 ± 104	1	3	7

CDC: Centre for Disease Control; IVD: Intra-venous drug users. ¹Based on the available clinical data, only 63 out of the total 444 HIV alone infected patients could be classified and ²only 40 out of the total 45 HIV/HBV coinfected could be classified.

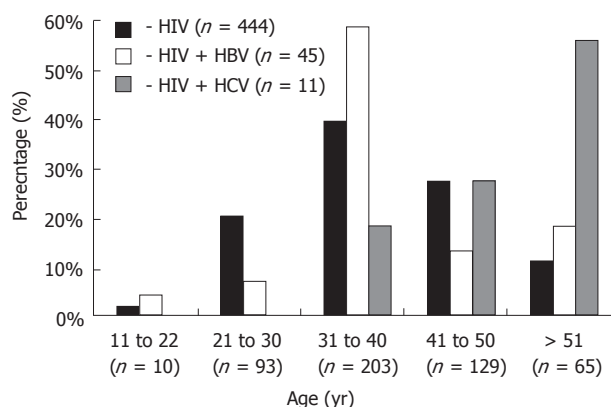

Figure 1 Age-related distribution of HBV and HCV co-infection in HIV infected patients.

From the remaining 489 anti-HCV seronegative cases, 300 were randomly selected for qualitative HCV-RNA testing by PCR, in which only 2 cases (0.6%) were positive for HCV-RNA, the CD4 counts were 58 and 205 cells per mm³ respectively. The RNA positivity in anti-HCV positive cases was highly significant (73% *vs* 0.6%) than the anti-HCV seronegative cases ($P < 0.001$).

DISCUSSION

India has the second highest number of people living with HIV^[23]. Moreover, among the HIV infected patients, 2-4 million are estimated to have chronic HBV co-infection while 4-5 million are co-infected with HCV^[9]. Co-infection of HBV and/or HCV with HIV complicates the clinical course, management and may also adversely affect therapy for HIV infection. The reported co-infection rates of HBV and HCV in HIV patients have been variable worldwide depending on the geographic regions, risk groups and the type of exposure involved^[24-26]. Within India HBV and HCV co-infection among HIV infected patients have been reported infrequently from region to region^[15-20]. However, our study indicated that HIV-infected patients are at a high-risk of viral co-infections, as evident from the high prevalence of HBV (9%) and HCV (2.2%), which is fairly higher than the HBV and HCV prevalence reported in the Indian general population^[11,12].

Our findings showed that study group predominantly comprised of heterosexually acquired HIV infections than other mode of transmission and the male gender were

Table 2 HBV marker profile of HBV/HIV co-infected patients (n = 40)

HIV/HBV coinfection group (CDC 1993 revised) (n = 40) ¹	HBV marker			
	HBsAg	HBeAg	Anti-HBe	HBV DNA
Group A	4 (10%)	1 (25%)	3 (75%)	1 (25%)
Group B	19 (48%)	9 (47%)	10 (53%)	9 (47%)
Group C	17 (42%)	12 (71%)	5 (29%)	13 (76%)

¹Based on the available clinical data, only 40 out of the total 45 HIV/HBV co-infected could be classified according to HIV disease group as per CDC-1993 revised classification.

significantly (86% *vs* 14%) higher than female ($P < 0.01$). This concurs previous report that male subjects were significantly at a higher risk to develop HBV co-infection^[14,18], justified by the age group against the pattern of co-infection analyzed in the present investigation. This data shows that the maximum levels (58%) of co-infection for HBV/HIV occurred in the 31-40 age-group, which is the normal age group where the HIV positivity is reportedly higher as per Indian literatures^[15-20]. This also suggests that sexual route could also be the common mode of transmission for both HBV and HIV. Further, the chronic HCV co-infection rate in our study is in line with Padmapriyadarsini *et al.*, from South India^[18]. In contrast to the HIV/HBV co-infection observed among the sexually active age group viz. (31-40 years), the HIV/HCV co-infection was higher (55%) among the > 50 years age group, which speculates that HCV transmission could have been non-sexual and/or parenteral.

The frequency of anti-HCV among our HIV subjects (2.2%) is much lower than that reported previously amongst HIV/HCV co-infected Indian subjects^[15-20] and much higher than from the general Indian community^[12]. The low frequency of HCV could be due to the low incidence of IVD use and infrequent transfusion in our study groups, which are relatively different from that reported from other parts of India where IVDs and transfusion history were the main risk factors identified for HCV infection among HIV patients^[15-20]. In our cohort, two individuals co-infected with HIV/HCV neither had transfusion history, IVDs use, tattooing, piercing nor sexual promiscuity with IVDs users; nevertheless presented details of high risk sexual behaviors and prior STI history, which suggests that sexual intercourse could have been the route of infection. In addition, both subjects had active HCV infection (positive HCV-RNA) but failed to

Table 3 HCV marker profile of HCV/HIV co-infected patients ($n = 11$)

HIV Disease Group of HIV/HCV coinfectd cases (CDC 1993 revised)	HCV coinfection ($n = 11$)	Anti- HCV and HCV RNA positive ($n = 6$)	Anti HCV alone positive ($n = 3$)	HCV RNA alone positive ($n = 2$)

Group B	3 (27%)	1	1	1
Group C	7 (64%)	4	2	1

seroconvert to anti-HCV. The CD4 T-cell counts (58 and 205 cells per mm^3) are suggestive of HCV detection by ELISA among patients with very low CD4 counts may not be useful for screening. In agreement with earlier reports our study propose that prior HIV infection facilitates HCV transmission much easier, though this mode is not widely documented through sexual contact, which however needs more studies with more number of cohorts under the various risk groups and matched controls.

Co-infection of hepatotropic viruses in HIV disease reportedly leads to massive impairment of cell mediated responses and enhances the kinetics of hepatotropic viral replication^[27-30]. Furthermore, HBV co-infection in HIV disease considerably complicates its diagnosis and management. Patients with AIDS apparently are less likely to clear HBV infection after exposure or more likely to reactivate latent HBV infection or both^[30,31]. Our study showed that co-infection with HBV or HCV is frequent in HIV disease, as evident from higher HBV-DNA and HCV-RNA positivity rates. The effects of HIV on the course of chronic HBV and HCV infection have largely been assessed^[1-5]. Our investigations are also suggestive of a higher degree of immunodeficiency, (CDC 1993 revised classification of HIV disease group (group A, B and C) concurrently with a higher rate of HBV and/or HCV replication and HIV disease progression. HBsAg-negative “occult HBV” was not seen in our HIV population. Further, the HBeAg and anti-HBe positivity pattern of our study cohort clearly shows that, both the HBe and anti-HBe status were inversely proportional to HIV disease progression among the HIV/HBV co-infected cases. Statistically there is a significant trend between HBsAg positivity and HBV DNA positivity between the three CDC defined HIV disease groups ($P < 0.01$).

We observed that the incidence of HBV co-infection rises with disease progression. Significant difference of co-infection existed between the symptomatic and asymptomatic groups of HIV infected patients ($P < 0.01$). The co-infection seems to have pronounced effect on the natural history of these infections. Although the effect of HBV infection on HIV is uncertain, HIV appears to have marked influence on the natural history of HBV infection. The increased viral replication of HBV in AIDS patients indicates that HIV significantly affects the HBV life cycle and the host ability to clear HBV infection. If this holds true, more HBV infection and more chronic carriers would be expected as the AIDS epidemic expands in this part of the country. Such a profile would have worrisome public health implications since more chronic liver diseases, including HCC, would be expected as the mortality rate associated with HIV is reduced^[32]. Chronic

HBV infection can be associated with severe liver damage in HIV positive drug abusers and homosexuals. HIV infection does not seem to attenuate and may even worsen HBV associated chronic liver damage^[30,33]. The long-term effect of immunodeficiency on the out come of hepatitis B infection remains to be evaluated. The HIV-RNA viral load difference was however not significant in our study groups. In regard to CD4 and CD8 counts, the HIV/HCV co-infected patients revealed a comparatively lower levels in the above parameters with the HIV and HIV/HBV co-infected patients, albeit statistically insignificant (data not shown). This could probably be due to small number of cases, wide range of CD4, CD8 counts and the HIV cases being in different stages of HIV disease. In the HIV/HCV co-infected groups, the HCV-RNA positivity was found to be higher in Group-C (71%) than group B (66%) but only one patient in group A showed HCV-RNA positivity. These observations are also concordant to previous reports of increased hepatotropic viral replication in immunocompromised subjects^[34,35]. However, this needs to be confirmed with adequate number of patients with different stages of HIV disease.

The present study has certain limitations. Firstly, this is a cross-sectional study unable to adequately establish a casual relationship between the time of exposure and subsequent infection. Secondly, the study was conducted with patients limited to a tertiary HIV referral hospital setting and not of a community setting. However the results can be implied to approximate and prepare for clinical care of our HIV-infected patients. Moreover, at the time of this study, HIV negative group was not available. In addition, the HCV-RNA testing used to screen HCV infection in terms of cost was quite prohibitive in our resources-limited setting. Immunosuppression from HIV infection may impair antibody formation, and false-negative HCV antibody tests have been reported in individuals co-infected with HIV^[36,37]. It is unlikely that the low seroprevalence of HIV/HCV co-infection was due to selection bias because subjects in the present investigation were selected from one tertiary referral hospital that covers a wide range of socio economic strata.

Uncertainties remain regarding the real effect of co-infection with HIV and HBV and HCV on the progression and outcomes of theses viral infections. The situation is largely due to difficulties in performing accurate natural history studies, particularly in the constantly developing field of HIV medicine. However, an increased infectivity for chronic HBV infections in HIV positive persons regardless of their clinical state or laboratory evidence of immune suppression that may have implications for hepatitis policies, and epidemiologic studies should be

considered to monitor a possible increase in the spread of HBV among population at risk for HIV and HBV. Prolonged survival of HIV infected patients co-infected with HBV or HCV may become an important clinical problem. Our findings strengthen the evidence for the significance of HIV infection on the natural history of chronic HBV infection, which by prolonging the period of infectivity could have influenced the epidemiology of HBV infection in India^[30,31]. It is thus far clear that apart from other infections, HIV infected individuals have a high probability of getting co-infected with HBV and/or HCV. HIV disease progression and enhanced immunosuppression has a direct bearing on the natural history and pathogenesis of these infections. Sexual transmission of both HBV and HCV also appears to be significant and is of epidemiological importance in the light of high heterosexual transmission of HIV in India. Monitoring of HIV infected patients for concurrent infection with HBV and HCV is therefore necessary.

The implication of HBV and/or HCV co-infection in HIV patients is of serious concern to the growing Indian economy as there is an overt increase in the trend of number of patients diagnosed with HIV disease in recent years. The knowledge of co-infection in a HIV positive patient is vital since these patients, as they live longer on antiretroviral treatment will also need to be managed for their co-infection with HBV and/or HCV. Hence, there is an urgent need to conduct, detailed studies on the interplay of HIV and hepatotropic viruses in the Indian community with a plethora of multifaceted approaches to investigate the real crisis of HIV/hepatotropic viral infection pattern at the earliest to efficiently control and manage the situation.

ACKNOWLEDGMENTS

We highly appreciate the cooperation and assistance received from all clinicians, paramedical and nursing colleagues of YR Gaitonde Centre for AIDS Research and Education (YRG CARE), Chennai, India and the patients who participated in the study.

COMMENTS

Background

The influence of HBV or HCV co-infections among subjects with HIV disease is of serious concern to the development of the Indian economy as an increase in the overall trend in the number of patients diagnosed with HIV disease is raising in the recent years. Therefore, scientific knowledge of hepatotropic co-infections in the HIV/AIDS community is important, as they live longer after prompt antiretroviral treatment, in addition to concurrent effective management of HBV or HCV co-infections. Hence, there arises an urgent need to carry out elaborate studies on the interplay of HIV and hepatotropic viruses in the community with a multifaceted approach to promptly explore the scientific facts behind the real crisis to efficiently control and manage the circumstances.

Research frontiers

Uncertainties remain regarding the real effect of co-infection with HIV and HBV or HCV on the progression and outcome of these infections due to the foreseeable difficulties in performing accurate natural history studies, particularly in the persistently developing field of HIV medicine. Although the effect of HBV infection on HIV is indecisive, HIV appears to have a marked role on the natural history of HBV infection in concordant to earlier reports. Therefore, we propose that HIV

influences the natural history of HBV and/or HCV replication, which may have implications for development of hepatitis policy guidelines and epidemiologic studies need to be aimed at strengthening approaches to monitor the possible increase in the spread of HBV and HCV among population at risk for HIV.

Innovations and breakthroughs

The low frequency of HCV in our cohort could be attributed to the low incidence of intravenous drug usage and the infrequent incidence of transfusion, which are substantially different to other reports from parts of India, where IDU and prior transfusion history are reportedly the main risk factors identified among HCV/HIV co-infection. On the contrary, two individuals co-infected with HIV/HCV never had the aforementioned predominant risks; nevertheless presented details of high risk sexual behaviors and prior STI history, which suggestive of the fact that sexual intercourse could also have been the route infection. In addition, both subjects had active HCV infection (evident from positive HCV-RNA) but failed to seroconvert to anti-HCV. The CD4 T-cell counts (58 and 205 cells per mm³) were suggestive of anti-HCV detection with very low CD4 counts and may not be useful for screening. In line with earlier reports, we propose that prior HIV infection could facilitate HCV transmission much easier, though this has not been widely described, and needs more prospective investigations with more number of cohorts with matched controls in the context of HIV/AIDS.

Applications

Though there are few available data on the prevalence of these infections in the Indian general population, information in the HIV positive community is inadequate. In view of the major mode of HIV spread in India being heterosexual, and parenteral route accounting for < 5% of the infections, screening the high-risk population for these infections would aid early detection of co-infections. Hence, initiation of prompt diagnosis and treatment would help decrease the further spread of these chronic viral infections.

Terminology

Hepatitis 'e' antigen (HBeAg) is a peptide and normally detectable in the bloodstream when the hepatitis B virus is actively reproducing, this in turn leads to the person being much more infectious and at a greater risk of progression to liver disease; however, some variants (precore mutant) of the hepatitis B virus do not produce the 'e' antigen at all, so this rule does not always hold true; Anti-HBe is an antibody produced in response to the Hepatitis B e antigen. In those who have recovered from acute hepatitis B infection, anti-HBe will be present along with anti-HBc and anti-HBs. In those with chronic hepatitis B, usually anti-HBe becomes positive when the virus goes into hiding or is eliminated from the body and this phase is generally taken to be a good sign and indicates a favourable prognosis; A positive (or reactive) HBV-DNA or HCV-RNA by PCR (qualitative) indicates the presence of virus that can be passed to others, whereas the negative result (non-reactive) usually means the virus cannot be spread to others; "Occult hepatitis B virus" (HBV) infection is generally defined as the detection of HBV-DNA in the serum or liver tissue of patients who test negative for hepatitis B surface antigen.

Peer review

The authors reported the prevalence rates of HBV or HCV in HIV-positive patients in south Indian area and suggested the higher replication status of HBV or HCV as the disease status of HIV infection progressed. The paper is well written.

Abstract

AIM: To investigate the germline mutations of *MSH6* gene in probands of Chinese hereditary non-polyposis colorectal cancer (HNPCC) families fulfilling different clinical criteria.

METHODS: Germline mutations of *MSH6* gene were detected by PCR-based DNA sequencing in 39 unrelated HNPCC probands fulfilling different clinical criteria in which *MSH2* and *MLH1* mutations were excluded. To further investigate the pathological effects of detected missense mutations, we analyzed the above related *MSH6* exons using PCR-based sequencing in 137 healthy persons with no family history. The clinicopathological features were collected from the Archive Library of Cancer Hospital, Fudan University and analyzed.

RESULTS: Four germline missense mutations distributed in the 4th, 6th and 9th exons were observed. Of them, three were not found in international HNPCC databases and did not occur in 137 healthy controls, indicating that they were novel missense mutations. The remaining mutation which is consistent with the case H14 at c.3488A>T of exon 6 of *MSH6* gene was also found in the controls, the rate was approximately 3.65% (5/137) and the type of mutation was not found in the international HNPCC mutational and SNP databases, suggesting that this missense mutation was a new SNP unreported up to date.

CONCLUSION: Three novel missense mutations and a new SNP observed in the probands of Chinese HNPCC

INTRODUCTION

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch syndrome, is an autosomal dominant inherited disease characterized by susceptibility to a wide spectrum of cancers, including cancer of the colon, rectum, endometrium, small bowel, and urinary tract^[1]. HNPCC syndrome accounts for 5%-10% of all colon-rectum cancer cases^[2]. Germline mutations in the *bMLH1* (MIM#120436; GDB: 249617) and *bMSH2* (MIM#120435; GDB: 203983) genes are detected in 30%-70% of HNPCC families^[3-5]. Recently, mutations in another MMR gene (*MSH6*), accounting for 10% of HNPCC kindreds, have also been shown to result in HNPCC^[6]. The number of mutations in the *MSH6* gene keeps increasing^[7] (<http://www.nfdht.nl>). Germline mutations of *MSH6* gene are mainly associated with patients with no *MSH2* and *MLH1* mutations. This study was to investigate the *MSH6* gene germline mutations by DNA sequencing in 39 Chinese HNPCC kindreds fulfilling the criteria in which *MSH2* and *MLH1* mutations are excluded, in order to identify HNPCC families and provide experimental information for HNPCC database.

MATERIALS AND METHODS

Materials

From January 1998 to October 2005, 39 Chinese HNPCC families fulfilling the HNPCC clinical criteria were registered at the Department of Abdominal Surgery

in Shanghai Cancer Hospital/Institute. Eleven families fulfilled Amsterdam criteria (AC I) and II (AC II)^[8,9], 11 additional families Japanese criteria^[10] and the remaining 17 kindreds Bethesda guidelines (BG)^[11]. Germline mutations of *MSH2* and *MLH1* were excluded by based-PCR sequencing in the probands of all the Chinese HNPCC families. Each proband was asked to give 10 mL peripheral blood samples and consent for access to archival tumor tissue. A total of 137 control blood samples were taken from healthy persons after obtaining informed consent, none of the individuals in the control group had a family history suggesting HNPCC or development of colon cancer in earlier age. This study was proved by the Medical Ethical Committee of Cancer Hospital, Fudan University, and the procedures of the study were in accordance with the international rules and regulations.

DNA extraction

Genomic DNA was extracted with the QIAGEN (Hilden, Germany) DNA extraction kit following the manufacturer's instructions. Concentrations of the genomic DNA were determined by an ultraviolet spectrophotometer (Beckman, DU640 type).

PCR amplification and DNA sequencing

According to the exon/intron boundary sequences of *MSH6* (GenBank accession number: NM_000179.1), 18 sets of primers were designed to amplify the entire coding region, including 10 exons and each splicing site of *MSH6* (Table 1). The primer pairs used to amplify the 18 fragments of *MSH6* have either M13 forward 5' primers or M13 reverse 3' primers to facilitate sequencing after amplification. PCR was carried out with Taq DNA polymerase (Promega, USA) as described elsewhere^[12]. The PCR conditions were as follows: preheating at 94°C for 7 min, followed by 30-38 cycles of denaturation at 94°C for 45 s, annealing at 56°C-68°C for 45 s and extension at 72°C for 45 s, and a final elongation at 72°C for 10 min (Table 1). PCR products were subjected to 2% agarose gel electrophoresis. After observation of clear and expected size bands, the products were purified and used as a template for sequencing reactions with BigDye terminator cycle sequencing kit (Applied Biosystems, Foster City, CA, USA). The sequencing primers were M13F or M13R. Automated fluorescence analysis was performed on a 3700 DNA sequence system (ABI, USA).

Bioinformatic analysis

Each result of sequencing was analyzed by DNASTar5.08 bioanalysis software. The type of mutations and potential significance were determined by comparing the corresponding amino acids and proteins in the following databases (<http://www.ncbi.nlm.nih.gov/>, <http://www.ensembl.org/homo-sapiens> and <http://www.insight-group.org>).

RESULTS

Four missense mutations were found in 39 probands of different Chinese HNPCC families, at codons 468 (CGT>CAT, Arg>His), 1163 (GAA>GTA, Glu>Val) (Figure 1), 666 (TCT>CCT, Ser>Pro) (Figure 2) and 1284

(ACG>ATG, Thr>Met), respectively (Table 2). To further investigate the pathological effects of these four missense mutations, we analyzed the four related *MSH6* exons using PCR-based sequencing in 137 healthy persons with no family history, showing that the mutation of codon 1163 which is consistent with the case H14 at c.3488A>T of exon 6 of *MSH6* gene was also found in the control persons, the rate was approximately 3.65% (5/137). The remaining three missense mutations did not occur in the 137 healthy controls. None of these four mutations was found in the *MSH6*-SNP database (www.ensembl.org/homo-sapiens). Thus, except that the mutation at c.3488A>T of *MSH6* gene in the H14 HNPCC case was an unreported new single nucleotide polymorphism (SNP), the remaining ones were novel missense mutations.

DISCUSSION

Hereditary non-polyposis colorectal cancer is an autosomal dominant inherited syndrome^[13]. Although its clinical diagnostic criteria were established in 1990, known as

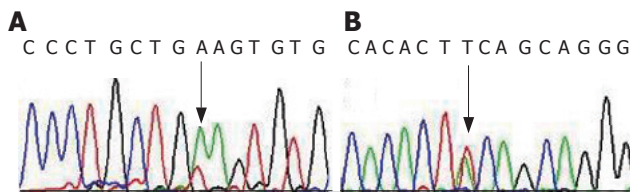

Figure 1 Missense germline mutation of exon 6 of *MSH6* gene in the proband of H14 HNPCC kindreds. Arrow indicates the mutation site. The single basyl substitution was transversed from A to T (A>T) at the codon 1163, the codon from GAA to GTA, causing the amiod acid changes from glutamine to valine, the change was identified as a new SNP. **A** and **B** represent the forward sequence and reverse, respectively.

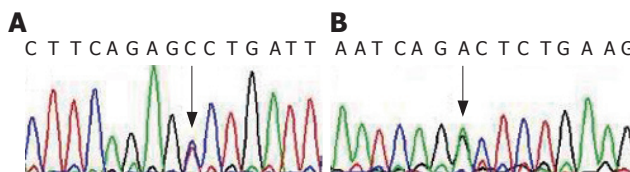

Figure 2 Missense germline mutation of exon 4.6 of *MSH6* gene in the proband of H40 HNPCC kindreds. Arrow indicates the mutation site. The single basyl substitution was transversed from T to C (T>C) at the codon 666, the codon from TCT to CCT, causing the amiod acid changes from serine to proline. **A** and **B** represent the forward and reverse sequence, respectively.

Amsterdam criteria, Japanese Criteria and Bethesda guidelines, a certain number of HNPCC families may be neglected for lacking characteristic clinical manifestations and family history. Molecular genetic screening is been regarded as a standard method for its diagnosis. Mutations of MMR genes are considered golden criteria for molecular diagnosis and monitoring family members. These mutations can be used to select persons who would benefit from genetic counseling and clinical surveillance programs for their relatives to reduce morbidity and mortality due to HNPCC-related tumors^[14]. Germline mutations in the coding regions of *MSH2* and *MLH1* are known to be responsible for up to 45%-64% of all HNPCC families^[15]. We have previously detected germline mutations of the entire coding regions of *MSH2* and *MLH1* genes in 24 AC probands, 15 JC probands and 19 BG patients using PCR-gene-sequencing with 17 germline mutations detected including two mutations occurred in a same patient^[16]. Three new mutations have been found by mRNA-based PCR sequencing^[17]. The remaining 39 probands without *MSH2* and *MLH1* might be associated with the other abnormal MMR genes such as *MSH6*.

MSH6 mutations are involved in the development of colorectal cancer^[18]. Germline mutations of *MSH6* have been reported in two atypical HNPCC Japanese families lacking mutations in *MSH2* and *MLH1*^[19,20]. Some researchers believe that *MSH6* gene might be the first candidate gene for detecting germline mutations in HNPCC families in which *MSH2* and *MLH1* mutations are excluded^[21]. It was reported that *MSH6* mutations account for 10% of kindreds in which *MSH2* and *MLH1* mutations are excluded^[6]. Our study has demonstrated four missense mutations of *MSH6* gene in the probands

Table 2 Germline mutations of *MSH6* gene in 4 probands of HNPCC families

Family No	Exon	Position of mutation	Base change	Result	Mutation type
H3	4.3	Codon 468	c.1403G>A	Arg>His	Missense mutation
H14	6	Codon 1163	c.3488A>T	Glu>Val	New SNPs
H40	4.6	Codon 666	c.1996T>C	Ser>Pro	Missense mutation
H61	9	Codon 1284	c.3851C>T	Thr>Met	Missense mutation

of 39 Chinese HNPCC families, which have not been reported (<http://www.nfdht.nl>). However, missense mutations in MMR genes are common and often pose a formidable problem of interpretation, because these changes do not necessarily affect the function of the protein. Further functional studies are required in order to determine whether the missense mutations are neutral polymorphisms or clinically relevant mutations. We detected the exons of these four missense mutations by direct sequencing of the *MSH6* gene using genomic DNA from blood samples of 137 healthy persons, the mutational rate was approximately 3.65% (5/137). Since “polymorphism” is a term that is usually used for genetic variants with a minor allele frequency $\geq 1\%$ in a given population^[22], single basyl transversion at c.3488A>T of exon 6 might represent a new SNP, although the changes are not found in SNP (<http://www.ensembl.org>). The remaining three missense mutations were not detected in genomic DNA from 137 healthy persons, suggesting that they are three novel missense mutations of *MSH6* gene in Chinese HNPCC families. The clinical features of the probands of these three novel missense mutations and one new SNP are shown in Table 3. In brief, the above mutation carriers occur more frequently in the left colon than in *MLH1* or *MSH2* mutation carriers. However, the relationship between the above typical features and germline mutations of *MSH6* gene in the probands of Chinese HNPCC families still remains unclear. To date, the International Collaborative Group on HNPCC (ICG-HNPCC) has found over 30 potentially pathogenic *MSH6* mutations. A significant proportion (35%) of them results in a single amino acid substitution, which is difficult to interpret. Since the pathogenicity of HNPCC mutations is linked to malfunction of MMR, whether the above three novel missense mutations are involved in human MMR needs to be further investigated.

ACKNOWLEDGMENTS

The authors are grateful to the patients who took part in this study and to Departments of Cancer Hospital for sending blood and tumor specimens. The authors also appreciate the help from Professor Sun MH for her detection of germline mutations of *MSH2* and *MLH1* gene in the probands of certain Chinese HNPCC cases and Professor Mo SJ for the supply of certain Chinese HNPCC cases.

COMMENTS

Background

Germline mutations in mismatched repair genes, such as *MLH1*, *MSH2* and *MSH6*, lead to hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. Germline mutations of *MLH1* and *MSH2* gene have been reported in Chinese HNPCC families. However, the germline mutation of *MSH6* has not yet been reported.

Research frontiers

Now many researchers are engaged in studies of HNPCC, especially in germline mutations of MMR genes such as *MSH2*, *MLH1* and *MSH6*. These studies can contribute to the early diagnosis of HNPCC and screening of HNPCC families. Few studies on germline mutations of *MSH6* gene are available.

Innovations and breakthroughs

Three novel germline mutations of *MSH6* gene have been found in 39 probands of Chinese HNPCC families by PCR-based sequencing, and a new SNP has been found by screening the missense mutations of genomic DNA in 137 healthy persons.

Applications

Germline mutations in genes can be used to diagnose early HNPCC and enrich international HNPCC mutation and SNP databases.

Terminology

HNPCC is an abbreviation of hereditary nonpolyposis colorectal cancer. Germline mutations are the mutations in genomic DNA.

Peer review

This paper is an interesting manuscript, the authors detected new HNPCC-related mutations and discovered three novel mutations and an additional SNP in 39 unrelated HNPCC probands. Data on patient characteristics, such as gender and age at diagnosis of colorectal cancer in the patient (or in the family) should be provided in detail.

Abstract

AIM: To evaluate the value of ¹⁸F-DG PET/CT in detecting recurrence and/or metastasis of colorectal cancer (CRC).

METHODS: Combined visual analysis with semiquantitative analysis, the ¹⁸F-DG PET/CT whole-body imaging results and the corresponding clinical data of 68 postoperative CRC patients including 48 male and 20 female with average age of 58.1 were analyzed retrospectively.

RESULTS: Recurrence and/or metastasis were confirmed in 56 patients in the clinical follow-up after the PET/CT imaging. The sensitivity of PET/CT diagnosis of CRC recurrence and/or metastasis was 94.6%, and the specificity was 83.3%. The positive predictive value (PPV) was 96.4% and the negative predictive value (NPV) was 76.9%. PET/CT imaging detected one or more occult malignant lesions in 8 cases where abdominal/pelvic CT and/or ultrasonography showed negative findings, and also detected more lesions than CT or ultrasonography did in 30.4% (17/56) cases. Recurrence and/or metastasis was detected in 91.7% (22/24) cases with elevated serum CEA levels by ¹⁸F-DG PET/CT imaging.

CONCLUSION: ¹⁸F-DG PET/CT could detect the recurrence and/or metastasis of CRC with high sensitivity and specificity.

INTRODUCTION

Colorectal cancer (CRC) is the most common gastrointestinal malignancy, and its incidence and mortality is still rising in China^[1,2]. Radical resection and postoperative chemotherapy remains to be the major management of CRC, but recurrence and/or metastasis occurs in 30%-50% of the patients after surgery^[3-6]. An early diagnosis and accurate staging of postoperative metastasis is crucial for prescribing an optimal individualized chemotherapy regimen and thus elevating the survival rate. Combined positron emission tomography and computed tomography (PET/CT) is currently widely used in clinical diagnosis of cancer, showing great superiority in tumor staging^[7-9]. In the present research, we investigated the diagnostic significance of fluorine 18 fluorodeoxyglucose (¹⁸F-DG) PET/CT in postoperative recurrence and/or metastasis of CRC by conducting a retrospective study of 68 patients.

MATERIALS AND METHODS

Subjects

A total of 68 postoperative CRC patients, 48 male and 20 female, examined in the PET/CT center of Jinling Hospital between August 2004 and August 2006 were included in the study cohort. The age of the patients ranged from 27 to 77 years, and the average was 58.1. A whole-body ¹⁸F-DG PET/CT was conducted in each case. The interval time between the operation and the examination ranged from 4 mo to 8 years, and the average was 2.5 years. The diagnosis of recurrence and/or metastasis was based on pathological evidence, colonoscopy findings, medical imaging results, and clinical follow-up outcome. The follow-up time ranged from 5 to 28 mo.

PET/CT imaging

Biography sensation 16 PET/CT (Siemens, Germany) was used. ¹⁸F-DG was produced by TR19 cyclotron (EBCO, Canada) and automatic chemical synthesizer (Beijing Patborn Biotech, China). The synthesis efficiency was 701%, and the radiochemical purity was higher than

95%. Prior to the FDG injection, blood samples were drawn from all patients to assure fasting glucose levels to be less than 6.60 mmol/L. Afterwards, 296-444 MBq of FDG was administered intravenously, and patients waited 50-60 min before undergoing PET and CT scanning. PET emission images were obtained with a weight-based protocol for 5-7 bed positions, with 3 min of acquisition time per bed position. A delayed imaging of the region of interest (ROI) or suspicious lesion region was conducted 3 h later. High resolution CT (HRCT) was conducted if any lesion was detected in the lung. Traverse, sagittal and coronary sections of CT, PET and combined PET/CT were obtained, with a section thickness of 5 mm, by reconstruction using an iterative algorithm, with CT-based attenuation correction applied.

Image interpretation had been individually performed by more than 2 experienced board-certified nuclear medicine physicians and radiologists. Visual assessment and semi-quantitative analysis were adopted in the image interpretation. ROI was determined at the section most clearly showing the hyper-intensive radioactivity, and the maximum standardized uptake value (SUV_{max}) was accessed. The diagnosis of a positive lesion was based on a SUV_{max} higher than 2.5 in the early imaging, while a typical positive lesion on a SUV_{max} higher than 2.5 and also ΔSUV_{max} ($\Delta SUV_{max} = SUV_{max, delayed} - SUV_{max, early}$) higher than 20% in the delayed imaging. The diagnosis of a malignancy lesion should be simultaneously based on the CT findings including the shape, size, intensity and distribution of the lesion, which could differentiate the physiological uptake.

RESULTS

Diagnosis of recurrence and/or metastasis of CRC with ^{18}F -DG PET/CT

Among the 68 examinees, recurrence and/or metastasis were later diagnosed in 56 patients, including 8 recurrences, 46 metastases, and 2 recurrence and metastases. The sensitivity of PET/CT diagnosis of CRC recurrence and/or metastasis was 94.6%, and the specificity was 83.3%. The positive predictive value (PPV) was 96.4% and the negative predictive value (NPV) was 76.9%. In 8 cases which abdominal/pelvic CT and/or ultrasonography showed negative findings, PET/CT imaging detected one or more occult malignant lesions, resulting in altered clinical staging. In 30.4 % (17/56) cases, PET/CT imaging detected more lesions than CT and ultrasonography did, showing disseminated metastases. PET/CT imaging displayed a superior sensitivity in detecting stump recurrence, local and distant metastasis compared with non-contrast CT scanning. Metastases were commonly detected in liver (18/56, 32.1%), lung (15/56, 26.8%), abdominal cavity and mesentery (14/56, 25%), retroperitoneum and psoas major (11/56, 19.6%). Others included bone, mediastinum lymph node, peritoneum, adrenal gland, ovary and brain. Liver and lung were the preferred metastasis foci, and blood metastasis was the major route of metastasis, followed by lymph node metastasis.

Influence of the ^{18}F -DG PET/CT diagnosis on clinical treatment

The treatment plans of 11 cases (11/68, 16.2%) were

altered based on the ^{18}F -DG PET/CT findings. Local metastasis focus was detected in the liver or lung in 3 cases, and surgical resections were conducted instead of intravenous chemotherapy and biotherapy. Conversely, disseminated metastases were detected in 6 cases, thus intravenous or oral chemotherapy was prescribed instead of surgery. Elevated serum carcinoembryonic antigen (CEA) level was detected in 2 cases while no specific lesion was found, as a result, intravenous chemotherapy was about to be prescribed. With the ^{18}F -DG PET/CT imaging however, the treatment plan was subsequently changed. In one case, PET/CT detected a local recurrence, so a reoperation was preformed in time. In the other case, metastases were detected in both the lung and bone, hence intravenous chemotherapy and local radiotherapy were performed. Second primary cancer was found in another 2 postoperative CRC cases. In one case of colon cancer, ^{18}F -DG PET/CT detected a rectal cancer as the second primary cancer. In the other case, rectal cancer was the first primary cancer while hyper-intensive ileocecal radioactivity was detected in the ^{18}F -DG PET/CT imaging, and colon cancer was confirmed after the reoperation.

^{18}F -DG PET/CT in postoperative CRC patients with elevated serum CEA levels

Elevated serum CEA level (363.7-863.2 μ g/L, average 185.9 μ g/L) was found in 24 cases, and recurrence and/or metastasis was detected in 22 of them by ^{18}F -DG PET/CT imaging with specific lesion observed. Diagnoses of recurrence and/or metastasis were confirmed in all of the 22 cases during the clinical follow-up. However, the negative findings of PET/CT in the remained 2 cases were concluded to be false negative in clinical follow-up. Multiple nodi and small metastasis focus were detected in the mesentery and vagina respectively, both with the diameter around 1 cm, and postoperative pathological evidence confirmed the diagnosis of metastasis. As a result, the positive rate of recurrence and/or metastasis detection with PET/CT in postoperative CRC patients with elevated serum CEA levels was 91.7%.

DISCUSSION

The prognosis of CRC is closely related to the histological type, intestinal wall invasion, malignant lymph node, operation manner and postoperative recurrence and/or metastasis. An emphasis of the postoperative follow-up is the local recurrence and distant metastasis, which could not be detected by traditional imaging techniques such as CR, magnetic resonance imaging (MRI) and ultrasonography until the lesion reaches a considerable size. Monitoring by tumor markers such as CEA and CA19-9 was not always accurate, and could not provide an orientation indication of the possible lesion either. PET/CT imaging provides whole-body overview at one examination, and could detect abnormal glucose metabolism before the morphological change of a lesion could be identified. Consequently, it has become an efficient and accurate noninvasive examination technique in the postoperative follow-up of CRC^[10]. In the present study, PET/CT imaging showed high sensitivity (94.6%), specificity (83.3%) and PPV (96.4%) in the

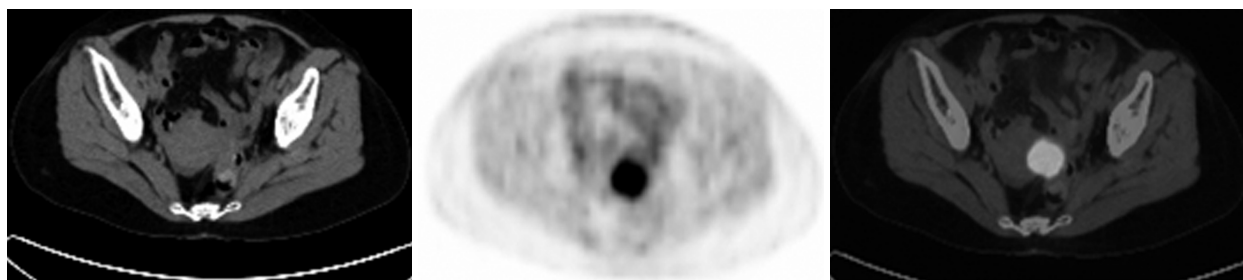

Figure 1 PET/CT imaging showing local recurrent rectal carcinoma in a 49-year-old female postoperative rectal cancer patient. CT scan did not find definite recurrence signs. PET imaging detected hyper-intensive radioactivity by the left side of uterus. The SUV_{max} was 7.5 and the T/N was 9.4. Combined PET/CT imaging indicated elevated ^{18}F -DG uptake of the anastomosis. The reoperation confirmed a recurrent tubular adenocarcinoma of the rectum.

diagnosis of the recurrence and/or metastasis of CRC. These findings are consistent with the Meta-analysis results of Huebner *et al.*^[10]. It is suggested that application of PET/CT imaging to detect recurrence and/or metastasis of CRC is appropriate. It is commonly recognized that PET has become an effective technique in detecting postoperative recurrence and/or metastasis of CRC. The sensitivity and specificity reported were over 90% and 70% respectively, both higher than that of traditional imaging techniques.

^{18}F -DG PET/CT imaging is more accurate than traditional imaging in detecting hepatic metastases. Kinkel *et al.*^[11] performed a meta-analysis to compare current noninvasive imaging methods in the detection of hepatic metastases from colorectal, gastric, and esophageal cancers. In studies with a specificity higher than 85%, the mean weighted sensitivity was 55% (95% CI: 41, 68) for ultrasonography, 72% (95% CI: 63, 80) for CT, 76% (95% CI: 57, 91) for MRI, and 90% (95% CI: 80, 97) for FDG PET. Thus they demonstrated a greater sensitivity of FDG PET than ultrasonography ($P = 0.001$), CT ($P = 0.017$), and also MRI ($P = 0.055$). Delbeke *et al.*^[12] demonstrated in their study on the effect of PET on management that PET helped clarify the final diagnosis misinterpreted on CT and/or CT portography in 28% of the patients ($n = 17$), leading to a change in surgical management. PET helped to plan surgery in 6 patients by identifying a resectable site of recurrence and helped to avoid unnecessary surgery in 11 patients by identifying unresectable disease.

In our study, PET/CT imaging detected one or more occult malignant lesions in 8 cases where abdominal/pelvic CT and/or ultrasonography showed negative findings, resulting in altered clinical staging. PET/CT imaging also detected more lesions than CT and ultrasonography did in 30.4% (17/56) cases, showing disseminated metastases and hence resulting in altered clinical treatment plans. PET/CT imaging increases the accuracy and certainty of locating lesions in colorectal cancer. The fused imaging of PET and CT is especially important for identifying lesions in abdominal and pelvic cavity. PET itself is insufficient to identify anatomic structures clearly and also incapable to interpret the nonspecific uptake of the gastrointestinal and muscles and the excretion of the urinary system. CT provides an attenuation correction, and its morphologic imaging is helpful to differentiate among physiological uptake, anastomosis inflammation, and the cancer recurrence. It also helps to detect tumors which showed

a negative uptake of ^{18}F -DG in PET imaging. Cohade *et al.*^[13] compared the diagnostic roles of ^{18}F -FDG PET and PET/CT in a population of patients with colorectal cancer. The frequency of equivocal and probable lesion characterization was reduced by 50% (50 to 25) with PET/CT, in comparison with PET. The frequency of definite lesion characterization was increased by 30% (84 to 109) with PET/CT. The number of definite locations was increased by 25% (92 to 115) with PET/CT. Overall correct staging increased from 78% to 89% with PET/CT on a patient-by-patient analysis. Our study also shows the superiority of combined PET and CT imaging in detecting recurrent and isolated hepatic metastasis of CRC (Figures 1 and 2).

When local recurrence and/or distant metastasis are diagnosed and the reoperation is planned, PET/CT imaging is greatly helpful in preoperative staging and evaluating the feasibility of the operation. It could detect the unresectable and additional occult lesions, and thus avoid unnecessary surgical resections and also economic expenditures. It could also provide further information regarding the surgical resection details based on the imaging findings in those cases which reoperation is needed. A better decision of clinical management based on preoperative PET/CT imaging results in better clinical outcome. Zubeldia *et al.*^[14] concluded that integration of FDG-PET into the presurgical evaluation of patients with hepatic metastases could substantially reduce overall costs and patients' morbidity. This substantial net saving, 5269 dollars averagely, results from the unique ability of FDG-PET in excluding patients with extrahepatic disease, and avoiding unnecessary surgical expenses. In our study, unnecessary surgeries were avoided in 7 cases where multiple distant metastases were found in PET/CT imaging, accounting for 70% (7/10) of the cases where reoperation was planned before PET/CT imaging. These imaging findings directly resulted in decreased medical expenses. In those cases with elevated serum CEA levels, PET/CT is helpful in detecting recurrence and/or metastasis based on both functional and morphological imaging. In the study of Shen *et al.*^[15], whole-body FDG-PET was performed in 50 patients suspected of having recurrent colorectal cancer and asymptotically increased serum level of CEA ($> 5 \mu\text{g/L}$), and the final diagnosis of recurrent colorectal cancer was established in 64 lesions of 45 patients. The diagnostic sensitivity and positive predictive value of FDG-PET was 95.3% on a patient-

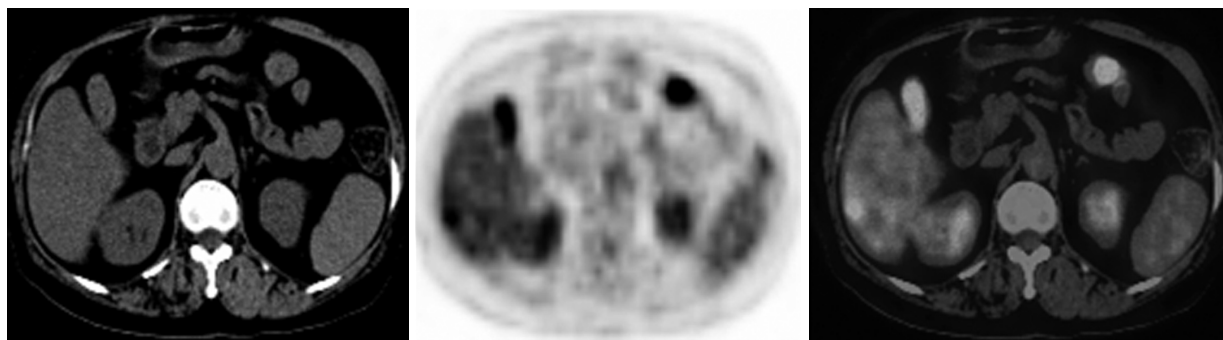

Figure 2 PET/CT imaging showing isolated hepatic metastasis in a 69-year-old female postoperative sigmoid carcinoma patient. CT scan did not find definite recurrence signs. PET imaging detected localized hepatic subcapsular hyper-intensive radioactivity. Local resection of liver lobe was performed in the reoperation, and metastatic adenocarcinoma was confirmed.

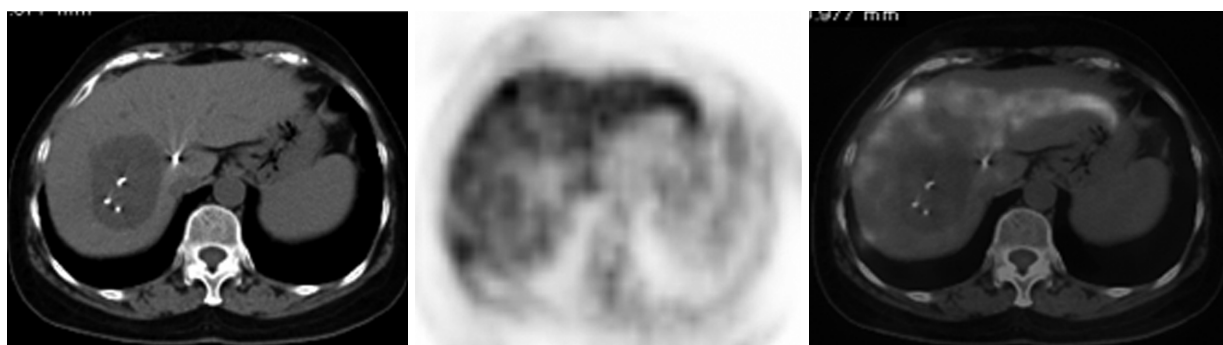

Figure 3 PET/CT imaging showing hepatic metastasis after local therapy in a 60-year-old male postoperative colon cancer patient. ^{125}I seeds brachytherapy was performed in the metastatic lesion of the liver, causing necrosis and ^{18}F -DG uptake decrease of the lesion. However, additional localized hepatic subcapsular hyper-intensive radioactivity was detected, indicating that new liver metastasis had occurred.

based analysis, and 96.9% on a lesion-based analysis. In our study, PET/CT detected one or more possibly malignant lesions in 91.7% (22/24) postoperative CRC patients with increased serum level of CEA. It was obvious that PET/CT is clinically significant in the detection of postoperative malignant lesions in CRC patients.

PET/CT could also be used in monitoring the treatment effect of local therapy of isolated liver and lung metastatic lesions. Local therapy approaches of hepatic metastasis include selective transcatheter arterial chemoembolization (TACE), radio frequency ablation (RFA), Argon-Helium cryoablation, gamma knife radiosurgery (GKS), ^{125}I seeds brachytherapy, and so on. Traditional imaging techniques could not discriminate between tissue edema and tumor remnant, and could not exclude the interference of iodinated oil retention either. By contrast, PET provides a functional imaging of the metabolism levels within the suspected foci and also the whole-body, so it substantially helps the clinicians in recognizing tumor remnants and evaluating whole-body status, which are crucial in making treatment decisions. In our study, 7 patients underwent local therapy of isolated liver or lung metastasis. Figure 3 shows the typical PET/CT imaging of one case underwent ^{125}I seeds brachytherapy of the localized hepatic metastasis.

In conclusion, our study demonstrated the superiority of ^{18}F -DG PET/CT in the imaging diagnosis of postoperative recurrence and/or metastasis of CRC.

It could detect not only recurrent tumor and/or occult metastasis in early stage, but also any other lesions showing abnormal metabolism level within the whole-body of postoperative CRC patients. The PPV was 96.4% and the negative NPV was 76.9%. The major causes of false positive were granulomatous inflammation at the anastomosis and inflammatory lymph node, while those of false negative were small lesion sizes (usually less than 1 cm in diameter). As a result, interpretation of ^{18}F -DG PET/CT imaging should also be based on clinical findings in order to minimize the chance of misdiagnose.

COMMENTS

Background

Combined positron emission tomography and computed tomography (PET/CT) is currently widely used in clinical diagnosis of cancer, however, the value of PET/CT in detection of recurrence and/or metastasis of colorectal cancer (CRC) remains to be confirmed furtherly.

Research frontiers

In the area of application of PET/CT in CRC, the research hotspot is to evaluate the value of this technique in pre-surgery staging, predicting therapy effects and detecting postoperative recurrence and/or metastasis of the disease.

Innovations and breakthroughs

In the present study, recurrence and/or metastasis were confirmed in 56 patients in the clinical follow-up after the PET/CT imaging. The sensitivity of PET/CT diagnosis of CRC recurrence and/or metastasis was 94.6%, and the specificity was 83.3%. The positive predictive value (PPV) was 96.4% and the negative predictive

value (NPV) was 76.9%. PET/CT imaging detected one or more occult malignant lesions in 8 cases where abdominal/pelvic CT and/or ultrasonography showed negative findings, and also detected more lesions than CT or ultrasonography did in 30.4% (17/56) cases. Recurrence and/or metastasis was detected in 91.7% (22/24) cases with elevated serum CEA levels by ¹⁸F-DG PET/CT imaging.

Applications

¹⁸F-DG PET/CT imaging is a useful technique for detecting recurrence and/or metastasis of CRC with high sensitivity and specificity. It could detect not only recurrent tumor and/or occult metastasis in early stage, but also any other lesions showing abnormal metabolism level within the whole-body of postoperative CRC patients.

Terminology

PET/CT: Combined the technologies of positron emission tomography and spiral computed tomography into a highly sensitive and quantitative molecular imaging modality. The "fused" image of PET and CT scan can provide complete information on the location, nature and extent of lesions.

Peer review

This is a good article in which authors demonstrated the superiority of ¹⁸F-DG PET/CT in the imaging diagnosis of postoperative recurrence and/or metastasis of CRC by conducting a retrospective study of 68 patients. The result is valuable for choice of imaging techniques for detecting recurrence and/or metastasis of CRC.

Abstract

AIM: To investigate the prognostic role of thymidylate synthase (TS) and thymidine phosphorylase (TP) mRNA levels in T3 or T4 gastric cancer treated with 5-fluorouraci-based adjuvant chemotherapy.

METHODS: Fifty-one patients with T3 or T4 gastric cancer received systemic 5-fluorouraci-based adjuvant chemotherapy, and intratumoral expression of TS and TP in 51 gastric cancer tissue samples was tested by real-time quantitative PCR.

RESULTS: The median disease-free survival (DFS) time was 10.2 mo in the patients. There were no significant differences in DFS between the groups with high and low levels of TP. However, the group with low level of TS had a longer DFS (14.4 mo vs 8.3 mo, $P = 0.017$). The median overall survival (OS) time was 18.5 mo, and there were significant differences in OS between the groups with high and low levels of TS or TP (for TS, 17.0 mo vs 21.3 mo, $P = 0.010$; for TP, 16.6 mo vs 22.5 mo, $P = 0.009$). Moreover, the coupled low expression of these two genes was strongly associated with a longer survival time of patients as compared with that of a single gene.

CONCLUSION: Expression of TS and TP mRNA is a useful predictive parameter for the survival of postoperative gastric cancer patients after 5-fluorouracil-based adjuvant chemotherapy.

Hua D, Huang ZH, Mao Y, Deng JZ. Thymidylate synthase and thymidine phosphorylase gene expression as predictive

INTRODUCTION

Since originally synthesized in 1957, 5-fluorouracil (5-FU) has been widely applied in clinical practice. Although 5-FU is considered one of the most effective agents against gastrointestinal carcinoma, its efficacy rate is only 10%-15% for gastric and colon cancer, and differs greatly among patients^[1,2]. As a pyrimidine analog, 5-FU exerts its antitumor effects through anabolism, which is determined by the rate of catabolism. Thus, the expression level of genes coding for key enzymes in metabolism may play a pivotal role in the sensitivity and efficacy of 5-FU^[3].

Thymidylate synthase (TS) is the target enzyme for 5-FU and catalyzes methylation of fluorodeoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), which is an important process of DNA biosynthesis^[4,5]. Several reports indicate that TS expression in clinical tumor samples is significantly related to the response to 5-FU in gastric cancer patients^[6]. Recent studies demonstrate that TS mRNA level may be an important independent prognosticator of survival in patients with gastric cancer^[7].

Thymidine phosphorylase (TP) is an enzyme involved in pyrimidine nucleoside metabolism. TP is expressed in a wide variety of solid tumors (carcinomas of the breast, stomach, colon, pancreas and lung), and its content is higher in tumor tissues than in adjacent normal tissues^[8]. TP levels might affect the sensitivity of 5-FU, and transfection of TP cDNA into cancer cells increases their sensitivity to 5-FU^[9]. It was also reported that high expression of TP in tumors is indicative of a poor prognosis^[10].

In this study, we examined the mRNA level of TS/TP in a panel of 51 patients with T3 or T4 gastric adenocarcinoma to probe its predictive value for the efficacy of 5-FU-based adjuvant chemotherapy. In addition, we tested if combination of expression levels of the analyzed genes has an increased effect on the prediction of patient survival.

MATERIALS AND METHODS

Patients and tissue samples

A total of 51 patients with T3 or T4 gastric adenocarcinoma who underwent gastrectomy at the 4th Affiliated Hospital of Suzhou University from August 2003 to April 2005 were enrolled in this study. Tumor tissue samples were obtained during surgery and stored in liquid nitrogen until preparation of RNA extracts. Inclusion criteria for patients included: (1) patients with histologically proved gastric cancer, (2) patients without early recurrence or non-curable resection, (3) patients receiving no other adjuvant treatments, such as radiotherapy or immunotherapy, (4) patients with their performance status score of 0-1 and a life expectancy over 6 mo. All patients gave their informed consent, and the study was approved by the Institutional Ethics Review Board.

Chemotherapy schedule

After surgery, all patients underwent 6 courses of 5-FU-based adjuvant chemotherapy. The chemotherapy protocol included intravenous infusion of 5-FU (375-500 mg/m² per day, d 1-5) and leucovorin (LV) (100-200 mg/m² per day, d 1-5) at three-week interval between two courses. The therapy was terminated or shifted to second-line chemotherapy when disease progression was observed or unacceptable toxicity appeared. All patients were treated in our hospital from 2003 to 2005.

Total RNA isolation and cDNA synthesis

RNA was extracted by using Trizol (Invitrogen Corporation, CA) according to the manufacturer's instructions. The amount of total RNA was estimated by ultraviolet absorbance at 260 nm, and the quality was determined by agarose gel electrophoresis in the presence of formaldehyde. cDNA strand synthesis was performed using a reverse transcription system (Promega Corporation, US).

Real-time quantitative PCR assay for TS and TP

Quantitative PCR was performed with the LightCycler TS/TP mRNA quantification kit^{PLUS} (Roche Diagnostics, Germany) as follows: denaturation of cDNA at 95°C for 5 min; 40 cycles of amplification of cDNA at 95°C for 10 s, at 62°C for 10 s, at 72°C for 10 s; cooling the rotor and thermal cycler at 40°C for 30 s. LightCycler TS/TP calibrator RNA was also used to compensate for the constant differences between detection of the target (TS/TP) and reference gene (glucose- 6-phosphate dehydrogenase, G6PDH) and to provide a constant calibration point between PCR runs. The amount of mRNA encoding for TS/TP was calculated using the LightCycler relative quantification software (Roche). All gene expression analyses were performed in a blinded fashion by the laboratory investigators.

Statistical analysis

To evaluate the association of TS and TP with disease-free survival (DFS) and overall survival (OS), TS and TP expression levels were categorized into a low and high value, using the median concentration as a cut point. The maximal χ^2 method was used to determine which expression value best segregated patients into poor and

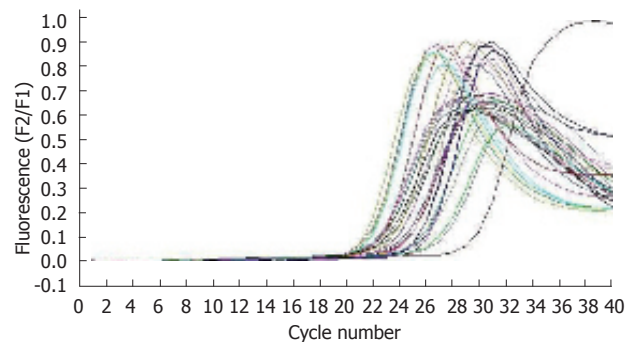

Figure 1 Amplification curve of RT-PCR on the target (TS/TP) and reference gene (G6PDH). TS: thymidylate synthase; TP: thymidine phosphorylase; G6PDH: glucose- 6-phosphate dehydrogenase.

good prognosis subgroups. The survival rate was calculated by the Kaplan-Meier method and statistical analysis was performed using the log-rank test. Cox's proportional hazard model was used to assess the prognostic importance of gene expressions adjusted for the following clinicopathologic features: age, gender, histological type, lymphatic metastasis. $P < 0.05$ was considered statistically significant. All analyses were performed using SPSS software (version 10.0.5; SPSS Inc. Chicago, IL).

RESULTS

Expression of 5-fluorouracil-related genes TS and TP in gastric tumor

A total of 51 eligible patients were enrolled in the study between August 2003 and April 2005. The quantitation of TS and TP mRNA levels in gastric cancer tissues was successfully performed in all specimens (Figure 1). Intratumoral expression of TS and TP genes ranged from 0.09 to 4.60 (median: 0.94) and 3.99 to 196.28 (median: 21.20), respectively.

No significant differences were observed between the mRNA levels of TS/TP and clinicopathological features such as gender, age and stage. The relationship between TS and TP expression levels and clinicopathologic factors are summarized in Table 1.

DFS in relation to expression of TS and TP

The median DFS of the 51 eligible patients was 10.2 mo. When the median value (21.20) of TP was assigned as the cut-off value, there was no significant difference in DFS between the high and low level groups (9.5 mo *vs* 14.0 mo, $P = 0.068$). Patients with a low expression level of TS showed a trend to correlate with prolonged DFS (14.4 mo *vs* 8.3 mo, $P = 0.017$).

OS in relation to expression of TS and TP

The median DFS was 16.2 mo in patients with low TS and TP expression, but only 8.30 mo in patients with high TS and TP expression. The median OS was 18.5 mo. When the median value of 5-fluorouracil-related TS and TP genes was designated as a cut-off value, there were significant differences in OS between the groups with high TS (TP) expression and low TS (TP) expression (17.0 mo *vs* 21.3 mo,

Table 1 Relationship between TS/TP mRNA levels and clinicopathologic factors

Factor	n	TS		P value	TP		P value
		High value	Low value		High value	Low value	
Age (yr)							
≥ 60	22	9	13	0.313	12	10	0.492
< 60	29	16	13		13	16	
Gender

Table 2 Coupled expression of TS + TP and patients survival

	TS + TP		P-value
	High value	Low value	
n	16	17	
DFS	8.3 (3.7-23.7)	16.2 (5.8-30.7)	0.013
OS	16.2 (5.3-29.7)	25.0 (9.2-32.1)	0.003

DFS: disease-free survival; OS: overall survival; TS: thymidylate synthase; TP: thymidine phosphorylase.

$P = 0.010$; 16.6 mo *vs* 22.5 mo, $P = 0.009$), (Figure 2A-B). Tumors tended to be associated with a low TS/TP mRNA expression level and a prolonged patient survival.

Coupled expression of TS and TP and patients survival

The relationship between the expression levels of TS and TP was determined for the survival of patients (Table 2). As Figure 2C shows, the survival of 16 patients with high expression of TS and TP was significantly shorter than that of 17 patients with low expression of TS and TP (for OS, 16.2 mo *vs* 25.0 mo, $P = 0.003$; for DFS, 8.3 mo *vs* 16.2 mo, $P = 0.013$). Thus, the coupled low expression level of the two genes resulted in longer OS as well as DFS in gastric adenocarcinoma patients in this study.

Analysis of clinicopathological features and prognosis

No significant differences were observed in OS and clinicopathological features. However, there existed a significant negative correlation between OS and TS or TP expression. Histological type, lymphatic metastasis and TS gene expression were analyzed by multivariate regression analysis, showing that TS expression level could be identified as a potential predictive marker for OS with a 2.52 hazard ratio for high TS expression (95% confidence interval = 1.30-4.862, $P = 0.006$).

DISCUSSION

Since the response rate of gastrointestinal carcinoma

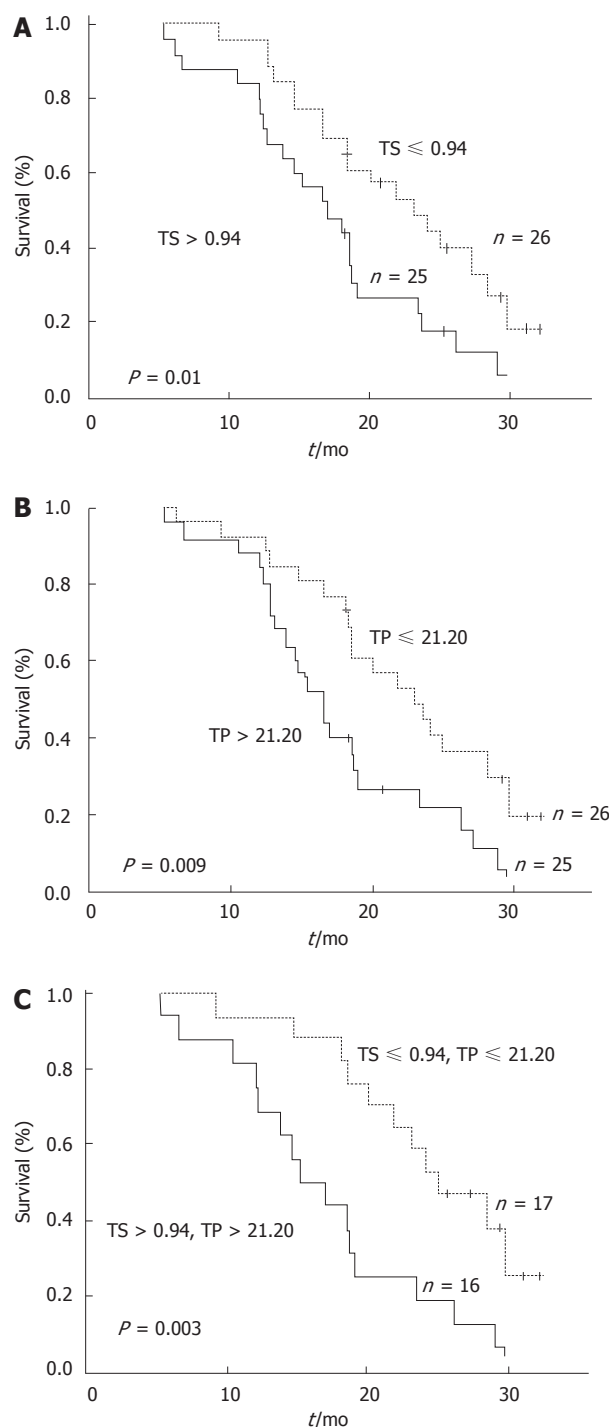

Figure 2 Kaplan-Meier survival curve for patients with intratumoral TS (A), TP (B), TS + TP mRNA levels above and below the median level of TS/TP (C). TS: thymidylate synthase; TP: thymidine phosphorylase.

to 5-FU as a single agent, is less than 30% and differs greatly among patients^[3], it is imperative to identify some indexes, which can be used to predict the efficacy of 5-FU in clinical settings. In the present study, we analyzed the mRNA levels of two genes in 51 patients with T3 or T4 gastric adenocarcinoma involved in 5-FU metabolism before 5-FU-based adjuvant chemotherapy to see if it is associated with survival. Our results showed that there was a significant correlation between TS/TP expression levels and survival of gastric cancer patients receiving postoperative FU-based adjuvant chemotherapy. The

identification of predicative markers for chemosensitivity by pharmacogenomics means could clarify which subset of patients might gain benefit, and enable clinicians to design individualized chemotherapy regimens^[11,12].

The primary biochemical mechanism responsible for cytotoxicity of 5-FU is the formation of 5-fluorouridine monophosphate (FdUMP), which can bind tightly to and inhibit thymidylate synthase in the presence of 5, 10-methylene tetrahydrofolate. TS catalyzes the reductive methylation of deoxyuridine-5'-monophosphate (dUMP) to deoxythymidine-5'-monophosphate (dTMP), which is the only pathway for de novo synthesis of dTMP, so inhibition of TS by FdUMP disrupts intracellular nucleotide pools necessary for DNA synthesis^[13,14]. As the main target of fluoropyrimidines, the expression level of TS is assumed to influence the efficacy of chemotherapy, although the amount of TS is not unanimously recognized as a determinant factor for 5-FU sensitivity^[7,15-18]. For example, Lenz *et al*^[7] showed that TS mRNA level influences response to 5-FU-based chemotherapy and survival of patients with primary gastric cancer. However, in two other studies^[16,17], TS mRNA levels did not reach statistically significant association with survival. In this work, patients with a lower TS expression level showed a trend to correlate with a longer DFS ($P = 0.017$) and a longer OS ($P = 0.010$) than those with a high TS expression.

TP is known to be higher in tumor tissue than in surrounding normal tissue^[19]. When 5-FU is administered, it is anabolized to FdUMP by TP in tumors^[20,21]. It was reported that the expression of TP can predict the efficacy of fluoropyrimidine chemotherapy and survival of patients^[21,22]. In the present study, although there was no significant difference in DFS in relation to TP expression, there existed significant differences in OS between the patients with high and low TP expression. Additionally, there would have an increased effect on prediction of survival in gastric cancer patients when TS and TP expressions were analyzed. These results indicate that measurement of TS and TP expression can identify a better survival prognosis of patients.

In summary, mRNA expression in TS and TP is a potential indicator in predicting the survival of patients with T3 or T4 gastric adenocarcinoma treated with 5-FU-based adjuvant chemotherapy. Further study is required to confirm our results and to establish the advantages of pre-treatment tumor biopsy for TS/TP screening, which permits a more rational decision on whether to precede a FU-based therapy.

COMMENTS

Background

5-fluorouracil (5-FU) is one of the most effective agents against gastrointestinal cancer. Its efficacy differs greatly among patients. As a pyrimidine analog, 5-FU exerts its antitumor effects through anabolism, which is determined by the rate of catabolism. Thus, the expression level of genes coding for key enzymes (such as TS and TP) in metabolism may play a pivotal role in the sensitivity and efficacy of 5-FU.

Research frontiers

As the key enzymes of fluoropyrimidines, the expression levels of TS and TP are assumed to influence the efficacy of chemotherapy, although TS or TP is not unanimously recognized as a determinant factor for 5-FU sensitivity. Some

studies showed that TS or TP mRNA level may serve as an important independent prognostic factor of survival in patients with solid tumor, including gastric cancer. However, there are no related reports about the relationship between TS/TP mRNA expressions and the clinical outcome of gastric cancer patients treated with 5-FU-based adjuvant chemotherapy.

Innovations and breakthroughs

The mRNA expression in TS and TP is a potential indicator in predicting the survival of patients with gastric adenocarcinoma. To our knowledge, it is the first report on the effect of TS/TP mRNA expression on the prognosis of Chinese patients with gastric cancer treated with 5-FU-based adjuvant chemotherapy.

Applications

Prospective controlled clinical trials are required to confirm our results and to establish the advantages of pre-treatment tumor biopsy for TS/TP screening, which permits a more rational decision on whether to precede a fluoropyrimidine-based therapy.

Terminology

5-fluorouracil (5-FU) is a widely used medicine in treatment of solid tumor. Thymidylate synthase (TS) is the target enzyme of 5-FU and catalyzes methylation of fluorodeoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP), which is an important process of DNA biosynthesis. Thymidine phosphorylase (TP) is an enzyme involved in pyrimidine nucleoside metabolism.

Peer review

The authors investigated the level of thymidylate synthase (TS) and thymidine phosphorylase (TP) mRNA in T3 or T4 gastric cancer patients treated with 5-fluorouracil-based adjuvant chemotherapy, and found that they were associated with overall survival and disease-free survival of the patients. They concluded that mRNA level of TS and TP may be a useful predictive parameter for the survival of postoperative gastric cancer patients after 5-fluorouracil-based adjuvant chemotherapy.

Abstract

As among persons with normal anatomy, occasional patients with situs inversus develop malignant tumors. Recently, several laparoscopic operations have been reported in patients with situs inversus. We describe laparoscopic hemicolectomy with radical lymphadenectomy in such a patient. Careful consideration of the mirror-image anatomy permitted safe operation using techniques not otherwise differing from those in ordinary cases. Thus, curative laparoscopic surgery for colon cancer in the presence of situs inversus is feasible and safe.

INTRODUCTION

Situs inversus (SI) is an uncommon anatomic anomaly. Situs inversus totalis denotes complete right-left inversion of thoracic and abdominal viscera^[1-7]. Accordingly, surgical procedures are considered more difficult in

patients with SI in other patients because of different anatomic positions of organs, especially in laparoscopic surgery. While laparoscopic colorectal surgery recently has become a standard procedure, only two previous reports of laparoscopic surgery for colonic disease in patients with SI are available^[3,8]. Here, we display some figures of laparoscopic hemicolectomy with radical lymphadenectomy in a patient with SI, highlighting differences from the ordinary situation.

CASE REPORT

A 53-year-old woman known since early childhood to have situs inversus totalis was referred to her personal physician upon detection of anemia. She underwent ovariectomy for ovarian cancer at the age of 48 years. With a diagnosis of ascending colon cancer according to barium enema radiograph and colonoscopy, the patient was admitted to our hospital for further evaluation and surgical treatment. Laboratory examination confirmed anemia (red blood cell count, $377 \times 10^4/\text{mm}^3$; hemoglobin, 9.3 g/dL; hematocrit, 29.9%). The serum concentration of carcinoembryonic antigen was elevated (89.8 ng/mL; reference range, 0 to 4.9 ng/mL). A chest radiograph showed dextrocardia and a right subphrenic gastric bubble (Figure 1). Abdominal ultrasonography and computed tomography (Figure 2) showed complete transposition of abdominal viscera, confirming situs inversus totalis. Furthermore, the superior mesenteric vein was located to the left of the superior mesenteric artery. Barium enema and colonoscopy showed an ulcerated lesion in the ascending colon. Histologic examination of a specimen from colonoscopic biopsy indicated adenocarcinoma. According to the findings above, laparoscopic hemicolectomy with radical lymphadenectomy was performed. With the patient in a lithotomy position, the operator was situated between the legs, the first assistant on the left, and the endoscopist on the right with a reversal of assistants' location for orthotopic patients. Trocars also were placed in a mirror-image manner, including a 12-mm umbilical trocar for the camera, a 12-mm trocar in the right iliac fossa and a 5-mm trocar in the left iliac fossa as working ports for the operator, and a 5-mm trocar in the left flank and a 12-mm trocar in the epigastrium for traction. The liver was located on the left and the spleen on the right. The mesentery was incised just caudal to the ileocolic vessels, and the fusion fascia was mobilized searching the anterior

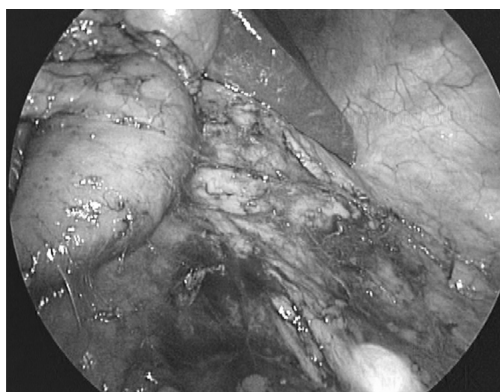

Figure 6 Full mobilization of the ascending colon including the tumor.

surface of the transverse portion of the duodenum. The ileocolic vessels were identified and divided after the superior mesenteric vein was exposed (Figure 3). Radical lymphadenectomy was continued up to the root of the middle colic artery (Figure 4), the left branch of the artery was divided (Figure 5). Mobilization of the ascending colon including the tumor (Figure 6) was followed by reconstruction using an end-to-end triangulating stapling method^[9] carried out extracorporeally through a 5-cm skin incision continued to the umbilical port. No additional ports were needed. Operation time was 191 min and blood loss was 60 mL, similar to typical findings in orthotopic patients. The procedure was not complicated apart from a need to appreciate mirror-image aspects of anatomy and surgery, including some awkwardness in handling surgical or endoscopic instruments in the presence of right-left inversion. Macroscopically, the tumor was a 45 mm × 25 mm ulcerated lesion in the ascending colon. Histologic

examination of the resected specimen disclosed a well-differentiated adenocarcinoma with serosal, lymphatic, and venous invasion, as well as lymph node metastasis. After an uneventful postoperative course, the patient was discharged on the 10th postoperative day.

DISCUSSION

Predisposition to situs inversus (SI), a rare congenital condition present in 1 of 5000 to 10 000 live births, is inherited in a simple autosomal recessive manner. SI may involve transposition of thoracic or abdominal organs,

or both. Situs inversus totalis denotes complete inversion of thoracic and abdominal viscera^[1-7]. Apart from genetic predisposition, no etiologies have been established, and SI itself has no pathophysiologic significance^[1,5]. However, surgical techniques need to allow for spatial implications of this condition. Cardiac and intestinal malformations as well as other visceral and vascular anomalies that can be associated with SI follow variable patterns^[1]. Careful preoperative anatomic assessment is vitally important in the presence of SI^[1,5]. Careful preoperative planning of laparoscopic procedures (positions of operator, assistants, and trocar sites as well as instrumentation) is needed, as mentioned in several previous reports of laparoscopic surgery in patients with SI^[2-4,6-8]. No specific intraoperative complications have been described in the reports above. Likewise, no unanticipated problems were encountered in our case. Patients with SI who develop malignant tumors in lung, liver, stomach, or colon have been encountered^[1,5]. In the present case, the patient was operated on by a surgeon with experience in over 400 laparoscopic colorectal operations. The position of the operator did not differ from that in orthotopic patients, but positions of assistants and trocars were reversed from the usual locations. Endoscopic instruments were used as they were ordinarily used, although mechanical awkwardness was noted in handling surgical or endoscopic instruments in the presence of reversed spatial relationship. Careful recognition of the mirror-image anatomy permitted safe radical lymphadenectomy and mobilization of the colon, while the surgical technique itself did not differ from the usual situation. Operative time and blood loss were comparable to those in orthotopic patients. Laparoscopic surgery for colon cancer in SI thus should be considered a

feasible, safe and curative procedure that surgeons should not hesitate to perform.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381892

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

Severe acute pancreatitis (SAP) develops in about 25% of patients with acute pancreatitis (AP). Severity of AP is linked to the presence of systemic organ dysfunctions and/or necrotizing pancreatitis pathomorphologically. Risk factors determining independently the outcome of SAP are early multi-organ failure, infection of necrosis and extended necrosis (> 50%). Up to one third of patients with necrotizing pancreatitis develop in the late course infection of necroses. Morbidity of SAP is biphasic, in the first week strongly related to early and persistence of organ or multi-organ dysfunction. Clinical sepsis caused by infected necrosis leading to multi-organ failure syndrome (MOFS) occurs in the later course after the first week. To predict sepsis, MOFS or deaths in the first 48-72 h, the highest predictive accuracy has been objectified for procalcitonin and IL-8; the Sepsis-Related Organ Failure Assessment (SOFA)-score predicts the outcome in the first 48 h, and provides a daily assessment of treatment response with a high positive predictive value. Contrast-enhanced CT provides the highest diagnostic accuracy for necrotizing pancreatitis when performed after the first week of disease. Patients who suffer early organ dysfunctions or at risk of developing a severe disease require early intensive care treatment. Early vigorous intravenous fluid replacement is of foremost importance. The goal is to decrease the hematocrit or restore normal cardiocirculatory functions. Antibiotic prophylaxis has not been shown as an effective preventive treatment. Early enteral feeding is based on a high level of evidence, resulting in a reduction of local and systemic infection. Patients suffering infected necrosis causing clinical sepsis, pancreatic abscess or surgical acute abdomen are candidates for early intervention. Hospital mortality of SAP after interventional or surgical debridement has decreased in high volume centers to below 20%.

INTRODUCTION

Dealing with the clinical course of acute pancreatitis (AP) and the management of severe acute pancreatitis (SAP) are complicated by limited understanding of pathogenesis and multi-causality of the disease, uncertainties to predict outcome and a few effective treatment modalities. AP comprises clinically a mild oedematous-interstitial inflammation, which is a self-limiting disease, and a severe type of AP with a local necrotizing inflammation and systemic complications. Despite the importance of recognizing severe disease early in the course, many patients initially identified as having mild disease, progress to severe pancreatitis over the initial period of disease. Clinical studies and experimental new data have led to considerable progress in understanding the pathophysiological events of the early period of human AP, but the underlying processes leading to acinus cell necroses and the propagation of the necrotizing inflammation by impaired microcirculation of pancreatic tissue compartments in the initial 48-72 h, are still unknown to a large extent. Hence, management of human AP has been empiric and conflicting opinions are still present regarding medical and surgical management concepts.

PATTERN OF INFLAMMATION

The tissue response of the pancreas to an injury like acinus cell necrosis leads to production and liberation of proinflammatory cytokines, chemokines and other biological active compounds^[1-4]. Clinical and experimental studies have verified activation of local macrophages and attraction of activated polymorphonuclear cells (PMNs) as first-line players in the defense and limitation of pancreatic tissue injury^[5-7]. Inflammatory mediators are primarily released from the splanchnic area and gain access to the systemic compartment mainly by lymphatic, portal vein and suprahepatic circulation^[1,8]. The lungs are the first

Table 1 Severe acute pancreatitis: Gut barrier dysfunction causes local changes and systemic complications

Local	Systemic consequences
Mucosal ischemia ^[10,15,16]	Priming of neutrophils ^[20-22]

Reperfusion injury of mucosal epithelia ^[18]	Bacterial translocation ^[25-27]
Increase of intestinal permeability ^[19]	Cytokine overproduction ^[1,2,28]
Gram-negative intestinal bacterial overgrowth ^[11]	Impaired systemic immunity ^[29,30]
Impaired mucosal immunity ^[11]	

pass taker of the porto-hepatic blood and lymph of the splanchnic compartments enriched of activated PMNs, cytokines and other biological active compounds. Gut barrier failure, with the ensuing translocation of bacteria and endotoxin, has been proposed as a major contributor to the development of local infection and multi-organ failure in SAP^[9]. Evidence of the association between gut injury and the subsequent development of infected necroses and distant organ failure continues to increase. Intestinal permeability disturbances have been found in humans with SAP 72 h after onset, correlating strongly with clinical outcome^[10]: the increase of permeability was significantly higher in patients who developed multi-organ failure and/or died compared to patients suffering from mild attacks^[11]. Intestinal permeability increases gradually during the course of SAP reaching a maximum at the end of the first week^[12]. In a recent prospective study of patients with AP, endotoxemia as a consequence of increase of gut permeability was found on the day of admission to the hospital significantly more common and of greater magnitude in severe attacks than in those with mild attacks, in non-survivors than in survivors, and in patients who developed multi-organ failure than in those who did not^[13,14] (Table 1).

The peritoneal compartment is the site of pro-inflammatory reaction to pancreatic necrosis, whereas an anti-inflammatory response dominates in the lymph collected from the thoracic duct, as well as in the systemic circulation during the first week after onset of systemic complications^[1]. The cytokine levels in the blood and lymph are closely associated with the severity of illness on admission, the magnitude of multi-organ failure syndrome (MOFS) and the outcome as well^[1,2]. Correlated with local and systemic complications, a compartmentalization of the inflammatory responses has been objectified. Local inflammatory cytokines at high concentrations are found in the portal and splanchnic circulation at the same time when in the systemic blood compartment anti-inflammatory compounds prevail over inflammatory cytokines. In SAP, a compensatory anti-inflammatory response affects the immunocompetence^[30,31]. Patients with SAP show impaired immune response in regard to reduced HLA-DR expression of monocytes and macrophages^[29,32], reduced numbers of CD4- and CD8-positive T-cells^[33,34], an impairment of mononuclear phagocytic capacity^[35] and an increase of the anti-inflammatory cytokine IL-10 and IL-1 receptor antagonist^[36]. Reduced immune competence,

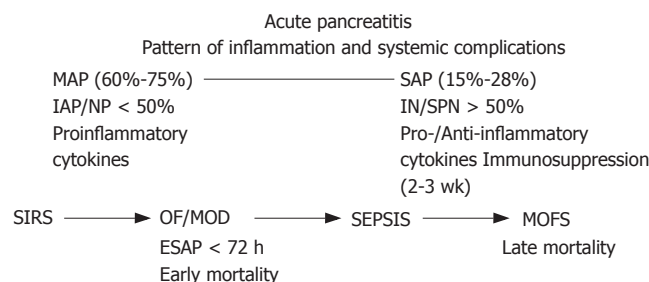

Figure 1 Pattern of inflammation and systemic complications in acute pancreatitis. MAP: Mild acute pancreatitis; SAP: Severe acute pancreatitis; IAP: Intestinal oedematous pancreatitis; NP: Necrotizing pancreatitis; IN: Infected necrosis; SPN: sterile pancreatic necrosis; SIRS: severe inflammatory response syndrome; OF: Organ failure; MOD: Multiorgan failure; SEPSIS: Leukocytes > 10 000/mm³ + fever > 38.5 rectal/> 48 h + metabolic acidosis base excess > -4 mmol/L; MOFS: Multiorgan failure syndrome; ESAP: Early severe acute pancreatitis.

as objectified by reduced expression of HLA-DR of monocytes and macrophages, predicts the development of organ failure and is associated with secondary infection^[29] (Figure 1).

CLASSIFICATION OF ACUTE PANCREATITIS

At the beginning of the 1980s, the morphologic feature of SAP was established by the definition of infected and sterile necrosis, pancreatic abscess and postacute pseudocysts as the principal morphologic and bacteriologic criteria for clinical severity and considered to be determinants of the clinical course^[37]. Macroscopically, necrotizing pancreatitis is characterized by focal or diffuse areas of devitalized parenchyma frequently associated with peripancreatic fatty tissue necroses extending sometimes to retroperitoneal spaces up to the pelvis. Intrapaneatic hemorrhage is variably present and may lead to an acute abdominal compartment syndrome. Infection of necrosis occurs in up to 30% of all patients with necrotizing pancreatitis^[27,38]. In the clinical setting of AP, post-acute pseudocysts and pancreatic abscess are late consequences of the disease^[39]. In both subgroups of AP, an inflammatory wall is developed which separates the inflammatory processes from the surrounding tissues. Both features have differences in clinical symptomatology and associated morbidity. Peripancreatic fluid collection that arises early during the course of AP is frequently a sign of severity. However, in most instances peripancreatic fluid collection disappears without any treatment^[40].

The Atlanta Classification is accepted worldwide as the first clinical reliable classification system of AP. But the accumulation of clinical data forces a revision of the Atlanta criteria of severity. Organ failure has been recognized as a more important determinant of survival than the extent of pancreatic necroses. Particularly early multi-organ failure at admission or in the first days predicts strongly the clinical course and the outcome. Severity of organ failure using multi-step criteria as introduced for septic patients by the SOFA-score is considered clinically relevant and increasingly applied for severity scoring and predicting outcome^[41]. The SOFA criteria for systemic

Table 2 Clinical course of AP/SAP

	Clinical	Pathophysiologic process
Early: d 1-10 after HA	Hypovolemia Abdominal pain	Fluid sequestration Liberation of pro- and anti-inflammatory cytokines
ESAP in about 20% of SAP	Dysfunction Pulmonary Renal Cardiocirculatory	Endotoxemia Liberation of vasoactive substances
	Liver Intestine	Disturbance of blood coagulation Translocation of endotoxin and bacteria
Late > 2 wk after HA	Local and systemic septic complications IN, SPN	Bacterial translocation CARS Anti-inflammatory reaction Immunosuppression

AP: Acute pancreatitis; SAP: Severe acute pancreatitis; ESAP: Early severe acute pancreatitis; HA: Hospital admission; IN: Infected necrosis; SPN: Sterile pancreatic necrosis; CARS: Compensatory antiinflammatory syndrome.

organ dysfunctions are clinically more reliable for decision making than the Atlanta criteria.

CLINICAL COURSE OF SAP

Acute pancreatitis is not a stable disease. Increasing amounts of intrapancreatic and retroperitoneal necroses are closely related to the frequency and severity of local and systemic complications^[27]. About 70%-80% of AP takes a mild course and is associated only with minimal organ dysfunctions. First clinical signs are abdominal pain located in the epigastrium, frequently radiating into the midback (Table 2). Clinical improvement can easily be achieved by fluid replacement, a pain treatment and re-institution of regular food intake. The initial 2-4 d after onset of symptoms are most important, when about 15%-25% of patients with AP take the course of a severe disease. Based on clinical and experimental data, this period is characterized by an initial hypovolaemic state^[42-44]. In SAP, hypotension or even shock occurs as a consequence of sequestration of protein-rich fluids into the pancreas, the retroperitoneal spaces and the abdominal cavity. The initial systemic inflammatory response syndrome causes a hyperinflammatory reaction exerting systemic organ dysfunctions of the lungs, kidneys, cardiocirculatory system and splanchnic intestinal compartments^[45,46]. Acute fluid collections arise early in the course of severe acute pancreatitis, lack a well-defined wall and are usually peripancreatic in location, and usually resolve without sequelae but may evolve into pancreatic pseudocysts or abscesses. Acute fluid collections rarely require drainage. About 60%-70% of fluid collection resolves spontaneously and has no connection with the pancreatic duct system^[47].

EARLY SEVERE ACUTE PANCREATITIS

About 20% of patients with SAP develop in the 72 h after onset of the disease organ failure or even have organ- or multi-organ failure at admission to hospitals^[48]. Despite application of maximum intensive care treatment,

Table 3 Severe acute pancreatitis-early organ failure

Admission	Dynamic of organ failure	Hospital mortality
ESAP (n = 47)	SOF 25 (53%) MOF 22 (47%)	Reversible 9 develop MOF 14 (30%) Reversible 1 progress to MOFS 21 (95%)
SAP (n = 111)	OF (-) 30 (27%) SOF 26 (23%) MOF 55 (50%)	14%

ESAP: Early severe acute pancreatitis; SOF: Single organ failure; MOF: Multiorgan failure; SAP: Severe acute pancreatitis; OF: Organ failure. Reversibility or assistance in spite of maximum intensive care treatment of early organ failure or early organ failure syndrome (n = 158)^[48].

30%-50% of the patients with early severe acute pancreatitis do not promptly respond to ICU treatment and take a complicated course with persistence of multi-system organ dysfunctions. Patients suffering from early and persistent multi-organ insufficiency syndrome have a high risk of mortality^[49]. Recently it has been shown that severe organ failure within the first week after onset of AP before any kind of intervention is closely linked to clinically relevant pancreatic infection which occurs two weeks later^[50]. Early multi-organ dysfunction syndrome (MODS) obviously triggers additional mechanisms that render bacterial translocation into clinically manifested sepsis. Early onset MODS > 2 organs has proved to be the predominant risk factor for death. Early mortality in the first 6-10 d of SAP is caused by severe inflammatory response syndrome (SIRS) associated with early multi-organ insufficiency syndrome (Table 3). Early mortality was reported between 42% and 60%^[51-53].

Presence of necrosis and infection

Gross destruction of the pancreatic gland by tissue necroses is observed in about 20% of patients with AP and takes place in the first week after onset^[54]. Experimental and clinical observations reveal that development of pancreatic necrosis is accompanied by an increase of local and systemic organ complications, increasing the risk of morbidity and mortality compared to patients with interstitial-oedematous pancreatitis^[55,56] (Figure 2). Most patients who develop early or late organ failure suffer from necrotizing pancreatitis. Autopsy data and surgical results have verified that more than 80% of deaths are correlated with the presence of necroses. The highest risk for local and systemic complications is seen in patients who show extended necrosis of more than $\geq 50\%$ of the pancreas by magnetic resonance tomography (MRT) or contrast-enhanced computer tomography (CECT)^[57,58]. Patients with sterile extended pancreatic necroses (> 50%) display clinically signs of sepsis including organ dysfunctions, septic fever, leucocytosis, hyperdynamic cardiocirculatory state and intestinal motility disorder. To discriminate clinical infection from sterile necrosis, the use of sepsis criteria is not reliable in patients with extended sterile necrosis.

In addition to the presence of pancreatic parenchymal necrosis, the occurrence and extent of the necrotizing process into extrapancreatic retroperitoneal fatty tissue

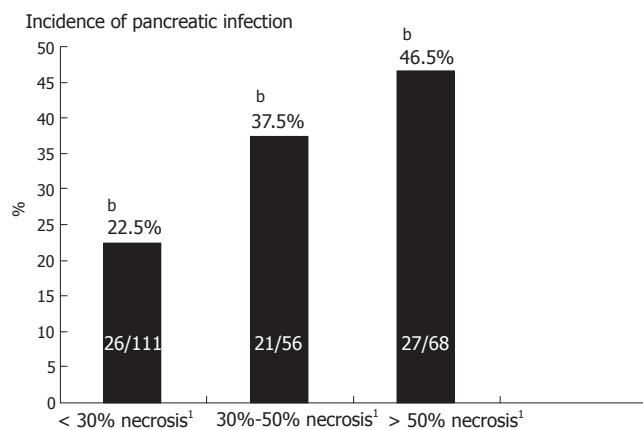

Figure 2 Relation between bacterial infection and extent of necrosis in 225 patients with severe acute pancreatitis. ¹On the basis of contrast-enhanced CT. ² $P = 0.008$ between the groups, Cochran-Armitage trend test.

spaces including tissue compartments of the mesentery of the small and large bowel, the peri-renal fat and the para- and retrocolic compartments, are important factors influencing the course of the disease and strongly affect the clinical severity^[59]. The overall infection rate of pancreatic tissue in necrotizing pancreatitis is up to 30% and may increase to 70% in the 3rd wk^[27] (Table 4).

The setting of pancreatic infection includes infected necrosis, pancreatic abscess and infected pancreatic pseudocysts. The bacteriological analysis of puncture aspirates or of intraoperative smears reveals predominantly gram-negative microbes deriving from the intestine. *Escherichia coli* was the most frequent pathogen followed by *Enterococcus* and *Klebsiella*^[27]. However, in recent years a shift of the bacterial pattern has been observed towards more gram-positive bacteria like *Staph aureus* and *Enterobacteriaceae*^[60,61]. The presence of candida species in infected necroses has been observed in 5%-15%^[62]. Candida patients have a higher mortality and experience more systemic complications than patients without candida infections of necroses. Recent data about the routine use of prophylactic antibiotics provided evidence that application of antibiotics contributes to the development of candida infection and to changes in bacterial spectrum of infected necroses with an increased incidence of gram-positive infections^[62,63].

CT-guided fine needle aspiration (FNA) of the necrotic area is a safe procedure to diagnose infection, identify bacteria and institute appropriate therapy. To distinguish pancreatic inflammation from secondary infection, gram staining and culture must be performed after guided aspiration^[64]. The knowledge of the bacteria and candida species and the pattern of chemo-resistance may lead to a rational antibiotic treatment.

MANAGEMENT OF SAP: PREDICTION OF SEVERITY AND OUTCOME

The management of patients with AP is challenging due to late hospitalization after onset of the acute attack and difficulty in distinguishing mild from severe disease in the first 48-72 h. Identification of risk factors for the

Table 4 Frequency of pancreatic infection in 427 patients¹ with necrotizing pancreatitis²

		NP (%)	AP (%)
Infected necrosis	99	23.2	6.9

development of necrotizing pancreatitis within the initial 24 h of hospitalization is of potential clinical importance. Patients who display at admission organ dysfunctions or an Apache II score ≥ 8 ^[65] or C-reactive protein (CRP) > 120 mg/dL^[66] or procalcitonin > 1.8 ng/mL^[67] or a hematocrit > 44 ^[44] should have early intensive care for optimal surveillance and ICU treatment. The use of early CECT or MRI for determination of severity is limited by several factors: (a) only a quarter of patients with acute pancreatitis develop necroses; (b) pancreatic necroses may not develop in the first 48 h; and (c) the presence of pancreatic necroses and the amount of necroses does not strongly correlate with the development of organ failure (Figure 3)^[68]. The CECT based Balthazar classification shows the highest diagnostic and predictive accuracy when performed after the first week of disease. The APACHE II scoring and the sequential Sepsis-Related Organ Failure Assessment (SOFA) have a highly reliable sensitivity and specificity and positive predictive value for the degree of severity of SAP. APACHE II-, Marshall- and SOFA score can objectify the responses of the patients to intensive care measures (Table 5) on a daily basis. The biochemical parameters, CRP, procalcitonin and IL-8 have a high predictive accuracy for the degree of severity of necrotising pancreatitis in the first days. Procalcitonin > 1.4 ng/mL has a diagnostic accuracy of 70% for infection of necrosis; and procalcitonin of > 3.8 ng/mL predicts MODS with a diagnostic accuracy of 92%^[71] (Table 6).

First line treatment of SAP

Admission hematocrit of > 47 and a failure of admission hematocrit to decrease at 24 h has been identified as reliable criteria of hemoconcentration of SAP in the very early period of the disease^[42-44]. Vigorous intravenous fluid resuscitation is required to overcome systemic hypovolemia caused by intravascular fluid loss^[72,73]. Intravenous fluid substitution for patients with predicted SAP should be established with 250-350 mL/h for the first 48 h^[42]. Restoration of normal cardiocirculatory functions objectified by heart-rate, systolic or mean arterial blood pressure, an oxygen saturation of venous blood of $> 95\%$, absence of a base deficit > 5 μ mol/L and urine flow of ≥ 50 mL/h are decisive criteria of treatment response.

In mild biliary acute pancreatitis, endoscopic retrograde cholangiopancreatography (ERCP) and removal of common bile duct stones do not change the natural course

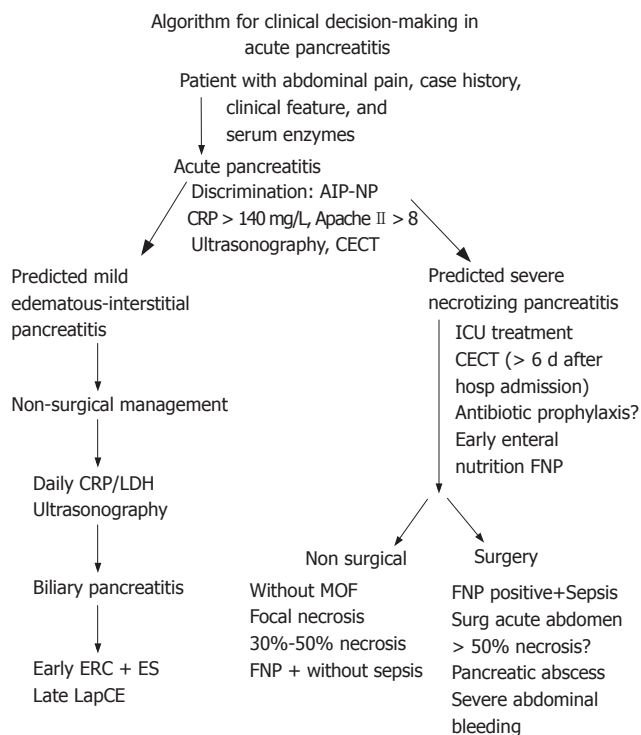

Figure 3 Algorithm for clinical decision making in acute pancreatitis. AIP: Acute interstitial pancreatitis; NP: Necrotizing pancreatitis; CRP: C reactive protein; CECT: Contrast-enhanced computer tomography; LDH: Lactate dehydrogenase; ERC: Endoscopic retrograde cholangiography; ES: Endoscopic sphincterotomy; CE: Laparoscopic cholecystectomy; FNP: Fine needle procedure; MOF: Multiorgan failure syndrome.

of pancreatitis. ERCP, endoscopic sphincterotomy and stone removal are applied after subsidence of clinical signs of AP. In severe biliary pancreatitis, **early sphincterotomy** and stone extraction are **beneficial when common bile duct stone has been diagnosed to be associated with SAP**. Early endoscopic extraction of common bile duct stones brings about disappearance of cholestasis and decompression of the pancreatic main duct. A significant reduction of biliary and systemic morbidity has been objectified by two **randomized controlled trials (RCTs)**^[74-76]. However, ERCP and sphincterotomy in SAP increases the risk of an additional pancreatic trauma in up to 10% of patients and may increase the risk of additional cholangitis episodes during the course of SAP.

Antibiotic prophylaxis turned out to be not very effective in regard to avoidance or reduction of infection of necrosis and associated systemic complications^[77]. Two randomized

double blinded prospective controlled multi-center trials proved antibiotic prophylaxis ineffective in regard to reduction of infection of necrosis and hospital mortality^[78,79] (Table 7). But patients with **pulmonary infection** and who show a positive blood culture associated with signs of sepsis should be **treated with antibiotics**. **Enteral feeding (EN)** in SAP reduces significantly the infection rate of necrosis and lowers the need for surgical interventions^[80-84]. However, hospital mortality and non-infectious complications are not altered by enteral feeding compared to parenteral nutrition (Table 8). The beneficial effect of EN may be more pronounced if it is **instituted early**^[85].

Non-surgical ICU-management is successful in most patients with AP who have **sterile pancreatic necroses** and who do **not develop organ failure** (Table 9). Patients having pancreatic necroses and who are fine needle procedure (FNP)-positive but do **not show clinical signs of sepsis**, do not need surgical intervention^[86-88].

Interventional treatment of infected necrosis

Surgical debridement has been documented to be

Table 8 Severe acute pancreatitis-enteral feeding reduces infection in the need for surgical intervention

effective for patients with proven infected necrosis and progressive clinical sepsis. Patients with SAP who develop a surgical acute abdomen during the course of ICU treatment need emergency surgery to avoid development of abdominal compartment syndrome^[57] or consequences of intestinal perforations. Patients with extended sterile necrosis (> 50% of the pancreas) are at high risk for infected necrosis with the consequence of progressive MODS. These patients are candidates for surgical and interventional measures after their clinical signs show non-response to maximum intensive care treatment. Patients with infected necrosis are managed by surgical and interventional treatment modalities (Table 10).

A variety of surgical treatment modalities are currently in use. The advantages of minimally invasive interventional debridement, whether performed by laparoscopic techniques or by a retroperitoneal approach, are up to now not based on results of controlled clinical trials. By use of minimal invasive techniques for infected necrosis in the late course of disease, the morbidity remains high for several days. Two to 7 reoperations with lavage are necessary to interrupt systemic complications of the local inflammatory process^[95-102] (Table 11). An open surgical debridement combined with continuous short-term lavage of the lesser sack interrupts clinical sepsis in patients suffering from extended necrosis with infection accompanied by multi-system organ failure. The early treatment related morbidity is much lower in patients treated with open surgery than after first pass of minimal invasive debridement. The frequency of reoperation is between 25% and 40% and up to 100% in patients after minimal access intervention. Hospital mortality in high volume centers is below 20% after open necrosectomy plus bursa lavage and after minimal invasive surgical approach as well.

Abstract

Adult polycystic liver disease (PCLD) is an autosomal dominant condition commonly associated with autosomal dominant polycystic kidney disease (ADPKD). However in the last decade, it has been recognized that there is a distinct form of autosomal dominant PCLD that arises without concomitant ADPKD. Early knowledge of the pathogenesis was gained from the study of hepatic cysts in patients with ADPKD. Bile duct overgrowth after embryogenesis results in cystic hepatic dilatations that are known as biliary microhamartomas or von Meyenburg complexes. Further dilatation arises from cellular proliferation and fluid secretion into these cysts. There is a variable, broad spectrum of manifestations of PCLD. Although PCLD is most often asymptomatic, massive hepatomegaly can lead to disabling symptoms of abdominal pain, early satiety, persistent nausea, dyspnea, ascites, biliary obstruction, and lower body edema. Complications of PCLD include cyst rupture and cyst infection. Also, there are associated medical problems, especially intracranial aneurysms and valvular heart disease, which clinicians need to be aware of and evaluate in patients with PCLD. In asymptomatic patients, no treatment is indicated for PCLD. In the symptomatic patient, surgical therapy is the mainstay of treatment tailored to the extent of disease for each patient. Management options include cyst aspiration and sclerosis, open or laparoscopic fenestration, liver resection with fenestration, and liver transplantation. The surgical literature discussing treatment of PCLD, including techniques, outcomes, and complication rates, are summarized in this review.

INTRODUCTION

Adult polycystic liver disease (PCLD) was first described in 1856 by Bristowe in association with autosomal dominant polycystic kidney disease (ADPKD)^[1]. PCLD is a rare (incidence < 0.01%) dominantly inherited disorder characterized by multiple diffuse cystic lesions of the liver parenchyma. An asymptomatic enlarged liver is usually the hallmark of the disease. However with more effective treatment of renal disease, increasing numbers of patients are living long enough to experience symptoms from their associated polycystic liver disease. Significant symptoms or complications from liver involvement can occur in up to 20 percent of cases^[2,3]. In symptomatic PCLD patients, surgical therapy is the mainstay of therapy including laparoscopic or open fenestration with or without hepatic resection and orthotopic liver transplantation. The surgical therapy should be tailored to the extent of disease in each patient. In this review, we will summarize the literature addressing the clinical presentation, associated medical problems, and appropriate surgical management of patients with adult polycystic liver disease.

PATHOGENESIS AND GENETIC BASIS OF POLYCYSTIC LIVER DISEASE

Although there is an isolated form of polycystic liver disease, knowledge concerning the pathogenesis of hepatic cysts was gained from the study of hepatic cysts in ADPKD. These lesions have been attributed to bile duct overgrowth after the arrest of embryogenesis and failure of the intralobar bile ducts to involute. This involutional failure results in cystic dilations that are known as biliary microhamartomas or von Meyenburg complexes (VMC)^[4]. Further study of these VMC confirmed that they maintain communication with the biliary tree^[5,6]. The growth of cysts in the liver is thought to arise from cell proliferation, solute and fluid secretion into the cysts, and expansion of abnormal cell matrices. Perrone and colleagues demonstrated, via culture derived epithelial cell lines, that these cysts are of biliary origin^[7]. Morphological studies demonstrate that the peripheral cysts arise from biliary microhamartomas, but the centrally located cysts arise from dilatation of the peribiliary glands in the liver^[8].

ADPKD is one of the most commonly inherited diseases with an incidence of 1 in 400 to 1 in 1000. It is

Figure 1 A: Type I PCLD; B: Type II PCLD; C: Type III PCLD.

a cause of 8%-10% of all chronic end-stage renal failure requiring dialysis^[9]. The number of ADPKD patients with hepatic involvement appears to be rising, likely due to increased life expectancy from improved renal replacement therapy and renal transplantation. Early literature suggested that 40%-50% of patients with ADPKD had polycystic liver disease^[10,11], but in more recent literature, this figure has increased to 75%-90%^[12]. Independent risk factors for hepatic involvement in the ADPKD include advancing patient age, female gender, and severity of renal disease. The increased prevalence in females may be due to stimulatory effects of estrogen. The reported prevalence of hepatic cysts in female patients with ADPKD ranges from 58% to 75% while the prevalence in male patients ranged from 42% to 62%^[13]. Further support for the stimulatory effect of estrogen comes from studies showing an increase in liver cyst volume in pregnant women and women receiving postmenopausal estrogen therapy^[14]. Finally, a correlation has been established between an increasing burden of hepatic cysts in patients as the severity of renal cystic disease increases^[13].

The first suggestions of an isolated form of polycystic liver disease were made in the mid-1980's^[15,16] and confirmation that there was a distinct autosomal dominant polycystic liver disease (ADPLD) occurred in the late 1990's^[17,18]. ADPLD, much rarer than its PKD counterpart, has a reported incidence of less than 0.01%. ADPLD is linked to a mutation on chromosome 19 that leads to a mutated protein hepatocystin which may play a role in abnormal biliary cell proliferation and differentiation^[19,20].

CLINICAL PRESENTATION

In 80% of patients, PCLD is asymptomatic^[2,3] and often diagnosed incidentally during work-up of other clinical problems. In patients with long-standing disease, the most frequent symptoms are abdominal pain, early satiety, nausea and vomiting, supine shortness of breath, lower body edema, biliary obstruction, and ascites. These symptoms are usually indicative of significant hepatic enlargement or compression of adjacent structures, but rarely can be from infection or malignant transformation^[21,22]. Laboratory studies including bilirubin, hepatic transaminases (AST and ALT), alkaline phosphatase, and gamma glutamyl

transferase (GGT) are usually normal in asymptomatic patients. In symptomatic patients undergoing evaluation, alkaline phosphatase and GGT may be elevated in up to 47% and 70% of patients respectively^[21,23-25]. AST may be elevated in up to 27% of patients and bilirubin levels may be elevated in up to 15%^[21,23].

CLASSIFICATION OF APLD

Gigot and coauthors have described a detailed classification scheme for patients with polycystic liver disease based on pre-operative computed tomography (CT). This description is based on the number and size of cysts as well as the amount of residual normal liver parenchyma between the cysts^[25]. Type I patients have a limited number (< 10) of large cysts with large areas of non-cystic parenchyma (Figure 1A). Patients with Type II PCLD have diffuse involvement of liver parenchyma by medium sized cysts with remaining large areas of non-cystic parenchyma (Figure 1B). Finally, Type III patients are characterized by massive, diffuse involvement of liver parenchyma by small and medium sized liver cysts and only a few areas of normal liver parenchyma between cysts (Figure 1C). This classification system offers a good platform for comparison of morphological disease between patients and their classification can aid us in formulating appropriate plans for therapy.

HEPATIC COMPLICATIONS OF POLYCYSTIC LIVER DISEASE

Hepatic complications from polycystic liver disease (PCLD) typically occur only in the setting of significant hepatomegaly. These cases usually present with a palpable abdominal mass, significant abdominal pain, early satiety, or dyspnea. Occasionally, severe abdominal pain will result from rupture of a hepatic cyst, hemorrhage into a cyst or if a cyst becomes infected^[2,26]. Despite longstanding polycystic liver involvement, only rarely does this entity lead to hepatic insufficiency or failure. The displaced hepatic parenchyma still functions quite well.

An infected hepatic cyst is a serious, but rare, complication. These patients will usually present with fever, leukocytosis, and right upper quadrant pain. This

acute presentation should be suspected in this population and treated early to prevent progression to bacteremia, sepsis, and death. The morbidity and mortality rates of a cyst infection have been reported at 3% and 2% respectively^[27]. Thus there should be early institution of antibiotics and a drainage procedure. Telenti and coauthors reviewed outcomes of patient's with infected hepatic cysts and strongly supported the use of antibiotics and a drainage procedure^[28]. In their review of 14 patients with infectious complications involving hepatic cysts, seven of the fourteen patients received antibiotics alone. Of these patients, two died without having a drainage procedure, four patients underwent drainage after their symptoms persisted through antibiotic therapy, and one patient was not offered drainage due to the difficult location of the infected cyst. In the seven patients treated with combined drainage and antibiotics, one patient died from post-operative sepsis and one died from unrelated causes, while five patients had no reported morbidity from their procedures. While this literature favors antibiotic therapy along with drainage, it is often difficult to determine which cyst(s) is/are actually infected. Imaging studies can often direct us toward an area of suspicion. On CT scanning, the finding of fluid-fluid levels within cysts, cystic wall thickening, or intracystic bubbles have been associated with infection of a hepatic cyst^[28,29]. Ultimately drainage of the suspected cyst provides the definitive answer whether this is from the open approach or percutaneously. In those cases where the cyst is too small or cannot be accurately identified on preoperative imaging, broad spectrum antibiotics should be instituted with narrowing of the spectrum if blood cultures implicate a specific organism^[28].

Rarely, jaundice occurs as a result of cystic compression of the biliary system. This manifests as a result of the normal progression of cyst growth and compression of the common hepatic duct or common bile duct^[30]. Relief of this obstruction is accomplished by surgical decompression or resection of the offending cysts.

ASSOCIATED MEDICAL CONDITIONS

Intracranial aneurysms and their association with ADPKD have been described^[9,31]. There also may be increased risk for intracranial aneurysm, rupture, or dissection with ADPLD. Geevargheese and colleagues estimated the prevalence of intracranial aneurysms within this population to be 10%. Because cerebral aneurysms can be a source of morbidity and mortality in these patients, they recommended screening by magnetic resonance angiography (MRA) or computed tomographic angiography (CTA) in all patients with PCLD^[32]. Also, Qian and coauthors reported an association between ADPLD and increased risk for intracranial aneurysms. In their cohort, six percent of patients with genetically confirmed ADPLD were found to have either intracranial aneurysm or dissection^[33]. Although there are no definitive recommendations, these reports should encourage screening radiography and treatment prior to any surgical intervention for their PCLD.

Other associated medical conditions with ADPKD and ADPLD that clinicians should be aware of are valvular

heart disease and pancreatic cysts. Classically, the valvular disease most frequently described has been mitral valve prolapse and mitral valve incompetence. In their clinical profile of ADPLD patients, Qian *et al* estimated that mitral valve prolapse occurred in up to 26% of ADPLD patients and mitral valve incompetence in up to 31% of this population^[33]. This indicates cardiac evaluation in patients with ADPLD. Finally, patients with ADPKD may have asymptomatic cysts within multiple organs, including the pancreas, spleen, ovaries, and lungs. Pancreatic cysts are the most common of the extrarenal cysts with a reported incidence of 9% among ADPKD patients over 30 years^[34-36].

THERAPEUTIC OPTIONS FOR APLD

The primary aims of surgical therapy for polycystic liver disease should be to significantly reduce the size of the polycystic liver without compromising liver function, and to provide long-term relief of symptoms. There is no clear consensus regarding the optimum timing of intervention and the surgical approach is based in part on the number, size, and location of the cysts. All patients should be carefully evaluated for significant symptoms and degree of disability, as well as the degree of hepatic and renal dysfunction that could affect morbidity and mortality. In addition, patients should be made aware of the risk and limitations of the surgery prior to proceeding with any surgical management.

In high risk patients and those with a large dominant cyst, percutaneous aspiration and sclerosis of cysts has been proposed as a feasible option but is associated with higher recurrence rates^[37-39]. Surgical options include: laparoscopic fenestration and/or resection, open fenestration and/or resection, and liver transplantation.

FENESTRATION

Prior to the advent of laparoscopic techniques, open fenestration was the standard therapy for patients with symptomatic PCLD. The technique of fenestration was first described by Lin and coauthors in 1968^[40]. This technique involves de-roofing and performing the widest possible excision of the cyst wall back to the interface of the liver parenchyma. This approach allows visualization, fenestration, and drainage of superficial and deeply seated cysts within the hepatic parenchyma and internal drainage within the peritoneal cavity. The site of fenestration must be carefully selected to avoid any bleeding or leakage of bile. Destruction of the fluid producing epithelial cyst lining, with cautery or Argon beam coagulation, may be helpful to reduce continual fluid loss from the fenestrated cysts. Patients, having type I PCLD, with superficial and large cysts of limited number are the best candidates for this procedure.

With the introduction of laparoscopy, there are increasing numbers of reports of laparoscopic fenestration of patients with PCLD^[24,25,41-46]. It can be performed with similar morbidity and mortality as the open fenestration, but this approach must be utilized in the appropriate population. Patients with majority of their cysts in segments VI, VII, and often VIII (when there is marked

hepatomegaly) and patients with deeply seated cysts that are difficult to visualize and fenestrate with laparoscopy may be better candidates for open fenestration. From the published series, these patients have a higher recurrence rate after laparoscopic fenestration due to the inability to adequately fenestrate all of their cysts^[42,43,46]. The 13 published series describing open and/or laparoscopic fenestration are summarized in Table 1.

Koperna and colleagues reported the largest series of patients who underwent open or laparoscopic fenestration for PCLD. In their series, thirty-nine out of forty-four patients underwent a fenestration (34 open and 5 laparoscopic) for their symptomatic polycystic liver disease, while the other four underwent hepatic resection. In their experience, those patients with multiple cysts of 5 cm or greater had a higher likelihood of recurrence as compared with patients having fewer and smaller cysts (27% *vs* 13%). They performed both techniques of fenestration with no mortalities and commented that the most common morbidity was post-operative ascites. They had a mean follow-up of seventy-five months with similar overall recurrence rates between the open and laparoscopic groups (13% *vs* 11%). They concluded that in the appropriate PCLD patients, laparoscopic fenestration should replace open fenestration because it has similar rates of success along with similar morbidity and mortality rates^[41]. Hepatic resection should be reserved for those patients with massive enlargement of the liver that would not benefit from simple fenestration. Combining all patients undergoing open or laparoscopic fenestration (Table 1), there was an overall high morbidity and low mortality rate of 30% and 1%, respectively. Despite an adequate fenestration, there is a moderate recurrence of symptoms and rate of re-operation (Table 1). There must be a careful evaluation of the extent of each patient's disease to determine whether fenestration alone or resection with fenestration should be recommended.

HEPATIC RESECTION WITH FENESTRATION

The combination of hepatic resection with fenestration appears to be a valuable option for those patients with symptomatic PCLD and more severe parenchymal involvement. Most of these patients are classified as Type II or III PCLD, based on Gigot's classification^[25]. Fenestration alone in this group is rarely successful because the liver parenchyma is more rigid due to the fibrosis around the cysts and the cysts do not collapse as expected after fenestration. However, combined fenestration and resection allows for the removal of multiple segments that are grossly affected and allows for reduction in liver mass. Likewise, the large superficial and deep-seated cysts within remnant segments with more normal parenchyma can also undergo fenestration. The 10 published series are reviewed in Table 2.

The largest experience is reported by Que *et al* in a long-term follow up of 31 patients. The majority of the patients in this group had more severe parenchymal involvement (type II and III PCLD) necessitating resection combined with fenestration. The extent and type of liver resection depended on severity of disease with 13 patients undergoing lobectomies, 2 undergoing extended liver resections, and 16 non-anatomic liver resections. An average of 4 liver segments were resected per patient with an average weight of the resected tissue being 3.9 kg (8.6 lbs)^[23]. Their mortality rate was 3% which is consistent with the other larger reported series which range from 3%-10% (Table 2). Despite a low mortality rate, the morbidity rates associated with this procedure are high and must be considered. This series reported a morbidity rate of 58%, while in other series the morbidity rates range from 20% to 100%. The most commonly reported morbidities are ascites, pleural effusions, transient biliary leaks, bleeding, and wound

infection^[2,43,47-52]. Que and coauthors had excellent results with an extremely low recurrence rate with 30 out of 31 patients remaining asymptomatic at a median follow-up of 28 mo. Importantly, they felt the extent of resection and fenestration was important for good long term outcomes. Overall, most of these patients had an improvement in their quality of life and functional status without deterioration in their hepatic or renal function^[23]. Although there are high morbidity rates, resection and fenestration provides patients' with severe parenchymal involvement an opportunity for symptomatic and clinical improvement with an acceptable recurrence rate.

LIVER TRANSPLANTATION

Liver transplantation as treatment for advanced PCLD, while more accepted in recent literature, still has a limited role in management of these patients. Although a majority of PCLD patients have normal liver function, orthotopic and living donor liver transplantation have been successfully utilized in the treatment of symptomatic PCLD^[53-64]. Aspiration, fenestration, or surgical resection can provide adequate palliation to those patients with large single cysts or dominant disease in one lobe, but the treatment of small, truly diffuse, cystic type PCLD may well require transplantation. Total hepatectomy and liver transplantation offers the chance of definitive treatment for this disease, but may be considered drastic, considering the absence of liver failure, the potential morbidity and mortality, and the organ shortage. In their early report of transplantation for PCLD, Starzl and colleagues described a "syndrome of lethal exhaustion" as the major indication to offer transplantation to these patients^[53]. These patients often reach the end of their functional lives, have intractable pain, and have a severely diminished quality of life. Indications for transplantation include cachexia, weight loss, recurrent cyst infections, portal hypertension, and ascites. Early reports have proposed these patients not wait until end-stage complications of their PCLD become manifest before offering the option of transplantation^[56,58,59]. Transplantation in those with end-stage PCLD, exhibited by severe disability, weakness, and malnutrition, has been shown to have higher infection-related mortality in early liver transplant series^[56,59]. Performing earlier

transplantation in appropriate candidates would seem to offer a greater chance of improved outcomes, meaningful recovery, and return to their prior functional status and quality of life. Furthermore, patients who have undergone prior more conservative therapies (aspiration, sclerosis, fenestration, or resection) may have post-surgical changes that make transplantation much more difficult^[53,58,59].

The option of transplantation should be balanced against the risks of surgery, long-term immunosuppression, and the need for concurrent or subsequent renal transplantation in those with ADPKD. Thus, transplantation should be limited to those patients with Type II/III PCLD with diffuse, small cystic disease that would not benefit from previously described therapies. Although the first reports of transplantation for PCLD by Kwok *et al*^[65] and Starzl *et al*^[53] occurred in the early 1990's, eleven to reflect studies in Table 3 describing transplantation for PCLD (Table 3). Two of the largest series reported by Lange *et al* and Pirenne *et al* report the outcomes of transplantation for PCLD in 17 and 16 patients, respectively^[56,59]. Lang and coauthors reported symptomatic relief in all patients following transplantation; however they did have 5 mortalities (29%) in their series. All five of these patients had severe anorexia, physical exhaustion, and evidence of malnutrition from end-stage PCLD prior to transplant and had postoperative infectious complications leading to their mortality. These deaths occurred at a mean of 41 d^[56]. Pirenne and colleagues reviewed their experience of 16 patients undergoing liver transplantation for severe PCLD. They reported two mortalities (12.5%): one intra-operative death from bleeding and air emboli in a patient who had undergone previous resection, and a second late death from post-transplant lung cancer. Patient and graft survival rates were 87.5% with follow-up from 3 mo to 10 years^[59]. In summary, liver transplantation offers the chance of immediate, complete, and definitive treatment in those patients with massive hepatomegaly secondary to diffuse PCLD. In these patients, fenestration and resection only offers temporary palliation, puts them at risk for potential morbidity and mortality, and jeopardizes the chances of further definitive treatment by transplantation. Several other series and their results are

reviewed in Table 3.

As more patients undergo transplantation for PCLD, it is important to assess their long term outcomes, especially quality of life. Kirchner and colleagues reviewed the quality of life, *via* the SF-36 and a self-designed questionnaire, in 23 of 36 patients who underwent liver or combined liver-kidney transplantation for PCLD. Of the respondents, 91% of patients felt “much better” or “better”, while only 9% felt “worse” than before. Fatigue, physical fitness, anorexia, vomiting, physical attractiveness, and interest in sex improved significantly after transplantation. Overall, patients with advanced PCLD have an improved quality of life after liver or combined liver-kidney transplantation^[66].

CONCLUSION

The management of patients with PCLD continues to be challenging. In the past several decades, there have been great advances in the knowledge of the pathogenesis, genetics, and effective treatment for PCLD. Understanding this disease, potential complications, associated medical conditions, and successful treatment strategies is essential for gastroenterologists and hepatobiliary surgeons. The ability to risk-stratify these patients by severity of disease can lead to earlier interventions and attempts at prevention of massive hepatomegaly that can be so debilitating. In patients with symptomatic PCLD, invasive management strategies should be based on the degree of symptoms, the severity of associated medical conditions, and the extent of their disease. Those symptomatic patients with large cysts or limited hepatic involvement would likely benefit from laparoscopic fenestration. Adequate hepatic resection with fenestration should be favored in patients with diffuse involvement of certain areas of hepatic parenchyma with remaining large areas of non-cystic parenchyma. Finally in the patient with diffuse, small cysts, transplantation is a valid option and should be pursued as primary therapy prior to development of debilitating disease that can increase complication rates.

GASTRIC CANCER

Rationales for expression and altered expression of apoptotic protease activating factor-1 gene in gastric cancer

He-Ling Wang, Han Bai, Yan Li, Jun Sun, Xue-Qing Wang

Received: May 20, 2007 Revised: June 18, 2007

Abstract

AIM: To elucidate the relationship between apoptotic protease activating factor-1 (Apaf-1) gene and gastric cancer.

METHODS: Thirty-five postoperative cancer and adjacent normal tissue samples were collected in the present study. Expression of the Apaf-1 gene in these samples was analyzed by semi-quantitative RT-PCR. Loss of heterozygosity (LOH) was used to determine whether there was loss of Apaf-1 gene in domain of 12q22-23 in the samples. Promoter methylation of Apaf-1 gene in the samples was analyzed by methylation specific (MSP) PCR.

RESULTS: The expression of Apaf-1 mRNA in gastric cancer tissue samples was 51%. The LOH frequency of D12S346, D12S1706, D12S327, D12S1657 and D12S393 was 33%, 8%, 58%, 12% and 42%, respectively. Fifty percent LOH was found at two sites and 17% LOH at three sites. Apaf-1 mRNA expression decreased significantly in 13 cases ($r_s = 0.487$, $P = 0.003$). The rate of Apaf-1 promoter methylation was 49% in gastric cancer tissue samples and 23% in para-cancerous tissue samples. Promoter methylation occurred significantly in 16 of 18 gastric cancer tissue samples with decreased expression of Apaf-1 mRNA ($r_s = 0.886$, $P = 10^{-6}$).

CONCLUSION: The expression of Apaf-1 gene is low in gastric cancer tissues. Methylation of Apaf-1 gene promoter and LOH in domain of 12q22-23 are the main reasons for the expression and altered expression of Apaf-1 gene.

INTRODUCTION

Formation and progression of gastric cancer are a continuous multiple-step process. Cell apoptosis is one of the main mechanisms for tumor genesis^[1-3], and Apaf-1 protein is an important apoptosis factor which is expressed abnormally in a series of tumor studies^[4-7]. It was recently reported that Apaf-1 gene is closely related to several cancer-inducing genes and tumor suppressor genes, such as p53 and Bcl2^[8-10]. However, the expression condition of Apaf-1 gene in gastric cancer and its correlation with the genesis of gastric cancer remain unclear. This study was to study the relation between Apaf-1 gene expression and gastric cancer genesis in promoter domain.

MATERIALS AND METHODS

Materials

Thirty-five postoperative cancer tissue and adjacent normal tissue samples (> 5 cm away from the center of cancer) were collected from gastric cancer patients from January 2005 to September 2005 at No.1 and No.2 Affiliated Hospitals of China Medical University. All these patients were pathologically diagnosed according to the new TNM classification criteria of Union Internationale Contre le Cancer^[11]. Of the 35 patients with progressive gastric cancer (25 males and 10 females with a mean age of 58.51 ± 12.24 years), 10 had moderately differentiated gastric cancer and 25 had poorly-differentiated gastric cancer, while 25 had lymphatic metastasis and 10 had no lymphatic metastasis. Tumor and adjacent normal tissues were isolated and maintained at -70°C . Total RNA extracting reagent Trizol (Invitrogen Co.), RT-PCR kit (TaKaRa Co.), methylating reagent (Sigma Co.) and Wizard DNA clean-up (Promega Co.) were used in the study.

Semi-quantitative RT-PCR analysis

Total RNA was extracted with Trizol reagent and cDNA

was synthesized with reverse transcriptase and Oligo (dT)₂₀ primer. Apaf-1 primer sequence was designed with primer 3, including functional caspase recruitment domain (CARD), upstream primer (5'-TTGCTGCCCTTCTCC ATG AT-3'), downstream primer (5'-TCCCAACTGAAA CCCAATGC-3') and amplification length (334 bp). The internal reference primer was β -actin, including upstream primer (5'-GTGGGGCGCCCCAGGCACCA-3'), downstream primer (5'-CTCCTTAATGTCACGCAC GATTTC-3') and amplification length (498 bp). Both pairs of primers were added into 25 μ L reaction system to react under the proper PCR reaction conditions (denatured at 94°C for 45 s, renatured at 58°C for 45 s and elongated at 72°C for 60 s, for 35 cycles). RT-PCR products were isolated with 2% agarose gel, imaged through Alpha Image 2000 automatic imager and analyzed using Fluorchem V 2.0 Stand Alone software.

LOH analysis

Down-regulation of Apaf-1 gene expression was correlated with allele loss at its 5 sites (D12S327, D12S1657, D12S393, D12S1706 and D12S346). These 5 polymorphic sites were selected for LOH analysis. DNA was extracted from tumor and normal tissues using phenol/chlorine method. Primer sequences derived from genome database (GDB) and amplification conditions are listed in Table 1. Two percent agarose gel electrophoresis revealed target genes but no hybrid band in each specimen. PCR products were added into the denaturing buffer (98% formamide, 10 mmol/L EDTA, 0.025% bromophenol blue and 0.025% xylene cyanol) at a ratio of 1:1, mixed uniformly, denatured at 97°C for 10 min and immediately placed into ice. Fifteen μ L of specimens was loaded in each hole, separated through 9% non-denaturing PAGE (in a 100 V low-temperature water bath for 2-3 h) and the electrophoresis results were analyzed through silver staining.

Methylation analysis at Apaf-1 promoter domain

DNA extracted from gastric cancer and adjacent normal tissues was treated with Na₂SO₃, purified and recovered with Wizard DNA clean-up (Promega Co.) for MSP analysis. A 49-378 base zone rich in CpG at Apaf-1 cDNA promoter domain was selected to design MSP primers, including upstream primer (5'-GAGGTGTCGTAG CCGTATTTC-3'), downstream primer (5'-CGAAAATTA

ACGAAATAAACGTC-3'), PCR reaction conditions (denatured at 94°C for 45 s, renatured at 58°C for 45 s and elongated at 72°C for 60 s, for 38 cycles) and amplification length (221 bp). Methylating primers included upstream primer (5'-ATTTGAGGT GTGTAGTGGTATTT G-3'), downstream primer (5'-ACCTCCAAAAATTAACAA AATAAACAT-3'), PCR reaction conditions (denatured at 94°C for 45 s, renatured at 56°C for 45 s, elongated at 72°C for 60 s, for 38 cycles) and amplification length (221 bp).

Statistical analysis

Statistical analyses were performed by the SPSS13.0 software package (SPSS, Inc, Chicago, IL). Continuous Data were expressed as mean \pm SD. Continuous variables were compared by *t*-test when appropriate, whereas categorical variables were compared by χ^2 test or Fisher's exact test when appropriate. Spearman rank correlation was analyzed. *P* < 0.05 was considered statistically significant.

RESULTS

Gene expression

The gene expression was increased 30%-70% in cancer tissue samples with an increased difference between Apaf-1/ β -actin cDNA optical density ratios in gastric cancer and adjacent normal tissue samples. In the present study, Apaf-1 expression decreased in 48.57% (17/35) of gastric cancer tissue samples (including expression loss in 2 cases), paired *t* test with SPSS13.0 statistical software showed that the relative Apaf-1 content was 0.96 ± 0.40 in adjacent normal tissue samples and 0.69 ± 0.36 in cancer tissue samples, respectively (*t* = 3.518, *P* < 0.01), and Apaf-1 expression was significantly higher in adjacent normal tissue samples than in cancer tissue samples. Apaf-1 mRNA expression did not increase in tumor tissue samples (Figures 1 and 2).

LOH analysis

The data from 2 fragments (i.e. genome DNA was a certain marked heterozygote in normal tissue or adjacent normal tissue samples) were sufficient for LOH analysis, but the data from one fragment were not sufficient for LOH analysis. LOH meant that there was 1 band with less genome DNA PCR amplification product or 1

band with significantly weaker signal of up to 50% in cancer tissue samples than that in adjacent normal tissue samples. As shown by LOH analysis of 5 polymorphic sites for Apaf-1 gene in the present study, the LOH detection rate was 34.29% (12/35), 8.57% (3/35), 57.14% (20/35), 11.43% (4/35) and 42.86% (15/35) at single D12S346, D12S1706, D12S327, D12S1657 and

D12S393, respectively. However, the LOH detection rate was 51.43% (18/35) at more than 2 sites (16.67% at 3 sites) (Figure 3), suggesting that the LOH of Apaf-1 gene was correlated with the genesis of gastric cancer. Apaf-1 mRNA expression decreased significantly in 13 cases ($r_s = 0.487$, $P = 0.003$), indicating that the LOH of Apaf-1 gene was correlated with its decreased expression in gastric cancer (Table 2 and Figure 3).

Promoter methylation

MSP analysis of methylation conditions for Apaf-1 gene promoter showed that the methylation rate of Apaf-1 gene was 48.57% (17/35) in gastric cancer tissue samples and 17.14% (6/35) in adjacent normal tissue samples, respectively ($P < 0.05$), demonstrating that Apaf-1 methylation was correlated with the genesis of gastric cancer. Significant promoter methylation occurred in 16 of 18 gastric cancer tissue samples while the expression of Apaf-1 mRNA was decreased ($r_s = 0.886$, $P = 10^{-6}$), displaying that promoter methylation was correlated with decreased expression of Apaf-1 gene (Table 3 and Figure 4). Promoter methylation and LOH of Apaf-1 gene occurred at polymorphic sites in 17 of 18 gastric cancer tissue samples and the expression of Apaf-1 mRNA was decreased.

DISCUSSION

Human Apaf-1 gene is located at chromosome 12q23 to

encode cytoplasm protein (130 KD). As an important apoptosis factor, Apaf-1 gene participates in the pathway of mitochondria-mediated apoptosis^[12]. However, the condition of Apaf-1 gene expression in gastric cancer and the correlation between expression of Apaf-1 gene and genesis of gastric cancer remain unclear. Although Apaf-1 is an important apoptosis factor and a tumor suppressor gene^[12-16], few studies on the relationship between Apaf-1 gene and gastric cancer are available.

In the present study, Apaf-1 gene expression in gastric cancer tissue samples was significantly lower than that in adjacent normal tissue samples, suggesting that Apaf-1 gene plays an important role in genesis and progression of gastric cancer.

According to the epigenetics theory on gene regulation, methylation of gene fragments (especially promoter domain) inhibits gene transcription, and acetylation of gene-related histone up-regulates gene expression. One of the carcinogenic mechanisms is gene silencing caused by hyper-methylation of CpG islet at tumor suppressor gene promoter domain and deacetylation of histone^[17-23]. It was reported that Apaf-1 gene is a tumor suppressor gene and seldom mutates, but has functional loss due to LOH and promoter methylation^[24]. Apaf-1 gene has different effects and expression patterns in cancer tissue of different sources. The lower (or inactive) expression of Apaf-1 gene is related to methylation silencing in acute leukemia and laryngeal squamous carcinoma^[24,25], and LOH in colon cancer, ovarian cancer and malignant melanocarcinoma^[26-28].

In the present study, Apaf-1 gene promoter was methylated in 14 gastric cancer tissue samples with a decreased expression of Apaf-1 as detected by the MSP technique. Apaf-1 expression decreased in 13 gastric cancer tissue samples with LOH at more than 2 sites (including promoter methylation in 6 cases) as demonstrated by 9% non-denaturing PAGE. These findings show that decreased expression of Apaf-1 gene in gastric cancer tissue is due to some complex reasons, among which, however, promoter methylation and LOH at polymorphic sites play a major role.

COMMENTS

Background

The expression condition of Apaf-1 gene in gastric cancer and its correlation with the genesis of gastric cancer remain unclear. The purpose of this study was to make it clear.

Research frontiers

The epigenetics theory on gene regulation is the highlight in recent tumor studies. This article describes the role of Apaf-1 gene eigenetics in gastric cancer.

Innovations and breakthroughs

This article focuses on the Apaf-1 expression condition in gastric cancer, and its relation with loss of heterozygosity and methylation in promoter domain.

Applications

Apaf-1 gene is an important apoptosis gene. Its status of methylation and LOH may contribute to the study on the etiology of gastric cancer.

Terminology

Methylation is a term used in chemical sciences to denote the attachment or substitution of a methyl group on various substrates. DNA methylation profiling

is gaining momentum as an epigenetic approach to understanding the effects of aberrant methylation (either hyper- or hypomethylation) both in basic research and in clinical applications.

Peer review

Low expression of Apaf-1 gene in gastric cancer tissue was shown in this study, indicating that methylation of Apaf-1 gene promoter and LOH in domain of 12q22-23 are the main reasons for expression and altered expression of Apaf-1 gene in gastric cancer

Abstract

AIM: To study the mechanism involved in the potentially beneficial effect of ultra low dose aspirin (ULDA) in prehepatic portal hypertension, rats were pretreated with selective COX 1 or 2 inhibitors (SC-560 or NS-398 respectively), and subsequently injected with ULDA or placebo.

METHODS: Portal hypertension was induced by portal vein ligation. Platelet activity was investigated with an *in-vivo* model of laser induced thrombus production in mesenteric circulation and induced hemorrhagic time (IHT). Platelet aggregation induced by ADP and dosing of prostanoid products 6-keto-PGF_{1α}, TXB₂, PGE₂ and LTb₄ were also performed.

RESULTS: The portal hypertensive group receiving a placebo showed a decreased *in vivo* platelet activity with prolonged IHT, an effect that was normalized by ULDA. SC-560 induced a mild antithrombotic effect in the normal rats, and an unmodified effect of ULDA. NS-398 had a mild prothrombotic action in portal hypertensive rats, similar to ULDA, but inhibited a further effect when ULDA was added. An increased 6-keto-PGF_{1α} was observed in portal hypertensive group that was normalised after ULDA administration. TXA₂ level after ULDA, remained unchanged.

CONCLUSION: These results suggest that the effect of ULDA on platelet activity in portal hypertensive rats, could act through a COX 2 pathway more than the COX 1, predominant for aspirin at higher doses.

INTRODUCTION

Portal hypertension is a major complication of chronic liver disease. In its pathophysiology, increased hepatic resistance is followed by a hyperdynamic circulatory state^[1]. This hyperdynamic state, in which nitric oxide (NO) and prostacyclin (PGI₂) are important vasoactive substances, induces a decreased platelet activity, even in the absence of hepatic damage. Although NO plays an important role in modifying platelet adhesion in portal hypertension^[2], PGI₂, a powerful vasodilator prostanoid with antithrombotic properties, was also found increased in mesenteric vascular bed^[3].

Ultra low dose aspirin (ULDA) has shown prothrombotic activity when analysed in humans and in the interface platelet-endothelial cell^[4,5]. Previous papers have shown the potentially beneficial effect of ULDA in portal hypertensive animals normalizing altered platelet activity and induced hemorrhagic time^[6]. Further experiments were performed to clarify if this effect was mediated mostly by a cyclooxygenase (COX) pathway or by modifying NO synthesis, the two aspirin mechanisms of action^[7], although a previous study with a different model suggested that ULDA could decrease PGI₂ synthesis^[8]. The same *in vivo* Laser induced thrombus formation, was used in portal hypertensive rats to investigate the effects of Indomethacin, a non selective COX inhibitor, and L-Nitro Arginin Methyl Ester (NAME), a non selective inhibitor of NO production. The results suggested that the effects of ULDA were more influenced by COX pathway than by NO synthesis inhibition^[9]. Addition of ULDA in portal hypertensive rats, when previously inhibiting COX with Indomethacin, increased number of emboli and duration

of embolization but blunted the normalization of induced hemorrhagic time, suggesting probably a more selective action on COX 1 or COX 2 pathway. TXA₂, the main product of arachidonic acid *via* the activity of COX 1 in platelets, increases platelet aggregation and its synthesis is inhibited by Aspirin. PGE₂ and PGI₂ are produced by COX 1 and 2 mainly in endothelial cells. PGE₂ has no probable role in portal hemodynamic changes observed in portal hypertensive rats^[10], but depending on its concentration, it can modulate platelet aggregation by regulating intracellular levels of cAMP^[11].

The present investigation was designed to clarify the mechanism of the effects of ULDA in portal hypertension, by using previous selective inhibition of cyclooxygenase COX 1 or COX 2 (with SC-560 and NS-398 respectively). Models of Laser induced Thrombosis and IHT were used and plasmatic levels of 6-keto-PGF_{1α} (the stable metabolite of PGI₂), PGE₂, TXB₂ (the stable metabolite of TXA₂) and LTB₄ were determined.

MATERIALS AND METHODS

Animals

Male Wistar rats (200-250g) purchased from Delpre Breeding Center (St. Doulchard, France) were housed separately and acclimatized before use under conditions of controlled temperature (25 ± 2°C) and illumination (12 h light/dark cycle). They were fed with standard rat chow and water *ad libitum*. Animals received care in compliance with the European Convention of Animal Care.

Surgical procedures

After one week of acclimatization, rats were randomized and separated into two groups: one consisted of sham-operated (Sh) rats and the other formed by portal hypertensive (PH) rats. Portal hypertension was induced by a calibrated portal vein stenosis, according to the procedure described by Vorobioff *et al*^[1].

Rats were anesthetized with Ketamine (Panpharma, Fougères, France) 90 mg/kg body weight, i.m. and then a midline abdominal incision was made. The portal vein was located and isolated from the surrounding tissues. A ligature of 3-0 silk was placed around the vein and snugly tied to a 20 gauge blunt end needle placed along side the portal vein. The needle was subsequently removed to yield a calibrated stenosis of the portal vein. Sham-operated rats underwent an identical procedure except that portal vein was isolated but not stenosed.

Animals were housed during fourteen days after the operation to develop portal hypertension in the corresponding group.

Thrombus induction

Animals were anaesthetized with 200 mg/kg of thiopental sodium (Pentothal[®], Laboratories Abbott, Rungis, France) a median laparotomy was performed. The intestinal loop was placed on the microscope table and vascular lesions were induced by Argon laser (Stabilite 2016, Spectra Physics, France). The wavelength used was 514 nm and the energy was adjusted to 120 mW. The laser beam was

applied during 1/15 s. The dynamic-course of thrombus formation was continuously monitored and recorded by placing the laser beam coaxially into the inverted light beam path of the microscope (Axiovert, Zeiss, France). Microscopic images were recorded through a digital camera (DX L107, color camera CCD, Basler, Vision Technologies) to visualize and digitalize data coupled to a Dell monitor. A schematic view of the apparatus used has been previously described^[12]. Arterioles between 15 and 25 μm diameter were used. The parameters assessed were the number of emboli removed by blood flow and the duration of embolisation (time between the first and the last emboli occurring during a 10 min observation period).

Induced hemorrhagic time

An experimental model of induced hemorrhagic time (IHT) was performed 10 min before thrombosis induction by laser. The tail of the rat was immersed in water for 5 min at 37°C and sectioned 6 mm from the extremity. IHT measured, corresponded to the time between the tail section and the end of bleeding, expressed in seconds.

Biological analysis

Platelet aggregation study: Platelet aggregation was made according to the method of Cardinal and Flower on a Chrono Log 500 *V/S* aggregometer (Coultronics, Margency, France) on the whole blood obtained from the rat after laser experimentation. Platelet aggregation was induced by ADP final concentration 5 μmol/L (Laboratoire Diagnostica, Stago, France). Two parameters were determined: Impedance, representing the maximum amplitude of aggregation expressed in Ohms. Velocity of aggregation expressed in ohms/min.

Prostanoids determinations: At the end of each experiment, blood was collected by cardiac puncture and centrifuged for 20 min at 4000 r/min to obtain Platelet Poor Plasma (PPP). Concentrations of 6-keto-PGF_{1α}, TXB₂, PGE₂ and LTB₄ were determined in plasma samples using competitive binding Elisa tests (R&D Systems Europe, Abingdon, UK) according to the manufacturer's instructions.

Drugs tested

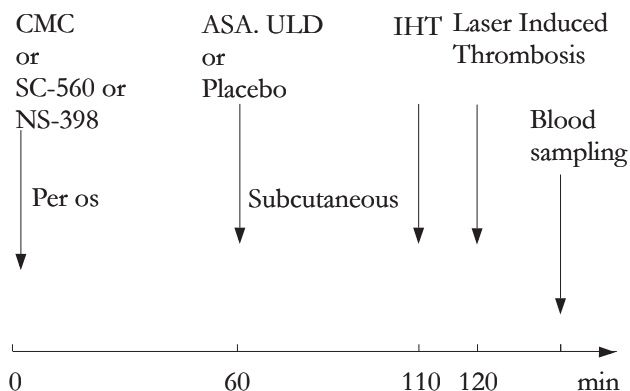

The Aspirin solution was purchased from Boiron Laboratories (Sainte-Foy-Les-Lyon, France). ULDA was prepared as follows: 1 g of pure, finely powdered aspirin was suspended in 99 mL of alcohol (70°). After being vigorously shaken, 1 mL of this dilution was then mixed with 99 mL of distilled water and vigorously shaken. The last process was repeated 13 more times^[11]. Alcohol and sterilized water following the above cited procedures without adding the Aspirin was used as control. ULDA or placebo were subcutaneously administered at a final volume of 1 mL/kg rat weight.

Selective inhibitors of COX 1, SC-560 and of COX 2, NS-398 were purchased from Cayman Chemical, (Ann Arbor Michigan, USA). They were administered per os at a dose of 10 mg/kg rat weight, suspended in Carboxymethylcellulose (CMC) 5 g/L at a final volume

of 1 mL/kg rat weight. The CMC solution was used as placebo.

Protocol

Fourteen days after the corresponding operation, 216 rats were randomly assigned in 12 groups and treated as follows:

Groups

Groups, procedures and treatments are detailed in Table 1.

Statistical analysis

Data are expressed as mean \pm SEM and compared using one way analysis of variance (ANOVA) followed by Bonferroni multiple comparison test. A value of $P < 0.05$ was considered significant. Statistical calculations were performed using GraphPad Prism version 4.00 for Windows (GraphPad Software, San Diego California USA, www.graphpad.com).

RESULTS

Thrombus induction and IHT

Groups with placebo (CMC): Portal hypertension decreased the number of emboli ($P < 0.05$) and the duration of embolisation ($P < 0.05$) and prolonged the Induced Hemorrhagic Time ($P < 0.01$). ULDA induced significant modifications to normalize these values ($P < 0.01$, $P < 0.001$ and $P < 0.001$ for Number of Emboli, Duration of Embolisation and IHT respectively). An increased number of shots needed to start the embolisation was observed in the portal hypertensive group, and this effect also normalised after ULDA ($P < 0.05$).

Effects of SC-560, selective inhibitor of COX 1: After the inhibition of COX 1, a non significant antithrombotic effect was observed in the sham operated group, and no further change in cirrhotic group. After ULDA, the prothrombotic effect remained active for Number of Emboli ($P < 0.05$) and IHT ($P < 0.01$) despite the opposite effect of pre-treatment with SC-560. No changes were observed in number of shots.

Effects of NS-398, selective inhibitor of COX 2: The pre-treatment with NS-398 induced a decreased induced hemorrhagic time in portal hypertensive rats, similar to the effect of ULDA without COX inhibitors. No effect of ULDA was seen after COX 2 inhibition (Figure 1A-D).

Table 1 Experimental groups

Group	Procedure and treatments		
	Phase 1: 14 d before treatments	Phase 2: 120 min before experiment	Phase 3: 60 min before experiment
ShP	Sham operated	Placebo (CMC)	Placebo (H ₂ O)
PHP	Portal hypertension	Placebo (CMC)	Placebo (H ₂ O)
PHPAs	Portal hypertension	Placebo (CMC)	ULDA
ShP	Sham operated	SC-560	Placebo (H ₂ O)
PHP	Portal hypertension	SC-560	Placebo (H ₂ O)
PHPAs	Portal hypertension	SC-560	ULDA
ShP	Sham operated	NS-398	Placebo (H ₂ O)
PHP	Portal hypertension	NS-398	Placebo (H ₂ O)
PHAs	Portal hypertension	NS-398	ULDA

ULDA: Ultra low dose aspirin; CMC: Carboxymethylcellulose; ShP: Sham-placebo; PHP: Portal hypertension-placebo; PHPAs: Portal hypertension-ULDA.

Biological analysis

Platelet aggregation induced by ADP (Figure 2A and B): Platelet aggregation has shown a decreased velocity in portal hypertensive animals and in sham operated animals pretreated with SC-560. An increased velocity was observed in portal hypertensive animals pretreated with SC-560 or NS-398 and with ULDA. None of the observed alterations were found in Amplitude and in Velocity.

Variations in metabolites of arachidonic acid (Figure 3A-D): 6 keto PGF_{1α} (Figure 3A): This stable metabolite of PGI₂ was found increased in portal hypertensive rats ($P < 0.01$). This increase was normalised by ULDA ($P < 0.05$) or SC-560 ($P < 0.05$).

TXB₂ (Figure 3B): Inhibition of COX 2 with NS-398 produced an increased level of TXB₂ in portal hypertensive animals (XI group), that was not modified by ULDA ($P < 0.05$ and 0.001 respectively).

PGE₂ (Figure 3C): An increase in PGE₂ was observed in portal hypertensive (PHP) group, treated with SC-560 ($P < 0.05$).

LTB₄ (Figure 3D): Dosage of LTB₄, a lipoxygenase (LOX) metabolite of arachidonic acid, was performed as control of experiment. No variations of production were found when comparing the different groups.

DISCUSSION

ULDA has shown prothrombotic effects with an *in vivo* model, testing the interaction between platelet and endothelial cells^[5,12]. Exploration of this effect in portal hypertensive rats revealed a decreased number of emboli as well as duration of embolisation and a prolonged IHT that were normalised by ULDA administration. In the search of an explanation for the mechanism involving this effect, previous publications of L-NAME (an inhibitor of Nitric Oxide synthesis) and Indomethacin (a nonselective COX inhibitor) effects on portal hypertensive rats showed that the effect of ULDA was more affected by Indomethacin than by NAME⁹. Moreover, Indomethacin seemed to

have contradictory effects. Despite the antithrombotic effect of Indomethacin, the *in vivo* prothrombotic effect of ULDA (increasing number of emboli and duration of embolization) was increased, and its beneficial effect of reducing IHT in portal hypertensive rats was blocked. The present experiment was done to verify the hypothesis that these contradictory modifications produced by Indomethacin over ULDA's prothrombotic effect were the result of different ways in which COX 1 and 2 could affect

platelet-endothelial cell interaction.

The results found in this study corroborate the previously described effects of ULDA in portal hypertensive rats, normalizing number of emboli, duration of embolisation and the IHT^[6,9].

In rats with portal hypertension, an increase in 6-keto $\text{PGF}_{1\alpha}$ was observed, probably due to the known increased PGI_2 production described for the mesenteric vascular bed in this animal model^[3]. The addition of ULDA normalised this effect. As reported in an *in vitro* model with a vascular fragment, ULDA was active only in vascular fragments with an elevated PGI_2 production^[8]. This last observation is similar to our present results since the ULDA effect of decreasing 6-keto $\text{PGF}_{1\alpha}$ is observed only in the portal hypertensive group.

The administration of SC-560, had a slightly antithrombotic effect in sham operated rats, decreasing non significantly the Number of Emboli. This could be explained by a decrease in platelet synthesis of TXA_2 ^[13]. There was a decrease in 6-keto $\text{PGF}_{1\alpha}$ in the portal hypertensive group with COX 1 inhibition, and this effect is probably due to the inhibition of the increased production of PGI_2 ^[14,15] and COX 1 over-expression observed in this model of portal vein ligation^[16-18]. It is interesting to note that COX 1 inhibition had almost not modified the prothrombotic effect of ULDA in portal hypertensive animals and observed as an increase in number of emboli ($P < 0.05$) and a decrease in IHT ($P < 0.01$).

The administration of NS-398 had not modified the *in vivo* parameters (NE, DE and IHT) in the Sham operated group. In the portal hypertensive group, a non significant tendency to increase NE and DE was observed, as well as a statistically significant shortened IHT. After pre-treatment

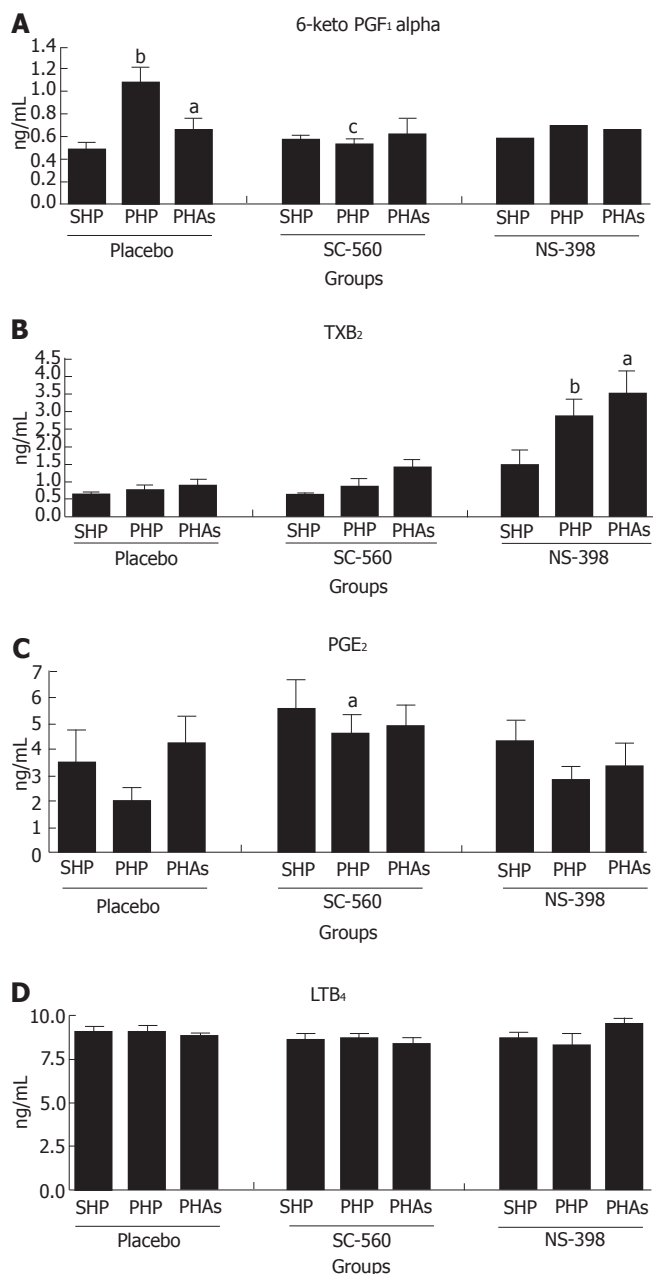

Figure 3 A: Plasmatic 6-keto PGF₁α concentrations (expressed in ng/mL): ^b*P* < 0.01 vs SHP (placebo); ^a*P* < 0.05 vs PHP (placebo); ^c*P* < 0.05 vs PHP (placebo); B: Plasmatic TXB₂ concentrations (expressed in ng/mL): ^b*P* < 0.001 vs PHP (placebo); ^a*P* < 0.05 vs SHP (NS-398) and *P* < 0.001 vs PHAs (placebo); C: Plasmatic PGE₂ concentrations (expressed in ng/mL): ^a*P* < 0.05 vs PHP (placebo); D: Plasmatic LTB₄ concentrations (expressed in ng/mL).

with the selective COX 2 inhibitor, NS-398, ULDA induced no further effect. There is an increase in TXB₂ in the portal hypertensive group with COX 2 inhibition, in which a decreased IHT was observed. Factors like trauma-hemorrhage, shear stress and pressure variations or lipopolysaccharide can modify TXA₂ synthesis in the liver or in endothelial cells^[19-21]. The increased TXB₂ was not modified by treatment with ULDA. It is interesting to have, in the portal hypertensive group, an increased PGE₂ after COX 1 inhibition and an increased TXB₂ after COX 2 inhibition, as if upon COX selective inhibition, the cell switched to a prostanoid produced by the non inhibited COX enzyme.

The effect of ULDA was confirmed in this study with a prehepatic portal hypertension with a normal liver. Further research will clarify if this potentially beneficial effect is produced in rats with cirrhosis and ascities. Other complex interactions can not be evaluated by this study. For example, a recent publication has pointed out that chronic COX inhibition with Indomethacin enhances the collateral vascular responsiveness to Arginin-Vasopressin, which is also able to activate platelets^[22,23].

In conclusion, despite that COX 1 inhibition caused a mild antithrombotic effect in sham operated rats, the prothrombotic effect of ULDA was not modified. COX 2 inhibition induced a mild prothrombotic effect over portal hypertensive rats, similar to that observed with ULDA alone confirming data of literature^[24] and the addition of ULDA in this group produced no further changes. ULDA induced a decrease in PGI₂ in portal hypertensive animals, without modifying TXA₂ levels. These results suggested a predominant COX 2 inhibition by ULDA, opposite to the predominant inhibition of COX 1 commonly observed with ASA in usual doses.

COMMENTS

Background

Ultra Low Dose Aspirin (ULDA) has shown prothrombotic properties capable of normalizing altered platelet function found in portal hypertension. This effect is clearly the opposite of the actual main use of Aspirin as an antithrombotic drug.

Research frontiers

The mechanism of this effect is unknown, but previous publications show changes in this effect after pretreatment with Indomethacin, a widely used non-selective COX inhibitor.

Innovation and breakthroughs

Only inhibition of NO synthesis, and perhaps Vasopressin has shown this property of modifying platelet alterations in portal hypertension.

Applications

ULDA could be useful in patients with prehepatic portal hypertension to control or decrease bleeding complications.

Peer review

Aspirin is widely known as a more powerful inhibitor of COX 1 than COX 2. This is the first paper showing a positive effect of Aspirin in portal hypertension, based in a not yet explained inhibition of COX 2, rather than COX 1.

Abstract

AIM: To elucidate the mechanisms of hepatocyte preconditioning by H₂O₂ to better understand the pathophysiology of ischemic preconditioning.

METHODS: The *in vitro* effect of H₂O₂ pretreatment was investigated in rat isolated hepatocytes subjected to anoxia/reoxygenation. Cell viability was assessed with propidium iodide fluorometry. In other experiments, rat livers were excised and subjected to warm ischemia/reperfusion in an isolated perfused liver system to determine leakage of liver enzymes. Preconditioning was performed by H₂O₂ perfusion, or by stopping the perfusion for 10 min followed by 10 min of reperfusion. To inhibit Kupffer cell function or reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, gadolinium chloride was injected prior to liver excision, or diphenyleneiodonium, an inhibitor of NADPH oxidase, was added to the perfusate, respectively. Histological detection of oxygen radical formation in Kupffer cells was performed by perfusion with nitro blue tetrazolium.

RESULTS: Anoxia/reoxygenation decreased hepatocyte viability compared to the controls. Pretreatment with H₂O₂ did not improve such hepatocyte injury. In liver perfusion experiments, however, H₂O₂ preconditioning reduced warm ischemia/reperfusion injury, which was

reversed by inhibition of Kupffer cell function or NADPH oxidase. Histological examination revealed that H₂O₂ preconditioning induced oxygen radical formation in Kupffer cells. NADPH oxidase inhibition also reversed hepatoprotection by ischemic preconditioning.

CONCLUSION: H₂O₂ preconditioning protects hepatocytes against warm ischemia/reperfusion injury *via* NADPH oxidase in Kupffer cells, and not directly. NADPH oxidase also mediates hepatoprotection by ischemic preconditioning.

INTRODUCTION

The interruption of hepatic blood flow followed by reperfusion, called ischemia/reperfusion, causes liver injury in a number of clinical interventions such as liver transplantation, hepatic resection, abdominal surgery with hepatic vascular occlusion, and hypovolemic shock^[1-4]. Especially in liver transplantation, ischemia/reperfusion injury can lead to the primary dysfunction of liver allografts; still the most feared complication after liver transplantation because of the associated high mortality, and the fact that there is no treatment other than retransplantation^[5-7]. The pathophysiology and substantial mechanisms of hepatic ischemia/reperfusion injury are increasingly well understood, and recent studies have drawn attention to ischemic preconditioning as one therapeutic strategy to decrease any injury^[4,8-10]. Ischemic preconditioning is a phenomenon by which brief periods of ischemia followed by reperfusion render tissues

resistant to subsequent prolonged ischemia/reperfusion. This phenomenon was originally characterized in a canine model of myocardial ischemia^[11], and has since been recognized in hepatic injury after ischemia/reperfusion in animal models^[12-14], as well as in humans^[15-18].

We have recently reported that hepatoprotection of ischemic preconditioning in rats is mediated by reactive oxygen species (ROS) produced by Kupffer cells. Moreover, we have shown that hepatic pretreatment with a sublethal dose of H₂O₂ mimics the hepatoprotective effect of ischemic preconditioning^[19]. Since H₂O₂ is produced as a consequence of ROS metabolism, it may be possible that H₂O₂ resulting from ROS production in Kupffer cells directly affects hepatocytes, and induces their adaptive response to ischemia/reperfusion injury. Therefore, in this study we sought to elucidate the mechanisms of H₂O₂ preconditioning to better understand the pathophysiology of ischemic preconditioning. We report here that H₂O₂ preconditioning did not protect hepatocytes directly, but via Kupffer cells, as in ischemic preconditioning. We also noted that the activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase in Kupffer cells may play an important role in hepatoprotection of H₂O₂, as well as in ischemic preconditioning.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats weighing 180-240 g were maintained on a commercial pellet diet and water *ad libitum*, in a room under normal lighting conditions. All animals received humane care in compliance with our institutional and National Institutes of Health guidelines.

In vitro experiments

Isolation of hepatocytes: Rat hepatocytes were isolated and cultured as previously described^[20]. Rat livers were minced after perfusion with 0.8 mg/mL collagenase (type I; Worthington Biochemical Corporation, Lakewood, NJ, USA) through the portal vein. Hepatocytes were separated from non-parenchymal cells by centrifugation at $50 \times g$ for 2 min at 4°C. The viability of the collected hepatocytes was $\geq 95\%$, as determined by the trypan blue exclusion test. Hepatocytes were resuspended in William's E medium containing 100 mL/L fetal calf serum, 27 mmol/L NaHCO₃, 100 nmol/L insulin, and 10 nmol/L dexamethasone at pH 7.4. Hepatocytes were then plated on type I collagen-coated 96-multiwell plates (Asahi Techno Glass Corporation, Tokyo, Japan) at a density of 4×10^4 cells/well and incubated overnight in an atmosphere of 95% air/5% CO₂ at 37°C.

Treatment of isolated hepatocytes: Isolated hepatocytes were treated by incubation for 10 min at 37°C with 100 μ L Krebs-Ringer N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES) buffer (KRH) at pH 7.4 containing various concentrations of H₂O₂, and washed twice with KRH. We set doses of H₂O₂ up to 1 mmol/L in accordance with earlier liver perfusion experiments^[19]. Hepatocytes were then incubated in an anaerobic

chamber under anoxic conditions using an AnaeroPack (Mitsubishi Gas Chemical Corporation, Tokyo, Japan), and subsequently subjected to reoxygenation at 37°C. The oxygen concentration in the chamber decreased to $< 0.005\%$ within 30 min after insertion of AnaeroPack. Control hepatocytes were cultured under normoxic conditions for the same length of time at 37°C.

Cell viability assay: Cell viability was determined by propidium iodide fluorometry as previously described, with some modification^[21]. Hepatocytes were incubated in 100 μ L KRH containing 30 μ mol/L propidium iodide, after H₂O₂ treatment. Fluorescence from each well was measured immediately before anoxic incubation and then at given times after reoxygenation. Cell viability after reoxygenation was calculated, with final fluorescence corresponding to the 100% cell death obtained by addition of 350 μ mol/L digitonin. We used a Cytofluor S4000 fluorescence reader (Applied Biosystems, Stafford, TX, USA), employing 530 nm excitation and 645 nm emission filters.

Liver perfusion experiments

Preconditioning before warm ischemia/reperfusion injury: Rats were anesthetized intraperitoneally with 50 mg/kg pentobarbital sodium, and the abdomen was opened. Livers were perfused through the portal vein with Krebs-Henseleit bicarbonate buffer (KHB) saturated with 95% O₂ and 5% CO₂ at 30 mL/min for 10 min at 37°C. For H₂O₂ preconditioning, livers were perfused with KHB containing 1 mmol/L H₂O₂ for 10 min, and then perfused with KHB for 2 min to wash out H₂O₂, as previously described^[19]. For ischemic preconditioning, the perfusion was stopped for 10 min, followed by reperfusion for 10 min. In control rats, livers were manipulated similarly except for adding H₂O₂ or stopping the perfusion, respectively.

Drug treatments: In some rats, 20 mg/kg gadolinium chloride (GdCl₃; Wako Pure Chemical Industries, Tokyo, Japan) was injected intravenously at 24 h before H₂O₂ preconditioning, under light ether anesthesia to inhibit Kupffer cell function^[22,23]. GdCl₃ was dissolved in saline, and control rats were injected with the appropriate vehicle solution. The efficacy of GdCl₃ injection was confirmed by immunohistochemical staining of liver sections with anti-ED2 antibody in the preliminary experiments. In other rats, diphenyleneiodonium chloride (DPI; Sigma-Aldrich, St. Louis, MO, USA), an inhibitor of NADPH oxidase, at a final concentration of 10 μ mol/L, was added to the perfusate^[24] during H₂O₂ preconditioning, or the reperfusion period after ischemic preconditioning. Livers were then perfused with KHB for 10 min to wash out DPI. DPI was dissolved in dimethyl sulfoxide (DMSO) at 20 mmol/L. Livers of vehicle-treated rats were perfused with KHB containing 500 μ L/L DMSO during each preconditioning.

Warm ischemia/reperfusion: After H₂O₂ preconditioning or ischemic preconditioning, livers were stored in KHB

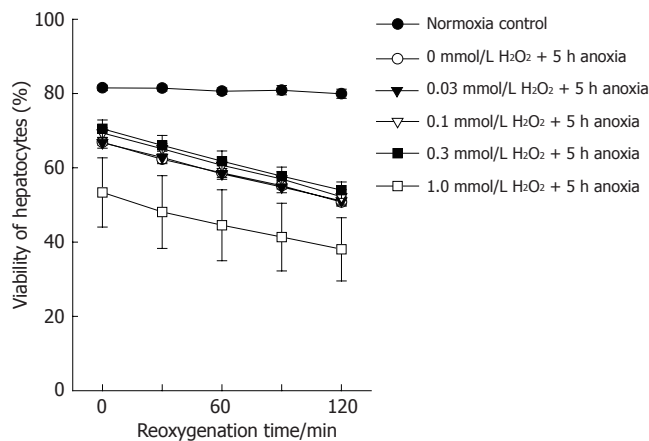

Figure 1 Viability of hepatocytes after anoxia/reoxygenation. (●): Viability of hepatocytes cultured under normoxia consistently. Viability of hepatocytes, pretreated with (○): 0 mmol/L; (▼): 0.03 mmol/L; (▽): 0.1 mmol/L; (■): 0.3 mmol/L; or (□): 1.0 mmol/L of H₂O₂ for 10 min before anoxia/reoxygenation.

at 37°C as previously described^[19]. After 40 min storage, livers were reperused in a recirculating system with 200 mL KHB saturated with 95% O₂ and 5% CO₂ at 37°C. The perfusate was collected after 60 min of reperfusion for determination of alanine aminotransferase (ALT) and lactate dehydrogenase (LDH) activity.

Biochemical assays: Commercial kits (Wako Pure Chemical Industries) were used to determine ALT and LDH activity in the perfusates.

Determination of oxygen radical formation in Kupffer cells after H₂O₂ preconditioning

Livers were perfused through the portal vein with KHB for 10 min, and then perfused with KHB containing 1 mmol/L H₂O₂ for 10 min. Subsequently, the livers were perfused with KHB containing 500 mg/L nitro blue tetrazolium (NBT; Sigma-Aldrich) for 10 min. Livers were then fixed by infusion of 10% formalin, embedded in paraffin, sectioned and stained with nuclear fast red. As formazan deposition is formed by the reaction of NBT with oxygen radicals in Kupffer cells, the number of formazan-positive cells was determined as the mean in 10 different areas of each section, observed by light microscopy at × 400 magnification (high power field).

Statistical analysis

All values are expressed as means ± SE. The difference between the means was analyzed with Student's *t* test, after confirming that the data passed normal distribution and equal-variance tests. *P* < 0.05 was considered significant.

RESULTS

Effect of H₂O₂ preconditioning on anoxia/reoxygenation injury of isolated hepatocytes

In the preliminary experiments, the viability of hepatocytes exposed to anoxia for > 3–4 h decreased after reoxygenation, compared to cells consistently cultured under normoxic conditions. Anoxic culture for

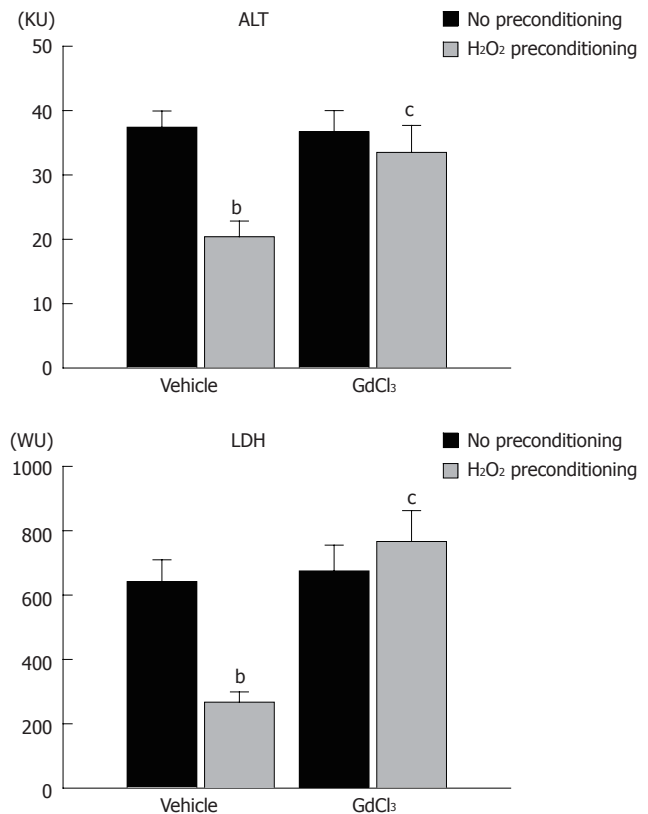

Figure 2 ALT and LDH activities in perfusate after ischemia/reperfusion in an isolated perfused liver system from no preconditioning control, H₂O₂ preconditioning, GdCl₃-no preconditioning, and GdCl₃/H₂O₂ preconditioning rats. Columns and bars represent means ± SE from six rats in each group. ^b*P* < 0.01 vs no preconditioning, ^c*P* < 0.05 vs vehicle treatment and H₂O₂ preconditioning. KU: Karmen unit; WU: Wróblewski unit.

6 h resulted in a marked and rapid loss of cell viability after reoxygenation. Accordingly, we set the anoxic time to 5 h, and determined cell viability serially for 2 h after reoxygenation. As shown in Figure 1, anoxia/reoxygenation decreased hepatocyte viability linearly, though the viability of normoxic controls was not affected during the corresponding period. Preincubation with 0–1 mmol/L H₂O₂ did not improve such anoxia/reoxygenation injury, and the highest concentration of H₂O₂ somewhat worsened cell viability.

Contribution of Kupffer cells to hepatocyte protection by H₂O₂ preconditioning

The results of the *in vitro* experiments suggested that H₂O₂ did not directly protect hepatocytes. We determined the contribution of Kupffer cells in H₂O₂ preconditioning, using an isolated perfused liver system. In untreated controls, which were perfused for the corresponding period without ischemia/reperfusion, ALT and LDH activity in the perfusate was 4.4 ± 0.6 and 35.1 ± 7.9, respectively (data not shown). As shown in Figure 2, warm ischemia/reperfusion markedly increased ALT and LDH activity in the perfusate to 37.4 ± 2.5 and 642 ± 68, respectively, with H₂O₂ preconditioning significantly reducing these values. GdCl₃ pretreatment itself did not change ALT and LDH activity after warm ischemia/reperfusion. In the H₂O₂-preconditioned group, however,

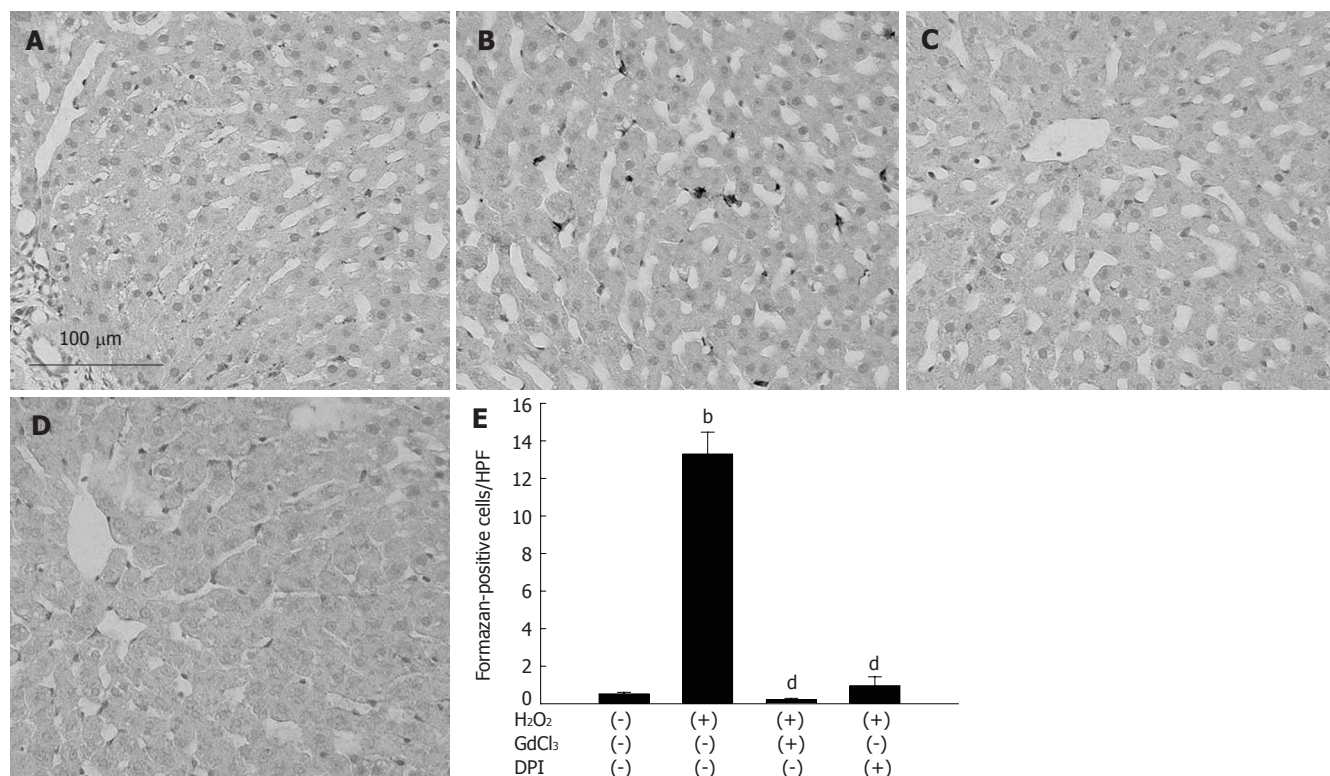

Figure 3 Oxygen radical formation in Kupffer cells after H₂O₂ preconditioning. **A:** Non-preconditioned livers; **B:** Livers after 10 min of H₂O₂ perfusion; **C:** Pretreatment with GdCl₃ and H₂O₂ perfusion; **D:** Treatment with DPI and H₂O₂ perfusion; **E:** The number of formazan-positive cells. Columns and bars represent means \pm SE from 3 rats in each group. ^b $P < 0.01$ vs non-preconditioned control; ^d $P < 0.01$ vs H₂O₂ perfusion.

GdCl₃ pretreatment reversed the decrease in ALT and LDH activity by H₂O₂ preconditioning.

Production of oxygen radicals in Kupffer cells after H₂O₂ preconditioning

To elucidate the mechanisms of the contribution of Kupffer cells in H₂O₂ preconditioning, we determined oxygen radical production in Kupffer cells. Livers were perfused with H₂O₂ for 10 min and then perfused with NBT. When non-preconditioned livers were perfused with NBT, formazan deposition did not develop (Figure 3A). As shown in Figure 3B, H₂O₂ perfusion induced formazan deposition in non-parenchymal cells. When rats were pretreated with GdCl₃ injection, H₂O₂ perfusion did not induce such dense deposition (Figure 3C). Moreover, formazan deposition did not develop after H₂O₂ perfusion in livers in which DPI was added to the perfusate during H₂O₂ perfusion (Figure 3D). The number of formazan-positive cells from three rats in each group is shown in Figure 3E; treatment with GdCl₃ or DPI significantly reduced the number of formazan-positive cells in H₂O₂-perfused livers to the non-preconditioned control level.

Contribution of NADPH oxidase to hepatoprotection by H₂O₂ preconditioning

To determine the contribution of NADPH oxidase to the effect of H₂O₂ preconditioning, DPI was added to the perfusate during H₂O₂ preconditioning, and livers were then subjected to warm ischemia/reperfusion. We confirmed that H₂O₂ preconditioning decreased ALT and LDH activity after warm ischemia/reperfusion in

a reproducible fashion. DPI treatment reversed this decrease in ALT and LDH activity induced by H₂O₂ preconditioning, although without H₂O₂ preconditioning, DPI alone did not change these values (Figure 4).

Contribution of NADPH oxidase to hepatoprotection by ischemic preconditioning

Finally, we determined whether DPI treatment could also reverse the protective effect of ischemic preconditioning. Ischemic preconditioning was performed with buffer containing DPI and livers were subjected to warm ischemia/reperfusion. As shown in Figure 5, ischemic preconditioning significantly reduced the increase in ALT and LDH activity after warm ischemia/reperfusion, with DPI reversing the hepatoprotection induced by ischemic preconditioning.

DISCUSSION

We have previously reported that brief liver perfusion with a buffer containing a low dose of H₂O₂ reduces warm ischemia/reperfusion injury similar to that with ischemic preconditioning^[19]. However, the mechanisms of such H₂O₂ preconditioning have not been clarified. Since H₂O₂ is produced as a consequence of ROS metabolism, and is now considered to be involved in not only pathological, but also physiological mechanisms^[25-27], it may be that H₂O₂ derived from Kupffer cells induces adaptation of hepatocytes to ischemia/reperfusion injury. Accordingly, in the present study, we sought to determine whether pretreatment with H₂O₂ directly protects

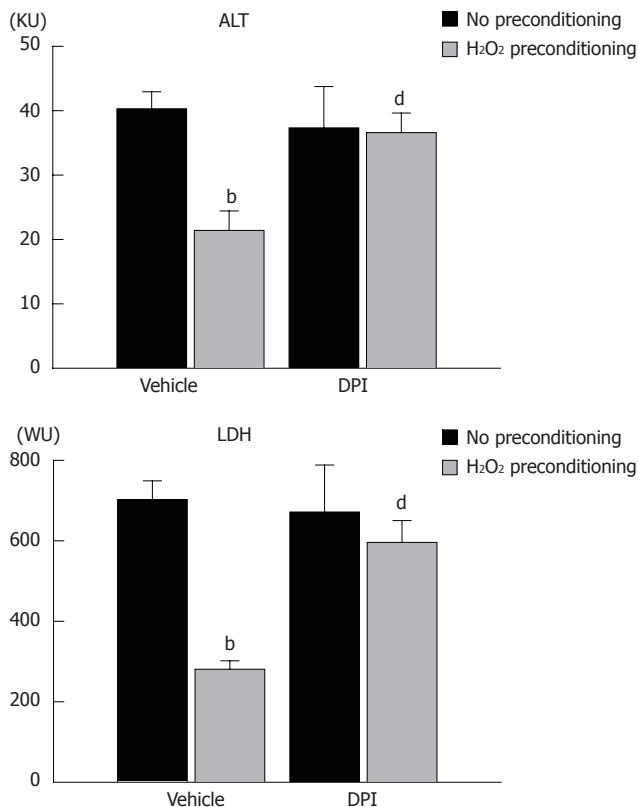

Figure 4 ALT and LDH activities in perfusate after ischemia/reperfusion in an isolated perfused liver system from no preconditioning control, H₂O₂ preconditioning, DPI-no preconditioning, and DPI/H₂O₂ preconditioning rats. Columns and bars represent means \pm SE from eight rats in each group. ^b*P* < 0.01 vs no preconditioning; ^d*P* < 0.01 vs vehicle treatment and H₂O₂ preconditioning.

isolated hepatocytes against subsequent warm ischemia/reperfusion injury.

To simulate ischemia/reperfusion injury *in vitro*, isolated rat hepatocytes were incubated under anoxic conditions using an anaerobic chamber, and subsequently subjected to reoxygenation, following a widely used model^[28,29]. Cell viability after reoxygenation was assessed with propidium iodide fluorometry. Propidium iodide binds to the double-stranded nucleic acids of permeable, non-viable cells^[21], and the fluorescence is linearly related to LDH release^[30]. Therefore, the changes in fluorescent intensity after anoxia/reoxygenation possibly represent *in vitro* ischemia/reperfusion injury. As shown in Figure 1, the viability of hepatocytes decreased slowly during anoxia and then rapidly after reoxygenation, compared with cells consistently maintained under normoxic conditions. These results were similar to those previously reported that showed necrotic hepatocytes after anoxia/reoxygenation^[29]. We pretreated cells with H₂O₂ before such anoxia/reoxygenation injury; however, the viability of hepatocytes was not improved with any of the concentrations of H₂O₂ examined. Pretreatment with 1 mmol/L H₂O₂ for 10 min even worsened hepatocyte viability, although liver perfusion with the same concentration of H₂O₂ for 10 min reduced warm ischemia/reperfusion injury in our earlier study^[19]. As some reports have indicated that isolated hepatocytes have lower tolerance to H₂O₂ than those *in vivo*, because of the absence of a sinusoidal structure^[31-33], the

present results might suggest that the effective dose of H₂O₂ in *in vitro* conditions is different from that during perfusion experiments. However, another interpretation is that sublethal H₂O₂ concentrations did not directly protect hepatocytes against warm ischemia/reperfusion injury.

Based on the hypothesis that Kupffer cells mediate hepatoprotection by H₂O₂ preconditioning, we performed liver perfusion experiments using rats in which Kupffer cell function was inhibited by GdCl₃ injection^[22,23]. As shown in Figure 2, GdCl₃ alone did not change ischemia/reperfusion injury, which showed that Kupffer cells were not involved in the development of warm ischemia/reperfusion injury in our model. Accordingly, it is suggested that hepatoprotection by H₂O₂ preconditioning cannot be ascribed to the suppression of the deleterious function of Kupffer cells. Moreover, GdCl₃ reversed the effect of H₂O₂ preconditioning. As previously recognized, inhibition of Kupffer cell function also reversed the effect of ischemic preconditioning^[19]. Therefore, we concluded that H₂O₂ preconditioning protected hepatocytes via Kupffer cells, as in ischemic preconditioning.

Kupffer cells are the principal source of oxygen radicals after prolonged hepatic ischemia/reperfusion^[34]. Moreover, even after a brief period of ischemia, Kupffer cells predominantly produce oxygen radicals^[19]. If H₂O₂ preconditioning protects hepatocytes via stimulation of Kupffer cells, as in ischemic preconditioning, a brief period of perfusion with H₂O₂ may induce oxygen radical

formation in Kupffer cells. As NBT reacts with oxygen radicals to form insoluble blue formazan, the NBT perfusion technique enables one to evaluate oxygen radical production *in situ*^[35,36]. As shown in Figure 3, histological analysis indicated that H₂O₂ perfusion stimulated Kupffer cells to produce oxygen radicals. It has been reported that structural changes in Kupffer cells, or transient increases in the phagocytosis of Kupffer cells, is induced by perfusion with 0.7 mmol/L H₂O₂ for 10 min or 1 mmol/L H₂O₂ for 5 min, respectively^[33,37]. These observations support our present findings; that stimulation of Kupffer cells with 1 mmol/L H₂O₂ for 10 min produced oxygen radicals.

Kupffer cells generate oxygen radicals by activating NADPH oxidase from a wide variety of stimulations^[38-40]. However, it has never been determined whether H₂O₂ activates NADPH oxidase in Kupffer cells. Therefore, we sought to determine the contribution of NADPH oxidase to oxygen radical production in Kupffer cells by brief H₂O₂ perfusion. As shown in Figure 3, oxygen radical formation induced by H₂O₂ perfusion was eliminated by inhibition of NADPH oxidase with DPI. Some of these histological findings suggested that even brief H₂O₂ perfusion induced oxygen radical formation via NADPH oxidase in Kupffer cells. The active NADPH oxidase complex, which is bound to the plasma membrane in Kupffer cells, primarily produces superoxide anion radicals by reducing extracellular oxygen with electrons from cytosolic NADPH^[40-42]. Since DPI acts on the cytosolic component of NADPH oxidase^[43] and H₂O₂ permeates the cell membrane^[41,44], an increase in intracellular H₂O₂ concentration by H₂O₂ treatment might act on NADPH oxidase in Kupffer cells. Subsequently, we examined the contribution of NADPH oxidase to the effect of H₂O₂ preconditioning against warm ischemia/reperfusion injury. As shown in Figure 4, inhibition of NADPH oxidase reversed the hepatoprotective effect of H₂O₂ preconditioning. Taken together with histological findings, the results indicate that NADPH oxidase in Kupffer cells mediates hepatocyte protection in H₂O₂ preconditioning.

Finally, we determined whether NADPH oxidase contributes to the effect of ischemic preconditioning. As shown in Figure 5, hepatocyte protection in ischemic preconditioning was also reversed by inhibition of NADPH oxidase. We concluded that H₂O₂ preconditioning, as well as ischemic preconditioning protects hepatocytes via NADPH oxidase in Kupffer cells. Moreover, the present results suggest that extracellular superoxide anion radicals produced by NADPH oxidase in Kupffer cells play a crucial role in hepatocyte protection by both H₂O₂ and ischemic preconditioning. Extracellular free radicals do not permeate the cell membrane^[41,44] and directly oxidize the lipid bilayer of the cell membrane^[45]. Thus, experiments to investigate the contribution of lipid peroxidation to hepatocyte preconditioning against ischemia/reperfusion injury are presently underway in our laboratory.

In conclusion, we report, to the best of our knowledge, a novel finding that hepatocyte protection against warm ischemia/reperfusion injury was achieved via NADPH oxidase in Kupffer cells. This was induced by preconditioning with a sublethal dose of H₂O₂

perfusion or brief ischemia/reperfusion. Based on the results of an earlier study, we assumed that a sublethal dose of H₂O₂ directly set off hepatocyte protection against ischemia/reperfusion injury. However, the present results reaffirmed the importance of Kupffer cells in induction of ischemic tolerance in liver. In general, Kupffer cells and their production of oxidative stress are considered to be a detrimental factor in hepatic ischemia/reperfusion injury^[1,3]. However, under sublethal conditions, they actually could play a principal role in hepatocyte preconditioning against such injury. According to this concept, to obtain hepatoprotection, Kupffer cell activation may have to be strictly controlled between a steady-state level and a stimulated injurious level. Investigations to elucidate how sublethal oxidative stress induces these protective effects on hepatocytes are needed to determine any clinical application.

COMMENTS

Background

As a therapeutic strategy against hepatic ischemia/reperfusion injury, which can occur in a number of clinical settings such as liver transplantation and hepatic resection, recent studies have drawn attention to ischemic preconditioning. Ischemic preconditioning is a phenomenon in which brief periods of ischemia followed by reperfusion render tissues resistant to subsequent prolonged ischemia/reperfusion. The authors have previously shown that reactive oxygen species derived from Kupffer cells mediate the hepatoprotection induced by ischemic preconditioning, and pretreatment with a sublethal dose of H₂O₂ mimics such hepatoprotection. However, the mechanism of H₂O₂ preconditioning or the role of H₂O₂ in the preconditioning phenomenon has not been determined.

Research frontiers

Clinical investigations of ischemic preconditioning in human liver resection and transplantation have recently been reviewed (*World J Gastroenterology* 2007; 13: 657-670). New findings about the beneficial role of reactive oxygen species in some experimental settings are increasingly being reported.

Innovations and breakthroughs

Cell-specific investigations of ischemic preconditioning have rarely been reported. The authors focused on Kupffer cells and their production of reactive oxygen species, which are in general regarded as detrimental factors in hepatic injury, and showed that, paradoxically, they mediated hepatoprotection induced by ischemic preconditioning. In the present article, we also demonstrated that superoxide anion radicals produced by NADPH oxidase in Kupffer cells were implicated in the hepatoprotective effects of ischemic and H₂O₂ preconditioning.

Applications

Investigations into the mechanisms of ischemic preconditioning will enable the establishment of a pharmacological preconditioning regime before liver transplantation or hepatic surgery, leading to a reduction in ischemia/reperfusion injury.

Terminology

Interruption of tissue blood flow followed by reperfusion causes tissue injury, called ischemia/reperfusion injury. Ischemic preconditioning is a phenomenon whereby brief periods of ischemia followed by reperfusion render tissues resistant to subsequent ischemia/reperfusion injury.

Peer review

This is an interesting study, well written and well designed. The methods are sound. The discussions are to the point and not overstated.

Abstract

AIM: To investigate the protective effects and mechanisms of Baicalin and octreotide on renal injury of rats with severe acute pancreatitis (SAP).

METHODS: One hundred and eighty SD rats were randomly assigned to the model group, Baicalin-treated group, octreotide-treated group and sham operation group. The mortality, plasma endotoxin level, contents of blood urea nitrogen (BUN), creatinine (CREA), phospholipase A₂ (PLA₂), nitrogen monoxide (NO), tumor necrosis factor (TNF)- α , IL-6 and endothelin-1 (ET-1) in serum, expression levels of renal Bax and Bcl-2 protein, apoptotic indexes and pathological changes of kidney were observed at 3, 6 and 12 h after operation.

RESULTS: The renal pathological changes were milder in

treated group than in model group. The survival at 12 h and renal apoptotic indexes at 6 h were significantly ($P < 0.05$) higher in treated group than in model group [66.67% *vs* 100%; 0.00 (0.02)% and 0.00 (0.04)% *vs* 0.00 (0.00)%, respectively]. The serum CREA content was markedly lower in octreotide-treated group than in model group at 3 h and 6 h ($P < 0.01$, 29.200 ± 5.710 $\mu\text{mol/L}$ *vs* 38.400 ± 11.344 $\mu\text{mol/L}$; $P < 0.05$, 33.533 ± 10.106 $\mu\text{mol/L}$ *vs* 45.154 ± 17.435 $\mu\text{mol/L}$, respectively). The expression level of renal Bax protein was not significantly different between model group and treated groups at all time points. The expression level of renal Bcl-2 protein was lower in Baicalin-treated group than in model group at 6 h [$P < 0.001$, 0.00 (0.00) grade score *vs* 3.00 (3.00) grade score]. The Bcl-2 expression level was lower in octreotide-treated group than in model group at 6 h and 12 h [$P < 0.05$, 0.00 (0.00) grade score *vs* 3.00 (3.00) grade score; 0.00 (0.00) grade score *vs* 0.00 (1.25) grade score, respectively]. The serum NO contents were lower in treated groups than in model group at 3 h and 12 h [$P < 0.05$, 57.50 (22.50) and 52.50 (15.00) $\mu\text{mol/L}$ *vs* 65.00 (7.50) $\mu\text{mol/L}$; $P < 0.01$, 57.50 (27.50) and 45.00 (12.50) $\mu\text{mol/L}$ *vs* 74.10 (26.15) $\mu\text{mol/L}$, respectively]. The plasma endotoxin content and serum BUN content (at 6 h and 12 h) were lower in treated groups than in model group. The contents of IL-6, ET-1, TNF- α (at 6 h) and PLA₂ (at 6 h and 12 h) were lower in treated groups than in model group [$P < 0.001$, 3.031 (0.870) and 2.646 (1.373) pg/mL *vs* 5.437 (1.025) pg/mL; 2.882 (1.392) and 3.076 (1.205) pg/mL *vs* 6.817 (0.810) pg/mL; 2.832 (0.597) and 2.462 (1.353) pg/mL *vs* 5.356 (0.747) pg/mL; 16.226 (3.174) and 14.855 (5.747) pg/mL *vs* 25.625 (7.973) pg/mL; 18.625 (5.780) and 15.185 (1.761) pg/mL *vs* 24.725 (3.759) pg/mL; 65.10 (27.51) and 47.60 (16.50) pg/mL *vs* 92.15 (23.12) pg/mL; 67.91 ± 20.61 and 66.86 ± 22.10 U/mL, 63.13 ± 26.31 and 53.63 ± 12.28 U/mL *vs* 101.46 ± 14.67 and 105.33 ± 18.10 U/mL, respectively].

CONCLUSION: Both Baicalin and octreotide can protect the kidney of rats with severe acute pancreatitis. The therapeutic mechanisms of Baicalin and octreotide might be related to their inhibition of inflammatory mediators and induction of apoptosis. Baicalin might be a promising therapeutic tool for severe acute pancreatitis.

INTRODUCTION

Severe acute pancreatitis (SAP) is a fatal systemic disease featuring acute onset, serious conditions, high incidence of complications and 20%-30% of mortality mainly due to multiple organ failure at its early stage^[1-4]. Octreotide has been shown to exert its therapeutic effects on SAP mainly *via* inhibiting pancreatin secretion, release of inflammatory mediators and platelet aggregation, and reducing endotoxin generation^[5-8]. It is found to improve prognosis and lower mortality by enhancing the kidney protection during SAP. Baical skullcap root is an essential of "Qingyitang", a representative prescription of Traditional Chinese Medicine for SAP. Baicalin is its main effective ingredient (monomer). The *in vitro* experiment of Baicalin has confirmed it has anti-bacterial, antiviral and anti-inflammatory activities. It also can inhibit platelet aggregation and eliminate oxygen-free radicals. It was found in animal experiments that Baicalin could reduce the generation of endotoxin. In addition, Baicalein, which is the initial metabolite of Baicalin, has potent effect in inhibiting pancreatin. All these pharmacologic actions can inhibit SAP during its multiple stages^[9]. It is difficult to popularize octreotide especially in remote areas with poor economy since it features high price, short half-life and inconvenient administration, while Baicalin features low price, extensive routes of administration and preparation, multiple pharmacologic actions and precise therapeutic effects.

The idea of Baicalin treatment of pancreatitis was brought forward in 1999 and validated in 2000. At the beginning, the one-time Baicalin injection *via* vena dorsalis penis or vena femoralis injection was applied, which resulted in poor therapeutic effects. Later, it was found one-time injection was inappropriate due to the short half-life of Baicalin. The expected therapeutic effects could hardly be met with one-time injection. In 2001, the intravenous drip and large dosage were applied, which resulted in sound therapeutic effects. The idea was originated from the study of the principal on pancreatitis treated by Baicalein injection. Baicalin is hydrolyzed into Baicalein. The stability, solubility and therapeutic effects of Baicalin injection are all superior to those of Baicalein injection. In this experiment, the feasibility of Baicalin treatment for SAP has been studied by comparing the protective effects and mechanisms of Baicalin and octreotide on kidneys of rats with SAP.

MATERIALS AND METHODS

Experimental animals

Clean grade healthy male Sprague-Dawley (SD) rat, weighing 250-300 g, were purchased from the Experimental

Animal Center of Medical School of Zhejiang University, China.

Experimental reagents

Sodium taurocholate and sodium pentobarbital were purchased from USA Sigma Company. Octreotide was purchased from Swiss Pharmaceutical Company Novartis, and 5% Baicalin injection (China National Invention Patent Number ZL200310122673.6) was prepared by the first author at 305 mmol/L osmotic pressure. Plasma endotoxin tachypleus amebocyte lysate kit was purchased from Shanghai Yihua Medical Science and Technology Corporation (Institute of Medical Analysis, Shanghai, China); the calculation unit for content is EU/mL. Serum nitrogen monoxide (NO) was purchased from Nanjing Jiancheng Bioengineering Research Institute; the calculation units for content is $\mu\text{mol/L}$. TNF- α ELISA kit was purchased from Jingmei Bioengineering Corporation; the calculation unit for content is pg/mL (ng/L). IL-6 ELISA kit was purchased from Shanghai Shenxiong Biotech Company (China); the calculation unit for content is pg/mL (ng/L). Serum secretory phospholipase A₂ enzyme Assay ELA kit (PLA₂) was purchased from R&D system Ins; the calculation unit for content is U/mL. The serum endothelin-1 ELA kit (ET-1) was purchased from Cayman Chemical Company (Catalog Number: 583151), the calculation unit for content is ng/L (pg/mL). The Bax and Bcl-2 antibodies were purchased from Santa Cruz Company, USA. The main reagents for DNA *in situ* nick end-labeling (TUNEL) staining (Takara *In Situ* Apoptosis Detection Kit) was purchased from TaKaRa Biotechnology (Dalian) Co., Ltd. PK (protease K) was purchased from Sigma Company (USA). DAB (biphenyldiamine) was purchased from China Hua-meimei Company, China.

Preparation of animal models

The improved Aho's method^[10] was adopted to prepare 135 SAP rat models *via* retrograde injection of 35 g/L sodium taurocholate to the pancreatic duct through epidural catheter and duodenal papilla. The 135 SAP rat models were randomly assigned to the model group, Baicalin-treated group and octreotide-treated group, 45 rats in each group, while other 45 rats were assigned to the sham operation group (SO group). In sham operation group, only exploratory laparotomy (i.e., entering abdominal cavity, checking the pancreas and duodenum and then abdomen closure) was performed. Thereafter, the above-mentioned groups were randomly subdivided into 3-h, 6-h and 12-h groups, 15 rats in each group. The rats were observed at 3, 6 and 12 h after operation for: (1) Mortalities of rats in all groups followed by execution of rats and observation of gross pathological changes of kidney; (2) Kidney tissue samples were collected, fixed in accordance with relevant requirements and observed for the pathological score changes of kidney under HE staining; (3) Tissue microarray was applied to prepare the tissue microarray sections (2 mm in diameter) and immunostained using SP (streptavidin-peroxidase) method. Expressions of Bax and Bcl-2 protein in the kidney tissue were observed under light microscope, and grading was carried out based on the percentage of positive cells as follows: (-) = positive

cell count < 10%, (+) = positive cell count 10%-20%, (++) = positive cell count 20%-50%, and (+++) = positive cell count > 50%; (4) TUNEL staining technique was applied to detect apoptotic cells in the kidney and then apoptotic index was calculated as follows: Apoptotic index = apoptotic cell count/total cell count \times 100%; (5) The changes in blood urea nitrogen (BUN), creatinine (CREA), phospholipase A₂ (PLA₂), nitrogen monoxide (NO), tumor necrosis factor (TNF)- α , IL-6 and endothelin-1 (ET-1) contents in blood samples obtained from the heart were determined; and (6) The correlations among these indexes were analyzed.

Procedures

Fast but water restraint was imposed on all rat groups 12 h prior to the operation. The rats were anesthetized by intra-peritoneal injection of 20 g/L sodium pentobarbital (0.25 mL/100 g), laid and fixed on table, routinely shaved, disinfected and draped. After establishing the right external jugular vein transfusion passage by using the microinfusion pump for continuous transfusion (1 mL/h per 100 g), 35 g/L sodium taurocholate was administered to prepare SAP model. To establish model control group, through median epigastrium incision, the bile-pancreatic duct and hepatic hilus common hepatic duct were confirmed, the pancreas was disclosed, the duodenal papilla inside the duodenum duct wall was identified, and then a No. 5 needle was used to drill a hole in the avascular area of mesentery. After inserting a segmental epidural catheter into the duodenal cavity *via* the hole, the bile-pancreatic duct was inserted toward the direction of papilla in a retrograde way, a microvascular clamp was used to nip the duct end temporarily and meanwhile another microvascular clamp was used to temporarily occlude the common hepatic duct at the confluence of hepatic duct. After connecting the anesthetic tube end with the transfusion converter, 35 g/L sodium taurocholate (0.1 mL/100 g) was transfused by retrograde transfusion using the micro-injection pump (made by Zhejiang University) at a speed of 0.2 mL/min. After 4 to 5 min post-injection, the micro-vascular clamp and epidural catheter were removed. After checking for bile leakage, the hole in the lateral wall of duodenum was sutured. The anesthetic in the abdominal cavity was absorbed up by disinfected cotton ball and then the abdomen was closed. Sham operation group received laparotomy *via* upper midline incision, turning over of the pancreas and duodenum and finally closure of the abdomen.

Dosage

In Baicalin-treated group, the animal experiments of 5% Baicalin injection have been completed including the acute toxicity test and SAP rat treatment by small, middle and large dose. The large dose (10 mg/h per 100 g) can achieve the best therapeutic effect and the dosage referred to the result of the previous preliminary experiment^[10]. Ten minutes after successful modeling, Baicalin-treated group was first injected 5% Baicalin injection (10 mg/100 g) *via* the external jugular vein, followed by continuous intravenous administration (10 mg/h per 100 g) by microinfusion pump. Octreotide-treated group was

first injected octreotide (0.2 μ g/100 g) *via* the external jugular vein, followed by continuous intravenous transfusion (10 mg/h per 100 g) by microinfusion pump at a transfusion speed of 0.2 μ g/h per 100 g. All above-mentioned dosages have been proved as effective dosages in the previous preliminary experiment^[10]. Both the sham operation group and model control group were injected normal saline of equivalent volume at the corresponding time points after operation. The diameter of the drilling needle is 2.0 mm.

Statistical analysis

The values were presented as mean \pm SD for normal distribution variables or median and quartile range for highly skewed variables. The significance of differences among the four groups was analyzed using Kruskal-Wallis test for highly skewed data and analysis of variance (ANOVA) for normal distribution data. Multiple comparisons were subjected to Bonferroni correction test. Chi-square test was used to evaluate equality of frequencies for discrete variables. Correlations were tested using Spearman rank correlation coefficients. A *P* value less than or equal to 0.05 was considered statistically significant. All statistical analyses were conducted using SPSS version 11.5 for windows.

RESULTS

Survival rate

The mortalities of model group were 0% (0/15), 13.33% (2/15) and 33.33% (5/15) at 3, 6 and 12 h, respectively, while those of Baicalin-treated group and octreotide-treated group were 0% at different time points, indicating a marked difference at 12 h (*P* < 0.05). The whole sham operation group survived at different time points.

Serum BUN content

Serum BUN content was markedly higher in model group and treated groups than in sham operation group at all time points (*P* < 0.001). However, the content was not significantly different between Baicalin- and octreotide-treated groups at all time points. The content was lower in Baicalin-treated group than in model group at 3 and 12 h (*P* < 0.05). The content was not different between octreotide-treated group and model group at 3 h. The content was lower in Baicalin-treated group than in model group at 6 h (*P* = 0.001), lower in octreotide-treated group than in model group (*P* < 0.05), and lower in octreotide-treated group than in model group at 12 h (*P* < 0.01) (Table 1).

Serum CREA content

The CREA content was significantly higher in model group and treated groups than in sham operation group at all time points (*P* < 0.001). However, no significant difference was found between Baicalin-treated group and model group at all time points. The content was lower in octreotide-treated group than in Baicalin-treated group at 3 h and 12 h (*P* < 0.01), and also lower in octreotide-treated group than in model group at 3 h (*P* < 0.01) and 6 h (*P* < 0.05). But no marked difference was observed between Baicalin-

Table 1 Comparison of different indexes level in blood [*M (Q_n)*]

Table 2 Comparison of serum CREA content (mean ± SD, μmol/L)

Groups	3 h	6 h	12 h
Sham operation group	17.867 ± 2.890	21.467 ± 3.044	19.733 ± 3.150
Model group	38.400 ± 11.344	45.154 ± 17.435	41.500 ± 12.122
Baicalin-treated group	37.615 ± 9.483	39.867 ± 13.648	50.733 ± 29.310
Octreotide-treated group	29.200 ± 5.710	33.533 ± 10.106	33.933 ± 9.145

and octreotide-treated groups. Moreover, the content was not different between octreotide-treated group and model group at 12 h (Table 2).

Gross changes and light microscopic changes of kidney

Sham operation group: Macroscopically, the morphous of kidney was normal without swelling, with no bleeding points on surface of renal cortex. Microscopically, there were normal structure of renal glomerulus, tubule and interstitium in most rats without visible pathological change; however, swelling and blurry boundary of renal tubular epithelial cells, and stenosis of lumens were found in very few rats.

Model group: Macroscopically, there was no gross change in the kidney at 3 h; but were kidney swelling, tension of renal envelope, scattered bleeding points on surface of renal envelope, and slightly hemorrhagic urine in pelvis in severe cases at 6 h and 12 h. Microscopically, there were capillary congestion of renal glomerulus, swelling, scattered necrosis and blurry boundary of renal tubule epithelial cell, stenosis or atresia of lumens, visible protein cast (Figure 1A), interstitial edema and inflammatory cell infiltration at 3 h; and capillary congestion of renal glomerulus, swelling and scattered necrosis of epithelial cell of renal tubule (Figure 1B), interstitial edema (Figure 1C) and inflammatory cell infiltration at 6 and 12 h. The floss and red cell with eosinophilic stainings were found in renal glomerulus and homogenous or red cell cast with eosinophilic staining in renal tubule (Figure 1D).

There was lamellar necrosis of epithelial cell of renal tubule in few rats.

Baicalin- and octreotide-treated groups: Macroscopically, the gross renal pathological changes were milder in Baicalin- and octreotide-treated group than in model group at 6 h and 12 h. Microscopically, there were less capillary congestion of renal glomerulus, swelling of renal tubular epithelial cell, floss and red cell with eosinophilic staining in renal capsule and inflammatory cell infiltration in treated group than in model group. Mild red cell cast was found occasionally in renal tubule of treated group. There were also renal interstitial edema and scattered necrosis of renal tubular epithelial cell in few cases. There was no visible difference between Baicalin- and octreotide-treated groups. Better therapeutic effects were achieved in octreotide-treated group.

Changes of pathological score of kidney in all groups

Pathological grading of kidney: The pathological grading of kidney was used (Table 3) and two pathologists performed the evaluation of degree of pathological changes in pancreatic tissue in double-blind fashion.

Comparison of pathological score of kidney: The score was significantly higher in model group, Baicalin- and octreotide-treated groups than in sham operation group at different time points ($P < 0.001$). However, the score was lower in Baicalin- and octreotide-treated groups than in model group at 6 h ($P < 0.05$). The score was lower in octreotide-treated group than in model group at 12 h ($P < 0.05$). There was not significant different between Baicalin- and octreotide-treated groups at different time points (Table 4).

Expression of Bax protein in renal tissue

Bax-positive staining was located in the kytoplasm of renal tubular epithelial cell (Table 5 and Figure 2A-E). The expression level was not different among all groups at 12 h. The level was higher in model group and Baicalin-treated group than in sham operation group at 3 h and

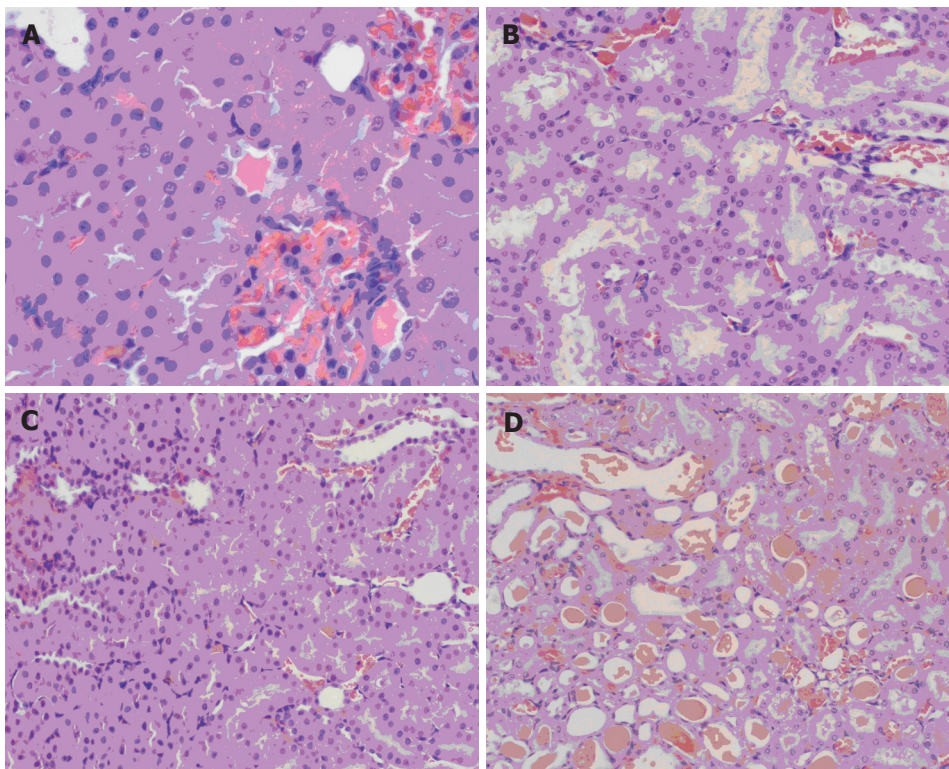

Figure 1 Light microscopic changes of kidney (HE, ×400). **A:** 3-h model group showing protein cast in renal tubule; **B** and **C:** 6-h model group showing scattered degenerative necrosis in renal tubular epithelial cells, and renal interstitial edema, respectively; **D:** 12-h model group showing visible red cell cast.

Table 3 Pathological score standard of kidney

Grade	Observation indexes
I	No cellular proliferation or fibrosis in renal glomerulus; no capillary congestion or microthrombus; swelling and blurry boundary of renal tubular epithelial cell; stenosis or atresia of lumens; protein cast and renal interstitial edema
II	Glomerular capillary congestion, scattered necrosis in renal tubular epithelial cell, interstitial edema and inflammatory cell infiltration
III	II + lamellar necrosis of renal tubular epithelial cell

Table 4 Comparison of pathological score of kidney in all groups [$M(Q_R)$]

Groups	3 h	6 h	12 h
Sham operation group	0.00 (0.00)	0.00 (0.00)	0.00 (0.00)
Model group	2.00 (1.00)	2.00 (1.00)	2.00 (1.25)
Baicalin treated group	1.00 (1.00)	1.00 (1.00)	2.00 (1.00)
Octreotide-treated group	1.00 (1.00)	1.00 (1.00)	1.00 (1.00)

6 h ($P < 0.05$), and also higher in octreotide-treated group than in sham operation group at 6 h ($P < 0.05$). The expression level was not different between model group and Baicalin-treated group at all time points. Similarly, the expression level was not different between Baicalin- and octreotide-treated groups. The level was lower in octreotide-treated group than in model group at 3 h ($P < 0.05$) (Table 6).

Expression of Bcl-2 protein in renal tissue

Bcl-2-positive staining was located in the cytoplasm of renal tubular epithelial cells. (Table 7 and Figure 3A-C). The

level was higher in model group than in sham operation group at all time points ($P < 0.05$). The level was higher in Baicalin-treated group than in sham operation group at 12 h ($P < 0.05$), lower in octreotide-treated group than in Baicalin-treated group ($P < 0.05$), lower in Baicalin-treated group than in model group at 6 h ($P < 0.001$), and also lower in octreotide-treated group than in model group at 6 and 12 h ($P < 0.05$) (Table 8).

Comparison of renal apoptotic index

The apoptotic cells were renal tubular epithelial cells. The index was not different between model group and sham operation group at different time points. Moreover, the index was not different among all groups at 3 and 12 h. The index was higher in Baicalin- and octreotide-treated groups than in sham operation group and model group at 6 h ($P < 0.05$). The index was not different between Baicalin- and octreotide-treated groups at all time points (Table 9 and Figure 4A-D).

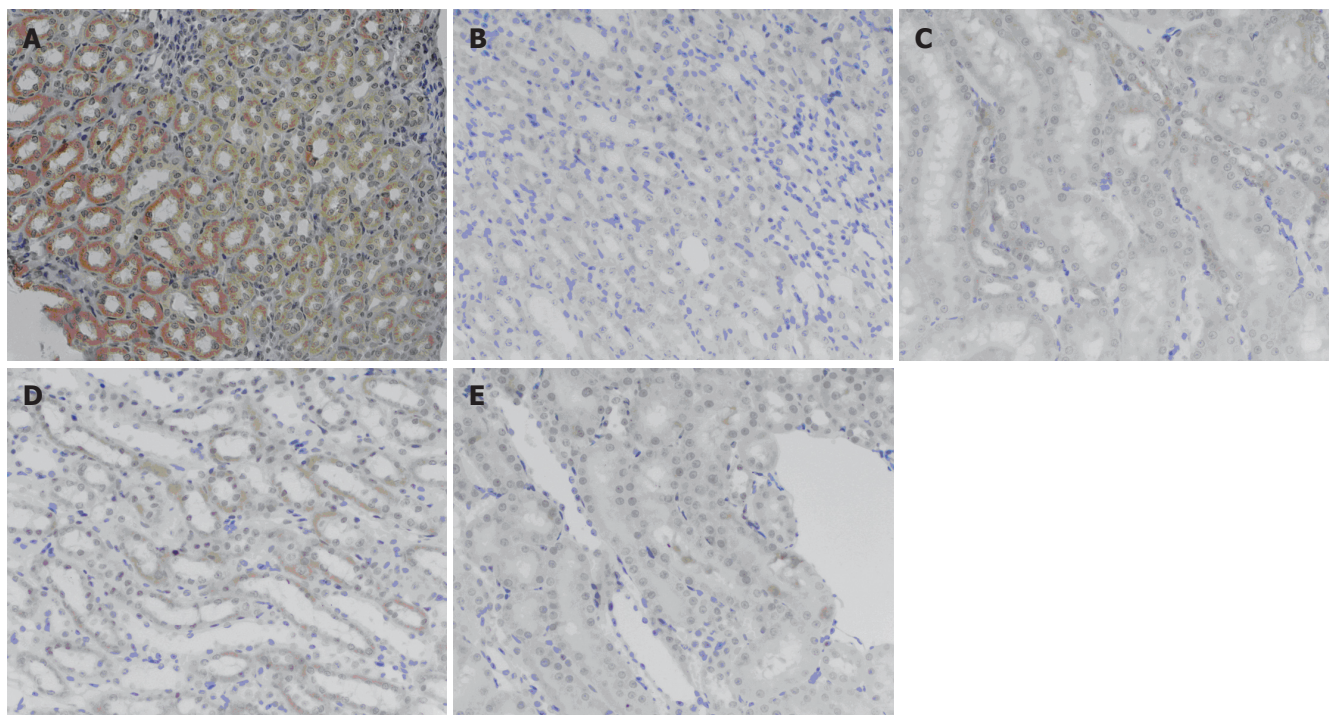

Figure 2 Bax expression in different groups (×200). **A:** 12-h model group showing high (+++) Bax expression; **B:** 3-h Baicalin-treated with negative (-) Bax expression; **C:** 12-h model group showing moderate (++) Bax expression; **D and E:** 6-h octreotide-treated group showing mild (+) Bax expression.

	(6 h)	15	15			
	(12 h)	15	15			

Comparison of plasma endotoxin content

The content was higher in model group and treated group than in sham operation group at all time points ($P < 0.001$). The content was not different between Baicalin- and octreotide-treated groups at 6 and 12 h. The content was lower in Baicalin- and octreotide-treated groups than in model group at 3 h ($P < 0.001$), lower in Baicalin-treated

group than in octreotide-treated group at 3 h ($P < 0.01$), lower in Baicalin-treated group than in model group at 6 h ($P < 0.05$), lower in octreotide-treated group than in model group at 6 h ($P = 0.001$), lower in Baicalin-treated group than in model group at 12 h ($P < 0.001$), and also lower in octreotide-treated group than in model group at 12 h ($P < 0.01$) (Table 1).

Comparison of serum PLA₂ content

Serum PLA₂ content in model group and treated groups significantly exceeded sham operation group at different time points ($P < 0.001$). At 3 h, PLA₂ content in Baicalin-treated group was significantly less than model group and octreotide-treated group ($P < 0.01$), but no marked difference was observed between octreotide-treated group and model group. At 6 h and 12 h, PLA₂ content in Baicalin- and octreotide-treated groups was significantly less than model group ($P < 0.001$). There was no marked difference between Baicalin-treated group and octreotide-treated group at 6 h, while octreotide-treated group had significantly less PLA₂ content than Baicalin-treated group at 12 h ($P < 0.001$) (Table 10).

Comparison of serum NO content

Serum NO content in model group, Baicalin-treated group and octreotide-treated group significantly exceeded sham operation group at different time points ($P < 0.001$). At 3 h and 12 h, Baicalin-treated and octreotide-treated groups had significantly less serum NO content than model group ($P < 0.05$). There was no marked difference in serum NO content between Baicalin-treated group and octreotide-treated group at different time points (Table 1).

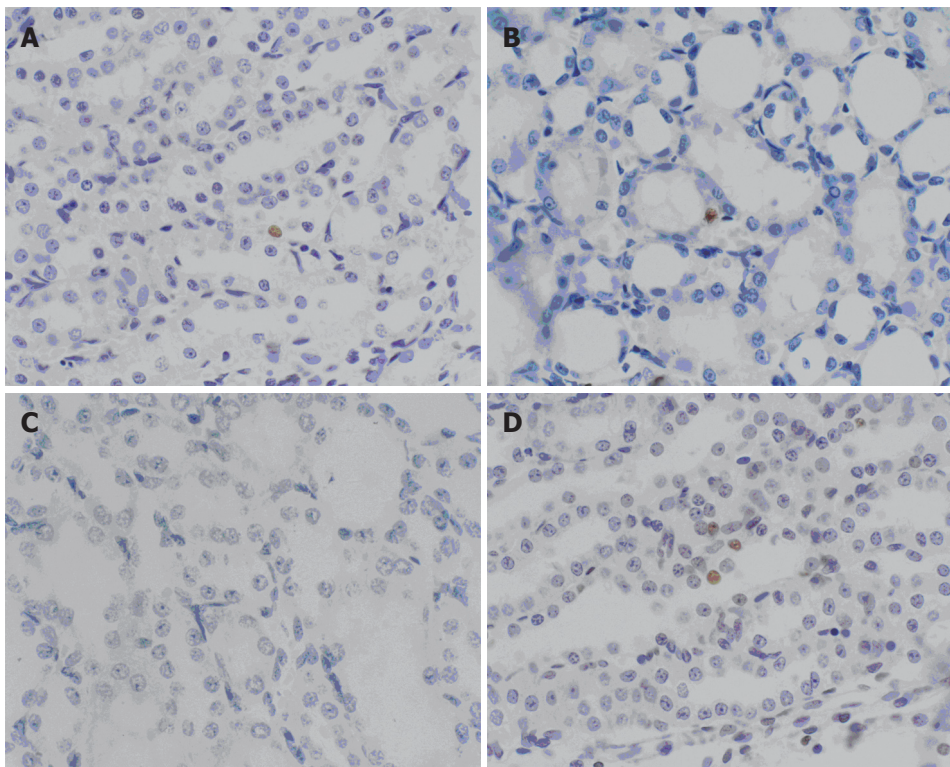

Figure 4 Apoptosis in different groups (TUNEL, × 400). **A**: 6-h octreotide-treated group showing apoptosis of renal tubular epithelial cells; **B**: 6-h Baicalin-treated group showing apoptosis of renal tubular epithelial cells; **C**: 6-h model group with no (-) apoptosis; **D**: 6-h octreotide-treated group showing apoptosis of renal tubular epithelial cells.

Comparison of serum TNF- α content

Serum TNF- α content in model group and treated groups significantly exceeded sham operation group at different time points ($P < 0.001$). There was no significant difference among model group, Baicalin-treated group and octreotide-treated group at 3 h and 12 h. At 6 h, serum TNF- α contents in Baicalin-treated group and octreotide-treated group were significantly less than model control group ($P < 0.001$); and octreotide-treated group had signif-

icantly less serum TNF- α content compared to Baicalin-treated group ($P < 0.01$) (Table 1).

Comparison of serum IL-6 content

Serum IL-6 contents at 3 h and 6 h were significantly higher in model control group and treated groups than in sham operation group ($P < 0.001$). Baicalin-treated group and octreotide-treated group had no significant difference in serum IL-6 content at all time points. Baicalin-

Table 10 Comparison of serum PLA₂ content (mean \pm SD, U/mL)

Groups	3 h	6 h	12 h
Sham operation group	14.62 \pm 3.02	17.49 \pm 3.82	19.02 \pm 5.07
Model group	76.10 \pm 16.70	101.46 \pm 14.67	105.33 \pm 18.10
Baicalin-treated group	56.25 \pm 22.43	67.91 \pm 20.61	66.86 \pm 22.10
Octreotide-treated group	74.37 \pm 19.94	63.13 \pm 26.31	53.63 \pm 12.28

and octreotide-treated groups had significantly lower serum IL-6 content compared to model control group at all time points ($P < 0.001$). The model control group had significantly higher serum IL-6 content than sham operation group at 12 h ($P < 0.001$), and so was Baicalin-treated group ($P < 0.01$), but no significant difference was found between octreotide-treated group and sham operation group (Table 1).

Comparison of serum ET-1 contents

Serum ET-1 content in model group was significantly higher than in sham operation group at all time points ($P < 0.001$). At all time points, Baicalin- and octreotide-treated groups had significantly lower serum ET-1 content than model group ($P < 0.001$). Octreotide-treated group had significantly lower ET-1 content compared to Baicalin-treated group at 3 h and 12 h ($P < 0.01$). At 3 h, Baicalin-treated group had significantly higher ET-1 content than sham operation group ($P < 0.01$), but no significant difference was found between octreotide-treated group and sham operation group. At 6 h, there was no marked difference between Baicalin-treated group or octreotide-treated group and sham operation group, or between Baicalin-treated group and octreotide-treated group. At 12 h, octreotide-treated group and sham operation group had no marked difference, and Baicalin-treated group had significantly higher ET-1 content than sham operation group ($P < 0.001$) (Table 1).

Comparison of correlations among various indexes

Correlation between apoptotic indexes and Bax and Bcl-2 expression in the kidney: The apoptotic index of Baicalin-treated group at 3 h and that of octreotide-treated group at 3 h and 6 h was positively correlated with Bax expression ($P < 0.001$). However, there was no correlation between apoptotic index and Bcl-2 expression.

Correlation between pathological score change and BUN and CREA of kidney: The pathological score of sham operation group at 12 h was positively correlated with BUN ($P < 0.01$) and CREA levels ($P < 0.05$). The pathological score of model group was positively correlated with CREA at 3 h ($P = 0.01$) and 6 h ($P < 0.001$). The score of Baicalin-treated group at 3 h and 6 h was positively correlated with CREA ($P < 0.05$). The pathological score of Baicalin-treated group was positively correlated with BUN at 6 h ($P < 0.05$) and 12 h ($P < 0.01$). The pathological score of octreotide-treated group at 3 h was positively correlated with BUN and CREA ($P < 0.05$), and that at 6 h and 12 h was positively correlated with CREA ($P < 0.01$) and BUN ($P < 0.01$), respectively.

Correlation analysis among inflammatory mediators: PLA₂ content at 12 h was positively correlated with TNF- α in model group ($P < 0.05$), and TNF- α was positively correlated with PLA₂ content ($P < 0.01$) at 3 h.

DISCUSSION

This study demonstrated that there were milder renal pathological changes and lower serum BUN content in treated groups as compared with model group. The survival rate was higher in treated groups compared to model group. All these indicate the potent therapeutic effect of Baicalin and octreotide on rats with severe acute pancreatitis. Baicalin showed superiority over octreotide in decreasing plasma endotoxin and PLA₂ content in SAP rats at 3 h, while octreotide was found to be superior to Baicalin in alleviating renal pathological changes and decreasing CREA, Bcl-2, TNF- α , PLA₂ (at 12 h) and ET-1 contents.

Regarding the mechanisms *via* which these two drugs improve renal pathological changes, we mainly hypothesized inhibition of inflammatory mediators and induction of apoptosis.

The endotoxin^[11] in plasma, and PLA₂^[12,13], NO^[14-18], TNF- α ^[19-21], IL-6^[22] and ET-1^[23,24] in serum are all important inflammatory mediators during SAP complicated with multiple organ injury. They are important indexes of severity and prognosis of acute pancreatitis and have two important features in common: (1) Dual effects: These inflammatory mediators, especially NO and ET-1, will protect body in low concentration and injure body in high concentration; and (2) There are interactions among different inflammatory mediators. This experiment confirmed a positive correlation between PLA₂ and TNF- α . According to many studies as well as our experiment, the concentrations of these inflammatory mediators increase during SAP^[25-31]. Our experiment demonstrated that almost all indexes of inflammatory mediators were lower in treated groups than in model group, while the indexes were not different between Baicalin- and octreotide-treated groups, thereby indicating that both drugs, with similar effects, could lower the concentration of inflammatory mediators, inhibit them and protect kidney.

Both necrosis and apoptosis are ways of death of injured cells^[32]. In contrast to necrosis, apoptosis does not cause intense inflammatory reaction^[33], while necrosis will cause systemic inflammatory response syndrome^[34]. At present, a consensus has been reached on apoptosis of pancreas during SAP^[35,36]. When necrosis and apoptosis coexist in pancreas and necrosis prevails, induction of pancreatic apoptosis will result in a protective effect. We believe this conclusion is also applicable to renal apoptosis, which has been demonstrated by this experiment.

This experiment clearly showed that the renal pathological changes were milder in treated group than in model group. The renal apoptotic indexes at 6 h were markedly higher in treated group than in model group. All these indicate the renal pathological changes have been alleviated after apoptosis of renal tubular epithelial cells. In addition, the renal apoptotic indexes were not different between model group and sham operation group, possibly

because apoptosis had not occurred in model group or its incidence was too low to be detected. The occurrence of apoptosis of renal cells in treated groups, however, demonstrated that both Baicalin and octreotide could induce apoptosis. But some researchers believe the pathological changes would be aggravated by renal apoptosis during SAP^[37,38], which is different from our view and therefore worth discussing.

Bax and Bcl-2 are two important apoptosis-regulating factors. The homo- or heterodimerization between anti-apoptotic Bcl-2 and proapoptotic Bax plays an important role in the apoptosis regulating function of the Bcl-2-related proteins. Interestingly, in an excess of Bax, Bax/Bax homodimers predominate, which promote apoptosis, whereas an excess of Bcl-2 leads to the formation of Bcl-2/Bax heterodimers, which inhibit apoptosis. Thus, the ratio of Bcl-2 to Bax appears to be a critical determinant of a cell's threshold for undergoing apoptosis. No expression of Bcl-2 gene has been found normal pancreatic tissue^[39]. In addition, there has been no report on expression of Bcl-2 gene in normal renal tissue. It was found in this experiment that the expression levels of both Bax and Bcl-2 protein had increased during SAP, possibly because the apoptosis-inducing and -inhibiting factors had been enhanced simultaneously. As a result of the conflict of the two factors, the apoptotic indexes were not different between model group and sham operation group. However, the apoptotic indexes at 6 h were higher in treated group than in sham operation group and model group, indicating that the apoptosis of renal tubular epithelial cells occurred because the apoptosis-inducing factor prevailed in treated group. It was also found that the apoptotic indexes at 3 h were positively correlated with Bax in Baicalin-treated group. The apoptotic indexes at 3 h and 6 h were positively correlated with Bax in octreotide-treated group. But there was no correlation between apoptotic indexes and Bcl-2. Thus these data indicate that Bax might have participated in the apoptosis of renal tubular epithelial cells. Compared to model group, the expression level of Bcl-2 protein was lower in Baicalin-treated group at 6 h, and in octreotide-treated group at 6 h and 12 h, thereby indicating that both Baicalin and octreotide can lower the expression level of Bcl-2 protein, enhance the apoptosis-promoting effect of Bax dimmer and thus protect kidney and alleviate its pathological changes.

The traditional histopathological section technique that has been surpassed by tissue microarray (TMA) features single sample and low efficiency^[40]. The TMA we adopted has advantages such as high throughput and reliable results and great potential in oncopathological study^[41,42]. Current studies are also mainly focused in this field^[43-50]. To our knowledge, this is the first report on the application of TMA to the pathological examination of pancreatitis around the world.

In conclusion, both Baicalin and octreotide can alleviate the renal pathological changes and improve the survival of SAP rats by inhibiting inflammatory mediators, decreasing the expression level of Bcl-2 protein and enhancing the apoptosis-promoting effect of Bax dimmer to induce the apoptosis of renal tubular epithelial cells. Tissue microarray is time- and energy-saving, highly efficient and

well representative in the pathological examination of pancreatitis. We believe Baicalin, a low-priced new drug with precise therapeutic effects, is hopeful to play certain role in SAP treatment in future.

COMMENTS

Background

Up to now, severe acute pancreatitis (SAP) is still an acute clinical disease featuring multiple complications, high mortality and difficult treatment. Recent studies found octreotide, a somatostatin analogue, could effectively treat SAP. However, octreotide is expensive, which has hindered its clinical application. Therefore, an important direction of the current study is to find other cheap and effective drugs. Baicalin injection (China National Invention Patent Number ZL200310122673.6) prepared by the first author would be one of the best choice to treat SAP. In this experiment, the feasibility of Baicalin treatment of SAP has been studied by comparing the protecting effects and mechanisms of Baicalin and octreotide on kidneys of rats with SAP.

Research frontiers

Both Baicalin and octreotide can alleviate inflammatory reactions by inhibiting the generation of inflammatory mediators and inducing renal cell apoptosis, and thereby exert therapeutic effects on SAP. The mechanism of Baicalin- and octreotide-induced renal cell apoptosis may be related to regulation of Bax and Bcl-2 protein expressions. The therapeutic effects and mechanism of Baicalin on SAP rats are similar to those of octreotide.

Innovations and breakthroughs

As a cheap medicine with extensive pharmacological actions, few side effects and convenient administration, Baicalin can hopefully become a new drug for treating SAP. The application of tissue microarrays in pathological examination of SAP has several advantages, including time- and energy-saving, high efficiency and good representativeness, and therefore is worth popularizing.

Applications

Both Baicalin and octreotide can alleviate the renal pathological changes and improve the survival of SAP rats by inhibiting inflammatory mediators, regulating the expression level of Bax and Bcl-2 protein and inducing the apoptosis of renal tubular epithelial cell. Tissue microarray is time- and energy-saving, highly efficient and well representative in the pathological examination of pancreatitis. We believe Baicalin, a low-priced new drug with precise therapeutic effects, is hopeful to play certain role in future SAP treatment.

Terminology

Baicalin is an important monomer of Baical skullcap root. Severe acute pancreatitis (SAP) is a fatal systemic disease featuring acute onset, serious conditions, high incidence of complications and 20%-30% of mortality.

Peer review

The authors analyzed the protecting effects and mechanism of Baical skullcap root in the treatment of SAP in rats. The authors showed that Baicalin seems to be equally effective as octreotide in terms of reduction of renal pathological alterations. This study is well performed and the results merit further investigation.

Abstract

AIM: To establish a scoring system for predicting the incidence of postoperative complications and mortality in general surgery based on the physiological and operative severity score for the enumeration of mortality and morbidity (POSSUM), and to evaluate its efficacy.

METHODS: Eighty-four patients with postoperative complications or death and 172 patients without postoperative complications, who underwent surgery in our department during the previous 2 years, were retrospectively analyzed by logistic regression. Fifteen indexes were investigated including age, cardiovascular function, respiratory function, blood test results, endocrine function, central nervous system function, hepatic function, renal function, nutritional status, extent of operative trauma, and course of anesthesia. Modified POSSUM (M-POSSUM) was developed using significant risk factors with its efficacy evaluated.

RESULTS: The significant risk factors were found to be age, cardiovascular function, respiratory function, hepatic function, renal function, blood test results, endocrine function, nutritional status, duration of operation, intraoperative blood loss, and course of anesthesia. These factors were all included in the scoring system. There were significant differences in the scores between the patients with and without postoperative complications, between the patients died and survived with complications, and between the patients died and survived without complications. The receiver operating characteristic curves showed that the M-POSSUM could accurately predict postoperative complications and mortality.

INTRODUCTION

With the progress in medical sciences, operative indications for many medical conditions are being expanded, the range of operations is growing, with operative complications increased accordingly. Assessment of the functional condition of organs and systems assists in quantifying the operative risks. Assessment methods allow us to judge the state of an illness and carry out the appropriate preventive treatment immediately, thereby decreasing operative complications and mortality. Numerous scoring systems are currently available, including the Glasgow coma scale (GCS), acute physiology, age and cHealth evaluation II (APACHE II)^[1], physiological and operative severity score for the enumeration of mortality and morbidity (POSSUM)^[2] and others^[3-5].

These scoring systems are important tools in deciding the course of treatment. The best known and most widely used scoring systems, APACHE II and POSSUM, have limitations when applied to high-risk general surgical patients. APACHE II is best suited to intensive care patients, but requires 24 h of observation, and weighing tables for individual disease state. POSSUM is limited by its somewhat subjective nature and incomplete evaluation of cardiac signs. We propose the modified POSSUM (M-POSSUM) as a reasonable, practical and objective scoring system that can be used across a broad disease spectrum in general surgery.

MATERIALS AND METHODS

Patients

The study group included 84 patients with postoperative complications who underwent surgery in our department from May 2002 to May 2004, 16 of them died. The control group included 172 patients without postoperative complications who were randomly selected during the same period of time. General clinical characteristics of the patients including age and gender are illustrated in Table 1. Diagnoses in the malignancy group included colorectal cancer, gastric carcinoma, pancreatic carcinoma, ampullary carcinoma and breast cancer. Diagnoses in the benign group included gastric ulcer, bowel obstruction, cholelithiasis and hyperthyroidism. Concomitant diseases included hypertension, coronary heart disease, pneumopathy, diabetes mellitus, hepatitis and hepatic cirrhosis, cholelithiasis, anemia, cerebrovascular disease and others.

The complications and deaths were caused by common illnesses. In this study, we defined complications as outlined in the book "Clinical General Surgery-Diagnostic Analysis and Treatment Gist". Patients were divided into a group of patients with complications and a group of patients without complications. The group of patients with complications was further divided into a group of patients who survived and a group of patients who died.

Methods

We recorded independent variables such as age, sex, function of all organs and systems, results of laboratory tests and special investigations, duration of operation and volume of intraoperative blood loss. The dependent variables were "complications or not" and "death or not" designated as "0" and "1." We used logistic regression analysis to determine significant risk factors and relative risk (RR).

The indices used were determined by our study results and the prescribed targets and standards of APACHE II and POSSUM. The remaining factors were assigned a point value score (0, 1, 2, 3, or 4). Thus a 15-factor, five-grade scoring system was developed. We compared the difference in M-POSSUM values between various groups, plotted receiver operating characteristic (ROC) curves and calculated the area under the curves to determine the accuracy of M-POSSUM in predicting perioperative and postoperative complication and mortality rates.

Statistical analysis

All information was stored in a computer database. The general clinical data were analyzed by chi-square test. Risk factors were analyzed by logistic regression analysis. Differences in quantitative data were analyzed by *t*-test. A ROC curve was used to evaluate the ability of M-POSSUM to predict postoperative complications and mortality. All these analyses were performed using the Statistical Package for Social Sciences (SPSS) version 11.5.

RESULTS

High risk factor analysis

The RR and *P* were analyzed by logistic regression (Table 2). Eleven significant variables determined were as follows: age, cardiovascular function, respiratory function, blood

Table 1 General clinical profile of patients studied

Clinic data	Postoperative complications	Postoperative death	Postoperative complications

test results, gastrointestinal function, endocrine function, nutritional status, hepatic function, renal function, type of incision and course of anesthesia.

Development of M-POSSUM

Using our study results as well as the prescribed targets and standards of APACHE II and POSSUM, we were able to overcome the shortcomings of APACHE II and POSSUM, eliminate some non-significant variables, and determine the indices to be used. The remaining factors were assigned a point value score (0, 1, 2, 3 or 4). Thus, a 15-factor, five-grade scoring system was developed (Table 3).

Evaluation of M-POSSUM

We compared the M-POSSUM scores of the groups (Table 4), which were significantly different in all groups. The frequency distributional graph of M-POSSUM is shown in Figure 1. The ROC curves and areas under them are shown in Figures 2A and 2B, and Table 5. We were able to use them to predict the morbidity and mortality rates in postoperative patients and determine the accuracy of M-POSSUM in predicting morbidity and mortality.

Table 3 M-POSSUM system

Index	0	1	2	3	4
Age (yr)	< 60	60-69	70-79	≥ 80	
Circulatory system	Normal Car Fun, BP, ECG	Car fun grade I, mild HP and abnormal ECG, sinoatrial bradycardia/tachycardia, low voltage of limb lead, BBB	Car fun grade II, Mod. HP, well controlled by med, occasional atrial premature beats	Car fun grade III, myocardial infarct < 3 mon, mod HP by med, ectopic, arythm, ST-T change, atrial fibrillation	Serious car, insuf, AHF, mal HP
Respiratory system	Normal	Long history of smoking, CB, asthma, URI, thick pulmonary markings	Mild COPD, mild PF change, mild pneumo	Mod COPD, Mod to serious abnormal PF	Respiratory failure

Alive	240	7.58 ± 2.83	-9.096	0.000
Dead	16	14.25 ± 3.02		
Alive with complication	68	10.28 ± 2.38	-5.693	0.000

Predictive formula

Logistic regression analysis yielded statistically significant equations for both morbidity and mortality. The morbidity equation was $\ln R/1-R = -7.287 + 0.765M-POSSUM$ ($P = 0.000$), and the mortality equation was $\ln R/1-R = -10.000 + 0.681M-POSSUM$ ($P = 0.000$). The predictive accuracy of morbidity equation and mortality equation was 83.6% and 94.1%, respectively.

DISCUSSION

In general surgery, postoperative morbidity rate ranges

15%-40%. Among patients at the age of 80 years or more undergoing abdominal surgery, the morbidity is higher and the mortality is about 4%^[6,7]. While the range and types of operation continue to expand and the treatment guidelines for carcinoma change (progressively emphasizing radical treatment, safety and function), postoperative morbidity and mortality are increasing. Scoring systems are used to objectively assess and quantify the severity of illness, determine prognosis, guide patient monitoring and treatment, and avoid preventable deaths. Ideally, an effective scoring system should also be able to provide useful comparisons between surgeons, surgical units, hospitals and regions.

In general surgery, patients at a higher risk are mostly the elderly, who often suffer from concurrent diseases. Most routine blood biochemistry tests cannot exactly reflect any organ's physiological status. Tests and special investigations cannot replace detailed case histories and overall somatoscopy. Baseline health status, previous complications and concurrent diseases can all be found in case history. The frequently used scoring systems, APACHE II and POSSUM, have some limitations^[8-13]. They lay stress on physiological criteria, but not on hepatic function,

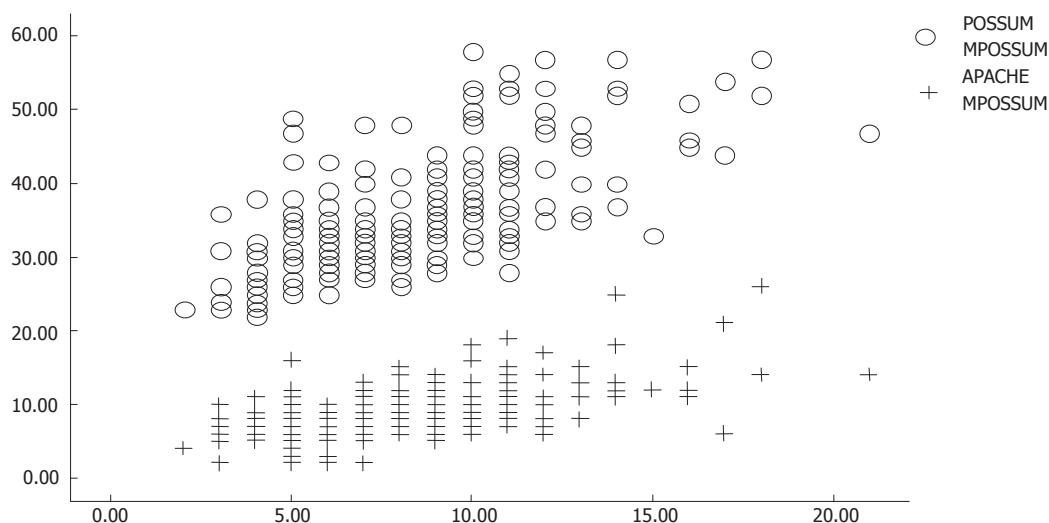

Figure 1 Relative spot chart of M-POSSUM and POSSUM with APACHE II.

Table 5 Area under ROC curves predicting morbidity and mortality

Variety	Area	SD	P
M-POSSUM (predicting for morbidity)	0.901	0.020	0.000
M-POSSUM (predicting for mortality)	0.955	0.016	0.000

blood glucose level and nutritional status, all of which were found to be independent factors affecting morbidity and mortality in our study. The POSSUM has been modified to form P-POSSUM, which is considered more accurate in predicting clinical results^[5,14]. However, no other reports support it^[15,16].

It has been accepted that age and morbidity is correlated with mortality. Elderly patients with concurrent diseases are more likely to develop perioperative and postoperative complications. In our study, a significant difference was found in the number of concurrent diseases between the groups of patients with and without complications. The concurrent diseases associated with a higher morbidity included high blood pressure, coronary disease, chronic lung disease, diabetes and hepatic cirrhosis. This is identical with the results in previous reports. Baue^[17] reported that the main causes of death after major operations are acute respiratory distress syndrome (ARDS), stress ulcer, renal failure, intra-abdominal abscess, multiple organ dysfunction syndrome (MODS) and systemic inflammatory response syndrome (SIRS). In our study, the complications in 16 patients who died were infection, fistula, and hemorrhage, leading to MODS and shock. We found that the factors with the highest correlation with death were blood pressure, electrocardiographic activity during anesthesia, hepatic function, renal function, nutritional status, gastrointestinal function and volume of intraoperative blood loss. Surgeons should therefore improve or correct such abnormalities before operation, to prevent complications, and should promptly identify and manage perioperative and postoperative complications.

A metabolically active organism is in a state of constant dynamic balance, and a static physiological index cannot reflect the dynamic changes. In our study, the significant independent factors were determined by linear multivariate

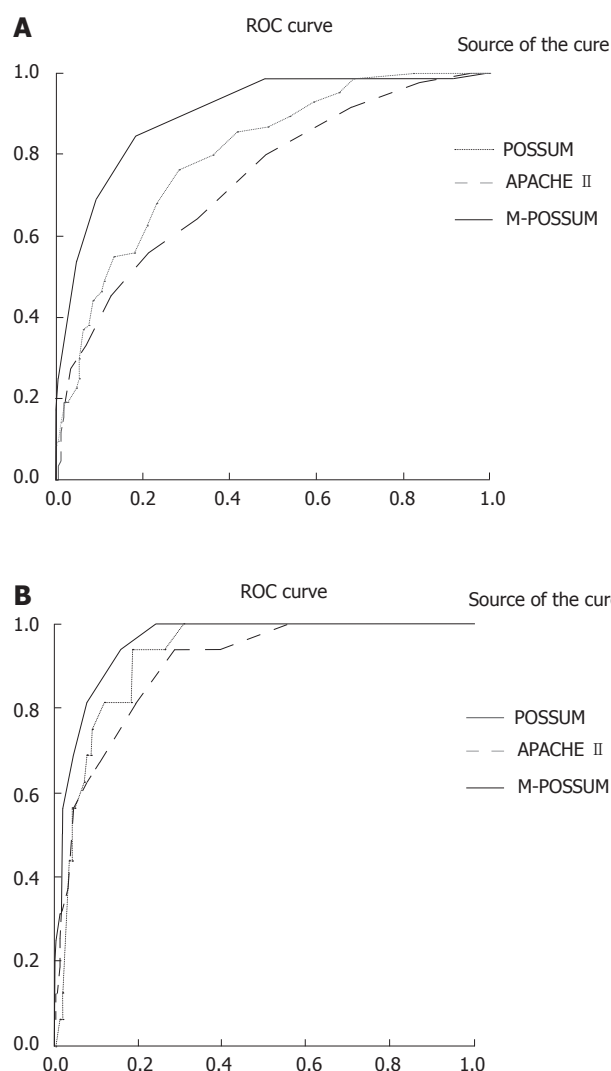

Figure 2 ROC curve of postoperative complications (A) and mortality (B). The red curve (M-POSSUM) covers the biggest area ($\times 100\%$) and illustrates the accuracy of M-POSSUM predicting the morbidity of post-operation before operation.

discriminant analysis.

In the present study, the main factors influencing morbidity were gastrointestinal function, course of anesthesia, nutritional status, renal function, respiratory function, he-

patic function, cardiovascular function and a non-excisable malignant tumor. The main factors influencing mortality were hepatic function, renal function, nutritional status, digestive tract function and a non-excisable malignant tumor. These results can guide surgeons to maintain stable blood pressure and monitor electrocardiographic activity perioperatively, and to be cautious about operating on late-stage malignant tumors, in order to decrease morbidity and mortality.

In contrast to APACHE II and POSSUM, the present scoring system is based on GCS, APACHE II and POSSUM, supplemented with the following indices: hepatic function (bilirubin), blood glucose level, gastrointestinal function and nutritional status (albumin). However, body temperature, heart rate, sodium and potassium, which are always normal preoperatively in general surgery, are not considered. To avoid repetition, duration of operation, volume of intraoperative blood loss and surgery are considered an operative wound index for a malignant tumor. M-POSSUM also takes blood pressure and electrocardiographic activity into consideration during anesthesia.

The area under the ROC curve reflects the accuracy of prediction. In general, the accuracy is low when the area is in the range of 0.5-0.7, intermediate when the area is between 0.7 and 0.9, and high when the area is greater than 0.9. The ROC curves for morbidity and mortality demonstrate that M-POSSUM is a more accurate predictor than POSSUM. The predictive accuracy for morbidity and mortality is 83.6% and 94.1%, respectively.

Using M-POSSUM, we can obtain a numerical estimate of the health status of an individual patient prior to operation, enabling us to adjust the type and duration of operation and determine reasonably individualized postoperative monitoring and treatment so as to decrease morbidity and mortality in general surgery, especially in aged patients.

In conclusion, M-POSSUM is more accurate than POSSUM and APACHE II in predicting postoperative morbidity and mortality, and therefore seems to be a better model for risk assessment.

COMMENTS

Background

With the development in surgical techniques, the surgical domain is enlarging and more diseases are managed with surgery. The incidence of post-operation complications and mortality is increasing because of the increasing number of elderly and tumor patients. Surgeons should be able to evaluate patients effectively preoperatively, by quantitating the operative risk, in order to decrease the incidence of postoperative complications and mortality. An attempt was made to achieve this in the present study.

Research frontiers

Modern surgeons are faced with many problems, such as an aging population

and complicated critical trauma. There is a significant increase in the number of patients suffering from advanced tumors and critical organ disease or dysfunction. Therefore, it is important to increase curative effects and decrease failure rates of therapy. These issues can be solved with the development of scoring systems such as APACHE I, II, III and POSSUM.

Innovations and breakthroughs

Three indices of POSSUM which are poorly correlated with postoperative outcome (body temperature, serum electrolytes and type of surgery) were excluded from M-POSSUM. Six indices which are better correlated with past history, course of anesthesia, hepatic function, gastrointestinal function, endocrine function and nutritional status were included. M-POSSUM correlates well with APACHE II and POSSUM, and is superior to both of them.

Applications

M-POSSUM can decrease postoperative complications after targeted preoperative therapeutic measures in intermediate and high risk patients.

Terminology

Scoring systems such as those defined by APACHE I, II, III and POSSUM, or the American Society of Anesthesiologists (ASA) are used to quantify the severity of an illness before treatment or surgery.

Peer review

This study is interesting and scientific and readable.

Abstract

AIM: To identify risk factors related to pancreatic fistula in patients undergoing distal pancreatectomy (DP) and to determine the effectiveness of using a stapled and a sutured closed of pancreatic stump.

METHODS: Sixty-four patients underwent DP during a 10-year period. Information regarding diagnosis, operative details, and perioperative morbidity or mortality was collected. Eight risk factors were examined.

RESULTS: Indications for DP included primary pancreatic disease ($n = 38$, 59%) and non-pancreatic malignancy ($n = 26$, 41%). Postoperative mortality and morbidity rates were 1.5% and 37% respectively; one patient died due to sepsis and two patients required a reoperation due to postoperative bleeding. Pancreatic fistula was developed in 14 patients (22%); 4 of fistulas were classified as Grade A, 9 as Grade B and only 1 as Grade C. Incidence of pancreatic fistula rate was significantly associated with four risk factors: pathology, use of prophylactic octreotide therapy, concomitant splenectomy, and texture of pancreatic parenchyma. The role that technique (either stapler or suture) of pancreatic stump closure plays in the development of pancreatic leak remains unclear.

CONCLUSION: The pancreatic fistula rate after DP is 22%. This is reduced for patients with non-pancreatic malignancy, fibrotic pancreatic tissue, postoperative prophylactic octreotide therapy and concomitant splenectomy.

INTRODUCTION

Distal pancreatectomy (DP), first performed by Billroth in 1884, is defined as the resection of pancreatic tissue to the left of the superior mesenteric vessels. This procedure was infrequently performed in the past because the tumours of the pancreatic tail and body were often irresectable at the time of diagnosis and due to the general dissatisfaction with this procedure for the management of chronic pancreatitis. However, the advent and development of imaging and diagnostic techniques has increased the frequency of DP. Recently, the indications for DP include malignant and benign pancreatic diseases, non-pancreatic malignancies, chronic pancreatitis, and trauma.

Pancreatic fistula is the most common major complication after DP, ranging from 5% to 40%. Pancreatic leakage often leads to further complications, such as fluid collections or intra-abdominal abscesses, wound infections, respiratory complications, and sepsis^[1]. The appropriate technique of closure the pancreatic stump is still under controversial^[1,2]. The most common used techniques for closure of the transected pancreatic parenchyma and for prevention of pancreatic fluid extravasations from the residual pancreatic tissue are the hand-sewn parenchymal closure and the stapled closure.

The risk factors in the development of pancreatic fistula are also unclear. The method of pancreatic stump closure, malignancy, trauma, patient's age, concomitant splenectomy, or obesity are implicated as potentially important^[3,4].

The purpose of this study was to determine possible risk factors that may be associated with the onset of pancreatic fistula after DP and to identify if the method of pancreatic stump closure plays a significant role in the development of pancreatic fistula.

Table 1 Main parameters for postoperative pancreatic fistula grading^[5]

Grade	A	B	C
Clinical conditions	Well	Often well	Ill appearing/bad
Specific treatment ¹	No	Yes/No	Yes
US/CT	Negative	Negative/Positive	Positive
Persistent drainage (after 3 wk)	No	Usually yes	Yes
Reoperation	No	No	Yes
Death related to fistula	No	No	Possibly yes
Signs of infection	No	Yes	Yes
Sepsis	No	No	Yes
Readmission	No	Yes/No	Yes/No

¹Partial (peripheral) or total parenteral nutrition, antibiotics, enteral nutrition, somatostatin analogue and/or minimal invasive drainage.

MATERIALS AND METHODS

A retrospective review of 64 patients who underwent DP from January 1996 to December 2005 at the Department of Digestive Surgery, Gemelli University Hospital of Rome, was conducted.

Patients' age, sex, indications for surgery, concomitant splenectomy, additional procedures, methods of pancreatic stump closure, and postoperative complications with a specific focus on pancreatic leaks, mortality, and duration of postoperative hospital stay were recorded. Operative details also included operating time and the texture of pancreatic parenchyma. No patient was excluded from the series.

The indications for DP included either primary pancreatic diseases or non-pancreatic malignancies. All the operations were performed by same surgical team. Division of the pancreatic parenchyma was by knife or linear stapler (GIA), while the pancreatic remnant was either closed by a linear stapler or by hand running absorbable monofilament 3-0 sutures. One open drain was positioned near the transected pancreas and it was removed when the daily fluid output was lower than 10 mL or when amylase concentration in the fluid drain was unremarkable in cases of pancreatic leaks (< 300 IU).

We used prophylactic octreotide in the last 34 patients (53%), postoperatively for 7 d, while in cases with fistula the octreotide was prolonged until recovery. The dose of octreotide was 0.5 mg three times a day.

Postoperative mortality and morbidity were registered for 30 d or during the total hospitalisation time, if longer. Postoperative pancreatic leaks were classified according to the international accepted definition reported by Bassi *et al.*^[5] for the international Study Group on Pancreatic Fistula (Table 1). Suspicion and diagnosis of fistula based on biochemical criteria included drainage of more than 10 mL of fluid in 24 h, with an amylase content of more than 3 times the serum amylase activity (> 300 IU) for more than 10 d after surgery. The amount of fluid amylase collected from the drainage tubes, as well as the serum amylase level were evaluated daily until postoperative d 10, and longer in cases with pancreatic fistula. The clinical criteria included the presence of clinical symptomatology such as fever greater than 38°C, leucocytosis with peripheral white blood

cells amount more than 10 000 cells/mm³, intra-abdominal pain or abscess, and the need of percutaneous drainage or reoperation. Intra-abdominal collections were detected by computed tomography (CT).

Oral feeding was generally started on second postoperative day in patients with insignificant amylase concentrations in the abdominal fluid collected by drainage or in patients with Grade A fistula. Conversely, patients with pancreatic fistula Grades B or C were kept with nothing by mouth and were supported with partial or total parenteral or enteral nutrition.

The following eight risk factors were analysed: age (patients older or younger than the age of 70 years old), gender, pancreatic disease or non-pancreatic malignancy, technique of pancreatic stump closure, splenic preservation, texture of the pancreatic parenchyma (soft or fibrotic tissue), additional procedures, and postoperative use of octreotide. The texture of the pancreatic parenchyma was adequately defined by histopathology examination.

Statistical analysis

All data were reported as the mean \pm standard deviation (SD) and/or median. The data were analyzed by means of SPSS 12.01 statistical package for Windows. Mann-Whitney *U* test and Chi-square test was used for group comparison and Students' *t* test to analyze normally distributed quantitative data. *P* < 0.05 was considered statistically significant.

RESULTS

All patients underwent DP for elective benign or malignant, pancreatic or non-pancreatic diseases. There were 30 males (47%) and 34 females (53%). The patients' age ranged from 42 to 84 years (median age, 72.3 years).

The indications for surgery included 38 patients (59%) with pancreatic disease and 26 patients (41%) with non-pancreatic malignancy. Forty-three patients (67%) underwent DP with splenectomy and one or more additional procedures due to primary malignancy: 17 of these patients (40%) had primary pancreatic malignancy infiltrated surrounding organs and 26 patients (60%) had non-pancreatic malignancy infiltrated pancreas. The overall number of additional procedures was 57. Spleen preserving DP was performed in 8 patients (13%); they all had benign or borderline diseases, while DP with splenectomy was performed in 13 patients (20%). The patients' demographics, indications for surgery, operative and technical factors are summarized in Table 2.

The median postoperative length of hospital stay, in patients without fistula, was 11 d (range, 6-15 d); while in patients with pancreatic fistula the median hospitalization was prolonged: 23 d (range, 16-28 d).

The postoperative mortality rate was 1.5% (one patient died due to sepsis), while the morbidity rate was 37% (*n* = 24). The patient with sepsis had both pancreatic and oesophago-jejunal fistula after total gastrectomy for cardiac cancer. The last 7 years no mortality rate occurred. Fourteen patients (22%) developed a pancreatic fistula; 4 of fistulas (28.6%) were classified as Grade A, 9 (64.3%)

as Grade B and only 1 as Grade C (7.1%). Two patients (3%) required a second operation due to postoperative intra-abdominal bleeding. None of patients required a reoperation because of intra-abdominal abscess or fluid collection; these patients were treated by percutaneous drainage. Postoperative results are showed in Table 3.

Pancreatic fistula was significantly more common in patients who underwent DP for primary malignant or benign pancreatic diseases ($P = 0.04$) and in patients who did not receive postoperative prophylactic octreotide therapy ($P = 0.01$). Of 26 patients who were operated for non-pancreatic malignant disease, only 3 (11%) experienced a leak, compared with 11 (29%) of the 38

patients who were operated for pancreatic disease only. Four (12%) of 34 patients who received octreotide developed a pancreatic leak, compared with 10 (33%) of 30 patients who did not.

The potential relationship between the texture of the pancreatic parenchyma and pancreatic leak was also evaluated, considering the remnant stump including resection margin: only 2 (5%) of the 37 patients with fibrotic pancreatic tissue experienced a leak, compared with 12 (44%) of the 27 patients with soft tissue ($P = 0.006$). Finally, we observed significant statistical difference comparing the patients who underwent concomitant splenectomy with them who did not: 10 (18%) of 56 patients with concomitant splenectomy experienced a pancreatic fistula, while 4 (50%) of 8 patients with spleen preserving procedure developed a pancreatic leakage.

The other factors such as age, gender, technique of pancreatic stump closure, and type of surgical procedures were not significantly associated with pancreatic fistula formation. The incidence of pancreatic fistula after DP according to the eight examined risk factors is summarized in Table 4.

DISCUSSION

In this report, we describe our 10-year experience with DP for pancreatic and non-pancreatic benign diseases and malignancies. Our findings identify the importance of four risk factors in the development of pancreatic fistula: fibrotic pancreatic parenchyma, non-pancreatic disease, concomitant splenectomy, and postoperative prophylactic

octreotide therapy were found to result in a statistically significant reduction in the rate of postoperative pancreatic leakage. No significant differences were found regarding to the onset of pancreatic fistula according to the rest of examined factors such as age, gender, technique of pancreatic stump closure, and additional procedures.

Mortality and morbidity after DP have significantly decreased the last decades^[6]. In this study, we support that DP can be performed with low perioperative mortality (1.5%), while the incidence of pancreatic fistula, which was the most common postoperative complication, was 22%. These results are in accordance with the most authors' conclusions^[3,4,7-9].

In the past, in most of published studies there was no definition of pancreatic fistula and the diagnostic criteria for this had not yet been completely established. Balcom *et al*^[10] defined fistula as the drainage of more than 30 mL of amylase-rich fluid, while Balzano *et al*^[4] used a strict definition of fistula: > 5 mL for five days after the fifth postoperative day. In this study, pancreatic leaks were classified according to the International Study Group on Pancreatic Fistula definition^[5]. Grade A of pancreatic fistula, called transient fistula, has no clinical impact, Grade B requires a change in management or adjustment in the clinical pathway, while in Grade C, a major change in clinical management or deviation from the normal clinical pathway occurs. Our results showed that the majority of pancreatic fistulas were belonged to Grade B. These patients were supported with parenteral nutrition, the drains were maintained in place, some of them were covered by antibiotics and all were leaded to a delay in discharge. The only patient with Grade C fistula died postoperatively due to sepsis.

The appropriate closure of the pancreatic stump after DP in order to reduce postoperative complications, especially the incidence of pancreatic fistula, remains an unsolved surgical problem. A great number of surgical techniques and instruments for treating the resected pancreatic surface and preventing pancreatic fistula after DP has been proposed: hand-sewn suture^[2,11], stapler^[1,2,7,11], a combination of stapler and suture^[2,7,11], the use of pledgetted suture^[7], fibrin-glue sealing^[12,13], and prolamine injection^[14]. The most commonly used techniques of pancreatic remnant management are the stapler and suture closure. Stapler division of the pancreatic parenchyma has already been found that is a simple, quick, and secure method of pancreatic stump closure^[1,6,15]. The study by Bassi *et al*^[16] is the only randomized controlled trial that compared the two techniques. They observed that using the stapler technique had better results in comparison with the suture closure (stapler 14% *vs* hand suture 33%). Takeuchi *et al*^[1] described a statistically significant reduction in fistula rate after stapler closure, Fahy *et al*^[9] described suture closure as a risk factor for pancreatic fistula, while Sheehan *et al*^[2] found that the suture closure of the pancreatic remnant was superior compared with the stapler closure (25% *vs* 14% respectively). Finally, Kajiyama *et al*^[15] and Bilimoria *et al*^[7] found no differences between the two techniques. In our study, the authors' technical approach involved stapler and suture closure of the resected pancreatic parenchyma; in 45% of the patients

the pancreatic parenchyma was closed using a linear stapler (GIA), while in 55% of the patients an absorbable monofilament 3-0 suture was used. We were unable to determine the advantage of one method of pancreatic remnant closure on the development of pancreatic fistula: onset of fistula was observed in 24% of patients in stapler group, and in 20% of patients in hand suture group.

Several studies have shown that fistula formation was not related to the main pancreatic duct ligation^[3,17], while others reported the opposite^[6]. We ligated and closed the main pancreatic duct with sutures in all patients after DP thinking that may be helpful in reducing possible pancreatic leaks. In almost all of them, we had no difficulty to find out the pancreatic duct. However, there was no significant difference according to the incidence of pancreatic fistula in our study in comparison with the literature studies^[3,4,7-9].

Many authors state that the texture of the pancreatic parenchyma seems generally to be one of the most important risk factors responsible for the increased rate of pancreatic fistula^[2,9]. The fibrotic pancreatic tissue is believed to be less likely to pancreatic leakage. In accordance with the reported studies, we observed that the patients with soft pancreatic tissue had higher incidence of pancreatic leakage compared with them who had fibrotic pancreatic parenchyma (44% *vs* 5%, $P = 0.006$).

We used postoperative prophylactic octreotide treatment in 53% of the patients and 12% of them developed a pancreatic leak, compared with 33% of patients who did not receive octreotide. However, the role of this treatment still remains unclear. Two randomized trials by Lowy *et al*^[18] and Yeo *et al*^[19] failed to identify a decrease in the pancreatic leakage in patients underwent pancreaticoduodenectomy, while Gouillat *et al*^[20] demonstrated a decreased leak rate in a randomized trial of patients who underwent pancreaticoduodenectomy. Buchler *et al*^[21] reported that the use of octreotide could prevent pancreatic fistula following pancreatic resection. They showed that the incidence of pancreatic fistula was 18% in the patients received perioperative octreotide treatment and 37% in patients received placebo after pancreatic resection. Suc *et al*^[22] also described the advantage of using octreotide after pancreaticoduodenectomy.

The present report also highlights the importance of the primary disease in development of pancreatic fistula after DP: the patients underwent DP for pancreatic disease only had a higher incidence of pancreatic fistula compared with them who underwent DP for non-pancreatic malignancies. There is no doubt that it represents a quite strange observation because in patients with DP due to extrapancreatic malignancies the pancreatic tissue is generally softer than them who undergo DP for pancreatic diseases and we have no scientific explanation. However, new and larger studies are needed to determine if the extrapancreatic malignancies are associated with lower risk of pancreatic fistula after DP or not. Interestingly, there are no studies in the literature, at our knowledge, that examine the primary disease as significant risk factor in the onset of pancreatic fistula. In published series, only the underlying pancreatic disease have examined

as a responsible factor for the occurrence of pancreatic leakage^[2,9]. This is the first study to show that primary (pancreatic and non-pancreatic) disease is a risk factor for postoperative morbidity after DP, especially for pancreatic leakage ($P = 0.04$).

In this study, postoperative comparison suggests that the patients underwent DP with splenectomy had a significantly lower incidence of postoperative pancreatic leakage compared with patients who underwent DP with spleen preserving. In contrast, Balzano *et al*^[4] reported that their patients with spleen preservation had less pancreatic leakage compared to patients with splenectomy (20% *vs* 38%, $P = 0.15$), while Lillemoe *et al*^[23] reported that the patients who underwent a DP with splenectomy had a similar complication rate (30% *vs* 29%) compared to patients who underwent spleen preserving DP, but with no specific focus on pancreatic leak.

Finally, we did not find a relation between the onset of pancreatic fistula and demographic factors (age, gender) nor with the technique of pancreatic closure (there has not been any correlation between pancreatic texture and the dissection technique used) and the additional procedures. In our series, fistula occurred similarly in patients who underwent pancreatic resection only and in patients who underwent one or more additional procedures.

In conclusion, pancreatic fistula after DP affects 22% of patients. None of the two techniques we used seemed useful to significantly reduce this incidence. Based on these findings, we support that the role that technique (either stapler or suture) of pancreatic stump closure plays in the development of pancreatic leak is unclear. Both techniques are regarded as simple, quick and secure although the fistula rate remains high. However, there is a clearly determined relationship between the primary pathology, the octreotide therapy, the texture of the pancreatic parenchyma, the concomitant splenectomy and the postoperative pancreatic fistula formation.

Abstract

AIM: To investigate if there is a correlation between electrical activity measured by electrogastrography (EGG) and contractile activity of the stomach as measured by antroduodenal manometry (ADM). We also studied whether the underlying motility disorder could be predicted from EGG parameters.

METHODS: We compared 21 parameters measured from EGG with 8 parameters measured from ADM. The ability of EGG to identify the underlying diagnosis was tested by comparing EGG parameters for each diagnosis group against other patients. The study comprised recordings from 148 patients and 125 females. Their median age was 45 (range 17-76) years.

RESULTS: We found few and weak correlations between EGG and ADM. Specifically the correlation between parameters reflecting the response to meal was poor ($r = -0.07$, $P = 0.39$). The discriminatory power of EGG for underlying motility disorder was also low. Patients with slow transit constipation (STC) showed a lower postprandial power in normogastric (3.7 ± 0.5 vs 4.0 ± 0.5) and tachygastric (3.5 ± 0.4 vs 3.7 ± 0.4) regions, a lower percentage of time with normogastria [87.2 (56.5-100)% vs 95.7 (0-100)%], and a higher percentage of time with tachygastria [9.3 (0-33)% vs 3.5 (0-100)%] and bradygastria [1.8 (0-20)% vs 0 (0-17.1)%]. Patients with irritable bowel syndrome had a higher percentage of time with normogastria [96.5 (62.5-100)% vs 93.3 (0-100)%] and a less unstable dominant frequency as measured by the instability coefficient [15 (3-77) vs 24 (2-72)].

CONCLUSION: EGG and ADM seem to measure different aspects of gastric motor activity but cannot

INTRODUCTION

Electrogastrography (EGG) is a technique for recording gastric myoelectric activity using cutaneous electrodes placed on the abdominal wall overlying the stomach. EGG detects rhythm and power (amplitude) of gastric myoelectricity^[1]. Studies have shown a good correlation between cutaneous EGG recordings and myoelectric signals recorded from gastric serosal leads^[2]. However, there are major concerns regarding the clinical usefulness of this non-invasive procedure^[3].

EGG has been advocated as a diagnostic test in the clinical evaluation of patients with unexplained nausea, vomiting and other dyspeptic symptoms to gain insight into the mechanisms of symptom generation. Conflicting results have been obtained in previous studies. In some studies, subsets of patients with upper abdominal symptoms have depicted prominent EGG abnormalities whereas healthy volunteers rarely have exhibited EGG rhythm or power disturbances^[4,5]. Other studies have found no difference in EGG parameters between dyspeptic patients and healthy volunteers^[6,7].

Patients with systemic diseases such as Parkinson's disease^[8], myotonic dystrophy^[9], and diabetes mellitus^[10] show abnormal EGG findings. However, in patients with progressive systemic sclerosis (which is usually associated with poor gut motility), EGG shows unchanged parameters^[11]. Similarly, EGG shows a greater variability compared to normal volunteers but no typical EGG pattern could be identified for different surgical procedures in surgical patients after cholecystectomy, Nissen fundoplication, subtotal gastrectomy or vagotomy and gastric pull-up operations^[12].

Antroduodenal manometry (ADM) records lumen-occluding contractions of the gastric antrum^[13]. Under physiological conditions there is a temporal correlation between myoelectric slow waves and contractile activity of the antrum. It is less clear if there is a spatial correlation between electrical and contractile activity. A small study in healthy females showed an unstable EGG peak power during fasting and an increase in EGG peak power after a solid test meal as indicative of a correlation between electrical activity and gastric motor activity^[14]. It is conceivable that there should be a correlation between electrical activity measured by EGG and contractile activity measured by ADM. It would be of interest to know if EGG can predict gastric contractile activity. Surprisingly, a direct head to head comparison between EGG and ADM has not been done previously.

The aim of the present study was to compare measures of electrical activity determined by EGG and antral contractile activity from antroduodenal manometry. We also investigated whether EGG could differentiate between different underlying diagnoses of motility disorders.

MATERIALS AND METHODS

Subjects

This was a retrospective analysis of data collected during 1994-2001. Adult patients suffering from various functional and motility disorders of the gastrointestinal tract were included in our study. All of them were subjected to a combined EGG and ADM study as part of their clinical work-up for suspected gastrointestinal motility disorders. The two measurements were done simultaneously using two different systems, thus synchronous analysis was not possible in this study.

Electrogastrography

This procedure has been described elsewhere^[6]. Briefly, a single bipolar channel was used. The EGG signal was recorded using a specially designed digital recorder (Digitrapper-EGG, Medtronic Synectics, Stockholm, Sweden) and sampled at a rate of 1 Hz. EGG recordings were examined visually for artefacts and then categorized into excellent (no artefacts), good (< 25% of recording time excluded because of artefacts), fair (< 50% excluded) or poor quality (\geq 50% excluded). After exclusion of artefacts, the remaining parts of the recordings were analysed with a software provided by the vendor (Polygram version 6.40, Medtronic Synectics, Stockholm, Sweden). This program could analyse the EGG using fast Fourier transformations of 256-s runs with an overlap of 196 s, so-called running spectral analysis, and can also make a Fourier transformation of an entire period in order to obtain a single power spectrum for that period. The parameters derived from the automated analysis of EGG are shown in Table 1. Dominant frequency instability coefficient (DFIC) and dominant power instability coefficient (DPIC) are measures of the variability of the EGG signal, which were computed as the standard deviations divided by the mean value of the dominant frequency and dominant power, respectively, from the running spectral analysis of each period.

Table 1 Electrogastrography (EGG) and antroduodenal manometry (ADM) variables

1	EGG variables
(1)	Preprandial (fasting) and postprandial percentage of time with dominant frequency in:
	Bradygastria (0.5-2 cycles per minute)
	Normogastria (2-4 cycles per minute) (0.5-2 cycles per minute)
	Tachygastria (4-10 cycles per minute)
(2)	Pre- and postprandial power attributed to the three frequency bands (bradygastria, tachygastria and normogastria)
(3)	Pre- and postprandial dominant power instability co-efficient (DPIC)
(4)	Pre- and postprandial dominant frequency instability co-efficient (DFIC)
(5)	Pre- and postprandial dominant frequency (DF)
(6)	Pre and postprandial period dominant power (PDP)
(7)	Power ratio (ratio of postprandial to preprandial power of dominant frequency)
2	ADM variables
(1)	Pre- and postprandial motility index (MI)
(2)	Pre- and postprandial contractile frequency
(3)	Pre- and postprandial median amplitude
(4)	MI ratio (ratio between postprandial and preprandial motility index)
(5)	Amplitude ratio (ratio between postprandial and preprandial amplitude)

Antroduodenal manometry

ADM was performed using a flexible catheter with either 6 or 8 water-perfused channels. The 6-channel catheter has 3 channels spaced 2 cm apart for the recording of antral motor activity whereas the 8-channel catheter has 5 channels spaced 1 cm apart for the same purpose. We used a pneumo-hydraulic pump (Arndorfer Medical Specialties, Greendale, WI, USA) with catheters connected to external pressure transducers. Data logging was done with a Polygraph 12HR and the Polygram (Medtronic Synectics, Stockholm, Sweden). The protocol included a 3-hour fasting period followed by a test meal (500 kcal standardized mixed meal) and 2-hour post-prandial recording^[15]. Numerical analysis was done on data from the most distal recording site in the gastric antrum. Data were extracted using the Polygram that was set to detect contractions with an amplitude > 9 mmHg. We determined the mean frequency and amplitude of contractions and motility index during the last hour before and the first hour after intake of the test meal. The motility index was calculated as the area under the curve above baseline per time unit. We compared 8 variables from ADM with 21 variables from EGG (Table 1).

Statistical analysis

Normally distributed and lognormal data were expressed as mean \pm SD and data with a non-normal distribution were given as a median and full range. We used Student's *t*-test and Mann-Whitney *U*-test for assessing differences between the groups. Correlations were studied using Pearson's product moment correlation. Logistic regression analysis was done to test EGG parameters for their discriminatory value in predicting underlying diagnoses. *P* < 0.05 was considered statistically significant.

RESULTS

A total of 185 patients were eligible for the study but 37 were excluded either because of previous gastric resection (*n* = 6), poor quality of the EGG recording (*n* = 23), or because of a technical failure (*n* = 8) in the EGG system. Another 4 patients were excluded from the comparison between EEG and ADM because ADM recordings did not show a recording from the antrum during the fasting or the fed period or both. Thus, the study population finally included 148 patients for comparing EGG parameters among various diagnosis groups and 144 patients for assessing the correlation between EGG and ADM parameters. The median age of the patients was 45 (range 17-76) years and 122 (82%) were females. There were 52 patients (35%) with IBS, 22 (15%) with enteric dysmotility (ED), i.e. abnormal small bowel motor activity but no bowel dilatation^[16], 26 (18%) with slow transit constipation (STC), 11 (7%) with chronic intestinal pseudo-obstruction (CIP), 13 (9%) with functional dyspepsia with or without gastroparesis and 24 (16%) with other diagnoses, including various systemic and neurological diseases.

Comparison of electrogastrography and antral manometry

Few correlations were found between EGG and ADM. The correlation matrix was analyzed between 21 EGG parameters and 8 ADM parameters in this study (Brady = bradygastria, Normo = normogastria, Tachy = tachygastria, DF = dominant frequency, DFIC = dominant frequency instability coefficient, DPIC = dominant power instability coefficient, PDP = period dominant power, Amp = amplitude, MI = motility index, Freq = frequency, Pre = preprandial, Post = postprandial) (Table 2).

Postprandial contractile activity (amplitude, frequency and motility index) showed weak, negative correlations with the postprandial dominant power instability coefficient. Preprandial tachygastria (reflected by the percent-

age of time with a dominant frequency in the tachygastria region and dominant frequency) was also negatively correlated with postprandial contractile amplitude. The comparison between EGG response to meal ingestion (ratio between postprandial and fasting power) and ADM response to ingestion of a 500 kcal test meal (ratio between postprandial and fasting motility index) revealed no correlation (*r* = -0.07, *P* = 0.44, Figure 1).

Electrogastrography and underlying diagnosis

The ability of EGG to identify diagnostic groups was tested by comparing EGG parameters for each group against all other patients included. Table 3 shows the discriminatory power of EGG for the larger patient groups. Variables with a normal or log-normal distribution were expressed as mean ± SD, else as median and full range. Patients with other diagnoses (*n* = 24) were not listed but included in the calculation of differences. Significant *P*-values were expressed as ^a*P* < 0.05, ^b*P* < 0.01, and ^d*P* < 0.001 (Brady: bradygastria, Tachy: tachygastria, Normo = normogastria, DFIC: dominant frequency instability coefficient, DPIC: dominant power instability coefficient, DF: dominant frequency, PDP: period dominant power).

In general, the discriminatory power of EGG was low. Only patients with STC in one diagnostic group, showed a reasonable number of differences in postprandial EGG parameters compared to those in all other diagnosis groups. STC patients had a lower postprandial power in the normogastric region (3.7 ± 0.5 vs 4.0 ± 0.5 , *P* < 0.01) and in the tachygastria region (3.5 ± 0.4 vs 3.7 ± 0.4 , *P* < 0.05). Similarly, the postprandial percentage of time with a dominant frequency was higher in bradygastric and tachygastria frequency bands and lower in the normogastric frequency band of STC patients (Table 3). Patients with STC also demonstrated a significantly lower postprandial dominant power (2.1 ± 0.6 vs 2.4 ± 0.5) compared to other patients.

In patients with CIP, EGG during fasting showed a sig-

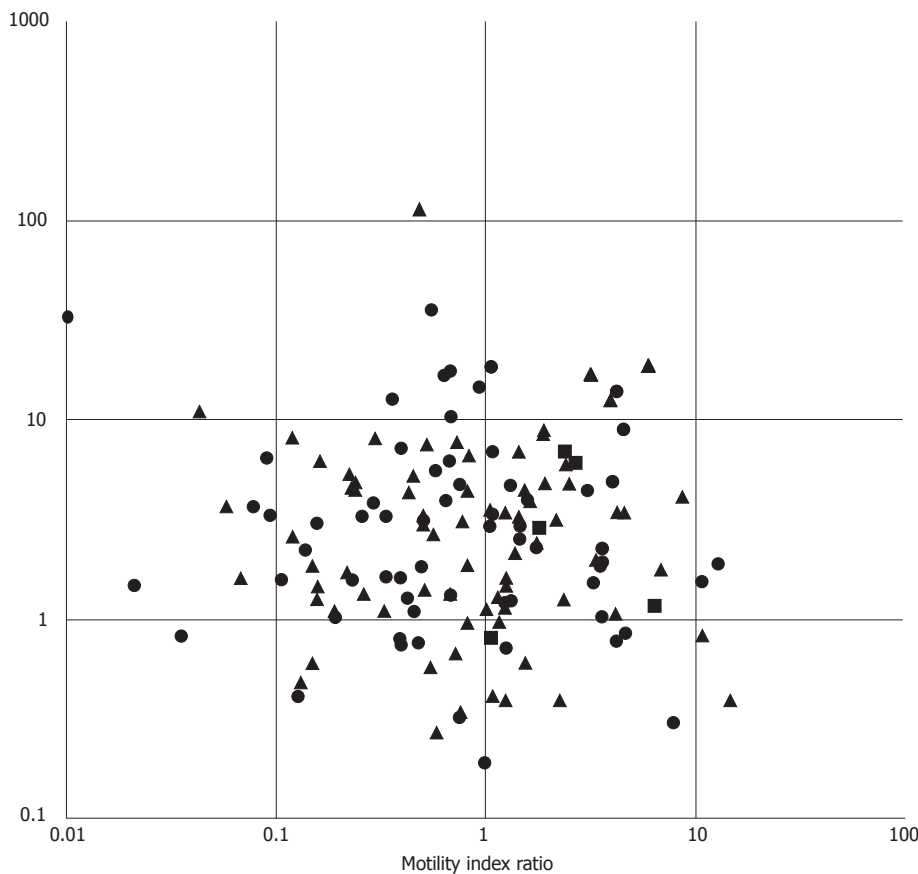

Figure 1 Scatterplot of motility index ratio and power ratio in 144 patients (logarithmic scales). Symbols indicate different qualities of the EGG record: ■ = excellent; ● = good; and ▲ = fair quality.

nificantly higher power in the tachygastric region (3.7 ± 0.4 vs 3.3 ± 0.4 , $P < 0.05$) and a higher period dominant power (2.4 ± 0.7 vs 2.0 ± 0.5) compared to patients without CIP. In patients with IBS there was a higher percentage of time with a normogastric dominant frequency in the postprandial period and a more stable dominant frequency mea-

sured by DFIC during both preprandial and postprandial periods (Table 3).

Twenty patients underwent gastric emptying studies. Five of them had delayed gastric emptying. No significant differences were found in EGG parameters among patients with or without delayed gastric emptying.

DISCUSSION

To the best of our knowledge, this is the largest series of simultaneous recordings of EGG and ADM in patients with motility disorders of the gut. In the present study, we studied the relationship between EGG parameters and antral manometric findings. We also tried to evaluate the role of EGG in discriminating between various motility disorders of the gastrointestinal tract. EGG is not capable to record spike activity, hence the major electrical indicator of contractile activity is absent in its recordings. However, an increase in wave amplitude on EGG (referred to as power from the spectral analysis) can be asserted as a reflection of contractile activity. It has been observed that EGG power increases after certain drugs or meals that stimulate motility and decreases after drugs or meals that inhibit motility^[12]. Therefore, to measure the significance of EGG power, it is best to compare EGG changes before and after the test meal given during EGG recording^[14]. We found few and weak correlations between ADM findings and EGG parameters, especially no correlation between the motility index ratio and the power ratio. This is contrary to the findings of another study^[17], where the EGG power ratio was significantly but weakly correlated with the motility index ratio. The number of patients in that study was, however, only 16. A partial correlation has also been found in children between the postprandial increase in amplitude of gastric electrical activity and antral motor activity^[18]. In the present study, a more stable dominant power, i.e. lower DPIC, was associated with a higher contractile activity and tachygastria during the preprandial period was associated with lower amplitudes of contraction during the postprandial period, but the correlations were weak in both cases.

One important reason for a poor correlation between EGG-recorded electrical activity and ADM-recorded motor activity of the stomach could be that EGG recordings are sensitive to the degree of gastric wall distension and its approximation to the anterior abdominal wall. An underlying motility disorder of the gut might cause the gastric wall to distend inappropriately in response to the test meal and therefore lead to an inadequate EGG recording of gastric myoelectric activity. In light of the weak correlation between ADM and EGG found in other studies^[17,18] and our observations, we think that EGG and ADM can measure two different aspects of gastric motor activity and a spatial relation cannot be fully determined between EGG and ADM.

Surprisingly, STC in the only diagnostic group stood out as clearly different from the other diagnostic groups on the basis of EGG parameters. Patients with STC exhibited differences mainly in the postprandial EGG parameters. Many studies have demonstrated a decrease in the density of interstitial cells of Cajal (ICC) in patients with slow transit constipation^[19-21]. It is possible that observed postprandial changes in EGG parameters might be the reflection of a more generalized gastrointestinal myoelectrical dysfunction in STC patients secondary to depletion of ICC and other neuroenteric abnormalities. Further studies are needed to validate the EGG findings in patients with STC in the present study.

It was reported that EGG is diagnostically useful in adult patients with CIP^[22]. Moreover, a comparison be-

tween normal subjects and children with CIP could reveal a significant increase of preprandial values for tachygastria and period dominant frequency and a decrease in normogastria and an increase in total tachygastria values in postprandial period^[23]. In our study, the CIP patients had a significantly higher power on EGG in the tachygastria region and a higher PDP during fasting.

Another field of interest among researchers interested in evaluating the clinical usefulness of EGG is functional dyspepsia with or without gastroparesis. Studies have shown abnormal EGG patterns such as abnormal slow wave propagation and coupling^[24], lower power ratio, lower postprandial level of increment in dominant power and a higher instability coefficient^[25,26] in patients with functional dyspepsia. However, abnormal parameters are not the same in different studies. Interestingly, significantly more gastric arrhythmias have been found in oesophageal reflux patients with dyspeptic symptoms than in those with no dyspeptic symptoms^[27].

Contradictory findings can be found when capability of EGG is assessed to predict delayed gastric emptying. It was reported that patients with impaired gastric emptying show a significantly lower percentage of normal gastric slow waves and a lower postprandial increment in dominant power^[28]. On the other hand, another study conducted in patients with systemic sclerosis has not found any correlation between delayed gastric emptying and EGG abnormalities^[11]. In our study, no difference in EGG parameters was found between dyspeptic patients with delayed gastric emptying and those with normal gastric emptying, possibly due to a small number of patients with gastric emptying.

Our study has certain limitations. One of them was the retrospective design of the present series, which is unlikely to have influenced the results of the present study concerning the correlation between EGG and ADM. On the other hand, the comparison of EGG parameters between different diagnostic groups was hampered by a small number of patients in certain groups. Another limitation was the absence of a control group to compare with patients with motility disorders. In the present series, however, comparison of both EGG and ADM comparison was available in each patient. In our opinion, the assessment of correlation between EGG and ADM is not affected by the absence of a control group. We used a single channel EGG instead of a multiple channel EGG in our study. Novel multi-channel EGG can study the propagation and coupling of slow waves in the stomach, and is perhaps more helpful than single channel EGG in the diagnosis of gastric dysfunction^[24]. It is possible that registrations from multiple channels would have a better chance to detect correlations with contractile activity, not least because sampling error from multiple channels would be smaller than those from a single channel. However, no data are available from comparisons between ADM and multi-channel EGG.

A high exclusion rate of patients in our series was due to EGG recordings that were not interpretable. Motion artefacts were common despite the stationary condition of the patients. Care was taken in preparing the skin so that the impedance between any two electrodes was less than

10 ohms. Nevertheless, many recordings exhibited low frequency aberrations and shifts of baseline. Moreover, various technical problems, such as faulty electrode cables or malfunction due to static electricity, also resulted in exclusion of a significant number of patients from analysis. We have not come across any account for such failures of EGG recording in previously published studies.

In short, no consistent relationship was observed between EGG and ADM in this series. No evidence was found in this study to favour a spatial correlation between the parameters measured by EGG and ADM. Moreover, the ability of EGG to identify motility disorders was generally poor in this study.

In conclusion, EGG findings in STC patients are interesting but further studies are required to validate the role of EGG in STC patients.

COMMENTS

Background

Electrogastrography is to measure the electrical activity of the stomach from electrodes attached to the abdominal surface. The usefulness of this technique for the diagnosis of gastrointestinal diseases is yet unknown. However, since electrical activity is pivotal for motor function, it is believed that measurement of electrical activity should reveal important diagnostic information in patients with motility disorders.

Research frontiers

The correlation between measures derived from electrogastronomy and other techniques such as manometry has received little attention. Such correlations are important for understanding the relation between different measurement techniques.

Innovations and breakthroughs

This is a head-to-head comparison of electrogastronomy and antroduodenal manometry, i.e. measurement of contractile activity of the stomach done at the same time from a large number of patients with gastrointestinal motility disorders.

Applications

This study could not show any correlation between antroduodenal manometry and electrogastronomy, suggesting that the two techniques can measure different aspects on gastric motor function. The study also showed that the ability of electrogastronomy to identify patients with different diagnoses was poor. To the surprise of the authors, patients with slow transit constipation, a severe form of intractable constipation, were the only group of patients identified by electrogastronomy. The reason for this is not clear, but it is known from previous research that patients with slow transit constipation have a lack of pacemaker cells in the gut, which could explain why they also had disturbed electrical rhythm in the stomach.

Terminology

Correlation is a measure of the relative correspondence of two sets of data. Manometry is the measurement of (in this case, intraluminal) pressure over time. Motility disorders comprise a large number of disorders that affect gastrointestinal motor activity. The most common disorder is irritable bowel syndrome.

Peer review

This is a well written paper on a subject with a considerable debate. Whether electrogastronomy and antroduodenal manometry can measure different aspects of gastric motor activity needs to be further studied.

Received: June 14, 2007 Revised: July 28, 2007

Abstract

AIM: To assess values of 24-h esophageal pH-monitoring parameters with dual-channel probe (distal and proximal channel) in children suspected of gastroesophageal reflux disease (GERD).

METHODS: 264 children suspected of gastroesophageal reflux (GER) were enrolled in a study (mean age $\chi = 20.78 \pm 17.23$ mo). The outcomes of this study, immunoallergological tests and positive result of oral food challenge test with a potentially noxious nutrient, enabled to qualify children into particular study groups.

RESULTS: 32 (12.1%) infants (group 1) had physiological GER diagnosed. Pathological acid GER was confirmed in 138 (52.3%) children. Primary GER was diagnosed in 76 (28.8%) children (group 2) and GER secondary to allergy to cow milk protein and/or other food (CMA/FA) in 62 (23.5%) children (group 3). 32 (12.1%) of them had CMA/FA (group 4-reference group), and in remaining 62 (23.5%) children neither GER nor CMA/FA was confirmed (group 5). Mean values of pH monitoring parameters measured in distal and proximal channel were analyzed in individual groups. This analysis showed statistically significant differentiation of mean values in the case of: number of episodes of acid GER, episodes of acid GER lasting > 5 min, duration of the longest episode of acid GER in both channels, acid GER index total and supine in proximal channel. Statistically significant differences of mean values among examined groups, especially between group 2 and 3 in the case of total acid GER index (only distal channel) were confirmed.

CONCLUSION: 24-h esophageal pH monitoring

confirmed pathological acid GER in 52.3% of children with typical and atypical symptoms of GERD. The similar pH-monitoring values obtained in group 2 and 3 confirm the necessity of implementation of differential diagnosis for primary vs secondary cause of GER.

INTRODUCTION

Acid gastroesophageal reflux (GER) in children at any age, could be the reason of various clinical manifestation (typical and atypical) of variable intensity, dependent on the range of reflux (high reflux, low reflux)^[1-9]. On the basis of reflux symptoms it is hardly possible to differentiate primary GER from GER secondary to allergy to cow milk protein and/or other food (CMA/FA)^[10-13]. In children suspected of gastroesophageal reflux disease (GERD), 24-h esophageal pH-monitoring is a diagnostic procedure that enables to confirm or exclude pathological reflux of acid gastric contents into esophagus i.e. acid GER^[14-20]. Diagnostic procedure, including food allergy contribution in GER, is necessary to distinguish primary GER from secondary GER. Such procedure includes immunoallergological tests i.e. Prick tests, cIgE, sIgE^[2,12,21-25]. Positive result of food oral challenge test with potentially noxious nutrient (biological trial) confirmed contribution of food allergy in triggering off reflux symptoms^[25,26]. Comparative analysis of 24-h intraesophageal pH monitoring with dual-channel probe (distal and proximal channel) in children suspected of gastroesophageal reflux disease (GERD).

MATERIALS AND METHODS

264 children suspected of GERD, of both sexes (140 boys-53.0% and 124 girls-47.0%) were enrolled in a study. Patients were 1.5 mo to 102 mo old, mean age $\bar{x} = 20.78 \pm 17.23$ mo. Information gathered at interview revealed that various gastrointestinal diseases appeared in family histories of all patients.

24-h esophageal pH monitoring

24-h intraesophageal pH-monitoring was performed with antimony dual-channel pH monitoring probe (distal channel/distal and proximal channel) and a device recording the values Digitraper MK III, Synectics Medical. Antimony electrode was calibrated with buffer solutions of pH = 7.0 and pH = 1.0. pH-monitoring probe, 2.1 diameter, was positioned in esophagus through one of the nostrils and pharynx with distal channel (2) at the height of 3-5 cm, and proximal channel (1) at 10, 15 or 20 cm above the upper edge of lower esophageal sphincter (LES). To localize the probe Strobel's mathematical mode, radiological examination, and manometry of LES were carried out^[27-29].

The type of dual-channel probe (sensors spacing 5, 10 or 15 cm) and its positioning in esophagus depended on the age of a patient (various lengths of esophagus) and clinical manifestation of GER (typical or atypical symptoms). The analysis of the type of reflux (acid/non-acid) was based on the pH monitoring values recorded in distal channel (2).

Recording from proximal channel (1) of the probe above LES (at various height) enabled the assessment of the range of reflux (high/low reflux) and the control of the proper positioning of the probe. It was also possible to compare the number of acid and non-acid refluxes in both positions of pH-monitoring. Esophageal pH monitoring always began in the morning, after fasting all night. The study lasted 24 h and comprised night sleep.

Patients discontinued particular medicines 3 d before the test. Among these medicines were: antacids, gastrokinetics, medications affecting tension of LES. Proton pump inhibitors, H₂-receptor antagonists were discontinued 7 d before the test^[30].

Computer calculations of measurements obtained from both channels concerned the following pH-monitoring parameters: number of episodes of acid GER (intraesophageal pH below 4.0), number of episodes of acid GER lasting more than 5 min (so-called "long episodes"), reflux index i.e. the percentage of time that the pH is below 4.0. ESPGHAN diagnostic criteria were implemented in diagnosis of acid GER in examined children^[14,15].

In children below 2 years of age the values of intraesophageal pH-monitoring were juxtaposed against normative values (borderline values) of Vandenplas *et al*^[16,17] and another authors^[18,19].

In older children (above 2 years of age) the borderline values at quantitative and qualitative assessment of pathological GER in both channels were^[14,15,31-33]: total number of acid GER episodes (pH < 4.0/24 h) = 50; number of episodes of acid GER lasting more than 5 min

≤ 2; the percentage of time with pH below 4.0 (%) - total acid GER index = 5.0%; the percentage of time with pH below 4.0 (%) - acid GER index supine = 2.5%.

Differentiation of pathological acid GER

In order to differentiate pathological GER into primary (idiopathic) and secondary - triggered off or aggravated by CMA/FA, the own diagnostic and therapeutic algorithm was administered in examined children. This algorithm comprises selected immunoallergological tests^[10,23-25,34].

Skin tests (Prick): (1) with 12 native food allergens i.e. fresh (cow's milk, soya, of hen's egg white, hen's egg yolk, chicken's meat, beef, wheat flour, peanuts, bananas, fish, orange, white sesame); (2) with 9 commercial inhalant allergens (SmithKline Beecham-USA) (house dust mites, grass, trees, bushes and weeds pollens, dog's fur, cat's fur, mixed feathers, wool).

71 out of 138 children, of different age, with pathological acid GER and 32 children with CMA/FA exclusively, underwent these test once in order to confirm or exclude the ability of early IgE-dependent hypersensitivity to food allergens and/or inhalant allergens (atopic factor influence and or cross reactions) to trigger off symptoms observed. Results of control tests were the point of reference in assessment of reaction to allergens. The diameter of blister ≥ 3 mm assessed after 15-20 min of allergen placement was concerned a positive result of skin Prick tests, compared to negative result of negative control.

Eosinophilia: One-time assessment of relative eosinophilia in full blood count and its analysis were performed in 138 children with pathological acid GER and in 32 children with CMA/FA exclusively. Improper percentage value of eosinophilia, determined in full blood count, was > 5%.

Total IgE concentration (c IgE) in serum-assessed with Fluoro-Fast method (3M Diagnostic Systems, USA): One-time assessment of serum IgE concentration was done in 170 children-138 with acid GER and 32 with CMA/FA exclusively. Serum c IgE concentration > 50 IU/mL was considered as elevated in examined children. Taking into consideration restricted specificity of one-time measurement of total IgE in diagnosis of atopy, this test was performed together with determination of specific Ig in this particular class for selected food allergens.

Qualitative and quantitative assessment of specific IgE against food allergens (a-s IgE) and inhalant allergens (i-s IgE) with Fluoro-Fast method (3M Diagnostic Systems, USA): Assay of allergen specific Ig concentration in examined children enabled confirmation of IgE-dependent pathomechanism of food allergy and determination of food allergens. These tests appeared to be helpful in cases where tests cannot be performed or their results are doubtful, due to various reasons. 103 patients suspected of allergy, with positive Prick tests results (food allergens and/or inhalant allergens and

increased total serum IgE concentration) underwent qualitative and quantitative assessment of a-s IgE and i-s IgE. Positive results of specific IgE were: a/a-s IgE against cow milk proteins, hen's egg white, hen's egg yolk, soy, fish, orange b/i-s IgE against grass, trees, bushes and weeds pollens, house dust mites and cat's fur, assayed in serum-presence supported in class ≥ 2 -5.

Oral food challenge test^[25,26]: Open or blind oral food challenge test (depending on the age of patient) was carried out in order to establish causative relationship between food and clinical symptoms, regardless of pathogenetic mechanisms of allergy (IgE-dependent or IgE-non-dependent)^[25]. The first stage of diagnostic procedure preceding the beginning of oral food challenge tests was eliminatory diet implementation, lasting 4 wk in 138 children with acid GER. Diet depended on elimination of the most common food allergens, suspected of triggering off symptoms in examined children. Eliminatory diet was determined on the basis of information gathered from medical history of past nutrition and the results of additional tests (skin Prick tests, s IgE)^[25,26]. At the time of study, patients didn't receive or had maximally reduced antiallergic and/or antihistaminic medications. 138 children at various age, with pathological acid GER, after eliminatory diet implementation (milk-free and/or hypoallergic diet) underwent 204 biological oral food challenge tests; 138 (67.6%) with cow's milk and 66 (32.4%) with other food. In order to establish primary diagnosis, open food challenge test was performed in the 104 youngest children (below 3 years of age) and blind food challenge test in 34 children (above 3 years of age) with mainly cow's milk (low-lactose Bebilon, Ovita Nutricia) or with other potentially noxious nutrients^[25,26]. Every time child spent 1-3 d at hospital (Laboratory of Allergy Diagnostics, of III Department of Pediatrics). Time of appearance of biological reaction in examined child was counted from the last food challenge up to 48-72 h after intake of specific nutrient in native, blind form. Every patient examined received every day observation chart for reporting intensity of clinical manifestation. In case of cow's milk allergy or soy milk allergy and/or other food allergy the time of challenge test lasted 4 wk. Positive result of food challenge test and/or positive results of immunoallergological tests enabled to qualify a selected 62 children into group 2-children with GER secondary to FA.

In order to exclude the cause of secondary GER other than food allergy, the results of additional examinations performed in patients were analyzed. Among these examinations were: chest and upper gastrointestinal tract X-ray with barium swallow, X-ray or computed tomography of sinuses (in school children). On the basis of the aforementioned examinations, the type, localization and character of coexisting ailments were assessed. In order to confirm or exclude infectious cause of the symptoms presented, the following tests were taken into consideration: full blood count, erythrocyte sedimentation rate, CRP, ASO, protein fraction pattern, concentration of IgA, IgM, IgG, IgG antibodies against *Helicobacter pylori* and

Table 1 Qualification of 264 children suspected of GERD into study groups (at diagnosis)

Groups of examined children	Sex	Examined children with reflux symptoms

iron level. Moreover, bacteriological examinations were performed in some children (tests of blood, urine, faeces, bile, pharyngeal and nasal excretion). Pilocarpine test (chlorine concentration in perspiration) was performed to exclude cystic fibrosis. Moreover, metabolic screening was done by assaying lactic acid, ammonia, acid-base balance parameters in blood^[2,9,13,34].

Assignment of children into study groups

264 children were assigned into specific study groups (Table 1) after consideration of the results of 24-h esophageal pH monitoring, complex differential diagnosis, oral food challenge test with noxious nutrient, eliminatory diet, and nutrition analysis.

Acid GER was diagnosed in 170 children. Out of 170 patients (64.4%) with acid GER, of both sexes i.e. 89 boys and 81 girls, 32 (12.1) infants with physiological GER (group 1) were selected. This selected group consisted of 17 boys (6.4%) and 15 girls (5.7%), aged 1.5-4 mo (mean age $\chi = 2.2 \pm 0.48$ mo).

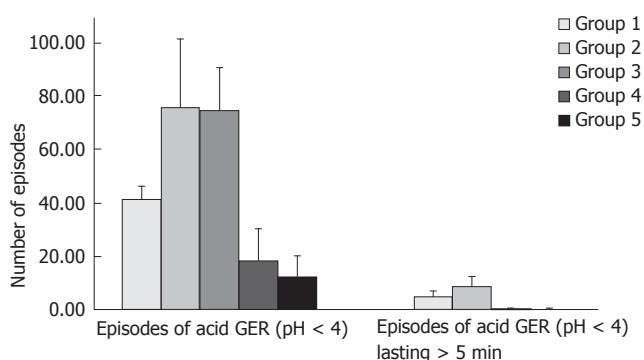

The diagnosis was put forward on the basis of the number of reflux episodes exclusively, recorded during pH monitoring. The results of remaining parameters were within the normative reference values (age-related normative values). Due to physiological character of reflux (not complicated), typical for the youngest patients, these infants were not the subject of prospective clinical observation and further clinical analysis.

In 138 children (52.3%) pathological acid GER was diagnosed and classified into primary and secondary GER. These children were assigned into group 2 and 3. Group 2 constituted 76 patients (28.8%) with pathological primary acid GER, of both sexes (39 boys-14.8%, 37 girls-14.0%), aged 4-102 mo (mean age $\chi = 25.2 \pm 27.28$ mo). In group 3 were 62 patients (23.5%), of both sexes (33 boys-12.5%; 29 girls-11.0%), aged 74 mo (mean age $\chi = 21.53 \pm 17.79$ mo) with pathological GER secondary to CMA/FA.

Acid GER was not confirmed in 94 (35.6%) out of 264 patients with symptoms suggesting GERD. These children were qualified into groups 4 and 5. Group 4-the reference group constituted 32 patients (12.1%), of both sexes (19 boys-7.2%; 13 girls-4.9%), aged 7-69 mo (mean age $\chi = 23.7$

**Figure 1** Summary analysis of number of episodes of acid GER (pH < 4) and episodes of acid GER (pH < 4) lasting > 5 min of 24-h pH-monitoring in 264 children suspected of GERD; pH-monitoring with 1st- or 2-channel probe. ¹Values of pH-monitoring parameters in group 1 did not undergo comparative analysis with corresponding values in remaining groups.

± 12.63 mo) with symptoms typical for cow milk allergy and/or other food allergy (CMA/FA). Group 5 constituted 62 patients (23.5%) (32 boys-12.1%; 30 girls-11.4%), aged 4-102 mo (mean age $\chi = 31.3 \pm 27.98$ mo).

Neither reflux cause nor allergic cause of the symptoms were confirmed in these children, and hence they were not the subject of prospective observation and further clinical analysis.

The study was approved by local Bioethical Committee of the Medical University of Bialystok and informed parental consent was obtained from parents of examined children.

Statistical analysis

The statistical analysis of the results comprised arithmetical mean, standard deviation, minimal and maximal values and median-for measurable features and quantitative percentage distribution for qualitative features. To compare the groups, features compatible with normal distribution, assessed with Kolomogorov compatibility test, were assessed together with the post hoc Bonferroni one-way analysis of variance. Features non-compatible with the distribution underwent Kruskal-Wallis test and if the differences were statistically significant, Mann-Whitney test was applied. Statistical significance was *P* < 0.05. Calculations were performed with the help of statistical package SPSS[®]12.0 PL.

RESULTS

24-h pH monitoring

Preliminary comparative analysis of selected values of 24-h intraesophageal pH monitoring parameters with single-channel probe (distal channel) was carried out in 32 children (12.1%) (group 1) and with dual-channel (distal and proximal channel) in 232 children (87.9%) (groups 2, 3, 4 and 5). The results of the analysis are presented in Tables 2, 3 and Figures 1-6 Results of pH esophageal monitoring in group 1 did not undergo comparative analysis with respective values obtained in children from remaining groups. Pathological acid GER was diagnosed in 138 children (52.3%), in 76 children primary GER (group 2) and in 62 children GER secondary to CMA/FA (group 3). Pathological acid GER was not confirmed in 94 children (35.6%), out of which 32 had CMA/FA diagnosed (group 4-reference group). In remaining 62 children neither GER nor CMA/FA were confirmed (group 5). The values of esophageal pH monitoring parameters obtained in individual groups: 2, 3, 4, and 5 were compared against each other. The analysis of mean values of pH monitoring parameters measured in children from individual groups is presented as follows.

According to the number of episodes of acid GER (pH < 4)

Distal channel (Table 2, Figure 1): In children with primary GER (group 2) the mean value of the parameter ($\chi = 75.68 \pm 25.61$) was similar to mean value ($\chi = 74.6 \pm 16.02$) in children with GER and CMA/FA (group 3). These values are higher than mean number of episodes of acid GER, constituting $\chi = 18.56 \pm 11.74$ and $\chi = 12.6 \pm 7.74$ in group 4 and 5, respectively.

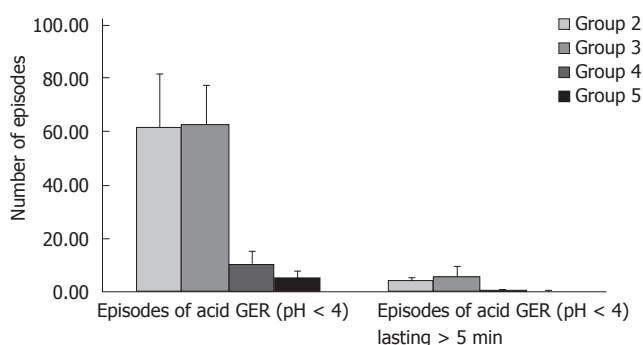

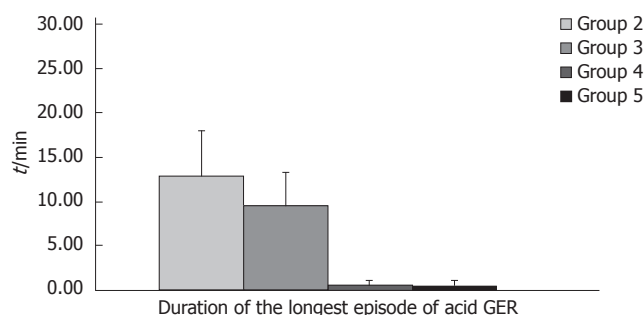

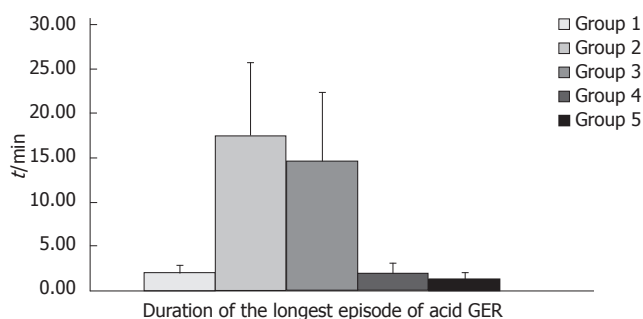

Proximal channel (Table 3, Figure 2): In children from group 2 mean value of the examined parameter ($\chi = 61.45 \pm 20.43$) was similar to mean value ($\chi = 62.48 \pm 14.67$) in children from group 3. These values are higher than mean number of episodes of acid GER $\chi = 10.5 \pm 4.5$ and $\chi = 5.36 \pm 2.09$ in group 4 and group 5, respectively.

According to number of episodes of acid GER lasting > 5 min

Distal channel (Table 2, Figure 1): In children from group 2 mean value of this parameter ($\chi = 5.17 \pm 1.95$) was lower than mean value ($\chi = 8.87 \pm 3.65$) in children from group 3. At the same time these values are higher

Table 3 Summary analysis of selected parameters of 24-h pH-monitoring in 232 children suspected of GERD; pH-monitoring with 2-channel probe

Groups of examined children with specific ailment <i>n</i> = 232	pH-monitoring parameters-proximal channel range of values; mean; standard deviation (\pm SD); median; statistical significance (<i>P</i>)

**Figure 2** Summary analysis of number of episodes of acid GER (pH < 4) and episodes of acid GER (pH < 4) lasting > 5 min of 24-h pH-monitoring in 232 children suspected of GERD; pH-monitoring with 2-channel probe.**Figure 4** Summary analysis of duration of the longest episode of acid GER of 24-h pH-monitoring in 232 children suspected of GERD; pH-monitoring with 2-channel probe.**Figure 3** Summary analysis of duration of the longest episode of acid GER of 24-h pH-monitoring in 264 children suspected of GERD; pH-monitoring with 1st or 2-channel probe. ^aValues of pH-monitoring parameters in group 1 did not undergo comparative analysis with corresponding values in remaining groups.

than mean values of parameters $\chi = 0.33 \pm 0.49$ and $\chi = 0.15 \pm 0.36$ measured in group 4 and 5, respectively.

Proximal channel (Table 3, Figure 2): In children from group 2 mean value of parameter measured ($\chi = 3.96 \pm 1.37$) was lower than mean value in group 3 ($\chi = 5.87 \pm 3.64$). At the same time these values are higher than mean values of episodes of acid GER lasting more than 5 min: $\chi = 0.28 \pm 0.46$ and $\chi = 0.11 \pm 0.32$ in group 4 and 5, respectively.

According to the duration of the longest episode of acid GER (minutes)

Distal channel (Table 2, Figure 3): In children from

group 2 mean value of this parameter ($\chi = 17.45 \pm 8.21$) was higher than mean value ($\chi = 14.61 \pm 7.68$) in children from group 3. These values were higher than mean time of the longest episode of acid GER: $\chi = 2.08 \pm 1.05$ and $\chi = 1.4 \pm 0.66$ in group 4 and 5, respectively.

Proximal channel (Table 3, Figure 4): In children from group 2 mean value of parameter measured ($\chi = 12.91 \pm 5.14$) was higher than mean value ($\chi = 9.51 \pm 3.78$) in children from group 3. At the same time these values are higher than mean time of the longest episode of acid GER: $\chi = 0.67 \pm 0.49$ and $\chi = 0.44 \pm 0.62$ in group 4 and 5, respectively.

According to total acid GER index (%)

Distal channel (Table 2, Figure 5): In children from group 2 mean value of this parameter ($\chi = 13.42 \pm 5.52$) was lower than mean value ($\chi = 17.17 \pm 6.96$) in children from group 3. These values are higher than mean values of total acid GER index: $\chi = 2.69 \pm 1.07$ and $\chi = 3.1 \pm 0.78$ in groups 4 and 5, respectively.

Proximal channel (Table 3, Figure 6): In children from group 2 mean value of this parameter ($\chi = 11.26 \pm 4.18$) was higher than mean value ($\chi = 10.47 \pm 3.8$) in children from group 3. At the same time these values were higher than mean values of total acid GER index: $\chi = 0.91 \pm 0.68$ and $\chi = 0.37 \pm 0.16$ in group 4 and 5, respectively.

According to acid GER index, supine position (%)

Distal channel (Table 2, Figure 5): In children from

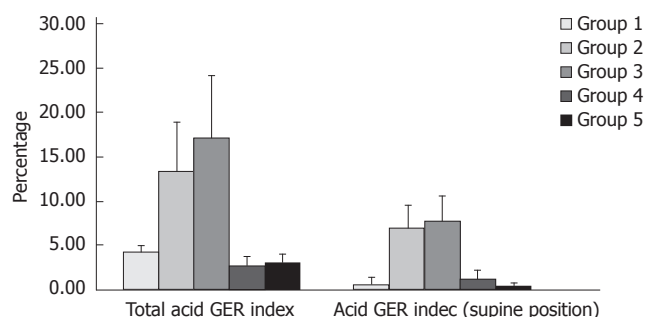

Figure 5 Summary analysis of total acid GER index and acid GER index (supine position) of 24-h pH-monitoring in 264 children suspected of GERD; pH-monitoring with 1st- or 2-channel probe. ¹Values of pH-monitoring parameters in group 1 did not undergo comparative analysis with corresponding values in remaining groups.

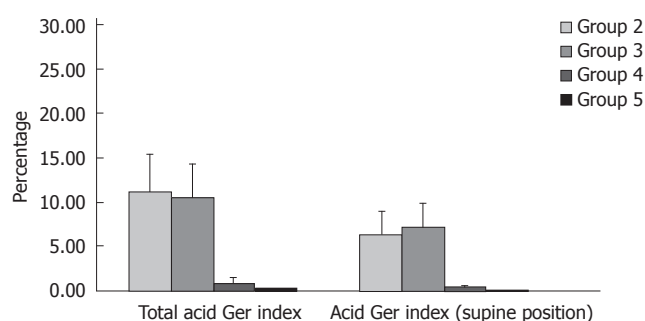

Figure 6 Summary analysis of total acid GER index and acid GER index (supine position) of 24-h pH-monitoring in 232 children suspected of GERD; pH-monitoring with 2-channel probe.

group 2 mean value of this parameter ($\chi = 6.96 \pm 2.64$) was lower than mean value ($\chi = 7.67 \pm 2.87$) in children from group 3. These values were higher than mean values of supine acid GER index: $\chi = 1.09 \pm 1.06$ and $\chi = 0.39 \pm 0.31$ in groups 4 and 5, respectively.

Proximal channel (Table 3, Figure 6): In children from group 2 mean value mean value of parameter measured ($\chi = 6.41 \pm 2.64$) was lower than mean value ($\chi = 7.16 \pm 2.76$) in children from group 3. These values were higher than mean value of supine acid GER index: $\chi = 0.43 \pm 0.22$ and $\chi = 0.09 \pm 0.11$ in groups 4 and 5, respectively.

The comparative analysis carried out between group 2 and 3 (children with GER) and between group 4 and 5 (children without GER) proved statistically significant differentiation ($P < 0.05$) of mean values (abnormal distribution) in the case of: number of episodes of acid GER, number of episodes of acid GER lasting more than 5 min and duration of the longest episode of acid GER in both channels (distal and proximal) as well as acid GER index: total and supine, in proximal channel exclusively.

This analysis also confirmed statistically significant differences ($P < 0.05$) of mean values (normal distribution) in the case of total acid GER index, in distal channel exclusively, among individual groups, especially between group 2 (children with primary GER) and group 3 (children with GER secondary to CMA/FA). However, in the case of supine acid GER, in distal channel, no statistical significance of its mean values between group 2 and group

3 was confirmed.

On the basis of pH monitoring recording at preliminary examination in children of individual groups (Table 4), phasic recording of intraesophageal pH monitoring values was registered in 9 children (14.5%) with pathological GER secondary to CMA/FA (group 3) and in 3 children (9.4%) with CMA/FA exclusively (group 4-reference group).

DISCUSSION

Of 264 examined children, acid GER was confirmed in 170 (64.4%) of them on the basis of 24-h esophageal pH monitoring. In 138 of these children (52.3%) GERD was confirmed.

Age of examined children did not reveal statistically significant differences among individual groups. Among 138 children, GERD was more often attributed to acid GER in boys (72-52.2%) in comparison to girls (66%-47.8%).

On the basis of the results of immunoallergological tests and verifying positive oral food challenge test^[25,26], pathological acid GER in 138 children was divided into primary (28.8% of children, group 2) and secondary to CMA/FA (23.5%, group 3). At the same time, on the basis of complex differential diagnosis other causes of acid GER were excluded.

Among 264 children with family history of gastrointestinal tract diseases, acid GER was not confirmed in 94 of them (35.6%).

The assumption of esophageal pH monitoring was that the higher the electrode sensor was positioned, the less number of short-term reflux episodes was recorded, and the total time of reflux is shortened, which is consequent upon better efficiency of neutralizing mechanisms and the ability to self-purification of this part of esophagus^[18,20,32,33].

The results of our studies do not support the stated hypothesis completely because the mean values of analyzed

pH monitoring parameters in proximal channel were not lower (not statistically significant) than in distal part of esophagus in children with GERD in groups 2 and 3.

Percentage values of the number of episodes of acid GER recorded in proximal channel accounted for 81%, in group 2 and 84% in distal channel, in group 3.

The number of episodes of acid GER lasting more than 5 min recorded in proximal part of esophagus accounted for 76% in group 2, whereas in distal part of esophagus made 66%, group 3.

The duration of the longest episode of acid GER recorded in proximal part of esophagus constituted 74%, group 2, whereas in distal part of esophagus it accounted for 65%, group 3. Total acid GER index recorded in proximal part of esophagus made 84%, group 2 and in distal part of esophagus 61%, group 3. Supine acid GER index in proximal part of esophagus accounted for 92%, group 2 and in distal part of esophagus it made 93%, group 3.

In children with primary GER (group 2) and secondary GER (group 3), the mean values of individual pH monitoring parameters did not reveal significant difference between both channels. On the basis of the results obtained, it appears that there was no significant quantitative difference in the episodes of acid GER, reaching both distal and proximal channel, regardless of the age of examined children.

It was shown that reflux episodes in proximal channel were similar in number only in patients with primary GER (group 2) and those with GER secondary to CMA/FA (group 3). It may be assumed that high gastroesophageal reflux reaching proximal channel is particularly meaningful in children of both groups, but with atypical symptoms, especially of respiratory tract (silent reflux), therefore suggesting the possibility of microaspiration of gastric content into the bronchial tree^[2,18-20].

Silent reflux in children below 3 years of age, with recurrent infections of respiratory tract in past history was confirmed on the basis of pH monitoring with single-channel probe in 56% and 57% of children's gastroenterological centers in Poland^[35,36].

According to these data the diagnostic value (sensitivity) of 24-h esophageal pH monitoring in detecting pathological GER accounted for 89% in all patients examined with this type of probe but made only 84% in patients with atypical symptoms.

On the basis of 24-h esophageal pH monitoring with dual-channel probe in children with symptoms out of gastrointestinal tract, within the same age group, in own studies the higher percentage of high gastroesophageal reflux was reported, which accounted for 77.4% and 88.3% in both groups, respectively. The results of own studies give information on the intensity of acid GER reaching distal and proximal part of esophagus, and mean values of examined pH monitoring parameters in distal and proximal part of esophagus reveal statistical significance between the groups. The comparable results of supine acid GER index in distal channel constitute an exception. This differentiation of pH monitoring parameters between the groups appears to be helpful in predicting, who of the examined children is at risk of primary GER, and which

symptoms are consequent upon GER secondary to CMA/FA. The result of preliminary study is also important, in which the increasing number of reflux episodes reflecting the higher value of reflux index, and it was comparable in distal and proximal channel, in both study groups.

Italian authors reported the interpretation of graphic recording of intraesophageal pH monitoring, in which they showed a phasic decrease of values after milk meal and their rapid increase after the following meal in children with GER and/or CMA^[37].

Quantitative characteristics of patients of individual groups proved that this phasic recording of pH was a common feature in 9 children (14.5%) with GER and CMA/FA (group 3) and in 3 children (9.4%) with CMA/FA (group 4-reference group), which accounted for 12 out of 94 children with cow milk allergy. Interestingly enough, this type of recording of pH monitoring was not observed in any of the children with GER but without allergy.

In conclusion, pH monitoring performed in children with typical and atypical GERD symptoms enabled to diagnose acid GER in 52.3% of all examined patients. In order to define the extent of reflux i.e. the dynamics of each reflux episode, dual-channel probe should be used to intraesophageal pH recording in distal and proximal channel. Finally, similar pH monitoring results obtained in both study groups with GERD confirm that pH monitoring is clinically important for diagnosing of acid GER but not for differential diagnosis for between primary and secondary GER patients. This support the necessity of early implementation of complex differential diagnosis that enables to distinguish the causes of primary GER from the causes of GER secondary to FA. This causal differentiation leads to necessity of defining proper treatment strategy. It also influences the efficacy of treatment and natural history of gastroesophageal reflux disease in children and the young.

Abstract

AIM: To assess the trends in the incidence of inflammatory bowel disease (IBD) over 23 years in the same area and to identify genetic factors related to incidence evolution.

METHODS: Patients with IBD arising from North-western Greece were systematically recorded through the 1983-2005 period. Trends in disease incidence and genetic patterns related to CARD15 variants were documented and correlated.

RESULTS: A total of 447 patients with IBD were recorded (23.5% Crohn's disease, 72.7% Ulcerative colitis and 3.8% indeterminate colitis). Mean annual incidence rates of CD and UC were 0.9/100 000 (95% CI 0.1-1.7) and 2.7/100 000 (95% CI 1.7-4.1) inhabitants, respectively. There was a statistically significant increase of CD incidence ($P < 0.01$) during the study period, in contrast to the UC incidence. There were no statistical differences in CARD15 variants over the study period.

CONCLUSION: The incidence of CD in North-western Greece has risen disproportionately to that of UC in the 21st century. This is not related to alterations of genetic background though.

INTRODUCTION

Inflammatory bowel disease (IBD) encompasses two distinct clinicopathological entities, Crohn's disease (CD) and ulcerative colitis (UC), possessing different etiological and epidemiological correlations. Both are considered of unknown aetiology, and various endogenous and exogenous factors have been etiologically implicated, leading to the concept of a multifactorial pathogenetic process involving interplay of environmental risk factors and immunologically triggered alterations^[1]. Environmental factors have for long been incriminated in the pathogenesis of both forms of IBD, usually based on data of geographic or temporal variation of disease incidence. A global north-south variation in the incidence of IBD has been reported^[2]. In Europe, the EC-IBD population based study showed a higher incident of UC (11.8/100 000 *vs* 8.7/100 000) and CD (7.0/100 000 and 3.9/100 000, respectively) in Northern compared to Southern Europe^[3]. Such variations do exist in the overall prevalence of each form, with variable data on the incidence trends of CD in recent years^[4-6], but an invariable increase in CD incidence in Southern European regions^[7,8]. Evaluation of the factors triggering this evolving incidence may allow for identifying major endogenous or exogenous factors related to the pathogenesis of the disease.

In North-western Greece, an area traditionally categorized to the poorest of Europe, previous studies have shown rarity of CD and common appearance of UC during the previous decades^[9,10]. This study assesses current evolution of incidence of CD and correlates these trends with genetic (CARD15 mutations) factors.

MATERIALS AND METHODS

Study area

The study area, North-western Greece, represents a population of 506 142 inhabitants according to the

National Census of 2001, including four Districts situated on the mainland (Districts of Ioannina, Arta, Preveza and Thesprotia) and two Districts situated in islands (Districts of Corfu and Lefkada). Urban residents represented about 40% of the total population, residing mainly in the District capitals.

Case identification and diagnostic criteria

Cases have been recorded in the frame of a systematic recording system for IBD, using multiple sources of retrieval, developed in this defined area of North-western Greece between January 1983 and December 2005. The health care system in our area includes both a National Health Service and a private sector. All gastroenterologists are members of North-western Greece Gastroenterology Group and were updated about the methods and aims of this study both through newsletters and meetings. The system records cases from the following sources: (1) in- and outpatients referred to the Hepato-gastroenterology Unit of the Ioannina University Hospital; (2) patients referred to outpatient Gastroenterology clinics in Districts hospitals and (3) patients referred to the private gastroenterologists practicing inside the area. A review of collected data was performed in the University Hospital of Ioannina, by two investigators (ME and EVT). Diagnosis of CD and UC was based on typical clinical, radiological, endoscopic and histological criteria and the diagnosis of intermediate colitis (IC) was only set when a distinct diagnosis of UC or CD could not be established. CD was classified according to the Vienna System^[11] and UC according to Lennard-Jones^[12]. Perianal disease was defined by the presence of perianal abscesses, fistulae or ulcers, but not by the presence of skin tags. A final diagnosis of CD, UC, or ulcerative proctitis (UP) though was made by two expert gastroenterologists and recorded as definite, probable, or possible following criteria previously published^[9]. Phenotypic details were obtained on 2 occasions by retrospective case-note review between January and December 2005 by 2 investigators (ME and EVT). Duration of follow-up was defined as the interval between diagnosis and latest case-note review. Details regarding other demographic characteristics were further supplemented by a patient interview or completed postal questionnaire. During the last year blood was collected from all CD patients. An incidence case was defined as any IBD patient, diagnosed during the study period, resident in the study area for at least one year before the diagnosis. All patients first diagnosed during the study period 1983-2005 were included in the study. All patients included in the study were evaluated at least twice during the study period.

The study protocol conformed to the ethical guidelines of the Declaration of Helsinki.

Genotyping

Three NOD2/CARD15 variants previously identified as being independently associated with Crohn's disease, R702W, G908R, L1007fsinsC^[13-15] were genotyped. Each individual reaction contained primers to amplify a nonpolymorphic genomic control sequence. A single thermocycling program was used for all reactions. The

Table 1 Demographic characteristics of IBD patients diagnosed during the period 1983-2005, in northwest Greece

	Crohn's disease	Ulcerative colitis
Total numbers of patients	105	325
Region of origin		
Ioannina	59	140
Arta	5	10
Preveza	2	36
Thesprotia	5	21
Corfu	33	113
Lefkada	1	5
Male: female (ratio)	66:39 (1.69)	208:117 (1.77)
Age at diagnosis (yr) (mean \pm SD)	33.2 \pm 12.9	45.7 \pm 16.1
(range)	(18-70)	(18-93)
Men	33.4 \pm 12.9	47.3 \pm 15.1
Women	33.1 \pm 13.2	42.9 \pm 17.3
Follow up (mo) (mean \pm SD)	92.9 \pm 72.3	119.6 \pm 73.8
(range)	(4-264)	(5-276)

products were electrophoresed on 1% agarose gels with ethidium bromide and viewed under ultraviolet light. An image was recorded digitally. Healthy controls match for age and gender with CD patients were randomly selected from Blood Donors in University Hospital of Ioannina and District Hospital of Corfu.

Statistical analysis

Incidence rates were calculated as the number of cases per 100 000 inhabitants, and 95% Confidence Intervals were estimated using the normal distribution. Population data were based on databases of the National Statistical Service (National Censuses 1981, 1991, and 2001). The significance of time trends of incidence rates was tested using the χ^2 -trends in proportion test. Frequency and susceptibilities of NOD2/CARD15 variants among CD patients, UC patients and controls was compared with the chi-square test. Odds ratios (OR) were calculated with the chi-squared distribution test and 95% confidence intervals (95% CI). The Fisher exact test was used for comparing differences between allele frequencies in patients and controls. The *P* values obtained were two-tailed and statistical significance was assumed below 0.01. Inference was aided by GraphPad InStat (version 3.00; GraphPad Software).

RESULTS

During the study period, a total of 447 IBD cases were recorded in the study area. One hundred and five patients were diagnosed with CD (23.5%), 325 with UC (72.7%), and 17 with Indeterminate Colitis (3.8%). The majority of the patients were derived from the regions of Ioannina and Corfu, accounting for 92% of the total CD cases and 78% of the total UC cases.

The main demographic and clinical characteristics of CD and UC patients are presented in Table 1.

A familial history of IBD was present in 11 patients (2.5%). Terminal ileal localization of the disease was present in 35 (33.3%), ileocolonic in 28 (26.7%) and colonic in 42 (40%) of the CD patients; stenotic disease

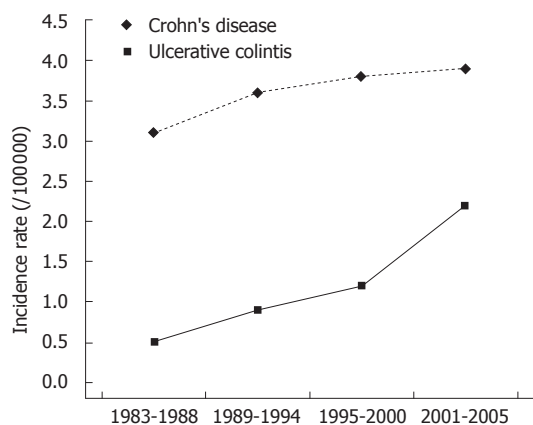

Figure 1 Trends in standardised incidence of Crohn's disease (CD) and Ulcerative colitis (UC) (Northwestern Greece 1983-2005).

Table 2 Evolution of genetic, demographic and clinical correlations of Crohn's disease through the study period

Period	Any CARD15 mutation	M:F ratio	Mean age (yr)	CD:UC ratio, cumulative	CD:UC ratio, b region of Ioannina	CD:UC ratio, region of Corfu	Perianal
Pre-1994	46.10%	1.4	30.4	0.23	0.26	0.2	13.80%
1995-1999	61.90%	3.4	35.4	0.32	0.46	0.3	27.20%
2000-2005	46.90%	1.55	33.1	0.61	> 1	0.5	31.30%
Total	51%	1.83	32.8	0.36	0.38	0.32	25.50%

was recorded in 23 (21.9%), fistulating in 25 (23.8%) and perianal disease in 26 (24.8%) CD patients. Of the UC patients, 71 (21.8%) had pancolitis, 99 (30.5%) had proctitis, and 155 (47.7%) had left-sided UC.

Mean annual crude incidence rates of CD and UC were 0.9 and 2.9/100 000 inhabitants, respectively. Age-adjusted incidence rates were 0.9/100 000 (95% CI 0.1-1.7) and 2.7 (95% CI 1.7-4.1), respectively. The age-adjusted mean annual incidence rate of IC was 0.2/100 000 (95% CI 0.1-0.4).

The incidence of CD was higher in men than in women. The highest incidence rate was found in the age group 18-44 years for men and women. UC incidence was higher in men also. The highest incidence rate was found in the age group 45-64 for both sexes.

There was a statistically significant increase of CD incidence ($P < 0.01$) during the study period, while the incidence of UC increased slightly and not in a statistically significant manner (Figure 1). As a consequence, the ratio of CD to UC practically doubled, surpassing 1 in the district of Ioannina, the largest population district and centre of the study, in the year 2002, and remaining above 1 for the following years (Table 2).

When demographic and clinical parameters were evaluated in correlation with the increase in CD incidence, age, gender, and regional patient distribution did not exhibit any statistically significant trends. There were also no differences in the percentages of patients with terminal ileal or colonic localization, and stenotic or fistulating disease during the pre-1995 period, compared

-/-, homozygous wild-type; +/-, heterozygous; +/+, homozygous mutant. CD: Crohn's disease; UC: Ulcerative colitis; OR: Odds Ratio; CI: Confidence Interval. The CARD15 gene variants determined in 96 CD patients (from 102 living CD patients out of 105, from our cohort 6 refused genetic test), 180 out of 300 living UC patients and 100 randomly chosen healthy blood donors.

to the 1995-1999 and the 2000-2005 periods. A statistically significant increase in the percentage of patients with perianal disease was observed in the latter two periods compared to the pre-1995 period (Table 2).

The association of CD with mutations in the three casual CARD15 variants is shown in Table 3.

There were no statistically significant differences on any mutations over time (Table 2).

DISCUSSION

North-western Greece is comprised of the mainland district of Epirus and the islands Corfu and Lefkada. Due to geographical reasons and relatively underdeveloped transport facilities to the rest of Greece the region can be considered secluded, and thus an ideal frame for epidemiological analysis of certain diseases. We have shown in the past that UC was a common entity in this region, while CD on the contrary was all too rare, with the CD:UC ratio in the 1980 s and early 1990 s being near 0.1^[9,10]. Herein, the results of this 23-year period study, clearly show a rapid and sustained increase in CD incidence from 2000 on in North-western Greece, an increase that overturned the CD:UC ratio in the largest province of the study, the region of Ioannina, by 2002.

These findings are in accordance with formerly published studies showing an increasing trend for CD^[16-22]. In these studies the increasing trend was often related to increasing age at diagnosis and could thus be related to improvements in average survival and surveillance (global increase^[20,21] or a higher proportion of older patients^[5,18,22]).

This is not the case in our study in which the majority of CD patients are young, similar to other studies^[6,19] and the average patient age has not altered significantly over the years. Furthermore this increase could not be

attributed to enhanced surveillance and patient reporting; characteristically, the increase in incidence is predominantly expressed in the region of Ioannina, which, hosting the study centre for the past 25 years, guarantees total patient reporting and absence of bias. Moreover, a similar increase was not observed for UC during this period. This rising incidence suggests that unknown triggering factors continue to work in North-western Greece. To explain this increase in CD incidence throughout the period 1983-2005 we hypothesized that certain etiologic factors exist, and we evaluated the potential role of genetic susceptibility changing slowly over time in this incidence trend.

Although there are differences in ethnic, racial and geographic distribution^[23], the genetic association of CD with CARD15 is undoubtedly replicated widely at present^[24,25]. There were no significant differences in the prevalence of CARD15 variants during the study period in our study, indicating an absence of alterations in the genetic background. The prevalence of the three CARD15 variants is similar with that found in cohorts in central Europe and much higher than in northern Europe^[25]. Yet these results are different from two other Greek studies: the first, based on the island of Crete outlined the rarity of SNP 13^[26], an inconsistency that may be attributed to the fact that Crete is an isolated geographic region where this mutation does not seem to predispose to the disease, or to the relatively small size of the examined sample. The relatively higher frequencies in all three SNPs in the second study may be attributed to patient selection (hospitalized patients in a period of time, high proportion of ileocolonic disease)^[27]. Our study, being population based, may be more representative of prevalence of CARD15 variants in Greece.

One could speculate that the increased incidence of CD recorded in recent years may actually reflect increase in detection, but not incidence of colonic disease, more easily recognized through increased endoscopy implementation. Although the total number of endoscopies performed naturally increased over time, there was no difference in endoscopy success rates, furthermore significant trends in disease localization over time were not recorded, apart from the already mentioned perianal CD (data not shown).

A potential criticism of the recruitment methods used in this study would be that ascertainment might have been incomplete, missing patients with CD or those with mild ulcerative proctitis who might have never required gastroenterologic consultation or hospital admission. However in the Greek population, during the time period of this study, there was an almost universal admission policy for investigation of IBD. Although North-western Greece has a relatively small population and isolated geographic area, this has actually been a great advantage and has resulted in a comprehensive study of the entire population, excluding any case leaks to other centers or existence of not notified cases followed-up by general practitioners.

In conclusion, we have shown that a significant increase in CD incidence in a secluded geographical region of Greece where CD was previously rare is not related to any alterations in the genetic profile or typical demographical factors. The study being population based

outlines the need for further investigation of the interplay of environmental factors and disease.

ACKNOWLEDGMENTS

The authors thank the patients that participated in this study. The authors acknowledge the contribution of Dr M Gazouli for advice and technical support in genetic analysis, Kleopatra Garallea, Gioula Georgitsi, Lamprini Gouma, Alexandra Kioulou, for organization and collection of blood specimens and Drs E Zervou and M Tzilianos for helping to collect samples from healthy blood donors. We thank all gastroenterologists of North-western Greece Gastroenterology Group and Medical personnel of 1st Department of Internal Medicine University Hospital of Ioannina.

COMMENTS

Background

The incidence of Crohn's disease and ulcerative colitis varies greatly between specific geographic areas, and is supposed to be related to exogenous factors such as affluence and dietary habits, as well as endogenous factors such as genetic predisposition. North-western Greece was characterized by a low incidence of Crohn's disease (CD) although Ulcerative Colitis (UC) was not uncommon according to a previous study undertaken in the early 1990s.

Innovations and breakthroughs

The present study is one of the few to evaluate genetic predisposition to Crohn's disease and ulcerative colitis through time in a given area. The presence of absence of relation to incidence evolution allows for evaluation of the etiological role of genetic predisposition in disease.

Applications

Similar studies, when applied in larger areas, may be hampered by planning difficulties though.

Terminology

NOD2/CARD15 mutations are mutations of a specific genetic locus that have been shown to interfere with altered immune response and induce increased predisposition to the development of Crohn's disease.

Peer review

The author examined the relation between the change in the annual incidence rates of IBD patients and CARD15 variants in North-western Greece. Although the incidence of CD has significantly increased during the study period, there was no statistical differences in NOD2/CARD15 variants among the Groups. The data is interesting and certainly provides the new evidences in this research field.

Abstract

AIM: To investigate the role of reactive oxygen species in the ulcer-aggravating effect of lead in albino rats.

METHODS: Albino Wistar rats were randomly divided into three groups and treated orally with 100 mg/L (low dose) or 5000 mg/L (high dose) of lead acetate for 15 wk. A third group received saline and served as control. At the end of wk 15, colorimetric assays were applied to determine the concentrations of total protein and nitrite, the activities of the oxidative enzymes catalase and superoxide dismutase, and lipid peroxidation in homogenized gastric mucosal samples.

RESULTS: Exposure of rats to lead significantly increased the gastric mucosal damage caused by acidified ethanol. Although the basal gastric acid secretory rate was not significantly altered, the maximal response of the stomach to histamine was significantly higher in the lead-exposed animals than in the unexposed control group. Exposure to low and high levels of lead significantly increased gastric lipid peroxidation to $183.2\% \pm 12.7\%$ and $226.1\% \pm 6.8\%$ of control values respectively ($P < 0.0$). On the other hand, lead exposure significantly decreased catalase and superoxide dismutase (SOD) activities and the amount of nitrite in gastric mucosal samples.

CONCLUSION: Lead increases the formation of gastric ulcers by interfering with the oxidative metabolism in the stomach.

INTRODUCTION

Reactive oxygen species (ROS) have been shown to be involved in the etiology of many inflammatory disorders of the gastrointestinal system^[1,2]. This is evidenced by the increased oxidative stress by pro-ulcerative factors in the gut such as *H. pylori*^[3,4], use of non-steroidal anti-inflammatory drugs^[5], smoking^[6], psychological stress, corticosteroid use^[7], and loss of sleep^[8]. Lipid peroxidation (LPO), a result of the reaction of oxyradicals and polyunsaturated acids, has been suggested as an attack factor in the gastric mucosa^[9]. Also GSH, an endogenous sulfhydryl compound, is an important substance in the cellular defense system^[10].

Nitric oxide (NO) depletion also plays significant roles in the pathogenesis of gastric ulcers. NO along with superoxide (O_2^-) and the products of their interaction initiate a wide range of toxic oxidative reactions causing tissue injury^[11]. Large amounts of NO, generated primarily by iNOS, can be toxic and pro-inflammatory. Likewise, neutrophils too produce oxidants and release granular constituents comprising lytic enzymes performing an important role in inflammatory injury^[12].

Although lead acetate does not initiate any excess generation of reactive oxygen species in a cerebral synaptosomal suspension, it has a marked ability to enhance the pro-oxidant properties of ferrous iron in the same system^[13]. It also amplifies oxidative stress induced by l-glutamate^[14]. Recent studies suggest that accumulated lead exposure is related to several chronic disorders of aging including disorders that have been associated with oxidative stress^[15-17]. Sass^[19] first reported that lead poisoning in dogs is associated with perforating gastrointestinal ulcers. Bercowitz and Laufer^[19] observed that gastrointestinal ulcer patients had accumulated lead in their teeth, thus suggesting a relationship between lead and ulcer. In a previous study, we reported that long term exposure of rats to lead predisposes the stomach to higher ulcerogenic effects of indomethacin and acidified ethanol^[20]. However, the exact mechanism(s) by which lead

promotes gastric ulceration is not yet understood. The objective of the present study thus was to investigate the involvement of ROS in the aggravation of ulceration in the stomach of lead-exposed rats.

MATERIALS AND METHODS

Chemicals and animals

Lead acetate and urethane were obtained from BDH chemicals Ltd, Poole, England. Epinephrine, 5,5-dithio-bis-2-nitrobenzoic acid, hydrogen peroxide, sodium pentobarbitone, and thiobarbituric acid (TBA) were purchased from Sigma (St Louis, MO USA). All other reagents were of analytical grade and were obtained from the British Drug Houses, Poole, UK.

Young male albino Wistar rats (80-90 g) were obtained from the small animal house, College of Medicine, University of Ibadan, Nigeria. They were randomly divided into three groups with adequate matching of weight. They were kept in wire meshed cages and fed with commercial rat pellets (Ladokun Feeds Ltd, Ibadan, Nigeria) and allowed to take water ad libitum.

Lead treatment

Animals were exposed to lead as previously described^[20]. The high lead group (HiPb) was given 5000 mg/L lead acetate in drinking water daily while the low lead group (LoPb) received 100 mg/L lead acetate in drinking water. The control animals received only drinking water. At the end of a 15 wk exposure, blood samples were collected from the rats for analysis of the Packed Cell Volume (PCV), red and white blood cell counts, and neutrophil numbers by standard methods. Afterwards, ulcer was induced as follows.

Induction of experimental ulcer

Acidified ethanol was used to induce experimental gastric ulcers. Thirty six hours fasted rats were given 1.0 mL of HCl/ethanol mixture containing 0.15 mol/L HCl in 70% mL/L ethanol^[21]. Four hours after administering the ulcerogen and under sodium pentobarbitone anaesthesia (60 mg/kg, ip), the animals were sacrificed. The stomachs were removed, inflated with 10 mL of 2% formaldehyde for 10 min to fix the tissue walls and opened along the greater curvature. The hemorrhagic lesions were stretched out on a glass plate and their sizes were estimated using an underlying graph paper with a 1 mm² grid. Lesion areas were summed up per stomach and expressed as % of total mucosal area.

Measurement of gastric acid secretion

Gastric acid secretion was studied in the 3 groups using a modification of the method originally described by Ghosh^[22]. The animals were fasted for 24 h at the end of the 15 wk lead treatment. Under urethane anaesthesia [250 g/L urethane (6 mL/kg body, ip)], the animals were surgically prepared for in situ stomach perfusion. The pylorus was semi-transected at its junction with the duodenum and a pyloric cannula inserted and tied into place. An oesophageal cannula for infusion from a flow

meter (Watson-Marlow Inc., USA) was passed through the mouth to the stomach. Ten minute effluent samples (10.0 ± 0.1 mL each) were collected *via* a pyloric cannula and titrated against 0.01 mol/L NaOH using phenolphthalein as indicator. Acidity was expressed in mol/L/L per min life. After obtaining a consistent basal acid output, each animal was injected *via* a femoral vein cannula with either 9 g/L NaCl or histamine acid phosphate.

Biochemical analysis

At the end of chronic lead exposure, the animals were killed under deep ether anaesthesia and the stomachs were removed. Each stomach was cut open through the greater curvature, rinsed in normal saline, weighed, and homogenized in 10 mL KCl (pH = 7.4). The homogenate was subsequently used for total protein estimation. The protein content of the gastric mucosa was estimated by the method of Lowry *et al*^[23] using bovine serum albumin as a standard.

Determination of lipid peroxidation. Lipid peroxidation was assayed by measuring the thiobarbituric acid reactive (TBAR) products using the procedure of Walls *et al*^[24]. Briefly, the homogenate was supplemented with 0.75 g/L TBA in 0.1 mol/L HCl. The reactants were then supplemented with 5 mL n-butanol-pyridine mixture, shaken vigorously for 1 min and centrifuged for 10 min at 4000 r/min. Absorbance was then read at 532 nm and the results expressed as nmol TBA per 100 mg wet tissue.

Determination of catalase activity. Activity of catalase in gastric mucosa was determined according to the procedure of Sinha^[25]. This method is based on the reduction of dichromate in acetic acid to chromic acetate when heated in the presence of H₂O₂, with the formation of perchromic acid as an unstable intermediate. The chromic acetate so produced is measured calorimetrically at 530 nm.

Determination of SOD activity. For determination of SOD activity, samples of gastric mucosal homogenates were taken as described above. A method originally described by Misra and Fridovich^[26] as reported by Magwere *et al*^[27] was employed. This method is based on the ability of superoxide dismutase to inhibit the autoxidation of epinephrine caused by O₂ generated by xanthine oxidase reaction.

Determination of nitrite in gastric mucosa. The gastric mucosa was cooled in ice-cold distilled water before homogenization (100 g/L). The crude homogenate was centrifuged at 21,000 g for 20 min at 4°C. Aliquots of the supernatants were taken to determine nitrite levels. The amounts of nitrite were measured in the gastric mucosa by performing the Griess reaction. 100 mL of sample were incubated with 100 mL of Griess reagent (Sigma) at room temperature for 20 min. Nitrite level was determined by measuring the absorbance at 550 nm using a spectrophotometer (DU 640B, Beckman, Fullerton, California, USA)^[28,29].

Determination of gastric mucous. Adherent gastric glandular mucous was measured by the method of Corne *et al*^[30]. Excised gastric glandular portion of the stomachs were transferred for 2 h to 0.1% Alcian blue dissolved

Table 1 Effects of lead exposure on acidified ethanol-induced gastric injury (mean \pm SEM, $n = 8$)

Treatment	Mass gain (% of initial mass)	Mucosal damage score (% of total mucosal area)	Total protein (mg/g)	Gastric mucus (mg/g)
Control	43.3 \pm 4.4	6.94 \pm 0.42	9.80 \pm 0.01	31.0 \pm 0.31
Low lead	17.4 \pm 6.3 ^a	9.72 \pm 0.65 ^a	7.50 \pm 0.14	28.0 \pm 0.27 ^a
High lead	6.3 \pm 5.1 ^a	12.50 \pm 0.51 ^a	6.20 \pm 0.01	23.0 \pm 0.24 ^a

^a $P < 0.05$ vs control.

in buffer solution containing 0.1 mol/L sucrose and 0.05 mol/L sodium acetate (pH adjusted to 5.8 with hydrochloric acid). After washing the stomach twice in 0.25 mol/L sucrose (15 min and 45 min), the dye complexed with mucous was eluted by immersion in 10 mL aliquots of 0.5 mol/L $MgCl_2$ for 2 h. The resulting blue solution was shaken with equal volumes of diethyl ether and the optical density of the aqueous phase was measured spectrophotometrically at 605 nm.

Statistical analysis

All values presented in tables are expressed as mean \pm SEM. The appropriate comparisons between groups were made using Student's *t*-test. The difference between the groups is taken to be significant at $P < 0.05$.

RESULTS

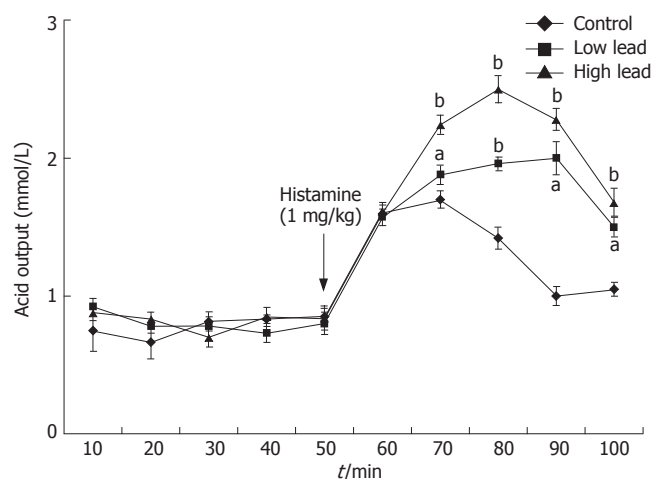

Development of gastric lesions

Administration of acidified ethanol caused severe damage to the rat stomachs under investigation. The site of the formation of lesions is the corpus mucosa. The mean ulcer score in the control animals was 6.94% \pm 0.42%. The severity of lesions was markedly increased by chronic exposure to both low and high lead concentrations (Table 1, $P < 0.05$). Also shown in Table 1 is the result of the total protein and adherent mucous content of the glandular stomach. Long term exposure to lead significantly decreased both gastric mucous and protein contents, the inhibition being greatest in the high lead treated group.

Basal rate of gastric acid secretion was not significantly affected by lead exposure. However, the maximal response of the stomach of lead-exposed animals to histamine was significantly higher than those of the unexposed control group (Figure 1).

Lipid peroxidation and gastric antioxidant enzymes

Lipid peroxidation (measured as the amount of TBA reactants in the gastric mucosa) in the unexposed control animals was 595 \pm 82 mmol/g tissue. Exposure of rats to low and high lead levels significantly increased gastric TBA reactant level to 183.2% \pm 12.7% and 226.1% \pm 6.8% of the control value, respectively (Figure 2A). On the other hand, SOD activity in the intact gastric mucosa (control group) averaged 334 \pm 22 nkat/g. Exposure of rats to low and high lead levels significantly decreased SOD activity to 78% \pm 3% and 66% \pm 6% of the control, respectively

**Figure 1** Gastric acid secretory output after administration of histamine (1 mg/kg) in rats (^a $P < 0.05$, ^b $P < 0.01$ vs control).

(Figure 2B). Similarly, lead exposure decreases gastric mucosal catalase activity to 88.22% \pm 3.21% and 55.29% \pm 2.15% of the control, respectively (Figure 2C).

Gastric mucosal nitrite concentration

The control gastric mucosal nitrite level was 62.4 \pm 4.2 nmol/g tissue (Figure 3). Chronic exposure of rats to lead for 15 wk depleted the gastric nitrite level to 51.6 \pm 3.1 nmol/g tissue ($P < 0.05$) and 49.7 \pm 2.5 nmol/g tissue ($P < 0.01$).

DISCUSSION

The present study investigated the role of oxidative stress in the ulcer-promoting action of prolonged lead exposure in rats. The doses and the duration of lead treatment used in our study have been shown to cause significant high blood lead levels in previous studies^[20,31]. Thus, there is no doubt that the animals had high blood lead levels. The acidified ethanol model has been used widely to produce gastric mucosal damage^[21]. We observed that long-term exposure of rats to lead given through drinking water significantly increased the incidence of gastric ulcer produced by the ulcerogen. This agrees with our previous report in which lead was shown to aggravate gastric ulcers induced by indomethacin and acidified ethanol^[20].

It is well established that gastric acid secretion plays a role in gastric ulcer. Moreover, many anti-ulcerogenic drugs act by reducing the acid secretion^[32]. The present result suggests that basal gastric acid secretory rate was not significantly affected by prolonged lead treatment. However, maximal stimulation by the established secretagogue, histamine, was markedly increased in the lead exposed rats. We had earlier reported that acid output from pylorus ligated stomach of lead exposed rats was increased by lead treatment. Further studies may therefore be required using different acid secretory models before a conclusion can be made on the exact effect of lead exposure on gastric acid secretion.

Lipid peroxidation has been implicated in the etiology

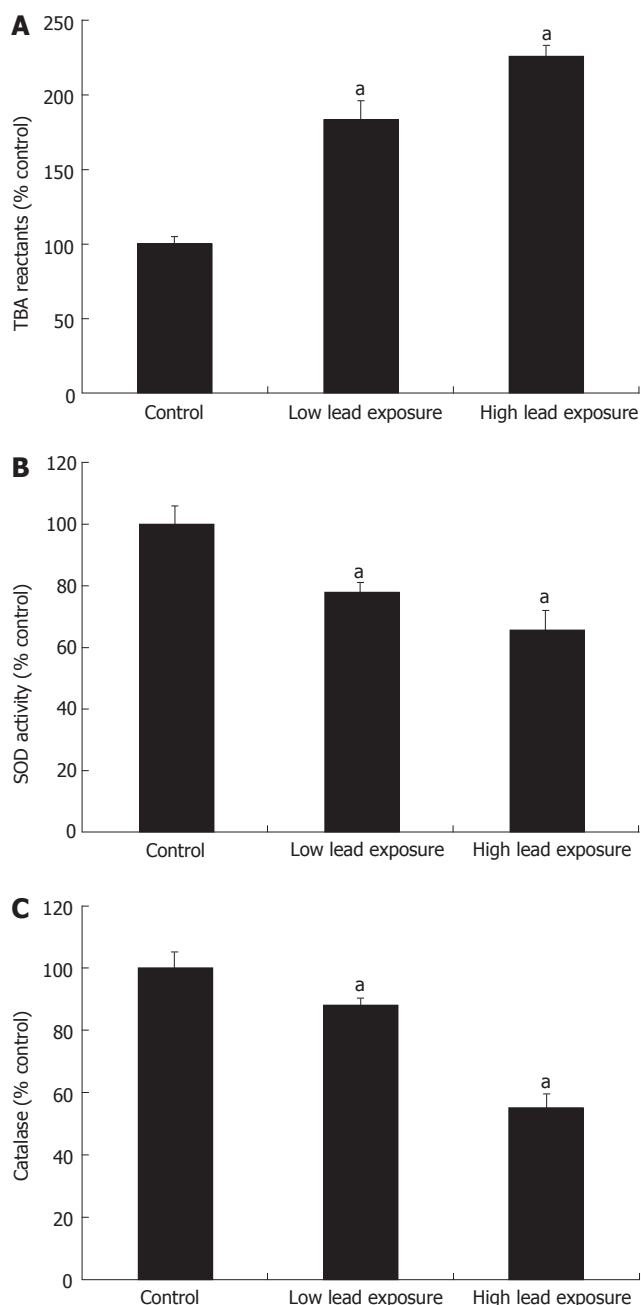

Figure 2 TBA reactants, superoxide dismutase and catalase activities in gastric mucosa of rats exposed to chronic lead treatments (mean \pm SEM, $n = 8$, ^a $P < 0.05$ vs control).

of damage to subcellular membranes and then injury in the cell. In the present study, lipid peroxidation, as measured by the amount of TBA reactants, was increased by lead exposure. The implication of this is that lead causes an increase in the formation of free radicals, which, if not mopped up by free radical scavengers as SOD, CAT, or glutathione, will expose the stomach to inflammation.

Wapnir *et al*^[33] reported that juvenile rats fed a diet containing 1% lead acetate for 7 wk suffered from malabsorption of certain amino acids, as the intestinal absorption of glycine, lysine, and phenylalanine were decreased. Furthermore, administration of HCl and ethanol has been shown to produce ulcerative lesions and

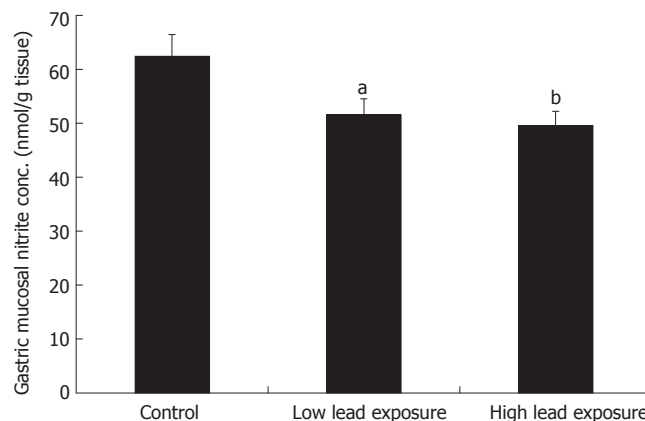

Figure 3 Gastric mucosal nitrite concentration in lead exposed rats (mean \pm SEM, $n = 8$ rats, ^a $P < 0.05$, ^b $P < 0.01$ vs control).

increased lipid peroxidation in the gastric mucosa with depletion of endogenous antioxidants^[21]. The result of this study showed a significant decrease in the protein glandular protein level of the rats given low and high doses of lead acetate. This may also explain the significant low levels of the antioxidizing enzymes SOD and CAT observed in the treated groups.

In gastroprotection, the first line of antioxidative enzyme is SOD which catalyses the dismutation of superoxide radical anion (O_2^-) into less noxious hydrogen peroxide (H_2O_2). H_2O_2 is then inactivated by the degradation into water by catalase or glutathione peroxidase^[35,36]. Depletion of these enzymes, as evident by the results of this study, therefore predisposes the stomach to a greater impact of the free radicals produced *via* increased lipid peroxidation, hence increased ulcer formation following lead exposure.

Apart from the free radical scavenging enzymes, another agent that has been widely believed to be involved in the regulation of various gastric functions and in the modulation of gastric mucosal integrity is nitric oxide (NO). This is evidenced by reports showing that suppression of NO production by NO synthase inhibitor worsens gastric lesions induced by ethanol in rats^[37,38]. NO has also been suggested to prevent infiltration by neutrophils, which are a source of superoxide radical anions^[39]. The reduction in the gastric tissue nitrite in the lead treated groups in the present study is therefore indicative for a reduced protective capacity of endogenous NO.

In summary, chronic exposure of rats to lead intensifies HCl/ethanol-induced gastric mucosal damage and this may be related to reduced gastric contents of endogenous NO and the antioxidative enzymes SOD and CAT.

COMMENTS

Background

A number of humans are occupationally exposed to high levels of lead through paints, car exhausts battery fumes, etc. Lead exposure also occurs through ingestion with food and via inhalation. Previous studies in dogs and rats have shown that long-term exposure to high level lead in drinking water predisposes the stomach to ulcer. The mechanism of this effect of lead is not understood.

Research frontiers

Oxidative stress has been shown to be a major causative factor for many diseases, including gastrointestinal ulcers. The hotspot of this study is to examine if the increased susceptibility of the stomach to ulcer after prolonged lead exposure can be explained (partly or totally) by an increased oxidative stress in the stomach.

Innovations and breakthroughs

The results of this study show that chronic exposure of rats to lead intensifies HCl/ethanol-induced gastric mucosal damage and this may be related to reduced gastric contents of endogenous nitric oxide and antioxidative enzymes.

Applications

The study suggests that prolonged exposure to lead may be a factor in the etiology of gastrointestinal ulcers.

Terminology

Oxidative stress: a condition of increased oxidant production in animal cells characterized by the release of free radicals and resulting in cellular degeneration. Free radicals damage components of the cells' membranes, proteins, or genetic material by "oxidizing" them—the same chemical reaction that causes iron to rust; Lead: a soft heavy toxic malleable metallic element; bluish white when freshly cut but tarnishes readily to dull grey; Lead poisoning: Lead can come into the body in a number of ways: through water that goes through lead pipes, through badly canned food and through small pieces of paint. Victims of lead poisoning may get headaches, dizziness, confusion, and problems seeing. They may also become slowly paralyzed, starting with the hands. In very serious cases, it can cause death.

Peer review

This is an interesting and generally well written paper with some new information.

Abstract

AIM: To evaluate attenuating properties of N-acetylcysteine (NAC) on oxidative stress and liver pathology in rats with non-alcoholic steatohepatitis (NASH).

METHODS: Male Sprague-Dawley rats were randomly divided into three groups. Group 1 (control, $n = 8$) was free accessed to regular dry rat chow (RC) for 6 wk. Group 2 (NASH, $n = 8$) was fed with 100% fat diet for 6 wk. Group 3 (NASH + NAC₂₀, $n = 9$) was fed with 100% fat diet plus 20 mg/kg per day of NAC orally for 6 wk. All rats were sacrificed to collect blood and liver samples at the end of the study.

RESULTS: The levels of total glutathione (GSH) and hepatic malondialdehyde (MDA) were increased significantly in the NASH group as compared with the control group (GSH; 2066.7 ± 93.2 vs 1337.5 ± 31.5 $\mu\text{mol/L}$ and MDA; 209.9 ± 43.9 vs 3.8 ± 1.7 $\mu\text{mol/g}$ protein, respectively, $P < 0.05$). Liver histopathology from group 2 showed moderate to severe macrovesicular steatosis, hepatocyte ballooning, and necroinflammation. NAC treatment improved the level of GSH (1394.8 ± 81.2 $\mu\text{mol/L}$, $P < 0.05$), it did not affect MDA (150.1 ± 27.0 $\mu\text{mol/g}$ protein), but led to a decrease in fat deposition and necroinflammation.

CONCLUSION: NAC treatment could attenuate oxidative stress and improve liver histology in rats with NASH.

INTRODUCTION

Non-alcoholic steatohepatitis (NASH) is a liver disease characterized by macrovesicular steatosis, hepatocyte necrosis, inflammation, Mallory bodies, and fibrosis^[1]. NASH is closely associated with the metabolic or insulin resistance syndrome^[2]. This is a cluster of disorders, such as obesity, diabetes mellitus, dyslipidemia, arteriosclerosis, and hypertension, with insulin resistance as a common feature^[3]. In initial phases, during which fat accumulates in the liver, no clinical symptoms are evident. In advanced stages, fibrosis is detectable, which might progress into cirrhosis in some patients^[4].

There are many models of NASH-like liver injuries in animals as the genetic model of *ob/ob* mice^[5], the methionine and choline deficient diet model^[6,7], and a model with high-fat liquid diet in which 71% of energy is derived from fat, 11% from carbohydrates, and 18% from protein^[8].

Oxidative stress is believed to play an important role in pathogenesis of NASH. It is likely involved in the progression of disease from steatosis to NASH and potentially cirrhosis. It has been shown that chronic oxidative stress, generated through the oxidation of cytotoxic free fatty acids, can lead to upregulation of cytokines^[9], induction of the liver cytochrome P450 enzyme 2E1 (CYP2E1), and depletion of hepatic antioxidant concentration^[6]. In addition, enhanced lipid peroxidation leads to the generation of byproducts, such as 4-hydroxynonenal (4-HNE) and malondialdehyde (MDA), which have been shown to further stimulate cytokine production. They are involved in hepatic stellate cell activation^[10], fibrogenesis, and enhanced extracellular matrix protein deposition.

According to the concepts of pathogenesis of NASH, these might make a wise basis for the use of antioxidants or drugs that could protect hepatocytes from oxidative stress. N-acetylcysteine (NAC) is a glutathione precursor which increases glutathione levels in hepatocytes^[11]. Increased glutathione levels, in turn, limit the production of reactive oxygen species (ROS)

which cause hepatocellular injury^[12]. Oral NAC treatment (1 g/d) of 11 NASH patients for 3 mo was demonstrated to improve liver function test significantly at the end of treatment period^[11]. In a controlled study, NAC (600 mg/d) was administered to NASH patients for 4 wk, and a significant improvement in aminotransferase levels was found^[13]. Although NAC was shown to improve liver function test in NASH patients, the mechanism remained unclear. Treatment of NASH with diet or diet plus NAC could attenuate oxidative stress as well as improve biochemical parameters and liver histopathology. However, the result of addition of NAC is not better than diet treatment alone^[14]. Therefore, this study was conducted to determine the effects of NAC on oxidative stress and liver pathology in a rat model of 100% fat diet induced NASH^[15].

MATERIALS AND METHODS

Animal preparation

This study was approved by the Ethics Committee of the Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand. Male Sprague-Dawley rats weighing 220-260 g from the National Laboratory Animal Center, Mahidol University, Salaya, Nakorn Pathom were used. The animals were allowed to rest for a week after arrival at the Animal Center, Department of Physiology, Faculty of Medicine, Chulalongkorn University. They were kept at a controlled temperature of $25 \pm 1^\circ\text{C}$ under standard conditions (12 h dark: 12 h light cycle), fed with regular dry rat chow ad libitum, and had freely access to drinking water.

Experimental protocols

Rats were randomly divided into three experimental groups. Group 1: Fed ad libitum with regular dry rat chow for 6 wk (control group, $n = 8$). Group 2: Fed ad libitum with 100% fat diet for 6 wk to induce NASH (NASH group, $n = 8$). Group 3: Fed ad libitum with 100% fat diet plus 20 mg/kg per day of NAC orally (NASH + NAC₂₀ group, $n = 9$) for 6 wk.

All rats were weighed weekly. They were sacrificed to collect blood, serum, and liver samples at the end of the study, 20 h after the last NAC treatment. The diagram of the experiment was shown as follow.

At the end of the study, all rats were anaesthetized using intraperitoneal injection of an overdose (45 mg/kg) of sodium pentobarbital, and the abdominal walls were opened. Blood was drawn by cardiac puncture for total glutathione assay and biochemical assay. The livers were excised quickly and cleaned in iced-cold NSS. One lobe of the liver was collected for MDA measurement, the remaining liver was fixed in 40 g/L formaldehyde solution for histological examination.

Total glutathione determination

Total glutathione levels were quantified using Cayman's GSH assay kit. This assay uses glutathione reductase for determination of glutathione. The sulfhydryl group of glutathione reacts with DTNB (5, 5'-dithiobis-2-

nitrobenzoic acid, Ellman's reagent) and produces a yellow colored 5-thio-2-nitrobenzoic acid (TNB). The mixed disulfide, GSTNB (between glutathione and TNB) that is concomitantly produced, is reduced by glutathione reductase to recycle glutathione and to produce more TNB. The rate of TNB production is directly proportional to this recycling reaction which is in turn directly proportional to the concentration of glutathione in the sample. Measurement of the absorbance of TNB at 405 nm provides an accurate estimation of glutathione in the sample.

Hepatic malondialdehyde (MDA) determination

One lobe of the liver was removed and weighed. One gram of the tissue was placed in a test tube containing 2.25 mL homogenization buffer (11.5 g/L KCl) and homogenized in an ice box using a homogenizer at a rotational speed of 12000 r/min for 1 min. MDA was quantified by using the thiobarbituric acid reaction as described by Ohgawa *et al*^[16]. MDA levels in the samples were determined the linear regression equation from a standard curve. The content of lipid peroxide is expressed as nmol of MDA/g of wet weight, and the total protein was determined by the Lowry method^[17] to correct the MDA level which is expressed in terms of $\mu\text{mol/g}$ protein.

Histopathological examination

The remaining liver samples were fixed in 40 g/L formaldehyde solution at room temperature. They were processed by standard methods. Briefly, tissues were embedded in paraffin, sectioned at 5 μm , stained with HE, and then picked up on glass slides for light microscopy. An experienced pathologist blinded to the experiment evaluated all samples. All fields in each section were examined for grading of steatosis and necroinflammation according to the criteria described by Brunt *et al*^[18].

The severity of steatosis was scored on the basis of the extent of involved parenchyma as 1 if fewer than 33% of the hepatocytes were affected, as 2 if 33%-66% of the hepatocytes were affected, as 3 if more than 66% of the hepatocytes were affected, and as 0 if no hepatocytes were affected.

Hepatic necroinflammation was graded from 0 to 3; score 1 (mild) = sparse or mild focal zone 3 hepatocyte injury/inflammation, score 2 (moderate) = noticeable zone 3 hepatocyte injury/inflammation, score 3 (severe) = severe zone 3 hepatocyte injury/inflammation, and score 0 = no hepatocyte injury/inflammation.

Statistical analysis

The data were expressed as mean \pm SEM using the SPSS version 11.5 for Windows program. Statistical comparisons between groups were analyzed by ANOVA and post hoc comparisons were done with Bonferroni correction. $P < 0.05$ were considered significant.

RESULTS

Body mass and general condition

The body mass at 6 wk of the NASH group and NASH

Table 1 Body mass and serum biochemical parameters in all groups

Parameter (mean \pm SEM)	Control (n = 8)	NASH (n = 8)	NASH + NAC ₂₀ (n = 9)
Body mass (g) at the beginning	239.0 \pm 2.27	245.1 \pm 1.0	251.4 \pm 1.7
at 6 wk	438.4 \pm 9.7	197.0 \pm 8.1 ^a	207.8 \pm 6.9 ^a
AST (U/L)	86.8 \pm 4.3	53.6 \pm 9.3 ^a	65.6 \pm 8.7
ALT (U/L)	40.2 \pm 2.4	23.0 \pm 1.9 ^a	25.4 \pm 5.7 ^a
Cholesterol (g/L)	71.8 \pm 1.8	94.8 \pm 3.1 ^a	91.4 \pm 3.5 ^a
Triglycerides (g/L)	90.3 \pm 19.1	147.8 \pm 32.6	89.2 \pm 28.2

^a*P* < 0.05 vs control.**Table 2** Effects of NAC on liver histology in rats with NASH (scores)

Group	n	Steatosis				Necroinflammation			
		0	1	2	3	0	1	2	3
Control	8	8	-	-	-	8	-	-	-
NASH	8	-	-	5	3	-	5	2	1
NASH + NAC ₂₀	9	-	6	2	1	3	4	1	1

+ NAC₂₀ group were decreased compared to the control (197.0 \pm 8.1 g, 207.8 \pm 6.9 g *vs* 438.4 \pm 9.7 g, *P* < 0.05). Despite weight loss, the general condition of 100% fat diet-fed rats remained good throughout the observation period. After the first 6 wk, rats were fed with regular dry rat chow for additional 4 wk. The body mass was significantly increased in all groups (Table 1).

Serum biochemical parameters

Serum biochemical parameters in the control and the experimental groups are given in Table 1. Serum AST and ALT activities decreased significantly in the NASH group when compared to the control group (AST; 53.7 \pm 9.3 U/L *vs* 86.8 \pm 4.3 U/L, ALT; 23.0 \pm 1.9 U/L *vs* 40.1 \pm 2.4 U/L, *P* < 0.05). Serum ALT but not AST activity returned to control levels in the NASH + NAC₂₀ group (ALT 25.4 \pm 5.7 U/L; AST 65.6 \pm 8.7 U/L). Serum cholesterol was significantly higher in the NASH group and NASH + NAC₂₀ group than that in the control group (94.8 \pm 3.1 g/L, 91.4 \pm 3.5 g/L *vs* 71.8 \pm 1.8 g/L, *P* < 0.05), whereas there were no significant differences in serum triglycerides (Table 1).

Total glutathione level in whole blood

Whole blood total glutathione levels were significantly higher in the NASH group compared to the control group (2066.7 \pm 93.8 μ mol/L *vs* 1337.5 \pm 31.5 μ mol/L, *P* < 0.05). Glutathione in NASH + NAC₂₀ group was significantly lower than in the NASH group (1394.8 \pm 81.2 μ mol/L *vs* 2066.7 \pm 93.8 μ mol/L, *P* < 0.05).

Hepatic MDA content

MDA was elevated significantly in the NASH group when compared to the control group (209.9 \pm 43.8 μ mol/g protein *vs* 3.8 \pm 1.7 μ mol/g protein, *P* < 0.05). There was no statistical significant difference in MDA levels in NASH + NAC₂₀ group (150.1 \pm 27.0 μ mol/g protein).

Histopathological examination

Liver sections from rats fed with the regular dry rat chow had normal morphological appearance. In the NASH group, all animals developed moderate to severe macrovesicular steatosis, hepatocyte ballooning, mild to moderate inflammation, and regeneration of hepatocytes (Table 2). NAC treatment improved steatosis and necroinflammation scores in animals of the NASH + NAC₂₀ group when compared with the NASH group (Figure 1).

DISCUSSION

Histopathology of NASH is similar to that of ethanol-induced hepatitis with the presence of macrovesicular steatosis, hepatocyte ballooning, necroinflammation, Mallory bodies, and fibrosis^[1]. To study the pathogenesis of or therapeutic options for NASH, there are many models that can be used including a genetic model (obese rats), a model of methionine and choline deficient diet, a model of high fat liquid diet, and a 100% fat diet^[5-8,15]. In this study, 100% fat diet was chosen to induce NASH in Sprague-Dawley rats as this procedure is fast, easy, and provides a comparable pattern of pathological changes as in humans although this model represents malnutrition induced steatohepatitis.

By feeding rats with 100% fat diet, the hepatic lesions of NASH were apparent within 6 wk. Histopathological examination showed macrovesicular steatosis, hepatocyte ballooning, Mallory bodies, and mild to moderate inflammation. One hundred percent fat diet caused mobilization of free fatty acid (FFA) from adipose tissue and transport into hepatocytes. In this condition, the liver failed to synthesize apolipoprotein that is required for packaging and exporting fat from the liver, triglycerides (TG) thus accumulate in the liver^[19]. β -oxidation of FFA in hepatocytes produces reactive oxygen species (ROS) which activate lipid peroxidation^[20]. ROS and lipid peroxidation cause direct damage to hepatocytes by disrupting membranes, protein, and DNA^[21,22]. Hepatocyte damage and lipid peroxidation products induce an inflammatory response.

AST and ALT are useful screening tests for detecting liver injury^[23]. They are found in hepatocytes and can not diffuse out of the cells in the physiological condition. When the hepatocyte is injured, plasma membrane can be disrupted and the leakage through extracellular fluid of the enzyme occurs where they can be detected at abnormal levels in the serum^[24]. AST and ALT activities have been found to be increased in NASH rats^[10,25-28]. In contrast, AST and ALT activities decreased significantly with 6 wk of 100% fat diet in this study. The decreased serum transaminases may be due to poor nutrition or hepatocyte death. Rats fed with 100% fat diet derived main energy from fat, when there were low in vitamin and mineral contents. The decreased AST and ALT levels were probably due to nutritional deficiency of pyridoxal phosphate which is a cofactor for both AST and ALT to catalyze the transfer of the α amino group from aspartate or alanine to α -ketoglutarate with made the release of pyruvate, oxaloacetate, and glutamate^[23]. In addition,

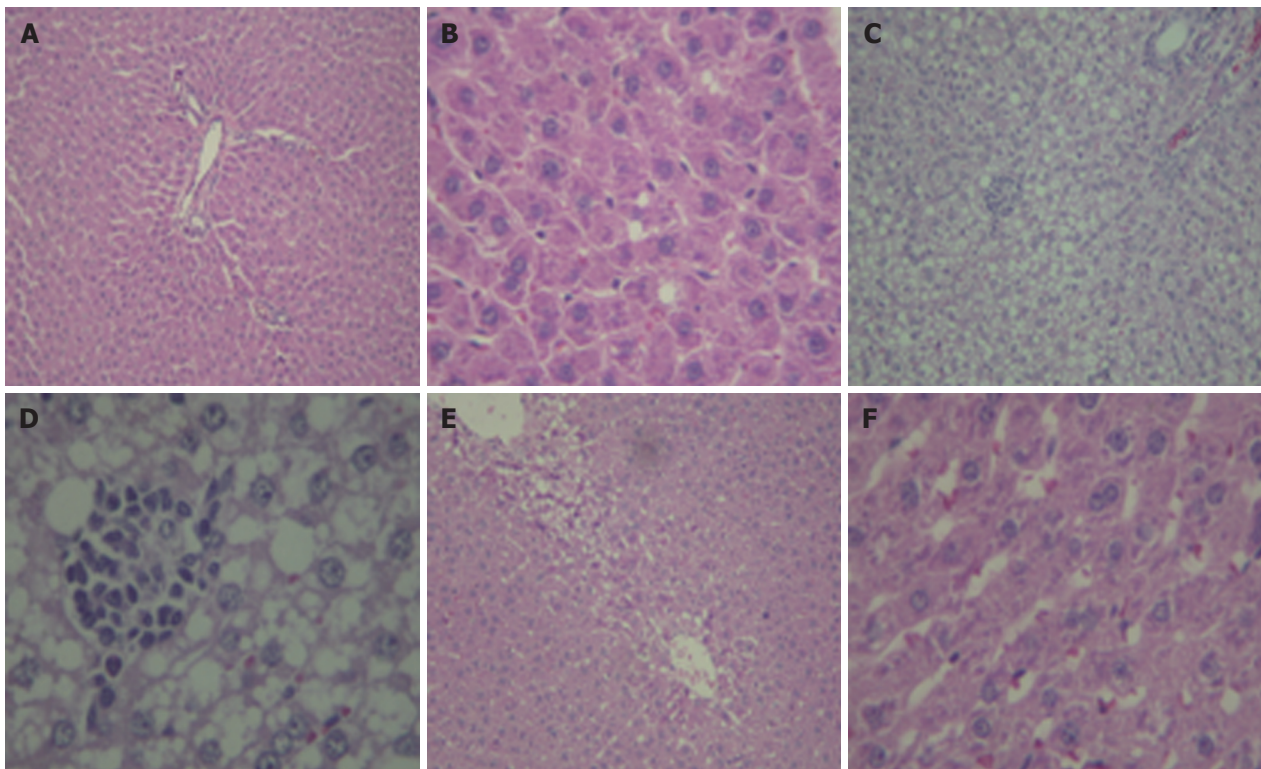

Figure 1 Hematoxylin and eosin staining of liver tissue. **A, B:** control; **C, D:** NASH, fed with 100% fat diet group showed macrovesicular steatosis, ballooning changes, Mallory bodies, hepatocyte necrosis, and infiltration of inflammatory cells; **E, F:** NASH + NAC₂₀, showed the improvement in steatosis and necroinflammation (**A, C, E:** x 10; **B, D, F:** x 40).

oxidative stress condition may be a cause of hepatocyte death, therefore, aminotransferases can not be produced.

In 100% fat diet-fed rats, body mass decreased significantly ($P < 0.05$) as compared to the control group. While serum cholesterol significantly increased, serum TG level was unchanged. Feeding with 100% fat diet for 6 wk caused a loss of body mass that may be due to a metabolic imbalance of carbohydrate, protein, and fat. Moreover, 100% fat diet contained highly saturated fat which may increase blood cholesterol concentration by 15% to 25%^[29]. This result was from an increase of fat deposition in the liver which then provides the increased quantities of acetyl CoA in the liver cell for production of cholesterol^[29]. The increased cholesterol was found in this experiment and had been observed in another study that used 10% lard oil and 2% cholesterol supplement adding into the standard diet^[29].

FFA causes oxidative stress that has the potential to induce NASH^[2]. FFA in the body is increased and this is associated with state of starvation^[2]. Stored FFA can be mobilized from adipose tissue through lipolysis^[2]. FFA metabolism increases the production of ROS which activated lipid peroxidation. Consequences are the disruption of membranes and the production of reactive metabolites such as MDA^[20]. This study found high hepatic MDA levels in 100% fat-diet fed rats in accordance with studies by others^[25-28]. Glutathione is the major intracellular non-protein antioxidant and plays a crucial role in the detoxification of free radicals^[30,31]. Serum level of glutathione was increased in patients with NASH^[32]. Similarly in this experiment, an increasing in total glutathione in whole blood with 100% fat diet

feeding could be explained by compensatory protection mechanism against oxidative stress.

NAC is a thiol compound that acts directly as free radical scavenger and as a precursor of reduced glutathione^[33]. Therefore, treatment with 20 mg/kg of NAC improved the total glutathione level to normal level in NASH + NAC₂₀ group and improved necroinflammation score. Because of some limitations of our study, such as dose of NAC, time for treatment, and the number of animals, the effect of NAC on reducing hepatic MDA level remained unclear. In our previous study, diet treatment alone and diet plus NAC groups, total glutathione, serum AST, ALT, cholesterol, TG, and hepatic MDA returned to normal levels as in the control group. In addition, the pathological changes of liver in these groups were improved^[14]. These results emphasized how crucial the nutritional composition of the diet is. Good proportion of nutrients (i.e., carbohydrate, lipid, and protein) is essential for growth and maintenance. These nutrients supply energy, promote growth, repair body tissues, and regulate metabolic processes^[34].

In conclusion, feeding with 100% fat diet for 6 wk induced macrovesicular steatosis, hepatocyte ballooning, and inflammation in rats similar to histopathology of NASH. Treatment with NAC in NASH could improve oxidative stress and liver histopathology.

COMMENTS

Background

Non-alcoholic steatohepatitis (NASH), in advanced stages, can cause liver fibrosis, eventually progressing to cirrhosis in some patients. Oxidative stress is believed

to play an important role in pathogenesis of NASH. N-acetylcysteine (NAC) is a glutathione precursor which increases glutathione levels in hepatocytes. Increased glutathione levels, in turn, limit the production of reactive oxygen species (ROS) which cause hepatocellular injury that could protect hepatocytes from oxidative stress.

Research frontiers

NAC is a thiol compound that acts directly as free radical scavenger. In the pathogenesis of NASH, prevention of oxidative stress could protect hepatocytes from injury. The hotspots of this study indicate that NAC treatment could attenuate oxidative stress and improve liver histology in rats with NASH.

Innovations and breakthroughs

According to a previous report, oral NAC treatment of NASH patients for several months was found to significantly improve aminotransferase levels. However, the mechanism remained unclear. This study is a novel and well conducted experimental study showing the efficacy of NAC on improvement of total glutathione level and hepatic MDA in rats with NASH. Furthermore, treatment with NAC showed improvement in steatosis and necroinflammation.

Applications

Our data indicate that NAC treatment could attenuate oxidative stress and improve liver histology in rats with NASH.

Terminology

NASH is a liver disease characterized by macrovesicular steatosis, hepatocyte necrosis, inflammation, Mallory bodies, and fibrosis. In initial phases, during which fat accumulates in the liver, no clinical symptoms are evident. In advanced stages, fibrosis is detectable, eventually progressing to cirrhosis. NAC is a glutathione precursor which increases glutathione levels in hepatocytes. Increased glutathione levels, in turn, limit the production of ROS which cause hepatocellular injury.

Peer review

This is an experimental work on a steatosis model in the rat, induced by 100% fat diet in which the co-administration of NAC protects against fat induced liver injury. This is a very interesting and well conducted experimental study showing the efficacy of NAC in preventing biochemical and histological alterations secondary to a fat rich diet.

Abstract

AIM: To give the evidence for rationalizing surgical therapy for early gastric cancer with different lymph node status.

METHODS: A series of 322 early gastric cancer patients who underwent gastrectomy with more than 15 lymph nodes retrieved were reviewed in this study. The rate of lymph node metastasis was calculated. Univariate and multivariate analyses were performed to evaluate the independent factors for predicting lymph node metastasis.

RESULTS: No metastasis was detected in No.5, 6 lymph nodes (LN) during proximal gastric cancer total gastrectomy, and in No.10, 11p, 11d during for combined resection of spleen and splenic artery and in No.15 LN during combined resection of transverse colon mesentery. No.11p, 12a, 14v LN were proved negative for metastasis. The global metastatic rate was 14.6% for LN, 5.9% for mucosa, and 22.4% for submucosa carcinoma, respectively. The metastasis in group II was almost limited in No.7, 8a LN. Multivariate analysis identified that the depth of invasion, histological type and lymphatic invasion were independent risk factors for LN metastasis. No metastasis from distal cancer (≤ 1.0 cm in diameter) was detected in group II LN. The metastasis rate increased significantly when the diameter exceeded 3.0 cm. All tumors (≤ 1.0 cm in diameter) with LN metastasis and mucosa invasion showed a depressed macroscopic type, and all protruded carcinomas were > 3.0 cm in diameter.

CONCLUSION: Segmental/subtotal gastrectomy plus D₁/D₁ + No.7 should be performed for carcinoma (≤ 1.0 cm in diameter, protruded type and mucosa invasion).

Subtotal gastrectomy plus D₂ or D₁ + No.7, 8a, 9 is the most rational operation, whereas No.11p, 12a, 14v lymphadenectomy should not be recommended routinely for poorly differentiated and depressed type of submucosa carcinoma (> 3.0 cm in diameter). Total gastrectomy should not be performed in proximal, so does combined resection or D₂⁺/D₃ lymphadenectomy.

INTRODUCTION

Gastric cancer is still one of the important causes of cancer-related death in China. Although early gastric cancer accounts for less than 10% of gastric cancers, excellent outcome of surgery has been reported, with a 5-year survival rate higher than 90%^[1-3]. In the past 20 years, most surgeons considered D₂ lymphadenectomy the standard and optimal surgical procedure for patients with early gastric cancer. Even total gastrectomy and D₃ lymphadenectomy with combined resection of other organs have been used to achieve curative (R₀) resection^[3-9]. The lymph node metastasis rate of early gastric cancer is reported to be 11%-18% and 70%-80% patients will undergo over-surgery with D₂ lymphadenectomy^[1,4,8,9]. Consequently, investigating the risk factors for lymph node metastasis is the key to rational surgery of early gastric cancer, which may improve the 5-year survival rate of patients and their quality of life. This study was to retrospectively analyze the location, frequency, degree of and risk factors for lymph node metastasis in 322 patients with early gastric cancer, in order to rationalize surgical therapy.

MATERIALS AND METHODS

Patients

Between February 1972 and August 2006, a consecutive series of 322 early gastric cancer patients underwent

Table 1 Site and frequency of lymph node metastasis of cancer in the lower and middle thirds of stomach

gastrectomy at the Department of Oncologic Surgery, First Affiliated Hospital, China Medical University. The patients (242 men and 80 women) ranged in age from 19 to 80 (53.8 ± 12.3) years participated in the study. Early gastric cancer was located in the lower third of stomach (L/LM) of 145 patients, in the middle third (M/ML/MU) of 14 patients, in the upper third (U/UM) of 11 patients, and in whole stomach (UML) of 4 patients. A total of 292 patients underwent distal gastrectomy, 10 proximal gastrectomy, 20 total gastrectomy, 2 combined resection of spleen, and 3 combined resection of transverse colon mesentery. D₁ lymphadenectomy was performed in 57 patients; D₁ + No.7 in 58 patients; D₁ + No.7, 8a, 9 in 63 patients; D₂ in 107 patients; and D₂⁺ or D₃ in 37 patients. The methods of pathology diagnosis, lymph node grouping and surgery have been described previously^[10].

Pathology

Serial section of specimens was performed for an accuracy pathological diagnosis. Mucosa carcinoma was diagnosed in 152 patients and submucosa carcinoma in 170 patients based on the depth of invasion. Protruded type was found in 23 patients, flat type in 38 patients, and depressed type in 263 patients, respectively in the light of macroscopic appearance. The tumor diameter ranged from 0.4 to 14.0 (3.2 ± 1.8) cm. Well or moderately differentiated tumor was found in 142 patients, and poorly differentiated tumor in 180 patients according to their histological type. Mass type was observed in 102 patients, nest type in 91 patients and diffused type in 129 patients, respectively, based on the histological growth pattern. Lymphatic vessel invasion occurred in 19 patients.

Statistical analysis

All data were analyzed by SPSS11.5. The correlation between clinicopathological factors and nodal involvement was evaluated by univariate analysis. Multivariate analysis was performed to evaluate the independent factors for predicting lymph node metastasis. $P < 0.05$ was considered statistically significant.

RESULTS

Evaluation of lymphadenectomy

Five patients underwent combined resection of other organs due to misdiagnosis as advanced gastric carcinoma. Depressed type of mucosa and submucosa carcinoma was diagnosed in 2 and 3 patients, respectively. Proximal gastric cancer without metastasis in No.10, 11p, 11d lymph nodes was diagnosed in 2 patients undergoing combined resection of spleen and splenic artery. Distal gastric cancer without metastasis in No.15 lymph node was diagnosed in 3 patients undergoing combined resection of transverse colon mesentery. No.5, 6 lymph nodes were negative in 20 patients with proximal gastric cancer after total gastrectomy.

Metastasis of distal gastric cancer was found in 2 out of the 37 patients undergoing extended lymphadenectomy ($> D_2$). Depressed type of mucosa and submucosa carcinoma was found in the 2 patients. Metastasis of group I lymph nodes was detected both in 285 patients with middle and distal gastric cancer who underwent $\leq D_2$ lymphadenectomy. The detection rate was 12.9% and 14.3%, respectively. A frequent metastasis of No.7, 8a lymph nodes (6.5%-8.2%) and an occasional metastasis of No.9 lymph nodes were also found. No metastasis was detected in No.11, 12a, 14v lymph nodes (Table 1).

Relationship between frequency of lymph node metastasis and location of focus

The number of retrieved lymph nodes in all patients was more than 15, ranging from 15 to 75 (median, 16). Lymph node metastasis was detected in 47 patients (14.6%), and the number of metastatic lymph nodes ranged from 1 to 16 (median, 2). Of the patients with lymph node metastasis, 33 were male (13.6%), 14 female (17.5%). Distal gastric cancer was diagnosed in 38 patients (15.5%), middle gastric cancer in 9 (14.5%), protruded type in 3 patients (14.3%), flat type in 4 patients (10.5%), and depressed type in 40 patients (15.2%). The diameter of tumor was ≤ 1.0 cm in 5 patients (19.5%), 1.1-2.0 cm in 13 patients (11.2%), 2.1-3.0 cm in 6 patients (10.0%), > 3.0 cm in 23 patients (19.2%). Mucosa carcinoma was found in 9 patients (2.9%), submucosa carcinoma in 38 patients (22.4%), poorly differentiated carcinoma in 35 patients (19.4%), well or moderately differentiated in 12 patients (8.5%), mass type in 15 patients (14.7%), nest type in 12 patients (13.2%), diffused type in 20 patients (15.5%), negative lymphatic invasion in 36 patients (57.9%), and positive lymphatic invasion in 11 patients (11.9%).

Of the 245 patients with distal gastric cancer, 35 had metastasis in group I lymph nodes (14.3%), and 18 in group II lymph nodes (7.3%). Metastasis was detected in all group

Growth manner	0.58	0.26-1.30	0.186
Macroscopic type	1.14	0.56-2.34	0.715

CI: Confidence interval. Depth of invasion, histological type, lymphatic invasion and tumor maximum diameter are the independent risk factors correlated with lymph node involvement.

I lymph nodes with a frequency of 5.7% for No.6, 6.5% for No.4, 4.9% for No.3, and 1.2% for No.5, respectively. In group II lymph nodes, the most frequent metastasis was detected in No.7 lymph nodes (5.3%) and No.8a lymph nodes (2.9%), and less frequent metastasis in No.9 lymph nodes (0.8%), No.1 lymph nodes (0.4%). Metastasis of group III lymph nodes was detected in only 2 patients.

Of the 62 patients with middle gastric cancer, 8 had metastasis of group I lymph nodes (12.9%), and 4 had metastasis of group II lymph nodes (6.5%). The rate

of metastasis of group I lymph nodes was 9.7% for No.3, 4.8% for No.1, 1.6% for No.5, and 1.6% for No.6, respectively. Metastasis of No.7 (4.8%) and No.8a (1.6%) lymph nodes was detected in group II lymph nodes. No lymph node metastasis was detected in the 11 patients with proximal gastric cancer.

Risk factors correlated with lymph node involvement

In this series, the mean number of retrieved lymph nodes was 19.3 ± 7.5 in patients without lymph node metastasis, and 20.8 ± 6.9 in patients with lymph node metastasis. The difference was not significant ($F = 1.741$, $P = 0.188$). The univariate analysis showed that three variables were significantly indicative of lymph node metastasis: depth of invasion, histological type, and lymphatic invasion ($P < 0.001$). The lymph node metastasis rate of poorly differentiated submucosa carcinoma with positive lymphatic invasion was significantly higher than that of well differentiated mucosa carcinoma with negative lymphatic invasion (Table 2).

The multivariate analysis showed that all the variables (depth of invasion, histological type, and lymphatic invasion) remained significant, indicating that the independent risks were correlated with lymph node involvement. The lymph node metastasis of submucosa carcinoma was 3.7 times higher than that of mucosa carcinoma. The lymph node metastasis of poorly differentiated carcinoma was 3.4 times higher than that of well differentiated carcinoma. The positive lymphatic invasion was 8.4 times higher than that of negative lymphatic invasion. The maximum diameter of the tumor was also an important variable correlated with lymph node involvement (OR = 1.23, $P = 0.042$), the rate of lymph node metastasis was associated with the maximum tumor diameter (Table 3).

Relationship between lymph node metastasis and clinicopathological factors for distal gastric cancer

Metastasis of distal gastric cancer hardly went beyond group I lymph nodes when the maximum tumor diameter was ≤ 1.0 cm. Corresponding to the increased maximum diameter, the rate of metastasis in group II lymph nodes was increased, but often limited in No.7, 8a lymph nodes. Only when the maximum tumor diameter was > 3.0 cm, could metastasis of No.1 and 9 lymph nodes be detected. Compared with protruded type of carcinoma, in which metastasis could only be detected in group I lymph nodes, depressed type of carcinoma often had combined metastasis in both group I and II lymph nodes, and the number of metastasis lymph nodes would increase significantly.

Metastasis of mucosa carcinoma was detected in all group I lymph nodes. Metastasis of poorly differentiated and depressed types of mucosa carcinoma in No.1 lymph nodes was detected in only 1 patient, whose tumor diameter was > 3.0 cm. Metastasis of submucosa carcinoma was detected in both group I and II lymph nodes, and the rate of lymph node metastasis was significantly higher than that of mucosa carcinoma ($P < 0.01$). Metastasis of poorly and well differentiated carcinoma was detected in group I and II lymph nodes, but the metastasis rate of poorly differentiated

carcinoma was significantly higher than that of well differentiated carcinoma ($P < 0.05$). The metastasis rate of positive lymphatic invasive carcinoma was also significantly higher than that of negative lymphatic invasive carcinoma ($P < 0.01$) (Table 4).

DISCUSSION

Since 1980's, D₂ lymphadenectomy has been widely accepted as the standard surgery for early gastric cancer, especially for submucosa carcinoma. However, it was reported that D₂ lymphadenectomy does not increase the long-term survival of patients, compared with D₁ or D₁⁺ lymphadenectomy^[7-9,11]. Since lymph node metastasis remains one of the most important predictors for survival, reduction in lymphadenectomy will probably result in residue of metastatic lymph nodes. Unnecessarily extended resection will induce a series of complications, which also result in a poor quality of life. Thus, it is important to standardize the optimal extent of lymph node dissection by investigating lymph node metastasis of early gastric cancer.

In the present study, total gastrectomy for carcinoma in the upper third of stomach was selected according to the status of No.5 and 6 lymph nodes. Metastasis was not detected in all proximal gastric cancer patients after total gastrectomy. Considering the complications after total gastrectomy, it was not used as a routine operation for proximal early gastric cancer. Furthermore, metastasis was not detected in No.10, 11p, 11d lymph nodes after combined resection of spleen or splenic artery and in No.15 lymph nodes after combined resection of transverse colon mesentery. Therefore, we conclude that combined resection of other organs should not be performed in early gastric cancer. In our study, most patients undergoing

combined resection were due to adhesion of serosa and transverse colon mesentery or due to inflammatory swelling of inflammatory splenic hilum lymph nodes. Thus, estimating the depth of invasion accurately is the key to optimal surgery. Endoscopic ultrasonography and three-dimensional spiral CT (3DCT) provide more accurate information on the depth of invasion. It was reported that 70%-80% of early gastric cancers can be diagnosed by endoscopic ultrasonography combined with three-dimensional CT^[12-14].

Whether D₂ lymphadenectomy for early gastric cancer should be performed remains controversial. Many researchers consider D₁ + No.7, 8a or D₁ + No.7, 8a, 9 lymphadenectomy as the standard operation for most of early gastric cancers^[15-17]. In our series, no metastasis of middle and distal gastric cancer was detected in No. 11p, 12a, 14v lymph nodes, suggesting that neither dissection of No. 11p, 12a, 14v lymph nodes nor D₂⁺/D₃ lymphadenectomy is necessary for distal early gastric cancer.

It was reported that the lymph node metastasis rate is 0%-3% for mucosa carcinoma and 20% for submucosa carcinoma. It has been shown that 9%-16% of metastatic lymph nodes are detected in group I, 4%-6% in group II, and 0.3%-1% in group III^[16-18]. In this study, the metastasis rate in group I and III lymph nodes is consistent with the reported data. The metastasis rate in group II was 7.3% for distal cancer and 6.5% for middle cancer, higher than that in former studies.

It has been widely accepted that the status of lymph node involvement is closely correlated with the depth of invasion, but the relationship between metastasis and focus diameter, histological type and macroscopic type is still controversial^[8,16,17,19-21]. Kunisaki *et al*^[17] reported that mucosa carcinoma (> 3.0 cm in diameter) has a

higher lymph node involvement, while there is no distinct correlation between the diameter, macroscopic type, histological type and metastasis of submucosa carcinoma. Shimoyama *et al*^[16] found that the metastasis rate for intestinal submucosa carcinoma (≤ 1.5 cm in diameter) and diffused submucosa carcinoma (≤ 1.0 cm in diameter) is very low (3%), and limited in group I lymph nodes. If the diameter went beyond the former cut-point, the rate of metastasis would increase significantly and No.7, 8a, 9 lymph nodes (2.3%) could be detected even in group II lymph nodes. Gotoda *et al*^[20] reported that lymph node metastasis of well differentiated mucosa carcinoma (≤ 3.0 cm in diameter) is seldom detected. Whereas lymph node metastasis of submucosa carcinoma (> 3.0 cm in diameter) with positive lymphatic invasion increase significantly.

In our study, no metastasis of distal gastric cancer (≤ 1.0 cm in diameter) with mucosa invasion was detected in group II lymph nodes. The rate of metastasis in group II lymph nodes significantly increased when the tumor diameter was > 3.0 cm. All the carcinomas (≤ 1.0 cm in diameter and/or mucosa invasion) with lymph node involvement showed depressed macroscopic type. The diameter of protruded carcinoma with lymph node involvement was > 3.0 cm. Multivariate analysis showed that the depth of invasion, histological type and lymphatic penetration were independent risk factors for lymph node metastasis and the maximum diameter was also an important factor. Our study also revealed the relationship between metastasis of distal gastric cancer in group II lymph nodes and the diameter, histological type, depth of invasion and lymphatic invasion of the tumor. The rate of involved lymph nodes significantly increased compared with poorly differentiated, sub-mucosa carcinoma and positive lymphatic invasion, suggesting that the following high risk factors for lymph node metastasis of distal gastric cancer in group II lymph nodes are tumor diameter > 3.0 cm, depressed type, poorly differentiated submucosa carcinoma and positive lymphatic invasion. Standard D₂ lymphadenectomy should be performed to achieve curative (R₀) resection in such patients.

In summary, selection of reasonable surgery for early gastric cancer should be based on the pathobiologic behaviour of the tumor. Segmental/subtotal gastrectomy plus D₁/D₁ + No.7 lymphadenectomy should be performed for carcinoma (≤ 1.0 cm in diameter, protruded type and mucosa invasion). Subtotal gastrectomy plus D₂ or D₁ + No.7, 8a, 9 lymphadenectomy is the most rational operation for poorly differentiated and depressed type of submucosa carcinoma (> 3.0 cm in diameter), whereas No.11p, 12a, 14v lymphadenectomy should not be performed routinely. Total gastrectomy should not be performed for proximal gastric cancer. Combined resection of other organs or D₂⁺/D₃ lymphadenectomy should always be avoided.

have been used to achieve curative (R₀) resection. However, it was reported that application of extended surgery does not reasonably increase the long-term survival of patients.

Research frontiers

It has been widely accepted that the status of lymph node involvement is closely correlated with the depth of invasion, but the relationship between metastasis and diameter of focus, histological type and macroscopic type is still controversial. Since lymph node metastasis remains one of the most important predictors for survival, reduction in lymphadenectomy will probably result in residue of metastatic lymph nodes. Unnecessarily extended resection will induce a series of complications, which also result in a poor quality of life.

Innovations and breakthroughs

The results of this study show that depth of invasion, histological type and lymphatic invasion are independent risk factors for lymph node metastasis. There is a relationship between the pathobiologic behavior of tumor and reasonable surgery for early gastric cancer.

Applications

With the knowledge of the risk factors and rules of lymph node metastasis, clinical doctors can select surgery for early gastric cancer more reasonably.

Terminology

D lymphadenectomy: Lymph node dissection according to the Japanese Gastric Cancer Association (JGCA) criteria. Lymph node dissection is divide into D₁ lymphadenectomy, D₂ lymphadenectomy and D₃ lymphadenectomy.

Peer review

The authors rationalized surgical therapy for early gastric cancer with different lymph node status and suggest that segmental/subtotal gastrectomy plus D₁/D₁ + No.7 should be performed for carcinoma (≤ 1.0 cm in diameter, protruded type and mucosa invasion). Subtotal gastrectomy plus D₂ or D₁ + No.7, 8a, 9 is the most rational operation for poorly differentiated and depressed type of submucosa carcinoma (> 3.0 cm in diameter), whereas No.11p, 12a, 14v lymphadenectomy should not be recommended routinely. Total gastrectomy or D₂⁺/D₃ lymphadenectomy should not be performed in proximal and combined resection.

Abstract

AIM: To investigate the effects of Cromolyn Sodium (CS) pretreated prior to reperfusion on the activity of intestinal mucosal mast cells (IMMC) and mucous membrane of the small intestine in ischemia-reperfusion (IR) injury of rats.

METHODS: Thirty-two Sprague-Dawley (SD) rats were randomly divided into four groups: sham group (group S), model group (group M), high and low dosage of CS groups, (treated with CS 50 mg/kg or 25 mg/kg, group C1 and C2). Intestinal IR damage was induced by clamping the superior mesenteric artery for 45 min followed by reperfusion for 60 min. CS was intravenously administrated 15 min before reperfusion. Ultrastructure and counts of IMMC, intestinal structure, the expression of tryptase, levels of malondialdehyde (MDA), TNF- α , histamine and superoxide dismutase (SOD) activity of the small intestine were detected at the end of experiment.

RESULTS: The degranulation of IMMC was seen in group M and was attenuated by CS treatment. Chiu's score of group M was higher than the other groups. CS could attenuate the up-regulation of the Chiu's score, the levels of MDA, TNF- α , and expression of tryptase and the down-regulation of SOD activity and histamine concentration. The Chiu's score and MDA content were negatively correlated, while SOD activity was positively correlated to the histamine concentration respectively in the IR groups.

CONCLUSION: Pretreated of CS prior to reperfusion protects the small intestine mucous from ischemia-reperfusion damage, the mechanism is inhibited IMMC from degranulation.

INTRODUCTION

Mast cell degranulation is an important component of inflammatory tissue responses^[1]. Bortolotto proved that ischemia-reperfusion injury was depending upon the presence of mast cells in skeletal muscle^[2].

Intestinal mucosal mast cells (IMMCs) are particularly frequent in close proximity to epithelial surfaces where they are strategically located for optimal interaction with the environment and for their putative functions for host defense^[3].

Some studies on the role of IMMC in small intestine ischemia-reperfusion injury have been reported^[4-7]. Lindstrom and his colleagues^[4] found the eosinophils and mast cells in rat ileum gradually increased after intestine ischemia (60 min)/reperfusion (60 min), and reported that the epithelium permeability increased significantly after ischemia-reperfusion. The researches of Kanwar and Schramm^[5,6] were focused on mast cells stimulating neutrophil adherence, resupination, recruitment, and the intestinal mucosal injury. Boros^[7] reported that mast cell degranulation prior to ischemia may induce a potentially protective mechanism in the small bowel mucosa and decrease ischemia-reperfusion injury in the dog.

Cromolyn Sodium (CS) is a MC membrane stabilizer. MC-stabilization protocols were proved to reduce the leukocyte recruitment^[8]. Kimura^[9] reported that the intestine ischemia and reperfusion could induce a decrease in the mucosal histamine content, an increase in plasma histamine levels, and an significantly enhance in mucosal permeability. However, MAR-99, another mast cell stabilizer, can prevented these changes by pretreatment prior to ischemia. Kalia^[10] found that all ketotifen-pretreated animals (1 mg/kg orally twice daily for 3 d before ischemia)

survived after ischemia-reperfusion and ketotifen could abrogate the leukocyte adherence induced by ischemia-reperfusion within the villus mucosal capillaries and supplying arterioles and largely prevented pulmonary injury.

The above studies proved that IMMC are associated with the small intestine injury after ischemia-reperfusion, and MC membrane stabilizer pretreatment prior to ischemia can protect against the injury, such as CS and MAR-99. While the studies about the intestinal mucosal injury with CS pretreatment after the small intestine ischemia before reperfusion were few. Oxidative stress is one of the mechanism about the small intestine ischemia-reperfusion injury has been generally acknowledged. We hypothesized that CS have an influence on the oxidative stress during the small intestine ischemia-reperfusion, and the purpose of our present study was to investigate whether CS pretreatment prior to reperfusion could protect against early intestinal mucosal damage induced by ischemia-reperfusion through inhibition of IMMC degranulation or oxidative stress. To test our hypothesis, we showed in a rat IR gut injury model: (1) the ultrastructure and counts of IMMC in the early reperfusion; (2) mucosal damage with CS pretreatment; (3) expression of tryptase in the IMMC; and (4) the levels of malondialdehyde (MDA), TNF- α , histamine and superoxide dismutase (SOD) activity of the small intestine in rats.

MATERIALS AND METHODS

Acute ischemia-reperfusion injury of the intestinal mucosa in rats

Thirty-two healthy Sprague-Dawley rats (200-250 g, provided by Animal Center of Sun Yat-Sen University and approved by the University Animal Study Committee) were randomly divided into four groups each of which contained 8 rats. Laboratory temperature was kept at 25°C-27°C. Surgery was conducted under general anesthesia with intra-peritoneal sodium pentobarbital (45 mg/kg) after they were fasted for 18 h. Tracheotomy was performed for ventilation. The right femoral vein was cannulated for fluid infusion and drugs. The rat abdomen was opened and its superior mesenteric artery (SMA) was found and clamped for 45 min. Then the clamp was released and reperfusion of the splanchnic region was maintained for 60 min (in M group). In control group, SMA was found but not clamped and i.v. saline solution via the right femoral vein at 30th min after the start of experiment (sham group). In another two groups, the same operation was done and CS (50 mg/kg or 25 mg/kg, The dosage and method of CS pretreatment according to Cordeiro *et al*^[11] for Cromolyn sodium is poorly absorbed by oral.) was given via right femoral vein 15 min before the opening of the clamp (C1 and C2 groups).

Preparation of specimens and measurements

After ischemia-reperfusion, the rats were killed and bled rapidly. A segment of 0.5-1.0 cm intestine was cut from 5 cm to terminal ileum and fixed in 4% formaldehyde polymerisatum, then embedded in paraffin for section. Another segment of small intestine was washed with frozen saline and dried with suction paper and at -70°C.

The segment of small intestine was stained with hematoxylin-eosin. The damages of intestinal mucosa were evaluated by two different pathologist according to the criteria of Chiu's method^[12]. Criteria of Chiu grading system consists from 5 subdivisions according to the changes of villus and gland of intestinal mucosa: grade 0, normal mucosa; grade 1, development of subepithelial Gruenhagen's space at the tip of villus; grade 2, extension of the space with moderate epithelial lifting; grade 3, massive epithelial lifting with a few denuded villi; grade 4, denuded villi with exposed capillaries; and grade 5, disintegration of the lamina propria, ulceration and hemorrhage.

Transmission electron microscopy

Intestines were immersed and fixed in 2.5% glutaraldehyde overnight at 4°C and washed three times in PBS. Then they were postfixed in aqueous 1% OsO₄ and 1% K₃Fe (CN)₆ for 1 h. After three times of PBS washes, the tissue was dehydrated through a graded series of 30% to 100% ethanol and 100% propylene oxide and then infiltrated in 1:1 mixture of propylene oxide and Polybed 812 epoxy resin for 1 h. The infiltration solution was changed to 100% resin. After 24 h of infiltration, the tissue was embedded in molds and cured at 37°C overnight, followed by additional hardening at 65°C for 2 d. Ultrathin (70 nm) sections were collected on 200-mesh copper grids and stained with 2% uranyl acetate in 50% methanol for 10 min, followed by 1% lead citrate for 7 min. Sections were photographed using a Hitachi H-600 transmission electron microscope (TOSHI-BA, Japan) at 80 kV onto electron microscope film.

Detection of concentration of protein in intestine

Intestinal tissues were homogenized with normal saline. Intestinal protein quantitation was by the Bradford method^[13] with a BSA standard using kits were provided by Shenerg Biocolor BioScience & Technology Company, Shanghai, China.

Detection of content of MDA in the intestine

Intestinal tissues were homogenized with normal saline. MDA content was determined by the TBA method (Jiancheng Bioengineering Ltd, Nanjing, China). Homogenate (0.1 mL) was taken to detect MDA content. Briefly, 0.1 mL 8.1% SDS, 0.8 mL acetic acid buffer, 0.8 mL 0.8% TBA and 0.2 mL distilled water were added into the sample tubes and one standard tube (containing 0.1 mL tetrathoxypropane). All the tubes were then incubated at 100°C for 1 h. After cooled at -20°C for 5 min, 2 mL of n-butyl alcohol was added into the sample, which was then vibrated for 1 minute and centrifuged for 10 min at 3000 r/min. The supernatant of the samples were assayed to detect absorbance at 532 nm; and the results were expressed as nmol/mL. The content of MDA in intestine was calculated as millimicromole per milligram of protein.

Detection of activity of SOD in the intestine

Intestinal tissues were made into a homogenate with normal saline, frozen at -20°C for 5 min and centrifuged for 15 min at 4000 r/min. Supernatants were transferred into fresh tubes for evaluation of SOD activity. SOD activity was evaluated with an SOD detection kit according to the

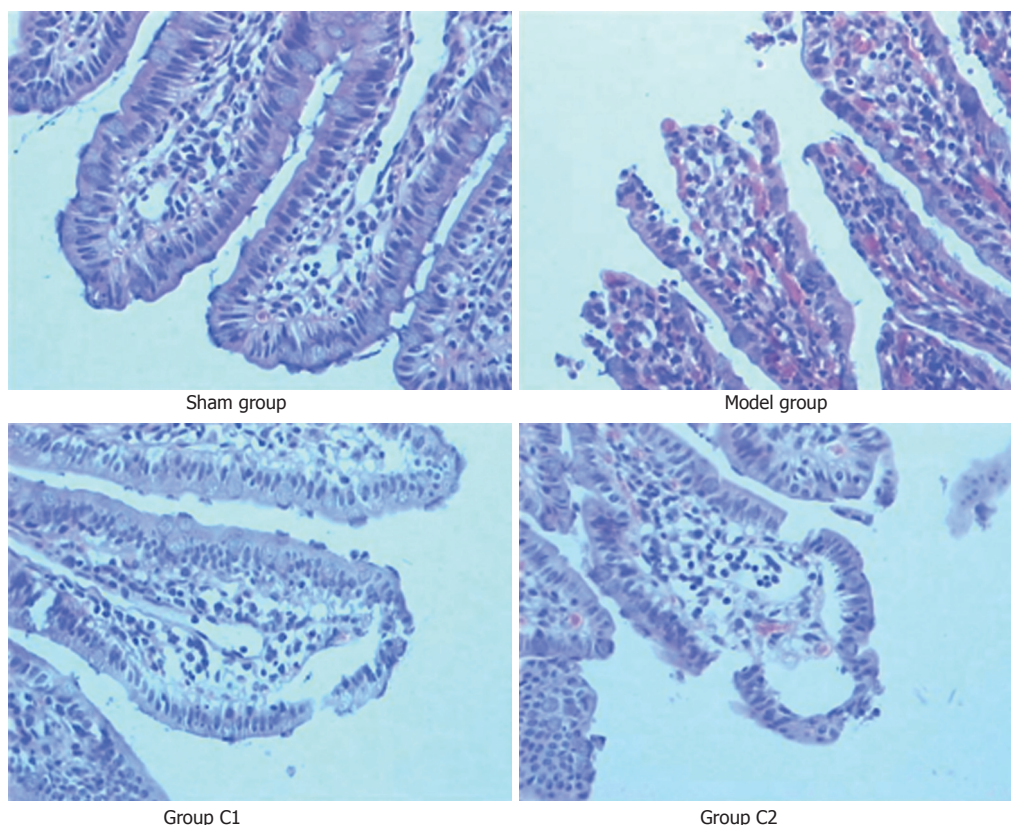

Figure 1 Microscopic appearance after hematoxylin and eosin staining ($\times 200$). In the model group, there are multiple erosions and bleeding in mucosal epithelial layer; the villus and glands were normal and no inflammatory cell infiltration was observed in mucosal epithelial layer in sham group; these mucosal changes are ameliorated by treatment with Cromolyn Sodium (group C1 and group C2).

manufacturer's instructions (Jiancheng Bioengineering Ltd, Nanjing, China). Results were expressed as nmol/mL. The activity of SOD in the intestine was calculated as U per milligram of protein.

Detection of the concentration of $TNF-\alpha$ in the intestine

Intestinal tissues were made into a homogenate with normal saline, frozen at -20°C for 5 min and centrifuged for 15 min at 4000 r/min. Supernatants were transferred into fresh tubes for evaluation of concentration of $TNF-\alpha$ (Biosource, USA) using a commercially available ELISA kit in accordance with the manufacturer's instructions, results were expressed as pg/mL. The concentration of $TNF-\alpha$ in the intestine was calculated as picogram per milligram of protein.

Detection of the concentration of histamine in the intestine

Intestinal tissues were made into a homogenate with normal saline, frozen at -20°C for 5 min and centrifuged for 15 min at 4000 r/min. Supernatants were transferred into fresh tubes for evaluation of concentration of histamine (RapidBio Lab, USA) using a commercially available ELISA kit in accordance with the manufacturer's instructions, results were expressed as ng/mL. The concentration of histamine in the intestine was calculated as nanogram per milligram of protein.

Immunohistochemical detection of tryptase in intestine

Five μm thick sections were prepared from paraffin-embedded tissue. After deparaffinization, endogenous peroxidase was quenched with 3% H_2O_2 in deionised water for 10 min. Nonspecific binding sites were blocked by incubating the sections in 10% normal rabbit serum for 1 h. The sections were then incubated with polyclonal rat anti-mast cell tryptase (dilution 1: 50) for 30 min at 37°C ,

followed by incubation with biotinylated goat-anti-rat IgG at room temperature for 10-15 min. After 3×5 min PBS rinses, the horseradish-peroxidase-conjugated streptavidin solution was added and incubated at room temperature for 10-15 min. The antibody binding sites were visualized by incubation with a diaminobenzidine- H_2O_2 solution. The sections incubated with PBS instead of the primary antibody were used as negative controls. Brown-yellow granules in the cytoplasm were recognized as positive staining for tryptase. We calculated the tryptase positive mast cells and their intensity in 5 representative areas at $\times 400$ magnification by Image-Pro Plus 5.0 (USA).

Statistical analysis

Data were expressed as mean \pm SD and analysis of variance was performed using SPSS 11.0 software. One-way analysis of variance was used for multiple comparison, least significant difference test (LSD-t) was used for intra-group comparison or Tamhane's T2 test was used if equal variances was not assumed. Pearson analysis was used for the correlation in the ischemia and reperfusion groups. Differences were considered significant when P was < 0.05 .

RESULTS

Changes of intestinal mucosa under light microscope

The villus and glands were normal and no inflammatory cell infiltration was observed in mucosal epithelial layer in sham group. Multiple erosions and bleeding were observed in model group. Light edema of mucosa villus and infiltration of few necrotic epithelial inflammatory cells neutrophil leukomonocyte were found in mucosa epithelial layer in C2 and C1 groups (Figure 1).

Table 1 Changes of IMMC counts, expression of tryptase, and Chiu's score in small intestine in various groups (mean \pm SD)

Group	n	IMMC (n/field)	Expression of tryptase	Chiu's score
S	8	10 \pm 2	126 \pm 4	0.4 \pm 0.5
M	8	25 \pm 8 ^b	173 \pm 4 ^b	4.9 \pm 0.4 ^b
C1	8	15 \pm 2 ^a	138 \pm 3 ^{b,d}	2.4 \pm 0.5 ^{b,d}
C2	8	17 \pm 2 ^a	155 \pm 8 ^{b,d,f}	2.9 \pm 0.4 ^{b,d,e}

^a $P < 0.05$, ^b $P < 0.01$ vs Group S; ^d $P < 0.01$ vs Group M; ^e $P < 0.05$, ^f $P < 0.01$ vs Group C1.

Chiu's score of small intestinal structure

The Chiu's score in sham group was the lowest, while in the model group it was the highest in the four groups ($P < 0.05$). The Chiu's score in C1 group was significantly lower than in C2 group after treated with CS ($P < 0.05$) (Table 1).

Changes of ultrastructure of small intestinal

The ultrastructure of small intestinal was normal in group S. There was seen the karyopyknosis of epithelial cell of small intestine in group M, the nuclear membrane was more irregularity, and the swelling microvillus became shorter and thicker, most of the microvillus were shedding. The nucleus of epithelial cell of small intestine in group C1 and C2 was deflated, the nuclear membrane was irregularity, and the light swelling microvillus became shorter (Figure 2).

Changes of ultrastructure of IMMC

The ultrastructure of IMMC was normal in sham group. There were abundant vacuolus with a reduction granulation in their endochylema in model group. There were few swollen granules with a reduction in IMMC homogeneity in C1 and C2 group (Figure 3).

Changes of MDA in small intestine

The content of MDA in intestine of model group was the highest in all experimental groups, it decreased significantly compared with the model group after treated with CS ($P < 0.05$) and there was no significant difference compared with the sham group ($P > 0.05$) (Table 2).

Changes of activity of SOD in small intestine

The activity of intestinal SOD decreased significantly in ischemia-reperfusion injury groups compared with the sham group ($P < 0.05$), treated with CS it increased significantly compared with the model group ($P < 0.05$), and there was no significant difference between group C1 and C2 ($P > 0.05$) (Table 2).

Changes of TNF- α in small intestine

The concentration of TNF- α of intestine in model group rats was higher than the other three groups ($P < 0.05$). There were no significant difference in sham group, C1 group and C2 group ($P > 0.05$) (Table 2). There was a positive correlation between the Chiu's score and the concentration of TNF- α in the ischemia and reperfusion groups ($r = 0.734$, $P < 0.05$).

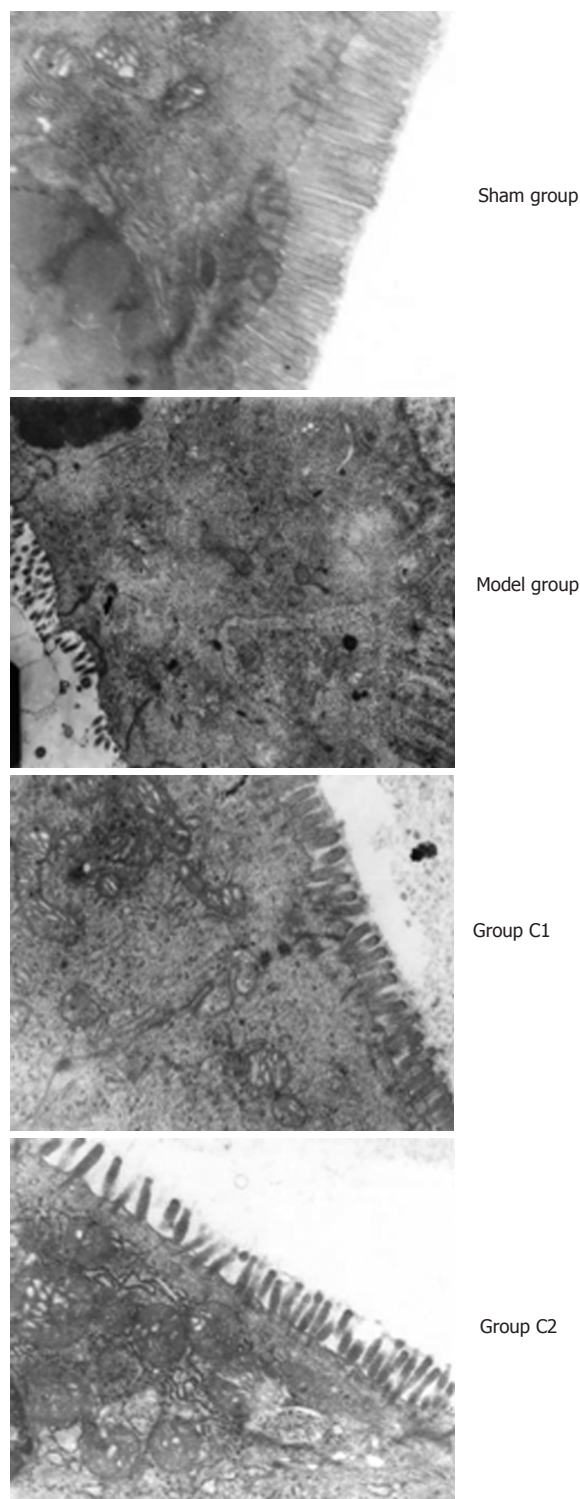

Figure 2 Changes of ultrastructure of small intestinal in each group ($\times 10000$). The ultrastructure of small intestinal was normal in group S. There were seen the karyopyknosis of epithelial cell of small intestine in group M, and the nuclear membrane was more irregularity, and the swelling microvillus became shorter and thicker, most of the microvillus were shedding. The nucleus of epithelial cell of small intestine in group C1 and C2 was deflated, the nuclear membrane was irregularity, and the microvillus became shorter and light swelling.

Changes of histamine in small intestine

The histamine concentration of intestine in the model and C2 groups decreased significantly compared with the sham group ($P < 0.05$), it increased significantly after pretreated with CS compared with the model group ($P < 0.05$). There

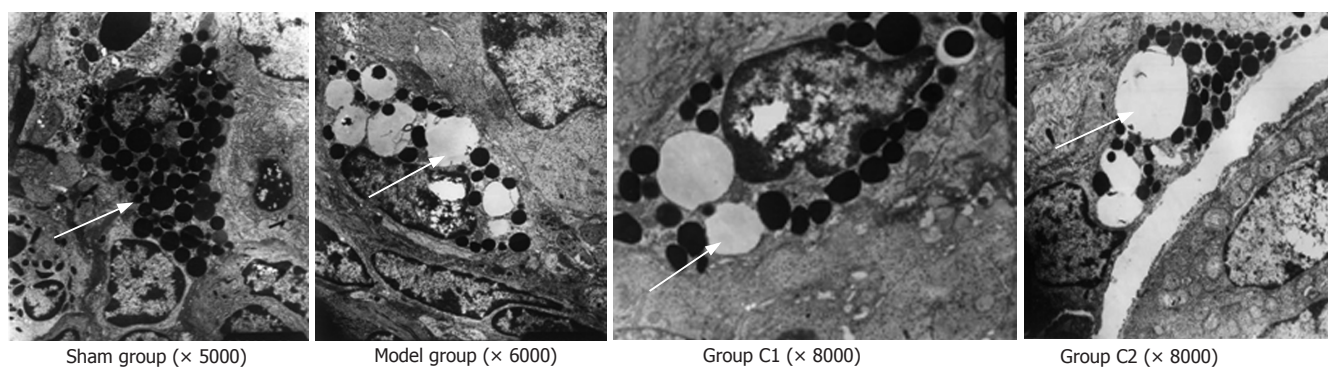

Figure 3 Ultrastructure of intestinal mucosal mast cells of rats in each group. There are abundant vacuolus with a reduction of granulation in their endochylema in model group; there are filled with granulation endochylema and there is no vacuolus in their endochylema in sham group, these changes of ultrastructure are ameliorated by treatment with Cromolyn Sodium (group C1 and C2).

Table 2 Changes of TNF- α , MDA content, SOD activity and histamine concentration in small intestine in various groups (mean \pm SD)

Group	n	TNF- α (pg/mg protein)	MDA (nmol/mg protein)	SOD (U/mg protein)	Histamine (ng/mg protein)
S	8	3.7 \pm 0.4	0.44 \pm 0.09	179.2 \pm 15.3	5.7 \pm 0.5
M	8	4.7 \pm 0.4 ^b	0.66 \pm 0.07 ^b	130.6 \pm 10.6 ^b	4.2 \pm 0.4 ^b
C1	8	3.8 \pm 0.4 ^d	0.45 \pm 0.06 ^d	147.9 \pm 12.4 ^{b,c}	5.3 \pm 0.6 ^d
C2	8	3.9 \pm 0.4 ^d	0.47 \pm 0.07 ^d	145.3 \pm 15.7 ^{b,c}	4.8 \pm 0.6 ^{a,c}

^a $P < 0.05$, ^b $P < 0.01$ vs Group S; ^c $P < 0.05$, ^d $P < 0.01$ vs Group M.

were no significant difference between C1 and C2 groups ($P > 0.05$) (Table 2). The Chiu's score and MDA content were negatively correlated to the histamine concentration respectively ($r = -0.676$, $P < 0.05$ or $r = -0.452$, $P < 0.05$), while the SOD activity was positively correlated to the concentration of histamine in the ischemia and reperfusion groups ($r = 0.579$, $P < 0.05$).

Counts and expression of tryptase of IMMC

Expression of tryptase in sham group was the lowest, while in the model group it was the highest in the four groups ($P < 0.05$), and the expression of tryptase in C1 group was significantly lower than in C2 group ($P < 0.05$). The number of IMMC increased significantly in ischemia-reperfusion injury groups compared with the sham group ($P < 0.05$), no difference was compared among the three groups ($P > 0.05$) (Table 1, Figure 4).

DISCUSSION

IMMC are located in close proximity to submucosal collecting venules, which are primary targets of leukocyte-endothelial interactions during ischemia-reperfusion injury. IMMC are particularly frequent in close proximity to epithelial surfaces where they are strategically located for optimal interaction with the environment and for their putative functions for host defense. They sense the foreign material invading the mucosa in an appropriate inflammatory response, and were considered as one of components of the fourth level of mucosal defense^[14]. Acute inflammation could lead to increase of IMMC counts and release of a multi-faceted spectrum of proinflammatory mediators by IMMC such as cytokines and chemokines, and MC

have the capacity to coordinate trafficking of leukocytes^[15]. Boros^[16] proved that intestinal ischemia induced the release of a variety of IMMC-derived inflammatory compounds and resulted in a spectrum of injury ranging from reversible permeability changes to structural mucosal damage.

The ischemia time of small intestine rats' model is from 30 min to 60 min^[17-19], here we used the median time (45 min). Cizova reported that the concentration of thio-barbituric acid reactive substances was increased at the end of the ischemia lasting from 30 to 90 min^[20], and CS plasma life *in vivo* is very short. Thus the reperfusion time in our study was watched in 60 min, it was the early reperfusion according to Hamar *et al*^[21]. All of previous studies were focused on the MC membrane stabilizer pretreatment prior to ischemia, and had proved that IMMC were associated with the damage to intestinal mucosal after the small intestine ischemia-reperfusion. While the main purpose of our study was to see whether pretreatment with CS prior to reperfusion also have the protective effects during early reperfusion after the small intestine ischemia.

Tryptase is one of the specificity markers of IMMC^[22]. We counted the IMMC counts through the expression of tryptase using immunohistochemical methods which is more accuracy than oluidine blue staining. Our study found that the expression of tryptase and IMMC counts increased significantly in 60 min reperfusion injury in model group. There were abundant vacuolus in IMMCs in the model group after they were degranulated by electron microscope. IMMC is the main source of histamine in intestine. The levels of intestinal histamine includes the concentration of histamine intra- and extro-IMMC. The level of intestinal histamine is mainly represent of the concentration of histamine intra-IMMC as the extracellular

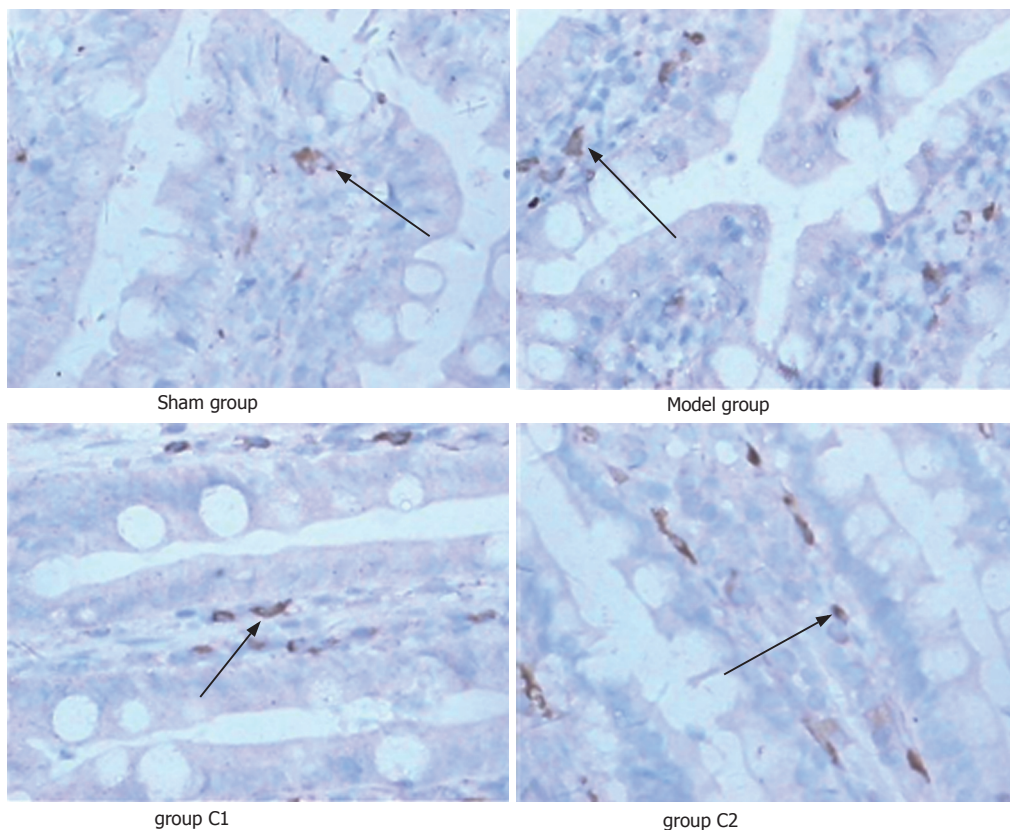

Figure 4 Immunohistochemical detection of tryptase in small intestinal of rats in each group ($\times 400$). Expression of tryptase and number of IMMC are increased in the model group; these changes were ameliorated by treatment with Cromolyn Sodium (group C1 and C2).

histamine released from IMMC in the gastrointestinal tract is rapidly cleared and degraded^[23] and the more IMMC degranulate, the lower concentration of histamine is found in intestine^[24]. Our study found the histamine level decreased significantly in model group while IMMC counts increased, suggesting that IMMC may degranulate and release histamine in 60 min reperfusion.

Histamine has many pathophysiological roles, and it is an important messenger in the gut^[25]. Akerstrom *et al*^[26] reported that anti-histaminergic pretreatment could decrease the trauma-induced leakage of albumin by mechanisms which may involve readjustments of pressures and flows in capillaries as well as a prevention of histamine effects on capillary permeability on a model of mechanical intra-abdominal trauma in rats. Our results found that the intestinal histamine concentration decreased after early ischemic-reperfusion, and there was a negative correlation between the small intestinal Chiu's score and the level of histamine in the intestine. This result suggested that histamine took part in the ischemia-reperfusion intestinal mucosal damage.

TNF- α is an inflammatory cytokine that may be an important mediator in the development of reperfusion-induced tissue injury and lethality^[27]. Grewal^[28] demonstrated that treatment of rats with anti-TNF antibodies could prevent neutrophil influx, tissue injury. Our study found that the intestinal TNF- α concentration increased after ischemic-reperfusion; and there was a positive correlation between the small intestinal Chiu's score and the level of TNF- α in the intestine. This result suggested that TNF- α also took part in the ischemia-reperfusion intestinal mucosal damage. Although the most intestinal TNF- α is considered by some one from the mast cells^[29], it has been

proved that many sorts of cells also release the TNF- α besides the mast cells. We believe the increase of the TNF- α is contributed by many factors.
