Abstract

Lynch syndrome, also known as hereditary non-polyposis colorectal cancer (HNPCC), is the most common form of hereditary colorectal cancer. Although great advances in the understanding of its molecular basis have taken place in the last decade, optimal selection of individuals for HNPCC genetic testing remains controversial. This is especially relevant since colonoscopy has been proven effective for reducing colorectal cancer incidence and mortality in individuals at-risk for this disorder. In this manuscript, we summarize the most significant contributions to this important issue that have appeared in the last few years.

INTRODUCTION

Lynch syndrome, also known as hereditary non-polyposis colorectal cancer (HNPCC), is the most common form of hereditary colorectal cancer (CRC), accounting for 2%-5% of all colorectal malignancies^[1]. It is characterized by early onset of CRC and other related neoplasms including

endometrial, ovarian, gastric and urinary tract cancer. This syndrome is inherited in a non-fully penetrant autosomal dominant pattern, and occurs as a result of germline mutations in mismatch repair genes, predominantly *MLH1* and *MSH2* (> 90% of cases), but also *MSH6* and *PMS2*. The abnormal function of these genes leads to the accumulation of errors during DNA replication, especially in repetitive sequences (microsatellites). As a result, tumors in patients with Lynch syndrome characteristically demonstrate microsatellite instability (MSI), as well as loss of expression of the affected protein^[1].

Although great advances in the understanding of its molecular basis have taken place in the last decade, optimal selection of individuals for HNPCC genetic testing remains controversial^[2]. This is especially relevant since colonoscopy has been proven effective for reducing CRC incidence and mortality in individuals at-risk for this disorder^[3]. In 1991, the International Collaborative Group on HNPCC established clinical criteria, known as the Amsterdam criteria, which provided a pivotal definition of this syndrome and were critical in identifying its molecular basis^[4]. In response to criticism that the Amsterdam criteria were too stringent, the extended Amsterdam II criteria were developed to include extracolonic HNPCC-associated cancers^[5].

The use of the Amsterdam criteria achieved the original purpose of classifying a family as having HNPCC, but their limited sensitivity hampered decisions about which patients should undergo genetic testing^[2]. In 1996, an international workshop on HNPCC hosted by the National Cancer Institute outlined a set of recommendations, known as the Bethesda guidelines, for the identification of individuals with HNPCC who should be tested for MSI and/or genetic testing^[6]. More recently, a second HNPCC workshop revised these criteria and proposed a new set of recommendations, the revised Bethesda guidelines^[7].

As it was previously mentioned, tumor MSI is a phenotypic indicator of defective DNA mismatch repair^[8]. The fact that more than 90% of HNPCC-related cancers exhibit MSI suggests that screening of tumors for MSI may be an efficient way of selecting individuals for HNPCC genetic testing^[9-12]. On the other hand, most mutations in either *MSH2* or *MLH1* genes result in abnormal MSH2 or MLH1 protein expression^[13,14]. As a consequence, immunostaining for these two proteins is associated with MSI^[15,16], but this association is not without exceptions^[17]. Indeed, a mutant protein product can be expressed and detected by immunostaining^[18],

whereas germline mutations may occur in patients with MSI-negative tumors^[19]. These conflicting results have precluded the establishment of a unique method for primary screening of mismatch repair deficiency.

Recently, the Epicolon study, a prospective, multicenter, nation-wide survey aimed at assessing the incidence and characteristics of hereditary and familial CRC in Spain^[20], has demonstrated that the revised Bethesda guidelines constitute a very useful approach to select patients at risk for HNPCC^[21]. Moreover, in patients fulfilling these criteria, both MSI testing and protein immunostaining were equivalent and highly cost-effective strategies to further select those patients who should be tested for *MSH2/MLH1* germline mutations. Considering this equivalence and the fact that immunostaining is more available than DNA analysis in a clinical setting, the use of immunohistochemistry may contribute to identify a larger proportion of patients with Lynch syndrome^[21,22].

The combination of revised Bethesda guidelines with tumor molecular analysis, however, is not fully accepted since some gene mutation carriers do not fulfill these clinical criteria^[23]. To overcome this limitation, a massive, universal tumor mismatch repair screening by MSI analysis and/or immunostaining in any given CRC patient has been proposed^[23,24]. Nevertheless, this approach is much less efficient^[21], a critical issue that could be somehow solved by improving tumor molecular analysis. In that sense, it has been recently demonstrated that the use of two microsatellite markers (combination of BAT25 or BAT26 with NR21 or NR24) performed as well as the entire pentaplex of mononucleotide repeats (BAT26, BAT25, NR21, NR22, and NR24 markers) and better than the recommended panel by the National Cancer Institute (BAT26, BAT25, D5S346, D2S123, and D17S250 markers) in identifying mismatch repair deficient tumors^[25]. Similarly, the introduction of BRAF V600E mutation analysis as a step prior to germline gene testing in patients with mismatch repair deficiency improves the cost-effectiveness of this approach, especially in those with incomplete or unknown family history^[26,27].

On the other hand, the revised Bethesda guidelines have also been criticized because of their broad and complex variables, their relatively low specificity, and their inability to establish the likelihood of carrying a mutation in a given patient^[24,28]. In addition, the need of performing tumor molecular analyses in patients fulfilling these criteria by some means constitutes a restriction since tissue samples are not always available. In that sense, as in hereditary breast-ovarian cancer syndrome in the past, identification of Lynch syndrome is moving toward complex algorithms and multivariable models combining personal and family history^[28-31].

The first approach to this goal was the Leiden model^[29], a regression logistic model derived from CRC patients attended in a high-risk clinic and designed to identify *MLH1/MSH2* mutation carriers, which has represented the only predictive model for years. Variables included in this model were fulfillment of the Amsterdam criteria, mean age of CRC diagnoses, and presence of any endometrial cancer in the family. However, it still included

rather complex variables, it was developed using a relatively small population in a high-risk setting, and it did not take into account tumor molecular.

More recently, a second model was developed in the United Kingdom in a large population-based cohort of early onset (< 55 years) CRC patients^[30] and consists of two consecutive stages: stage 1, based exclusively on clinical variables (age, sex, tumor location, presence of synchronous or metachronous CRC, family history of colorectal and endometrial cancer, and age of the youngest relative with CRC) and available on the web^[32]; and stage 2, based on tumor MSI or immunostaining data. The area under the ROC curve of this model, which predicts *MLH1*, *MSH2* and *MSH6* germline mutations, was 0.82 (95% CI, 0.72-0.91). However, its applicability to CRC patients older than 55 years or those with other Lynch syndrome-associated tumors has not been assessed yet^[30].

The third approach is a Mendelian model for determining *MLH1*, *MSH2* and *MSH6* carrier probabilities based on published estimates of mutation frequencies and cancer penetrances in both mutation and non-mutation carriers, and including MSI data^[31]. This Bayesian model uses the CancerGene software^[33] and provides the likelihood of finding a mutation in both probands and relatives on the basis of clinical and molecular information (age at diagnoses of colorectal and endometrial cancer, age of healthy relatives, MSI analysis and genetic testing). The area under its ROC curve was 0.83 (95% CI, 0.78-0.88). The performance of this model on clinical practice and different population settings is still unknown^[31].

Finally, the PREMM1,2 model (accessible at the Dana-Farber Cancer Institute web site^[34]) has demonstrated an excellent ability to discriminate between risk groups (area under the ROC curve of 0.80; 95% CI, 0.76-0.84), categorized by the estimated risk for probability of a mutation^[28]. This study provides a new model based on a logistic regression analysis from one of the largest cohorts published so far of patients at-risk for hereditary CRC with proved mutation in the *MSH2/MLH1* genes. The authors recommend using their model as an initial assessment for individuals at risk for this disorder, before molecular information is available to the clinician. Based on the risk estimate generated from the model and other factors (accessibility to genetic services, timelines of genetic information, insurance coverage, and availability of tumor block), the clinician may choose whether genetic evaluation should be pursued as well as the approach to testing (MSI analysis and/or immunostaining, versus direct germline testing)^[28]. The model does not include tumor molecular data to further refine the estimated probability nor takes into account *MSH6* gene mutations, although updates of the model are planned.

In summary, at the beginning of the 21st century, there is no unique, universally accepted strategy for the identification of Lynch syndrome. However, the tremendous advanced experiences in recent years allow us to be optimistic. Indeed, besides the fact that ongoing investigations may eventually elucidate the most effective and efficient approach to select individuals for HNPCC gene testing, the attention paid by the whole medical

community to this disease in the last decade will definitely contribute to make Lynch syndrome recognition more widely accessible.

Abstract

Gastroesophageal reflux disease (GORD) is a pathological process in infants manifesting as poor weight gain, signs of esophagitis, persistent respiratory symptoms and changes in neurobehaviour. It is currently estimated that approximately one in every 350 children will experience severe symptomatic gastroesophageal reflux necessitating surgical treatment. Surgery for GORD is currently one of the common major operations performed in infants and children. Most of the studies found favour laparoscopic approach which has surpassed open antireflux surgery as the gold standard of surgical management for GORD. However, it must be interpreted with caution due to the limitation of the studies, especially the small number of subject included in these studies. This review reports the changing trends in the surgical treatment of GORD in children.

INTRODUCTION

Symptomatic gastroesophageal reflux (GOR) has been identified in children with increasing frequency over the

last two decades^[1]. The perceived increase in incidence since the late 1970s is due to an improved awareness of the condition, and to increasingly sophisticated diagnostic techniques for identifying the disorder^[2]. The term GOR implies a functional or physiological process in a healthy infant with no underlying systemic abnormalities^[3]. It is a self-limiting process in infants that usually resolves by 6 to 12 mo of age^[4]. Gastroesophageal reflux disease (GORD) is a pathological process in infants manifesting as poor weight gain, signs of esophagitis, persistent respiratory symptoms and changes in neurobehaviour^[3].

Conservative first line management involves thickened feeds, positioning of the infant and parental reassurance. Second line management is through medication and includes the use of antacids, H₂ antagonists, proton pump inhibitors (PPIs) and pro-kinetic agents. Surgical intervention should be considered after the patient has failed conservative and medical interventions. It is currently estimated that approximately one in every 350 children will experience severe symptomatic GOR necessitating surgical treatment^[2].

Surgery for GORD is currently one of the common major operations performed in infants and children by paediatric surgeons in the United States^[5]. Prior to 1991, the open Nissen fundoplication was the standard surgical procedure for severe GORD in adults^[6]. The first laparoscopic Nissen fundoplication was performed by Dallemagne and colleagues in Belgium in April 1991^[6]. It has been shown that the principles learned through open antireflux surgery can be applied to the laparoscopic approach, and this breakthrough has since been translated to pediatric surgery.

This study reviews the aetiology, risk factors, signs, clinical symptoms, diagnosis, and management of GORD in children. A Pubmed database search was performed. All abstracts were reviewed and all articles and prospective randomized clinical trials of GORD in children were further scrutinized. Further references were extracted by cross-referencing.

PATHOGENESIS AND RISK FACTORS

The pathogenesis of reflux is not completely understood. A combination of factors appears to contribute to the development of GORD in infants and children. It appears that a decrease of lower esophageal sphincter tone plays a role in contributing to reflux. Transient lower esophageal sphincter relaxation not associated with swallowing has been implicated as the major mechanism allowing the

Table 1 Clinical manifestations of GORD^[11]

	GOR	GORD
Symptoms	'Happy sitter'	Regurgitation/persistent vomiting/feeding refusal/hypersalivation Arching/irritability/persistent crying
	Regurgitation	Abdominal pain/heart burn/hematemesis/chest pain
	Vomiting but thriving	Sleep disturbance Silent reflux- stridor, wheezing, cough Sandifer's syndrome - head turning episodes to lengthen the oesophagus and LES pressure; repetitive stretching and arching, which gives the appearance of seizure/dystonia
Complications	GORD Esophagitis	Esophagitis/failure to thrive Reactive airway disease/recurrent pneumonia Apnoea/bradycardia/acute life threatening events Barrett's esophagus/esophageal ulceration and perforation/stricture formation Anaemia/seizure

gastric contents to return into the esophagus^[7].

Delayed gastric emptying has also been implicated as another mechanism in GORD in children^[8]. It predisposes to gastric distension, increased acid secretion and esophagitis. Other factors associated with the mechanism of reflux include positional factors, neurological disease, stress manoeuvres and hiatus hernia^[9].

While many factors contribute to reflux mechanism, the composition of the refluxate and the time spent with an acidic refluxate (pH < 4) are related to the development of GORD^[10].

CLINICAL SYMPTOMS AND DIAGNOSIS

Clinical manifestations

Clinical manifestations of GORD cover a wide spectrum with truly physiological reflux at one end to complicated esophagitis at the other (Table 1)^[11]. Complications such as respiratory symptoms and neurobehaviour may be present. In older children the most common symptoms are recurrent emesis, esophagitis, chronic respiratory infections or asthma caused by repeated aspiration, which seldom represent an immediately life-threatening condition^[12]. However, in infants, GORD often occurs in association with other congenital anomalies, indicating that certain anatomical factors might influence the development of reflux^[12]. There is recognition that severe GORD can cause life-threatening bradycardic and apnoeic spells and even sudden death in infants^[13]. A number of disorders have been associated with symptomatic GOR^[14]. A higher prevalence of GORD is present in children who have a history of esophageal atresia with repair^[15]. Neurologically impaired children have an increased incidence of GORD and comprise the majority of pediatric patients

Table 2 Disorders that have been associated with symptomatic GORD^[2]

Neurological	Mental retardation from any cause Brain injury from any cause Cerebral palsy Down's syndrome Microcephaly Seizure disorders Mobius syndrome Cornelia-de lange syndrome Hydrocephalus
Gastrointestinal	Gastric outlet obstruction from any cause Esophageal atresia Pharyngeal swallowing uncoordination Congenital duodenal obstruction (Ladd's band, diaphragm) Congenital abdominal defects (omphalocele, gastroschisis) Short bowel syndrome Hirschsprung's disease Portal hypertension Ascites
Cardiac	Anomalies causing left heart failure
Respiratory	Congenital diaphragmatic hernia Tracheal or subglottic stenosis Cleft palate Pierre Robin syndrome Phrenic nerve palsy Bronchopulmonary dysplasia
Prematurity	
Multiple anomalies	

who undergo antireflux surgery^[16,17]. Hiatus hernia and respiratory diseases have also been associated with the occurrence of GORD in children^[18,19]. Table 2 shows the disorders that have been associated with symptomatic GORD.

A complete history and clinical examination are still the mainstays in diagnosing GORD. Evaluation should pay particular attention to the occurrence and frequency of symptoms and associated complications. If the initial evaluation points toward GOR, a period of lifestyle modification and empirical pharmacotherapy may be used to confirm the diagnosis. At this stage, parental reassurance, education and anticipation are important^[20]. If the history and clinical examination point towards symptomatic GOR or GORD, a variety of diagnostic studies are available to assess the extent of the reflux, severity of the complications and contributing factors.

Diagnosis

No single definitive investigation can diagnose GORD. Therefore the choice is based on the clinical context. A 24-h pH probe remains the gold standard in diagnosing GORD. This test will determine the extent of esophageal acid exposure by measuring the frequency and duration of acid reflux exposure^[20]. Radiography and pulmonary scintiscan may be useful in identifying the severity of pulmonary infections due to aspiration. The barium contrast upper gastrointestinal study is also helpful in identifying the presence of hiatus hernia and stricture. It is useful to exclude anatomical abnormalities^[20]. Gastric

emptying studies are used to assess gastric motility and identify patients who have increased gastric emptying in the absence of mechanical obstruction. Gastroscopy is helpful in detecting reflux esophagitis and biopsy is taken to assess the severity of esophagitis^[20]. Esophagogastric manometry is an accurate method for quantifying the resistance of the lower esophageal sphincter to reflux of gastric juice. The esophageal motility study is used to evaluate peristaltic contractions in the esophageal body. The benefits and limitations of commonly used diagnostic tests are described in Table 3.

TREATMENT

The objectives of therapy include decreasing the symptoms, frequency and duration of reflux episodes, healing the injured mucosa and preventing complications^[21]. The approach to the treatment of GORD is age-dependent^[22]. The management of symptomatic disease often follows the line of conservative therapy which includes posture and feeding techniques, medication and antireflux surgery.

Conservative treatment

Frequent small feeds of thickened formula or food minimise gastric distension and reduce GOR. Elevation of the upper body at 60 degrees, maintained for 24 h a day, favours esophageal clearance and effectively reduces symptoms of reflux in two-thirds of infants while awake and during sleep^[2]. Positional therapy is based on the gravitational phenomenon and when discontinued the reflux may reappear.

Medical treatment

If conservative measures do not improve symptoms, medical therapy is recommended. Pharmacological therapies are aimed at the various steps in the pathophysiology of GORD. These include the use of antacids, hydrogen ion-blocking drugs, PPIs and prokinetic agents. Antacids work by neutralising gastric acid. H₂-blockers and proton pump inhibitors work by decreasing the secretion of gastric acid. Prokinetic agents work by increasing esophageal peristalsis, increasing the lower esophageal sphincter pressure and enhancing gastric emptying.

Surgical treatment

Until the early 1990s, antireflux surgery was the main stay treatment for severe GORD, until the emergence of PPIs^[23]. Surgical treatment of GORD has considerable appeal as it offers potential cure and avoids the need for long-term medication use. The primary indication for performing an antireflux operation is the control of intractable and symptomatic GOR which has been clearly demonstrated by 24-h pH probe and a barium study of the esophagus^[2]. Operative treatment is usually undertaken after an unsuccessful trial of a few weeks of medical therapy; for patients with severe complications of reflux, such as aspiration, failure to thrive or esophagitis with stricture. Antireflux surgery may be performed shortly after diagnosis is established^[2]. However, the majority of children appear to present for surgery after only a barium

Table 3 Benefits and limitations of commonly used diagnostic tests

Study	Advantages	Disadvantages
Barium esophagram	Readily available Evaluates upper GI structure	Inadequate screen for GORD Results are operator dependent
24-h pH probe	Quantification of reflux Evaluates atypical symptoms Monitors medical treatment	Requires hospitalization Requires special equipment and trained personnel
Endoscopy with biopsy	Evaluates persistent GORD, PUD, <i>H. Pylori</i> infection, allergic enteropathy and Barrett's oesophagus	Invasive and requires sedation/general anaesthesia

study; less than 25% undergo basic objective testing such as endoscopy and fewer have pH or gastric emptying studies^[1].

The major objectives of operative repair are to increase the high pressure zone in the lower esophagus by accentuating the angle of His and increasing the length of the abdominal esophagus^[2]. Surgical therapy is effective because it improves sphincter function, which is one of the main contributing factors in most cases of GORD^[6]. The most widely used fundoplication procedure was originally described by Nissen and Rosette in 1959. Nissen fundoplication is still a commonly used technique, with intra-abdominal positioning of the distal esophagus, hiatus hernia repair, and a 360° fundal wrap^[24]. The term 360° fundoplication refers to total fundoplication. The technique has been developed and we now have the option of a partial fundoplication wrapping technique which refers to any wrap less than 360°. For example, Thal fundoplication requires only a partial wrap (210°-270°) of the fundus around the anterior side of the oesophagus^[24], Toupet fundoplication a 270° posterior partial fundoplication^[25] and Watson fundoplication a 120° anterior partial fundoplication^[26].

Pediatric surgeons have documented high rates of failure and morbidity for antireflux surgery^[27]. The problems with antireflux surgery occur especially in children with neurological impairment, repaired esophageal atresia or chronic lung disease^[28]. The combination of antro-duodenal dysmotility and a wrap at the proximal stomach often cause difficulty eructating or vomiting and raised intragastric pressure with discomfort ("gas bloat syndrome"), resulting in forceful vomiting or retching^[23]. This can cause wrap disruption or slippage of the wrap into the chest, the main causes of operative failure. Martinez *et al*^[16] reported that more than 30% of children with neurological impairment had major complications or died within 30 d of surgery. Within a mean follow up period of 3.5 years, 25% had documented operative failure and overall, 71% had recurrent symptoms of GOR.

In children, the level of experience of the surgeon and surgical centre and appropriate case selection are key factors for determining the surgical outcome. Hassall^[28] suggested that children who are the best candidates for

fundoplication have no neurological impairment, have endoscopically-established GORD and have exhibited an improvement in symptoms with PPIs therapy.

Most fundoplication surgery in the pediatric population is done through an open abdominal approach. In recent years, many reports have been published on the advantages and effectiveness of the laparoscopic approach for the management of patients with GORD^[27].

CONCLUSION

Globally, the surgical management of GORD in children has changed dramatically with the refinement and clinical acceptance of the laparoscopic approach for fundoplication. Retrospective studies have established the benefits of the laparoscopic approach including more rapid recovery, faster return to unrestricted activity and decreased hospital stay while maintaining low complication and recurrence rates^[29,30]. A clear increase in the number of publications related to laparoscopic fundoplication was noted supporting the global emergence and place of this technique in the management of GORD in pediatric surgery. Therefore, it shows there has been a change in the way children with GORD are managed surgically.

Collins *et al*^[31] reported studies involving 120 patients that showed laparoscopic fundoplication complication rates for children were similar to those reported for open fundoplication. Blucher *et al*^[32] reported that hospital stays after laparoscopic fundoplication were considerably shorter and patients returned to school and regular activities sooner. Somme^[30] showed, in studies of 55 infants less than one year old, that in the laparoscopic Nissen fundoplication group, the time to initiation of feeding was significantly shorter than in the open Nissen fundoplication group. Rothenberg's^[33] single large prospective study of laparoscopic fundoplication in 220 infants and children further supported the benefits of laparoscopic fundoplication. It showed that although the learning curve for laparoscopic fundoplication may be steep, the procedure is safe and effective in the pediatric population. The clinical results were comparable to the traditional open fundoplication but with a significant decrease in morbidity and hospitalization. A more recent prospective comparative study by Mattioli *et al*^[34] confirmed that a minimally invasive approach was safe and effective for the treatment of primary GORD in children. Several studies reported that laparoscopic fundoplication has good long term outcomes^[28,35] irrespective of neurological impairment associated with GORD^[36].

Four failure patterns after open fundoplication have been described: the slipped or misplaced fundoplication, the disrupted fundoplication, the herniated fundoplication and the fundoplication that is too tight or too long^[37]. Since the introduction of laparoscopic fundoplication, two additional failure patterns have emerged: the twisted fundoplication and the two-compartment stomach^[37]. Some reports have emphasized the high incidence of early post-laparoscopic complications and re-operation^[38-40]. The long learning curve for all-laparoscopic technique has been identified as a confounding factor^[38-40]. However, most of these studies are based on laparoscopic fundoplication in

adults, and whether the results will translate to children remains to be seen.

The minimal trauma to the upper abdominal wall in the laparoscopic approach results in less impairment of respiration and minimizes the need for narcotics and sedatives postoperatively^[41]. A prospective comparative study of the fundoplication approach on analgesia requirement by Dick *et al*^[42] showed the benefit of laparoscopic approach over open approach in decreased duration of pain as indicated by the decreased duration of analgesia following surgery. Thanks to the reduction of trauma-related problems, the laparoscopic approach has improved cosmetic results^[30].

Laparoscopic surgery has been perceived as having higher procedure costs but lower total costs, primarily because of reduced duration of hospital stay^[43]. However, a more recent retrospective study on cost effectiveness by Blewett *et al*^[44] reported that although laparoscopic surgery was associated with a shorter hospital stay, no effect on total hospital costs was seen. They concluded that laparoscopic procedures were comparable with open operations in terms of operative costs^[44,45]. Therefore, from an economic point of view, the perception that laparoscopic procedures are more cost effective is still inconclusive and subject to further study.

In conclusion, laparoscopic antireflux surgery has surpassed open antireflux surgery as the gold standard in the surgical management of GORD in children. The next question to be addressed should be which operative technique can complement the laparoscopic approach to produce the best operative results. Longer term outcome studies also need to be done to confirm the status of laparoscopic antireflux surgery as the gold standard of surgical treatment for GORD in children.

COMMENTS

Background

Gastroesophageal reflux disease (GORD) is a pathological process in infants manifesting as poor weight gain, signs of esophagitis, persistent respiratory symptoms and changes in neurobehaviour. Surgery for GORD is currently one of the common major operations performed in infants and children by paediatric surgeons.

Research frontiers

This study reviews the aetiology, risk factors, signs, clinical symptoms, diagnosis, and management of GORD in children. A Pubmed database search of GORD in children was performed.

Related publications

Pubmed database search must be performed for finding related articles.

Innovations and breakthroughs

Most fundoplication surgery in the pediatric population is done through an open abdominal approach. In recent years, many reports have been published on the advantages and effectiveness of the laparoscopic approach for the management of patients with GORD. Retrospective studies have established the benefits of the laparoscopic approach including more rapid recovery, faster return to unrestricted activity and decreased hospital stay while maintaining low complication and recurrence rates. Laparoscopic antireflux surgery has surpassed open antireflux surgery as the gold standard of surgical management for GORD in children. The next question to be addressed should be which operative technique can complement the laparoscopic approach to produce the best operative results and more long term outcome studies need to be done to confirm the status of

laparoscopic antireflux surgery as the gold standard of surgical treatment for this disease.

Applications

The study results suggest that surgery for GORD is currently one of the common major operations performed in infants and children while the principles learned through open antireflux surgery can be applied to the laparoscopic approach, and this breakthrough has since been translated to pediatric surgery.

Terminology

GOR: implies a functional or physiological process in a healthy infant with no underlying systemic abnormalities. It is a self-limiting process in infants that usually resolves by six to 12 mo of age. Nissen fundoplication: is a commonly used technique, with intra-abdominal positioning of the distal esophagus, hiatus hernia repair, and a 360° fundal wrap. 360° fundoplication refers to total fundoplication. Thal fundoplication: requires only a partial wrap (210°-270°) of the fundus around the anterior side of the oesophagus. Toupet fundoplication: a 270° posterior partial fundoplication. Watson fundoplication: a 120° anterior partial fundoplication.

Peer review

This is a decent review on surgical options for pediatric reflux disease. It's well organized with a very good presentation and readability.

Abstract

The diagnosis of pancreatic cancer is devastating for patients and their relatives as the incidence rate is approximately the same as mortality rate. Only a small percentage, which ranges from 0.4% to 4% of patients who have been given this diagnosis, will be alive at five years. At the time of diagnosis, 80% of pancreatic cancer patients have unresectable or metastatic disease. Moreover, the therapeutic alternatives offered by chemotherapy or radiotherapy are few, if not zero. For all these reasons, there is an imperative need of analyzing and understanding the primitive lesions that lead to invasive pancreatic adenocarcinoma. Molecular pathology of these lesions is the key of our understanding of the mechanisms underlying the development of this cancer and will probably help us in earlier diagnosis and better therapeutic results. This review focuses on medical research on pancreatic cancer models and the underlying genetic alterations.

INTRODUCTION

The diagnosis of pancreatic cancer is devastating for patients and their relatives as the incidence rate is approximately the same as mortality rate. Only a small

percentage, which ranges from 0.4% to 4% of patients who have been given this diagnosis, will be alive at five years^[1,2]. At the time of diagnosis, 80% of pancreatic cancer patients have unresectable or metastatic disease^[3]. Moreover, the therapeutic alternatives offered by chemotherapy or radiotherapy are few, if not zero. For all these reasons, there is an imperative need of analyzing and understanding the primitive lesions that lead to invasive pancreatic adenocarcinoma. Molecular pathology of these lesions is the key of our understanding of the mechanisms underlying the development of this cancer and will probably help us in earlier diagnosis and better therapeutic results. This review focuses on medical research on pancreatic cancer models and the underlying genetic alterations.

CARCINOGENESIS IN PANCREAS

Histologically the development of adenocarcinoma of the pancreas has its roots in cuboidal ductal epithelium alterations. These alterations are named PanIN (pancreatic intraepithelial neoplasia) and are classified into different progressive types (Figure 1). The PanIN-1A lesions present only minimal alterations from the normal epithelium, such as tall columnar cells with some crowding while the PanIN-1B lesions present increased crowding of columnar cells with papillary projections. The PanIN-2 lesions apart from previous alterations develop nuclear atypia. Finally, the PanIN-3 lesions present atypical ductal hyperplasia with severe atypia and are more likely to progress to invasive carcinoma^[4].

With the example of proposed progression model for colorectal neoplasia in mind, scientists tried to propose a model of progression for pancreatic neoplasia using the multi-hit hypothesis. The concept is the following: the first hit seems to be the point when mutations in the K-ras oncogene and overexpression of the HER-2/neu gene product occur. If some of these altered cells survive, they are susceptible to the second hit which is the inactivation of the p16 tumor suppressor gene. The third hit is represented by the loss of the tumor suppressor genes p53, DPC4, and BRCA2^[5-10]. This theory is supported by the experimental work of Rozenblum *et al*^[11] who analyzed the DNA from 42 pancreatic adenocarcinomas for alterations in the K-ras, p53, p16, and DPC4. They found that all 42 (100%) carcinomas presented point mutations in the K-ras oncogene, 82% genetic alterations in p16, 76% in p53, and 53% in DPC4. Concomitant activation of K-ras gene with inactivation of all three suppressor genes was presented in 38% of the tumors studied. Moreover, all these mutations had their origin in somatic cells^[11].

These genetic alterations are correlated with histological findings of metaplasia, hyperplasia, dysplasia, and neoplasia. In addition, they most likely represent the precursor lesions for pancreatic adenocarcinoma. We shall try to present the genetic alterations of pancreatic cancer in more detail with the aim of better understanding and thus, earlier intervention.

CELL-CYCLE REGULATORS

The cell division cycle in pancreatic carcinoma, as other tumors, is an extremely complicated process. It is regulated by three major protein players, which act at particular checkpoints and permit, or not, the progression of cell division: (1) The cyclin dependent kinases (CDKs); (2) The cyclins; (3) The cyclin-dependent kinase inhibitors (CKIs).

In general, CDKs form complexes with their regulatory subunits named cyclins in order to help the cell to enter the S-phase. CDKs phosphorylation and CKIs are inhibitory signals for the complex activation process and consequently, for cell division progression. When the cell is found at G₁ checkpoint, before starting DNA replication, it has two possibilities: the first two possibilities: the first to progress to cell division and the other to remain in a quiescence state. The activation of CDK4 by cyclinD with the formation of CDK4/cyclinD complex leads the cell beyond the restriction point. The next step is hyperphosphorylation of the retinoblastoma protein, Rb, catalyzed by CDK4/cyclinD or CDK2/cyclinE complex. The phosphorylation results in the dissociation of Rb from its complex with transcription factors such as E2F with immediate consequences on activation of target genes that are required for G₁/S transition^[12,13].

The oncogene products (p21, p16, p27) act as CKIs by blocking the hyperphosphorylation of the Rb oncogene *via* inactivation of CDK4/cyclinD and CDK2/cyclinE complexes. The cell thus cannot traverse the G₁/S checkpoint. Moreover, the p53 tumor suppressor gene can activate CKIs. When DNA alterations or negative external signals are present, p53 gene product is increased and stimulates transcription of the p21 gene, as a CKIs^[14-17].

TELOMERASE ACTIVITY

Enzymes like telomerase play pivotal roles in cell-cycle regulation and have important implications in cell immortality. Telomeres have the property of not being reattached once they have been cut off from their fellow chromosome. Chromosomes lose 50-100 nucleotides from their telomeric sequence with every division. In this way, chromosomal length is reduced and programmed cell death may ensue. The stabilization of telomeric sequences is attributed to telomerase activation.

All normal somatic cells, with the exception of proliferating cells of self-regenerating tissues, do not present telomerase activity compared to malignant tissues. Reactivation or upregulation of telomerase has been detected in many types of cancer such as breast, lung, and bladder, gastric and colorectal cancer. Hiyama *et al*^[18] using the TRAP assay (telomeric repeat amplification protocol), a highly sensitive PCR-based telomerase assay, tried to detect

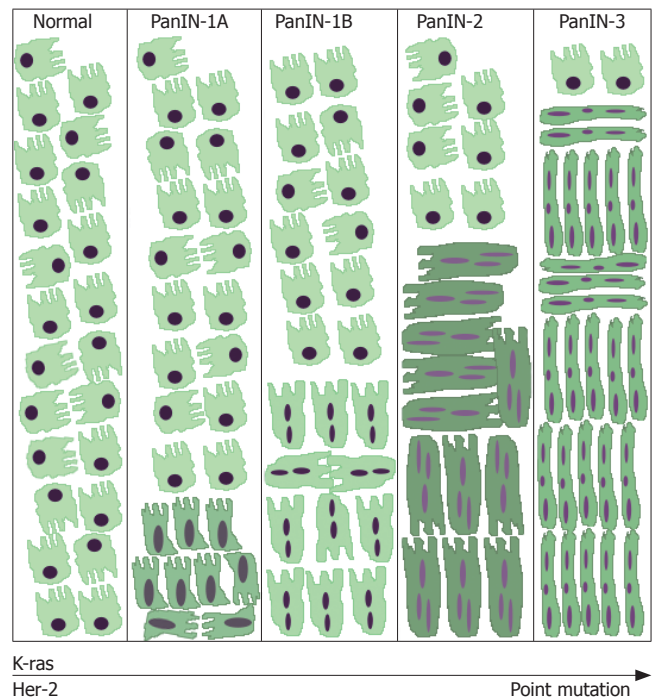

Figure 1 The most important genetic abnormalities associated with pancreatic cancer.

if there was telomerase activity in pancreatic tissue cancer and if possible, to correlate these results with telomere length. The authors studied 43 pancreatic cancer tissues, 11 benign tumors tissues, 3 chronic pancreatitis tissues, and 6 metastatic lesions from patients with pancreatic cancer. Telomerase activity was detected in 41 out of 43 (95%) pancreatic cancer samples analyzed, in all metastatic lesions (100%), but in none of the benign lesions. Unfortunately, the range of telomere length was the same in the malign and the benign lesions. This study showed the future utility of this enzyme in pancreatic cancer diagnosis.

ONCOGENES

Oncogenes are genomic sequences that are activated under special conditions. Activation results in initiation of carcinogenesis either through encoding protein up-regulation or through encoding proteins with altered function.

The family of the ras protein is synthesized in the cytoplasm and arrives at the inner surface of cytoplasmic membrane with the role of transforming an inactive guanosine 5'-diphosphate (GDP)-bound form into an active guanosine 5'-triphosphate (GTP)-bound form. Ras oncogene, when it is found in its active form or under pressure of external signals, activates several downstream effectors such as Raf-1, Rac, Rho, or phosphatidylin-3 kinase (P13K) with important implications for cell differentiation and proliferation^[19,20].

Mutations in K-ras oncogene are point mutations, a single amino acid change. They are located mainly on codon 12 and, rarely, on codon 13 and 61. K-ras gene mutations are found not only in 70%-95% of pancreatic carcinoma tissues but also in pancreatic juice, fine-needle aspirations of the pancreas, endoscopic retrograde

cholangiopancreatography brushings, duodenal fluid, and blood and stool of pancreatic cancer patients^[21,22]. Wilentz *et al*^[23] examined the duodenal fluid of patients with periampullary cancer for K-ras mutations. The results of this study showed a high specificity (100%) but a low sensitivity of K-ras mutations^[23]. Of crucial clinical importance is the observation by Berthelemy *et al*^[24] that pancreatic secretions may present cells with these genetic alterations even one year before the diagnosis of pancreatic cancer. Contrary to that, K-ras mutations may be present as benign condition in chronic pancreatitis without evidence of progression to pancreatic cancer even after 78 mo of follow-up^[25].

K-ras mutations seem to be prerequisite for pancreatic carcinogenesis. The K-ras mutation rate increases with advancing cellular atypia. This mutation, in association with other genetic alterations, may help to identify precursor lesions in future.

p21

There is evidence that p21 acts in cyclinD1 synthesis, where overexpression is a marker of poor outcome in many human cancers including pancreatic cancer. Expression of p21 is regulated by other suppressor genes which are implicated in pancreas carcinogenesis. Biankin *et al*^[26], using immunohistochemical methods, examined the expression of p21 in 451 PanIN lesions from 60 pancreatic cancer tissues and tried to correlate this expression with the histopathological grade of the lesions. Overexpression of p21 was present at 9% of the normal ducts, 16% of PanIN-1A, 32% of PanIN-1B, 56% of PanIN-2, 80% of PanIN-3 lesions and, finally, in 85% of invasive carcinoma. These observations suggest that p21 overexpression is an early event in this type of cancer and that there is a relationship between overexpression and progressive lesions. In addition, this study showed that overexpression of p21 is controlled by mutant K-ras and HER-2/neu genes rather than by p53 overexpression^[26].

TUMOR SUPPRESSOR GENES

Tumor suppressor genes encode proteins with a protective role against malignant phenotypes. Their inactivation may lead to initiation and progression of carcinogenesis. When the balance between oncogenes and tumor suppressor genes is disrupted, the result is the initiation of carcinogenesis.

DPC4/SMAD4

SMAD4, known as DPC4 (deleted in pancreatic carcinoma locus4) and as a tumor suppressor gene, is located at 18q21.1. SMAD4 encodes a protein with major implications in signal transduction, through activating members of the TGF- β superfamily^[27].

The SMAD family consists of nine members with a central role in the transduction of the TGF- β signaling from the cell surface to the nucleus. SMAD2 and SMAD3 are also named “receptor-regulated SMADs” because of their property of being phosphorylated by receptor kinases forming heteromeric complexes with SMAD4.

These complexes enter the nucleus and bind to DNA - a prerequisite step for transcriptional activation of TGF- β responsive genes. Moreover, SMAD2/SMAD4 and SMAD3/SMAD4 complexes can downregulate c-myc proto-oncogene and upregulate p21 and p15 expression. p21 does not permit the formation of CDK4/cyclinD and CDK6/cyclinD complexes and their subsequent transcription^[28-30].

TGF- β (transforming growth factor- β) is a member of the dimeric polypeptide growth factor family that regulates cell proliferation and differentiation, embryonic development, wound healing, and angiogenesis. In normal cells, TGF- β promotes differentiation and apoptosis and does not permit the cell to go beyond the G₁ phase. Contrary to that, tumor cells that encode for proteins participating in this signaling pathway are altered and the protective role of TGF- β against tumor phenotypes is abolished. The tumor cells begin to proliferate without restriction and with an increased production of TGF- β . A vicious cycle begins: an increased amount of TGF- β leads to increased invasiveness of tumor cells by destruction of extracellular matrix and promotion of molecular adhesive proceedings. The results of two studies show that 100% of pancreatic adenocarcinomas and 83% of colon cancers have a mutation which affects at least one gene involved in the TGF- β pathway^[32].

Due to this process, SMAD4 expression is well-examined in human cancers. It is found that 50% of pancreatic cancers and 30% of colorectal and biliary cancers present mutant genes. It has been shown that in pancreatic adenocarcinomas, 30% present homozygous deletions while 20% present intragenic mutations in one allele coupled with loss of heterozygosity^[33,34].

The protective character of SMAD4 expression against carcinogenesis was studied by Tascilar *et al*^[35]. They examined the SMAD4 expression in patients with pancreatic carcinoma who had undergone surgical resection. Patients with positive SMAD4 expression survived 4.5 mo longer than patients with negative SMAD4 expression. For a patient with a very poor prognosis, this gain is significant.

Wilentz *et al*^[36] studied the expression of SMAD4 gene in 188 PanIN lesions from 40 adenocarcinomas using immunohistochemical methods. All three “early” PanIN-1A, PanIN-1B, PanIN-2 lesions expressed DPC4 but it was only seen in one third of the PanIN-3 lesions. The conclusions from this study suggest that the loss of DPC4 gene expression occurs late in pancreatic carcinogenesis and, unfortunately, cannot be used for the differential diagnosis of the benign lesions from the malignant ones^[36].

Finally, the last property of SMAD4 restoration is its influence on angiogenesis. It seems to decrease VEGF and to increase TSP-1 (trombospondin) expression, an angiogenesis inhibitor^[37].

p16

On chromosome 9q21, there is a locus called p16^{INK4A}/p14^{ARF}, which encodes for two tumor suppressor genes. Genetic alterations of this locus through gene mutation, deletion, or promoter hypermethylation are found in 80%

to 95% of sporadic pancreatic cancers^[38]. Additionally, expression of p16 has been studied in many types of cancer such as melanomas, gliomas, and leukemias.

p16 suppressor gene is also named *cdkn2* (cyclin-dependent kinase-2) because it is a cyclin-dependent kinase 4 inhibitor. Loss of its expression results in an increasing activity of cyclin dependent kinase 4 with the direct consequence of Rb protein hyperphosphorylation and subsequent uncontrolled cell proliferation.

There are three different mechanisms for p16 inactivation: small mutations as seen in 40% of the cases, deletion of both alleles in the following 40%, and gene silencing through hypermethylation in the remaining 20% of the cases^[38-40].

Genetic analyses have shown that p16 alterations are very common in pancreatic adenocarcinomas but these alterations are not necessarily seen in cultured cell lines. The question is whether p16 mutations and deletions are prerequisite for the establishment of such a cell line. Several studies on p16 expression in pancreatic adenocarcinomas have opposing results. Huang *et al*^[41] report that only 26.7% of examined pancreatic cancers present deletions or mutations on this tumor suppressor gene. In a study by Bartch *et al*^[42], this percentage increased to 34.4%. Later, Hu *et al*^[43] studied 62 pancreatic cancer tissues using immunohistochemical methods and reported that 42% of the examined tissues did not express the gene at all. Moreover, loss of p16 expression could be correlated with less differentiated tumors, shorter overall survival, and the presence of metastatic disease^[43].

It appears that there are at least two genetic alterations that must be present: K-ras mutations and p16 mutations. Human cancers hardly present simultaneous alterations in these two genes. This information may be useful in the future in differential diagnosis of adenocarcinomas of unknown origin.

p53

In human cancers, the most frequent mutant gene is the p53. It is located on the short arm of chromosome 17 and its mutations are either due to loss of heterozygosity in 95% of pancreatic adenocarcinomas or to sequence alterations in 75% of cases with small changes most likely in amino acid sequence such as G: C→A: T (transition)^[44-46].

p53 is a nuclear phosphoprotein with the ability to bind to specific DNA elements and to activate gene transcription. It has a central position in cell cycle regulation through its role in inactivating a variety of genes and interrupting cell proliferation at G₁/S checkpoint.

Mutant status of p53 has been examined in pancreatic adenocarcinomas indirectly through p53 immunostaining and directly through molecular analyses using sequence analyses or polymerase chain reaction. The results of these studies show that mutant p53 correlates with shorter postoperative survival of patients and metastatic disease. However, all these studies have two main drawbacks. One is that the number of examined tissues was not adequate and the other is that the results obtained by the two methods - immunohistochemistry and molecular analyses

- are not consistent. Using both techniques, Ruggeri *et al*^[46] studied 126 cases of sporadic adenocarcinomas, 10 cases of familial adenocarcinomas, 77 cases of non-neoplastic but histologically abnormal pancreatic lesions, and 23 cases of metastatic lesions. The results of this published study show that p53 mutations were present at 56% of sporadic pancreatic adenocarcinomas, 33% of familial pancreatic adenocarcinomas. However, p53 alterations did not correlate with tumor grade, stage, or metastatic disease^[46].

Generally speaking, genetic alterations of p53 tumor suppressor gene are an early event in pancreas carcinogenesis but not an initiating event.

Mdm-2

The mdm-2 gene encodes a protein with possible implications in appearance of malignant character of a cell. Its overexpression in absence of gene amplification has been studied in sarcomas and gliomas as well as in the presence of DNA-damaging agents. It was suggested that expression of mdm-2 gene is regulated by p53 tumor suppressor gene but Ruggeri *et al*^[47] proved that there is no association between these two genes and moreover amplification and overexpression of mdm-2 is an infrequent event in the development of pancreatic adenocarcinomas.

MATRIX METALLOPROTEINASES (MMPS)

MMPs comprise a family of at least twenty members that act as zinc-dependent enzymes. The well-known collagenases, stromelysins, and gelatinases are members of this family. Their principal role is the degradation of extracellular matrix components. MMPs play a role only under special conditions such as tissue remodeling, embryonic development, and wound healing. Cytokines, growth factors and mechanical stress could be the triggers for MMPs production^[48]. Abnormal expression of MMPs has been described in periodontitis, rheumatoid arthritis, tumor cell invasion, and metastasis^[49].

At a structural level, MMPs consist of a signal peptide and a catalytic domain. At the functional level, proteolytic processes must be present in order to activate the enzymes.

MMPs have a pivotal position in carcinogenesis as well as in angiogenesis. Firstly, they degrade the basement membrane and the extracellular matrix components, offering tumor cells the best nutritive conditions for their establishment at the primary site and permitting the circulation of tumor cells and their extravasation at distant, metastatic sites^[48]. In addition, MMPs are capable of removing sites of adhesion, exposing new binding sites, and releasing chemoattractants^[50].

It seems MMPs play a role in as an "angiogenic switch", to facilitate the expression of proangiogenic factors such as VEGF and bFGF in order to overcome the negative signals of angiogenic inhibitors such as trombospondins, angiostatsins, and INFs^[48]. Due to these properties, the inhibition of MMPs represents the scientific rationale for the development of chemotherapeutic agents against pancreatic cancer.

Table 1 The most important pancreatic-prone syndromes

Syndrome	Mutation	Inheritance	Manifestations
Familial atypical mole-malignant melanoma syndrome (FAMMM)	CDKN2A	AD	Multiple atypical nevi Malignant melanoma
Hereditary pancreatitis	PRSS1 Kazal type 1 (SPINK1)	AD	Extracutaneous cancers Relapsing pancreatitis Young age of onset Associated pancreatic insufficiency, diabetes and pseudocysts
Hereditary non-polyposis colon cancer (Lynch II)	HMSH2, HMLH1, HPMS2, p16 BRCA2	AD	Adenocarcinoma of the colon and extracolonic adenocarcinomas (endometrium, ovary)
Familial adenomatous polyposis	APC	AD	Innumerable colonic polyps with highly possible malignant transformation
Ataxia-telangiectasia	ATM	AR	Progressive cerebral ataxia, telangiectasias, sinopulmonary infections, oculomotor apraxia, immune deficiencies, 3-fold operative risk for PC
Li-Fraumeni	p53	AD	Predisposition to several neoplasms
Peutz-Jeghers	LKB1/STK11	AD	Multiple oromucosal and intestinal hamartomas

Epidermal growth factor receptors

The family of epidermal growth factor receptors (EGFR) consists of four types of receptors: HER-1, HER-2, HER-3, and HER-4, which have been studied in detail due to their implications in carcinogenesis. These four structurally similar receptor tyrosine kinase proteins are present on various domains: extracellular, transmembrane, and intracytoplasmic. Ligands of these proteins are EGF (betacellulin), TGF α (epiregulin), HB-EGF (amphiregulin) and three neuregulins (1, 2 and 3)^[51,52].

Upon binding to ligands, these receptors undergo homo- or hetero-dimerization at the cell surface with subsequent phosphorylation of serine residues in the intracytoplasmic domain. This phosphorylation is translated into a downstream signal with resultant gene activation that leads to cell proliferation, decreased apoptosis, angiogenesis, and metastasis^[53].

Overexpression of EGFR is a common characteristic in epithelial tumors such as breast, lung, and colorectal cancer. This expression has been associated with aggressive tumor growth and poor clinical outcome. Safran *et al*^[54] studied 154 patients with metastatic pancreatic cancer for HER-2 overexpression by immunohistochemical means. They reported positive results for 21% of the cases studied.

All these important implications of HER-2 gene in carcinogenesis constitute the scientific rationale for new approaches in targeted therapy of pancreatic cancer.

FAMILIAL PANCREATIC CARCINOMA

It has been statistically observed that 5%-10% patients with pancreatic cancer have a close relative with the same cancer while this rate among controls is only about 0.6%^[55]. Lynch *et al*^[56] have shown that the risk for a person to develop pancreatic cancer is increased by 30% when there is a family history of any cancer among first-degree relatives. The European Registry of Hereditary Pancreatic Diseases (EUROPAC) identifies an individual at high risk for developing pancreatic cancer (PC) when he/she has two or more first-degree relatives with PC, or has three or more relatives of any degree with PC, or has any two

relatives who have been given this diagnosis and the sum of their ages is under 110 years.

Studies of family histories might lead us to a better understanding of genetic alterations in human pancreatic adenocarcinoma. Patients with cancer in their families present an inherited germ-line genetic mutation in a cancer-causing gene. Among genes which have shown to be involved with familial pancreatic carcinogenesis are BRCA-2 and a large genetic area on locus 4q32-q34. Germ-line BRCA-2 mutations (mainly 6147delT) are present in approximately 17%-19% of familial pancreatic families in accordance with the results of recent studies^[57-59].

Table 1 summarizes the most important pancreatic-prone syndromes. Much additional work needs to be done before the genetic basis of pancreatic cancer is completely understood in sporadic cases as well as in familial cases. This information will help us to identify the primary genetic factor and if possible to organize a counseling program for individuals at high risk.

NOVEL THERAPEUTIC AGENTS

Since 1997, the standard first-line chemotherapeutic agent for pancreatic adenocarcinoma has been gemcitabine (2'-2'-difluorodeoxycytidine), a difluorinated analogue of deoxycytidine, which is a member of the antimetabolites. The patient's benefit using this chemotherapeutic agent is an improvement in quality of life; however, the survival benefit is marginal. Antimetabolites cannot prolong the median survival time of patients with metastatic disease for more than six months.

The rationale for further understanding of genetic alterations of pancreatic cancer is based on the need for earlier diagnosis and development of more effective therapies. MMPs present very interesting links with extracellular matrix participating in its degradation and in the process of neovascularization. Marimastat, a MMPs inhibitor, was administered in 414 patients with advanced pancreatic cancer as first-line chemotherapy in different doses (5, 10, and 25 mg orally twice a day) compared to the standard chemotherapy, gemcitabine, in a clinical study. Unfortunately, the study results are not encouraging. There

is no difference in the median survival interval between the two agents or with regard to marimastat dose escalation. The most important clinical information from this study is the longer overall survival time of patients with no metastatic disease *versus* patients with metastatic disease (200 *versus* 89 d). Thus, it is concluded that marimastat should be used in an adjuvant and not in a first-line setting^[60,61].

Inhibition of EGFR by monoclonal antibodies (MoABs) that inhibit ligand binding or by tyrosine kinase inhibitors (TKIs) that bind to the adenosine triphosphate binding site of the growth factor receptor represents another therapeutic approach for pancreatic adenocarcinoma. Cetuximab (Erbix) is the first human-mouse chimeric IgG1 antibody which has been approved for EGFR-positive expression in colorectal cancer. Currently, it is used in large clinical trials for EGFR-positive expression in pancreatic cancer. This novel agent presents more than one mechanism of action such as arrest of cell-cycle, activation of apoptosis, inhibition of angiogenesis, and inhibition of distant metastasis. It is interesting that EGFR inhibition contributes to angiogenic inhibition^[62]. The next step is a clinical study comparing gemcitabine alone and in combination of an EGFR-inhibitor. Another novel agent which could be used as targeted therapy in pancreatic carcinoma is ABX-EGF, a fully humanized IgG2 monoclonal antibody that has a higher binding affinity to EGFR than the previous one. There is evidence that ABX-EGF, in combination with chemotherapy, could eradicate some tumors and prolong overall survival. Unfortunately, the number of patients with pancreatic cancer and EGFR overexpression is limited^[63].

Several TKIs (gefitinib, erlotinib, PKI-166) have been tried as targeted therapies in pancreatic adenocarcinoma. Oral administration of PKI-166 in combination with intraperitoneal injections of gemcitabine in nude mice with implanted human pancreatic carcinoma cells into their pancreas showed significant regression of tumor growth and inhibition of metastasis. This inhibition was mediated directly by antitumor effect and indirectly by anti-angiogenic effects. Some clinical phase III studies are in process, which compare a combination of TKIs and gemcitabine versus gemcitabine alone as a first-line treatment for pancreatic cancer^[64,65].

Due to rapid cancer cell division, the tumor growth increases rapidly. The young cells need oxygen and nutrients supplied by newly made vessels, otherwise, they will die. This information represents the scientific rationale for the development of new drugs that will target several points along the angiogenic pathway. The targeted therapy advantage is that it applies only to new vessels, and will not present widespread toxicity. It acts by blocking vascular epithelial growth factor (VEGF) through monoclonal antibodies or through agents responsible for VEGF receptor tyrosine kinase inhibition. A multicentre phase II trial, which studies the efficacy of bevacizumab plus gemcitabine for advanced pancreatic cancer, is currently taking place with satisfactory results: the median time to progression is 5.5 mo and the estimated 1-year survival rate is 54%^[66].

Another therapeutic approach to pancreatic cancer

is the antisense therapy. The mechanism of action is the inhibition of protein expression through trapping mRNA by specific RNA sequences. There are ongoing trials on murine xenografts on the human pancreatic cancer cell line, AsPC-1, where liposome-mediated gene transfer of antisense K-ras is used^[67].

CONCLUSION

During the past decade, important steps have been made towards understanding the primary lesions that may lead to pancreatic adenocarcinoma. Molecular biology is the major key in this effort. Furthermore, a biologic and molecular staging of this disease may lead us to earlier diagnoses, efficient familial counseling, better management, and new therapeutic approaches.

Abstract

Hepatitis C virus (HCV) infection is one of the major causes of chronic liver disease, including cirrhosis and liver cancer and is therefore, the most common indication for liver transplantation. Conventional antiviral drugs such as pegylated interferon-alpha, taken in combination with ribavirin, represent a milestone in the therapy of this disease. However, due to different viral and host factors, clinical success can be achieved only in approximately half of patients, making urgent the requirement of exploiting alternative approaches for HCV therapy. Fortunately, recent advances in the understanding of HCV viral replication and host cell interactions have opened new possibilities for therapeutic intervention. The most recent technologies, such as small interference RNA mediated gene-silencing, antisense oligonucleotides (ASO), or viral vector based gene delivery systems, have paved the way to develop novel therapeutic modalities for HCV. In this review, we outline the application of these technologies in the context of HCV therapy. In particular, we will focus on the newly defined role of cellular microRNA (miR-122) in viral replication and discuss its potential for HCV molecular therapy.

INTRODUCTION

Hepatitis C virus (HCV), first identified in 1989, is a single-stranded positive-sense RNA flavivirus with 6 major genotypes and over 70 subtypes^[1,2]. According to the estimation of the World Health Organization, approximately 170 million people, 3% of the world population, are HCV positive with 3 to 4 million de novo infections each year. Unfortunately, 55%-85% of those infected fail to clear the virus and progress to develop chronic infection. Over a period of 20 to 30 years cirrhosis develops in about 10% to 20% and hepatocellular carcinoma (HCC) develops in 1% to 7% of persons with chronic infection^[3]. Currently, no safe and effective vaccine is available to prevent HCV infection. Conventional treatment, such as interferon taken alone or in combination with ribavirin, is only effective in part of the patients, but is often financially inaccessible for people in developing countries^[4,5].

To explore the potential of new therapeutic strategies, it is critical to better understand the viral and host factors involved in virus cell entry, replication and virus-cell interaction. An apparent two-way dialogue exists in which the virus apparently takes advantage of the cells' own signal transduction systems to facilitate virus entry and support replication^[6]. Indeed, remarkable progress has been achieved in understanding the properties of the HCV genome and viral proteins. Contributions have come through several different sources, including vaccination of chimpanzees, structural studies, binding studies with recombinant envelope proteins, and the use of clinical isolates, HCV-like particles (HCV-LPs), HCV pseudotyped particles (HCVpp), and cell culture-derived HCV particles (HCVcc) in infectivity assays^[7,8]. Cellular pathways or molecules involved in viral entry, such as CD81, scavenger receptor class B type I (SR-BI), LDL receptor, L-SIGN, DC-SIGN and asialoglycoprotein receptor (ASGPR) could be putative therapeutic targets^[9-12].

New technologies, particularly RNA interference (RNAi) induced by small interfering RNA (siRNA), are gaining favour as effective therapeutic entities for HCV infections. RNAi works at a posttranscriptional level by

degrading cognate mRNA. As HCV is a single-stranded RNA that functions as both a messenger RNA and a template for replication, it is a prime candidate for RNAi. Moreover, previous reports have shown that by blocking cellular determinants of viral entry and replication, such as CD81, HSP90, or p68, either by RNAi, antisense oligonucleotides or chemically engineered "antagomirs", leads to significant reduction of viral invasion^[13-15]. In this review, we outline the novel small RNA based technologies in designing therapeutic approaches for HCV treatment, according to the mechanism of viral entry, replication and virus-cell interaction. In particular, we will discuss emerging evidence that a liver-specific, small non-coding microRNA (miRNA) is involved in replication of HCV through a novel mechanism and outline its therapeutic potential.

MOLECULAR CHARACTERISTICS OF HCV ENTRY AND REPLICATION

HCV, contains a single-stranded RNA genome of about 9400 nucleotides in length, composed of a 5' and 3' non-coding region (NCR) with a single open reading frame encoding a polyprotein precursor of approximately 3000 amino acids that is cleaved into three structural (core, E1, E2) and seven non-structural (p7, NS2-NS5B) proteins^[16,17].

Since the discovery of HCV, numerous studies have demonstrated its mechanism of cell entry, but it is still unclear how the virus penetrates cell membranes. In order to elucidate the infection pathway, it is first required to identify and understand both the putative viral and cell factors involved in this process. The viral envelope glycoproteins E1 and E2, cleaved from the polyprotein by the endoplasmic reticulum (ER)-resident host enzymes signal peptidase and signal peptide peptidase, have been widely regarded as the critical determinants for virus cell entry. To date, several models have been designed to investigate E1/E2 function. These include HCV-LPs expressing E1-E2 heterodimers instead of glycosylated individual E1 and E2^[18-21], HCVpp consisting of unmodified HCV envelope glycoproteins E1 and E2 assembled onto retroviral or lentiviral core particles^[22-26], vesicular stomatitis virus (VSV)/HCV pseudotypes expressing HCV E1 or E2 chimeric proteins containing transmembrane and cytoplasmic domains of the VSV G glycoprotein, or HCVcc neutralization assays with E1 or E2 antibody^[27-30]. These models have shown that both envelope glycoproteins E1 and E2 are essential for host cell entry. The lack of either E1 or E2 significantly decreases HCV infection activity whereas deletion of the whole envelope protein coding sequence abolishes the particle infectivity. Additionally, several cell surface molecules have been identified using these models and are now considered as critical components in mediating HCV attachment and entry.

Similar to viral entry, HCV replication requires both viral and cellular factors. Although our current knowledge of the HCV life cycle is still mainly at the hypothetical level, several minimum viral components and host cell factors have been proposed. The HCV 5' NCR, in

particular the IRES sequence, plays an important function in ribosomal assembly and the NS3 to NS5B coding region are necessary for function of the replicase complex^[31-35]. Found as interaction partners of NS5A and NS5B, human vesicle-associated membrane protein-associated proteins VAP-A and VAP-B were first identified from the host cell^[36,37]. More recently, the geranylgeranylated protein FBL-2, the immunophilins cyclophilin B and FKBP8 have been identified as important host factors for HCV replication^[38-40]. Furthermore, the host enzyme IMPDH, essential for the *de novo* synthesis of GTP nucleotides, may be involved in HCV replication as the IMPDH inhibitors ribavirin and mycophenolic acid suppresses replication^[41,42]. Interestingly, the mammalian liver-specific miRNA (miR-122) has been recently defined to facilitate HCV replication, indicating that this small RNA may present a novel target for antiviral intervention^[43].

miR-122 AND HCV REPLICATION

miRNAs are approximately 22 nucleotide noncoding RNAs that can downregulate various gene products by inducing either cleavage or a reduction in the translational efficiency of the target mRNA^[44,45]. In the last 5 years, over 3000 miRNAs have been identified in vertebrates, flies, worms, plants and even viruses. Most miRNAs have been shown to participate in essential biological processes, such as cell proliferation, apoptosis, differentiation and metabolism^[46]. The 22 nucleotide mature miR-122, derived from a noncoding polyadenylated RNA transcript of the hcr gene, is a liver-specific developmental regulator. It can be detected as early as 12.5 d post-gestation and reach a plateau immediately before birth, then slowly increase up to 70% of the total miRNA population in adult liver^[47-49]. miR-122 is the first identified host miRNA linked to HCV viral replication. A further novelty to these findings is the fact that miR-122 upregulates, rather than downregulates, viral RNA by interaction with the 5' NCR of the viral RNA. Previous work had suggested that miRNA can only negatively regulate gene expression through targeting the 3' NCR of mRNA.

Interestingly, Jopling *et al*^[43] have observed that though both Huh7 and HepG2 cells are derived from human hepatocytes, HCV RNA can only replicate in Huh7 cells. This may link to the fact that Huh7 is miR-122 positive, while HepG2 is miR-122 negative. To determine if miR-122 is required to regulate HCV replication, they transfected antisense oligonucleotides into Huh7 liver cells to suppress miR-122 function. The results showed that the amount of viral RNA was reduced by about 80% when miR-122 was silenced, but it is still unclear whether it is simply a direct or indirect interaction through cellular factors. Thus, to further address this issue, two putative binding sites, located in each of the viral NCR, were tested as possible targets for miR-122. It was found that only the binding sequence located in the 5' NCR was responsible for miR-122 targeting. This is notably very different from the common observation that miRNA target the 3' NCR, leading to suppression or degradation of target mRNA. Recently, a study in mice has shown synthesized antisense single-stranded 23-nucleotide RNA molecules

can effectively inhibit production of miR-122 *in vivo*^[50]. Therefore, miR-122 seems a potential target for HCV treatment, although the mechanism for this new miRNA role is still very much unclear.

THERAPEUTIC STRATEGIES BASED ON GENE SILENCING TECHNOLOGY

As current antiviral regimens have proven largely unsatisfactory, particularly for patients with genotype 1 infection, it is important to explore novel therapeutic strategies. Small interfering RNAs and antisense oligonucleotides (ASO) have emerged as efficient nucleic acid-based gene silencing tools to target highly conserved or functionally important regions within the HCV genome or essential host cell factors for entry or replication (Figure 1).

RNAi, induces gene silencing at a post-transcription level by double-stranded small interference RNA (siRNA) and represents an exciting new technology that could have applications in the treatment of viral diseases. Particularly, HCV could be an attractive target for RNAi therapy, as it is a RNA virus. The HCV genome is a positive single-stranded RNA that functions both as the viral messenger RNA and a template for RNA replication *via* a negative-strand intermediate. Instead of a 5' cap, the IRES, located at the 5' NCR, plays an essential role to bind eukaryotic ribosomal subunits and initiates the assembly of the translationally active 80S complex. Consequently, this sequence is more conserved than any other part of the viral genome, at least among the six known HCV genotypes^[51,52]. Thus, IRES seems an ideal target for RNAi mediated anti-HCV therapy and several groups have demonstrated efficient inhibition of HCV replication by designing siRNAs toward this region^[53-55]. In addition, RNAi directed against the viral core, NS3, NS4B, NS5A and NS5B regions can suppress HCV infection. McCaffrey *et al*^[56] was the first to demonstrate feasibility of siRNA targeting HCV NS5B *in vivo*. By co-expression of an NS5B-luciferase fusion gene with an anti-NS5B siRNA expression plasmid they found a significant reduction of luciferase expression in the mouse liver indicating selective degradation by the NS5B siRNA. Additionally, several other groups have observed suppression of HCV replicon by siRNA-mediated targeting either NS5B or NS3 region^[57-59].

Besides these viral elements, numerous host cellular factors, such as CD81, SR-BI, HSP90, p68 or USP18, could be typical targets for potentiating RNAi antiviral therapy. CD81, expressed in most human cells, is able to bind to HCV E2 protein and is, therefore, considered an essential receptor for HCV entry. Further investigation, by either ectopic expression of CD81 in Huh7-Lunet cells (low expression of CD81) or modulation of CD81 cell surface density in Huh-7.5 cells (high expression of CD81) by RNAi, revealed that density of cell surface-exposed CD81 is a key determinant for HCV entry into host cells^[60]. SR-BI, primarily expressed in the liver and steroidogenic tissues, was identified as another potential HCV receptor based on coprecipitation with recombinant E2. A 90% down-regulation of SR-BI expression in Huh7 cells by

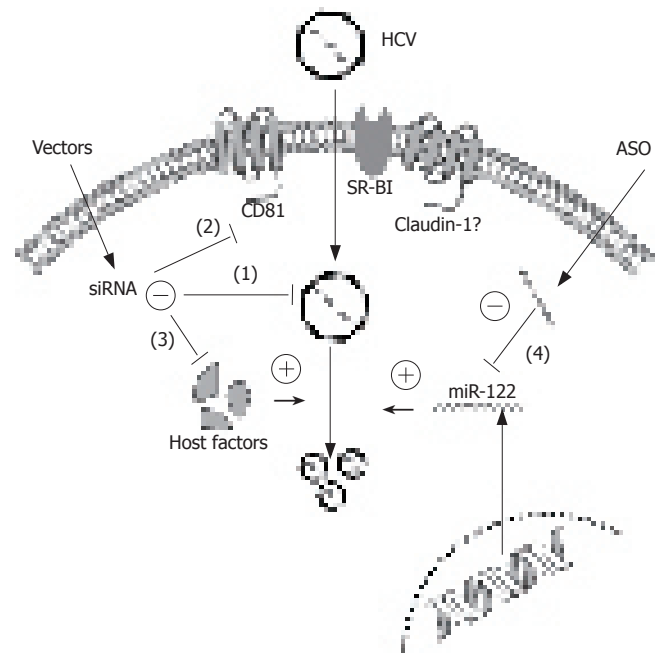

Figure 1 Novel anti-viral strategies based HCV life cycle. RNAi technology, inducing gene silencing at posttranscriptional level mediated by siRNA, can be applied to prevent HCV replication and infection by targeting either viral RNA (1) or host factors, such as surface receptor (2) or cellular molecules (3). miR-122 is a liver specific miRNA that is involved in HCV replication and therefore silencing of miR-122 by antisense oligonucleotides (ASO) could be considered as a potential therapeutic modality (4).

RNAi caused a 30%-90% inhibition of HCVpp infection, depending on the HCV genotype^[61,62]. However, either CD81 or SR-BI alone is not capable of virus binding indicating that at least one additional host protein, possibly the recently identified co-receptor, Claudin-1^[63], is required for cell entry of enveloped virions *via* the CD81/SR-BI pathways.

Although using siRNA to target either viral or host factors could be considered effective tools to significantly block HCV infection and replication, an advanced method by knockdown both viral and cellular factors may further improve the therapeutic efficacy. Work by our group has shown that both entry and replication can be simultaneously targeted using shRNAs directed against two regions of the HCV RNA and one region of the host cell receptor, CD81. The triple shRNA expression vector was effective in concurrently reducing HCV replication, CD81 expression, and E2 binding, comparable to conventional single shRNA anti-HCV vectors^[64].

Antisense oligonucleotides represent an alternative gene-silencing tool that can be employed as HCV therapy. ASO-based inhibition of HCV has been demonstrated extensively in the past^[65-71]. Currently, ASO is the most promising method to block the function of miRNA, such as miR-122. For instance, a 2'-O-methylated RNA oligonucleotide with exact complementarity to miR-122 was introduced to inactivate its function in Huh7 cells, in order to determine the relationship between miR-122 and HCV replication. Subsequently, Krutzfeldt *et al*^[50] developed a pharmacological approach for silencing miRNA *in vivo*, by chemically modified,

cholesterol-conjugated single-stranded RNA analogues to complementarily target miR-122. By injection of these 'antagomirs' into the tail veins of mice, efficient and specific suppression of endogenous miR-122 was observed. Hence, designing ASO based molecular medicines would provide new agents for human major diseases, because upregulation of certain miRNAs linked to a set of diseases such as cancer, diabetes or HCV.

LIVER-TARGETED VIRAL DELIVERY SYSTEMS

Obviously, RNAi or ASO technologies could be regarded as potentially effective novel modalities for anti-HCV treatment. Nevertheless, the success depends on developing effective delivery systems, to target therapy to the liver. Regarding to treat a liver-hosted and long-term persistent hepatitis virus, an ideal vector would be able to transfer genetic material efficiently and specifically into the target cells/tissues, resulting in high level, properly regulated and prolonged expression, without toxic and immunogenic side effects. Since viruses have many advantages as transgenic vehicles, we will discuss two of the most promising delivery systems: lentiviral and adeno-associated viral (AAV) vectors.

Lentiviral vectors, are mainly based on human immunodeficiency virus type 1 (HIV-1) and have been shown to effectively transduce liver, muscle, and hematopoietic cells. These vectors integrate their payloads into the host genome ensuring transmission to progeny cells^[72]. Although lentiviral-mediated short hairpin RNA (shRNA, precursor of siRNA) delivery has been widely developed for therapeutic application, there are few reports referring to HCV treatment^[57,64]. There are currently some limitations for the use of lentiviral vectors: (1) production efficiency limits *in vivo* transfection; (2) possibility of insertional mutagenesis or generation of wild-type virus leading to safety considerations. To circumvent these drawbacks the following strategies may be required to achieve further improvement: firstly, newer generations, such as the gutted third generation, relatively high titers of VSV-G pseudotyped HIV-1 vectors, other types such as HIV-2 and simian immunodeficiency virus (SIV) vectors, or even immunodeficiency viruses derived from nonprimates, including felines and equines, are also being developed to overcome conventional problems^[73-76].

Analogically, with the superiority of low pathogenicity and long-term gene expression, AAV could be another ideal viral vector for siRNA delivery, although no reference of AAV-mediated anti-HCV RNAi therapy has been reported so far. Particularly AAV serotype 8, a new member of the AAV family isolated from rhesus monkeys, is an attractive candidate for hepatic-directed shRNA transfer because of 10- to 100-fold increased transduction efficiency in mouse liver models, compared with the previous AAV2 based vectors^[77]. Since derived from nonhuman primate, AAV8 is less prone to recognition by prevailing antibodies that generate side immunological effects in human^[78]. Moreover, the safety and transgenic delivery efficacy could be further improved by conjugating

other strategies, such as utilizing liver-specific promoters, hybridization of AAV8 with other serotypes, or modification of viral capsids.

Furthermore, since miRNA context based siRNA cassette (second-generation shRNA) can be driven by a regulated pol II promoter instead of conventional pol III promoters^[79], liver-targeted expression of shRNA could be achieved by employing a liver-specific pol II promoter in viral delivery system.

CONCLUSION

The treatment of HCV remains a challenge that requires further elucidating the process of viral life cycle and developing novel therapeutic approaches. In fact, recent progress has provided the possibilities of identifying novel antiviral targets and designing new therapeutic strategies. According to the previous description, miR-122 is one of the most emergent targets for HCV therapy that is commonly abundant in human livers and thus promotes viral replication. Therefore, downregulation of miR-122 by antisense based 'antagomirs' or oligonucleotides significantly suppressed viral replication. However, before such a method can be applied in the clinic, the role of miR-122 in maintaining normal hepatic function must be further investigated. Krutzfeldt *et al*^[50] have demonstrated that silencing of miR-122 by 'antagomirs' do not show any apparent toxicity to mice, but the more recent study has shown that miR-122 is downregulated in the rodent and human hepatocellular carcinomas (HCC). Using the animal model of diet-induced hepatocarcinogenesis, Kutay *et al*^[80] have observed that the reduced expression of miR-122 probably occurs between 36 and 54 wk when neoplastic transformation occurs. These findings suggest that the downregulation of miR-122 might be associated with hepatocarcinogenesis and, therefore, further investigation into the function of miR-122 is required before therapeutic application can be commenced. In conclusion, the recent progress of understanding the viral life cycle and identification of novel targets, in combination with the newly developed ASO and RNAi technology, may pave the way for new anti-HCV therapy.

ACKNOWLEDGMENTS

We would like to thank Dr. Herold J Metselaar for his general support. S.D.H. is supported by a "Translational research" grant of the Erasmus MC, Rotterdam.

CONCLUSION: Our data supports that Turkish patients with MLH1- and MSH2-defective tumors have some distinct features from each other. Although prognostic importance remains controversial, immunohistochemical analysis of mismatch repair genes may be used as a routine histopathological examination of sporadic colorectal carcinomas.

Abstract

AIM: To assess the incidence of MLH1 (the human MutL homologue) and MSH2 (the human MutS homologue) protein expression in Turkish patients with sporadic colorectal cancers and to compare their survival and clinicopathological features.

METHODS: We validated the tissue microarray technology in 77 colorectal carcinomas by analyzing the immunohistochemical expression of proteins involved in two main pathways of colorectal carcinogenesis: p53 protein for loss of heterozygosity tumors; MLH1 and MSH2 proteins for microsatellite instability (MSI).

RESULTS: Our analysis showed that 29 (39.2%) had loss of MLH1 expression, 5 (6.8%) had loss of MSH2 expression and 2 cases had loss of expression of both proteins. We found that 60% of MSH2-negative tumors were located in the right side of the colon; all MSH2-negative cases were women. In addition, the loss of MSH2 expression was correlated with low p53 expression. Neither MLH1 nor MSH2 expressions were associated with prognosis, although there seemed a tendency of longer survival (71.7 ± 8.65 mo *vs* 47.08 ± 5.26 mo) for the patients with MLH1-negative *versus* MLH1-positive carcinomas. There were not significant differences in overall and recurrence-free survival among MLH1/MSH2-positive and -negative cases.

INTRODUCTION

In humans, mismatch repair (MMR) system is mediated by at least six genes, including human MutL homologue (hMLH1), human MutS homologue (hMSH2), hMSH3, hMSH6, hPMS1, and hPMS2^[1]. MMR deficiency leads to the accumulation of base-base mismatches and short insertion/deletion mispairs, generated as a consequence of DNA replication errors and homologous recombinations. Most cell deficient in *hMLH1* and *hMSH2* genes often display a high level of genomic instability, characterized by changes in repeated numbers of simple repetitive sequences, microsatellite instability (MSI)^[2,3]. The detection of MSI status is based on molecular analysis. According to this, three tumor phenotypes have been defined: Microsatellite stable (MSS), low-frequency MSI (MSI-L) and high-frequency MSI (MSI-H). A germline mutation in one of MMR genes, accompanied by somatic inactivation of the other allele, may result in high level of microsatellite instability (MSI-H)^[4-6].

In patients with hereditary nonpolyposis colon carcinoma (HNPCC), MSI was detected in 80% of the tumor samples^[7]. It has been reported that MMR genes

are involved in the 10%-15% of sporadic colorectal carcinomas^[3,8]. In sporadic MSI-H colorectal carcinomas, the mechanism of development of mutator phenotype is inactivation of MLH1 by promoter hypermethylation. Sporadic MSI-H tumors tend to be poorly differentiated and/or mucinous subtype^[9-11]. They are usually diploid; p53 mutations, loss of heterozygosity at 18q, APC mutations and K-ras mutations are found less frequently than in MSS tumors^[12,13]. In literature, there are controversial results about the prognostic importance of MSI status in sporadic colorectal carcinoma.

Establishing the presence of MSI requires polymerase chain reaction-based technology, examining DNA sequences of intact and tumor tissue. This is an expensive and time-consuming procedure that is not readily available in all pathology laboratories. Immunohistochemically identifying MSI tumors is a less costly alternative procedure. There are some studies which have shown a high correlation of MLH1 and MSH2 immunohistochemical patterns of expression with the DNA analyses. MSI-H correlates with loss of immunohistochemical staining of either MLH1 or MSH-2 in the tumor nuclei^[14-17]. The sensitivity of the immunohistochemical technique for detecting MSI-H tumors is about 80% to 100%^[15-17].

To our knowledge, this is the first published study in Turkey concerning investigation of MSI status in sporadic colorectal carcinomas. Therefore, it is important to find out prognostic importance of MSI status in patients with colorectal carcinoma in Turkish population to perform their appropriate treatment and follow-up. In this study, we determined (1) the frequency of MLH1- and MSH2-deficient colorectal carcinomas in Turkish patients, (2) the relationship between MLH1/MSH2 expression and clinicopathological features, and (3) the predictive and prognostic relevance of loss of MLH1 and/or MSH2 expression in recurrence-free and overall survival.

MATERIALS AND METHODS

Tissue specimens

A total of 77 colorectal carcinoma specimens were obtained from the archives of the Department of Pathology of Cerrahpasa Medical College, Istanbul University. Patients with familial adenomatosis polyposis or inflammatory bowel disease were excluded. Tumors were staged according to the TNM staging system^[18]. Tumor type and grade of differentiation were determined by criteria of the World Health Organization^[19]. Peritumoral Crohn's-like reaction, pattern of growth and lymphocytic infiltration were also evaluated according to literature^[20,21]. Tissue microarray (TMA) was applied to study normal colorectal mucosa and colorectal carcinomas. The patients had received neither chemotherapy nor radiation therapy before tumor resection. Their pathological specimens and slides were revised. After revision, two slides and corresponding two paraffin blocks were chosen, one for normal colorectal mucosa and one for colorectal carcinomas tissues for each case. Corresponding areas for normal mucosa and carcinomas were marked on chosen

paraffin blocks. In TMA, 2-mm cores were taken from these selected areas, two for normal mucosa and two for cancer areas, and then they were embedded into microarray block. Each block containing 60 cores also contained other tissues (for example, sausage blocks included tissues from breast, thyroid, prostate, skin, gastric mucosa, lymph node, etc) for negative and positive controls.

Immunohistochemistry

Formalin-fixed paraffin-embedded TMA blocks were cut into 3- μ m thick sections and mounted on polarized glass slides. After mounting, they were kept in an oven at 56°C overnight. Sections were deparaffinized in xylene and rehydrated. They were incubated in a microwave containing 10 g/L EDTA solution 3 times for 5 min each, and then kept in room temperature for 20 min and placed in 10 mL/L hydrogen peroxide for 10 min. After being washed with distilled water and phosphate-buffered saline (PBS), sections were incubated overnight at 4°C with primary antibodies of MSH2 (Ab-1, Clone 2MSH01, NeoMarkers; 1:25) and MLH1 (Clone 14, Zymed Lab; 1:50) with pre-antibody blocking solution (Immunovision-Sitogen). Primary antibody was replaced with PBS for a negative control. After being washed with PBS, the sections were incubated with primary antibody enhancer for 30 min and then with HRP polymer for 30 min. After being washed thrice with PBS for 10 min each, the sections were stained with a streptavidin-peroxidase detection system.

Immunostaining for p53 (p53 AB-5 clone DO-7, Neomarkers; 1:100) was almost the same as above-mentioned, except using citrate buffer solution instead of 10 g/L EDTA solution in microwave.

Immunohistochemical evaluation

Stained tissues in tissue microarray slides (TMS) were scored under the light microscope and the extent and intensity of staining with MLH1, MSH2 and p53 antibodies were evaluated independently by two pathologists (SE and EU) without knowledge of clinicopathological data. Tumors showing loss of nuclear MLH1 or MSH2 expressions were classified as MLH1- or MSH2-negative, respectively. Nuclear immunostaining of normal epithelial cells, lymphocytes and stromal cells served as internal positive controls. For p53, tumors showing a proportion of stained nuclei of > 10% were classified as p53-positive.

Statistical analysis

Spearman rank, Kendall correlation test, Cox regression and Kaplan-Meier test were used, when appropriate. $P < 0.05$ was considered statistically significant.

RESULTS

There were positive staining of normal control mucosa in the lower third of the epithelium and nuclear staining of lymphocytes from a control germinal centre (Figure 1A and B). Three MLH1/MSH2-stained cases were excluded from the study because the quality of immunostaining was unsatisfactory. Of the remaining 74 colorectal

adenocarcinomas, 42 (56.7%) cases demonstrated normal expression of both MLH1 and MSH2 gene products

(MLH1+/MSH2+) (Figure 2A and B). Loss of MLH1 or MSH2 expression was detected in 32 (43.2%) of all cases examined. Complete loss of MLH1 expression (Figure 3A) and normal immunoreactivity for MSH2 were observed in 27 (36.48%) cases of adenocarcinoma, while 5 (6.8%) cases displayed complete loss of MSH2 expression (Figure 3B) and normal immunoreactivity for MLH1. Two (2.07%) adenocarcinoma cases showed lack of both MLH1 and MSH2 expressions.

Immunohistochemical pattern of MLH1/MSH2 expressions was found to be related to some clinical and pathological variables (Tables 1 and 2). MSH2-negative carcinomas occurred only in women ($P = 0.049$). In addition, MSH2-negative carcinomas developed more frequently in patients ≥ 50 years than did MSH2-positive ($P \geq 0.05$). Majority of MSH2-negative tumors (60%) were located in the right colon ($P > 0.05$). However, no any preferential location for MLH1-negative cases was observed. There was no significant correlation between MLH1/MSH2 expression and tumor size and tumor type, while a significant relation was detected between tumor invasion and MSH2 expression (Table 2).

All MSH2-negative tumors had no or low p53 expression, while MSH2-positive cases had p53 expression $\geq 10\%$ ($P < 0.05$). MLH1/MSH2 expressions were not significantly associated with other histopathological variables, such as perineural invasion, lymphatic/blood vessel invasion, peritumoral Crohn's-like lymphoid reaction. On the other hand, 80% of cases with loss of MSH2 expression had no perineural, lymphatic and blood vessel invasion (Table 2).

Our study included 32 (41.6%) females and 45 (58.4%)

males, with average age of 56 (range, 23-77) years. The mean follow-up in surviving patients was 34 (range, 3-97) mo. The patients with MSH2-negative/MLH-positive carcinomas more frequently died of disease (average 12.5 ± 1.06 mo post-operatively) than the patients with MLH1-positive/MSH2-positive carcinomas (47.08 ± 5.26 mo post-operatively) (Table 3). However, overall and disease-free survival analysis did not show significant differences among the four groups of patients

In COX regression analysis, only lymph node metastasis and stage were found as independent prognostic factors in all clinicopathological features. But loss of MLH1 and MSH2 expressions did not show prognostic significance (Table 4).

DISCUSSION

One of the two different pathogenetic pathways in colorectal carcinogenesis is mutator pathway which is characterized by explicit microsatellite instability (MSI). Mutator pathway covers DNA mismatch repair genes like MLH1 and MSH2. Identification of MSI status of

large bowel adenocarcinomas is clinically important, since patients with MSI carcinomas demonstrated several distinct features compared to microsatellite stability (MSS) carcinomas^[22-25]. It has also been suggested that MSI carcinomas might be particularly sensitive to 5-fluorouracil-based adjuvant chemotherapy^[26,27]. Besides, patients with MSI tumors are considered to be at risk of developing metachronous colorectal cancers and need long-term colonoscopic surveillance^[28].

As mentioned in previous studies, immunohistochemical analysis of MLH1 and MSH2 protein expression represents a rapid, easier and less costly alternative method for detection of colorectal tumors of the mutator phenotype^[3,15,16,29-32]. This analysis could be performed in the histopathology laboratories as routine immunohistochemical staining, while genetic analysis of MSI status is time-consuming and expensive and requires specialized equipment^[3,28]. This difference is important for developing countries like Turkey. Lindor *et al*^[11] showed that absence of expression of MLH1 or MSH2 had a 100% specificity and 92.3% sensitivity for predicting a tumor with MSI-H phenotype. So, immunohistochemical

analysis of MLH1/MSH2 proteins can be used as a prescreening method for mutation analysis of mismatch repair genes^[33-35]. The inactivation of MLH1 and MSH2 genes is resulted in loss of expression of these proteins by immunohistochemistry.

We report here our first results of MMR (mismatch repair) analysis in Turkish sporadic colorectal carcinomas. To our knowledge, this TMA-based study about MSI status was completely performed for the first time in Turkey. We found loss of MLH1 expression in 29 (39.2%) and loss of MSH2 expression in 5 (6.8%) of cases. In

Table 4 Results of COX regression analysis

	P
Loss of MLH1 expression	0.127

Peritumoral lymphocytic inflammation	0.952
Stage	0.000
Lymph node metastasis	0.000

addition, loss of either MLH1 or MSH2 expression was seen in 32 (43.2%) of cases, while loss of expression of both MLH1 and MSH2 was detected in 2 (3.1%) of cases. A previous study demonstrated that 351 (87.3%) cases

expressed either one or both of MLH1 and MSH2; MLH1 and MSH2 were not expressed in 35 (8.7%) and 19 (4.7%) cases, respectively; and 3 cases showed neither MLH1 nor MSH2 expression^[33].

Lanza *et al*^[28] found that 106 (80.3%) MSI-H carcinomas showed complete loss of MLH1 expression, 14 (10.6%) displayed complete loss of MSH2 expression, 12 (9.1%) MSI-H carcinomas demonstrated normal expression of both MLH1 and MSH2, but no MSI-H tumors showed lack of both MLH1 and MSH2 expression. In contrast, nuclear immunoreactivity for MLH1 and MSH2 proteins was observed in all MSS and MSI-L tumors analyzed^[28]. The common finding of all these studies is that MLH1 extinction is more frequent than MSH2 extinction. This supports the hypothesis that involvement of the MLH1 gene is prevalent in the development of sporadic large bowel MSI cancers.

In our study, unlike previous studies, MLH1-negative cases had no gender, age or tumor localization predominance. On the other hand, loss of MSH2 seemed to be related to some parameters more than loss of MLH1; for example, all MSH2-negative cases were women, 60% of them were located in the right colon and no serosal involvement was detected in MSH2-negative cases. Other interesting but statistically insignificant findings were both MLH1-negative/MSH-negative cases had peritumoral Crohn's-like lymphocytic infiltration and prominent intratumoral neutrophilic infiltration.

Although there was no statistical significance, 80% of MSH2-negative cases did not show perineural invasion, lymphatic invasion and blood vessel invasion. Bernardo *et al*^[36] found that only vascular invasion was significantly correlated with MSH2 expression. Similarly, Wright *et al*^[14] found that in MLH1- and MSH2-negative carcinomas, extramural vascular, lymphatic and perineural invasion were all significantly less than the others.

In our study, 72.4% of MLH1-negative and 80% of MSH2-negative cases were ≥ 50 years. Tumor size was ≥ 5 cm in 58.6% of MLH1-negative cases and 60% of MSH2-negative cases. But there was no significant correlation between these parameters. Lanza *et al*^[28] showed that MLH1- and MSH2-negative carcinomas were located in the proximal colon, more often of > 7 cm in diameter, poorly-differentiated, and had expanding pattern of growth and intense peritumoral Crohn's-like lymphoid reaction.

Several studies demonstrated that MSI tumors were correlated with clinicopathological features, such as right colon location, mucinous type, expansive borders, peritumoral Crohn's-like lymphoid reaction and peritumoral lymphoid response^[10,29,31,37]. A Japanese study of a series of colorectal carcinomas did not find any correlation between MSI status and any clinicopathological features except for tumor location in the proximal colon^[38].

The *p53* gene is mutated in 70% of colorectal carcinomas^[39]. Over-expression of *p53* has been used as an indicator of *p53* mutational status in many studies^[33]. In the present study, there was no significant difference between *p53* expression and MLH1 expression, whereas a significant correlation between low *p53* expression and loss of MSH2 expression was detected ($P < 0.05$).

Park *et al*^[33] demonstrated that there was a significant difference in *p53* expression between the MLH1-positive group and MLH1-deficient group, indicating a correlation of loss of MLH1 or MSH2 expression with low *p53* expression. We found that all MSH2-negative tumors showed low *p53* immunostaining. This finding supports that different carcinogenic pathways, different molecular changes and different genes can be affected. Thus, an inverse correlation between genetic alterations of *p53* and the mismatch repair system may simply reflect different carcinogenic pathways.

It has been reported that survival in patients with colorectal cancer with MMR gene defect is better than without one^[24,27]. In our study, loss of MLH1/MSH2 expression had no significant correlation with the survival. It has been clearly elucidated that tumor stage and lymph node metastasis are the independent prognostic factors for colorectal carcinomas. Hameed *et al*^[40] found similar results in their study. Chapusot *et al*^[41] found that three independent factors were significantly associated with the loss of expression of MLH1 and MSH2: proximal location, the presence of Crohn's-like lymphoid reaction and poor differentiation.

Interestingly, in our study overall survival of the cases with loss of only MLH1 or both MLH1 and MSH2 expression was longer than those with both MLH1- and MSH2-positive or with only MSH2-negative expression. Although this finding is not statistically significant ($P = 0.065$), we think that this analysis should be repeated and combined with the result of genetic analysis which will be planned for near future. This finding showed some similarities with other studies. Lanza *et al*^[28] found that cases with MLH1-negative carcinomas more often died of disease, but the survival of the cases was not statistically significant. However, Gafa *et al*^[37] found that cases with both MLH1- and MSH2-negative carcinoma showed a better clinical outcome and survival.

In conclusion, our findings suggest that the assessment of MSI status using immunohistochemistry is important in genetic and biologic characterization of colorectal carcinomas. Turkish patients with colorectal cancers show some similarities with other populations in terms of histopathological features and MSI status. Although prognostic importance remains controversial, immunohistochemical analysis of MMR genes may be used as routine histopathological examination of colorectal cancer tissues. However, genetic analysis should be combined with these results.

COMMENTS

Background

Human colorectal cancer (CRC) is one of the leading cancers in most countries. Understanding pathogenetic pathways in colorectal carcinogenesis is important for diagnosis and treatment of these patients. DNA mismatch repair (MMR) genes like MLH1 and MSH2 identify of MSI status of large bowel adenocarcinomas as microsatellite stable (MSS) or MSI. MMR deficiency leads to the accumulation of base-base mismatches and short insertion/deletion mispairs, generated as a consequence of DNA replication errors and homologous recombinations.

Research frontiers

Simply, microsatellite instability (MSI) tumors are seen more frequently in

hereditary polypsis colon cancers. Last studies showed that MSI was found also in sporadic CRC. So, searching MSI status of CRC is clinically important, since patients with carcinomas demonstrated several distinct features compared to MSS carcinomas. In this point immunohistochemistry is useful method since it is easy, cheap and reliable method to detect these patients.

Innovations and breakthroughs

This analysis was performed for the first time in Turkey. Loss of MLH1 and/or MSH2 expression is important finding to predict their different morphology and behaviour in CRC cases.

Applications

Searching MSI status of CRC should be performed more commonly. Immunohistochemical analysis of MSI status of CRC cases may be used as screening method in developing countries.

Peer review

This is the first study of MMR deficiency and its prognostic importance in sporadic CRCs in Turkish population, which makes it valuable. The study assessed the incidence of MLH1 and MSH2 expression losses in Turkish sporadic CRCs and the data was compared with survival and clinicopathological features of the patients.

Abstract

AIM: To investigate whether the pro- and anti-inflammatory cytokine gene polymorphisms, *IL1B*-511C/T, *IL1B*-31C/T, *IL6*-634C/G, *TNF*-1031T/C, *TNF*-857C/T, and *IL10*-1082A/G, interact with smoking and drinking habits to influence infection with *H. pylori*.

METHODS: The subjects were 410 Japanese transit company employees. C-reactive protein and conventional cardiovascular risk factors were evaluated. Serum anti-*H. pylori* antibodies were measured. The genotypes of *IL1B*-511C/T, *IL1B*-31C/T, *IL6*-634C/G, *TNF*-1031T/C, *TNF*-857C/T, and *IL10*-1082A/G polymorphisms were determined by allelic discrimination using fluorogenic probes and a 5' nuclease assay.

RESULTS: In gender- and age-adjusted logistic analyses, the subjects with *TNF*-857T/T had a significantly lower odds ratio (OR) for *H. pylori* seropositivity (reference -857C/C; OR = 0.15, 95% CI: 0.03-0.59, $P = 0.007$). After stratification according to smoking and drinking status, among never-smokers, the subjects with *IL1B*-511C/T had a significantly lower OR (reference -511C/C; OR = 0.30, 95% CI: 0.10-0.90, $P = 0.032$). Among drinkers in the 1-5 times/wk category, the subjects with *IL1B*-511T/T had a significantly lower OR (reference C/C; OR = 0.38, 95% CI: 0.16-0.95, $P = 0.039$), and the subjects with *IL1B*-31C/T and T/T had a significantly higher OR (reference C/C; C/T: OR = 2.59, 95% CI, $P = 0.042$; 1.04-6.47; C/C: OR = 3.17, 95% CI: 1.23-8.14, $P = 0.017$). Among current smokers, the subjects with

IL6-634C/G had a significantly higher OR (reference C/C; OR = 2.28, 95% CI: 1.13-4.58, $P = 0.021$). However, the interactions terms between the aforementioned genotypes and lifestyles were not statistically significant.

CONCLUSION: Contrary to previous findings, the results herein suggest that the *TNF*-857T/T genotype may be protective against chronic infection with *H. pylori*. Drinking and smoking habits may influence the effect of cytokine gene polymorphisms. Further studies are required to clarify the effects of the pro- and anti-inflammatory cytokine polymorphisms and gene-environmental interactions on *H. pylori* infection.

INTRODUCTION

The prevalence of *H. pylori* infection is generally higher in developing countries than in developed countries^[1]; however, the Japanese population has a high prevalence of *H. pylori* seropositivity^[2]. Infection with *H. pylori* represents a key factor in the etiology of various gastrointestinal diseases, including asymptomatic chronic active gastritis, peptic ulceration, gastric adenocarcinoma, and gastric mucosa-associated lymphoid tissue lymphoma^[3]. *H. pylori* has also been implicated in a number of extra-gastrointestinal disorders, such as atherosclerosis^[4], cerebral vascular disease^[5], idiopathic thrombocytopenic purpura^[6], and rosacea^[7]. Because of the greater prevalence and various pathogenic activities of *H. pylori* in Japanese, it is important to understand the basis for genetic susceptibility and identify the environmental factors that maintain chronic infection.

The mucosal production of pro-inflammatory cytokines, such as interleukin (IL)-1 β , IL6, and tumor necrosis factor (TNF)- α , appears to be enhanced by infection with *H. pylori*^[8,11]. Interleukin-1 β and TNF- α inhibit gastric acid secretion, providing a favorable condition for *H. pylori* to survive in the stomach^[12]. Although one study failed to show

inhibition of gastric acid secretion by IL-6^[13], several studies have shown that gastric colonization with *H. pylori* leads to elevated IL-6 levels in the gastric mucosa^[14,15]. Thus, IL-6 may be one of the factors that maintain chronic infection with *H. pylori*. Furthermore, IL-10, an anti-inflammatory cytokine, may reduce the inflammation associated with *H. pylori* infection^[16].

The host's ability to regulate cytokine production has been shown to be influenced by the presence of cytokine gene polymorphisms. Therefore, *H. pylori*-susceptible cytokine gene backgrounds have recently been investigated. Regarding the *IL1B* gene, Japanese subjects with the -31T/T genotype have a significantly higher odds ratio (OR) for *H. pylori* seropositivity as compared to subjects with the -31C/C or C/T genotypes^[17]. A strong relationship involving *IL1B* -31T/T has been demonstrated in Japanese Brazilians^[18]; however, such an association has not been shown to exist in Italians^[19] or Jamaicans^[20]. Regarding the *TNF* gene, Japanese subjects with the -1031C/C genotype have a significantly lower OR compared to those with the -1031T/T genotype^[21]; however, an association was not found in Italians^[19], Jamaicans^[20], or Japanese Brazilians^[22]. Thus, the effect *IL1B* and *TNF* polymorphisms on infection with *H. pylori* remains controversial. Furthermore, among Jamaicans, the *IL6*-634C/G polymorphism (denoted -572G/C) was not associated with *H. pylori* seropositivity^[20], and the *IL10*-1082C/G polymorphism was not associated with *H. pylori* infection among Jamaicans^[20] or Italians^[19]. Little is known regarding the effects of the *IL6* and *IL10* promoter polymorphisms on infection with *H. pylori*.

Smoking cigarettes and drinking alcohol may have an effect on chronic infection with *H. pylori*^[23,26]. Therefore, interactions between the genome and lifestyle factors should be elucidated. An interaction between the *IL1B* genotype and one's cigarette smoking status on the eradication of *H. pylori* has been reported^[27]. It has also been reported that the effect of the *IL1B*-31T/T genotype on *H. pylori* infection is modified by smoking cigarettes and drinking alcohol^[18,28], but the interactions between other cytokine gene polymorphisms and lifestyle factors on *H. pylori* infection have not been fully investigated.

The aim of this study was to investigate whether the pro- and anti-inflammatory cytokine gene polymorphisms, *IL1B*-511C/T, *IL1B*-31C/T, *IL6*-634C/G, *TNF*-1031T/C, *TNF*-857C/T, and *IL10*-1082A/G, interact with smoking cigarettes and drinking alcohol to influence infection with *H. pylori* in Japanese.

MATERIALS AND METHODS

Subjects

The subjects were transit company employees (1255 men and 94 women, 35-60 years of age), who had their annual health checkup between April 2003 and March 2004. We used a self-administered questionnaire that included items regarding clinical history, smoking cigarettes, and consumption of alcohol. The questionnaire was distributed to the subjects prior to their annual health checkup, and was collected at the time of the checkup. Answers to

the questionnaire and written informed consent to view pertinent health checkup data were obtained from 413 men and 5 women, for a response rate of 32.9% and 5.3%, respectively. Eight subjects were excluded due to inadequate blood samples. Ultimately, we analyzed a total of 410 employees (405 men and 5 women). No subject had a history of an internal malignancy or gastric surgery.

This study was conducted with written informed consent from all the subjects and approved by the institutional ethical board for epidemiological studies and human gene and genome studies of the Hokkaido University Graduate School of Medicine.

Data collection

Subjects were classified as current, never- or ex-smokers. Alcohol consumption habits were categorized as never/rarely, 1-5 times/wk, or 6-7 times/wk.

Blood samples were drawn from the antecubital vein of the subject after a 12 h fast while in a seated position and with minimal tourniquet use. The anti-*H. pylori* antibody titer was measured using an enzyme immunoassay (E plate; Eiken Chemical, Tokyo, Japan)^[29]; an assay value < 10 U/mL was considered negative and a value > 10 U/mL was considered positive.

Genomic DNA was extracted from each subject's peripheral blood lymphocytes using an EZ1 DNA blood kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions. We genotyped the *IL1B*-511C/T (dbSNP: rs16944), *IL1B*-31C/T (dbSNP: rs1143627), *IL6*-634C/G (rs1800796), *TNF*-1031T/C (dbSNP: rs1799964), *TNF*-857C/T (dbSNP: rs1799724), and *IL10*-1082A/G (dbSNP: rs1800896) polymorphisms by allelic discrimination using fluorogenic probes and the 5' nuclease (TaqMan) assay, as previously described^[30,31]. To detect a polymorphism in *IL6*-634C/G, the following MGB probes were prepared: a C allele-specific probe, 5'-FAM-CAACAGCCCCCTCACAG-MGB-3', and a G allele-specific probe, 5'-VIC-CAACAGCCGCTCACAG-MGB-3'. Each of the reporters was quenched with MGB, which was typically located at the 3' end. The primers for the PCR involving the promoter region, including the -634C/G polymorphism of *IL6*, were as follows: forward, 5'-GGATGGCCAGGCAGTTCTA-3', and reverse, 5'-CCAGTCATCTGAGTTCTTCTGTGTT-3'. The reaction mixture contained approximately 40 ng of template DNA, 5.0 µL of TaqMan Universal PCR master mixture, and 0.3 µL of 40 × assay mixture, in a volume of 10 µL. The *IL1B*-511C/T, *IL1B*-31C/T, *TNF*-1031T/C, *TNF*-857C/T, and *IL10*-1082A/G polymorphisms were similarly genotyped using the TaqMan[®] SNP genotyping products: C_1839943_10, C_1839944_10, C_7514871_10, C_11918223_10, and C_1747360_10, respectively (Applied Biosystems, Foster City, CA, USA). Real-time PCR was performed on a 7500 Real-time PCR System (Applied Biosystems) using a protocol consisting of incubation at 50°C for 2 min and 95°C for 10 min, followed by 50 cycles for *IL6* or 40 cycles for the other genotypes, denaturation at 92°C for 15 s, and annealing/extension at 60°C for 1 min. The FAM and VIC fluorescence levels of the PCR products were measured at 60°C for 1 min, resulting in the

clear identification of all six genotypes of *IL1B*, *IL6*, *TNF*, or *IL10* on a two-dimensional graph.

Statistical analysis

The differences in the frequency of each characteristic between the *H. pylori*-seropositive and -seronegative groups were examined by the chi-square test. Hardy-Weinberg equilibrium analyses were performed to compare the observed and expected genotype frequencies using the chi-square test. A logistic regression analysis was used to evaluate the associations between each cytokine genotype and *H. pylori* seropositivity, with adjustment for age and gender, to obtain the OR and 95% confidence intervals (CI). After stratification according to cigarette smoking and alcohol consumption status, the adjusted OR for each genotype of *H. pylori* seropositivity was calculated. The interaction term for the genotype/lifestyle factors was included in the logistic model with the main effect.

The haplotype was analyzed using Haploview, version 3.32^[32], and linkage disequilibrium between loci was measured using Lewontin's *D'*^[33]. The adjusted OR for the *IL1B* and *TNF* haplotypes was analyzed by logistic regression models. Statistical analyses were conducted with SPSS software for Windows, version 14.0 (SPSS; Chicago, IL, USA).

RESULTS

The characteristics of the groups according to *H. pylori* seropositivity are shown in Table 1. Two hundred thirty-seven subjects (57.8%) were *H. pylori*-seropositive. The *H. pylori*-seropositive group was older and drank alcohol more frequently than the *H. pylori*-seronegative group.

H. pylori seropositivity, according to the genotypes of *IL1B*, *IL-6*, *TNF*, and *IL-10*, are shown in Table 2. The distribution of genotypes in each group was in the Hardy-Weinberg equilibrium. *TNF*-857C/T genotypes were significantly different between the *H. pylori*-seropositive and -seronegative subjects.

¹*H pylori* seropositivity (%).

alcohol consumption status, the age- and gender-adjusted ORs of *IL1B* and *IL-6* genotypes for *H pylori* seropositivity are shown in Table 4. Among never-smokers, subjects with *IL1B*-511C/T had a significantly lower OR for *H pylori* seropositivity (reference -511C/C; OR = 0.30, 95% CI: 0.10-0.90). Among the 1-5 times/wk drinkers, *IL1B*-511T/T had a significantly lower OR (reference C/C; OR = 0.38, 95% CI: 0.16-0.95), and *IL1B*-31C/T and -T/T had significantly higher ORs (reference C/C; C/T: OR = 2.59, 95% CI: 1.04-6.47; C/C: OR = 3.17, 95% CI: 1.23-8.14). Among current smokers, *IL6*-634C/G had a significantly higher OR (reference C/C; OR = 2.28, 95% CI: 1.13-4.58); however, the interaction terms between the aforementioned genotypes and lifestyles were not statistically significant. The remaining genotypes revealed no statistically significant ORs after stratification (data not shown).

Complete linkage disequilibrium existed between the two *IL1B* promoter lesions ($D' = 1$, $r^2 = 0.048$) and strong linkage disequilibrium existed between the two *TNF* promoter lesions ($D' = 0.953$). The estimated haplotype frequency of *TNF* (-1031T/C and -857C/T) was as follows: TC = 64.1%, CC = 18.9%, TT = 17.0%, and CT = 0%. The estimated haplotype frequency of *IL1B* (-511C/T and -31C/T) was as follows: CT = 58.9%, TC = 38.3%, TT = 1.7%, and CC = 1.1%.

The adjusted ORs of the combination of the two

¹*H pylori* seropositivity (%). ²Each reference group represented all the other combinations of genotypes. ³ORs of the groups with < 7 subjects were not analyzed: CT/TT = 4, TT/TT = 4, CC/CT = 6, TT/CC = 2, and CT/CC = 3.

IL1B promoter genotypes and the *TNF* genotypes for *H pylori* seropositivity are shown in Table 5. The subjects with *TNF*-1031T/T and -857T/T had significantly lower ORs for *H pylori* seropositivity (reference, all the remaining combinations of genotypes; OR = 0.15, 95% CI: 0.04-0.60); however, subjects with *TNF*-1031T/T and -857T/T were similar to the subjects with -857T/T.

DISCUSSION

In the current study, the *TNF*-857T/T genotype had a significantly reduced OR for *H. pylori* seropositivity. Because the subjects with both *TNF*-1031T/T and -857T/T genotypes were similar to the subject who was classified with the *TNF*-857T/T genotype only, the combination of genotypes also had a reduced OR.

It has been reported that Japanese subjects with the -1031C/C genotype have a significantly lower OR for *H. pylori* infection when compared to those with the -1031T/T genotype, and that subjects with -857T/T and -1031T/T have significantly higher ORs for *H. pylori* infection when compared to those with -1031C/C and -857C/C^[21]. However, neither -1031T/C nor -857C/T polymorphisms were associated with *H. pylori* infection in Italians^[19] or Jamaicans^[20], and neither the genotypes nor the combination of genotypes were associated with Japanese Brazilians^[22]. The genotype distributions of -1031T/C and -857C/T among the aforementioned Japanese subjects were quite similar to the distributions in the subjects enrolled in our study. However, the subjects between the studies differed as follows: (1) our subjects were younger than in the previously published study, (2) nearly all of our subjects were male, while approximately one-half of the previous study subjects were female, and (3) our study subjects were healthy workers, unlike the subjects in the previous study that included outpatients participating in a *H. pylori* eradication program, outpatients with chronic diseases, as well as health checkup examinees; these differences may have been the basis for the discrepant results. Further studies are needed to elucidate age and sex specific effects of *TNF*-857C/T polymorphism on *H. pylori* infection.

In the current study, the subjects with the *TNF*-857T/T genotype had the highest level of *TNF*- α secretion, resulting in low gastric acid secretion, and they were resistant to chronic *H. pylori* infection. Higuchi *et al.*^[34] reported that the level of *TNF*- α and the transcription promoter activity produced by concanavalin A-activated peripheral blood mononuclear cells in subjects with -1031C or -857T alleles were higher than in those subjects with the -1031T or -857C alleles. Skoog *et al.*^[35] reported that subjects with -863A tightly linked with -1031C had a significantly lower serum *TNF*- α level. Moreover, in another study it was shown that *ex vivo* lipopolysaccharide-stimulated whole-blood *TNF* production was higher in healthy *TNF*-857C homozygotes^[34]. Thus, further studies will be needed to clarify the effect of the *TNF* genotype on susceptibility to infection with *H. pylori* and production of *TNF*- α .

The *TNF* gene has more than three relatively frequent bi-allelic single-nucleotide polymorphisms in the promoter region: -863C/A, -308G/A, and -238G/A^[35]. It has been reported that the *TNF*-308A allele is highly associated with *H. pylori* infection in Italy^[19], but the -308A allele is rare in Japan, and the other major allele, -238A, is also rare in Japan (1.7% and 2.0%, respectively)^[35]. Moreover, the -863C/A allele is tightly linked with -1031C/T^[36]. Therefore, we investigated the two promoter region polymorphisms of *TNF*. However, since the *TNF*-857 T/T

genotype is not frequent in the population, simple and easy methods for genotyping are required for practical use.

The two *IL1B* promoter genotypes were not associated with *H. pylori* infection in our entire group of subjects. In like manner, no association was found in Italians^[19] or Jamaicans^[20]. However, a previous Japanese study showed that subjects with the -31T/T genotype had a significantly higher OR (1.74, 95% CI: 1.15-5.63) for *H. pylori* infection as compared to those subjects with the -31C/T or -31CC genotypes^[17]. Furthermore, a study of Japanese Brazilian subjects found an association (OR of T/T = 1.45, 95% CI: 1.02-2.07)^[28]. The subjects in the two previous studies involved an adequate number of female subjects and the Japanese study subjects were older than our study subjects. These differences may have accounted for our inability to obtain statistically significant results. In addition, the sample size of the previous Japanese study was nearly the same as that of our study ($n = 437$), but the sample size of the Japanese Brazilian study was almost twice as large as that of our study ($n = 963$). If a real OR of the T/T genotype was approximately 1.5, a smaller sample size as in our study may have failed to reach statistical significance.

Smoking cigarettes and drinking alcohol augment the T/T genotype effect on *H. pylori* infection^[18,28]. In our study, 1-5 times/week drinkers with T/C and T/T genotypes had significant ORs. In previous studies, the subjects were divided into drinkers or non-drinkers^[18,28] and the pattern of drinking enhanced the T/T genotype effect on chronic *H. pylori* infection. The drinkers in the previous study involved moderate and heavy consumption of alcohol, but the difference in T/T genotype augmentation between moderate and heavy consumption of alcohol was not analyzed. In our study, the results suggested that moderate drinking enhanced the T/T genotype effect on chronic *H. pylori* infection. Therefore, further studies are needed to elucidate the interactions between the volume of alcohol consumption and genotypes on *H. pylori* infection.

In our study, 1-5times/wk drinkers with the -511T/T genotype had a significantly lower OR since -31C and -511T were tightly linked (-511T/C and -31C/T combinations: 59.8% for T-C, 1.7% for T-T, 38.3% for C-T, and 1.1% for C-C). Non-smokers with -511C/T had a significantly lower OR. Chance may have influenced the significance of the result. Moreover, because this study was cross-sectional, changes in cigarette smoking and alcohol consumption habits were not involved in the analyses. Thus, the changes from previous habits may have affected the ORs.

Lipopolysaccharide (LPS)-stimulated *IL*-1 β expression by whole blood leukocytes *in vitro* was lower in subjects with -31T and -511C^[37,38]. Since *IL*-1 β inhibits gastric acid secretion, thereby providing a favorable environment for *H. pylori* to survive in the stomach^[12], the results of the previous Japanese study and the moderate drinkers of our study were compatible to the *in vitro* *IL*-1 β expression studies.

The *IL*6-634C/G (denoted -572G/C in reference 20) polymorphism was not associated with *H. pylori* seropositivity among Jamaicans^[20]. In our study, the polymorphism was also not associated with *H. pylori* seropositivity among our entire group of subjects. However, current smokers with

the -634C/G genotype had a significantly higher OR for *H pylori* infection.

Persons with the C allele of the *IL6*-174G/C polymorphism are common among Caucasians, but extremely rare among East Asians^[39,40]. However, persons with the G allele of the *IL6*-634C/G polymorphism are common among East Asians, and this genotype significantly relates to recurrent pregnancy loss^[39], bone mineral density^[41], and diabetic nephropathy^[42]. Additionally, the -634G allele is associated with an elevated production and secretion of IL-6 by peripheral blood mononuclear cells *in vitro*^[42].

In a study of young and healthy Caucasians, the *IL6*-174 polymorphism was not associated with the *IL6*-174 genotypes in non-smokers, but in smokers where the -174C allele was associated with a higher number of leukocytes, lymphocytes, and monocytes^[43]. In our study, the smokers with the -634G/G genotype had no significant results, perhaps because of a smaller sample size. In contrast, we found that the impact of the -634G allele on CRP elevation was greater in non-smokers than in current smokers (in press at *Hypertens Res*). Thus, the effect of *IL6* gene polymorphisms and the gene-environment interactions on *H pylori* infection should also be further elucidated.

In our study, the *IL10*-1082C/G polymorphism was not associated with *H pylori* infection. As previously mentioned, negative results were reported for Jamaicans^[20] and Italians^[19]. Other *IL10* promoter polymorphisms, such as -819C/T and -592C/A, have been reported^[19] and a Japanese study showed that the combination of the *IL8*-251T/A and *IL10*-819C/T polymorphisms was significantly associated with *H pylori* infection, but the *IL10*-819C/T polymorphism alone did not have a statistically significant effect^[44]. Furthermore, associations between *IL10*-1013A/A^[45] and -819C/T^[16] genotypes on non-cardia gastric cancer were reported. An experiment in mice showed that increased IL-10 levels may reduce the inflammation of *H pylori* infection^[16]. Unfortunately, we did not evaluate other *IL10* promoter polymorphisms or the *IL8*-251T/A polymorphism; further studies are required to clarify how these polymorphisms effect *H pylori* infection.

Because this study examined IgG antibodies to *H pylori*, which can reflect a previous infection, IgG seropositivity to *H pylori* may not reflect active infection. However, the relative sensitivity, specificity, and rates of agreement between the results obtained using the enzyme immunoassay employed in the present study (i.e., the E plate) and those obtained by the culture/rapid urease test have been reported to be 100%, 80.0%, and 97.1%, respectively^[29]. Strains isolated from Japanese gastric ulcer patients were used as antigens to prepare the E plate. Thus, this serological method to detect *H pylori* infection in Japanese is a suitable method for this type of genotype-associated study.

In summary, we observed the *TNF*-857T/T genotype significantly reduced the OR for *H pylori* seropositivity. Because the ORs for the subjects with both *TNF*-1031T/T and -857T/T genotypes were the same as the subject who was classified with the *TN*-857T/T genotype alone, the combination of genotypes also revealed a reduction in the

OR. In the entire group of subjects analyzed, the promoter region polymorphisms of *IL1B*, *IL6*, and *IL-10* had no association with *H pylori* infection. After stratification according to cigarette smoking and alcohol consumption, never-smokers with the *IL1B*-511C/T genotype and 1-5 times/week drinkers with the *IL1B*-511T/T, *IL1B*-31C/T, and -31T/T genotypes, had a significant association with *H pylori* infection. Among current smokers, the *IL6*-634C/G genotype also had a significant association. However, interactions terms between the aforementioned genotypes and lifestyles were not statistically significant. Further studies are required to clarify the effects of the pro- and anti-inflammatory cytokine polymorphisms and the gene-environment interactions on *H pylori* infection.

Abstract

AIM: To establish the therapeutic potential of proteasome inhibition, we examined the therapeutic effects of MG132 (Z-Leu-Leu-Leu-aldehyde) in an experimental model of acute pancreatitis.

METHODS: Pancreatitis was induced in rats by two hourly intraperitoneal (ip) injections of cholecystokinin octapeptide (CCK; 2 x 100 μ g/kg) and the proteasome inhibitor MG132 (10 mg/kg ip) was administered 30 min after the second CCK injection. Animals were sacrificed 4 h after the first injection of CCK.

RESULTS: Administering the proteasome inhibitor MG132 (at a dose of 10 mg/kg, ip) 90 min after the onset of pancreatic inflammation induced the expression of cell-protective 72 kDa heat shock protein (HSP72) and decreased DNA-binding of nuclear factor- κ B (NF- κ B). Furthermore MG132 treatment resulted in milder inflammatory response and cellular damage, as revealed by improved laboratory and histological parameters of pancreatitis and associated oxidative stress.

CONCLUSION: Our findings suggest that proteasome inhibition might be beneficial not only for the prevention, but also for the therapy of acute pancreatitis.

INTRODUCTION

Proteasome inhibition is an emerging strategy to attenuate the inflammatory response^[1]. Inhibiting the proteasome blocks nuclear factor- κ B (NF- κ B) activation by detaining proteolysis of its inhibitory subunit, the I κ B. Preventing NF- κ B activation then decreases NF- κ B dependent proinflammatory gene expression, resulting in reduced inflammatory response. However studies also reveal that NF- κ B, one of the major initiators of pro-inflammatory pathways, has anti-inflammatory roles in the resolution of inflammation. Thus inhibiting NF- κ B during the resolution of inflammation has been shown to protract the inflammatory response *in vivo*^[2].

Acute pancreatitis is a severe inflammatory disease characterized by intrapancreatic activation of digestive enzyme zymogens that leads to acinar cell injury and subsequent inflammatory response^[3-5]. The inflammatory response is first localized only to the pancreas, but due to the release of inflammatory mediators, later overspreads and becomes systematic affecting other organs including the lung and kidney. This exacerbation of pancreatitis results in multiple organ failure and systemic inflammatory response syndrome that is responsible for the mortality of acute pancreatitis. There have been many experimental attempts for the treatment of acute pancreatitis, however most failed to succeed in the clinics^[6,7]. This might stem from the fact that many studies aim to examine only the prophylactic effects of compounds. One thing is clear however, the therapeutic potential of a compound in acute pancreatitis can only be established if it is given after onset of the disease^[8,9]. In our previous study the peptide aldehyde proteasome inhibitor MG132 prevented the development of pancreatic inflammation when administered

before the induction of the disease^[10]. In order to estimate the clinical potential of proteasome inhibition, we also had to examine the therapeutic effects of the compound administered after the onset of pancreatitis. Given the NF- κ B inhibitory effects of MG132, it was also crucial to determine whether NF- κ B inhibition with MG132 after the onset of pancreatic inflammation might worsen or ameliorate pancreatitis.

The following paper will summarize the observed effects of therapeutic administration of MG132 in this experimental model of acute pancreatitis and suggest that proteasome inhibition might be beneficial for the therapy of the disease.

MATERIALS AND METHODS

Experimental protocol

For the *in vivo* studies male Wistar rats (provided by the Animal Center of the University of Szeged) weighing 250–300 g were used. The animals were kept at constant room temperature with a 12-h light-dark cycle, and were allowed free access to water and standard laboratory chow (Biofarm, Zagyvaszántó, Hungary). Animal experiments performed in this study were approved by the Animal Care Committee of the University and complied with the European Communities Council Directive of 24 November 1986 (86/609/EEC). In each experimental group eight rats were used ($n = 8$). Acute pancreatitis was induced by injecting 100 μ g/kg of CCK (synthesized in the Department of Medical Chemistry, Szeged, Hungary as described by Penke *et al.*^[11]; dissolved in physiological saline) twice with an interval of 1 h (Figure 1). Ninety minutes after the first CCK injection, the animals were injected intraperitoneally (ip) either with 10 mg/kg of MG132 [Z-Leu-Leu-Leu-aldehyde; Sigma; dissolved in 0.25 mL dimethyl sulfoxide (DMSO)] or with an equal volume of DMSO (Sigma) alone. Controls received physiological saline (PS) and DMSO in the same manner. Four hours after the first CCK or saline injections, the animals were anesthetized (with pentobarbital sodium 50 mg/kg, ip) and killed by exsanguination through the abdominal aorta. Pancreases and lungs were quickly removed, the former were cleaned of fat and lymph nodes, weighed, frozen in liquid nitrogen and stored at -80°C until use.

Procedures

Nuclear protein extraction: Nuclear protein extracts were prepared as described previously^[12].

Electrophoretic mobility shift assay (EMSA) of NF- κ B: EMSA of NF- κ B was carried out as described previously^[12,13].

Western blotting: Western blot analysis of pancreatic heat shock protein 72 (HSP72) and I κ B α was performed as described by Rakonczay *et al.*^[12,14]. α -tubulin was used as a loading control.

Serum amylase activity assay: The pancreatic weight/body weight ratio was utilized to evaluate the degree of pancreatic edema. To measure the serum amylase activities,

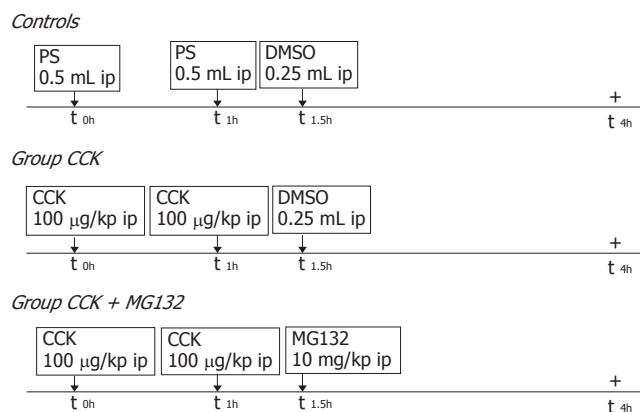

Figure 1 Experimental protocol of acute pancreatitis.

all blood samples were centrifuged at $2500 \times g$ for 20 min. The serum levels of amylase were determined by a colorimetric kinetic method (Dialab, Vienna, Austria).

Pancreatic tumor necrosis factor- α and interleukin-6 levels: Tumor necrosis factor- α (TNF- α) and interleukin-6 (IL-6) concentrations were measured in the pancreatic cytosolic fractions with ELISA kits (Bender Medsystems, Vienna, Austria) according to the manufacturers' instructions.

Pancreatic and lung myeloperoxidase activity: Pancreatic and lung myeloperoxidase (MPO) activity, as a marker of tissue leukocyte infiltration, was assessed by the method of Kuebler *et al.*^[15].

Real time quantitative polymerase chain reaction (RT-qPCR): RT-qPCR was performed on a RotorGene 3000 instrument (Corbett Research, Australia) with gene-specific primers (designed with the software PrimerExpress, Applied Biosystems, USA) and SYBRGreen I protocol as described previously^[10]. Relative expression ratios were normalized to cyclophilin and calculated with the Pfaffl method^[16]. The PCR primers used were as follows: cyclophilin, forward primer, 5'-TCTCTTCAAGGGACAAGGCTG-3', reverse primer, 5'-TGGCAAATCGGCTGACG-3'; pancreatitis-associated protein (PAP), forward primer, 5'-CCTCTGCACGCATTAGTTGC-3', reverse primer, 5'-TGAAACAGGGCATAGCAGTAGG-3'.

Lipid peroxidation, reduced glutathione levels and activities of superoxide dismutase and catalase: Lipid peroxides may undergo metal- or enzyme-catalyzed decomposition to form multiple products, including malondialdehyde (MDA). Pancreatic MDA levels were measured according to the MDA/TBA-high performance liquid chromatographic (HPLC) method of Wong *et al.*^[17] and were corrected for the protein content of the pancreas. Reduced glutathione (GSH) levels were determined spectrophotometrically with Ellman's reagent^[18]. Pancreatic total superoxide dismutase (SOD) activity was determined on the basis of the inhibition of epinephrine-adrenochrome autoxidation^[19].

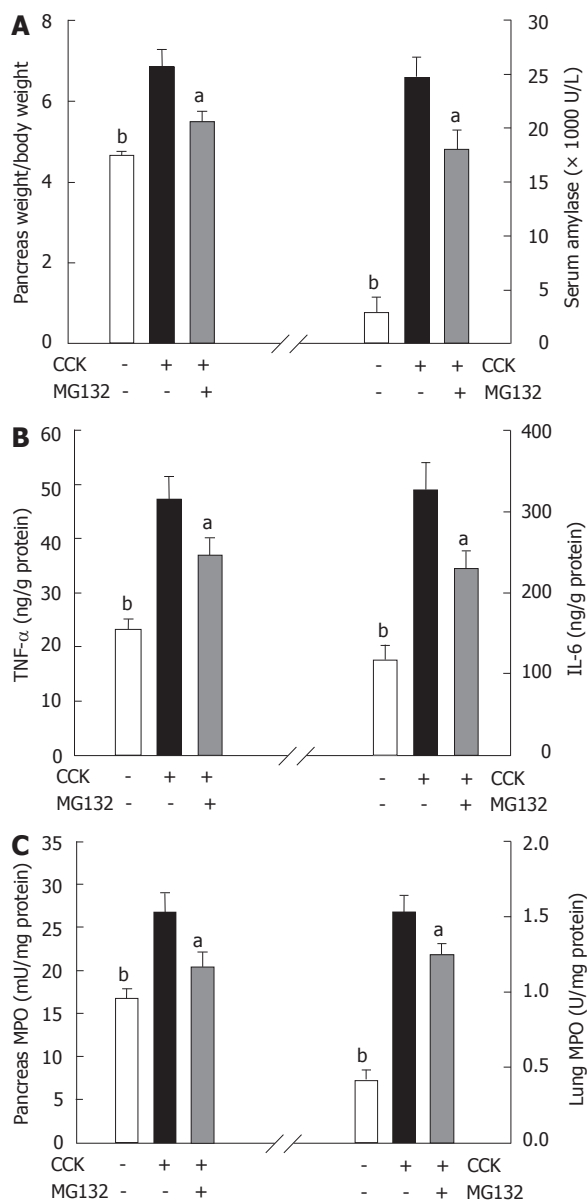

Figure 2 Effects of MG132 on laboratory parameters of acute pancreatitis. ^a $P < 0.05$; ^b $P < 0.01$.

Ferric reducing ability of plasma (FRAP): The total antioxidant activity of the plasma was determined with the method of Benzie and Strain^[20]. Ferric to ferrous ion reduction in a complex with tripyridyl-triazine - at low pH causes the development of an intense blue color, which has an absorption maximum at 593 nm. FRAP values are obtained by preparing a calibration curve with a solution of known Fe (II) concentration.

Histological evaluation of CCK-induced acute pancreatitis

A portion of the pancreas was fixed in 8% neutral formaldehyde solution and subsequently embedded in paraffin. Sections were cut at 4 μ m thicknesses and stained with hematoxylin and eosin (HE). The slides were coded and read for the traditional histological markers of pancreatic tissue injury by two independent observers who were blind to the experimental protocol. Semiquantitative grading of intestinal edema, inflammation, hemorrhage, vacuolization

and acinar cell necrosis was performed on a scale of 0 to 3 (0-absent, 1-mild, 2-moderate, 3-severe).

Statistical analysis

Results were expressed as mean \pm SD. Differences between experimental groups were evaluated by using analysis of variance (ANOVA). Values of $P < 0.05$ were accepted as significant.

RESULTS

Pancreatic weight/body weight ratio and serum amylase activity

Injecting 2×100 μ g/kg body weight of CCK resulted in elevated serum amylase levels and pancreatic weight/body weight ratio, signs of acinar injury and pancreatic inflammation^[21,22]. These actions of CCK were interfered by MG132 treatment (Figure 2A).

Intrapancreatic proinflammatory cytokine levels

Inflammatory mediators, like TNF and IL-6 couple the local pancreatic inflammation with systemic complications such as pancreatitis-associated lung and renal injury^[23,24]. In our study CCK significantly increased the expression of TNF and IL-6 in the pancreas compared to controls. MG132 treatment reduced intrapancreatic TNF and IL-6 levels (although, compared to Group CCK, the effect of MG132 on pancreatic TNF levels were not statistically significant, as shown in Figure 2B).

Pancreatic and lung myeloperoxidase activity

Neutrophils produce an enzyme called myeloperoxidase that can be used to identify the amount of neutrophils infiltrating a tissue after inflammation^[25]. CCK hyperstimulation increased MPO activity in both the pancreas and lung, reflecting the elevated levels of neutrophil infiltration within these organs. Proteasome inhibition with MG132 decreased MPO activity in the lung and pancreas (Figure 2C).

Expression of pancreatitis-associated protein

Pancreatitis-associated protein (PAP), the acute-phase protein of the pancreas, is overexpressed in acute pancreatitis^[26]. Supramaximal CCK doses significantly increased the expression of PAP mRNA. MG132 treatment could interfere markedly with this effect of CCK (Figure 3).

Parameters of oxidative stress

Two hourly injections of CCK induced pancreatic inflammation and underlying oxidative stress. Thus, the ferric reducing ability of plasma (FRAP), as an index of total antioxidant capacity was reduced four hours after the induction of pancreatitis. Moreover CCK stimulation depleted SOD activity and GSH, the two important antioxidant defense systems and increased malondialdehyde content (the marker of lipid peroxidation) in the pancreas. MG132 treatment inhibited the production of reactive oxygen species due to CCK hyperstimulation, as judged by the improvements of above mentioned laboratory parameters of antioxidant power and oxidative stress (Figure 4A and B).

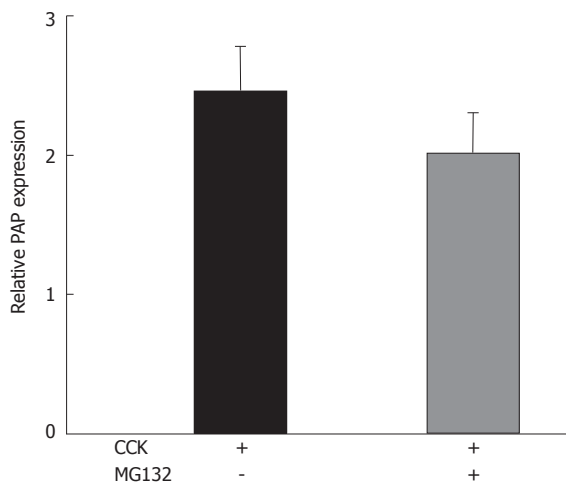

Figure 3 Effect of MG132 on mRNA expression of pancreatitis associated protein (PAP) in experimental acute pancreatitis.

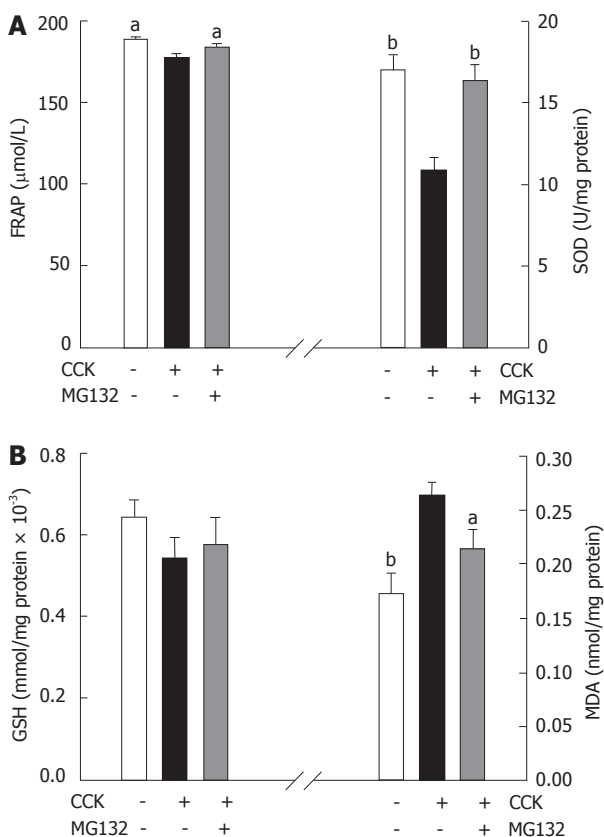

Figure 4 Effects of MG132 on measures of oxidative stress in experimental acute pancreatitis. ^a $P < 0.05$; ^b $P < 0.01$.

Pancreatic heat shock protein 72 (HSP72) levels

Induction of heat-shock proteins is a useful tool to increase cellular tolerance against stress^[27,28]. Injections of CCK elevated the levels of pancreatic HSP72 four hours after the first CCK injection. MG132, the well-known inducer of heat-shock proteins, further increased the expression of HSP72 in the pancreas (Figure 5A and B).

Pancreatic NF- κ B activation

In the pancreas, supramaximal doses of CCK triggered the

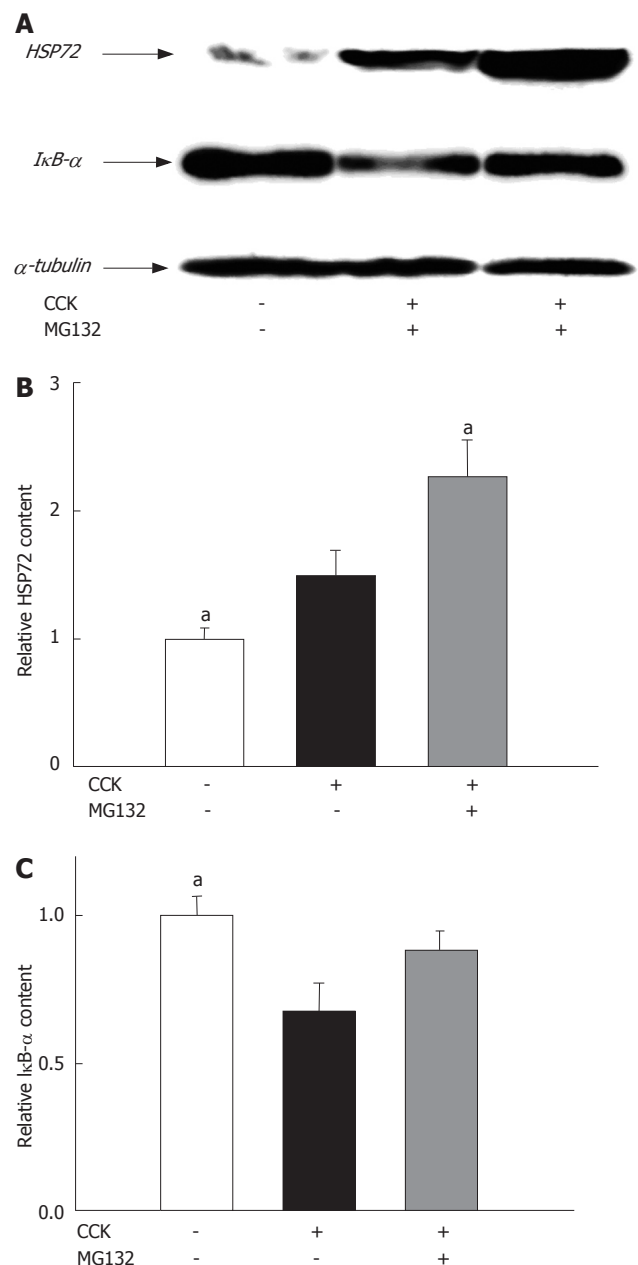

Figure 5 Effects of MG132 on HSP72 expression and IκB degradation in experimental acute pancreatitis. ^a $P < 0.05$.

degradation of IκB α and subsequent activation of NF- κ B, based on Western blots and EMSAs carried out on pancreatic samples of animals involved in our study. Inhibiting the proteasome decreased IκB α degradation (Figure 5A and C) and DNA-binding of NF- κ B (Figure 6A and B) (The effects of MG132 on IκB α degradation were not significant statistically).

Histological findings

CCK hyperstimulation resulted in cytoplasmic vacuolization and death of acinar cells, edema formation, and infiltration of inflammatory cells in the pancreas samples of CCK-treated animals (Figure 7A). Treating the animals with the proteasome inhibitor MG132 inhibited the cellular damage and inflammatory response due to CCK, as reflected by milder histopathological changes in the pancreas (Figure 7B).

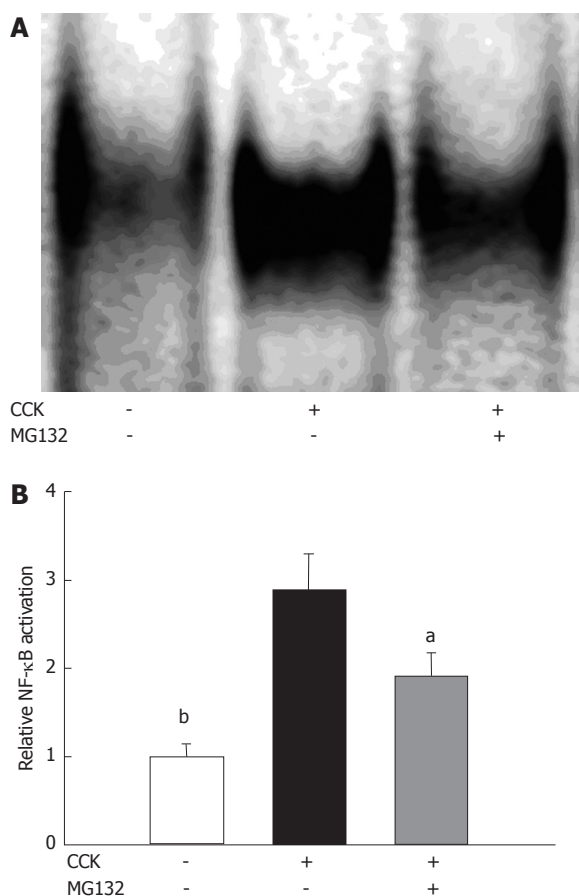

Figure 6 Effect of MG132 on NF- κ B activation in experimental acute pancreatitis. ^a $P < 0.05$; ^b $P < 0.01$.

DISCUSSION

Acute pancreatitis is a severe inflammatory disease triggered by abnormal activation of intrapancreatic proteases and enhanced transcriptional activity of stress-responsive transcriptional factors like NF- κ B^[3-5]. Intrapaneatic activation of digestive enzyme zymogens can be prevented by the inhibition of lysosomal hydrolases like cathepsin B^[29-31]. NF- κ B activation can also be prevented by inhibiting the proteasome and other proteases (like calpains) that degrade the inhibitory I κ B subunit^[32-35]. MG132 is a peptide aldehyde proteasome inhibitor with a broad inhibitory range, showing selectivity towards both serine and cysteine proteases including cathepsins and calpains^[1,36]. To make it more complex, MG132 has the ability to induce heat shock proteins (including HSP72), which increases cellular tolerance to stress^[37,38].

In our earlier study we have shown that pretreatment of rats with MG132 protected against acute pancreatitis by preventing NF- κ B activation and inducing the expression of HSP72^[10]. However the therapeutic value of prophylactic treatment in acute pancreatitis is indeed very doubtful. In order to validate the therapeutic potential of proteasome inhibition in pancreatitis, we also tested the effects of therapeutic administration of MG132 in an experimental model of the disease. Pancreatitis was induced by two hourly injections of the cholecystokinin octapeptide (CCK). In this model of the disease, CCK hyperstimulation resulted in pancreatic inflammation characterized by intracellular activation of digestive enzymes and elevation of their serum levels, cytoplasmic vacuolization and death

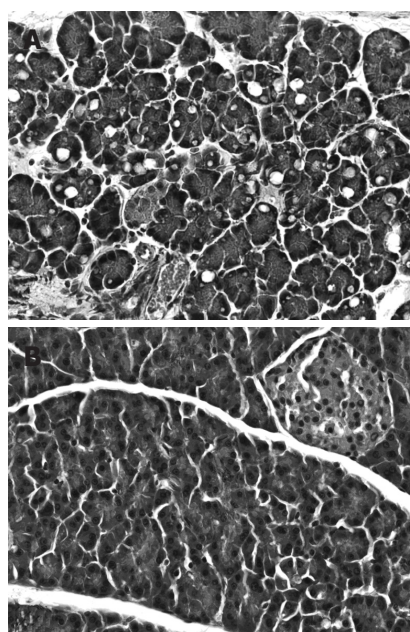

Figure 7 Effect of MG132 on pancreatic morphological damage in CCK-induced pancreatitis (HE, x40).

of acinar cells, edema formation, infiltration of inflammatory cells and oxidative stress. Thus severity of pancreatitis could be very accurately detected by monitoring the laboratory parameters of the disease.

Administering MG132 90 min after the onset of pancreatic inflammation could still ameliorate the severity of the disease. So MG132 treatment could decrease cellular damage, inflammation and subsequent oxidative stress associated with pancreatitis. These beneficial effects of MG132 can be explained by its ability to induce the expression of HSP72 that protects cells against stressful conditions. MG132 also decreased the transcriptional activity of NF- κ B. NF- κ B, however, has a dual role in inflammatory diseases, because besides triggering proinflammatory cellular events during first phase of the inflammatory response, it has also anti-inflammatory role during the resolution of inflammation^[2]. In CCK-induced pancreatitis, NF- κ B activation peaks in the first phase of the disease^[39]. Since in MG132 treatment had more pronounced effects on HSP72 than on NF- κ B, thus it is likely that in our case the induction of heat shock proteins made larger contribution to the observed beneficial effects of MG132 in acute pancreatitis and than NF- κ B inhibition.

Our observation that MG132 could ameliorate the severity of acute pancreatitis when administered 90 min after the induction of the disease is indeed very promising. Considering this, we have to note that although supramaximally stimulating doses of CCK cause the inflammatory response that underlies many of the features of human pancreatitis, still CCK-induced pancreatitis is a mild model of the disease^[40]. Thus MG132 and other proteasome inhibitors should be further tested in other, more severe models of pancreatitis in order to accurately determine the clinical potential of proteasome inhibition for the treatment of acute pancreatitis.

Abstract

AIM: To investigate the antiproliferative effect of the histone deacetylase (HDAC) inhibitor MS-275 on cholangiocarcinoma cells alone and in combination with conventional cytostatic drugs (gemcitabine or doxorubicin) or the novel anticancer agents sorafenib or bortezomib.

METHODS: Two human bile duct adenocarcinoma cell lines (EGI-1 and TFK-1) were studied. Crystal violet staining was used for detection of cell number changes. Cytotoxicity was determined by measuring the release of the cytoplasmic enzyme lactate dehydrogenase (LDH). Apoptosis was determined by measuring the enzyme activity of caspase-3. Cell cycle status reflected by the DNA content was detected by flow cytometry.

RESULTS: MS-275 treatment potently inhibited the proliferation of EGI-1 and TFK-1 cholangiocarcinoma cells by inducing apoptosis and cell cycle arrest. MS-275-induced apoptosis was characterized by activation of caspase-3, up-regulation of Bax and down-regulation of Bcl-2. Cell cycle was predominantly arrested at the G₁/S checkpoint, which was associated with induction of the cyclin-dependent kinase inhibitor p21^{Waf/CIP1}. Furthermore, additive anti-neoplastic effects were observed when MS-275 treatment was combined with gemcitabine or doxorubicin, while combination with the multi-kinase inhibitor sorafenib or the proteasome inhibitor bortezomib resulted in overadditive anti-neoplastic effects.

INTRODUCTION

Cholangiocarcinoma (CC) accounts for 3% of all gastrointestinal cancers^[1] and is the second commonest primary hepatic tumor^[1,2]. It is characterized by the malignant proliferation of cholangiocytes that line intra-hepatic and extra-hepatic bile ducts and ductules. Biliary tumors are highly malignant and have a poor prognosis^[3]. The incidence of intra-hepatic CC is rising in North America, Australia and Asia^[2,4,5]. In addition to the well described risk factors, such as primary sclerosing cholangitis, liver fluke infestations or hepatolithiasis^[6], recent studies suggest that chronic hepatitis B and C infections, HIV, non-alcoholic steatohepatitis, especially when combined with cirrhosis, also contribute to intra-hepatic CC risk^[7]. On the other hand, the incidence of extra-hepatic CC is declining^[2,4,5,8] most likely as a result of increasing rates of cholecystectomy over the past decades^[2,5].

Treatment options for cholangiocarcinoma are limited. Unfortunately, the majority of patients suffer from advanced CC at presentation. Therefore, curative surgical resection or liver transplantation can only be offered to a minority of CC patients, leaving biliary drainage, radiotherapy or conventional chemotherapy as unsatisfactory palliative treatment options for advanced CC^[6], with marginal effect on survival or quality of life^[9].

Histone deacetylase (HDAC) inhibitors receive growing interest as cancer therapeutics due to their

ability to induce cell differentiation, growth arrest and apoptosis^[10]. Acetylation and deacetylation of histones play an important role in the regulation of gene transcription and in the modulation of chromatin structure^[11,12]. The steady state of histone acetylation is tightly controlled by antagonistic effects of histone acetyltransferases (HAT) and HDAC. Aberrant gene expression resulting in functional inactivation of HAT activity or over-expression of HDAC can promote tumor cell proliferation and survival^[13]. Moreover, deregulation of HDAC recruitment to transcriptional promoters is a mechanism by which these enzymes contribute to tumorigenesis^[14].

HDAC inhibitor monotherapy can inhibit the growth of various tumors *in vitro* and *in vivo*^[11,15,17]. Importantly, HDAC inhibitors are relatively non-toxic to non-transformed cells^[18,19], leading to their evaluation in phase I / II clinical cancer trials^[14,15,20].

The synthetic orally available HDAC inhibitor, MS-275, potently inhibits histone deacetylases of several human tumor cells^[21]. With a benzamide backbone, MS-275 is structurally unrelated to previous HDAC inhibitors, while showing a 30-fold stronger HDAC inhibitory activity than other natural HDAC inhibitors like sodium butyrate^[22]. Recently, we and others demonstrated strong anti-proliferative activity of MS-275 towards several human cancer cells *in vitro* and *in vivo*^[21,23,24]. MS-275 has now entered clinical trials both for single and combination therapy in solid and haematological malignancies. Since HDAC inhibition has not yet been evaluated for its anti-neoplastic effects on cholangiocarcinoma, we characterized the anti-neoplastic potency of the HDAC inhibitor MS-275 in human CC cells. We showed that MS-275 potently inhibited growth of CC cells, especially in combination with conventional cytostatic drugs or new, targeted anticancer agents, such as sorafenib (NexavarTM) or bortezomib (VelcadeTM). Furthermore, we provided an insight into major underlying mechanisms of MS-275-induced growth inhibition of CC cells.

MATERIALS AND METHODS

Cell lines and drugs

The poorly differentiated human bile duct adenocarcinoma cell line EGI-1^[25] (DSMZ # ACC385) and the human papillary bile duct adenocarcinoma cell line TFK-1^[26] (DSMZ # ACC344) were derived from patient cells prior to any exposure to chemotherapy or radiotherapy. Both cell lines were cultured in RPMI 1640 medium supplemented with 100 mL/L fetal calf serum (FCS), 100 kU/L penicillin and 100 mg/L streptomycin (Biochrom, Berlin, Germany) and kept at 37°C in a humidified atmosphere containing 50 mL/L CO₂ in air.

MS-275 (N-(2-Aminophenyl)-4-[N-(3-pyridineyl-methoxycarbonyl)aminomethyl]-benzamide) was purchased from ALEXIS Biochemicals (Lausen, Switzerland). The 26S proteasome inhibitor bortezomib (VelcadeTM) was bought from Millennium Pharmaceuticals, Inc. (Cambridge, MA, USA). The multi-kinase inhibitor sorafenib tosylate (NexavarTM) was a kind gift from Bayer Health Care (West Haven, CT, USA). Stock solutions were prepared in dimethyl sulfoxide (DMSO) and stored at -20°C until use. Gemcitabine hydrochloride (GemzarTM)

was bought from Lilly Pharma (Gießen, Germany). Doxorubicin hydrochloride was from Sigma (Deisenhofen, Germany) and also prepared in DMSO and stored at -20°C. All drugs were diluted in fresh medium before each experiment. In all experiments, the final DMSO concentration was ≤ 5 g/L, not affecting cell growth. To evaluate the effects of the drugs, cells were incubated with either control medium or medium containing rising concentrations of the respective drug(s). Cell culture material was from Biochrom (Berlin, Germany). All other chemicals were from Sigma if not stated otherwise.

Measurement of growth inhibition

Drug-induced changes in cell numbers of EGI-1 and TFK-1 cells were evaluated by crystal violet staining as previously described^[27]. In brief, cells in 96-well microtiter plates were fixed with 10 g/L glutaraldehyde. Then cells were stained with 1 g/L crystal violet in phosphate buffer solution (PBS). The unbound dye was removed by washing with water. Bound crystal violet was solubilized with 2 mL/L Triton-X-100 in PBS. Light extinction which increases linearly with the cell number was analyzed at 570 nm using an ELISA-Reader. To check for possible overadditive anti-proliferative effects, combination treatments of MS-275 plus conventional cytostatics (gemcitabine or doxorubicin) or plus sorafenib or plus bortezomib were performed. Increasing concentrations of the respective drug were combined with 0.25 and/or 0.5 μ mol/L MS-275. The anti-neoplastic effects of the combination therapies were compared to those of each drug alone. Concentration range and effectiveness of the respective drugs have been determined in prior experiments.

Determination of cytotoxicity

Cells were seeded at a density of 8000 cells/well into 96-well microtiter plates and incubated with rising concentrations of MS-275 for 1, 2.5, 5 or 24 h. Release of the cytoplasmic enzyme lactate dehydrogenase (LDH), indicating cytotoxicity, was measured by using a colorimetric kit from Roche Diagnostics (Mannheim, Germany) as described elsewhere^[28].

Detection of apoptosis

Preparation of cell lysates and determination of caspase-3 activity were performed as described previously^[27]. The activity of caspase-3 was calculated from cleavage of the fluorogenic substrate Ac-DEVD-AMC (Calbiochem, Bad Soden, Germany). Cell lysates were incubated with substrate solution (caspase-3 substrate Ac-DEVD-AMC 20 mg/L, HEPES 20 mmol/L, glycerol 100 mL/L, DTT 2 mmol/L, pH 7.5) for 1 h at 37°C, and substrate cleavage was measured with a VersaFluor fluorometer (excitation: 360 nm emission: 460 nm) from Biorad (Munich, Germany).

Cell cycle analysis

Cell cycle analysis was performed by the method of Vindelov and Christensen as described previously^[29]. Cells were trypsinized, washed and the nuclei were isolated using the CycleTest PLUS DNA Reagent Kit (Becton Dickinson, Heidelberg, Germany). DNA was stained with propidium iodide according to the manufacturers' instructions. The DNA content of the nuclei was measured by flow

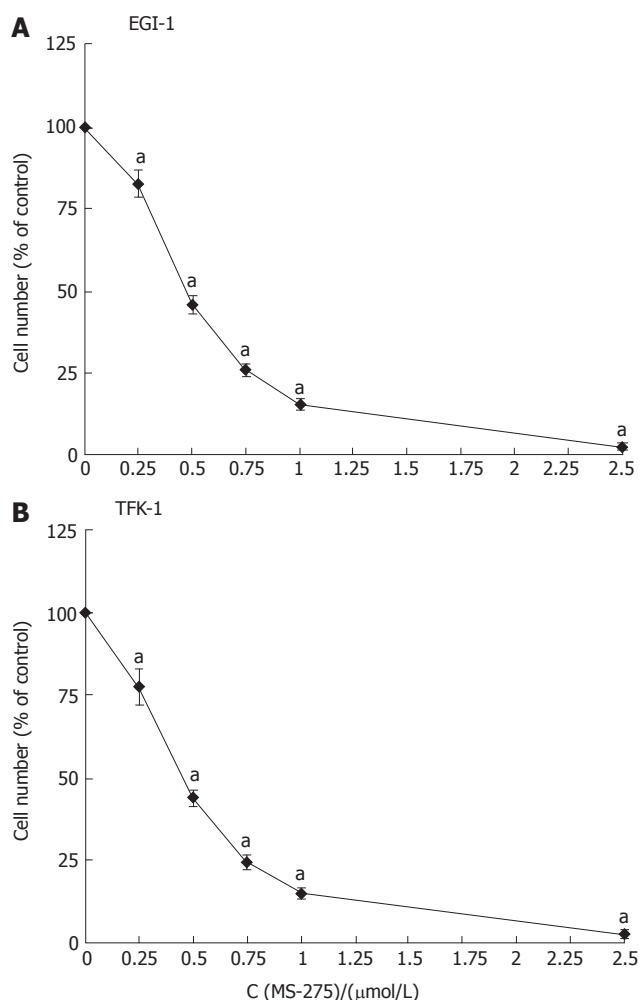

Figure 1 Anti-proliferative effects of MS-275 on human EGI-1 and TFK-1 cholangiocarcinoma cells. mean \pm SEM, $n > 5$, ^a $P < 0.05$ vs controls.

cytometry and analyzed using ModFit software (Becton Dickinson, Heidelberg, Germany).

Western blot analysis

Western blotting was performed as described previously^[30]. In brief, whole-cell extracts were prepared by lysing cells. Lysates containing 30 μ g protein were subjected to gel electrophoresis. Proteins were then transferred onto PVDF membranes by electroblotting for 90 min. Blots were blocked with 50 g/L non-fat dry milk in TBS-Tween-solution for 1 h at room temperature, and then incubated at 4°C overnight with antibodies directed against anti-human Bax (1:1000), p27^{Kip1} (1:200) (both from Santa Cruz Biotechnology, CA, USA), Bcl-2 (1:1000), or p21^{Waf-1/Cip1} (1:1000) (both from Cell Signaling, MA USA). Anti- β -actin (1:5000) from Sigma (Deisenhofen, Germany) served as loading control. After incubation with horseradish peroxidase-coupled anti-IgG antibodies (1:10 000, GE Healthcare, Uppsala, Sweden) at room temperature for at least 1 h, the blot was developed using enhanced chemiluminescent detection (GE Healthcare) and subsequently exposed to Hyperfilm ECL film (GE Healthcare, Uppsala, Sweden).

Statistical analysis

If not stated otherwise, data were expressed as means of at least three independent experiments \pm SEM. Significance

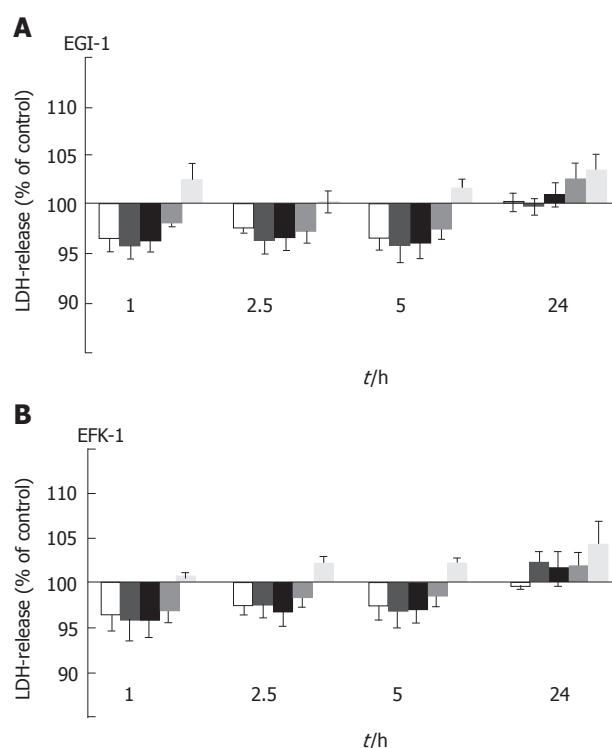

Figure 2 MS-275-induced LDH release into the supernatant of EGI-1 and TFK-1 cells. mean \pm SEM, $n > 3$ independent experiments; No significant increase in LDH release was observed.

between controls and treated samples was calculated by Student's two-sided *t*-test. Caspase-3 measurements were evaluated using the two-sided Welch *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

Growth inhibitory effects of the HDAC inhibitor MS-275

The growth inhibitory effects of MS-275 on CC cells were studied by crystal violet staining. Treating EGI-1 and TFK-1 cells with 0.25–2.5 μ mol/L MS-275 for 3 d reduced the growth of both cell lines in a dose-dependent manner by up to 100% (Figure 1). The IC₅₀ value of MS-275, determined after 72 h of incubation, was 0.48 ± 0.02 μ mol/L for EGI-1 cells and 0.46 ± 0.02 μ mol/L for TFK-1 cells. Determination of growth inhibition after 24 h and 48 h of incubation revealed that MS-275 inhibited cell proliferation in a time-dependent manner (data not shown).

LDH release after MS-275 treatment

Cytotoxicity was evaluated by LDH release of the cells into the culture medium. Incubating EGI-1 and TFK-1 cells with 0.1–1 μ mol/L MS-275 for up to 24 h did not result in a significant increase of LDH release (Figure 2), indicating that MS-275 does not directly affect cell membrane integrity and does not have immediate toxic effects even at higher concentrations.

Induction of apoptosis by MS-275

To determine the contribution of apoptosis to the observed growth inhibitory effect of MS-275, the activation of caspase-3, one of the key enzymes in the

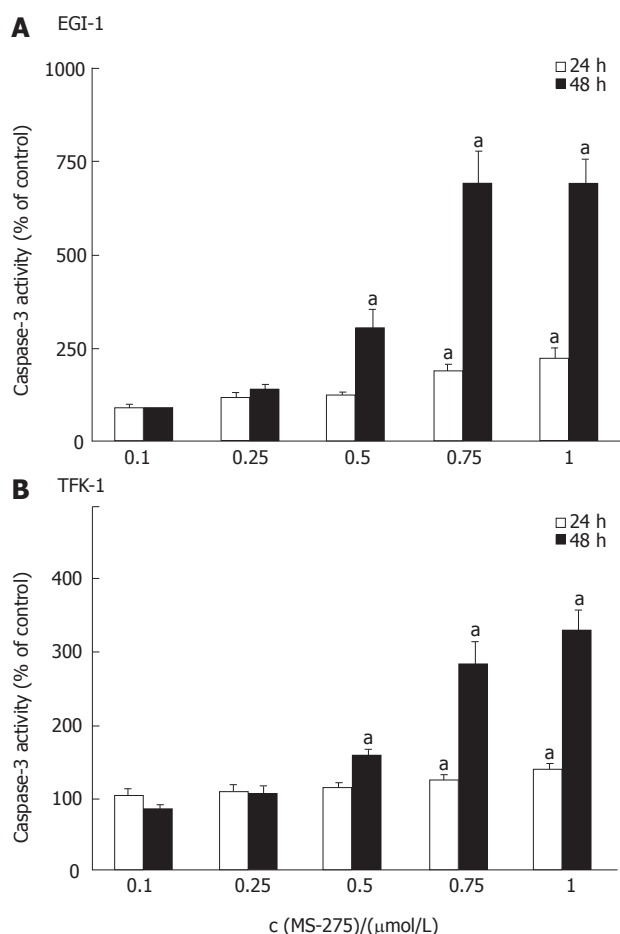

Figure 3 MS-275-induced apoptosis-specific caspase-3 activity increase in EGI-1 and TFK-1 cells. mean \pm SEM, $n > 3$ independent experiments, $^aP < 0.05$ vs controls.

apoptotic signaling cascade, was determined after 24 h and 48 h of incubation. In both cell lines, HDAC inhibition by MS-275 resulted in a time- and dose-dependent increase of caspase-3 enzyme activity (Figure 3). After 48 h, 1 $\mu\text{mol/L}$ MS-275 led to a 3-fold increase of caspase-3 activity in TFK-1 cells and even 7-fold increase in EGI-1 cells.

Cell cycle regulation

To test whether an induction of cell cycle arrest contributed to the antiproliferative potency of MS-275 in cholangiocarcinoma cells, we performed flow cytometric cell cycle analyses. Incubating EGI-1 and TFK-1 cells with 0.1–1 $\mu\text{mol/L}$ MS-275 for 24 h resulted in a dose-dependent arrest in the G_0/G_1 phase of the cell cycle, whereas the proportion of cells in the S phase significantly decreased (Figure 4). The G_0/G_1 -phase arrest by MS-275 was significant above concentrations of 0.1 $\mu\text{mol/L}$ in TFK-1 and 0.25 $\mu\text{mol/L}$ in EGI-1 cells. Moreover, the proportion of cells in the G_2/M phase also increased, indicating an additional block in the G_2/M phase. The G_2/M -phase arrest was more pronounced in TFK-1 cells.

Bax, Bcl-2, p21^{Waf-1/CIP1} and p27^{Kip1} expression

To further characterize the apoptotic and cell cycle arresting effects of the HDAC inhibition, we performed Western blotting. Treating EGI-1 and TFK-1 cells for 48 h with

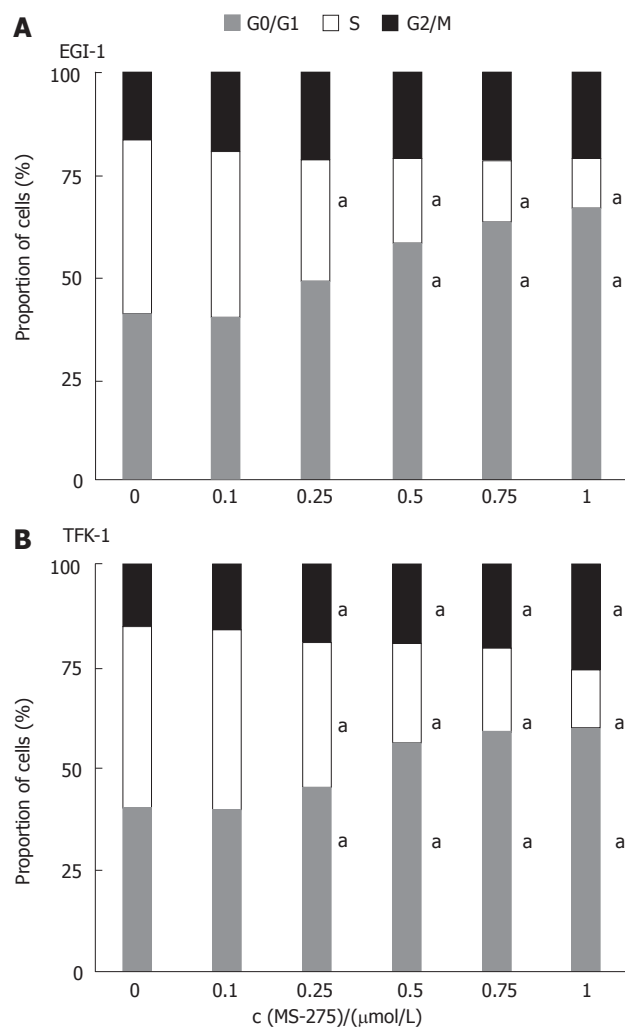

Figure 4 Induction of cell cycle arrest by MS-275 on EGI-1 and TFK-1 cells. means of > 3 independent experiments, $^aP < 0.05$ vs controls.

MS-275 (0.1–1 $\mu\text{mol/L}$) resulted in a dose-dependent decrease of anti-apoptotic Bcl-2, whereas the expression of the pro-apoptotic Bax was increased in both cell lines (Figure 5A). Moreover, upon MS-275 treatment, a dose-dependent increase in the expression of p21^{Waf-1/CIP1} was observed. By contrast, no regulation of the cyclin-dependent kinase inhibitor (CDKI) p27^{Kip1} was detected (Figure 5B).

Antineoplastic potency of MS-275 in combination with other drugs

To test potential (over-) additive anti-proliferative effects of MS-275-based combination treatment, EGI-1 or TFK-1 cells were treated with combinations of 0.5 $\mu\text{mol/L}$ MS-275 plus either gemcitabine (0–500 nmol/L) or doxorubicin (0–100 nmol/L) for 2 d. In both combinations, an augmentation of the anti-proliferative effect was observed (Figure 6). Although the anti-proliferative efficacy of gemcitabine monotherapy differed in EGI-1 and TFK-1 cells, the addition of MS-275 caused an enhanced anti-proliferative efficacy in either cell line (Figure 6A and B). Similar results were obtained when co-administering MS-275 and doxorubicin, with additive growth inhibitory effects on both cell lines (Figure 6C and D).

Recently, we could demonstrate that the multi-kinase

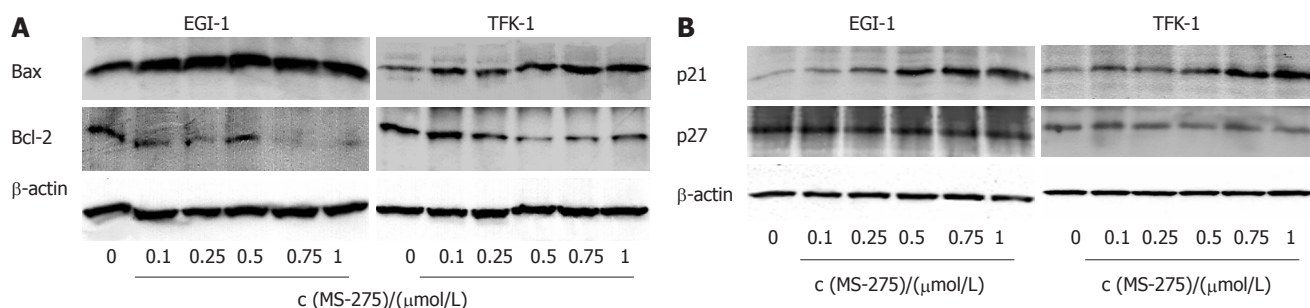

Figure 5 MS-275-induced modulation of apoptosis- and cell cycle-relevant proteins ($n = 3$ independent experiments).

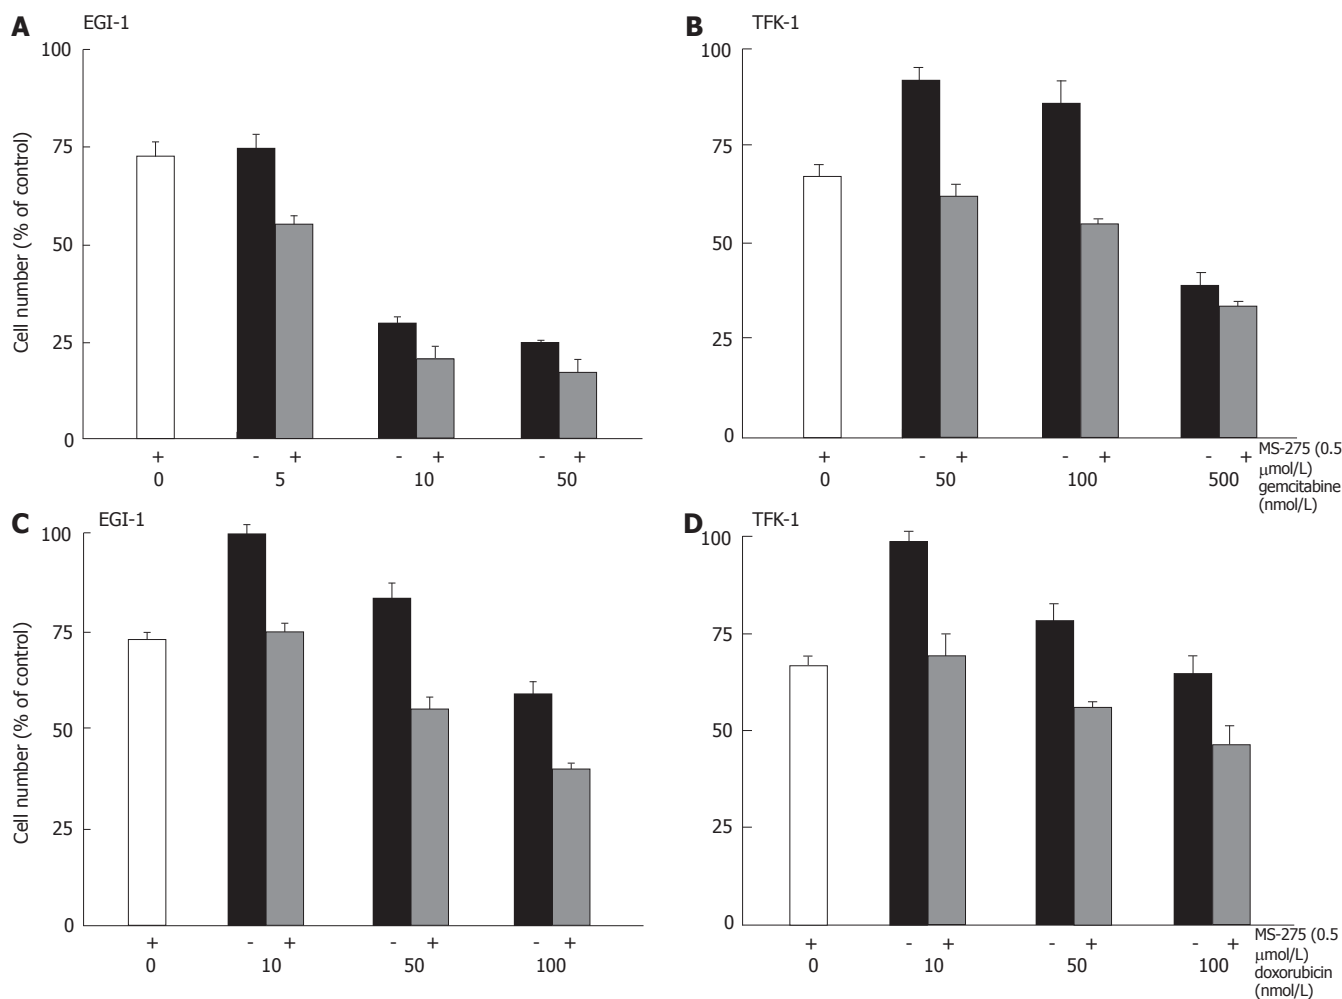

Figure 6 Anti-proliferative effects of MS-275 plus cytostatics on EGI-1 and TFK-1 cells. mean \pm SEM, $n = 3-4$ independent experiments.

inhibitor sorafenib potently inhibited the proliferation of cholangiocarcinoma cells^[31]. To check out the potency of inhibiting multiple targets of mitogenic signaling pathways for enhanced inhibition of cholangiocarcinoma cell growth, we treated EGI-1 and TFK-1 cells with MS-275 and sorafenib. After two days of incubation, a pronounced (over-)additive growth inhibitory effect of the combination was observed on both cell lines (Figure 7A and B).

Applying the proteasome inhibitor bortezomib alone (1-10 nmol/L) for two days reduced the growth of TFK-1 and EGI-1 cells by up to 65% and 84%, respectively. Again, additive and overadditive growth inhibitory effects were observed, when bortezomib was combined with MS-275 (Figure 7C and D).

DISCUSSION

Treatment options of advanced cholangiocarcinoma (CC) are unsatisfactory, and the prognosis of patients suffering from advanced CC is poor. New, effective and well-tolerated therapy strategies are urgently needed.

Aberrant gene expressions resulting in functional inactivation of histone acetyltransferase (HAT) activity or over-expression of histone deacetylases (HDAC) have been shown to contribute to tumor cell proliferation^[13]. For this reason, HDAC inhibition has been regarded as a promising anticancer strategy to inhibit the multiple cellular processes that are dysregulated in various neoplastic cells^[14].

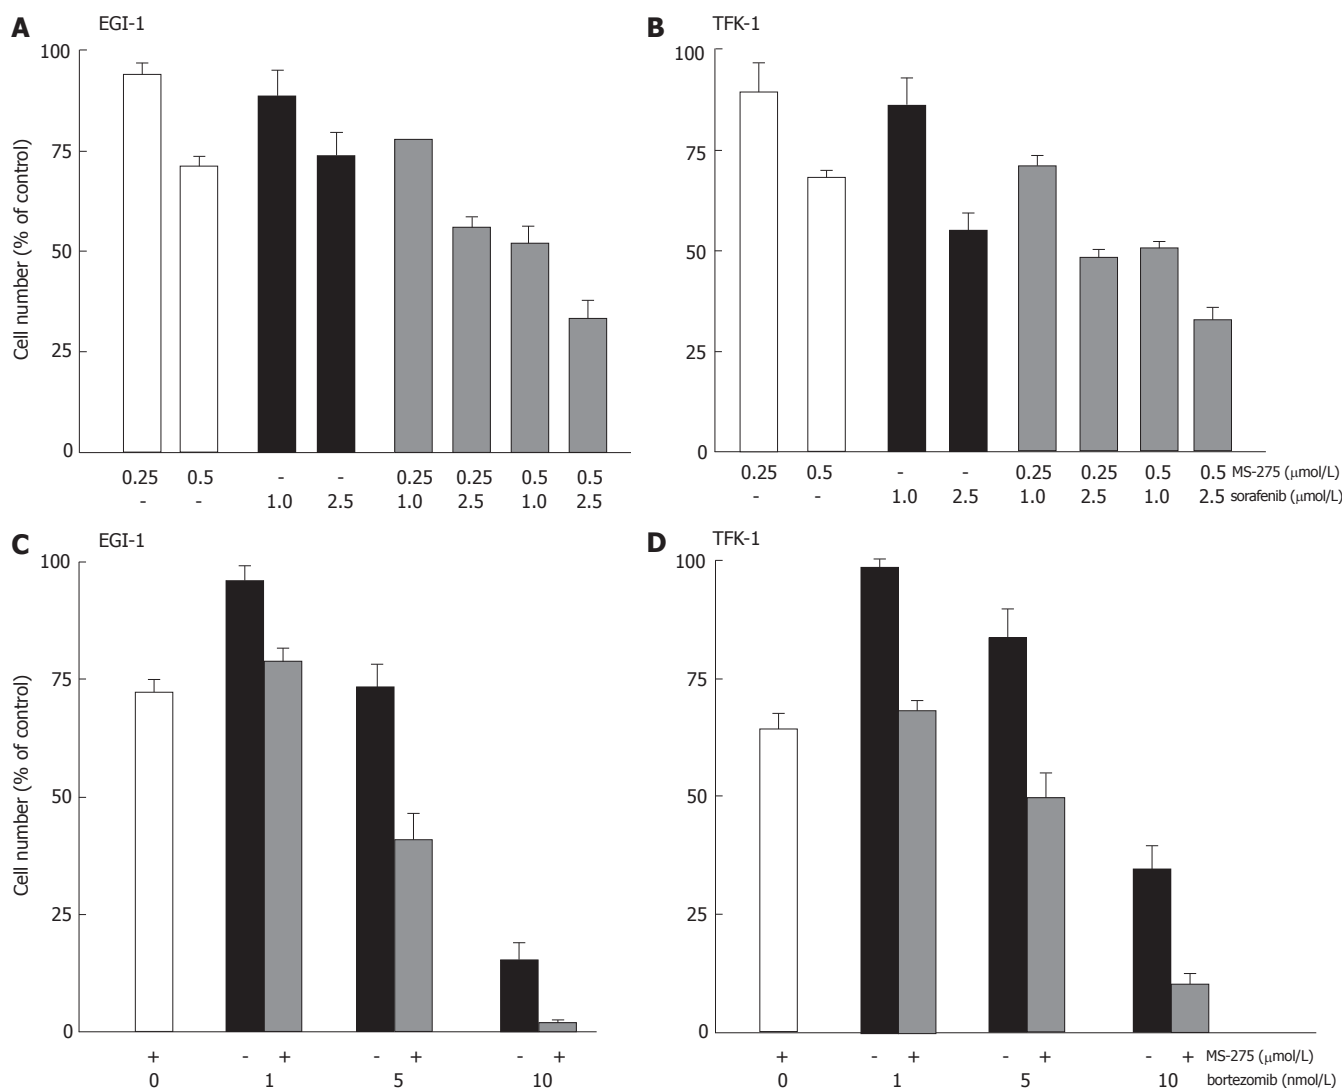

Figure 7 Anti-proliferative effects of MS-275 plus sorafenib or bortezomib on EGI-1 and TFK-1. mean \pm SEM, $n = 3-4$ independent experiments.

The novel synthetic benzamide derivative MS-275 is an orally available HDAC inhibitor which has been shown to exert strong anti-proliferative effects on a variety of human cancers^[21], but its potential suitability for the treatment of cholangiocarcinomas have not been tested so far. Here, we provide evidence that inhibition of HDAC activity by MS-275, alone or in combination with conventional chemotherapeutics or new, targeted anticancer drugs, may be a promising approach for the treatment of cholangiocarcinoma.

MS-275 potently inhibited cell growth of the cholangiocarcinoma cells EGI-1 and TFK-1 in a time- and dose-dependent manner. Submicromolar concentrations of MS-275 were already sufficient to significantly inhibit the proliferation of EGI-1 and TFK-1 cells, and the concentration needed to induce halfmaximal anti-neoplastic effects (IC_{50} value) was approximately 0.5 μ mol/L in both cell lines. This is comparable to our previous findings on the effects of MS-275 on the growth of gastrointestinal neuroendocrine tumor cells^[24].

Recent studies have shown that inhibition of HDAC activity induces apoptosis in a variety of cancers, including breast and prostate cancer, neuroblastoma, hepatoma,

gastrointestinal neuroendocrine tumor cells and some types of hematologic malignancies^[24,32-34].

The mechanisms involved in the HDAC inhibitor-induced apoptosis are complex and differ among cell types^[35]. They can involve both intrinsic pathways and extrinsic pathways of apoptosis. MS-275 can induce mitochondrial permeability transition with a subsequent release of pro-apoptotic cytochrome c into the cytosol, resulting in the activation of caspase-9 and caspase-3, thus triggering the intrinsic apoptotic pathway^[36-38]. Additionally, other HDAC inhibitors have been shown to upregulate pro-apoptotic Fas, a member of the tumor necrosis factor receptor superfamily and the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL-) receptors/death receptors DR4 and DR5, thereby triggering the extrinsic pathway, paralleled by down-regulation of the caspase-8 inhibitor c-FLIP, leading to caspase-8 and subsequently to caspase-3 activation^[39,40]. Moreover, an altered expression of several pro- and anti-apoptotic intracellular genes by HDAC inhibitors has been reported. Up-regulation of pro-apoptotic Bak and induction of conformational changes of the pro-apoptotic protein Bax are some of the HDAC inhibitor-induced upstream events that trigger the

mitochondrial pathway of apoptosis^[33,41,42]. HDAC inhibitors can also down-regulate anti-apoptotic proteins, such as Bcl-2, Bcl-XL, XIAP, Mcl-1, and survivin^[37,43], further tilting the balance in favor of apoptosis. Here, we demonstrated that the pro-apoptotic effect of HDAC inhibition by MS-275 in CC cells is mediated by the activation of caspase-3 and a shift in the balance of pro-apoptotic Bax over anti-apoptotic Bcl-2.

HDAC-inhibition-induced changes in the expression pattern of apoptosis-related proteins seem to be cell type-specific. For example, in hepatoma and breast cancer cells, HDAC inhibition decreased the expression of Bcl-2, while expression of pro-apoptotic Bax was increased^[33,44], in line with the present study. On the other hand, no changes in the expression pattern of Bax and Bcl-2 were found in HDAC-inhibitor-treated glioma cells^[45], and in gastrointestinal neuroendocrine tumor cells, Bcl-2 expression was down-regulated upon MS-275 treatment, while Bax remained unchanged^[24]. Especially for an estimation of suitable combination treatment regimens being based on the enhanced induction of apoptosis, it is necessary to check out cell type-specific changes in the expression pattern of HDAC-induced pro- and anti-apoptotic proteins.

To further characterize the growth inhibitory activity of MS-275, we performed cell cycle analyses. Upon treatment with MS-275 we found that cell cycle progression was blocked both in the G₀/G₁ and the G₂/M phase. The induction of cell cycle arrest was associated with an increase in the expression of the cyclin-dependent kinase inhibitor (CDKI) p21^{Waf-1/Cip1}. p21^{Waf-1/Cip1} is a key component of cell cycle checkpoints, i.e., the G₁/S^[46] and the G₂/M checkpoints^[47,48]. Accordingly, HDAC inhibitors were found to inhibit both the G₁/S and G₂/M transition^[49-51].

The combination of HDAC inhibitors with existing chemotherapeutic agents appears to be a promising approach to reduce the dose of other anti-neoplastic drugs and to overcome drug resistance. For non-cholangiocarcinoma tumors (e.g. glioblastoma and breast cancer cells), a potentiation of anti-neoplastic effects has already been described for HDAC inhibitors combined with cytostatic drugs^[52]. However, except for the interaction of HDAC and topoisomerase inhibitors, in which HDAC-inhibitor-mediated increases in topoisomerase II levels appear to contribute to lethality^[53], little is known about the mechanisms by which HDAC inhibitors increase the anti-neoplastic efficacy of cytostatic agents. Maggio *et al*^[37] reported that combination of MS-275 with nucleoside analogues (e.g. Fludarabine) produced high synergy in triggering mitochondrial dysfunction and caspase activation in human leukemia cells. In our study, the nucleoside analogue gemcitabine and the topoisomerase-II-inhibitor doxorubicin were chosen for the evaluation of synergy with MS-275 in CC cells. While both combinations resulted in additive anti-proliferative effects, further studies are needed to clarify the exact mechanisms underlying the observed potentiation by MS-275. Nevertheless, the fact that MS-275-based combination therapies with cytostatics lead to an enhanced growth inhibition of CC cells gives rise to the hope that a HDAC-inhibitor-based combination therapy may hold a promise for more effective treatment of CC.

The same holds true for the combination of HDAC inhibition and multi-kinase inhibition by sorafenib, which mainly targets raf and ras kinases that are members of the MAPK (mitogen-activated protein kinase) pathway. The MAPK pathway is centrally involved in the regulation of multiple cellular functions, such as cell growth, apoptosis and cell cycle progression^[54]. Recently, we could demonstrate a potent growth inhibition of CC cells by sorafenib monotherapy^[31]. HDAC inhibitors can also down-regulate the MAPK-signaling pathway, as exemplified by HDAC-induced growth inhibition of transformed hepatocytes due to the suppression of oncogenic ras and ERK1/2 (extracellular regulated kinase)^[55]. Here we found that coapplication of MS-275 and sorafenib resulted in an additive to overadditive growth inhibition of CC cells, indicating that HDAC-based dual-targeting of MAPK and pro-apoptotic pathways may have promising clinical implications for the future treatment of CC.

Finally, we also studied how far combination treatment of MS-275 together with the proteasome inhibitor bortezomib could enhance the anti-neoplastic effects of the monotherapies. Bortezomib has recently been shown to enhance the anti-proliferative effects of HDAC inhibitors on several non-CC cancer cells^[56-58]. The sensitizing effect of bortezomib has been attributed to a blockade of the cytoprotective nuclear factor kappa B (NFκB)^[59,60]. There is accumulating evidence that NFκB activation status plays an important role in regulating the response of cells to HDAC inhibitors^[61]. Thus, in non-small cell lung cancer, HDAC inhibitors are only modestly effective due to high steady state levels of NFκB^[11,57], but addition of bortezomib dramatically increased the pro-apoptotic effect of the HDAC inhibitor sodium butyrate^[57]. Our findings are in line with these data in clearly demonstrating that bortezomib overadditively enhanced the anti-proliferative effect of MS-275 on CC cells. Thus, the combined treatment with HDAC inhibitors and bortezomib (and possibly sorafenib as a third agent) appears to be a promising approach for the treatment of cholangiocarcinomas.

In conclusion, our study provides first evidence that the HDAC inhibitor MS-275 potently inhibits the growth of human CC cells by inducing both cell cycle arrest and apoptosis. Importantly, we could demonstrate that combination treatment of MS-275 with gemcitabine, doxorubicin, and especially sorafenib or bortezomib leads to (over-)additive growth inhibitory effects. Our study may provide a rationale for future *in vivo* evaluations of MS-275 in combination therapies for growth control of advanced cholangiocarcinomas.

ACKNOWLEDGMENTS

We thank André Bosch and Björn Hoffmann for expert technical assistance, and Bayer Health Care (West Haven, CT, USA) for providing us with sorafenib.

COMMENTS

Background

Cholangiocarcinomas (CC) are highly malignant and have a poor prognosis. Since there is no satisfactory therapy for advanced CC, we studied the effects of the

histone deacetylase inhibitor MS-275 alone or in combination with bortezomib or sorafenib on the proliferation of cholangiocarcinoma cells.

Research frontiers

Histone modifications have been identified to play prominent roles in the epigenetic regulation of gene transcription. Accumulating evidence indicates that dysregulation of epigenetic processes causes transcriptional repression of a subset of genes, contributing to the pathogenesis of many human diseases, including cancer. In the past decade, substantial progress has been made in understanding the relationship between aberrant epigenetic changes and tumorigenesis. Enzymes involved in these epigenetic events include histone acetyltransferases (HAT) and histone deacetylases (HDAC), which tightly control the steady state of histone acetylation. Recently, histone deacetylase inhibitors receive growing interest as cancer therapeutics, due to their ability to induce growth arrest, differentiation and/or apoptosis.

Innovations and breakthroughs

Previous studies already demonstrated that targeting the histone deacetylase (HDAC) activity by specific HDAC inhibitors is an effective treatment option for cell growth control of haematological malignancies and of several solid tumors. Especially the novel, orally available HDAC inhibitor MS-275 has been shown to exert strong anti-proliferative effects on a variety of cancers.

Applications

In this paper, we studied the anti-proliferative effect of the potent histone deacetylase inhibitor MS-275 on cholangiocarcinoma cells for the first time. MS-275 significantly inhibits the proliferation of cholangiocarcinoma cells by inducing apoptosis and cell cycle arrest. Importantly, we could further demonstrate that combination treatment using MS-275 together with doxorubicin, gemcitabine, sorafenib or bortezomib, respectively, leads to (over-)additive growth inhibitory effects, thus providing a rationale for future *in vivo* evaluations.

Terminology

Histone acetyltransferases (HAT) and histone deacetylases (HDAC): HAT and HDAC are two sets of histone-modifying enzymes, which control the steady state of histone acetylation. The equilibrium of acetylation (HAT) and deacetylation (HDAC) of histones plays an important role in the modulation of chromatin structure and in the regulation of gene transcription.

Peer review

This manuscript is a good suggestion to be considered and it is true that the treatment options for advanced cholangiocarcinomas are still unsatisfactory. New therapeutic approaches are urgently needed.

Abstract

AIM: To compare efficacy and tolerability of four proton pump inhibitors (PPIs) commonly used in the short-term therapy of esophagitis in elderly patients.

METHODS: A total of 320 patients over 65 years with endoscopically diagnosed esophagitis were randomly assigned to one of the following treatments for 8 wk: (1) omeprazole 20 mg/d; (2) lansoprazole 30 mg/d; (3) pantoprazole 40 mg/d, or (4) rabeprazole 20 mg/d. Major symptoms, compliance, and adverse events were recorded. After 8 wk, endoscopy and clinical evaluation were repeated.

RESULTS: Per protocol and intention to treat healing rates of esophagitis were: omeprazole = 81.0% and 75.0%, lansoprazole = 90.7% ($P = 0.143$ vs omeprazole) and 85.0%, pantoprazole = 93.5% ($P = 0.04$ vs omeprazole) and 90.0% ($P = 0.02$ vs omeprazole), rabeprazole = 94.6% ($P = 0.02$ vs omeprazole) and 88.8% ($P = 0.04$ vs omeprazole). Dividing patients according to the grades of esophagitis, omeprazole was significantly less effective than the three other PPIs in healing grade 1 esophagitis (healing rates: 81.8% vs 100%, 100% and 100%, respectively, $P = 0.012$). Pantoprazole and rabeprazole (100%) were more effective vs omeprazole (89.6%, $P = 0.0001$)

and lansoprazole (82.4%, $P = 0.0001$) in decreasing heartburn. Pantoprazole and rabeprazole (92.2% and 90.1%, respectively) were also more effective vs lansoprazole (75.0%, $P < 0.05$) in decreasing acid regurgitation. Finally, pantoprazole and rabeprazole (95.2% and 100%) were also more effective vs lansoprazole (82.6%, $P < 0.05$) in decreasing epigastric pain.

CONCLUSION: In elderly patients, pantoprazole and rabeprazole were significantly more effective than omeprazole in healing esophagitis and than omeprazole or lansoprazole in improving symptoms. *H. pylori* infection did not influence the healing rates of esophagitis after a short-term treatment with PPI.

INTRODUCTION

Old age is known to be a significant risk factor for severe esophagitis^[1,2], chronic relapses^[3], as well as severe complications of the disease^[1,4]. Clinical features of esophagitis in elderly patients are quite different from those of young or adult subjects. Indeed, elderly patients present less frequently the typical symptoms of heartburn, acid regurgitation and/or epigastric pain. Conversely, the prevalence of other non-specific symptoms, i.e. anorexia, weight loss, anaemia, and/or vomiting significantly increases with age^[2]. Thus, the diagnosis of reflux esophagitis may be missed in the elderly, and a substantial number of patients may suffer subclinical relapses of the disease^[5].

The treatment of esophagitis is based on gastric acid suppression with antisecretory drugs. Proton pump inhibitors (PPIs) are widely used and their effectiveness and safety have been demonstrated also in patients of old age^[6]. Currently, five PPIs are available on the market:

omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole. Some age-associated differences in pharmacokinetics and pharmacodynamics of the PPIs have been reported^[7]. However, it is unknown if these differences are associated with different clinical effects, i.e. healing rates and/or symptom relief, particularly in older patients.

The aim of this study was to compare the clinical efficacy and tolerability of four PPIs used for the short-term therapy of esophagitis in elderly patients.

SUBJECTS AND METHODS

Study design

This was an open, single-centre, randomized study including elderly subjects that consecutively underwent an upper gastrointestinal endoscopy. It was conducted according to the Declaration of Helsinki and the guidelines for Good Clinical Practice. All patients gave their informed consent prior to participation in the study.

The inclusion criteria were: (1) age 65 years or over and (2) endoscopic diagnosis of esophagitis grade I to IV according to the Savary-Miller classification^[8]. Major exclusion criteria were: history of Zollinger-Ellison syndrome, pyloric stenosis, previous surgery of the esophagus and/or gastrointestinal tract (except for appendectomy and cholecystectomy), and gastrointestinal malignancy. Patients were excluded if they had received antacids, sucralfate, prokinetics, H₂-blockers, and/or PPIs for more than 7 d in the four weeks prior to the start of the study.

Assessments

At the initial visit, demographic data, medical history, clinical symptoms, non-steroidal anti-inflammatory drug (NSAID) use, and antisecretory therapy were recorded. At study entry, an endoscopy was performed to diagnose acute esophagitis (inclusion criteria). After 2 mo of treatment, endoscopy was repeated to evaluate healing of acute esophagitis. All patients were examined during therapy to record side effects and to count tablets. Compliance was defined as "good" when more than 90% of the tablets had been taken by the patients. Adverse events were rated by the investigator as not related, unlikely, possibly related, or likely related to the medication.

Endoscopic diagnoses

Reflux esophagitis was endoscopically defined by epithelial defects according to the Savary-Miller criteria^[8] and classified as grade I: non-confluent erosions; grade II: confluent erosions; grade III: lesions extending to the entire circumference of the lower esophagus; and grade IV: deep ulcer or esophagitis with complications, i.e. stenosis and/or hemorrhagic lesions. Patients with diffuse erythema and/or fragility of the lower esophagus were not included. Hiatus hernia was diagnosed when the Z-line and the gastric folds extended 2 cm or more above the diaphragmatic hiatus^[9]. Patients with Barrett's esophagus were not included unless erosive esophagitis was also present.

Histology and *H. pylori* infection

During endoscopy, six gastric biopsies were taken from

both the antrum (three biopsies), and from the body (three biopsies). Two antral and two body biopsies were used for histological analysis, while one from each site was used for the rapid urease test (CLO test, Delta West Pty Ltd, Western Australia). For histological examination, biopsy specimens were immediately fixed in buffered neutral formalin and embedded in paraffin. Sections were stained with hematoxylin-eosin and modified Giemsa for the detection of *H. pylori* and evaluated according to the Sydney classification^[10]. Patients were considered *H. pylori* negative if both histology and the rapid urease test were negative; patients were considered *H. pylori* positive if either their histology or rapid urease test, or both, were positive for Hp infection^[11].

Symptomatology

Symptoms were assessed during a structured interview. The patient was questioned about the principal symptoms, i.e. acid regurgitation, heartburn, and other symptoms of reflux esophagitis, i.e. epigastric pain, dysphagia, vomiting, and anaemia (loss of ≥ 3 grams of haemoglobin during the last 3 mo) and expressed as absent/present.

Treatments

Patients included in the study were consecutively assigned to one of the following regimens for two months: omeprazole 20 mg once daily, lansoprazole 30 mg once daily; pantoprazole 40 mg once daily, or rabeprazole 20 mg once daily. Randomization was performed by a computer-generated list in blocks of four with a 1:1:1:1 ratio. All PPIs were taken in the morning fasting just before breakfast. Patients who resulted *H. pylori* positive were treated with the PPI plus two antibiotics i.e., amoxicillin 1g twice daily and claritromycin 250 mg twice daily or metronidazole 250 mg four times daily for 7 d^[12].

Statistical analysis

Statistical analysis was performed by means of the SPSS version 13. Results were evaluated using both "per protocol" (PP) and "intention-to-treat" (ITT) analyses; the 95% confidence intervals (95% CI) were also calculated. The ITT population was defined as all patients initially enrolled who had taken at least one dose of study medication. Statistical analysis was performed using the χ^2 test (comparison of outcomes with the treatments) and Fisher exact test (healing rates related to *H. pylori* infection, symptoms). All p values were two-tailed with statistical significance indicated by a value of $P < 0.05$.

RESULTS

A total of 320 consecutive elderly (156 males and 164 females, mean age 77.4 ± 7.9 years, range from 65 to 93 years) with an endoscopic diagnosis of acute esophagitis, grades 1 to 4 according to the Savary-Miller classification, were included in the study. Demographic and clinical characteristics of patients are shown in Table 1.

Nineteen patients (5.9% of the total population) dropped-out from the study due to: adverse events (2 patients), low compliance (11 patients), and refusal of endoscopy after two months of treatment (6 patients).

Table 1 Demographic and clinical characteristics of the study population

	All patients	Omeprazole	Lansoprazole	Pantoprazole	Rabeprazole
Number of patients	320	80	80	80	80
Males/Females	156/164	44/36	36/44	39/41	37/43
Mean age (yr)	77.4 ± 7.9	77.9 ± 6.4	77.8 ± 9.2	76.8 ± 6.1	77.0 ± 9.5

Table 3 Healing rates of esophagitis after eight weeks of PPI treatment in elderly patients with esophagitis divided according to the grades of severity of esophagitis according to the Savary-Miller classification

Severity grades	Omeprazole		Lansoprazole		Pantoprazole		Rabeprazole	
	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%
I grade ^a	27/33	81.8	25/25	100	20/20	100	14/14	100
II grade ^c	18/22	81.8	28/29	96.5	36/40	90.0	46/48	95.8
III-IV grades ^e	15/19	78.9	15/21	71.4	16/17	94.1	11/13	84.6

^a $P = 0.012$; ^c $P = 0.215$; ^e $P = 0.458$.

Among the 301 patients who completed the study, 271 had healed esophagitis and 30 were unhealed. The overall PP and ITT healing rates of esophagitis were 90.0% (95% CI = 86.6-93.4) and 84.7% (95% CI = 80.7-88.6), respectively. Dividing patients according to treatments, the PP and ITT healing rates of esophagitis were: omeprazole = 81.0% and 75.0%, lansoprazole = 90.7% ($P = 0.143$ vs omeprazole) and 85% ($P = 0.167$ vs omeprazole), pantoprazole = 93.5% ($P = 0.04$ vs omeprazole) and 90.0% ($P = 0.02$ vs omeprazole), rabeprazole = 94.6% ($P = 0.02$ vs omeprazole) and 88.8% ($P = 0.04$ vs omeprazole) respectively (Table 2). Dividing patients according to the grades of esophagitis, a significantly lower healing rate was observed in patients with grade 1 esophagitis treated with omeprazole com-

pared to patients treated with lansoprazole, pantoprazole, or rabeprazole (healing rates: 81.8% vs 100%, 100% and 100%, respectively, $P = 0.012$). Omeprazole was less effective than the three other PPIs also in patients with grade 2 esophagitis (healing rates: 81.8% vs 96.5% vs 90% vs 95.8%, respectively) and than pantoprazole and rabeprazole in grade 3-4 esophagitis (healing rates: 78.9% vs 94.1% vs 84.6%, respectively); probably due to the low number of patients, however, the differences were not statistically significant (Table 3).

At baseline 188 of 288 patients (65.3%) were identified as infected with *H. pylori* in the gastric mucosa. No differences were observed in the healing rates of esophagitis between *H. pylori* positive and *H. pylori* negative patients (90.4% vs 89.0%, $P = \text{NS}$). After two months, 149 of 188 (79.3%) who were treated with triple therapies for one week were *H. pylori* negative while 39 patients (20.7%) remained *H. pylori* positive after treatment. No significant differences in the healing rates of esophagitis were observed between successfully and unsuccessfully treated *H. pylori* patients (negative *H. pylori* vs still-positive after treatment: 89.9% vs 92.3%, $P = \text{NS}$) (Table 4).

After two months of PPI treatment, a significant reduction of symptoms as compared to baseline was observed both in healed and in unhealed patients. While heartburn improved significantly more effectively in healed patients than unhealed patients (rates of heartburn

Table 4 Healing rates of esophagitis in elderly patients divided according to *H pylori* infection

	Omeprazole (<i>n</i> = 71)	Lansoprazole (<i>n</i> = 71)	Pantoprazole (<i>n</i> = 74)	Rabeprazole (<i>n</i> = 72)	All (<i>n</i> = 288)

Table 5 Symptoms in elderly patients with esophagitis before and after two months of PPI therapy

Symptoms	Before therapy		After therapy	
	All	Healed	Unhealed	Healed vs unhealed
	<i>n</i> = 301	<i>n</i> = 271	<i>n</i> = 30	<i>P</i> value
Heartburn (<i>n</i> , %)	131 (43.5)	9 (3.3)	6 (20.0)	0.0001
Acid regurgitation (<i>n</i> , %)	39 (13.0)	4 (1.5)	0 (0.0)	0.874
Epigastric pain (<i>n</i> , %)	143 (47.5)	10 (3.7)	2 (6.6)	0.781
Dysphagia (<i>n</i> , %)	10 (3.3)	0 (0.0)	0 (0.0)	--
Vomiting (<i>n</i> , %)	60 (19.9)	0 (0.0)	0 (0.0)	--
Anaemia (<i>n</i> , %)	28 (9.3)	0 (0.0)	0 (0.0)	--

disappearance = 96.7% *vs* 80%, *P* = 0.001), other symptoms improved significantly both in healed and unhealed patients (Table 5). The rates of symptom disappearance in the four treatment groups, i.e. omeprazole, lansoprazole, pantoprazole, and rabeprazole, were 86.9%, 82.4%, 100%, and 100% for heartburn, 100%, 75.0%, 92.9%, and 90.1% for acid regurgitation, and 95.0%, 82.6%, 95.2, and 100% for epigastric pain, respectively (Table 6). Comparisons between the four PPIs demonstrated that pantoprazole and rabeprazole were more effective than omeprazole (100% *vs* 86.9, and 100% *vs* 86.9%, respectively, *P* < 0.05) and than lansoprazole (100% *vs* 82.4%, *P* = 0.0001 and 100% *vs* 82.4%, *P* = 0.005, respectively) in decreasing heartburn. Lansoprazole was less effective in improving acid regurgitation and epigastric pain than omeprazole (*P* = 0.0001, *P* = 0.033, respectively), pantoprazole (*P* = 0.005, *P* = 0.028, respectively), and rabeprazole (*P* = 0.026, *P* = 0.0001, respectively) (Table 6).

All four PPIs were well tolerated. Adverse events were reported only by four patients (1.3%): urticaria, glossitis, nausea, and headache. Two patients discontinued therapy due to treatment-related side effects. No significant differences were found in the prevalence of adverse events among the four treatment groups.

DISCUSSION

This study demonstrates that in patients over 65 years PPI therapy for 2 mo is very effective in healing acute esophagitis. The pooled ITT and PP healing rates were 84.7% and 90.0%, respectively. These are comparable to previous data from double-blind studies carried out in non-elderly sub-

Table 6 Symptom disappearance after therapy in elderly patients divided according to PPI regimens %

jects treated for 8 wk with omeprazole 20 mg or lansoprazole 30 mg daily^[13], pantoprazole 40 mg daily^[14], or rabeprazole 20 mg daily^[15]. In this population of older patients, pantoprazole and rabeprazole were significantly more effective in healing esophagitis than omeprazole. Moreover, pantoprazole and rabeprazole were more effective than lansoprazole and omeprazole in improving heartburn, and than lansoprazole in improving acid regurgitation and epigastric pain.

Previous studies were focused on potential discrepancies in efficacy among the different PPIs used for treatment of reflux esophagitis. While some previous reports suggest that acid-suppressive effect of the four PPIs is different on the basis of equivalent molecular dose, clinical studies that support such a different efficacy in healing esophagitis or improving symptoms of GERD on a PPI-equivalent molecular doses are lacking. A meta-analysis of 38 studies evaluating acute therapy of esophagitis reported that the PPIs were superior to ranitidine and placebo in healing erosive esophagitis, without significant differences in efficacy between omeprazole 20 mg daily and lansoprazole 30 mg daily, or pantoprazole 40 mg daily, or rabeprazole 20 mg daily^[16]. Similarly, in another meta-analysis, no differences in healing rates of esophagitis were reported between standard doses of lansoprazole, pantoprazole, rabeprazole, and omeprazole^[17]. More recently, a meta-analysis of eleven studies with 23 treatment arms reported no significant difference in the two-month healing rates of esophagitis between omeprazole 20 mg daily (*n* = 3.137

patients, pooled healing rate = 84.5%) and other PPIs, including lansoprazole, pantoprazole, rabeprazole, and esomeprazole at standard doses ($n = 3.397$ patients, pooled healing rate = 89.4%)^[18]. However, none of the studies included in these meta-analyses were carried out specifically in elderly patients. Indeed, to our knowledge, this is the first study that compared the efficacy of different PPIs in curing esophagitis and improving symptoms in elderly patients.

Why pantoprazole and rabeprazole were more effective than omeprazole in healing esophagitis and than omeprazole and lansoprazole in improving symptoms in elderly patients is not clear. Very recently it was suggested that omeprazole has considerable potential for drug interactions since it has high affinity for the cytochrome CYP2C19 and a lower affinity for the cytochrome CYP3A4, while pantoprazole, and maybe rabeprazole, appear to have lower potential for interactions with other drugs^[19]. Data from this study cannot confirm this hypothesis since no information was collected on concomitant treatments, with the exception of NSAID and aspirin. Interestingly, a previous multicentre study, carried out in 164 elderly patients with esophagitis reported that a 2-month therapy with pantoprazole 40 mg/d was highly effective in healing reflux esophagitis (81.1% and 93.7% by ITT and PP analyses, respectively), although the majority of patients received other drugs for concomitant illnesses (76.2% of patients), without that the presence of concomitant treatments adversely affected the efficacy or tolerability of pantoprazole^[20].

Very recently, a systematic review of randomized controlled trials in patients with reflux esophagitis reported that esomeprazole demonstrated higher short-term healing rates when compared with standard dose PPIs^[21]. While no data were reported comparing rabeprazole 20 mg to esomeprazole 40 mg, two studies included in the analysis compared pantoprazole 40 mg daily to esomeprazole 40 mg daily. This comparison found no differences in healing rates between the two treatments both in patients with moderate-severe esophagitis, i.e. Los Angeles grades B and C (healing rates with pantoprazole = 83.2% *vs* esomeprazole = 80.7%, $P = \text{NS}$)^[22] and in the subgroup of 550 patients aged 65 years or over included in the large multicenter EXPO study (healing rates with pantoprazole = 87.4% *vs* esomeprazole = 90.4%, $P = \text{NS}$)^[23]. Unfortunately, information on esomeprazole was not available for the present study.

In this elderly population, *H. pylori* infection did not influence the response to short-term treatment with PPIs. This finding confirms the data of previous studies performed in elderly populations showing that *H. pylori* infection does not have a negative effect on healing of esophagitis, nor does it worsen reflux symptoms at two-month follow up^[24]. It is also evident from our study that *H. pylori* eradication does not affect the cure rate of esophagitis during a two-month course of PPI, in agreement with a recent multicentre randomized study also performed in elderly patients^[25].

In conclusion, PPIs are highly effective and well tolerated in curing gastroesophageal reflux disease in elderly patients. Pantoprazole and rabeprazole were significantly

more effective than omeprazole in healing esophagitis and than omeprazole or lansoprazole in improving symptoms. *H. pylori* infection does not influence the healing rates of esophagitis after a short-term treatment with PPI.

Abstract

AIM: To investigate the role of angiopoietin (Ang) -1, -2 and -4 and its receptors, Tie-1 and -2, in the growth and differentiation of gastrointestinal stromal tumors (GISTs).

METHODS: Thirty GISTs, seventeen leiomyomas and six schwannomas were examined by immunohistochemistry in this study.

RESULTS: Ang-1, -2 and -4 proteins were expressed in the cytoplasm of tumor cells, and Tie-1 and -2 were expressed both in the cytoplasm and on the membrane of all tumors. Immunohistochemical staining revealed that 66.7% of GISTs (20 of 30), 76.5% of leiomyomas (13 of 17) and 83.3% of schwannomas (5 of 6) were positive for Ang-1. 83.3% of GISTs (25 of 30), 82.4% of leiomyomas (14 of 17) and 100% of schwannomas (6 of 6) were positive for Ang-2. 36.7% of GISTs (11 of 30), 58.8% of leiomyomas (10 of 17) and 83.3% of schwannomas (5 of 6) were positive for Ang-4. 60.0% of GISTs (18 of 30), 82.4% of leiomyomas and 100% of schwannomas (6 of 6) were positive for Tie-1. 10.0% of GISTs (3 of 30), 94.1% of leiomyomas (16 of 17) and 33.3% of schwannomas (2 of 6) were positive for Tie-2. Tie-2 expression was statistically different between GISTs and leiomyomas ($P < 0.001$). However, there was no correlation between expression of angiopoietin pathway components and clinical risk categories.

CONCLUSION: Our results suggest that the angiopoietin pathway plays an important role in the differentiation of GISTs, leiomyomas and schwannomas.

INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are rare mesenchymal tumors of the gastrointestinal tract that may occur from the oesophagus to the anus, including the omentum^[1,2]. Despite their rarity, GISTs are the most common primary mesenchymal tumors of the gastrointestinal tract^[1-3]. The mechanisms of tumorigenesis, progression and differentiation of GISTs are unknown. Traditionally, all primary mesenchymal spindle cell tumors of the gastrointestinal (GI) tract were uniformly classified as smooth muscle tumors (e.g., leiomyomas, cellular leiomyomas or leiomyosarcomas). Tumors with epithelioid cytologic features were designated leiomyoblastomas or epithelioid leiomyosarcomas^[4]. Recently, Sircar *et al*^[5] postulated that GISTs originate from Cajal cells in the gastrointestinal tract and differ from leiomyomas and schwannomas, which are of mesenchymal cell origin. Cajal cells are thought to be gastrointestinal pacemaker cells that regulate intestinal motility^[6]. GISTs are characterized by frequent expression of the bone marrow leukocytic progenitor cell antigen CD34^[7] and the c-kit proto-oncogene^[2,3,5].

Some GISTs have mutations in the genes encoding C-kit and platelet-derived-growth factor alpha (PDGFRA) that cause constitutive tyrosine kinase activation^[3,8-10]. Tumors expressing C-kit or PDGFRA oncoproteins were indistinguishable with respect to activation of downstream signaling intermediates and cytogenetic changes associated with tumor progression. C-kit and PDGFRA mutations appear to be alternative and mutually exclusive oncogenic mechanisms in GISTs^[9,10].

Recently, there has been a growing interest in understanding the role of receptor tyrosine kinases (RTK), such as vascular endothelial growth factor

receptor (VEGFR), platelet-derived growth factor receptor (PDGFR) and stem cell factor receptor (KIT) in promoting tumor growth and metastasis^[3,9,11]. As both Tie-1 and Tie-2 possess unique multiple extracellular domains, they are thought to represent a new subfamily of RTKs^[12,13]. Tie signaling is involved in multiple steps of the angiogenic remodeling process during development, including destabilization of existing vessels, endothelial cell migration, tube formation and the subsequent stabilization of newly formed tubes by mesenchymal cells^[14-17].

The angiopoietin (Ang) family has been identified as a key regulator of angiogenesis^[18] and is composed of subtypes Ang-1, Ang-2, Ang-3, and Ang-4^[18-21]. They are the ligands for Tie receptors and the major mediators of the mitogenic and permeability-enhancing effects in endothelial cells^[17,22]. In addition, angiopoietins are survival factors for endothelial cells, and a marked dependence on angiopoietins has been shown in newly formed, but not established tumor vessels^[23,24].

Ang-1 has been shown to act as an obligatory agonist promoting structural integrity of blood vessels^[18,20], whereas Ang-2 has been found to function as a naturally occurring antagonist, promoting either vessel growth or regression depending on the levels of other growth factors, such as VEGF-A^[19,25]. The effect of Ang-3 and Ang-4 have been less characterized, but they also show context-dependent actions as antagonistic and agonistic ligands, respectively^[21,26]. Signaling through Tie-2 has been extensively studied, and the results suggest that signaling involving phosphatidylinositol 3' kinase (PI3K) activation is a major pathway^[27,29]. The ligand-independent function of Tie-1 involves shedding of the receptor^[30,31] and heteromatrix complex formation with Tie-2^[30,32]. Recently, it has been found that Ang-1 and Ang-4 can activate Tie-1^[33].

Coexpression of angiopoietin and its receptor, either Tie-1 or Tie-2, has been reported in tumor cells, suggesting the presence of an autocrine and/or a paracrine angiopoietin/Tie growth pathway in solid tumors^[34-36]. Further, the expression levels of angiopoietin and its receptors have been shown to correlate with progressive tumor growth and development of metastasis by many types of carcinomas^[35-38].

These studies suggest that the angiopoietin pathway is involved in tumor cell growth and differentiation. However, there are no data detailing angiopoietin expressions and Tie receptor expressions in GIST, leiomyoma or schwannoma, or the role of angiopoietin in the etiology of these tumors. The purpose of this study was to investigate the expression of angiopoietins and Ties in GISTs.

MATERIALS AND METHODS

Samples

A total of thirty GISTs included 26 cases from the stomach and four from the small intestine. Seventeen leiomyomas included four from the oesophagus, five from the stomach and eight from the large intestine. Six schwannomas included five from the stomach and one

from the large intestine. Specimens were selected from surgical pathology archival tissues at Nagasaki University Hospital between 2001 and 2006. The GISTs were 0.8-12.0 cm in diameter, the leiomyomas were 0.1-4.5 cm, and the schwannomas were 0.6-5.0 cm. In this study, GISTs were defined as tumors expressing both c-kit and CD34 surface antigens. GISTs were classified by risk categories, mitosis counts and tumor size^[39]. The number of mitoses was determined by counting 50 high-power fields (HPF, $\times 400$) using a Nikon (Tokyo, Japan) E400 microscope. Leiomyomas were defined as expressing α -smooth muscle cell actin (SMA) but not c-kit, CD34 or S100-protein. Schwannomas were defined as expressing S100-protein but not c-kit, CD34 or SMA. Two independent pathologists (T. Nakayama and I. Sekine) determined tumor identification/classification.

Immunohistochemical staining

The subcellular localization of Ang-1, -2 and -4 and Tie-1 and -2 was determined in GISTs using polyclonal antibodies directed against unique sequences. These antibodies were devoid of any cross-reaction with other proteins in the angiopoietin family. Formalin-fixed and paraffin-embedded specimens were cut into 4 μ m thick sections, deparaffinized and preincubated with normal bovine serum to prevent non-specific binding. The sections were incubated overnight at 4°C with primary polyclonal antibody to human Ang-1, -2 or -4 ([N-18],[N-18],[L-18], respectively, 1 μ g/mL; Santa Cruz Biotechnology, Inc., Santa Cruz, CA), Tie-1 or -2 ([C-18],[C-20], respectively, 1 μ g/mL; Santa Cruz Biotechnology, Inc.), followed by alkaline phosphatase-conjugated anti-goat IgG antibody (0.4 μ g/mL; Santa Cruz Biotechnology, Inc.) for Ang-1, -2 and -4, and anti-rabbit IgG antibody (0.4 μ g/mL; Santa Cruz Biotechnology, Inc.) for Tie-1 and -2. The reaction products were visualized using a mixture of 5-bromo-4-chloro-3-indolyl phosphate and nitroblue tetrazolium chloride (BCIP/NBT; Roche Diagnostic Corp., Indianapolis, IN). Negative controls replaced the primary antibody with non-immunized rabbit or goat serum, and the hemangioma tissue of human skin served as the positive control^[40]. Ang-1, -2 and -4 and Tie-1 and -2 expressions were classified into three categories depending upon the percentage of cells stained and/or the intensity of staining: -, 0 to 10% tumor cells positive; +, > 10% tumor cells positive.

Statistical analysis

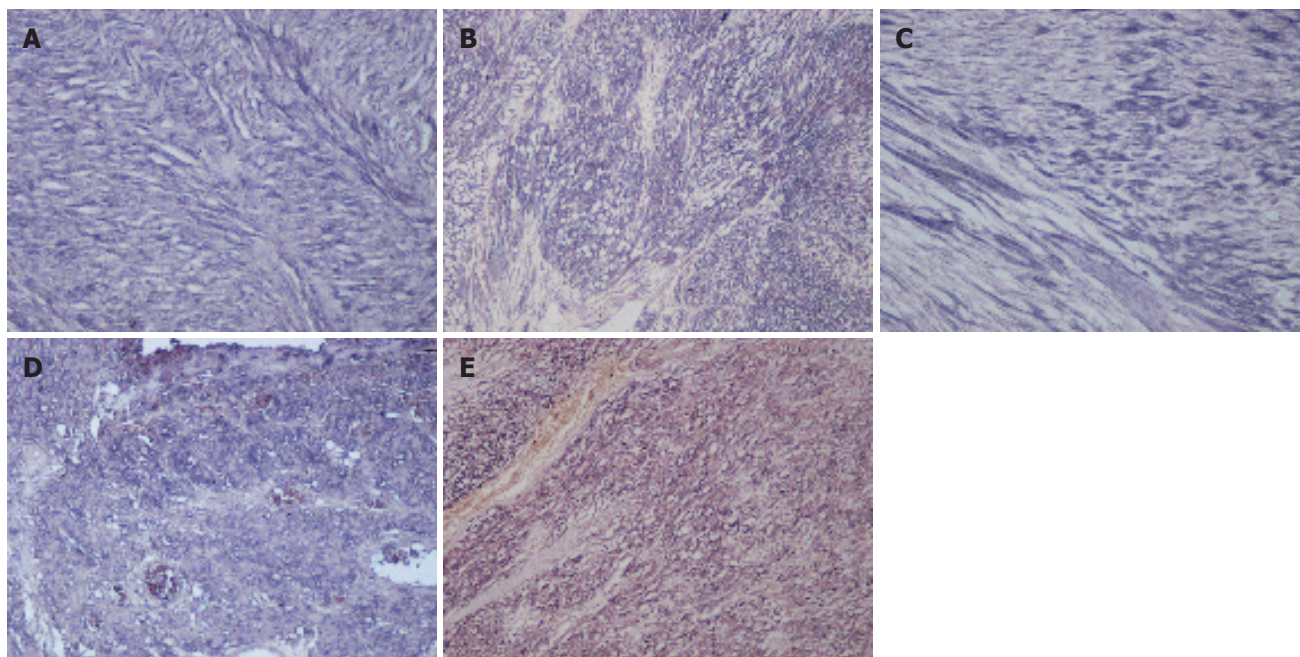

The Stat View II program (Abacus Concepts, Inc., Berkeley, CA) was used for statistical analysis. Analyses comparing the degree of Ang-1, -2 and -4 and Tie-1 and -2 expressions in GISTs, leiomyomas and schwannomas were performed using the Mann-Whitney's test.

RESULTS

The results of immunohistochemical stainings for Ang-1, -2 and -4 and Tie-1 and -2 are summarized in Table 1. Ang-1, -2 and -4 and Tie-1 and -2 were heterogeneously expressed in GISTs, leiomyomas and schwannomas and

^a*P* < 0.001 *vs* leiomyoma.**Figure 1** Immunohistochemical staining of Angiopoietin pathway components. Alkaline phosphatase reaction products demonstrating Ang-1 (A), Ang-2 (B), Ang-4 (C), Tie-1 (D) and Tie-2 (E) expression. Ang-1, -2 and -4 were expressed in the cytoplasm, and Tie-1 and -2 were expressed in both the cytoplasm and the cell membrane of GIST cells (x 200).

localized to the cytoplasm and/or membrane of tumor cells. Immunohistochemical staining revealed Ang-1, -2 and -4 in the cytoplasm of GIST (Figure 1A-C), leiomyoma (Figure 2A-C) and schwannoma (Figure 3A-C) cells. Tie-1 and -2 were found in the membrane and cytoplasm of GIST (Figure 1D and E), leiomyoma (Figure 2D and E) and schwannoma (Figure 3D and E) cells. Immunohistochemical staining revealed that 66.7% of GISTs (20 of 30), 76.5% of leiomyomas (13 of 17) and 83.3% of schwannomas (5 of 6) were positive for Ang-1. 83.3% of GISTs (25 of 30), 82.4% of leiomyomas (14 of 17) and 100% of schwannomas (6 of 6) were positive for Ang-2. 36.7% of GISTs (11 of 30), 58.8% of leiomyomas (10 of 17) and 83.3% of schwannomas (5 of 6) were positive for Ang-4. There were no statistical differences in Ang-1, -2 or -4 expression between GISTs and leiomyomas or schwannomas. 60.0% of GISTs (18 of 30), 82.4% of leiomyomas and 100% of schwannomas (6 of 6) were positive for Tie-1. 10.0% of GISTs (3 of 30), 94.1% of leiomyomas (16 of 17) and 66.7% of schwannomas (2 of 6) were positive for Tie-2. Tie-2 expression was statistically different between GISTs and leiomyomas (*P* < 0.001). However, there was no correlation between Tie-1 expression and histological differences.

GISTs were classified by risk category, mitosis counts and tumor size in Table 2. All six cases within the high risk category expressed Ang-1 and -2 and Tie-1 and -2 proteins. All three cases with over 10 mitoses per 50 HPFs strongly expressed Ang-1, -2 and -4 and Tie-1 and -2. Finally, only two tumors that measured over 10 cm strongly expressed Ang-1, -2 and -4 and Tie-1 and -2. However, there was no correlation between Ang-1, -2 and -4 and Tie-1 and -2 expression and each classification.

DISCUSSION

The coexpression of Ang-1, -2 and -4 and Tie-1 and -2 has been reported in tumor cells, suggesting the presence of an autocrine and/or a paracrine angiopoietin/Tie growth pathway in solid tumors^[35-38]. Angiopoietins (Angs) also have been shown to play a role in the proliferation and/or differentiation of stromal tumors and normal mesenchymal cells^[41,42]. Angiopoietin expression in GISTs has not been reported yet. Further, there have been no studies of Tie receptor expression in GISTs, leiomyomas and schwannomas or of the potential roles of angiopoietins and its receptors in the growth of these tumors. This is the first study to determine the expression of Tie receptors

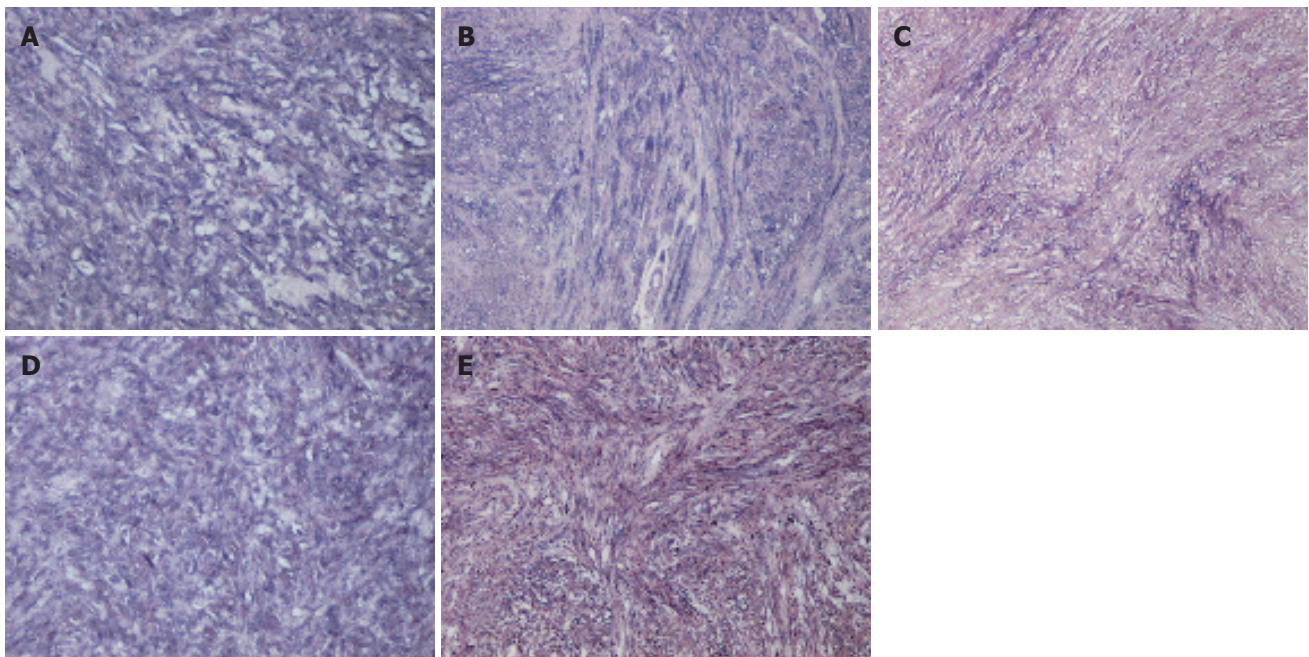

Figure 2 Immunohistochemical staining of human intestinal leiomyomas. Alkaline phosphatase reaction products demonstrating Ang-1 (A), Ang-2 (B), Ang-4 (C), Tie-1 (D) and Tie-2 (E) expression (x 200).

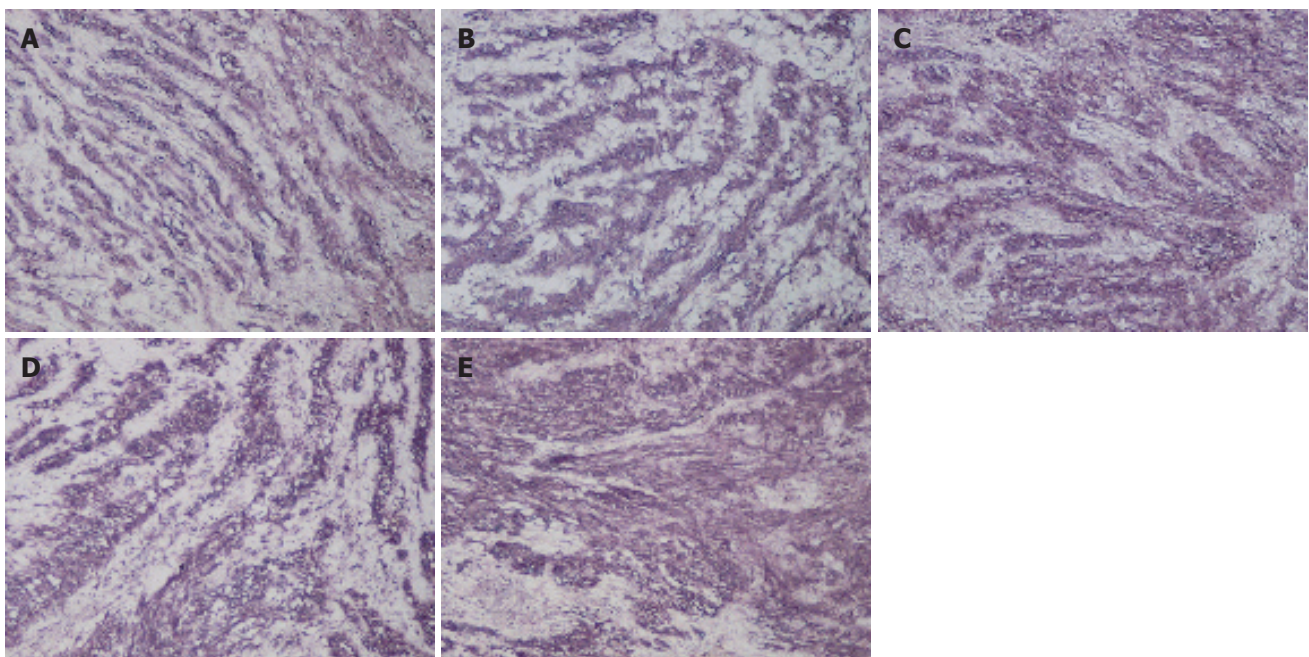

Figure 3 Immunohistochemical staining of human intestinal schwannomas. Alkaline phosphatase reaction products demonstrating Ang-1 (A), Ang-2 (B), Ang-4 (C), Tie-1 (D) and Tie-2 (E) expression (x 200).

in GIST and stromal tumors. Our results demonstrate substantial levels of angiopoietins and Tie receptors in the cytoplasm of GIST, leiomyoma and schwannoma cells. Therefore, we suggest that angiopoietins and its receptors may play an important role in growth and/or differentiation of intestinal stromal tumors via autocrine and/or paracrine pathways.

We did not find any statistical correlation between risk grade and the expression of Angs or Ties for GISTs. However, all four GISTs in the high risk category

expressed Angs and Ties (Table 2). Further, all four GISTs that had higher mitosis counts (over ten per 50 HPFs) were positive for Angs and Ties. Our data suggest that high risk GISTs might express Angs and Ties at higher than normal levels. Future studies will examine angiopoietin pathway components in high risk GISTs.

Ang-2 induces a variety of enzymes and proteins important in the degradation process, including matrix-degrading metalloproteinases, metalloproteinase interstitial collagenase, and serine proteases, such as urokinase-

NS: not significant.

type plasminogen activator (u-PA)^[43,44]. In this study, we did not evaluate the invasive activities of GIST cells because all of the GISTs were solitary and showed clear margins. However, the activation of these various factors by angiopoietins may allow for the development of a prodegradative environment that facilitates migration and invasion of tumor cells.

There has been a growing interest in understanding the role of receptor tyrosine kinases (RTK), such as vascular endothelial growth factor receptor (VEGFR)^[11], platelet-derived growth factor receptor (PDGFR)^[9] and stem cell factor receptor (KIT)^[3] in promoting tumor growth and metastasis. Joensuu *et al*^[45] reported a patient in whom Imatinib (STI-571, Gleevec), a tyrosine kinase inhibitor, was effective against a GIST. Imatinib has proven to be remarkably efficacious in heavily pretreated GIST patients with advanced disease^[46]. Further, anti-angiopoietin reagents are being used in clinical trials for the therapy of gastric, lung and breast cancer^[47,48].

Sunitinib (sunitinib malate; SU11248; SUTENT®; Pfizer Inc, New York, NY, USA) is a novel multi-targeted tyrosine kinase inhibitor with high binding affinity for VEGFR and PDGFR that recently has shown anti-tumor and anti-angiogenic activities^[49]. This drug recently received approval from the US Food and Drug Administration (FDA) for two applications: advanced gastrointestinal stromal tumors (GISTs)^[50] and renal cell carcinoma^[51], in patients who are resistant or intolerant to treatment with Imatinib. Since the Tie receptor is an RTK, Sunitinib may be suitable to down-regulate the activity of the angiopoietin pathway. In fact, this study presents data that supports the clinical validity of Sunitinib in GISTs.

ACKNOWLEDGMENTS

We are grateful to Mr. Toshiyuki Kawada (Nagasaki University Graduate School of Biomedical Sciences) for his excellent immunohistochemical assistance.

Abstract

AIM: To clarify whether perimuscular connective tissue contains more lymphatic vessels than the shallower layers in human gallbladders.

METHODS: Lymphatic vessels were stained immunohistochemically with monoclonal antibody D2-40, which is a specific marker of lymphatic endothelium, in representative sections of 12 normal human gallbladders obtained at the time of resection for colorectal carcinoma liver metastases. In individual gallbladder specimens, nine high-power ($\times 200$) fields with the highest lymphatic vessel density (LVD), termed "hot spots", were identified for each layer (mucosa, muscle layer, and perimuscular connective tissue). In individual hot spots, the LVD and relative lymphatic vessel area (LVA) were measured microscopically using a computer-aided image analysis system. The mean LVD and LVA values for the nine hot spots in each layer were used for statistical analyses.

RESULTS: In the mucosa, muscle layer, and perimuscular connective tissue, the LVD was 16.1 ± 9.2 , 35.4 ± 15.7 , and 65.5 ± 12.2 , respectively, and the LVA was 0.4 ± 0.4 , 2.1 ± 1.1 , and 9.4 ± 2.6 , respectively. Thus, both the LVD and LVA differed significantly ($P < 0.001$ and $P < 0.001$, respectively; Kruskal-Wallis test) among the individual layers of the wall of the gallbladder, with the highest LVD and LVA values in the perimuscular connective tissue. Most (98 of 108) of the hot spots within the perimuscular connective tissue were located within 500 μm of the lower border of the muscle layer.

CONCLUSION: The perimuscular connective tissue

contains more and larger lymphatic vessels than the shallower layers in the human gallbladder. This observation partly explains why the incidence of lymph node metastasis is high in T2 (tumor invading the perimuscular connective tissue) or more advanced gallbladder carcinoma.

INTRODUCTION

Gallbladder carcinoma is a highly lethal disease^[1,2]. Lymph node metastasis occurs early and is a major reason for the dismal prognosis for this disease^[3-5]. The incidence of lymph node metastasis increases with the depth of penetration of the primary tumor; it ranges from 0% to 8%^[5-9] for tumors that are limited to the mucosa or muscle layer (T1 disease according to the TNM staging system^[10]), whereas it ranges from 33% to 62%^[5-7,9,11,12] for tumors that have invaded the perimuscular connective tissue (T2 disease). This suggests that lymph node metastasis is frequent once the primary tumor has invaded the perimuscular connective tissue of the gallbladder.

The architecture of the lymphatic system of the gallbladder has been examined in various experimental animals, and a well-developed set of lymph channels has been described in the perimuscular connective tissue^[13,14]. In 1989, Kambayashi reported similar findings for canine gallbladders^[15]. The current study was conducted to clarify immunohistochemically whether the perimuscular connective tissue contains more lymphatic vessels than the mucosa or muscle layer of normal human gallbladders, using monoclonal antibody D2-40, which is a specific marker of the lymphatic endothelium^[16-19], and a computer-aided image analysis system. The goal of the present study was to suggest the hypothesis that the presence of more and large-

er lymphatic vessels in the perimuscular connective tissue is linked to the reported high incidences of lymph node metastasis in T2 (tumor invading the perimuscular connective tissue) or more advanced gallbladder carcinoma^[5-7,9,11].

MATERIALS AND METHODS

Twelve patients with colorectal carcinoma liver metastases underwent partial hepatectomy combined with cholecystectomy between January and December, 2005. The patient group included eight men and four women, with a median age of 68.5 years (range, 42-80 years). None of the patients had a history of biliary disease or chronic liver disease. The gallbladder specimens obtained from the patients, all of whom gave informed consent for histologically examining the specimens, were included in the present study.

Individual resected specimens were submitted to the Department of Surgical Pathology in our hospital for gross or histologic examination, which revealed that none of the liver tumors involved the gallbladders. The gallbladders ($n = 12$) were opened and examined grossly by experienced surgical pathologists, who found neither mucosal lesions nor gallstones in any of the viscera. The gallbladder specimens were then fixed in formalin. A single longitudinal representative section, which passed through both the tip of the fundus of the gallbladder and the cystic bile duct, was cut from each gallbladder specimen and embedded in paraffin. Routine histologic examination with hematoxylin and eosin staining detected no abnormalities in any of the representative sections.

Anatomy of the gallbladder

The gallbladder is divided into three equal parts: the fundus, body, and neck. Histologically, the wall of the viscus comprises three layers: the mucosa, muscle layer, and perimuscular connective tissue (subserosal layer)^[10].

Lymphatic vessel parameters

Lymphatic vessel density (LVD) was defined as the number of lymphatic vessels per mm²; a high-power ($\times 200$) field with the highest LVD in an area was referred to as a "hot spot", in line with earlier studies^[20,21]. Relative lymphatic vessel area (LVA) was defined as the percentage of positively stained lymphatic vessel area in a hot spot^[20,21].

Immunohistochemistry

The paraffin-embedded blocks of the representative sections ($n = 12$) were used for immunohistochemistry. Three serial sections (3 μ m thickness) were cut from each block: one for routine histologic examination using hematoxylin and eosin staining, one for immunohistochemical staining with monoclonal antibody D2-40, and one as a negative control.

The mouse monoclonal antibody D2-40 (Signet Laboratories, Inc., Dedham, MA) was used at a dilution of 1:200. The streptavidin-biotin immunoperoxidase method was used for detecting immune complexes. The sections were deparaffinized and rehydrated, then microwaved at 500 W for 7 cycles of 3 min each in 10 mmol/L citrate buffer (pH 6.0) to retrieve antigenic activity. After blocking of endogenous peroxidase, the sections were incubated overnight

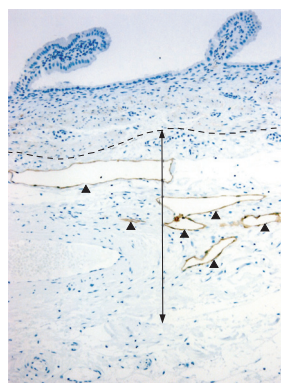

Figure 1 D2-40 antibody-positive lymphatic vessels in the wall of a human gallbladder. The perimuscular connective tissue contains more and larger lymphatic vessels (arrowheads), most of which are located within 500 μ m (two-headed arrow) of the lower border of the muscle layer (broken line), than the mucosa or muscle layer (Original magnification, $\times 100$).

at 4°C with D2-40. The sections were then incubated at room temperature for 30 min with goat anti-mouse immunoglobulin conjugated to a peroxidase-labeled amino acid polymer, as provided in the SAB-PO (M) Kit (Nichirei Biosciences Inc., Tokyo, Japan). Diaminobenzidine was used as the chromogen, and the sections were counterstained with hematoxylin. Negative controls were treated in the same manner, except that incubation with the primary antibody was omitted. Sections of normal human tonsil were used as positive controls.

Computer-assisted morphometry of lymphatic vessels

The representative sections stained with the D2-40 antibody ($n = 12$) were examined for LVD and LVA using an Olympus FX 380 microscope (Olympus Co. Ltd., Tokyo, Japan). By scanning each representative section at low power ($\times 20$), a total of nine hot spots, three for each part of the gallbladder (fundus, body, and neck), was identified per layer (mucosa, muscle layer, and perimuscular connective tissue) of the gallbladder. In individual hot spots, the outlines of individual immunohistochemically stained lymphatic vessels were identified and traced using a computer-aided image analysis system (FlvFs, ver 1.10; Flovel Co. Ltd., Tokyo, Japan) at $\times 200$ magnification, to measure LVD and LVA.

Statistical analysis

The mean LVD and LVA for the nine hot spots per each layer (or per each part) of the gallbladder were subjected to statistical analyses. The Kruskal-Wallis test was used to compare the lymphatic vessel parameters (LVD and LVA) among individual layers (or individual parts). Statistical evaluations were performed using the SPSS 11.5J software package (SPSS Japan Inc., Tokyo, Japan). A P value < 0.05 was considered to be statistically significant.

RESULTS

D2-40 antibody-positive lymphatic vessels were found in all 12 gallbladder specimens (Figure 1). Computer-assisted morphometric analysis of the lymphatic vessels showed that both the LVD and LVA values differed significantly ($P < 0.001$ and $P < 0.001$, respectively) among the individual layers of the wall of the gallbladder, with the highest LVD and LVA values found in the perimuscular connective tissue (Table 1). Most (98 of 108) of the hot spots within the perimuscular connective tissue were located

Table 1 LVD and LVA values for individual layers of the wall of the gallbladder (mean \pm SD, $n = 12$)

Layer of the wall of the gallbladder	LVD (per mm ²)	Pvalue ^a	LVA (%)	Pvalue ^a
Mucosa	16.1 \pm 9.2	< 0.001 ^b	0.4 \pm 0.4	< 0.001 ^b
Muscle layer	35.4 \pm 15.7		2.1 \pm 1.1	
Perimuscular connective tissue	65.5 \pm 12.2		9.4 \pm 2.6	

LVD: lymphatic vessel density; LVA: relative lymphatic vessel area; ^aKruskal-Wallis test, ^b $P < 0.001$ between mucosa, muscle and perimuscular connective tissue of the gallbladder for both LVD and LVA.

within 500 μ m of the lower border of the muscle layer (Figure 1). The LVD and LVA values did not differ among the fundus, body, and neck (data not shown; $P = 0.837$ and $P = 0.756$, respectively).

DISCUSSION

The monoclonal antibody D2-40, which was generated against an oncofetal antigen that is expressed in fetal testes and in testicular germ cell tumors, is recognized as a highly specific lymphatic marker that does not react with the vascular endothelium^[16-19]. Although it is difficult or sometimes impossible to distinguish morphologically lymphatic vessels from venules or capillaries on routine histologic examination, immunohistochemical staining using D2-40 enables easy identification of lymphatic vessels^[16-19]. Using this method, we have clearly demonstrated that the LVD and LVA values are significantly higher in the perimuscular connective tissue than in the mucosa or muscle layer of normal human gallbladders.

A tumor that invades the deep layers of the gallbladder generally shows a higher histologic grade (less differentiation) than a superficial tumor^[5,7]. It is very likely that a less-differentiated tumor that invades the perimuscular connective tissue (T2 disease) causes a higher incidence of nodal involvement than a differentiated tumor within the superficial layers (T1 disease). Another explanation for the high incidences of nodal disease in T2 gallbladder carcinoma is the higher abundance of vessels in the perimuscular connective tissue than in the shallower layers^[15,22], as clearly demonstrated in the present study. The presence of more and larger lymphatic vessels in the perimuscular connective tissue (Figure 1) may increase the likelihood that the tumor will permeate the lymphatic vessels. The hot spots were prominent in the shallow (≤ 500 μ m) zone of the perimuscular connective tissue of the gallbladder (Figure 1); this observation may partly explain why lymph node metastasis often occurs even in tumors with shallow (≤ 2 mm) subserosal invasion^[12].

The results of the current study may provide a basis for the investigation of lymphangiogenesis in gallbladder carcinoma. Recent evidence suggests that lymphangiogenesis plays a key role in the development of nodal metastases from various human malignancies, including head and neck squamous cell carcinoma^[21], cutaneous melanoma^[20,23], breast carcinoma^[24], and colorectal carcinoma^[25]. However, to the best of the knowledge, no investigations of this type have been conducted on gallbladder carcinoma. Fur-

ther investigations into the role of lymphangiogenesis in gallbladder carcinoma are warranted.

The limitations of the present study include the retrospective nature of the analysis, the low number of specimens examined, and the gallbladder specimens taken from patients with colorectal carcinoma liver metastases. Despite these limitations, the present work more clearly defines than earlier studies the abundance of lymphatic vessels in the perimuscular connective tissue of the human gallbladder.

In conclusion, the perimuscular connective tissue (subserosal layer) has more and larger lymphatic vessels than the shallower layers of the human gallbladder. This observation partly explains why the incidence of lymph node metastasis is high in T2 (tumor invading the perimuscular connective tissue) or more advanced gallbladder carcinoma.

Abstract

AIM: To investigate the clinical performances of rapid stool test (ImmunoCard STAT HpSA, Meridian Diagnostic Inc.) in the evaluation of eradication therapy of *H pylori* and to compare it with a well-known and validated laboratory stool test (Amplified IDEA Hp StAR, Dako).

METHODS: Stool samples of 122 patients were evaluated after eradication therapy of *H pylori*. *H pylori* status was assessed by 13C-urea breath test (UBT). Stool specimens were tested using either the rapid immunoassay kit or the laboratory immunoassay kit.

RESULTS: Forty-three patients were infected and 79 non-infected. Sensitivity and specificity of ImmunoCard STAT and Hp StAR were 58.14% and 76.4%, and 97.47% and 98.73%, respectively ($P > 0.05$). Overall agreement between the two tests was 92.6% (113 of 122 cases).

CONCLUSION: ImmunoCard STAT seems to have rather low performances, and it cannot be regarded as a reliable tool in the post-treatment setting. Also Hp StAR cannot be recommended to confirm *H pylori* eradication after treatment.

Trevisani L, Cifalà V, Fusetti N, Gilli G, Tombesi P, Torchiario M, Boccia S, Abbasciano V. Diagnostic accuracy of a rapid fecal test to confirm *H pylori* eradication after therapy: Prospective comparison with a laboratory stool test. *World J*

INTRODUCTION

Nowadays, there is an increasing interest in non-invasive methods to diagnose *H pylori* infection. Indeed, they can profitably replace endoscopy in predicting the diagnosis and determining the management of some types of patients, according to a "test and treat" strategy^[1]. Post-therapy testing to confirm eradication is also growing in importance, as resistant strains of *H pylori* are now widely prevalent in both USA and Europe, with a failure rate of current eradication regimens ranging from 10% to 20%^[2,3]. Furthermore, in patients with bleeding peptic ulcer, the risk for rebleeding is greatly increased if *H pylori* infection persists^[4].

Until some years ago, the only non-invasive test that reliably demonstrated whether eradication was successful was the urea breath test (UBT)^[5]. It is easy to perform and does not need special transport conditions, but requires expensive and specific instruments. In the last years, several stool antigen tests have been put on the market and approved by the U.S. Food and Drug Administration for detection of *H pylori* before and after therapy. They are considered reliable in either pre-treatment or post-treatment settings^[1,6,7], even though some controversial results have been reported after eradication therapy^[8-12]. These tests are based on an enzyme immunoassay carried out in laboratory, and this limit delays the diagnostic report. Moreover, if stool samples are not frozen immediately after receipt and stored frozen until titration at a temperature lesser than -20°C, sensitivity of the test can drop^[13]. More recently, some rapid stool tests not requiring laboratory assay have been put on the market. These near-patient tests are cheap, easy and quickly performed, and have good diagnostic accuracy in the pre-treatment setting^[14-19]. For these reasons, they could represent a valid alternative to both UBT and traditional stool tests. However, at present there are few data about their clinical usefulness in the post-treatment setting.

In this prospective pilot study, we investigated the clinical performances of a rapid stool test in the evaluation

of eradication therapy and compared it with a well-known and validated *H pylori* stool test requiring laboratory assay.

MATERIALS AND METHODS

Patients

One hundred thirty consecutive outpatients undergoing ^{13}C -UBT to determine their post-treatment *H pylori* status at least 6 wk after the end of antimicrobial therapy, were asked to deliver a stool specimen the day after ^{13}C -UBT was performed. Eight of them did not deliver it and were excluded from the study; the remaining 122 patients (46 males and 76 females; mean age \pm SD: 54.94 ± 13.90 years) were definitively enrolled. They were previously given the following regimens: Proton pump inhibitor (PPI) + Clarithromycin + Amoxicillin in 49 cases; PPI + Clarithromycin + Tinidazole (or Metronidazole) in 30 cases; PPI + Levofloxacin + Amoxicillin in 13 cases; Ranitidine bismuth citrate + Clarithromycin in 4 cases; PPI + Bismuth citrate + Metronidazole + Tetracycline in 2 cases; and undetermined in 24 cases. Exclusion criteria were: use of antibiotics, histamine-2 receptor antagonists, bismuth or PPIs in the last 6 wk; chronic use of corticosteroids or non-steroidal anti-inflammatory drugs; previous gastric surgery; severe concomitant diseases; pregnancy or lactation. All patients gave their informed consent, and the study was approved by our Ethical Committee.

Methods to assess *H pylori*

The post-treatment *H pylori* status was assessed by ^{13}C -UBT that was assumed as the gold standard according to previous reports^[1,10,20,21]. ^{13}C -UBT was carried out at least 6 wk after the end of antimicrobial therapy according to previously validated protocols^[20]. In brief, the patients were fasted overnight, and the baseline breath sample was collected. Afterwards, they drank a 200-mL water solution containing 75 mg of ^{13}C -urea and 1.4 g of citric acid (BREATHQUALITY-UBT ^{13}C -UREA, AB Analitica, Padova, Italy), and a further breath sample was collected 30 min later. Samples were analyzed by an infrared spectrometer and positive result was defined by a cut-off of 2.5‰. The doctor who performed the ^{13}C -UBTs was blinded to the results of all the other tests.

A portion of each fresh stool sample was tested by using a rapid immunochromatographic assay commercial kit (ImmunoCard STAT HpSA, Meridian Diagnostic Inc., OH, USA) (ImmunoCard STAT) for the detection of *H pylori* antigens in stools. All tests were performed by a single unique observer (L.T.) who was unaware of the *H pylori* status. He evaluated each sample according to the method previously described^[18]. A positive result was defined if both a pink-red band (test line) and a blue-colored band (control line) appeared in the reading window. If only a blue band appeared in the reading window, the result was considered negative.

The remaining portion of each stool specimen was frozen and stored, and successively tested by using a commercial kit (Amplified IDEA Hp StAR, Dako,

Table 1 Performances of Immuno Card STAT and HpStAR tests

	ImmunoCard STAT	Hp StAR
Sensitivity, % (95% CI)	58.14% (42-73)	76.74% (61-88)
Specificity, % (95% CI)	97.47% (91-100)	98.73% (93-100)
PPV, % (95% CI)	92.59% (76-99)	97.06% (85-100)
NPV, % (95% CI)	81.05% (72-88)	88.64% (80-94)
Global accuracy, % (95% CI)	83.61% (76-90)	90.98% (84-95)

False negative, <i>n</i>	18	10

CI: Confidence interval; PPV: Positive predictive value; NPV: Negative predictive value.

Glostrup, DK) (Hp StAR), widely validated in literature in both the pre-treatment and post-treatment settings^[22-24]. This monoclonal enzyme immunoassay has been reported to be more accurate than polyclonal enzyme immunoassay in determining *H pylori* status after eradication treatment^[25]. The Hp StAR test is an *in vitro* qualitative procedure for the detection of *H pylori* antigens in stool samples, and needs a laboratory to be performed. It is a sandwich-type enzyme immunoassay using immunoassay technology. The test was performed according to the manufacturer's instructions as previously described^[18]. According to the manufacturer's guidelines, an absorbance 450 nm (A_{450}) ≥ 0.190 was defined as a positive and $A_{450} < 0.190$ as a negative test result.

Estimation of sample size and statistical analysis

Sample size calculation was performed to obtain a good accuracy power, i.e. at about 95%, and the significance study threshold was chosen at 5% (type I error: 0.05). Stool tests sensitivity, specificity, predictive values of positive and negative results, diagnostic accuracy, and their 95% confidence intervals (95% CI) were calculated using standard methods. Differences in the test performances between the two methods were analysed by using Fisher's exact test. A *P* value < 0.05 was regarded as statistically significant.

RESULTS

According to the study protocol, UBT showed eradication in 79 (64.8%) patients, and persistency of *H pylori* infection in 43 (35.2%) patients.

ImmunoCard STAT was positive in 27 cases (two false-positives), and negative in 95 (18 false-negatives), with a sensitivity and specificity of 58.14% and 97.47%, respectively. Hp StAR was positive in 34 patients (one false-positive), and negative in 88 (10 false-negatives), with a sensitivity and specificity of 76.74% and 98.73%, respectively. The overall agreement between the two tests in the evaluation of *H pylori* status was 92.6% (113 of 122 cases).

The diagnostic performances of ImmunoCard STAT and Hp StAR are reported in Table 1. Despite Hp StAR seemed to work better than ImmunoCard STAT, no significant difference was observed between the two stool tests.

DISCUSSION

Rapid tests for the detection of *H pylori* antigens in stool can be very useful in clinical practice, as they are cheap, easy and quickly performed, and can be done in the doctor's office within 10 min. Several studies demonstrated their high diagnostic accuracy in untreated patients^[14-18], and they can reliably replace UBT in this setting. Conversely, their clinical usefulness to evaluate *H pylori* status after eradication therapy has been scarcely investigated. Our study demonstrated that sensitivity, negative predictive value, and global accuracy of rapid stool test were rather low (58.1%, 81%, and 83.6%, respectively), so this test cannot be regarded as a reliable tool in the post-treatment setting. On the contrary, several authors reported that rapid stool tests have post-treatment performances similar to the pre-treatment ones, and are also indicated to assess the success of eradication therapy^[26-33]. However, other authors reported lower performances of rapid stool tests after eradication therapy in either adults^[34] or children^[14], and Gisbert *et al*^[35] suggested that they cannot be recommended to confirm *H pylori* eradication after treatment. In a multicenter trial investigating the same commercial kit used in our study, Kato *et al*^[14] found a sensitivity of only 75% in the post-treatment setting, but in this study only frozen stools were tested. Conversely, we tested fresh stools, as this option better reflects what happens in the near-patient environment, such as the doctor's office. Using fresh stools, we expected results better than (or at least similar to) those obtained by Kato *et al*^[14]. On the contrary, they were worse because sensitivity of Immuno Card STAT was 58.14%, resulting in wrong diagnosis in 20 of 122 patients, with a global accuracy of 83.6%.

In our study, all tests were read by a single unique observer, who in all cases was able to assess the positivity or negativity of the test. Indeed, the test was classified as positive even if the intensity of the pink-red band appearing in the reading window (test line) was very weak, according to the manufacturer's instructions. Conversely, other authors observed that the test line was so weakly visible that they judged the result as equivocal, in a percentage ranging from 5% to 11.9%^[15,26].

We compared the rapid stool test with another, well-known, monoclonal enzyme immunoassay (Hp StAR), which has to be performed in laboratory. No significant difference was observed between the two tests, and their concordance was 92.6%, similar to that reported in our prior study investigating the same commercial kits in the pre-treatment setting^[18]. It follows that in our study the performances of the laboratory monoclonal test provided unsatisfying also results, with a sensitivity lower than 80% and a global accuracy of 90.98%, and we think it cannot be recommended to confirm *H pylori* eradication after treatment. Our opinion is supported by a recent systematic review on the role of stool antigen test for the diagnosis of *H pylori*, which showed relatively low accuracy in some post-treatment studies with polyclonal stool antigen test, and suggested that its use in clinical practice is yet to be defined^[23]. Indeed, the Maastricht 2-2000 Consensus Conference also recommended UBT as the most reliable,

non-invasive test to assess eradication efficacy^[1].

In our study, we did not use invasive methods (such as histology or rapid urease test) to evaluate *H pylori* status, as we and our Ethical Committee judged it unethical that patients with no indications to gastroscopy had to undergo invasive procedures to assess *H pylori* eradication. However, ¹³C-UBT was assumed as the gold standard to evaluate *H pylori* status, as it is considered the method of choice to monitor success of therapy in both adults and children, and is recommended by current guidelines^[1,36,37]. Indeed, strong evidences of sensitivity and specificity of ¹³C-UBT close to 100% emerge from some good reviews^[20,38,39], and these performances remain very high (quite over 90%) also using low doses of ¹³C-urea^[40].

In conclusion, our study suggests that rapid stool test is not very accurate in the post-treatment setting, and it cannot be recommended to evaluate the success of eradication therapy, as well as the laboratory monoclonal test. However, the conflicting results reported in literature about this topic make the planning of wide multicenter trials quite necessary, to reach a definitive answer to this controversial question.

COMMENTS

Background

In the last years, several stool antigen tests have been put on the market and approved by the U.S. Food and Drug Administration for detection of *H pylori* before and after therapy. These tests are based on an enzyme immunoassay carried out in laboratory, and this limit delays the diagnostic report.

Research frontiers

Recently, some rapid stool tests not requiring laboratory assay have been put on the market. These near-patient tests are cheap, easy and fast to be performed, and have good diagnostic accuracy in the pre-treatment setting. Several authors reported that rapid stool tests have post-treatment performances similar to the pre-treatment ones, and are also indicated to assess the success of eradication therapy.

Innovations and breakthroughs

Our study suggests that sensitivity, negative predictive value, and global accuracy of rapid stool test are rather low, so it cannot be regarded as a reliable tool in the post-treatment setting.

Applications

Our study suggests that rapid stool test is not very accurate in the post-treatment setting, and it cannot be recommended to evaluate the success of eradication therapy.

Peer review

This is a well-designed paper and the results are correctly presented. Through comparison with the well-known and validated laboratory stool test (Amplified IDEA Hp StAR, Dako), the authors suggest that rapid stool test cannot be regarded as a reliable tool in the post-treatment setting. Also Hp StAR cannot be recommended to confirm *H pylori* eradication after treatment.

Abstract

AIM: To evaluate the classification and severity of Crohn's disease in different racial groups.

METHODS: Patients with Crohn's disease from the outpatient clinic of the University Hospital Prof. Edgard Santos were enrolled in the study. This hospital is a reference centre for inflammatory bowel disease. Race was determined using self-identification. The Vienna's classification was applied for all subjects. The severity of Crohn's disease was determined according to the number of surgical procedures, hospital admissions in the last year and treatment with steroids and immunosuppressors. Statistical analysis was calculated using *t* test for means, χ^2 or F for proportions. A *P* value < 0.05 was considered to be significant.

RESULTS: Sixty-five patients were enrolled. Non-white patients were more frequently diagnosed with Crohn's disease in the age less than 40 years than white patients. The behaviour of disease was similar in both groups with a high frequency of the penetrating form. There was a tendency for non-white patients to have a greater frequency of hospital admissions in the last year compared to white subjects. Non-whites also had a higher rate of colonic and upper gastrointestinal involvement, and were also more frequently on treatment with immunosuppressors than white patients although this difference was not statistically significant.

CONCLUSION: Non-white patients with Crohn's disease

INTRODUCTION

Genetic and environmental factors appear to have a role in the pathogenesis of Crohn's disease. The incidence of the disease among first degree relatives of patients is greater than the incidence in the general population^[1]. So far it is believed that the illness is more common among whites than Afro-descendants^[2]. The greatest prevalence is described in Jews^[1] and a low prevalence is described in the Asian population^[3]. The prevalence of Crohn's disease in Brazil is not known however the illness is considered to be of low prevalence in developing countries^[4]. Data from Latin America have found an incidence of 0.03 cases per 100.000 person-years in the period of 1987 to 1993^[5].

In contrast to the increased number of studies about the behaviour of many other diseases according to the racial groups, there is relatively little knowledge about the influence of race in Crohn's disease^[6]. Studies have noted the different characteristics of Crohn's disease among racial groups and the possibility of different pathogenetic mechanisms of this illness in different countries. A more severe disease on presentation and an earlier diagnosis in successive generations has been observed in some patients of Jewish ancestry^[7]. A North American study has demonstrated a genetic heterogeneity between Afro-American patients and non-Jews Caucasians with Crohn's disease^[8]. In the same study it was observed that the Crohn's disease is more common than ulcerative colitis in Afro-Americans with inflammatory bowel disease.

As there is a high miscegenation of races in the Brazilian population the characterization of Crohn's disease within each racial group has become an interesting topic. The evaluation of these aspects may contribute to the

knowledge of the importance of genetic and environmental factors to the development of this illness. The aim of the present study is to evaluate the classification and severity of Crohn's disease in different racial groups.

MATERIALS AND METHODS

This is a sectional study in which patients with diagnosis of Crohn's disease who are followed up in the outpatient clinic of the University Hospital Prof. Edgard Santos were enrolled from March to December of 2006. This clinic is a reference centre for Crohn's disease. We included patients older than 18 years after they had signed the informed consent. The study was approved by the Ethics Committee of the Institution.

The diagnosis criteria for Crohn's disease were based on clinical, laboratorial, radiological, endoscopic and pathologic evaluations^[9].

The demographics variables analysed were: age, gender, self-identification of race and Jewish ancestry. The self-identification was based on the criteria of the Brazilian Governmental Statistics Agency (IBGE). The distribution of the population of Bahia according to the IBGE 2000 Demographic Census using these criteria is: whites, 23%; Afro-Brazilians, 13%; Asians, < 1%; mixed-race, 62%, and Indians, 5%. The state of Bahia has the largest number of self-identified Afro-Brazilians, as well as the one of the highest combined percentages (75%) of Afro-Brazilians and mixed-race residents^[10]. In this study patients were classified according to race into whites and non-whites.

The characterization of the Crohn's disease has been made using the criteria of the Vienna classification: age at diagnosis, localization and behavior colonic disease was compared with non-colonic and penetrating disease with non-penetrating. Other variables analysed were: mean age, gender, smoking, family history of Crohn's disease, perianal and rectovaginal fistula, presence of granuloma in the biopsy and time of diagnosis.

Evaluation of severity of the disease included surgical procedures, hospitalization in the last year and use of immunosuppressors and steroids. Comparison between racial groups was carried out by the χ^2 or F when the expected value was less than 5. For comparison between means the *t* was used. The differences observed were considered significant when the probability of the alpha error *P* was < 0.05.

RESULTS

During the study period sixty-five patients were enrolled, one patient refused to participate. Table 1 shows the characteristics of Crohn's disease in whites and non-white patients according to the Vienna classification; 21 (32.3%) were white, 28 (43.1%) were mixed-race Brazilians and 16 (24.6%) were Afro-Brazilians. Three individuals had Jewish ancestry: two were women, all had presented with ileal disease, and two were classified as L1 (ileum terminal) and one as L3 (ileocolonic). Jewish ancestry was detected only in white patients.

Table 2 shows other variables of the disease including mean age, gender, history of smoking, perianal fistula, rectovaginal fistula, and presence of granuloma in the biopsy

Table 1 Vienna Classification in whites and non-whites patients with Crohn's disease in Bahia-Brazil, 2006

Vienna Classification	Total <i>n</i> = 65	White <i>n</i> = 21	Non-whites <i>n</i> = 44	<i>P</i>
Age at diagnosis				
A1 (< 40)	45 (69.2)	11 (52.4)	34 (77.3)	<i>P</i> < 0.05
A2 (\geq 40)	20 (30.8)	10 (47.6)	10 (22.7)	
Behavior				
B1-Nonsticturing, nonpenetrating	24 (36.9)	8 (38.1)	16 (36.4)	NS ^a
B2-Stricturing	5 (7.7)	2 (9.5)	3 (6.8)	
B3-Penetrating	36 (55.4)	11 (52.4)	25 (56.8)	
Localization ^b				
L1-Ileum terminal	15 (25.4)	7 (36.8)	8 (20.0)	NS ^c
L2-Colon	14 (23.7)	3 (15.8)	11 (27.5)	
L3-Ileocolonic	23 (39.0)	8 (42.1)	15 (37.5)	
L4-Upper gastrointestinal tract (UGT)	7 (11.9)	1 (5.3)	6 (15.0)	NS ^d

NS: no statistically significant difference. ^aComparison between penetrating and non-penetrating; ^bData on 59 patients; ^cComparison between colonic and non-colonic; ^dComparison between UGT and non-UGT.

Table 2 Others parameters in whites and non-whites patients with Crohn's disease in Bahia-Brazil, 2006

Parameters	Total <i>n</i> = 65	Whites <i>n</i> = 21	Non-whites <i>n</i> = 44	<i>P</i>
Age (mean \pm SD)	37.3 \pm 13.0	39.4 \pm 13.9	36.3 \pm 12.6	NS

and time of diagnosis in all patients and in white and non-white patients. Only two white patients had family history of Crohn's disease and one of them had Jewish ancestry and a twin sister with the disease.

Table 3 shows the comparison of parameters of the severity of Crohn's disease between whites and non-white patients.

DISCUSSION

This study was carried out in the state from Brazil with the highest frequency of Afro-descendants. Perhaps this type of ancestry explains the low number of patients with Crohn's disease included in this study. This small number can limit the external validation of the result of the study, but it is important to note that this is a reference center and the study included almost all patients being followed up.

The comparison between whites and non-whites

NS: no statistically significant difference. ^aalmost reached statistical significance (*P* = 0.07).

showed a statistically significant difference in the age at diagnosis. Similar results have been demonstrated by other studies that have detected a greater frequency of diagnosis of Crohn's disease before the age of 40 years in Afro-descendants^[12]. This can be attributed to a more severe disease with earlier symptoms. We also found that the behaviour of the illness was similar in whites and non-whites, with a high frequency of patients with the penetrating form of the disease in both groups^[11]. This result can be explained by the fact that this study has been carried out in a reference center for the treatment of Crohn's disease to where more complex cases are referred.

The colonic localization seemed to be more frequent among non-white patients. We believe that if we had evaluated a higher number of patients the comparison of this variable might have reached statistical significance. This finding is in agreement with an American study that found African American patients were more likely to have ileo-colonic or colonic disease compared to white patients^[13]. A large North American Cohort^[14] observed that African American patients were more likely to develop upper gastrointestinal and colorectal disease than whites, but less likely to have ileum involvement. A Chinese study found a greater rate of upper gastrointestinal Crohn's involvement and less terminal ileum disease in Chinese patients^[15]. This was also observed in the present study in non-white patients. Possibly a difference in the balance between genetic inheritance and environmental factors contribute to the differences in the location of the disease among white and non-white patients^[1].

The presence of ileal disease in all cases with Jewish ancestry raises the possibility of a genetic contribution in the location of this illness. Jewish ancestry was observed only in white patients. The immigration of individuals from countries of Jewish culture might be one of the forms for insertion of this disease in the white patients in the studied population.

In general, there is a slight female predominance in patients with Crohn's disease, although this is not described in all studies. The highest frequency of female patients observed in our study has been described before especially among women in late adolescence and early adulthood, suggesting that hormonal factors may play a role in disease expression^[4]. A large North American cohort study^[14] described a slight female predominance of inflammatory

bowel disease among African Americans compared to whites and Hispanics.

The presence of family history and the high frequency of a previous history of smoking among white patients point out to the importance of genetic aspects and smoking as possible risk factors for the illness in this group of patients. The presence of family history of Crohn's disease only in whites in comparison to non-whites has been previously demonstrated and the authors noted the probable influence of genetic factors in these patients in contrast to the non-white individuals^[14]. Possibly, environmental factors are contributing to the development of the illness in the latter group. Likewise, in a study involving 65 Chinese patients with Crohn's disease the absence of mutation in the CARD15 gene raises the question of whether environmental factors, such as lifestyle, are important in the pathogenesis of this illness. One study that evaluated Western patients has proposed a new hypothesis in which ingestion of highly fermentable but poorly absorbed short-chain carbohydrates and polyols to the distal small intestinal and colonic lumen is an important factor underlying the susceptibility to Crohn's disease^[17]. Further studies are needed in order to address the importance of lifestyle in these patients especially regarding food intake.

Studies about single-nucleotide polymorphisms of the TNF- α promoter gene have found some differences in these polymorphisms between racial groups. Caucasians appear to more frequently have the phenotype of high production of TNF^[18]. Several studies that evaluated cytokine genes polymorphisms have concluded that they have a greater influence on the classification of Crohn's disease rather than in the susceptibility to the illness^[19]. Possibly the evaluation of cytokine gene polymorphisms will be another important topic in the inheritance of Crohn's disease.

The non-white patients had an increased period of time from diagnosis, equal or greater than ten years. This result could be explained by the earlier age at diagnosis in non-white patients and similar ages in both groups at the moment of the study. The greater duration of disease in non-white patients did not influence any change in the behaviour of disease as it would be expected probably because this difference in time was not great enough.

The analysis of severity of the disease showed a greater frequency of partial colectomy and hospitalisation in the last year and treatment with steroids and immunosuppressors in non-white patients. Probably the small number of patients can explain the lack of statistical significance. Nevertheless, it is interesting to note that the variable hospitalisation in the last year almost reached statistical significance. As these patients were evaluated in a single center by the same group of physicians who use a similar therapeutic approach this reinforces the possibility for a more severe illness in non-white patients.

The importance of the description in medical charts of the racial group was emphasized in a former publication which concluded that ethnic and racial differences in the causes, expression and prevalence of some illnesses exist^[20]. In countries with high level of miscegenation, the study of the characteristics of multi-factorial illnesses, as it is the case of Crohn's disease, in the different racial

groups will be able to contribute to the knowledge of its genetics and environmental determinants. The identification of groups at risk for high prevalence and greater severity of the illness may lead to an earlier diagnosis, better treatment response and better quality of life of these patients.

In conclusion, the presence of family history and Jewish ancestry in white patients with Crohn's disease reinforces the importance of the genetic inheritance in these subjects. In this study, non-white patients presented with an earlier diagnosis of the disease and seemed to have had a more severe illness without aspects that might strengthen the influence of genetic inheritance. These data suggest a possible role of environmental factors in the presentation of the disease in non-white patients. Further studies aiming to evaluate the genes associated with Crohn's disease may help in the comprehension of the pathogenetic mechanisms of this illness in this population.

COMMENTS

Background

Crohn's disease is a multifactorial disorder and its pathogenesis is not entirely understood. Environmental and genetic factors are involved, but so far is still not clear the definitive relevance of racial factors.

Research frontiers

There are many studies about genetics aiming to elucidate the factors involved in the pathogenesis of Crohn's disease. So far several studies have found that there are genetic markers differences between races. In addition the importance of environmental factors for some racial groups has been emphasized.

Innovations and breakthroughs

Some studies have showed differences between racial groups in the presentation and severity of Crohn's disease. This article found that non-white were more frequently diagnosed with Crohn's disease in the age less than 40 years than white patients in one population with high rate of miscegenation.

Applications

This article emphasizes the importance to give special attention to racial aspects during follow-up and therapeutics of patients with Crohn's disease because probably distinct racial groups have different aspects in the pathogenesis of the disease. Therefore studies that evaluate the role of genetic markers in Crohn's disease need to consider racial features when describing the studied population.

Peer review

This article included some interesting data for the researchers in this field.

Abstract

AIM: To evaluate the feasibility and safety of performing laparoscopic cholecystectomy (LC) in non-teaching rural hospitals of a developing country without intra-operative cholangiography (IOC). To evaluate the possibility of reduction of costs and hospital stay for patients undergoing LC.

METHODS: A prospective analysis of patients with symptomatic benign diseases of gall bladder undergoing LC in three non-teaching rural hospitals of Kashmir Valley from Jan 2001 to Jan 2007. The cohort represented a sample of patients requiring LC, aged 13 to 78 (mean 47.2) years. Main outcome parameters included mortality, complications, re-operation, conversion to open procedure without resorting to IOC, reduction in costs borne by the hospital, and the duration of hospital stay.

RESULTS: Twelve hundred and sixty-seven patients (976 females/291 males) underwent laparoscopic cholecystectomy. Twenty-three cases were converted to open procedures; 12 patients developed port site infection, nobody died because of the procedure. One patient had common bile duct (CBD) injury, 4 patients had biliary leak, and 4 patients had subcutaneous emphysema. One cholecystohepatic duct was detected and managed intraoperatively, 1 patient had retained CBD stones, while 1 patient had retained cystic duct stones. Incidental gallbladder malignancy was detected in 2 cases. No long-term complications were detected up to now.

CONCLUSION: LC can be performed safely even in non-

teaching rural hospitals of a developing country provided proper equipment is available and the surgeons and other team members are well trained in the procedure. It is stressed that IOC is not essential to prevent biliary tract injuries and missed CBD stones. The costs to the patient and the hospital can be minimized by using reusable instruments, intracorporeal sutures, and condoms instead of titanium clips and endobags.

INTRODUCTION

Laparoscopic cholecystectomy (LC) is the gold standard for the treatment of symptomatic gallstones and other benign diseases of the gallbladder. It is the commonest operation performed laparoscopically worldwide^[1-3]. Initially there were some concerns about its safety owing to its rapid adoption by untrained surgeons. However, when a careful, correct technique is employed, the operation is extremely safe^[1]. The advantages of LC over open cholecystectomy in terms of minimal postoperative pain and postoperative pulmonary dysfunction, reduction in hospital stay, recovery periods, and improved cosmetic results have been established in a number of studies^[2,4-8]. Large series of LC have been reported with few complications^[6,9-12] and most surgeons and patients prefer LC to open cholecystectomy now.

The first operative cholangiography was reported in 1936 by Micken. Mirrizi in 1937 performed the first cystic duct cholangiography and this procedure remains the most accepted method for performing intra-operative cholangiography (IOC) today^[13]. IOC has high sensitivity in detecting CBD stones, but its routine use is associated with increased costs and operation room time. The routine

use of IOC in all cases of LC is still controversial^[14] with some authors supporting routine IOC^[2,15,16], some favoring selective IOC^[17-19], while others reporting no advantage of IOC^[20-24] in preventing biliary injuries and missed CBD stones.

Unfortunately, access to laparoscopic surgery is limited in most of the rural areas of the state of Jammu and Kashmir. There are only two teaching hospitals offering the facility of laparoscopic surgery to a population of nearly 60 lakhs since 1995. Due to the absence of trained laparoscopic surgeons and the non-availability of laparoscopic equipment, the concept of minimal access surgery could not reach the underprivileged rural population with incomes of less than two dollars a day. Another major hurdle that had to be overcome was the misinformation prevalent both among surgeons and patients regarding the costs and the complication rate of LC.

It was only in Jan 2001 that laparoscopic equipment was installed in three non-teaching hospitals in the rural areas of Kashmir to cater the underprivileged population. A strategy had to be evolved to train the staff and to perform LC safely without the use of costly disposables, titanium clips, and endobags as the hospitals could not bear the extra expenses of these equipments. Taking into consideration the financial status of the population, the facility was provided free of cost.

This multicentre prospective study was conducted from Jan 2001 till Jan 2007 with the following aims: To evaluate the feasibility of performing LC in rural health centers of Kashmir without resorting to IOC and to evaluate the means to decrease the costs incurred by the hospitals.

MATERIALS AND METHODS

Patients undergoing LC for benign disorders of gall bladder in three non-teaching rural hospitals of Kashmir valley from Jan 2001 to Jan 2007 were included in the study.

To begin, only few surgeons were trained in laparoscopic surgery. The other team members were made familiar with the electronic equipment and the hand instruments. Seminars including video clips of various laparoscopic procedures and proper ways of troubleshooting the equipment and managing complications were conducted as a part of training. Emphasis was laid on the safety of the patient and the equipment. An indigenous costless endotrainer (Figure 1) was designed from a cardboard carton of 5% Dextrose bottles, to train the team members including paramedical personnel in the theatre.

Patient selection for surgery was made pre-operatively on the basis of history, physical examination, and radiological and laboratory diagnostic evidence of gall bladder disease. Ultrasonography was focused on the characteristics of any gallstones (size, number, and location), gallbladder polyps, the status of the common bile duct, the size of the gallbladder, the thickness of the gallbladder wall, and assessment of the liver and pancreas.

Exclusion criteria: (1) cases of acute cholecystitis after 48 h of the attack, (2) multiple previous upper abdominal

Figure 1 Indigenous endotrainer used for training the staff.

operations, (3) coagulopathies, (4) and ASA grade III and onwards.

Those patients who had ultrasound documented choledocholithiasis or who had a history of jaundice with raised alkaline phosphatase and ultrasound documented CBD of more than 9 mm in diameter were sent to the nearest tertiary care centre for ERCP prior to taking them up for laparoscopic cholecystectomy.

At least one of the donor's and patient's blood samples was cross matched. Informed consent was obtained after a detailed discussion was held with the patient and attendants about the benefits and possible complications of LC.

To reduce the duration of the hospital stay, patients were admitted on the day of surgery and were allowed to have liquids up to 6 h before the operation.

Patients were asked to void urine before surgery and a Foley's catheter was not used.

Procedure

All operations were performed under general endotracheal anesthesia. In early cases standard four port LC was done. The Sulcus of Ruvier was used as a guide for location of Calot's triangle. The dissection of the cystic pedicle was initiated by lifting the posterior fold of peritoneum and creating a wide posterior window in the Calot's triangle. The gallbladder-cystic duct junction (the critical anatomical landmark) was identified. No attempts were made to dissect at cystic duct-CBD junction to avoid inadvertent injury. In patients in whom the Calot's triangle could not be clearly identified fundus first dissection was done by Berci's spatula. IOC facilities were not available so IOC was not performed. In cases having multiple small stones the cystic duct was partially opened and milking was done by a laparoscopic right angled forceps. Mostly 00 Vicryl sutures were placed both on cystic duct and cystic artery before cutting in between. This was done because of fear of internalization of clips into the common bile duct as reported by some authors^[25] and to reduce the costs of the titanium clips. A fan retractor placed through an additional 5 mm port and a 30 degree telescope were used in grossly obese patients to obtain a clear view of anatomy. Gall bladder was removed through epigastric port after reducing the stone load. In case of infected or thick walled gallbladders specimens were removed in low cost condoms

Table 1 Patient characteristics and other observations

S. No.	Observation	Variable
1	Age (yr)	47.2 (13 to 78)
2	Female/Male	976/291
3	Previous abdominal surgeries	519
4	Preoperative ERCP	49

instead of costly endopouches.

Drains were placed selectively. All port wounds were infiltrated with long-acting local anesthetic. Antibiotic prophylaxis was ensured with 2 peri-operative doses of third generation cephalosporin intravenously. Post-operative analgesia was achieved with Diclofenac (p.o, 50 mg 3 times a day). All patients had oral liquids and were encouraged to have food in the evening after the operation, provided there was no nausea or vomiting.

The drain was usually removed after 24 h if drainage was minimal. The majority of patients were discharged on the first postoperative day if they lived in the area. Those living in outlying communities were encouraged to stay in town for 48 h. Patients were reviewed at weeks 1 and 4 postoperatively in the surgical OPD.

RESULTS

This series involved 1267 patients with symptomatic diseases of gall bladder from ages 13 to 78 years, (mean 47.2) who presented to Government Gousia hospital, District Hospital Baramulla and Ahmed's Hospital, Kashmir for LC from Jan 2001 till Jan 2007. The female to male ratio was 3.4:1. About 41% patients had undergone previous abdominal or pelvic surgery (commonest being lower segment cesarean section). Accordingly, the insertion point of the Veress needle and the first trocar was adjusted to avoid the risk of bowel perforation or injury.

The average operating time from insertion of Veress needle till closure of all ports was 39 minutes (ranging

Table 3 Causes of conversion

S. No.	Causes of conversion	No. of patients	%
1	Dense adhesions at Calot's	11	0.86
2	Significant bleeding	6	0.47

8	Faulty equipment	1	0.08
	Total	23	1.82

from 11 min to 190 min), and the mean length of postoperative hospital stay was 26 h (ranging from 18 h to 72 h). Two cases of incidental gallbladder malignancy were detected by histopathological examination of the specimens.

The outcomes of this series are reported in Tables 1 and 2. There was no mortality in our series. Only one common bile duct injury was sustained during our 6 years experience which was identified peri-operatively, repaired and a T tube placed after conversion to open procedure. Twenty seven patients had port site infections but none had evidence of deep space or systemic infection. The most common post-operative complaint was right shoulder tip pain which usually lasted for 3 to 5 d. Twenty three cases were converted to open cholecystectomy after failed laparoscopic technique early in the series (Table 3).

DISCUSSION

The first LC was performed in 1986 by Muhe^[26]. LC has become the operation of choice for benign disorders of gallbladder^[2,6,27]. Numerous publications, mostly from large surgical centres, have exhaustively dealt with the operative technique, complications and the benefits of LC. The results of this case series of LC performed in non-teaching rural hospitals of a developing country are comparable to those from tertiary care settings and rural hospitals^[2,4,5,8-13,28].

The low rate of morbidity and nosocomial infections may be due to reduced hospital stay, the favorable staff-to-patient ratio, attention to aseptic technique, and environmental sanitation. Surgeons and patients prefer LC to open cholecystectomy now and this procedure is cost-effective, cosmetically superior, and produces far less morbidity, as substantiated by other studies from rural hospitals of developing countries^[4,8,27,28]. Access to LC is equally important for rural communities of the developing world.

Nonetheless, several limitations are worth noting. The relatively high start-up costs (the capital equipment and training of medical and nursing staff) have to be considered. These can be minimized by using a costless indigenous endotrainer. It is possible to decrease the costs of the procedure both for the patient as well as the hospital by using reusable trocars and cannulae, reusable instruments, intracorporeal ligatures instead of costly titanium clips, and condoms in place of endobags as

reported by other studies too^[5]. To prevent injuries due to blunting of the tip, the trocars have to be sharpened after every 30-40 procedures.

Laparoscopy and LC are invasive procedures associated with a range of minor and major complications^[29]. Bleeding is one of the most frequent and dangerous complications of LC. Clinically significant bleeding occurs in 0.5% of LC^[6]. In our series, bleeding was observed in 12 (0.95%) patients, but in most cases it was controlled laparoscopically. Only 6 (0.47%) patients had significant bleeding that required conversion to the open procedure. Though bleeding is a potentially catastrophic complication inherent to the laparoscopic technique, it is also the most preventable one, as it is largely related to operator technique. In our study 1 (0.08%) patient suffered injury to the common bile duct. The frequency of this complication is 0%-0.8% in LC^[9,10,11,12,15]. The low number of major bile duct injuries without resorting to IOC as reported in our study is comparable to results from other centres which recommend routine or selective IOC and questions the value of operative cholangiography during LC.

The reported rate of conversion to open cholecystectomy ranges between 1.88% to 10.1%^[6,9,15,27,31]. In our series, 23 (1.82%) of all procedures were converted to the open technique (Table 3). In most cases, uncontrollable bleeding and dense adhesions at Calot's were the main reasons for conversion to the open procedure.

A controversial topic that was addressed in our study is whether IOC is helpful in preventing biliary tract injuries and missed CBD stones. Even though some authors are of the view that IOC is essential to detect biliary tract injuries and detect missed CBD stones^[2,15,16], others feel that it is an unnecessary step^[20-24]. Some authors recommend selective use of IOC^[17,18,19]. Choledocholithiasis occurs in 3.4% of patients undergoing LC but more than one third of these pass the calculi spontaneously within 6 wk of operation^[31]. Collins C concluded that treatment decision based on assessment by operative cholangiography alone would result in unnecessary intervention in 50% of patients who had either false positive studies or subsequently passed the calculi. The other arguments against IOC are that the biliary tract injury has already occurred before IOC can be performed. Routine IOC picks up unsuspected stones in 1%-4% of cases only, needs additional radiological personnel and more cost; hence routine IOC is not advisable^[20].

The patient should be evaluated thoroughly for detection of any CBD stones before surgery. Pre-operative ERCP followed by immediate LC is the treatment of choice for such cases. High quality pre-operative ultrasound imaging is unlikely to miss any stones more than 3-4 mm in size. These stones usually migrate into the duodenum and may not require any immediate therapeutic approach^[20]. In our series we had one case of retained CBD stones which were managed by post-operative ERCP. In our opinion proper case selection and sticking to the basic principals of LC like identification of Sulcus of Ruvier, making a wide posterior window, decompressing a tense gallbladder^[32], proper traction, hydrodissection with saline, and using the fundus first technique in difficult cases^[3,6] all can help to minimize the CBD injuries, need

for IOC, and conversion to open procedure.

Cystic duct stones (CDS) should be suspected in all cases having a wide cystic duct in the presence of multiple small gall bladder calculi. Careful retraction and manipulation should therefore be done to minimize the risk of CDS slipping into the CBD^[33]. The partial opening of cystic duct with milking of stones by a laparoscopic right angled forceps should be employed in such cases. After missing a stone in the cystic duct early in our series it has become a policy in our unit to routinely perform this maneuver in all cases having a wide cystic duct in the presence of multiple small gallbladder calculi.

Port site infection, usually involving the umbilical cannulation site through which the gallbladder is extracted, occurs in 0.3%-9.0% of cases^[27,34,35]. Port site infection was seen in 12 (0.95%) of our patients, and all of these were treated successfully with local wound toilet and oral antibiotics.

Since the patients were admitted only on the day of surgery and early ambulation and feeding was instituted, the average duration of hospital stay was 26 h. Recent studies have demonstrated that laparoscopic cholecystectomy can be performed as one day-surgery^[7,36]. In our series, this was true in most of the cases.

Successful performance of laparoscopic cholecystectomy requires proper training, discipline, skills and technology, and ongoing maintenance of competency. We believe this series demonstrates that procedural training and ongoing practice assessment can provide timely, safe, and appropriate access to this latest surgical technique even in rural hospitals of developing countries. The success and complication rate in this consecutive series of 1267 attempted LCs (23 conversions to open cholecystectomy, 1244 successfully completed LCs associated with minor complications) without IOC competes favorably with results achieved in tertiary care centres and rural hospitals^[2,4,5,8-13,28].

CONCLUSION

The outcomes of this series of LCs conducted in three non-teaching rural hospitals of a developing state (Jammu and Kashmir) are similar to those of other case series from tertiary care centres and meet the published standards of care. It is hereby concluded that laparoscopic cholecystectomy can be performed safely even in rural health centres of a developing country provided proper equipment is available. The surgeons and other team members should be well trained in the procedure for which even an indigenously built costless endotrainer can be used. The case selection at the start should be stringent until enough experience is gained to manage difficult cases. IOC is not essential to prevent biliary tract injuries or missed CBD stones. This operation can be made more cost effective especially in rural sector of a developing country like India by using intracorporeal knotting in place of costly titanium clips and condoms in place of endobags. Using properly sterilized resharpended metallic trocars and cannulae can further reduce the costs without increasing the incidence of port site sepsis as substantiated by the results of our series.

The minimal hospital stay and early return to work with the resultant positive financial implications after LC for those patients who are bread earners for their families are significant. The authors strongly suggest that LC should be the surgical treatment of choice for patients of benign disorders of gallbladder. It is up to the governments of these underdeveloped countries to provide the facility free of cost to its citizens.

ACKNOWLEDGMENTS

We thank Dr. Muzaffar Ahmed Jan in Kashmir Health Services and Dr. Nazir Kanungoo in Govt. Gousia Hospital for their help throughout this study and Mr. Mir Muneeb for his timely help in drafting the manuscript.

Abstract

AIM: To describe the distribution of micrometastases in the surrounding liver of patients with primary liver cancer (PLC), and to describe the minimal length of resection margin (RM) for hepatectomy.

METHODS: From November 2001 to March 2003, 120 histologically verified PLC patients without macroscopic tumor thrombi or macrosatellites or extrahepatic metastases underwent curative hepatectomy. Six hundreds and twenty-nine routine pathological sections from these patients were re-examined retrospectively by light microscopy. In the prospective study, curative hepatectomy was performed from November 2001 to March 2003 for 76 histologically verified PLC patients without definite macroscopic tumor thrombi or macrosatellites or extrahepatic metastases in preoperative imaging. Six hundreds and forty-five pathological sections from these patients were examined by light microscopy. The resected liver specimens were minutely examined to measure the resection margin and to detect the number of daughter tumor nodules, dominant lesions, and macroscopic tumor thrombi inside the lumens of the major venous system. The paraffin sections were microscopically examined to detect the microsatellites, microscopic tumor thrombi, fibrosis tumor capsules, as well as capsule invasion and the distance of histological spread of the micrometastases.

RESULTS: In the retrospective study, 70 micrometastases were found in surrounding liver in 26 of the 120

cases (21.7%). The farthest distance of histological micrometastasis was 3.5 mm, 5.3 mm and 6.0 mm in 95%, 99% and 100% cases, respectively. Macroscopic tumor thrombi or macrosatellites were observed in 18 of 76 cases, and 149 micrometastases were found in the surrounding live in 25 (43.1%) of 58 cases with no macroscopic tumor thrombi. The farthest distance of histological micrometastasis was 4.5 mm, 5.5 mm and 6.0 mm in 95%, 99% and 100% cases, respectively. Two hundred and sixty-seven micrometastases were found in surrounding liver in 14 (77.8%) out of 18 cases with macroscopic tumor thrombi or macrosatellites. The farthest distance of histological micrometastasis was 18.5 mm, 18.5 mm and 19.0 mm in 95%, 99% and 100% cases, respectively.

CONCLUSION: The required minimal length of RM is 5.5 mm and 6 mm respectively to achieve 99% and 100% micrometastasis clearance in surrounding liver of PLC patients without macroscopic tumor thrombi or macrosatellites, and should be greater than 18.5 mm to obtain 99% micrometastasis clearance in surrounding liver of patients with macroscopic tumor thrombi or macrosatellites.

INTRODUCTION

Primary liver cancer (PLC) is the fifth most common cancer in the world. The number of new cases is estimated to be 564000 per year. About 80% of all cases are found in Asia. Hepatocellular carcinoma (HCC) accounts for more than 80% of all PLCs, while intrahepatic cholangiocarcinoma (ICC) and hepatocellular-cholangiocarcinoma (HCCC) account for less than 20%. Most patients with PLC also suffer from concomitant cirrhosis, which is the major clinical risk factor for hepatic cancer. Overall, 80%

of PLCs can be attributed to chronic hepatitis B virus infection in Asia, especially in China. Hepatic resection and liver transplantation are considered the only curative treatment for PLC. For most cirrhotic patients who fulfill the Milan criteria, liver transplantation is the ultimate choice of treatment, but its application is limited due to the lack of donors^[1]. Hepatic resection remains the treatment of choice for PLC despite unsatisfactory outcomes due to the high incidence of intrahepatic recurrence^[2,3]. Resection margin (RM), which refers to the shortest distance from the edge of the lesion to the line of parenchymal transection margin^[4], is vital to a safe operation and a complete clearance of micrometastases in surrounding liver. Because of underlying chronic liver diseases, the optimal RM in radical hepatectomy of PLC remains controversial and ambiguous^[4-20] and has not been well illustrated theoretically. Although there were prospective studies on micrometastases in 55 patients^[17], 36 patients^[18] and 23 patients^[19] and surgical margin in 40 patients^[20] with PLC, they did not distinguish patients with macroscopic tumor thrombi or macrosatellites from those without macroscopic tumor thrombi or macrosatellites. To ensure a complete clearance of micrometastases in surrounding liver, the minimal length of RM depends on the farthest distance of histological micrometastasis. This study was to describe the distribution of micrometastases in the surrounding liver of patients with PLC, and the minimal length of resection margin for hepatectomy.

MATERIALS AND METHODS

Specimens

From November 2001 to March 2003, 120 histologically verified PLC patients without macroscopic tumor thrombi or macrosatellites or extrahepatic metastases underwent curative hepatectomies (Table 1). Six hundred and twenty-nine routine pathological sections from these patients were re-examined retrospectively by light microscopy. In the prospective study, hepatectomy was performed from March to November 2003 for 76 histologically verified PLC patients without definite macroscopic tumor thrombi or macrosatellites or extrahepatic metastases in preoperative imaging (Table 1). Six hundred and forty-five pathological sections from these patients, including 389 routine pathological sections, were examined by light microscopy. A computerized database was used to collect clinicopathological data of all patients in the prospective group, including the macroscopic width and histological involvement of surgical margin assessed by pathologists. Any postoperative recurrence was entered into the database immediately after diagnosis. No difference was found in age, sex, HBsAg (+) and tumor size between the two groups ($P > 0.05$).

All surgical procedures were performed by the same surgical team in Department of Hepatobiliary Surgery, Eastern Hepatobiliary Surgery Hospital, Second Military Medical University. All pathology slides were reviewed independently by two hepatobiliary pathologists.

Preparation of fresh specimens

The resected liver specimens were photographed and then examined to measure the RM. Macroscopically, the

Mt: macroscopic tumor thrombus; Ms: macrosatellite. TBIL: total bilirubin; PALB: pre-albumin; PT: prothrombin time.

number of daughter tumor nodules, besides the dominant lesion, were recorded, and the presence of macroscopic tumor thrombi inside the lumens of the major venous system and the level of its infiltrated venous branches were also noted. The size of tumors and vertical, transverse and anteroposterior dimensions of the specimens were documented according to their different shapes and photographed before 3-6 rectangle specimens were cut in the portal vein direction, hepatic vein direction and other directions, which measured approximately 2 mm by 10 mm in thickness and width, including 3-5 mm tumor and 10-25 mm liver parenchyma in length. The specimens were fixed in 10% formalin and stained with hematoxylin and eosin for microscopic examination.

In the presence of a multinodular lesion, the nodule with the largest diameter was taken as the dominant nodule except that 2-3 nodules were considered synchronous multicentric liver carcinogenesis if they located in different hepatic lobes with no significant difference in size, at a distance beyond 5 cm and had no macroscopic tumor thrombi. All the remaining macroscopically evident tumor nodules, or daughter nodules, macroscopic tumor thrombi and micrometastases were assumed to have radially disseminated from the dominant nodule without other preferred direction except for portal vein and hepatic vein directions.

Correction for shrinkage

The tissue shrinkage rate secondary to the process of histological slide preparation was estimated by comparing the width of specimens from non-tumor liver in its final state on the slide and its fresh state before formalin immersion.

Documentation of pathological features

Various pathological features were studied, including the presence and absence of microsatellites, microscopic tumor thrombi, fibrosis tumor capsules, and capsule invasion (whether the tumor capsule was infiltrated partially or completely by the tumor), or liver invasion (whether the tumor infiltrated directly into the adjacent non-tumor liver), and the distance of micrometastases.

Table 2 Distribution of micrometastases in surrounding liver of 178 cases of primary liver cancer without macroscopic tumor thrombi or macrosatellites

Distance (mm)	Retrospective group (120 cases)			Prospective group (58 cases)		
	Cases	Percent	Accumulative percent	Cases	Percent	Accumulative percent
0	94	78.3	78.3	35	60.3	60.3
1	9	7.5	85.8	8	13.8	74.1
2	10	8.3	94.2	4	6.9	81
3	2	1.7	95.8	6	10.3	91.4
4	4	3.3	99.2	3	5.2	96.6
5	1	0.8	100.0	2	3.4	100.0

Measurement of micrometastases

The size of all micrometastases detected in the adjacent non-tumor liver was estimated by the microscope scale. The shortest distance between the edges of the dominant nodule and the farthest micrometastasis was considered the distance of histological spread.

Statistical analysis

SPSS10.0 for Windows was used to compute the distribution of frequencies and SAS6.12 System to compute the statistical significance of difference for unpaired data. Time of recurrence and survival after recurrence were determined by Kaplan-Meier analysis, and the relation between micrometastases and clinicopathological characteristics was compared using the T stat test or Wilcoxon test. $P < 0.05$ was considered statistically significant.

RESULTS

Micrometastasis in liver parenchyma surrounding the lesion

Of the 120 cases, 24 (20%) had no encapsulation, 54 (45%) had incomplete encapsulation and 42 (35%) had almost complete encapsulation. Seventy micrometastases were found in the liver parenchyma surrounding the lesions in 26 cases (21.7%), among which 27 macrosatellites were found in 16 (1-10 per case), 12 microscopic tumor thrombi in 6 (1-3 per case), and 26 microscopic tumor thrombi in 4 (3-15 per case) and macrosatellites in 5 (1-2 per case). The farthest distance of micrometastasis was 3.5 mm, 5.3 mm and 6.0 mm in 95%, 99% and 100% cases, respectively (Table 2).

Of the 76 cases, 12 (15.8%) had no encapsulation, 55 (72.4%) had incomplete encapsulation and 9 (11.8%) had almost complete encapsulation. Among the 58 cases free of macroscopic tumor thrombi or macrosatellites, 25 (43.1%) exhibited 149 micrometastases in the liver parenchyma surrounding the lesions, among which, 9 macrosatellites were found in 5 (1-3 per case), 69 microscopic tumor thrombi in 12 (1-20 per case), and 37 microscopic tumor thrombi in 8 (1-12 per case) and macrosatellites in 34 (1-20 per case) (Figure 1A-C). The farthest distance of micrometastasis was 4.5 mm, 5.5 mm and 6.0 mm in 95%, 99% and 100% cases, respectively (Table 2). In 18 cases with macroscopic tumor thrombi or macrosatellites, 267 micrometastases were found in 14 (77.8%), 3 micrometastases

Table 3 Distribution of micrometastases in surrounding liver of 18 cases of primary liver cancer with macroscopic tumor thrombi or macrosatellites

Distance (mm)	Cases	Percent	Accumulative percent
0	5	27.78	27.8
3	7	38.89	66.7
6	3	16.67	83.3
9	0	0	83.3
12	1	5.56	88.9
15	1	5.56	94.4
18	1	5.56	100.0

in 1, 56 microscopic tumor thrombi in 5 (1-18 per case), and 154 microscopic tumor thrombi in 8 (6-33 per case) and macrosatellites in 54 (2-11 per case) (Figure 1D and E). The farthest distance of micrometastasis was 18.5 mm, 18.5 mm and 19.0 mm in 95%, 99% and 100% cases, respectively (Table 3). As only 18 cases had macroscopic tumor thrombi or macrosatellites and it was impossible to obtain the liver parenchyma surrounding the lesion beyond 2 cm, the practical farthest distance should be greater than 18.5 mm. The tissue shrinkage rate was $89.7\% \pm 5.6\%$.

Relation between micrometastases and clinicopathological characteristics

The yield rate of micrometastasis among patients with incomplete encapsulation was statistically higher than that among patients with no or complete encapsulation ($P < 0.05$). The yield rate of micrometastasis in the liver parenchyma surrounding the lesion was positively correlated with the preoperative serum AFP level ($P < 0.01$), tumor size ($P < 0.01$) and presence of macroscopic tumor thrombi or macrosatellites ($P < 0.01$) in patients with PLC (Table 4).

DISCUSSION

Postoperative intrahepatic recurrence results either from residual intrahepatic metastasis or from de novo tumor due to the underlying hepatitis or liver cirrhosis^[21-24]. The incidence of multicentric carcinogenesis in postoperative tumor is around 50%^[24,25]. Theoretically, hepatectomy for PLC only resects the main tumor and surgical margin, the high risk area of intrahepatic metastasis^[25]. Of the 6 PLC patients with only macrosatellites, 4 had no micrometastasis, which may be synchronously multicentric carcinogenic. In addition, of the 13 patients with 2-3 nodules who were clinically considered to be synchronously multicentric carcinogenic, only 4 had macrosatellites without microscopic tumor thrombi, while 1 of them had microscopic tumor thrombi. Furthermore, treatment after postoperative recovery, aiming at the activity of hepatitis or liver cirrhosis, may decrease recurrence due to metachronously multicentric carcinogenesis^[26-28]. Therefore, the aim of hepatectomy for PLC is not only to resect the main tumor and possible micrometastasis but also to decrease postoperative morbidity.

Up to date, prospective studies on micrometastases are

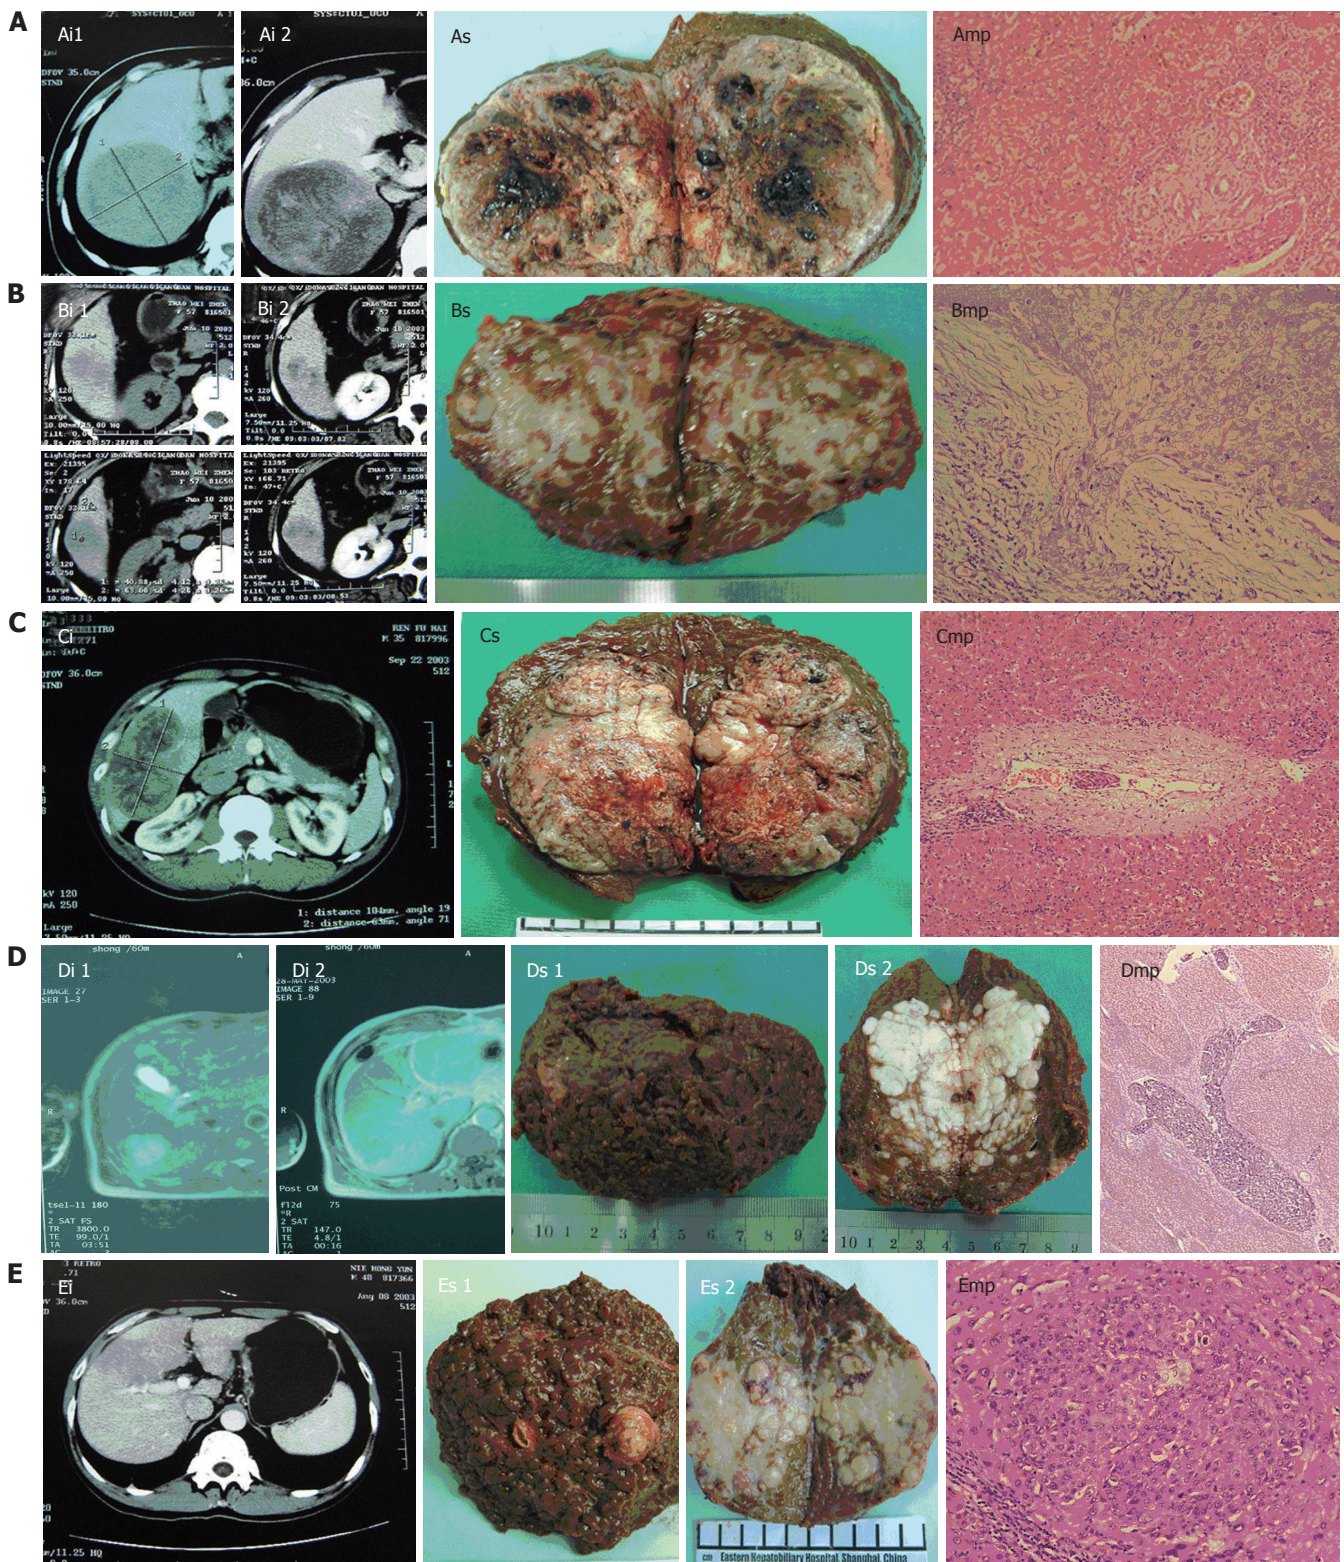

Figure 1 Imaging (i), specimens (s) and microscopic pathology (mp) of 5 PLC patients. **A:** case 24, tumor size 12.0 cm x 11.0 cm x 10.5 cm, with microscopic tumor thrombi (metastatic distance 6 mm, x 100); **B:** case 40, tumor size 4.0 cm x 3.8 cm x 3.5 cm, with microscopic capsular infiltration (x 200); **C:** case 58, tumor size 10.5 cm x 6.5 cm x 6.0 cm, with microscopic tumor thrombi (metastatic distance 2 mm, x 100); **D:** case 38, tumor size 6.5 cm x 4.0 cm x 3.6 cm, with macroscopic tumor thrombi in the branches of right portal vein and microscopic tumor thrombi of arborization (x 16); **E:** case 52, tumor size 7.0 cm x 5.0 cm x 5.0 cm, with macroscopic tumor thrombi in the branches of right portal vein and microsatellites (metastatic distance 3.5 mm, x 100).

only available from 55^[17], 36^[18] and 23 patients^[19] and surgical margin in 40 patients^[20] with PLC, but they did not distinguish patients with macroscopic tumor thrombi or microsatellites from those without them, and micrometastasis

from synchronously multicentric micro-foci. The farthest distance of micrometastasis^[17-20] was more than 1.0 cm.

Clinical follow-up studies showed that although safety margin at resection is not a prognostic factor, patients with

None of both						58	8	18	32	

Mt; microscopic tumor thrombus; ms: microsatellite. Incomplete encapsulation: part encapsulation or encapsulation breakthrough or with lesion inside encapsulation.

a surgical margin of over 1 cm^[7-9] are free from tumor recurrence and a surgical margin of 0.5-1.0 cm^[10-13] does not affect the prognosis and postoperative recurrence rate of hepatectomy for HCC after hepatectomy. These findings are not consistent with the reported results^[17-20].

In the present study, the farthest distance of micrometastasis was 3.5 mm, 5.3 mm and 6.0 mm in 95%, 99% and 100% patients without macroscopic tumor thrombi or macrosatellites, respectively, which is different from the reported results of other prospective studies on micrometastasis^[17-20], but is in agreement with clinical follow-up studies^[10-13]. Because routine pathological sections, in which the liver parenchyma surrounding the lesion obtained is relatively less (0.2-1.0 cm), are mainly used to make diagnosis, it was impossible to achieve accurate record of resection margin and integrated clinical data for all PLC patients. The result of our prospective study on micrometastasis in PLC patients without macroscopic tumor thrombi or macrosatellites or extrahepatic metastases showed that the farthest distance of micrometastasis was 5.5 mm and 6 mm in 99% and 100% cases, respectively, which was in agreement with that of our retrospective study. These findings can explain the difference found in prospective studies on micrometastases^[17-20] and clinical follow-up studies^[7-13].

In conclusion, the farthest distance of micrometastasis is 18.5 mm and 19.0 mm in 99% and 100% of patients with macroscopic tumor thrombi or macrosatellites, respectively. The required minimal length of RM is 5.5 mm and 6 mm respectively to achieve 99% and 100% micrometastasis clearance in surrounding liver of PLC patients without macroscopic tumor thrombi or macrosatellites, and should be greater than 18.5 mm to obtain 99% micrometastasis clearance in patients with macroscopic tumor thrombi or macrosatellites.

Abstract

AIM: To investigate whether changes in the frequency of peripheral natural killer T (NKT) cells were correlated with liver disease in patients who had metabolic predispositions to nonalcoholic fatty liver disease (NAFLD).

METHODS: Peripheral blood samples were obtained from 60 Chinese NAFLD patients and 60 age and gender matched healthy controls. The frequency of peripheral NKT cells was detected by flow cytometry. Clinical and laboratory data were collected for further analysis.

RESULTS: NAFLD patients had a lower frequency of peripheral NKT cells than healthy controls ($1.21\% \pm 0.06\%$ vs $1.62\% \pm 0.07\%$, $P < 0.001$). Further analysis revealed that the frequency of peripheral NKT cells was negatively correlated with body mass index, waist circumference and serum levels of alanine aminotransferase. Logistic regression analysis revealed that elevated body mass index [hazard ratio (HR): 2.991], aspartate aminotransferase levels (HR: 1.148) and fasting blood sugar (HR: 3.133) increased the risk of NAFLD, whereas an elevated frequency of peripheral NKT cells (HR: 0.107) decreased the risk.

CONCLUSION: Changes in the frequency of peripheral NKT cells were correlated with NAFLD and a decreased frequency of peripheral NKT cells was a risk factor for NAFLD.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD), ranging from nonalcoholic steatosis to nonalcoholic steatohepatitis (NASH) and cirrhosis, may be the most common liver disease in western countries, with a prevalence of 20%-30% in the general population^[1,2]. Nonalcoholic steatosis is considered to be a benign condition, but NASH can progress to cirrhosis and liver failure, and the 5-year survival rate for an individual diagnosed with NASH is estimated to be 67%^[3]. Although NAFLD has been extensively studied in recent years, the exact pathogenesis of this disease remains unknown.

Natural killer T (NKT) cells were originally defined in mice in the last decade as a lymphocyte subtype that co-expresses natural killer receptors together with T cell receptors^[4]. A striking characteristic of these T cells is the recognition of lipid antigens presented by the restrictive non-classical, non-polymorphic MHC class I-like CD1d molecule^[5]. The capacity for rapid secretion of cytokines, such as interleukin-4, interferon- γ , interleukin-10 and interleukin-13, assures these cells an immuno-modulatory role in autoimmune, allergic, antimicrobial and anti-tumor immune responses^[6].

Recently, several lines of evidence from animal experiments have suggested a link between NKT cell deficiency and NAFLD^[7-10]. Hepatic NKT cells were reduced in leptin-deficient *ob/ob* mice^[7] and in mice fed with a high fat diet^[8]. Adoptive transfer of NKT cells^[9] or oral administration of liver-extracted proteins^[10] ameliorated steatosis and glucose intolerance in leptin-deficient *ob/ob* mice. These metabolic improvements were partly associated with an increase in hepatic NKT cell numbers^[9,10].

These experimental results support a regulatory role for NKT cells; however, their role in the clinical setting of NAFLD remains unclear. This observation prompted this investigation of the possible role of NKT cells in NAFLD patients. The present study questions whether changes in the frequency of peripheral NKT cells are correlated with liver disease in patients with a metabolic predisposition to NAFLD.

MATERIALS AND METHODS

Subjects

This study was carried out at the First Affiliated Hospital of Zhejiang University School of Medicine. All subjects were volunteers attending their annual examination at our hospital from Sep 5 to Oct28, 2005. Informed consent was obtained from all subjects and the study protocol was approved by the hospital Ethics Committee.

The diagnosis of NAFLD was based on the criteria established by the Fatty Liver and Alcoholic Liver Disease Study Group of the Chinese Liver Disease Association^[11]. The exclusion criteria specific to this study included persons with a self-reported history of acute infection or tissue injury in the previous 3 mo, patients with a history of a malignant tumor or autoimmune disease, and patients above 65 years old or below 20 years old. A total of 60 eligible NAFLD patients were enrolled (50 males and 10 females, median age 40.0 years, range from 24 years to 65 years).

For each NAFLD patient, one control was enrolled with matching gender and age (within 3 years). A total of 60 healthy controls were enrolled (50 males and 10 females, median age 42.0 years, range from 25 years to 65 years). All controls were free of viral hepatitis and autoimmune disease and had alcohol consumption within “sensible” limits (less than 30 g/d for men and less than 20 g/d for women). Exclusion criteria were the same as for the patient group.

Clinical examination

The clinical examinations were administered in the mornings after an overnight fast, and the subjects were also instructed to refrain from exercise during the day before their examination. The examination consisted of a physical examination by a physician, blood draw, blood pressure measurement, anthropometry and a health habit inventory. Body mass index (BMI, kg/m²), used as an index of body fat, was calculated as weight in kilograms divided by height in meters squared. The waist to hip ratio was calculated as waist circumference divided by hip circumference.

Laboratory investigation

Blood samples were obtained from an antecubital vein and the samples were used for the analysis of biochemical values and NKT cells frequency. Biochemical values were measured by the Hitachi autoanalyzer model 7600 (Hitachi Corp, Japan). The biochemical values included alanine aminotransferase (ALT), aspartate aminotransferase (AST), triglyceride, total and high-density lipoprotein cholesterol and fasting blood sugar (FBS).

The frequency of peripheral NKT cells was measured by flow cytometry as previously described^[12,13]. In brief, two-color flow cytometric analysis was performed with an EPICS-XL flow cytometer (Beckman-Coulter Corp, USA) using System II software. FITC-conjugated anti-Vα24 monoclonal antibody (Immunotech, France) was used to label NKT cells, and isotype matched controls were also used in all experiments. Vα24⁺ T cells were considered to be NKT cells in the present study.

Table 1 Data comparison between NAFLD patients and healthy controls (mean ± SE)

Variable	Healthy controls	NAFLD patients
Age (yr)	43.0 ± 1.3	43.0 ± 1.3
Height (cm)	166.7 ± 6.2	167.1 ± 6.9
Weight (kg)	62.6 ± 7.6	75.3 ± 10.4 ^b
Body mass index (kg/m ²)	22.50 ± 0.29	26.91 ± 0.37 ^b
Waist circumference (cm)	80.2 ± 0.8	92.0 ± 1.1 ^b
Hip circumference (cm)	93.7 ± 0.5	100.3 ± 0.7 ^b
Waist-hip ratio	0.856 ± 0.006	0.916 ± 0.006 ^b
Systolic blood pressure (mmHg)	119.5 ± 2.2	130.3 ± 2.0 ^b
Diastolic blood pressure (mmHg)	73.3 ± 1.4	81.0 ± 1.2 ^b
Alanine aminotransferase (U/L)	21.5 ± 1.8	46.9 ± 3.6 ^b
Aspartate aminotransferase (U/L)	24.4 ± 1.0	36.0 ± 2.8 ^b
Triglyceride (mmol/L)	1.712 ± 0.142	2.632 ± 0.144 ^b
Total cholesterol (mmol/L)	4.583 ± 0.111	4.973 ± 0.117 ^d
High density lipoprotein cholesterol (mmol/L)	1.264 ± 0.277	1.277 ± 0.033
Fasting blood sugar (mmol/L)	4.356 ± 0.068	5.567 ± 0.311 ^b

^b*P* < 0.001 *vs* healthy controls; ^d*P* < 0.01 *vs* healthy controls.

Statistical analysis

Dates are presented as mean ± SE. The data were analyzed by SPSS11.5 statistical software. The Mann-Whitney *U* test or Student's *t*-test were used for comparisons of the data. Spearman correlation analysis was used to estimate the relationship between the frequency of peripheral NKT cells and other variables. Logistic regression analysis (Backward: Wald; Entry: 0.05, Removal: 0.10) was used to evaluate the risk factors for NAFLD. *P* < 0.05 (2-tailed test) was considered statistically significant.

RESULTS

Clinical and laboratory data

NAFLD patients and healthy controls were different in terms of weight, BMI, waist circumference, hip circumference, waist to hip ratio, systolic blood pressure, diastolic blood pressure, ALT, AST, triglyceride, total-lipoprotein cholesterol and FBS, while there was no difference in terms of age, gender, height, or high-density lipoprotein cholesterol between the two groups (Table 1).

Frequency of peripheral NKT cells

NAFLD patients had a lower frequency of peripheral NKT cells, 1.21% ± 0.06% in NAFLD patients versus 1.62% ± 0.07% in healthy controls (*P* < 0.001) (Figure 1).

Relationship between the frequency of peripheral NKT cells and other variables

Spearman correlation analysis revealed that there was a poor correlation between the frequency of peripheral NKT cells and BMI (*r* = -0.322, *P* = 0.001), waist circumference (*r* = -0.237, *P* = 0.021) and ALT levels (*r* = -0.217, *P* = 0.035).

We further analyzed the relationship between the frequency of peripheral NKT cells and the three variables. As shown in Figure 2, the frequency of peripheral NKT cells was decreased in the subjects with high BMI (BMI ≥ 24 kg/m²), or in the subjects with high waist circumference

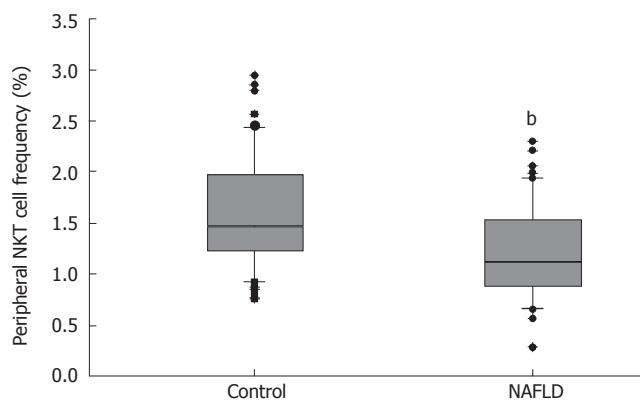

Figure 1 Frequency of peripheral NKT cells in NAFLD patients versus healthy controls. Boxes show values within 25th and 75th percentiles, horizontal bar represents the median, 80% of values are between the extremities of vertical bars (10th-90th percentiles), and extreme values are represented by individual symbols. ^b*P* < 0.001 vs healthy controls.

(waist circumference ≥ 90 cm for male and ≥ 85 cm for female), or in the subjects with elevated ALT (ALT ≥ 50 U/L). This result partially indicated that the frequency of peripheral NKT cells was negatively correlated with BMI, waist circumference and ALT.

The risk factors in NAFLD

Stepwise regression analysis was performed on the 11 variables that were different between the two groups (weight and hip circumference were excluded) using the dichotomous variable logistic regression model. The results showed that four features were closely associated with the risk for NAFLD, including the frequency of peripheral NKT cells, BMI, AST and FBS (Table 2).

DISCUSSION

These results indicate that changes in the frequency of peripheral NKT cells are correlated with liver disease in patients with a metabolic predisposition to NAFLD. This finding was supported by three main results. First, NAFLD patients had a lower frequency of peripheral NKT cells, a unique T lymphocyte subtype that shares some characteristics with natural killer cells^[14]. NKT cells have been shown to play important regulatory roles in various liver diseases such as viral hepatitis^[15], autoimmune liver disease^[16], metabolic liver disease^[17] and hepatic malignant tumor^[18]. The frequency of peripheral NKT cells was decreased in patients with hepatitis C^[15] and autoimmune hepatitis^[16]. The decreased frequency of peripheral NKT cells may be caused by down-regulation of T cell receptors, apoptosis of the cells and/or compartmentalization into peripheral organs^[15]. The decreased frequency of peripheral NKT cells in NAFLD patients in the present study indicates that NAFLD may represent another liver disease related to a decreased frequency of peripheral NKT cells.

The second result was that the frequency of peripheral NKT cells was negatively correlated with BMI, waist circumference and ALT. NAFLD has been shown to be strongly associated with excess body weight and central

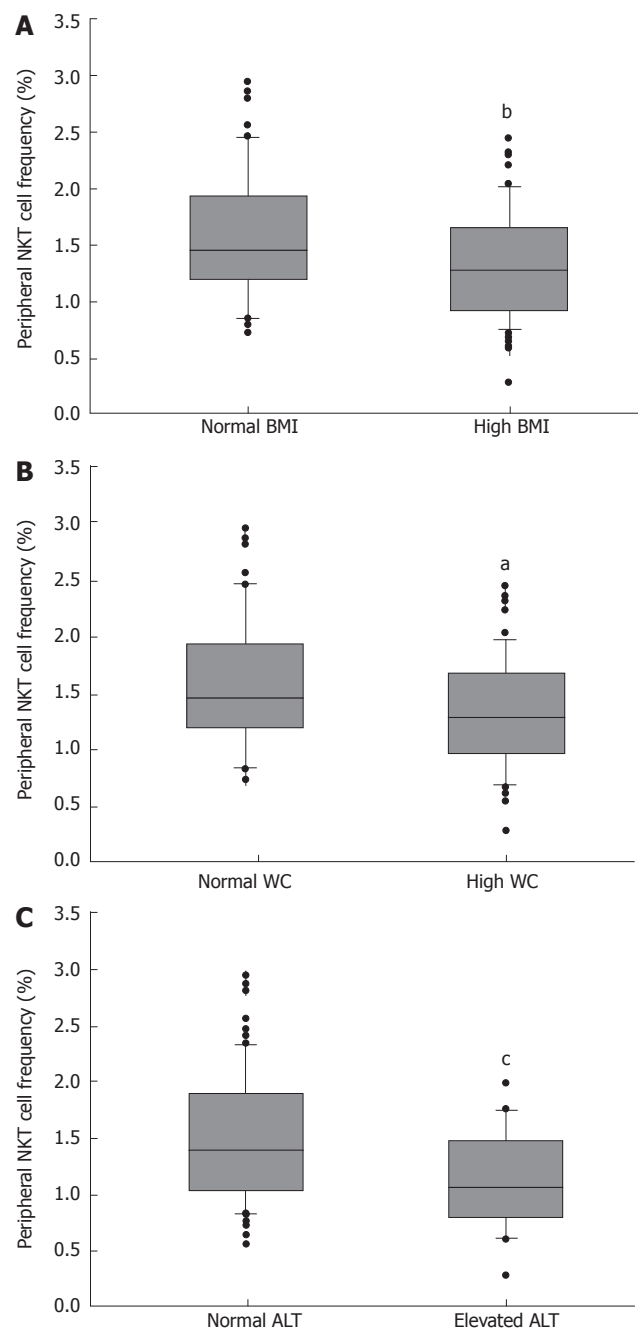

Figure 2 Relationships between the frequency of peripheral NKT cells and BMI, waist circumference and ALT. **A:** The frequency of peripheral NKT cells was compared between the subjects with BMI ≥ 24 kg/m² (*n* = 68) and the subjects with BMI < 24 kg/m² (*n* = 52), ^b*P* < 0.01 vs subjects with BMI < 24 kg/m²; **B:** The frequency of peripheral NKT cells was compared between the subjects with waist circumference ≥ 90 cm for male and ≥ 85 cm for female (*n* = 47) and the subjects with normal waist circumference (*n* = 73), ^a*P* < 0.05 vs subjects with normal waist circumference; **C:** The frequency of peripheral NKT cells was compared between the subjects with ALT ≥ 50 U/L (*n* = 21) and the subjects with ALT < 50 U/L (*n* = 99), ^c*P* < 0.01 vs subjects with ALT < 50 U/L.

adiposity in particular^[19-21]. Most NAFLD patients are overweight, and the prevalence of NAFLD is much more common in obese than in non-obese individuals (76% vs 16%)^[19]. BMI and waist circumference, used as indicators for obesity and central obesity, are closely related with NAFLD^[19-22]. ALT is also closely related with NAFLD, and excluding causes such as chronic hepatitis and alcohol-induced liver disease, NAFLD explains 80% to 90% of the

Table 2 Results of the logistic regression analysis of risk factors for NAFLD

Variable	β	SE	Wald value	P-value	OR	95% CI of OR
NKT	-2.239	0.984	5.181	0.023	0.107	0.016-0.733

remaining cases of elevated ALT^[23]. Therefore, elevated ALT has been used as a noninvasive surrogate marker for NAFLD^[21,24]. In the present study, the frequency of peripheral NKT cells was found to be significantly correlated with BMI, waist circumference and ALT, but the *r* values were very low, indicating that the correlation between these terms was very weak. However, as BMI, waist circumference and ALT were all strongly associated with NAFLD, the present findings might suggest that peripheral NKT cells are correlated with NAFLD.

The third result supporting the correlation of NKT cells with NAFLD was that the decreased frequency of peripheral NKT cells was a risk factor for NAFLD. Previous studies revealed that overweight, diabetes mellitus and elevated liver enzymes were risk factors for NAFLD in agreement with our results^[1,19,25,26]. In addition, this study showed that the decreased frequency of peripheral NKT cells was another risk factor for NAFLD. This association may due, at least in part, to a diminished protective effect of the lower number of NKT cells against vulnerable factors such as lipopolysaccharide (LPS)^[8]. This finding also suggests that NKT cells are associated with NAFLD, and could lead to immune manipulations of NKT cells as a therapeutic tool in NAFLD in the future. Interestingly, data from animal experiments confirmed the therapeutic role of NKT cells in NAFLD^[9,10].

This study had some limitations, however. The first limitation was regarding the methodology used to evaluate peripheral NKT cells. Until recently, NKT cells could not be unambiguously identified. α GalCer/CD1d tetramers and V α 24/V β 11 double-staining are considered to be two standard methods for NKT cell identification^[27]. V α 24 staining alone as used in the present study may overestimate the numbers of V α 24 and V β 11 double-positive NKT cells. However, because NKT cells represent a subtype of T lymphocytes, staining NKT cells with V α 24 and CD3 reduces the possibility of overestimation, and the same method has also been used by previous studies^[12,13]. The second limitation was that hepatic NKT cells were not studied in NAFLD patients or in healthy controls. NKT cells arise mainly in the thymus and migrate to peripheral tissues, such as the liver and pancreas, where they accumulate in large numbers^[28]. It would be much more meaningful to study hepatic NKT cells in NAFLD patients, but it was not convenient to get enough liver

tissue samples from NAFLD subjects, in part due to ethical reasons. The third limitation is that the involvement of peripheral NKT cells in NAFLD was not studied. NKT cells have several subtypes such as CD4⁺CD8⁻, CD4⁻CD8⁻ (DN) and CD4⁻CD8⁺, and different subtypes have different functions^[6]. Further studies are needed to understand the relationship between the subtypes of NKT cells and NAFLD.

In conclusion, these results suggest that changes in the frequency of peripheral NKT cells were correlated with liver disease in patients who had a metabolic predisposition to NAFLD, and a decreased frequency of these cells was a risk factor for NAFLD. These findings suggest a potential role for peripheral NKT cells in the pathogenesis of NAFLD.

ACKNOWLEDGMENTS

The authors thank all subjects for their valuable contributions to the present work. We are also grateful to Dr. Wei Wu for his technical assistance in flow cytometry and Professor Yi Shen for his excellent assistance in statistical analysis.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) has been extensively studied in recent years, but the mechanism of this disease remains unclear. The most popular two-hit hypothesis keeps that hepatic fat accumulation is the first hit and concomitant hepatic inflammation is the second hit. Several potential pathogenic factors including insulin resistance, mitochondrial dysfunction, lipid peroxidation and immunity abnormality have been intensively investigated.

Research frontiers

To explore the role of NKT cells in the clinical setting of NAFLD.

Related publications

Recent evidences from animal experiments indicated an association between NKT cells and NAFLD. It was observed that hepatic NKT cells were reduced in leptin-deficient *ob/ob* mice and in mice fed with a high fat diet. Adoptive transfer of NKT cells or oral administration of liver-extracted proteins ameliorated steatosis and glucose intolerance in leptin-deficient *ob/ob* mice.

Innovations and breakthroughs

Previous evidences supporting the association between NKT cells and NAFLD were all from animal experiments. Whether NKT cells also play important regulatory role in the clinical setting of NAFLD remains unclear. In this study, the authors found that changes in the frequency of peripheral NKT cells were correlated with NAFLD and a decreased frequency of peripheral NKT cells was a risk factor for NAFLD.

Applications

The results may provide new theoretic and experimental evidences for the study of the pathogenesis of NAFLD, and new therapeutic approaches for NAFLD by regulating the balance of NKT cells in the body.

Terminology

NKT cells were originally defined in mice in the last decade as a lymphocyte subtype that co-expresses natural killer receptors together with T cell receptors. A striking characteristic of these T cells is the recognition of lipid antigens presented by the restrictive non-classical, non-polymorphic MHC class I-like CD1d molecule. NKT cells play an important immuno-modulatory role in autoimmune, allergic, antimicrobial and anti-tumor immune responses.

Peer review

The paper by Xu *et al* describes that a reduced number of peripheral NKT cells is associated with NAFLD. The topic of the paper is highly interesting. The patients have to be much better characterized.

Abstract

AIM: To evaluate the effect of preoperative transcatheter arterial chemoembolization (TACE) on proliferation of hepatocellular carcinoma (HCC) cells.

METHODS: A total of 136 patients with HCC underwent liver resection. Of 136 patients, 79 patients received 1 to 5 courses of TACE prior to liver resection (TACE group), who were further subdivided into four groups: Group A ($n = 11$) who received 1 to 4 courses of chemotherapy alone; Group B ($n = 33$) who received 1 to 5 courses of chemotherapy combined with iodized oil; Group C ($n = 23$) who received 1 to 3 courses of chemotherapy combined with iodized oil and gelatin sponge; and Group D ($n = 12$) who received 1 to 3 courses of chemotherapy combined with iodized oil, ethanol and gelatin sponge. The other 57 patients only received liver resection (non-TACE group). The expressions of Ki-67 and proliferating cell nuclear antigen (PCNA) protein were detected in the liver cancer tissues by immunohistochemical method.

RESULTS: The Ki-67 protein expression was significantly lower in Groups C and D as compared with non-TACE group ($31.35\% \pm 10.85\%$ vs $44.43\% \pm 20.70\%$, $30.93\% \pm 18.10\%$ vs $44.43\% \pm 20.70\%$, respectively, $P < 0.05$). The PCNA protein expression was significantly lower in Groups C and D as compared with non-TACE group ($49.61\% \pm 15.11\%$ vs $62.92\% \pm 17.21\%$, $41.16\% \pm 11.83\%$ vs $62.92\% \pm 17.21\%$, respectively, $P < 0.05$). The Ki-67 protein expression was significantly higher in Group A as compared with non-TACE group ($55.44\% \pm 13.72\%$ vs $44.43\% \pm 20.70\%$, $P < 0.05$). The PCNA protein expression was significantly higher in Groups

A and B as compared with non-TACE group ($72.22\% \pm 8.71\%$ vs $62.92\% \pm 17.21\%$, $69.91\% \pm 13.38\%$ vs $62.92\% \pm 17.21\%$, respectively, $P < 0.05$).

CONCLUSION: Preoperative multi-material TACE suppresses the proliferation of HCC cells, while a single material embolization and chemotherapy alone enhance the proliferation of HCC cells.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies. Curative local resection is recognized as a safe and effective method for patients with HCC^[1]. Unfortunately, only a minority of patients currently diagnosed with HCC may benefit from this radical option. Transcatheter arterial chemoembolization (TACE) has become one of the most popular and effective palliative methods for patients with HCC. Various mixtures of anticancer drugs, iodized oil and gelatin sponge have been used as TACE agents. There have been a few reports on comparison of the efficacy of different TACE regimens on patients with HCC^[2].

Proliferating cell nuclear antigen (PCNA) is an auxiliary factor in DNA polymerase, and is expressed in the nuclei, particularly in the late G₁ and S phases. Ki-67 is expressed throughout the cell cycle (late G₁, S, G₂, and M phases) of proliferating cells, but is absent in quiescent (G₀) cells. Therefore, PCNA and Ki-67 are believed to be useful markers for proliferative activity^[3]. Our previous study showed that expression of p53 can enhance expression of PCNA and Ki-67 after TACE^[4].

As far as we are aware, the effects of different TACE regimens on proliferation of HCC cells have not been

investigated previously. In particular, it is unclear whether TACE can enhance or suppress proliferation of HCC cells by modulating the expressions of PCNA and Ki-67 proteins. In the present study, we examined the effects of the four main types of TACE used clinically (pure intra-arterial chemotherapy; chemotherapy plus iodized oil; chemotherapy plus iodized oil plus gelatin-sponge; chemotherapy plus iodized oil plus alcohol plus gelatin-sponge) on proliferation of HCC cells *in vivo*.

MATERIALS AND METHODS

Patients

From Feb 1992 to Feb 2001, a total of 136 patients with HCC were referred to our hospital for surgery. There were 122 men and 14 women with mean age of 45 (ranged from 20 to 70) years. A diagnosis of HCC was obtained for all patients by preoperative ultrasound (US) or/and computed tomography (CT) or/and magnetic resonance image (MRI) or/and digital subtraction angiography (DSA) and plasma AFP levels and confirmed by pathological biopsy.

Surgical procedure

The patients were divided into two groups according to treatment manners. In the TACE group, 79 patients underwent 1-5 courses of chemoembolization prior to liver resection. In the control group, 57 patients received initial liver resection without preoperative TACE. The extent of liver resection was carried out based on the location of tumor, the severity of concomitant liver cirrhosis and preoperative liver reserve function.

TACE methods

By Seldinger's technique, indirect portal-veinography through the superior mesenteric artery was firstly performed to observe portal vein flow, thrombus, mislocalized tumor-feeding artery. Then a catheter was inserted selectively and superselectively into the right or left hepatic artery or the tumor-feeding artery. The patients in TACE group were divided into four subgroups: one to four courses of only infusion of chemotherapeutic agents, including 5-fluorouracil (5-FU) 1000 mg (NanTong Pharmaceutical Factory, China), mitomycin-c (MMC) 10 mg (Kyowa Hakko Kogyo Co. Ltd., Japan), carboplatin 300 mg (QiLu Pharmaceutical Factory, China), or epirubicin (E-ADM) 60 mg (Zhejiang HiSun Pharmaceutical Co. Ltd., China), were performed in 11 patients (Group A); one to five courses of first infusion of the same chemotherapeutic agents as group A, then embolization with mixture composed by iodized oil (Lipiodol, Guerbet, France) 5-20 mL according to the tumor size and E-ADM were performed in 33 patients (Group B); one to three courses of chemotherapy combined with iodized oil, the same as group B, plus adequate gelatin sponge particle embolization were performed in 23 patients (Group C); one to three courses of chemotherapy combined with iodized oil, ethanol and gelatin-sponge, that is, firstly, the same chemotherapy as group A, secondly, embolization with mixture composed of iodized oil 5-20 mL and waterless ethanol 1-5 mL (two ratio 4:1), finally,

embolization with adequate gelatin sponge particle, were performed in 12 patients (Group D). Of them, 50 patients underwent one course of TACE; 19 patients underwent two courses of TACE; 10 patients underwent three or more courses of TACE during an interval of 52.8 ± 12.2 d (mean \pm SD). Of them, 25 patients had ≤ 1 mo interval; 29 patients had ≤ 2 mo interval; 16 patients had ≤ 3 mo interval; and 9 patients had > 3 mo interval.

Immunohistochemical method

The formalin-fixed, paraffin-embedded specimens were examined immunohistochemically using anti-Ki-67 monoclonal antibody M7187 (1:50 dilution) and anti-PCNA monoclonal antibody M0879 (1:200 dilution) (LSAB kit Dako). Positive controls were normal lymph nodes. Negative controls were generated by substituting for the primary antibody with a non-specific IgG (normal rabbit IgG) and tris-buffered saline. Ki-67- and PCNA-positive cells showed brown-yellow staining in the nuclei of cancer cells (Figures 1 and 2). Rate of positive immunostaining for Ki-67 or PCNA was calculated as the ratio of the number of positively stained tumor cells to the total number of tumor cells counted per section. All slides were reviewed and scored in a blind fashion by two observers without knowledge of the corresponding clinical data. A few cases with discrepant scoring were reevaluated jointly on a second occasion, and an agreement was reached.

Statistical analysis

Data were expressed as mean \pm SD and analyzed by means of SPSS 10.0 software package (SPSS, Chicago, IL, USA, 1999) using Student's *t* test, Crosstabs (Chi-square and Fisher exact probability test) and K Independent Samples, when appropriate A *P* value < 0.05 was considered statistically significant.

RESULTS

Expression of Ki-67 and PCNA proteins

Ki-67 and PCNA protein expressions of HCC cells, respectively, were $44.43\% \pm 20.70\%$ and $62.92\% \pm 17.21\%$ in non-TACE group, $55.44\% \pm 13.72\%$ and $72.22\% \pm 8.71\%$ in Group A, $45.26\% \pm 14.97\%$ and $69.91\% \pm 13.38\%$ in Group B, $31.35\% \pm 10.85\%$ and $49.61\% \pm 15.11\%$ in Group C, and $30.93\% \pm 18.10\%$ and $41.16\% \pm 11.83\%$ in Group D. Ki-67 protein expression was significantly higher in Groups A and B as compared with Groups C and D, was lower in Groups C and D as compared with non-TACE group, and was higher in Group A as compared with non-TACE group ($P < 0.05$). PCNA protein expression was significantly higher in Groups A and B as compared with Groups C, D and non-TACE group, and was lower in Groups C and D as compared with non-TACE group ($P < 0.05$).

Correlation between courses of TACE and expressions of Ki-67 and PCNA proteins

Ki-67 and PCNA protein expressions of HCC cells, respectively, were $44.43\% \pm 20.70\%$ and $62.91\% \pm 17.21\%$

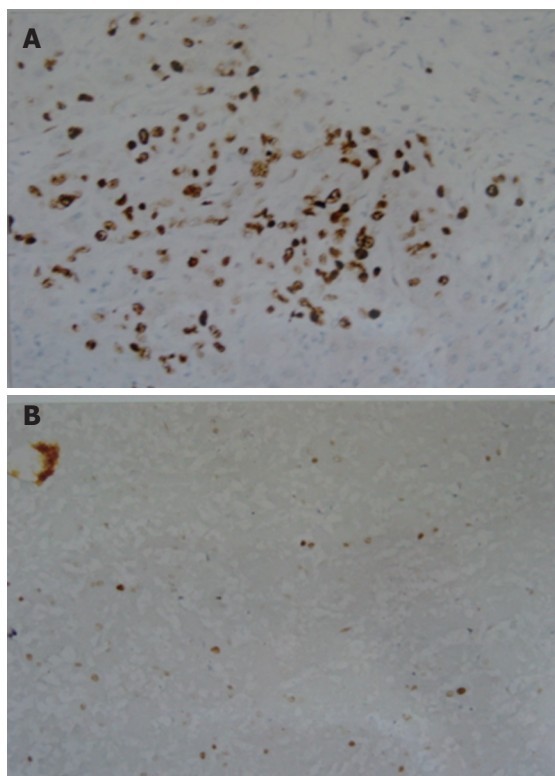

Figure 1 Ki-67 immunostaining of HCC cells ($\times 200$). **A:** Non-TACE group; **B:** Group D.

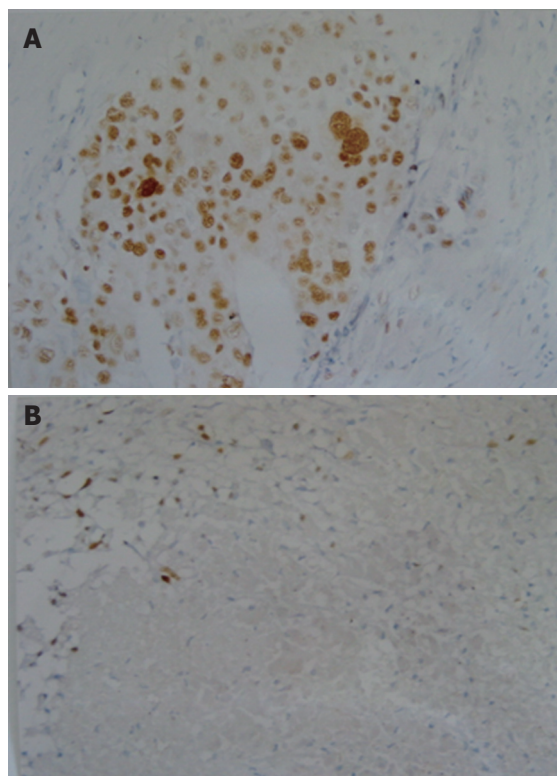

Figure 2 PCNA immunostaining of HCC cells ($\times 200$). **A:** Non-TACE group; **B:** Group C.

in non-TACE group, $41.34\% \pm 16.69\%$ and $62.00\% \pm 18.47\%$ in one-course of TACE group, $39.24\% \pm 14.48\%$ and $57.70\% \pm 15.54\%$ in two-courses of TACE group, and $38.33\% \pm 20.90\%$ and $53.97\% \pm 18.13\%$ in three- or four- or five-courses of TACE group, indicating that Ki-67 and PCNA protein expressions were insignificantly decreased as the courses of TACE increased.

Correlation between interval of TACE and expressions of Ki-67 and PCNA protein

Ki-67 and PCNA protein expressions of HCC cells, respectively, were $44.43\% \pm 20.70\%$, $62.91\% \pm 17.21\%$ in non-TACE group, $35.42\% \pm 15.46\%$ and $53.19\% \pm 18.28\%$ in ≤ 1 mo interval of TACE group, $40.66\% \pm 18.53\%$ and $58.09\% \pm 15.90\%$ in 1-2 mo interval of TACE group, $42.22\% \pm 14.80\%$ and $66.83\% \pm 17.93\%$ in 2-3 mo interval of TACE group, and $50.62\% \pm 12.33\%$ and $72.53\% \pm 12.93\%$ in > 3 mo interval of TACE group. Comparison between groups indicated that the Ki-67 protein expression was significantly lower in " ≤ 1 mo" interval group as compared with " > 3 mo" interval and non-TACE groups ($P < 0.05$), while the expression of PCNA protein was significantly lower in the " ≤ 1 mo" and "1-2 mo" interval groups as compared with " > 3 mo" interval and non-TACE groups ($P < 0.05$).

DISCUSSION

HCC is one of the most common malignant neoplasms. The majority of the HCC patients are treated with palliative approaches to improve the respectability rate

and prolong survival. TACE has been one of the most common and effective palliative approaches. The prognosis of patients treated with TACE depends not only on use of an effective TACE regimen but also on tumor factors^[5].

To our knowledge, few data currently are available regarding the molecular mechanism of TACE treatment for patients with HCC, and the current study is the first report detailing the correlations between the expressions of Ki-67 and PCNA protein and different TACE regimens.

The two proliferative indices assessed in our study were Ki-67 and PCNA. Ki-67 presents throughout the cell cycle (late G₁, S, G₂, and M phases) of proliferating cells, but is absent in quiescent (G₀) cells^[6]. PCNA is a non-histone nuclear protein of 36 kDa, an auxiliary pro-DNA polymerase δ that plays a major role in synthesizing DNA, and is believed to be expressed in the nuclei, particularly in the late G₁ and S phases^[6]. Univariate and multivariate analyses showed that the high labeling index of PCNA resulted in high tumor recurrence risk, more aggressive growth and poor survival^[7-9].

The current study demonstrated that the effects of TACE on proliferation of HCC cells depended on its regimens. We found that the mean percentage of Ki-67 and PCNA protein expression was in a decreasing order as follows: Groups A and B $>$ non-TACE group $>$ Group C and D, which suggested that TACE using iodized oil, gelatin sponge particle and/or ethanol significantly inhibited proliferation of HCC cells, whereas TACE using iodized oil alone and chemotherapy alone increased proliferation of HCC cells, which is in agreement with

our previous reports that TACE using iodized oil, gelatin sponge particle and/or ethanol significantly decreased proliferative index (PI) and S-phase fraction (SPF) of HCC cells^[10]; alone iodized oil TACE and chemotherapy alone increased PI and SPF of HCC cells^[10]; PCNA protein expression of HCC cells was significantly higher in the TACE group which mostly consisted of iodized oil and anticancer drugs^[11], and multi-material TACE easily resulted in decreasing of HCC volume^[12].

The best interval of treatment for repeated TACE or second stage resection is controversial. Hsu *et al*^[13] considered 3 to 21 d interval was adequate to prevent the regrowth of residual tumor cells. Zhu *et al*^[14] considered 1 to 3 mo interval was best for resectable tumors, and longer interval for unresectable tumors. Moreover, 1 to 2 mo interval by Liang *et al*^[15], 2 to 3 mo interval by Lai *et al*^[16], 3 mo interval by Zhang *et al*^[17], 3 to 4 mo interval by Kenji *et al*^[18], and > 3 mo interval by Teng *et al*^[19] were proposed as the best interval. The above-mentioned data were based on the clinical and pathological data. In this study, we found that there were significantly lower Ki-67 and PCNA protein expressions in the “≤ 1 mo” and “> 1 and ≤ 2 mo” interval Groups as compared with “> 3 mo” interval Group ($P < 0.05$). In other word, the remaining cancer cells after TACE treatment had significantly lower proliferative activity at 1 to 2 mo interval than > 3 mo interval. According to this molecular and genetic study and previous clinical and pathological study, we considered the best interval of treatment for repeated TACE or second stage resection is between 2 and 3 mo.

This study demonstrated that Ki-67 and PCNA protein expressions decreased as the courses of TACE increased. Taken collectively, the present data together with our previous study^[12] and findings by Spreafico *et al*^[20] and Lai *et al*^[16] that tumor necrosis, shrinkage of the tumor mass, proliferation and encapsulation of perimass fibrous tissue were closely related to the courses of TACE and findings by Zhang *et al*^[21] that the survival in patients with multi-times TACE was better than those with single one, suggest that TACE could be performed multi-times, provided the patients' condition is preferable. But the liver cirrhosis rate after TACE treatment had significant correlation with the courses of treatment^[22]. The selective and superselective catheterization is the best way to avoid damaging the normal liver tissue.

In conclusion, the present study demonstrates that the proliferative activity of residual HCC cells after being treated by TACE using iodized oil, gelatin sponge, and/or ethanol is significantly decreased as compared with TACE using iodized oil alone or pure intra-artery chemotherapy. The effect of TACE on proliferation of HCC cells has negative correlation with number of course of TACE and positive correlation with the interval of TACE.

COMMENTS

Background

Transcatheter arterial chemoembolization (TACE) has become one of the most popular and effective palliative methods for patients with HCC. Various mixtures of anticancer drugs, iodized oil and gelatin sponge, have been used as TACE agents.

There have been a few reports on comparison of the efficacy of different TACE regimens on patients with Hepatocellular carcinoma (HCC).

Research frontiers

The effects of different TACE regimens on proliferation of HCC cells had not been investigated previously.

Innovations and breakthroughs

In the present study, the effects of the four main types of TACE used clinically on proliferation of HCC cells *in vivo* have been examined.

Applications

Best mixtures and methods could be used for TACE.

Terminology

TACE: Transcatheter arterial chemoembolization.

Peer review

As mentioned TACE is one of the most popular and effective palliative method for patients with HCC. Various mixtures and methods had been used for TACE. In this study, the effectiveness of the TACE methods was compared. It is an interesting study.

Abstract

Diffuse intestinal Kaposi's sarcoma shares macroscopic and histopathologic features with gastrointestinal stromal tumors. Correct diagnosis may pose a clinical challenge. We describe the case of a young HIV-1-infected African lady without advanced immunodeficiency, who presented with a diffuse spindle cell tumor of the gut. Initial diagnosis was of a gastrointestinal stromal tumor, based on endoscopy and histopathology. Further evaluation revealed evidence for human herpesvirus 8 (HHV8) and the diagnosis had to be changed to diffuse intestinal Kaposi's sarcoma. Antiretroviral triple therapy together with chemotherapy was commenced, and has led to the rapid remission of intestinal lesions. With a background of HIV infection, the presence of HHV8 as the causative agent of Kaposi's sarcoma should be determined, as distinct treatment is indicated.

INTRODUCTION

Diffuse Kaposi's sarcoma bears a significant morbidity and mortality risk in individuals with HIV infection. It is commonly observed in untreated male homosexual HIV-

1-infected individuals and is associated with advanced immune deficiency. Progressive disease is a very rare condition in HIV-infected women^[1,2]. In Africa, Kaposi's sarcoma is one of the most frequently occurring tumors. It exists in epidemic and endemic forms, the latter not being associated with HIV infection^[3]. Diagnosis remains a challenge, particularly in a setting where clinical findings could be readily explained by alternative diagnoses, which may be more common.

CASE REPORT

A 29-year-old African woman was admitted to our gastroenterology ward in December 2005 with persisting diffuse abdominal pains and abdominal bloating after returning from Nigeria. She also complained of swelling of the right leg for several months. She was known to be infected with HIV-1 and receiving no specific therapy because of only mild immunodeficiency (absolute CD4 count 304/mm³, CD4/CD8 ratio 0.94 on admission) despite a high viral load (180 000 HIV-1-RNA/mL). Previous history included diabetes, hypothyroidism and arterial hypertension. On examination, mild swelling of the right leg was observed. Ultrasound suggested a deep venous thrombosis, which was treated initially with low molecular weight heparins. Pathologic findings in the blood test included normocytic anaemia, mild thrombocytosis and slightly raised LDH, amylase and lipase levels. Abdominal CT scan was normal. On endoscopy of the upper GI tract, candida oesophagitis, diffuse, non-erosive gastritis and duodenitis with several ulcerous lesions were observed (Figure 1). Colonoscopy revealed diffuse polypoid lesions throughout the entire colon, with aphthous lesions in the sigma (Figure 2). Histopathology showed ulcerative duodenitis. No evidence for T. whippeli, fungi, giardiasis, CMV or HSV infection was found in biopsies. However, a mesenchymal CD34-positive and weakly CD117-positive, SM actin-negative stroma-like tumor was found in all biopsies from the colon. The nuclear proliferation antigen Ki67 was positive in 10%-20% of tumor cells. The diagnosis of a gastrointestinal stromal tumor (GIST) was made by the pathologist. Figure 3 shows spindle cell proliferations in colon biopsies involving the lamina propria; these are readily observed in gastrointestinal stromal tumors.

Because of the diffuse involvement of the entire GI tract, the histological diagnosis was questioned and the patient was readmitted for further biopsies. The possibility

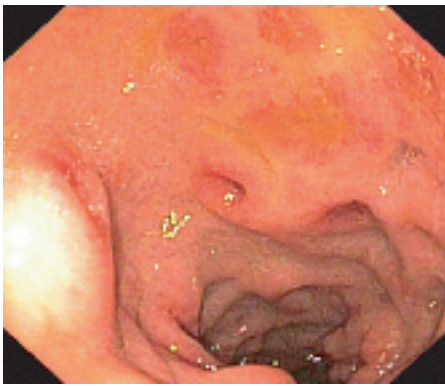

Figure 1 Inflammation of the duodenal mucosa with ulcerous lesions can be seen.

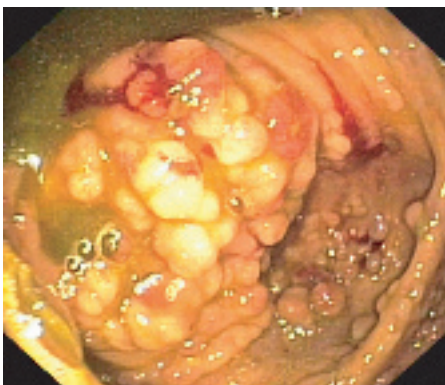

Figure 2 Diffuse polypoid lesions are present in the colon.

of an atypical clinical presentation of a gastrointestinal stromal tumor due to underlying HIV infection was discussed.

In the meantime, her clinical condition had deteriorated with marked weight loss and persistent abdominal pain. Examination of her right foot revealed several tumour-like lesions, which were diagnosed as dermatitis exsudativa by a consultant dermatologist, and a skin biopsy was taken. Ultrasound of the persistently swollen right leg revealed an enlarged lymph node in the right groin, but no signs of a DVT.

Again, gastrointestinal endoscopy was performed, showing a macroscopic appearance similar to the previous investigations, and several biopsies were taken. Finally, further histopathologic examination, including HHV-8 staining of these biopsies, now suggested diffuse Kaposi's sarcoma of the intestine. Retrospective evaluation of the biopsies previously taken from the colon also revealed HHV-8 reactivity.

The diagnosis of diffuse Kaposi's sarcoma was further supported by the detection of HHV-8 in the skin biopsies as well as in the blood. Antiretroviral combination therapy, including two nucleoside reverse transcriptase inhibitors and a boosted protease inhibitor together with 2-weekly liposomal Doxorubicin, was commenced. On her last follow-up visit 6 mo later, the abdominal symptoms and swelling of the leg had resolved completely. Endoscopy of the upper and lower intestinal tract showed no further

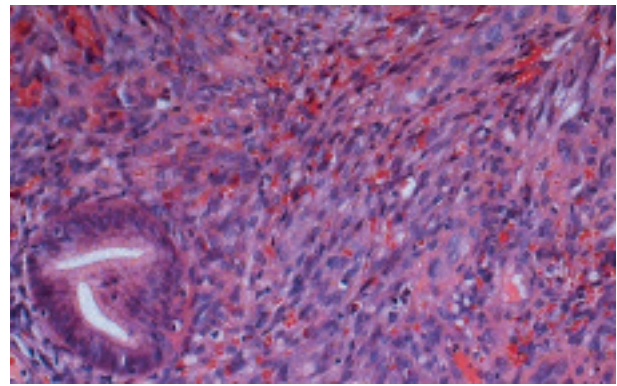

Figure 3 Proliferation of spindle cells is seen in the lamina propria. Slit-like spaces are present, with red blood cells between them.

evidence of Kaposi's sarcoma in the colon, with only small residuals remaining in the duodenum.

DISCUSSION

GIST and Kaposi's sarcoma both present as diffuse intestinal lesions with spindle cells, and their diagnosis may be confused because of the presence of CD34-expressing spindle cells with only weak CD117 (c-kit) positivity. Most GISTs show positive immunostaining for CD117 and CD34, but are negative for HHV8. Recent data show the presence of CD117 positivity in up to 56% of Kaposi sarcomas, and overexpression occurs in HHV8-coinfected cells^[4]. However, the original cells in Kaposi's sarcoma are of vascular origin, and the presence of human herpesvirus 8 can be found in at least 95% of cases^[5]. HHV8 PCR should be performed early to confirm or exclude the diagnosis of Kaposi's sarcoma, especially in immunodeficient patients, because distinct treatment may be indicated^[6].

In HIV-positive patients, highly active antiretroviral therapy (HAART) has clearly influenced the occurrence of Kaposi's sarcoma, and is the most important therapy to stop the progression and improve the prognosis of diffuse disease, as also demonstrated by our case^[7]. In individual cases with widespread disease and multiple organ involvement, the use of liposomal anthracyclines may be beneficial for the induction of complete remission^[8]. The presence of c-kit positivity may rather warrant the use of a selective tyrosine kinase inhibitor, such as imatinib mesylate. To date, however, clinical experience is limited to a few patients with Kaposi's sarcoma refractory to conventional therapy^[9]. Further studies using this novel therapeutic approach clearly need to be performed.

Abstract

A 17-year-old girl with colicky abdominal pain and chronic anemia presented to the gastrointestinal service of the University Hospital of Essen. In the routine workup, there were no pathological findings despite the anemia. Because of the fluctuation of symptoms with a climax at the time of menstruation, consecutive ultrasound studies were performed revealing a visible mass inside the gallbladder. This finding was confirmed by a magnetic resonance imaging (MRI) study performed at the same time. Because of the severe anemia by that time, a cholecystectomy was performed, and histology reconfirmed the diagnosis of isolated gallbladder endometriosis. The patient recovered well and has had no recurrence of the disease to date.

INTRODUCTION

Endometriosis is the presence of functioning endometrial tissue outside the uterine cavity. Indeed, when this hormonally active tissue implants in the gastrointestinal tract, it can cause cyclical bleeding, resulting in anemia and pain. Herein, we describe a very rare case of an endometrial tissue manifestation in the gallbladder.

CASE REPORT

A 17-year-old girl with colicky abdominal pain and chronic anemia of unknown origin was referred to the University Hospital of Essen. The right upper quadrant pain was most severe during menstruation. Similar symptoms had occurred one year prior to admission and led to further hospital stays; however, despite extensive diagnostic efforts, a satisfying diagnosis was lacking and the treatment was for symptoms only. The patient was treated with repetitive iron replacement and blood transfusions, which led to several complications including thrombophlebitis, with the need for surgical intervention. Physical examination revealed no pathological findings apart from a local tenderness to palpation in the right upper quadrant of the abdomen. Routine laboratory studies confirmed a normocytic hypochromic anemia. No further abnormalities were seen in routine laboratory studies; liver function tests were within normal limits, as was hepatitis serology including tests for major hepatotropic viruses.

Several diagnostic means were used to identify the cause of symptoms, including oesophago-gastro-duodenoscopy and colonoscopy as well as radiologic studies. Endoscopic examinations showed physiologic findings in the upper and lower gastrointestinal tract. Radiographic examinations, including barium follow-through, initial ultrasound (US) and magnetic resonance imaging (MRI) of the abdomen, were normal. Computed tomography (CT) of the abdomen showed a questionable radiopaque tissue in the wall of the gallbladder, with concomitant inflammation. These findings, combined with the history of complaints, led to the presumed diagnosis of gallbladder endometriosis. US examination was performed once more on d 14 of the menstrual cycle and repeated every second day, showing continual expansion of the suspected tissue. After 12 d and maximum extension of the tissue, a second MRI of the liver was performed, and the diagnosis of endometriosis of the gallbladder could be confirmed (Figure 1).

According to the radiologic findings and the continued abdominal complaints, laparoscopic cholecystectomy was discussed with the Department of General Surgery and finally performed. The postoperative course was uneventful. Twelve months after surgery the patient was still without any complaints, and during the laboratory follow up her hemoglobin level remained within the normal range; no further transfusions have been necessary. Histopathological examination confirmed the clinical diagnosis of endometriosis of the gallbladder.

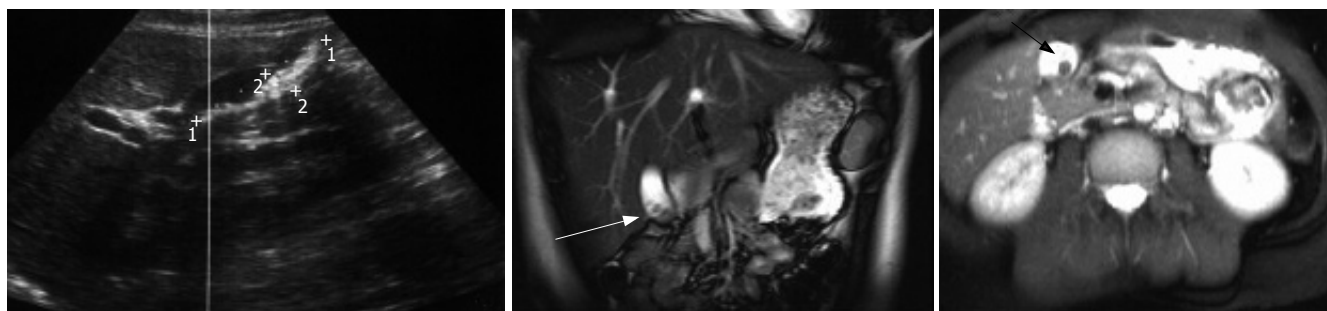

Figure 1 Computed tomography (CT) of the abdomen showed a radiopaque tissue in the wall of the gallbladder, with concomitant inflammation. US examination showed continual expansion of the suspected tissue. After 12 d and maximum extension of the tissue, a second MRI of the liver was performed, and the diagnosis of endometriosis of the gallbladder could be confirmed.

DISCUSSION

Endometriosis, defined as the presence of endometrial tissue outside the uterine cavity and musculature, was first described by von Rokitasky in 1860. Although it usually occurs in the pelvis, endometriosis has been found in almost every region of the human body. As a response to physiologic hormonal changes that occur during the menstrual cycle, this ectopic endometrium will invade, distort and occasionally destroy normal organs. The prevalence of this abnormality has been reported to be between 8% and 18% in young women^[1,2]. The majority of extrauterine endometrial tissue invades ovaries and the pelvic peritoneum. Ectopic endometriosis in other sites of the female body usually involves the gastrointestinal tract, but ectopic tissue may also present within the urinary tract^[1,3,4]. In addition, symptomatic mediastinal, bronchial and pleural endometriosis have been documented^[3,5-8] and the presence of endometrial tissue has been identified in thigh muscle tissue^[9,10], the inguinal canal^[10], nasal mucosa^[11], incisional scars^[12] and, in very few cases, in the gallbladder^[13]. The clinical diagnosis of intestinal endometriosis may be difficult to make because of non-specific symptoms and the missing relationship between symptoms and the menstrual cycle. However, endometriosis should always be considered in women with recurrent abdominal pain and intestinal symptoms, especially in young females with gynaecologic complaints. The high prevalence of irritable bowel syndrome increases the risk of misdiagnosis in these rare cases.

According to its localization, intestinal endometriosis is often an incident finding in laparoscopic procedures^[14-18]. Recognition requires a high index of suspicion. Thus, physicians should be aware of endometriosis as a differential diagnosis in female patients with recurrent periumbilical or abdominal pain and other episodic bowel symptoms.

An important component of the evaluation is a bimanual pelvic examination that includes combined rectovaginal palpitation. Because findings may vary considerably throughout the menstrual cycle, all examinations should be performed immediately before and again after menses^[3,4].

In many cases, radiologic findings are useful in raising the possibility of detection of endometriosis, providing supportive evidence for a preliminary diagnosis^[19-22]. Intestinal endometriosis appears radiographically as a

tapered, often eccentric, constricting deformity. Although CT scanning and US are often unable to differentiate between abscesses and hematomas from endometriotic lesions^[4,18,23], such indirect imaging methods may be useful in defining the anatomic extent of pelvic endometriosis^[4]. MRI is useful for monitoring the response to treatment, but it cannot be relied upon as a diagnostic substitute for laparoscopy^[23-26].

As intestinal endometriosis is usually nonmucosal, enteroscopy is helpful in excluding other gastrointestinal disorders, especially neoplasia^[27,28]. Unequivocal diagnosis relies upon histological confirmation of the presence of the endometrium within one or several organs of the gastrointestinal tract. It is of particular importance in such morphologic interpretations to avoid confusing endometrial tissue with carcinomatous glands. In postmenopausal women in particular, less prominent stromal elements leave scattered endometrial glands, which appear similar to well-differentiated adenocarcinomas. In general, when a diagnosis of intestinal endometriosis is made, hormonal therapy is often the first therapeutic option, similar to the standard approach to pelvic endometriosis^[29-31]. Low-dose estrogen-progesterone compounds can cause pseudopregnancy states that result in the decidualization of endometrial tissue and often relieve symptoms like dysmenorrhea. However, their use in more severe diseases is questionable and generally not recommended for symptomatic intestinal diseases. The most effective agents currently available are the synthetic androgen danazol and the gonadotropin-releasing hormone (GnRH) agonists. New approaches tend to use add-back estrogen replacement to improve the quality of life and reduce the side effects of these treatments^[32]. Although both are effective in decreasing pelvic pain associated with endometriosis and appear to decrease the size of endometrial implants, there are no studies of these agents in intestinal disease, and there is some concern that treatment can result in increased fibrosis^[33]. In cases of mucosal endometriosis, laparoscopic ablation can be accomplished using a carbon dioxide laser^[34,35]. In cases of endometriosis causing partial obstruction of the colon or small intestine, segment resection of the involved area is considered to provide the best results, and it also serves to exclude any underlying carcinoma^[4,36]. In patients who have failed medical therapy and who have intractable symptoms,

hysterectomy and salpingo-oophorectomy can be performed at the time of resective surgery to minimize the risk of symptomatic disease in the future. Similar surgery also can be performed in postmenopausal patients^[37-39].

Because of the isolated endometrial manifestation in the gallbladder and the age of the patient in this case, a surgical approach and laparoscopic cholecystectomy seemed to provide the best results. Considering the long history and suffering of this patient for over one year, it appears that familiarity with this nonneoplastic process and an appropriate index of suspicion is often lacking in physicians - even for patients with typical presentations.

Abstract

A 78-year-old man with liver cirrhosis was found to have multiple hepatocellular carcinomas (HCCs) and underwent 3 sessions of transcatheter arterial chemoembolization. Fourteen months after diagnosis, the patient presented with left hemiparesis. Contrast-enhanced magnetic resonance imaging showed multiple metastases with ring-shaped enhancement in the cerebrum and cerebellum. There were no metastases to other organs. The metastatic lesions almost completely disappeared after whole-brain radiotherapy with a total dose of 50 Gy. Neurologic symptoms decreased, and the patient's quality of life improved. The patient underwent 2 more sessions of transcatheter arterial chemoembolization. Twelve months after the diagnosis of brain metastasis, the patient remains alive. The present case indicates that radiotherapy can improve quality of life and prolong survival in some patients with brain metastases from HCCs.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most
www.wjgnet.com

common malignancies in Asian countries, including Japan^[1]. Although recent advances in treatment have helped prolong the survival of patients with HCC, they consequently increase the risk of intrahepatic recurrence and extrahepatic metastasis. The most frequent sites of extrahepatic metastasis are the lung, bone, lymph nodes and adrenal glands^[2,4]. Brain metastasis is rare: it is found at autopsy in 2.2% of cases of HCC in Japan^[5]. The extremely poor prognosis of patients with brain metastasis is a significant problem. A recent study of a large number of patients reported a median survival time of only 1 mo^[6]; other studies have reported similar results^[7,8]. Furthermore, quality of life (QOL) is decreased because of neurologic symptoms, such as headache, mental change and hemiparesis/hemiplegia, and many patients die of neurologic causes^[6,7]. Radiotherapy is a possible treatment for brain metastasis, but its efficacy remains unclear. This paper reports a case of multiple brain metastases from HCCs, for which whole-brain radiotherapy had a dramatic therapeutic effect.

CASE REPORT

A 78-year-old man had visited a hospital for treatment of liver cirrhosis for more than 10 years. Tests for both hepatitis B surface antigen and antibodies to hepatitis C virus were negative. A routine contrast-enhanced computed tomography (CT) examination revealed multiple HCCs. The patient underwent transcatheter arterial chemoembolization (TACE). Four months later, he visited our hospital. The HCCs were not suitable for resection or ablation because of their number, size and location. Accordingly, the patient underwent 2 more sessions of TACE (Figure 1). Twelve months later, endoscopic sclerotherapy was performed for esophageal varices.

Fourteen months later, contrast-enhanced CT showed multiple enlarged HCCs (Figure 2). Laboratory data were as follows: aspartate aminotransferase, 28 IU/L (normal, 8-35 IU/L); alanine aminotransferase, 15 IU/L (normal, 5-43 IU/L); lactate dehydrogenase, 220 IU/L (normal, 106-211 IU/L); alkaline phosphatase, 191 IU/L (normal, 104-338 IU/L); γ -glutamyl transpeptidase, 35 IU/L (normal, 5-50 IU/L); total bilirubin, 0.8 mg/dL (normal, 0.3-1.1 mg/dL); albumin, 4.1 g/dL (normal, 3.8-5.1 g/dL); prothrombin time, 67% (normal, 70%-130%) (Child-Pugh score 5; class A). The serum levels of alpha-fetoprotein and des-gamma-carboxy prothrombin were 113.7 ng/mL (normal, < 10 ng/mL) and 217 mAU/mL (normal, < 40 mAU/mL), respectively. At that time, the patient was admitted to our hospital for the treatment of HCC. On

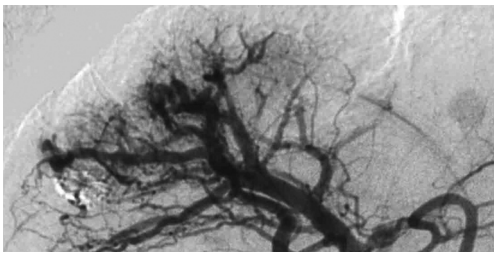

Figure 1 Hepatic arteriography at the time of the third session of TACE shows arterial tumor vessels with arterioportal shunting.

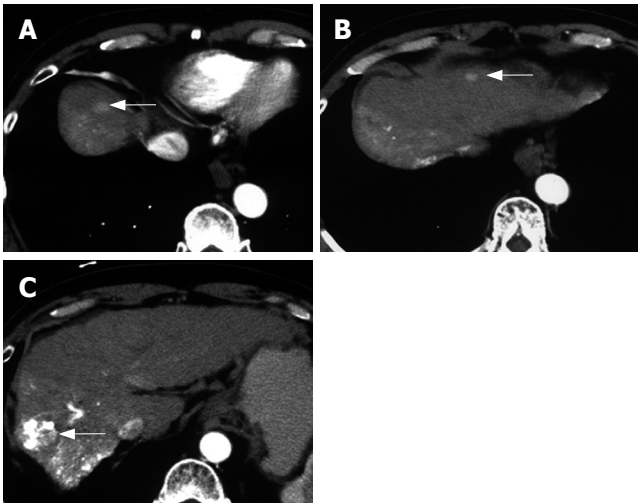

Figure 2 Contrast-enhanced CT at the time of the diagnosis of brain metastases shows multiple hypervascular HCCs (arrows) (A, B, C). Lipiodol retention in the main tumor is seen (C).

admission, he complained of gradual and progressive left hemiparesis of 1 mo duration. Unenhanced magnetic resonance (MR) revealed 12 tumors, less than 2 cm in diameter, in the cerebrum and cerebellum; these tumors showed hypointensity on T1-weighted MR images and hyperintensity on T2-weighted MR images (Figure 3A-D). On contrast-enhanced MR with gadolinium-DTPA, the tumors showed ring-shaped enhancement (Figure 3E-H). On the basis of the results of chest and abdominal CT, endoscopic examinations, and bone scintigraphy, the brain tumors were diagnosed as metastases from HCCs; there were no metastases to other organs, including lung, bones, lymph nodes and adrenal glands. The patient received whole-brain radiotherapy with a total dose of 50 Gy in 25 fractions over 5 wk. Most metastatic lesions shrank immediately after radiotherapy. Three months after the completion of radiotherapy, the tumors had almost completely disappeared (Figure 3I-L). Neurologic symptoms had almost completely resolved and the patient's QOL had improved. No severe acute or late radiologic toxicity was observed. The patient underwent 2 more sessions of TACE. Hepatic functional reserve was good during the clinical course (Child-Pugh score 6 to 7). Twenty-three months after initial diagnosis, the patient stopped attending our hospital. Twenty-six months after the initial diagnosis of HCC, and 12 mo after the diagnosis

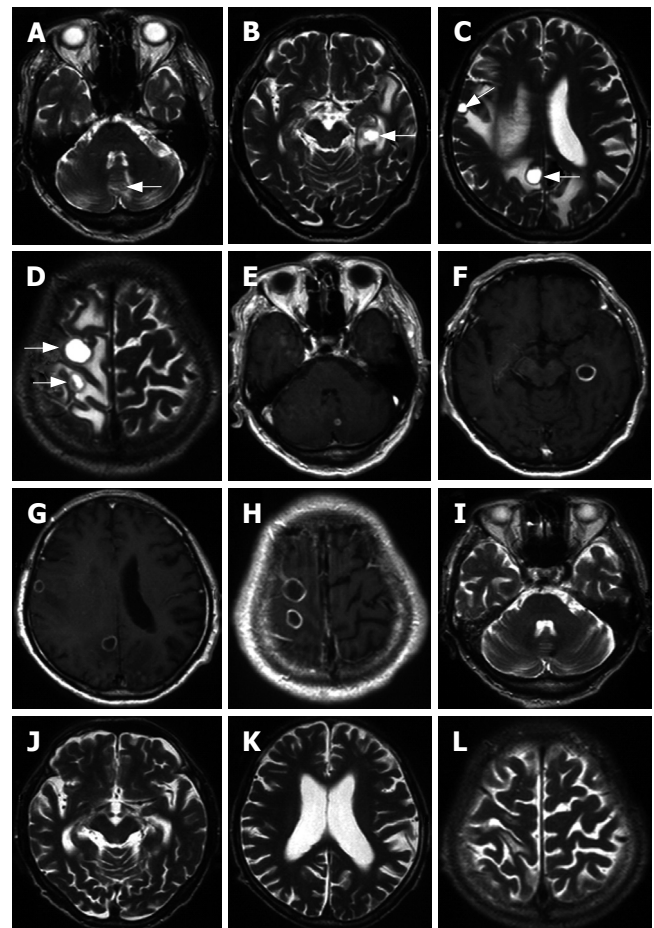

Figure 3 Unenhanced T2-weighted MR images show hyperintense tumors in the cerebrum and cerebellum (arrows) (A, B, C, D). Contrast-enhanced T1-weighted MR images show ring-shaped enhancement of the tumors (E, F, G, H). On T2-weighted, unenhanced MR images, captured 3 mo after the completion of radiotherapy, the brain tumors have almost completely disappeared (I, J, K, L).

of brain metastasis, the patient is alive and receiving supportive treatment at the original hospital.

DISCUSSION

Patients with brain metastasis from HCCs generally have advanced intrahepatic disease^[7], and most patients have simultaneous metastases to other sites, usually the lung^[7,8]. On the other hand, cases of brain metastasis from early-stage HCCs^[9] or without other extrahepatic metastases^[9,10] are occasionally reported. Clinicians should consider the possibility of brain metastasis from HCCs whenever neurologic symptoms develop in patients with HCC.

Recent studies have found that brain metastases from HCCs show homogeneous or ring-shaped enhancement on contrast-enhanced imaging^[7]. The enhancement pattern of the present case was ring-shaped, which may be due to the central necrosis of tumors^[7]. Brain metastases from HCCs tend to bleed in proportion to the size of the tumor^[8]. MR is useful for distinguishing such tumoral hemorrhage from nontumoral hemorrhage^[8].

Most patients with extrahepatic metastases from HCCs die of primary HCC or hepatic failure rather than the metastases because of the advanced stage of intrahepatic

disease or poor hepatic functional reserve, or both^[4]. Such outcomes imply that active treatment for metastasis might not prolong survival unless the primary HCC is controlled and the hepatic functional reserve is good. In addition to shortening survival, extrahepatic metastasis often decreases QOL. It is therefore worth considering active treatment for metastasis in such cases regardless of prognosis.

There is no established therapeutic strategy for brain metastasis from HCCs. Craniotomy, radiotherapy or both are commonly performed. Chang *et al*^[6] reported that patients with brain metastases who receive craniotomy, radiotherapy or both survive longer than patients who receive supportive care only (more than 4 mo compared with less than 1 mo). Chen *et al*^[11] reported that clinical improvement associated with a stable lesion is observed in patients with brain metastasis who receive radiotherapy. On the other hand, Kim *et al*^[12] reported that radiotherapy fails to stabilize the condition of patients with brain metastasis: the cause of death in most patients is progressive cachexia or hepatic failure. The applicability of radiotherapy should be carefully determined in each case from the viewpoints of prognosis and QOL. Recently, stereotactic radiosurgery has increasingly been used with or without whole-brain radiotherapy for the treatment of brain metastasis^[13]. Future studies will be required to select an appropriate radiation method according to the number and sizes of metastatic lesions in the brain.

Possible reasons why the present patient survived for a long time after the diagnosis of brain metastases are as follows. First, the brain metastases did not cause life-threatening conditions, such as brain herniation or massive cerebral hemorrhage. Second, radiotherapy had a dramatic therapeutic effect on the brain metastases. Third, there were no other life-threatening extrahepatic metastases. Fourth, the primary HCCs could be controlled with repeated TACE, and hepatic functional reserve was good.

In conclusion, radiotherapy can improve QOL and prolong survival in some patients with brain metastases from HCCs. Further studies should be performed to establish a therapeutic strategy using radiotherapy for such patients.

ACKNOWLEDGMENTS

The authors thank Dr. Yoji Shimizu, Dr. Kazuya Takahashi and Dr. Shigeo Nakamura, Department of Neurosurgery, Himeji Red Cross Hospital, for diagnosing the brain

metastases and evaluating the therapeutic effects of radiotherapy.

Abstract

Hepatocellular Carcinoma (HCC) is a common malignancy worldwide. While bleeding from the gastrointestinal tract (BGIT) has a well known association with HCC, such cases are mainly due to gastric and esophageal varices. BGIT as a result of invasion of the gastrointestinal tract by HCC is extremely rare and is reportedly associated with very poor prognosis. We describe a 67-year-old male who presented with BGIT. Endoscopy showed the site of bleeding to be from a gastric ulcer, but endoscopic therapy failed to control the bleeding and emergency surgery was required. At surgery, the ulcer was found to have arisen from direct invasion of the gastrointestinal tract by HCC of the left lobe. Control of the bleeding was achieved by surgical resection of the HCC en-bloc with the lesser curve of the stomach. The patient remains alive 33 mo after surgery. Direct invasion of the gastrointestinal tract by HCC giving rise to BGIT is very uncommon. Surgical resection may offer significantly better survival over non-surgical therapy, especially if the patient is a good surgical candidate and has adequate functional liver reserves. Prognosis is not uniformly grave.

INTRODUCTION

Hepatocellular carcinoma (HCC) is an important malignancy and is responsible for more than 250 000 deaths worldwide each year^[1]. Bleeding from the gastrointestinal tract (BGIT) is a common complication of HCC and a frequent cause of death from this disease. Most cases of BGIT are due to esophageal and gastric varices^[2] and the rest are mainly due to peptic ulcers. However, invasion of the gastrointestinal tract by HCC, through metastasis or direct invasion, is found in only 4-12% of cases at autopsy^[3-5,12]. These lesions tend to be asymptomatic and are thus mainly only discovered at post-mortem examination. Direct invasion of the stomach by HCC is extremely rare. A detailed literature review showed only 10 cases of HCC with direct or contiguous invasion of the stomach have been reported^[2,6-12]. We describe the case of a 67-year-old Chinese man with this uncommon clinical entity, who presented with BGIT and was managed by surgical resection.

CASE REPORT

A 67-year-old Chinese man presented to the Accident and Emergency Unit with a 3 d history of non-specific epigastric pain associated with postural dizziness and exertional dyspnea. There was no history of significant alcohol consumption and his hepatitis B and C status were unknown. History was negative for melaena, hematemesis, and hematochezia. He had a history of one episode of mild hemoptysis subsequent to which he was diagnosed as having bronchietasis due to heavy smoking.

Physical examination revealed a cachectic patient who was alert but had marked pallor of the conjunctiva. He was mildly hypotensive with a supine blood pressure of 105/60 with no postural drop. His pulse rate was 78 beats per minute, and he was not tachypneic. Palpation of the abdomen revealed mild epigastric tenderness on deep palpation but no significant organomegaly. He did not exhibit any stigmata of chronic liver disease. Bowel sounds were normal as was the digital rectal examination. There was no clinical sign of cardiac failure.

Initial investigations showed a white cell count of 8.5×10^9 (normal range $4.0-10.0 \times 10^9/L$), hemoglobin of 4.2 g/dL (normal range 14.0-18.0 g/dL), platelet count of 274×10^9 (normal range $140-440 \times 10^9$) and amylase of 71 U/L (normal range 30-110 U/L). He was transfused with 3 units of packed red cells, and an urgent

Figure 1 Endoscopic picture showing active bleeding from the lesser curve of the stomach.

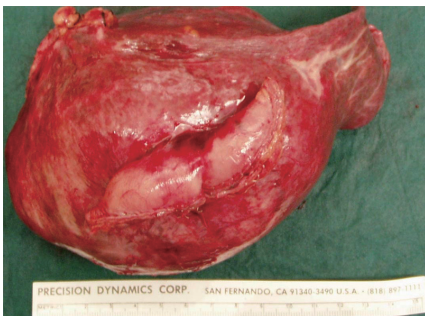

Figure 2 Inferior view of the resected tumor specimen with adherent stomach wall.

referral to the surgical service was made. Esophageal-gastroduodenoscopy and colonoscopy were suggested but the patient declined referral or admission and discharged himself from the hospital against medical advice.

One month later, he presented himself at the outpatient specialist surgical clinic. Hemoglobin level on arrival was 9.4 g/dL. He finally consented to endoscopic examination as an outpatient procedure. Esophageal-gastroduodenoscopy was carried out on the same afternoon, during which an actively bleeding ulcer was seen in the lesser curve (Figure 1). Repeated injection with adrenaline failed to stop the bleeding and he was immediately transfused with packed cells and prepared for emergency surgery.

At celiotomy, a 10 cm tumor arising from segments II and III of the liver was found; the tumor involved the lesser curve of the stomach and had eroded into the lumen. On-table referral to the hepato-biliary surgical service was made. Resection of segments II and III of the liver with en-bloc wedge resection of the lesser curve of the stomach was carried out both to control the hemorrhage and as a definitive therapy for the tumor (Figure 2).

The patient's post-operative recovery was uneventful. He was discharged from the surgical intensive care unit on the 2nd post-operative day. He tested positive for hepatitis B surface antigen and his serum hepatitis B antibody was found to be less than 10 IU/ml. The resected liver segments showed cirrhotic changes and a large necrotic tumor measuring 10 cm × 9 cm × 9 cm. Surgical margins were free of tumor. Histology revealed a trabecular hepatocellular carcinoma that was grade 2 by Edmondson's grading. He was discharged from the hospital in good

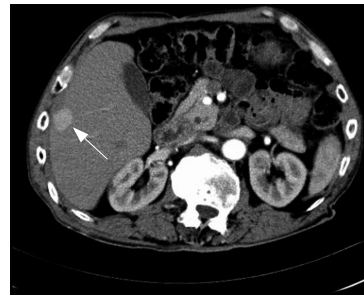

Figure 3 HCC recurrence in the right lobe. Enhanced axial hepatic arterial-phase CT performed on follow-up after initial resection shows a hypervascular lesion in segment 5/6 suspicious for HCC recurrence (arrow). Incidental note is made of a small cyst in the right kidney.

health on the 9th post-operative day. An early post-operative CT scan showed no residual tumor, but a repeat CT scan performed 9 mo later showed multiple new lesions of HCC in the liver (Figure 3). He opted for conservative management and was still alive 2 years and nine months after surgery.

DISCUSSION

HCC is a highly malignant type of tumor. Extrahepatic metastases occur in 30%-75% of patients, commonly affecting the lungs, regional lymph nodes, bones and adrenal glands^[3]. Direct gastrointestinal tract involvement is rarely seen. In a clinical study, Chen *et al*^[12] reported 8 out of 396 patients (2%) with HCC who developed gastrointestinal involvement during the course of the disease. Lin *et al*^[2,6-12] similarly reported gastrointestinal metastases in 11 out of 2237 patients with HCC (0.5%). Only 10 cases of HCC invading directly into the stomach could be found in the literature. Eight of these presented with BGIT, and only one of the 10 subsequently underwent surgical resection of the HCC.

Of these 10 cases reported^[2,6-12], 6 had received some form of regional therapy, such as trans-arterial chemoembolization (TACE), intra-arterial chemotherapy or radiotherapy, either alone or in combination, prior to the HCC invading the gastro-intestinal tract. This includes 4 of the 5 patients with direct invasion of the gastrointestinal tract by contiguous HCC reported by Chen *et al*^[12]. Chen *et al*^[12] postulated a relationship between regional therapy and the development of direct invasion of the gastrointestinal tract by HCC. It was proposed that when a large, subcapsular, massive-type HCC adjacent to the gastrointestinal tract is treated with TACE, the wall of the gastrointestinal tract could be affected by the inflammatory response secondary to TACE and become adherent to the tumor capsule. Viable tumor tissue could then invade the GI tract.

Our patient presented with non-specific symptoms and only a very low hemoglobin level, suggesting gastrointestinal bleeding. He was not known to be a hepatitis B carrier or a patient with HCC at initial presentation and, thus had no history of regional therapy for HCC. However the resected tumor was

large, measuring 10 cm × 9 cm × 9 cm. In the published literature, of the 19 cases of HCC with gastrointestinal tract involvement (both direct invasion and distant metastasis) reported by Lin *et al*^[7] and Chen *et al*^[12], 14 tumors were considered to be large and 17 were larger than 6 cm, with the tumor sizes of the remaining 2 cases not being described. A casual relationship between tumor size and the probability of direct invasion to the surrounding viscera should therefore be considered.

In previously reported cases of HCC with gastrointestinal tract involvement, treatments have included surgery, TACE and local injection with ethanol. Results of treatment have been poor, with almost all patients dying within 5 mo except for 1 case described by Nicoll *et al*^[11]. In this reported case, the HCC invaded the stomach and the patient was treated with surgical resection. He was reported to be still alive 7 mo after resection. Our patient similarly had surgical resection with clear margins and remains alive 33 mo after surgery. Thus, such contiguous invasion of the stomach does not always represent terminal disease. Surgery should be considered wherever feasible as other modalities of treatment for HCC, including chemotherapy, are poorly efficacious^[13].

Large HCCs may have a predisposition towards contiguous involvement of the gastro-intestinal tract, including the stomach. Diagnosis is difficult as most patients are asymptomatic and diagnosis by endoscopy is rarely achieved as these lesions have no special or characteristic endoscopic features. In our patient, diagnosis was made during emergency surgery to control bleeding from a supposed gastric ulcer. Based on limited case reports, the accepted paradigm is that an HCC directly invading the gastrointestinal tract is associated with very poor prognosis and that it may not be worthwhile to pursue an aggressive treatment policy. However, the scientific basis of this belief is limited, and this case report shows that aggressive resection can both resolve the acute clinical problem (gastrointestinal bleeding) as well as result in a relatively long-term survival. Surgery remains a viable option in patients with HCC and presenting with bleeding from the upper gastrointestinal tract as a result of direct invasion by a tumor.

Invasion of the upper gastrointestinal tract by HCC is extremely uncommon. In our case, the patient did not present with any signs and symptoms of chronic liver disease or hepatomegaly suggestive of hepatocellular carcinoma. The discovery of hepatocellular carcinoma invading directly into the stomach was an incidental finding from laparotomy performed for a bleeding peptic ulcer.

Resection of segments II and III of the liver with en-bloc wedge resection of the lesser curve of the stomach was performed as a definitive procedure. This report demonstrates that the prognosis is not necessarily dismal in such cases if there are no distant metastases. Surgical resection may offer a significantly better survival over non-surgical therapy, especially if the patient is a good surgical candidate and has adequate functional liver reserves.

INTRODUCTION

Hepatocellular carcinoma (HCC), with an estimated 1 million cases per year, is the 5th most common cancer in the world, particularly in the Southeast Asia^[1]. HCC with extrahepatic metastasis has been reported in approximately 50% of cases; lungs, abdominal lymphatics, adrenal glands, great veins adjacent to the liver, the diaphragm, or the skeleton could be involved. Bone metastasis in HCC has been reported in 10.1% of patients, with the vertebrae being the most frequently affected, followed by (in decreasing order) ribs, sternum, and pelvis^[2]. The mandible is a rare site of HCC metastasis. Here we report a rare case of mandibular metastasis of HCC with intractable bleeding and the bleeding was controlled successfully by radiotherapy.

CASE REPORT

A 74-year-old woman was suffering from chronic hepatitis C-related HCC for 6 years. Segmental hepatectomy was done initially. She had undergone transcatheter arterial chemoembolization (TACE) 9 times, and percutaneous ethanol injection (PEI) 3 times for tumor recurrence. She had 3 years of progression-free survival.

She was referred to our clinic due to a 1 cm × 1 cm ulcerative mass in the left buccal region, with preauricular swelling for 2 wk. Biopsy was done over the buccal mass. Two days later, she presented in the emergency room with the chief complaint of progressive facial swelling and persistently blood oozing from the left buccal tumor. The laboratory tests were AST (GOT) 58 U/L, ALT (GPT) 49 U/L and platelet count $179 \times 10^3/\mu\text{L}$. Her liver disease was in the status of Child-Pugh class A. CT scan demonstrated a 6.2 cm × 5.0 cm osteolytic lesion in the left parapharyngeal space with destruction of the left mandible (Figure 1A). The lesion extended from the mandibular ramus to temporal muscle space (Figure 1B). Diffuse and massive bleeding occurred from the ulcerative

Abstract

Hepatocellular carcinoma (HCC) metastasizes to the mandible is infrequently seen. Solitary bony metastasis to the mandible is rarer. The intractable bleeding caused by rupture of the metastatic HCC is challenging to clinicians. We present a case of a 74-year-old woman with HCC under control without progression for 3 years. Left facial swelling and episodes of bleeding developed recently and biopsy revealed a metastatic HCC. Computer tomography showed a large tumor in parapharyngeal space with evident mandibular ramus destruction. Bleeding occurred from the metastatic tumor but could not be controlled by electrocauterization, Surgicel™, tissue glue, and bone wax and angiographic embolization. Palliative radiotherapy (2400 cGy in 6 fractions) was tried and the intractable bleeding was successfully stopped after the radiotherapy. Because of the hypervascular and osteolytic nature of the solitary mandibular metastatic lesion, the bleeding was troublesome. Radiotherapy provided successful control of intractable bleeding from the metastatic tumor.

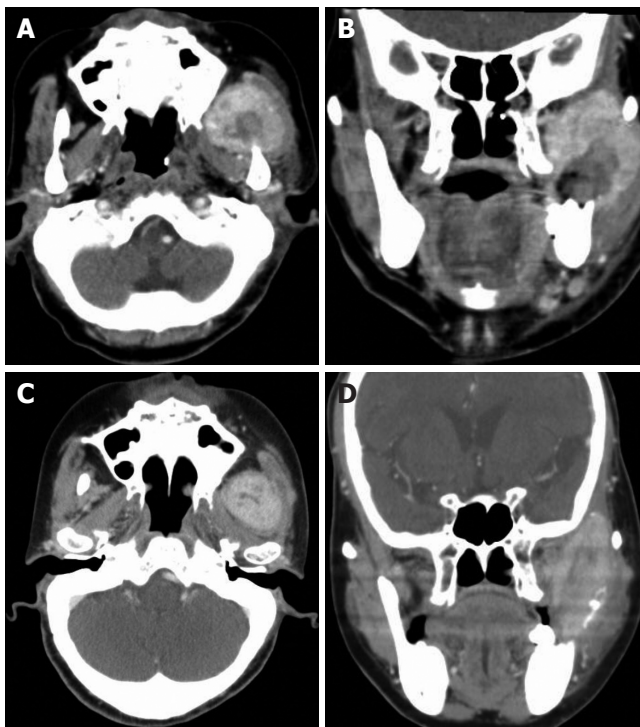

Figure 1 Axial and coronal CT scan of the neck with intravenous contrast showing a 6.2 cm x 5.0 cm, heterogeneously enhancing mass, which appears to be a left parapharyngeal mass involving the pterygoid muscle and temporal muscle (A and B); axial and coronal CT scan of the head and neck showing a 4.0 cm x 2.5 cm mass which shrunk after completion of radiotherapy (C and D).

mass the next morning after admission. Hemorrhage could not be stopped by electrocauterization or suture ligation alone, but it was stopped temporarily by the use of electrocauterization, Surgicel™, tissue glue, and bone wax concomitantly after 700 mL blood loss. The mandibular lesion was proved pathologically to be a metastatic HCC. Bone scan showed the mandibular lesion was a solitary metastasis of HCC. CT scan of the brain, chest, abdomen and pelvis failed to reveal any evidence of metastatic disease.

Unfortunately, a second episode of hemorrhage occurred 5 d later. Due to antecedent experience of difficult hemostasis, we tried vascular embolization. Under angiography, the injection of contrast medium through the left common carotid artery and external carotid artery showed a hypervascular stain about 3.8 cm in the left masticator space. The left maxillary artery and the main feeding artery were occluded by the injection of permanent embolizer (500 to 700 U of polyvinyl alcohol particles, PVA). Over 90% of tumor stain was obliterated after embolization and the main feeding artery was occluded. However, slow but profuse oozing from the left buccal wound persisted. After discussion with radiation oncologist, palliative radiotherapy was suggested in the handful treatment options. We arranged radiotherapy for the left mandibular metastatic lesion (2400 cGy in 6 fractions). Oozing decreased about 3 d after the start of radiotherapy and stopped 5 d after the completion of radiotherapy and the tumor shrunk after radiotherapy (Figure 1C and D). Now the woman was stable with disease at a follow-up period of 5 mo.

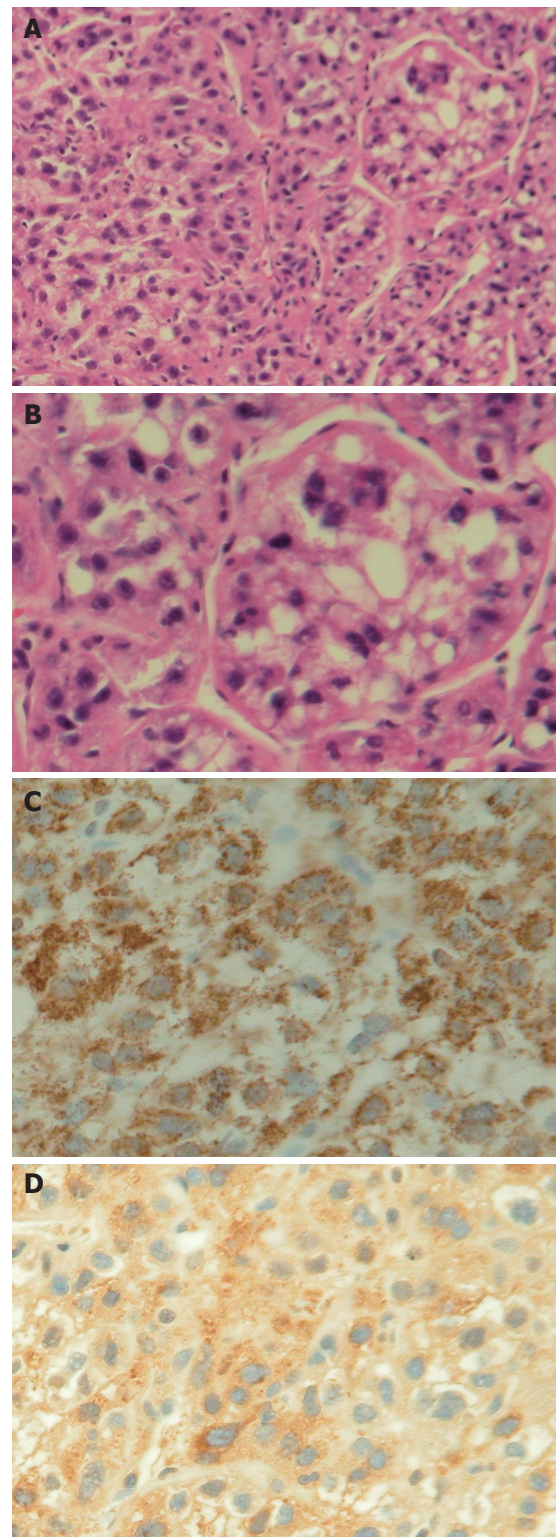

Figure 2 Histopathology of the metastatic lesion. A: The tumor is composed of polygonal cells featuring abundant clear to eosinophilic cytoplasm and microvesicular fatty change, and the tumor cells are arranged in broad trabeculae surrounded by sinusoid spaces which are characteristic of hepatocellular carcinoma (HE, x 100); B: Histology of the metastatic tumor (HE, x 200); C: The tumor cells showing immunoreactivity to Hep Par-1 with a cytoplasmic granular staining pattern (x 200); D: The tumor cells showing focal immunoreactivity to AFP (x 200).

Histopathological examination of the ulcerative mass at the mandible revealed the metastasis was from well-differentiated HCC (Figure 2A and B). Neoplastic cells

were diffusely stained by hepatocyte-paraffin-1 (Hep Par-1) (Figure 2C) and focally positive for α -fetoprotein (AFP) (Figure 2D).

DISCUSSION

With advances in surgical techniques and an improvement in perioperative care, surgical mortality rates in HCC patients receiving hepatectomy have reduced significantly. Postoperative recurrence is universally high and remains the main cause of late deaths. The development of PEI and TACE contributes to the better local control of HCC. Nevertheless, distant metastasis of HCC is more and more frequently seen after the better control of primary disease. The most common sites of HCC metastasis are the lungs, bones, brain, and skin^[3]. The mode of extrahepatic spread from HCC is usually hematogenous metastasis. The incidence of bone metastasis from HCC accounts for approximately 1.6%-16% and the most common sites are the vertebrae, followed by pelvis and ribs^[4]. Mandible is rarely metastasized by HCC. In addition, bone metastasis usually manifests as multiple lesions. Solitary bony metastasis in HCC is infrequently met, as in our patient.

Two modes of spread were ever proposed for the tumor spreading from the liver to the maxillofacial territory. The metastatic dissemination reaches the lungs first, and possibly the maxillofacial area later through the communication between the hepatic artery and portal vein. It has been postulated that there is a connection between the azygos and hemiazygos veins and the vertebral venous plexus (Batson's plexus)^[2,5]. There is the existence of free communication between the neck, thorax, abdomen and pelvis venous systems with the non-valve vertebral venous plexus that extends from cranial base to coccyx. Any pressure increment inside the abdomen can create an ascendant flow through the vertebral venous plexus. The HCC cells could reach maxillofacial territory through these two hematogenous connections and grow into a metastatic lesion in the mandibular region.

Any malignancy in head and neck, either primary or metastatic lesions, can manifest as bleeding. However, HCC metastatic lesions, as seen in our case, are hypervascular and osteolytic in nature. It may rupture spontaneously to cause hemorrhage and could be devastating. Chen *et al*^[6] reported a case of life-threatening hemorrhage from a sternal metastasis of HCC. The acute hemorrhage in mandibular metastasis of HCC was

ever reported to be managed by SurgicelTM (Johnson & Johnson, New Brunswick, NJ) and bone wax packing^[7]. In our patient, three methods were utilized to stop bleeding: electrocauterization, SurgicelTM, tissue glue and bone wax in the 1st episode, but failed. Embolization was used in the 2nd hemorrhagic episode and failed again. Hypervascularity of the tumor and no single identifiable bleeder partly explained the reason of failure in two earlier methods. Palliative radiotherapy (2400 cGy) successfully stopped the bleeding and shrunk the tumor. The mechanisms behind hemostasis after radiation therapy were decrease of the tumor size, the tumoral vascularity, and induced fibrosis in the peripheral osseous structure. Surgery for the solitary mandibular metastasis of HCC was not considered in this patient. The metastatic lesion in our patient was osteolytic and invaded into the temporal muscle space. The lesion located in proximity of the skull base and was considered inoperable.

In conclusion, we reported a rare case of solitary mandibular metastasis of HCC and the intractable bleeding from the metastatic lesion was controlled successfully by palliative radiation therapy. Palliative therapy could be an option when coping with refractory bleeding in head and neck malignancies.

Abstract

Patients suffering from hepatocellular carcinoma (HCC) with tumor thrombus in the portal vein generally have a poor prognosis. Portal vein tumor thrombus must be distinguished from portal vein blood thrombus, and this identification plays a very important role in management of HCC. Conventional imaging modalities have limitations in discrimination of portal vein tumor thrombus. The application of positron emission tomography (PET) with ^{18}F -fluorodeoxyglucose (^{18}F -FDG) for discrimination between tumor extension and blood thrombus has been reported in few cases of HCC, while portal tumor thrombosis and portal vein clot identified by ^{18}F -FDG PET/CT in HCC patients has not been reported so far. We present two HCC cases, one with portal vein tumor thrombus and one thrombosis who were identified with ^{18}F -FDG PET/CT. This report illustrates the complimentary value of combining the morphological and functional imaging in achieving a correct diagnosis in such clinical situations.

Sun L, Wu H, Pan WM, Guan YS. Positron emission tomography/computed tomography with ^{18}F -fluorodeoxyglucose identifies tumor growth or thrombosis in the portal vein with hepatocellular carcinoma. *World J Gastroenterol* 2007; 13(33): 4529-4532

INTRODUCTION

Hepatocellular carcinoma (HCC) has a dismal prognosis and carries a high risk of invasion of the portal vein^[1]. Contrast CT and MRI markedly increase the detection rate of portal vein tumor thrombus, especially in small branches of the portal vein by its contrast enhancement features in cross-sectional images. However, all the noninvasive techniques currently used are imperfectly able to differentiate portal vein tumor thrombus from portal vein blood thrombus, and relying exclusively on contrast enhancement characteristics to make a conclusion runs the risk of misdiagnosis due mainly to the intrinsic limitations of the imaging modalities themselves^[2]. This pattern of positron emission tomography/computed tomography (PET/CT) has been reported in cases of several types of malignant tumors^[3], while portal vein tumor growth and portal vein thrombosis identified by PET/CT in hepatocellular carcinoma patients have not been reported so far. We herein present two cases identified by PET/CT with ^{18}F -fluorodeoxyglucose (^{18}F -FDG), which differentiates portal vein tumor thrombus from blood clot by recognizing different metabolic neoplastic activities and macromorphological characteristics.

CASE REPORT

Case 1

A 60-year-old woman with a five-year history of non-Hodgkin's lymphoma and hepatitis B virus infection was detected with a liver mass by ultrasound. She reported no vomiting, fever, diarrhea, or weight loss. On physical examination, abdomen was normal except for tender in the left liver area on palpation. Serum alpha fetoprotein (AFP) level was more than 1000 ng/mL, and HBsAg, HBeAb and HBcAb all were positive. Contrast-enhanced CT showed a mass with satellite lesions, and the left portal vein was not revealed clearly on the portal phase (Figure 1). A distinct lesion with high ^{18}F -FDG uptake was demonstrated in the region of the left portal vein (Figure 2A). The ^{18}F -FDG PET/CT showed a mass of high ^{18}F -FDG uptake with satellite lesions and lower metabolism in the central necrotic area (Figure 2B). HCC was confirmed by liver biopsy. It

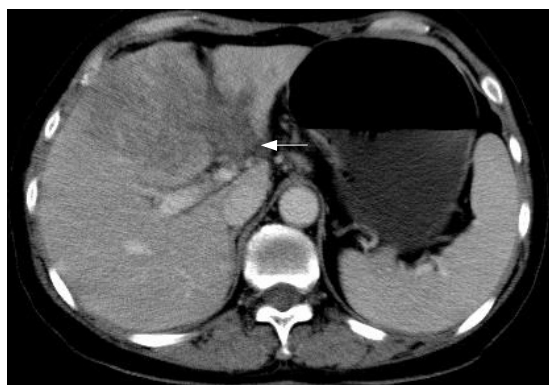

Figure 1 Portal phase of contrast-enhanced CT demonstrating the left portal vein tumor thrombus (white arrow).

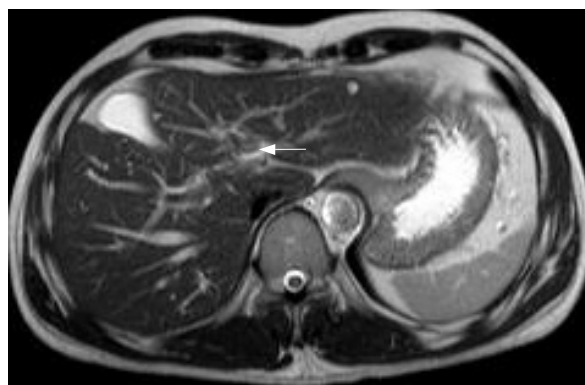

Figure 3 MRI T2 imaging showing a thrombus in the left portal vein.

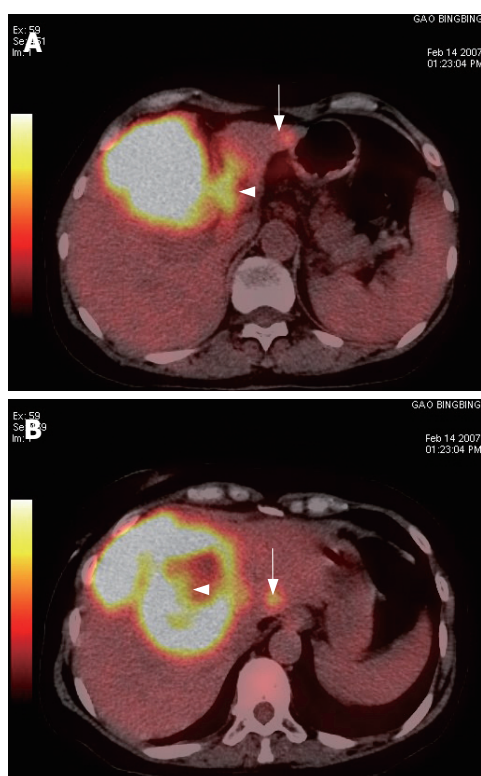

Figure 2 A: Integrated PET/CT image showing high FDG uptake by tumor thrombus in the left portal vein (arrow head) and a liver mass with a satellite lesion (arrow); B: Fused PET/CT imaging showing necrosis in the center of the mass (arrow head) with a satellite lesion (arrow).

is suggested that ^{18}F -FDG PET/CT may have a great potential value to discriminate tumor thrombus from blood thrombus and to detect satellite or metastatic lesions in patients suffering from HCC. The patient underwent once transcatheter arterial chemoembolization (TACE) and her conditions were relatively stable at the 2-mo follow-up.

Case 2

A 50-year-old man with hepatitis B virus infection for 20 years was detected by ultrasound to have a portal block 6 mo after HCC resection. Blood thrombus was suspected on contrast CT and MRI. Physical examination showed no abnormal abdominal findings. AFP level was less than

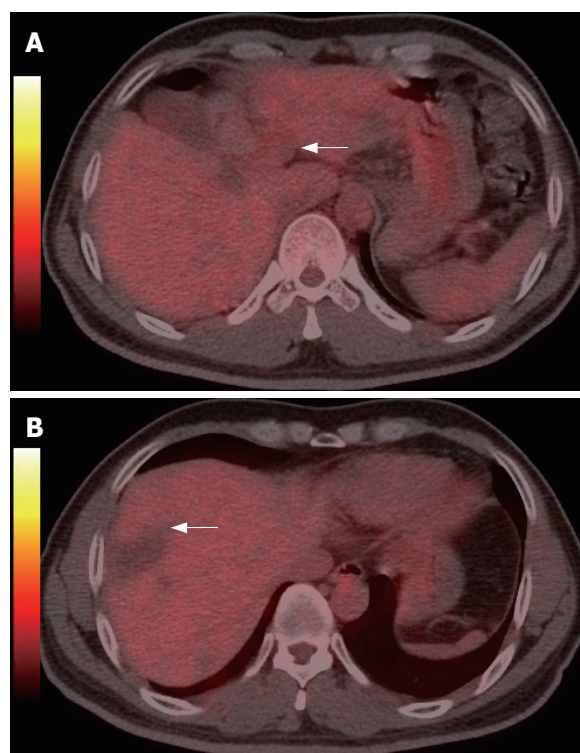

Figure 4 Fused PET/CT imaging showing no hypermetabolism (arrow) in the region of the left portal vein (A) and in the region of previous hepatic resection (B).

20 ng/mL and contrast-enhanced MRI demonstrated a thrombus in the left portal vein (Figure 3). Thus a portal vein tumor growth was suspected, with the necessity to differentiate it from portal vein blood thrombosis. Subsequently, the ^{18}F -FDG PET/CT revealed neither a lesion with high FDG uptake in the left portal vein (Figure 4A), nor such a lesion at the margin of previously resected hepatic region (Figure 4B). No distant metastatic lesions were found in the whole-body PET/CT scan. The patient underwent 5-mo follow-up of ultrasound examination, which produced normal results when checking the region for interpretation of the previously abnormal findings. The patient remained well during another 5-mo follow-up period and the thrombus disappeared on the latest ultrasound examination. Thus a diagnosis of the left portal vein blood thrombus was established at last.

DISCUSSION

Patients suffering from HCC with portal vein tumor thrombus generally have a poor prognosis, as tumor proliferation is often rapid and accompanied by intrahepatic metastases, liver dysfunction, portal hypertension and esophageal varices^[4]. Conventional imaging modalities have limitations in discriminating portal vein tumor thrombus. The application of ¹⁸F-FDG PET for discrimination between tumor extension and blood thrombus has been reported in few cases of HCC, while portal vein tumor thrombus and portal vein blood clot identified by ¹⁸F-FDG PET/CT in HCC patients have not been reported so far. Compared with conventional CT and MRI, PET/CT with ¹⁸F-FDG as a radiotracer has some advantages in evaluation of hepatic malignancies, including diagnosing, staging and restaging tumors, evaluating biologic characters, making up treatment plan and monitoring tumor response, early detecting of recurrence and providing prognosis assessment. PET/CT is getting more and more widely applicable in clinical practice with combined functional and anatomical images. With lower false-positive and false-negative rate, it is more sensitive and specific than PET alone^[5].

Hanajiri *et al*^[6] and Beadsmoore *et al*^[7] found that ¹⁸F-FDG PET was more sensitive than conventional CT and MRI in detecting suspected vein tumor thrombus in patients with HCC, although portal vein tumor thrombus and portal vein blood thrombus identified by PET/CT in HCC patients have not been reported thus far. Tumor thrombus differentiates itself from blood thrombus by its intense uptake of ¹⁸F-FDG as a result of its high metabolic neoplastic activity. Histological grade of differentiation and macroscopic vascular invasion are strong predictors of both survival and recurrence of tumor in patients with cirrhosis who have received transplants because of HCC. Cillo *et al*^[8] reported that using HCC grades (grade 1 and 2) based on preoperative fine-needle aspiration biopsy to select candidates for liver transplantation was associated with an extremely low rate of tumor recurrence which was comparable with that of incidentally detected HCC. Although HCC accumulates ¹⁸F-FDG to various degrees, a high positive rate of ¹⁸F-FDG accumulation has been reported in patients with high-grade HCC^[9] and in those with markedly elevated AFP levels. The standardized uptake value (SUV) ratio is related significantly to disease-related deaths as well as other predictive factors, including the number, size and stage of tumors, involvement of vessels and involvement of the capsule, and provides information about prognostic relevance in patients with HCC before surgery^[10].

As to our first case, the PET/CT examination not only confirmed the diagnosis of portal vein tumor thrombus, but also suggested the low grade of cell histology that was confirmed by the results of liver biopsy. Histological examination using percutaneous needle biopsy could be the most definite assessment of HCC grades. However, it is invasive and the specimen retrieved does not always represent the entire lesion owing to sampling errors. Histological grade and vascular invasion cannot be determined preoperatively^[11]. Case 1 showed that ¹⁸F-FDG PET/CT might have a great potential in discriminating

tumor thrombus and blood thrombus and in detecting satellite or metastatic lesions in patients suffering from HCC. It may play an important role in evaluating biologic characters of tumors.

In the second patient, there was no high metabolic lesion in the left portal vein area and in the region of previous hepatic resection. In addition, the whole body PET/CT examination found neither intra-hepatic nor extra-hepatic lesions; an overall 10-mo follow-up confirmed the diagnosis of blood thrombus. ¹⁸F-FDG PET has been proved an effective whole-body imaging technique that detects metabolic changes preceding structural findings. Unexplained rise of serum AFP levels in HCC patients after the treatment of their malignancy is an early indicator of tumor recurrence or extra-hepatic metastases^[12]. ¹⁸F-FDG PET/CT provides fused images that demonstrate the complementary roles of functional and anatomic assessment in the diagnosis of cancer recurrence by the precise localization of suspected foci with ¹⁸F-FDG uptake whose characterization can be interpreted as malignant or benign. ¹⁸F-FDG PET/CT is better than conventional CT in judging tumor residue of HCC after treatment, and in guiding further treatment of HCC.

We reported two cases of HCC, one with a portal vein tumor thrombus and the other with a portal vein blood thrombus; both were identified by ¹⁸F-FDG PET/CT. Thus it demonstrates the complimentary value of morphological and functional imaging in achieving a correct differentiation. PET/CT with ¹⁸F-FDG as a radiotracer may further enhance the HCC diagnostic algorithm by accurate diagnosis, staging, restaging and evaluating its biological characters.

Abstract

To elucidate the role of music therapy in gastrointestinal endoscopic procedures following the conflicting outcomes reported in two recent studies. The findings of our recent meta-analysis that examined this matter were discussed in the context of later studies. Our meta-analysis illustrated the beneficial effects of music therapy on patient anxiety levels when used as a single measure of relaxation and analgesia. Beneficial effects were also shown on analgesia and sedation requirements and procedure duration times when used as an adjunct to pharmacotherapy. These findings are in agreement with those of both studies excluded from analysis and those that followed it. Music therapy is an effective tool for stress relief and analgesia in patients undergoing gastrointestinal endoscopic procedures.

Rudin D. Frequently overlooked and rarely listened to: Music therapy in gastrointestinal endoscopic procedures. *World J Gastroenterol* 2007; 13(33): 4533

<http://www.wjgnet.com/1007-9327/13/4533.asp>

TO THE EDITOR

I greatly enjoyed reading the well-conducted, well-written studies by Ovayolu *et al*^[1] and Bechtold *et al*^[2] exploring the affects of music therapy on patients undergoing gastrointestinal endoscopic procedures. Those studies reported conflicting outcomes, which we aimed to resolve in our meta-analysis^[3].

Our meta-analysis involved 641 patients undergoing

esophagogastroduodenoscopy, flexible sigmoidoscopy or colonoscopy, with or without intervention through music therapy. The intervention was conducted by patient exposure to patient or researcher selected music, delivered with/without headphones, before and/or during the procedure. For patients that did not receive pharmacotherapy, anxiety levels were used as efficacy measures. For patients that did receive pharmacotherapy, medications were not uniformly administered within studies, and thus anxiety levels could not be used for that purpose. Alternately, medication requirements and procedure durations were noted. Our meta-analysis yielded significantly lower anxiety levels for the former group, whereas the latter group exhibited significant reductions in analgesia requirements and procedure duration times, while reductions in sedation requirements approached significance. Our findings are in agreement with those of both studies excluded from analysis^[3] and those that followed it^[2,4]. Furthermore, these findings are of particular importance, as sedation, analgesia use and procedures of prolonged duration are linked to cardiopulmonary complications. Further, patients undergoing intervention reported greater satisfaction rates and were more willing to have the procedures repeated^[3]. Additionally, while our meta-analysis was insufficiently sized to determine a preferable intervention protocol, we suggested that patient selected music, delivered through headphones, may provide maximal benefits while circumventing potentially undesirable exposure of the medical staff to that particular music. Accordingly, despite only minor benefits reported by some^[2], we suggest that this safe and cost-effective measure not be overlooked^[3].

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology

Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China

E-mail: wjg@wjgnet.com

<http://www.wjgnet.com>

Telephone: +86-10-85381892

Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Morse SS. Factors in the emergence of infectious diseases. Emerg Infect Dis serial online, 1995-01-03, cited 1996-06-05; 1(1): 24 screens. Available from: URL: <http://www.cdc.gov/ncidod/EID/eid.htm>

Patent (list all authors)

- 16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

Abstract

Nonalcoholic fatty liver disease (NAFLD) has, although it is a very common disorder, only relatively recently gained broader interest among physicians and scientists. Fatty liver has been documented in up to 10 to 15 percent of normal individuals and 70 to 80 percent of obese individuals. Although the pathophysiology of NAFLD is still subject to intensive research, several players and mechanisms have been suggested based on the substantial evidence. Excessive hepatocyte triglyceride accumulation resulting from insulin resistance is the first step in the proposed 'two hit' model of the pathogenesis of NAFLD. Oxidative stress resulting from mitochondrial fatty acids oxidation, NF- κ B-dependent inflammatory cytokine expression and adipocytokines are all considered to be the potential factors causing second hits which lead to hepatocyte injury, inflammation and fibrosis. Although it was initially believed that NAFLD is a completely benign disorder, histologic follow-up studies have showed that fibrosis progression occurs in about a third of patients. A small number of patients with NAFLD eventually ends up with end-stage liver disease and even hepatocellular carcinoma. Although liver biopsy is currently the only way to confirm the NAFLD diagnosis and distinguish between fatty liver alone and NASH, no guidelines or firm recommendations can still be made as for when and in whom it is necessary. Increased physical activity, gradual weight reduction and in selected cases bariatric surgery remain the mainstay of NAFLD therapy. Studies with pharmacologic agents are showing promising results, but available data are still insufficient to make specific recommendations; their use therefore remains highly individual.

INTRODUCTION AND EPIDEMIOLOGY

Nonalcoholic fatty liver disease (NAFLD) is an increasingly recognized cause of liver-related morbidity and mortality. It represents a spectrum of hepatic disorders characterized by macrovesicular steatosis that occur in the absence of alcohol consumption in amounts generally considered to be harmful to the liver (less than 40 g of ethanol per week). That spectrum ranges from simple hepatic steatosis without concomitant inflammation or fibrosis to hepatic steatosis with a necroinflammatory component that may or may not have associated fibrosis (non-alcoholic steatohepatitis-NASH) and can progress to cirrhosis.

Although the association of macrovesicular steatosis of the liver with inflammatory changes and fibrosis in obese subjects has been known for several decades, it was largely ignored as a clinical entity. The term "nonalcoholic steatohepatitis" was first introduced in 1980 by Ludwig *et al* and is used to describe the distinct clinical entity in which patients have liver biopsy findings indistinguishable from alcoholic hepatitis, but lack a history of significant alcohol consumption^[1].

The true incidence and prevalence of NAFLD are unknown. Population-based studies most often use imaging modalities or serum alanine aminotransferase levels to diagnose NAFLD^[2-4]. These studies are limited by the inability to make a definitive diagnosis of NAFLD or to distinguish between NAFLD and NASH, which requires liver biopsy. Studies that have used strict definitions for diagnosis including biopsies were most often based on specific subsets of the population (e.g. diabetics, obese individuals, in-hospital patients) and they cannot be applied to the general population^[5-7]. Despite the limitations of the published data, several facts are consistently present. Fatty liver and NASH have been reported in all age groups, including children^[4,8]. The prevalence increases with increasing body weight^[6,9]. Fatty liver has been documented in up to 10% to 15% of normal individuals and 70% to

80% of obese individuals. Correspondingly, about 3% of normal individuals and 15% to 20% of morbidly obese subjects ($\text{BMI} > 35 \text{ kg/m}^2$) have steatohepatitis^[6,10]. These findings are of particular concern given the increasing prevalence of obesity in virtually all age groups. The highest prevalence is in those between 40 and 60 years of age^[7,11,12]. Although earlier studies found higher prevalence of NASH in women (65 to 85 percent of all patients), more recent studies have shown that NASH occurs with equal frequency in both sexes^[1,7,11,13]. In the United States, there appear to be ethnic differences in the prevalence of NASH. A higher prevalence of hepatic steatosis was found in Hispanics (45%) compared with Caucasians (33%) or Afro-Americans (24%)^[14].

There is increasing evidence that NAFLD represents the hepatic component of a metabolic syndrome characterized by obesity, hyperinsulinemia, peripheral insulin resistance, diabetes, hypertriglyceridemia, and hypertension. Type 2 diabetes mellitus is a major component of the metabolic syndrome and is associated with both obesity and NASH^[1,12,13,15]. It has been described in 34% to 75% of patients with NASH. Diabetes is not only associated with NAFLD, but also may be a risk factor for development of progressive liver fibrosis^[16]. Obesity has been reported in 70 to 100 percent of cases of NASH, and most patients are 10% to 40% above ideal body weight^[1,12,13,15]. Numerous reports have documented resolution of fatty liver following gradual weight loss. Subjects with abdominal obesity are more prone to developing diabetes and hypertension as well as fatty liver. Hyperlipidemia (hypertriglyceridemia and/or hypercholesterolemia), which is frequently associated with both obesity and type 2 diabetes, has been reported in 20% to 80% of patients with NASH^[1,12,13,15].

In addition, NAFLD has been associated with several rare disorders of lipid metabolism and insulin resistance (e.g. abetalipoproteinemia, lipotrophic diabetes, Mauriac and Weber-Christian syndrome), as well as with total parenteral nutrition, acute starvation, intravenous glucose therapy, abdominal surgery (e.g. extensive small bowel resection, biliopancreatic diversion, and jejunal bypass), use of several drugs (e.g. amiodarone, tamoxifen, glucocorticoids, and synthetic estrogens) and several types of chemicals (e.g. organic solvents and dimethylformamide)^[17-31]. The incidence, mechanism, and natural history of these forms of NAFLD are unknown.

Several studies reported that many patients with NASH have biochemical evidence of iron overload, with elevation of transferrin saturation and serum ferritin level. Patients with NASH were found to be homozygous or heterozygous for the Cys282Tyr mutation in the HFE gene in significantly higher percent than the general population. However, the hepatic iron index was < 1.9 in all patients. The presence of iron overload has been reported to be associated with increased hepatic fibrosis, but this finding was not confirmed by other reports. The significance of the HFE mutations in NASH remains to be fully established^[32-36].

is principally associated with the metabolic syndrome. Therefore, two types of NAFLD can be recognized: primary NAFLD (associated with metabolic syndrome) and secondary NAFLD (associated with other specific metabolic or iatrogenic conditions distinct from the metabolic syndrome).

Pathophysiology of primary NAFLD still hasn't been completely clarified. The so called 'two hit' model of the pathogenesis of NAFLD has been proposed since 1998^[37]. Liver fat accumulation is the suggested 'first hit' or the first step. It is a consequence of excessive triglyceride accumulation caused by discrepancy between influx and synthesis of hepatic lipids on one side and their β -oxidation and export on the other (Figure 1)^[38]. This imbalance occurs with all of the previously mentioned potential etiologic factors. The steatotic liver subsequently becomes vulnerable to presumed 'second hits' leading to hepatocyte injury, inflammation and fibrosis. The most widely supported theory implicates insulin resistance as the key mechanism in primary NAFLD, leading to hepatic steatosis, and perhaps also to steatohepatitis. The presumed factors initiating second hits are oxidative stress and subsequent lipid peroxidation, proinflammatory cytokines (principally $\text{TNF-}\alpha$), and hormones derived from adipose tissue (adipocytokines) (Figure 1).

Obesity, type 2 diabetes, hyperlipidemia and other conditions associated with insulin resistance are generally present in patients with NAFLD. Insulin resistance has also been observed in patients with NAFLD who are not obese and in those with normal glucose tolerance^[39-41]. The molecular mechanism leading to insulin resistance is complex and hasn't been elucidated completely. Several molecules (tumor necrosis factor alpha, PC-1 membrane glycoprotein, leptin, and fatty acids) appear to interfere with the insulin signalling pathway^[42]. Alterations in lipid metabolism associated with insulin resistance result from the interaction between the effects of insulin resistance located primarily in muscles and adipose tissue and impact of the compensatory hyperinsulinemia on tissues that remain insulin sensitive. These alterations include enhanced peripheral lipolysis, increased hepatic uptake of FFAs and increased hepatic triglyceride synthesis. FFA influx and neosynthesis outweigh FFA oxidation and triglyceride secretion, resulting in the net effect of hepatic fat accumulation. This can explain a key role of insulin resistance in the development of hepatic steatosis and, potentially, steatohepatitis (Figure 2)^[43-48].

The resulting accumulation of fat within the hepatocytes has several effects. FFAs impair insulin signalling and cause hepatic insulin resistance *via* mechanisms involving activation of PKC-3, JNK, I- κ B kinase β (IKK- β) and $\text{NF-}\kappa\text{B}$ ^[49,50]. Hepatic insulin resistance then increases mitochondrial fatty acids oxidation. Also, FFAs and their metabolites are ligands for peroxisomal proliferators-activated receptor- α (PPAR- α), the transcription factor that regulates the expression of different genes encoding enzymes involved in mitochondrial, peroxisomal and microsomal fatty acids oxidation. Finally, it appears that both consequences of fat accumulation within the liver (fat-induced hepatic insulin resistance and up-regulation of PPAR- α -regulated genes) result in increased FFA oxidation. Mitochondrial and peroxisomal fatty acids oxidation are both capable of producing

HOW DOES IT DEVELOP? - NAFLD PATHOGENESIS

A large body of evidence clearly indicates that NAFLD

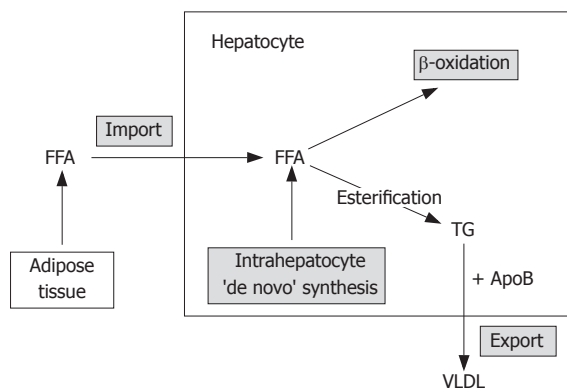

Figure 1 Lipid metabolism within the hepatocytes. Liver lipid content is determined by the equilibrium of several processes: import of free fatty acids (FFAs) from the adipose tissue, *de novo* FFA synthesis in hepatocytes, beta-oxidation of FFAs, esterification of FFAs into triglycerides and export of triglycerides as very low density lipoproteins (VLDL). Hepatic steatosis is a consequence of imbalance in those processes in favour of excessive triglyceride (TG) accumulation. FFA: free fatty acids; TG: triglycerides; VLDL: very low density lipoproteins; Apo B: apolipoprotein B.

hepatotoxic free oxygen radicals that contribute to the development of oxidative stress^[51-54]. Considering all these data, it appears that insulin resistance could in fact deliver both 'hits' in the pathogenesis of NASH. Considerable mitochondrial structural abnormalities were found in patients with NASH, but not in those with simple hepatic steatosis^[46,55-58]. It has also been found that several genes important for mitochondrial function were underexpressed in NASH patients^[59]. Aforementioned oxidative stress and subsequent lipid peroxidation are the factors supposed to alter both mitochondrial DNA and mitochondrial oxidative phosphorylation, leading to mitochondrial structural abnormalities and ATP depletion^[60,61]. However, it is also possible that these mitochondrial abnormalities are the preexisting conditions that enable excessive free oxygen radical species production in the setting of enhanced FFA beta-oxidation^[46]. This would mean that, in the absence of preexisting mitochondrial defects, insulin resistance will lead only to the development of simple hepatic steatosis.

Many studies demonstrated that oxidative stress is a prominent feature of NASH^[62-64]. Apart from hepatocytes, ROS production and oxidative stress in obese patients can also originate in adipose tissue (both in adipocytes and in macrophages infiltrating adipose tissue)^[65,66]. Inflammatory cells within the liver represent the third potential source of ROS and oxidative stress, especially in the setting of already developed steatohepatitis.

Hepatocyte reactive oxygen species accumulation (oxidative stress) could, at least to some extent, be responsible for further progression from steatosis to steatohepatitis and fibrosis. This could occur by three main mechanisms: lipid peroxidation, cytokine induction and Fas ligand induction. ROS-triggered lipid peroxidation of plasma or mitochondrial membranes causes cell necrosis or induces apoptosis. Lipid peroxidation also initiates release of malondialdehyde (MDA) and 4-hydroxynonenal (HNE) that can bind to hepatocyte proteins forming

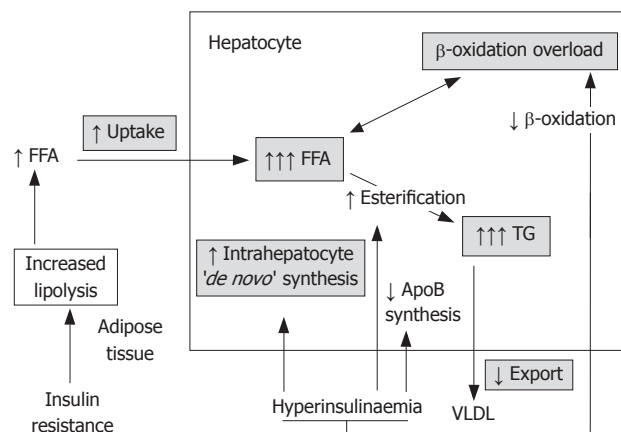

Figure 2 Effects of insulin resistance on lipid metabolism. Insulin resistance and resulting hyperinsulinemia lead to hepatocyte lipid accumulation in the liver by several mechanisms. In adipose tissue, insulin resistance enhances triglyceride (TG) lipolysis and inhibits esterification of free fatty acids (FFAs). The result are increased circulating levels of FFAs, which are then taken up by the liver. Additionally, in hepatocytes hyperinsulinemia increases the 'de novo' synthesis of fatty acids and inhibits their beta oxidation. The consequence is accumulation of FFAs within hepatocytes. Hepatic TG synthesis is driven by the increased hepatocyte FFA content and favoured by insulin-mediated upregulation of lipogenic enzymes, such as peroxisome proliferator-activated receptor gamma (PPAR- γ) and sterol regulatory element binding protein 1 (SREBP-1). Meanwhile, reduced very-low-density lipoprotein (VLDL) production and TG export may be impaired by decreased synthesis of apolipoprotein B (apo B) or reduced binding of TG to apo B by microsomal triglyceride transfer protein (MTP). The resulting accumulation of fat within the hepatocytes initiates further damage causing hepatic insulin resistance and reactive oxygen species production. (abbreviations: \uparrow -increased; \downarrow -inhibits; FFA: free fatty acid; TG: triglyceride; VLDL: very low density lipoprotein; Apo B: apolipoprotein B.

neoantigens and initiating a potentially harmful immune response, cross-link cytokeratins to form Mallory hyaline, or activate hepatic stellate cells promoting collagen synthesis and stimulate neutrophil chemotaxis^[62,67]. ROS also increases expression of Fas-ligand on hepatocytes that interacts with normally expressed membrane receptor Fas on the adjacent hepatocytes causing apoptotic cell death^[68]. ROS may also initiate the activation of the transcription factor NF- κ B, which leads to increased production of proinflammatory cytokines (TNF- α , TGF- β , IL-6, IL-8)^[69].

Furthermore, there are convincing data that inflammatory cytokines (TNF- α , IL-6 and IL-1 β) also play an important role in the pathogenesis of NAFLD^[70]. They may cause systemic and hepatic insulin resistance^[71]. They also cause hepatocyte injury and apoptosis, neutrophil chemotaxis, and hepatic stellate cell activation^[72-74]. Crespo *et al* have found that obese patients with NASH compared to those without it have significantly increased liver expression of TNF- α and its receptor p55, as well as increased expression of TNF- α in adipose tissue^[75]. This increased expression correlated with the degree of liver fibrosis. FFAs accumulated in hepatocytes stimulate NF- κ B-dependent inflammatory cytokine expression (TNF- α , IL-6, IL-1 β)^[76,77]. Kupffer cells are, as the liver specific macrophages, also a potent source of proinflammatory cytokines. Activating stimulus could be hepatocyte-derived cytokines, clearance of oxidated lipid deposits *via* scavenger receptors^[70], or gut-derived endotoxins in patients with small intestinal bacterial overgrowth^[78]. Finally, adipose

tissue is in obese people infiltrated by macrophages^[65], making it another possible source of proinflammatory cytokines^[75,79]. It appears that cytokines produced by adipose tissue macrophages (particularly TNF- α) could mediate systemic and hepatic insulin resistance^[71], as well as cause a reduction in the secretion of the protective adipocytokine adiponectin^[80].

Adipocytokines are peptides produced by visceral adipose tissue. Among them, adiponectin and leptin are directly involved in different metabolic and inflammatory pathways and could be particularly important in the pathogenesis of NAFLD. Adiponectin appears to have a pivotal role in improving fatty acid oxidation and decreasing fatty acid synthesis^[81]. Liver and muscle cells have adiponectin receptors. Stimulation of adiponectin receptors in the liver leads to the activation of PPAR- α and AMP-activated protein kinase (AMPK)^[82-84]. Consequently, adiponectin increases fatty acid β -oxidation and thereby decreases hepatic triglyceride content and hepatic insulin resistance. Adiponectin also has a direct anti-inflammatory effect, suppressing TNF- α production in the liver^[80,81]. Recent studies showed reduced serum levels of adiponectin and reduced hepatic expression of its receptor in patients with NASH compared to those with simple steatosis^[85,86]. It seems that increased production of TNF- α and the generation of ROS are the ones responsible for the reduction in adiponectin secretion^[66,80]. This again implicates that TNF- α and ROS-mediated suppression of adiponectin may play an important role in the pathogenesis of progressive NAFLD. A study in obese leptin-deficient mice demonstrated significant improvements in hepatic steatosis, hepatomegaly, and aminotransferase levels following administration of adiponectin^[81].

Leptin is another peptide produced in adipose tissue that may have an important role in the development of insulin resistance. Leptin inactivates insulin receptor substrate (dephosphorylation of insulin-receptor substrate 1) inducing peripheral and hepatic insulin resistance^[87]. Blood leptin levels correlate with the degree of fibrosis in patients with chronic hepatitis C^[88]; however Angulo *et al* have found no correlation between leptin levels and stage of liver fibrosis in a study of 88 patients with NAFLD^[89]. Cohen *et al* have found that leptin, at the levels comparable with those present in obese individuals, induces hepatic insulin resistance by dephosphorylation of insulin-receptor substrate 1^[87].

In the end, hepatocyte injury and associated inflammation will lead to the activation of hepatic stellate cells and synthesis of extracellular matrix proteins with liver fibrosis as the final consequence. In addition, apoptotic cell death is also of great importance in hepatic fibrogenesis^[68]. It leads to stellate cell activation by the means of ingestion of apoptosing hepatocytes by Kupffer cells and subsequent release of TGF- β ^[90,91]. There are several more mediators possibly involved in the pathogenesis of liver fibrosis in NAFLD. The adipocytokine leptin may play a role in fibrogenesis^[89,92]. The reduced production of adiponectin associated with obesity may also contribute to the development of liver fibrosis^[93]. Angiotensin II, which is also secreted by adipose tissue and is raised in the serum

of obese patients, stimulates hepatic stellate cells and thus has profibrogenic effect^[94]. Finally, hyperglycaemia and hyperinsulinaemia associated with insulin resistance are also suggested to be the key-factors in the progression of fibrosis through the up-regulation of the synthesis connective tissue growth factor by stellate cells^[95].

Despite all of the recent advances in understanding the pathogenesis of NAFLD, the reason why only a minority of patients with classical risk factors for NAFLD develop more than simple steatosis still remains largely unclear (Figure 2).

WHAT TO EXPECT FOR THE PATIENT?

- NATURAL HISTORY AND CLINICAL COURSE OF NAFLD

In spite of the increasing interest and significant progress in understanding of NAFLD, its natural history still hasn't been clearly defined. The reason for this is mostly the lack of large prospective histologic follow-up studies. However, some concepts are clear: NASH progresses to cirrhosis less frequently than alcoholic steatohepatitis, with significantly better long-term survival of NASH patients^[96,97].

Nevertheless, in a population-based study that used data from a large long-term epidemiology project, patients with NAFLD had a slightly higher mortality than the general population^[98]. Liver-related death was the third most common cause of mortality in those patients, compared to the thirteenth place of liver-related death in the general population^[98]. Another retrospective study of 132 patients found that poor outcomes (cirrhosis and liver-related mortality) occurred in 22 percent of patients in whom initial biopsies showed ballooning degeneration and Mallory hyaline or fibrosis, compared to 4 percent in patients with steatosis alone^[97].

There has been a lot of speculation about the rate of progression of disease. Initial studies with paired biopsies showed histologic progression in 30% to 50% of NASH patients, but they had limited conclusions due to small patient numbers^[12,15,99,100].

The largest reported series of NAFLD patients with sequential liver biopsies published in 2005 included 103 patients with a mean interval of 3.2 years between biopsies^[101]. Fibrosis stage progressed in 37%, remained stable in 34% and regressed in 29% of patients. Diabetes, low initial fibrosis stage and higher body mass index were associated with higher rate of fibrosis progression. Another study of 22 patients with a median 4.3-year interval between biopsies also found progression of fibrosis in about a third of patients, with obesity and higher body mass index being the only associated factors^[102].

According to these results it is obvious that NAFLD, and especially NASH, is not a completely benign condition as it was initially believed. Now it is clear that it may lead to end-stage liver disease, and small number of patients with NAFLD may eventually end up with liver transplantation. Interestingly, steatosis and steatohepatitis recurrence after liver transplantation has been described^[103]. Furthermore, several studies suggest that hepatocellular carcinoma (HCC)

might also be among possible NAFLD outcomes^[104-106]. Further studies are required before the risk of HCC in NAFLD can be more precisely defined.

HOW TO DIAGNOSE? - THE ROLE OF THE LIVER BIOPSY

Most patients with NAFLD come to medical attention due to an accidental finding of elevated liver function tests. Although aminotransferase levels are elevated in the majority of patients, normal values don't exclude the presence of necroinflammatory changes or fibrosis. That was best illustrated in a study of 51 subjects with normal ALT levels where 12 had bridging fibrosis and 6 had cirrhosis^[107].

In the longitudinal histologic study of 103 patients aminotransferase improvement correlated with improvement in activity grade, but change in aminotransferase levels did not correlate with a change in fibrosis stage. Interestingly, aminotransferase levels decreased significantly between biopsies both in patients with progressive fibrosis as well as in those without it^[101].

Imaging methods are of little value in diagnostic evaluation of NAFLD. Finding of hyperechoic liver on ultrasonography is frequent in NAFLD, but it is neither sensitive nor specific enough. Moreover, all of the three most commonly used imaging methods (US, CT, MRI) have been shown to be incapable of differentiating between NASH and other forms of NAFLD^[108].

The role of the liver biopsy in NAFLD has been widely discussed, and correlation between histologic findings and clinical features or disease prognosis extensively studied. Liver biopsy is currently the only way to confirm diagnosis of NAFLD and distinguish between fatty liver alone and NASH. It also permits determination of disease severity and possibly gives insight into prognosis. Nevertheless, no guidelines or firm recommendations can yet be made as for when and in whom is liver biopsy necessary.

Another problem with liver biopsy is that it has several significant limitations. First, the quality of liver biopsy specimens is variable. Furthermore, studies have shown significant inter- and intra-observer variability in biopsy specimen interpretation^[109,110]. Additionally, it has long been known that affection of liver parenchyma in various chronic liver diseases is not homogenous, and biopsy is, therefore, subject to sampling variability^[111]. This has also been proven for NASH in a study in which two liver biopsies were performed in 51 patients with NAFLD^[112]. None of the histological features displayed high agreement between two samples from the same patient. Six of 17 patients (35%) with bridging fibrosis on one sample had only mild or no fibrosis on the other and, therefore, could have been understaged with only one biopsy. The negative predictive value of a single biopsy for the diagnosis of NASH was at best 0.74, and discordance of one or more stages was 41%.

In order to overcome some of the frequently present difficulties in liver biopsy interpretation, Matteoni *et al* divided NAFLD into four categories or types, based on the presence of steatosis, lobular inflammation, hepatocyte

ballooning and Mallory bodies/fibrosis^[97]. Types 3 and 4 were associated with worse clinical outcomes. The first histological scoring system for NASH was proposed by Brunt *et al* and it was designed based on a model used in other chronic liver diseases and included 3 qualitatively assessed grades of necroinflammatory activity (based on degree of steatosis, ballooning and inflammation) and 4 stages of fibrosis^[113]. However, it didn't include the whole spectrum of NAFLD and it couldn't be used in assessment of response to therapy. Therefore, another scoring system has been developed, which specifically includes only features of active injury that are potentially reversible in the short term^[110]. The score, named NAS (NAFLD Activity Score), is the unweighted sum of the scores for steatosis (0-3), lobular inflammation (0-3), and ballooning (0-2), while fibrosis was not included. The primary purpose of NAS is to assess overall histological change; it wasn't designed to replace the pathologist's determination of steatohepatitis, nor to represent an absolute severity scale.

In spite of all the efforts, there is still no international consensus regarding the histopathological criteria that would firmly define non-alcoholic steatohepatitis and differentiate between NAFLD entities. Therefore, a large amount of confusion between pathologists and clinicians is still present. As an illustration, in NAS development study interrater agreement on the diagnosis of steatohepatitis was 0.61, and only 68% of liver biopsies with steatosis, ballooning and lobular inflammation all present were diagnosed as NASH^[110].

Several clinical and biochemical risk factors for progressive disease have been identified, as they could potentially facilitate patient selection for liver biopsy. In one study, age over 45, obesity, diabetes mellitus, and aspartate transaminase/alanine transaminase (AST/ALT) ratio greater than 1 were significant predictors of severe liver fibrosis^[116]. In another study, age over 50 years, BMI over 28, triglycerides over 1.7 mmol/L and alanine aminotransferase more than two times normal were independently associated with septal fibrosis^[114].

In conclusion, for the time being, the decision to perform liver biopsy remains highly individual, as well as the interpretation of the histopathologic finding.

AVAILABLE TREATMENT OPTIONS

NAFLD, a hepatic manifestation of metabolic syndrome, is emerging as the most common clinically important form of liver disease in obese patients^[9,14]. Obesity, along with insulin resistance, type 2 diabetes and dyslipidemia, is a central risk factor for NAFLD. Lifestyle modifications, which should include long-term weight management through induction of negative calorie balance (primarily reducing dietary carbohydrate and saturated fat intake), regular physical exercise with maintenance of weight loss and cognitive-behavior programs are the mainstays of the successful therapy of metabolic syndrome. Specific diet and exercise guidelines for NAFLD patients have not been established, but several types of diets have been proposed for treatment of obesity by different medical and commercial sources^[115-117]. Although the published

results of several studies in NAFLD population are mostly insufficient due to their small sample size, they have reported that short term weight loss with concomitant exercise leads to improvement in liver biochemical tests and to resolution of hepatic steatosis^[118-120]. Moderate weight loss with incorporated regular physical activity is advocated in contrast to rapid weight loss, which could aggravate the underlying liver disease. A recent study showed that weight reduction of 5 or more percent accompanied by regular exercise (at least twice a week) for one year were associated with improvement and normalization in ALT levels^[121]. Keeping this weight (< 5% gain) for two consecutive years was associated with maintaining normal ALT levels. Another recent study reported that intense dietary intervention can achieve a reduction in mean waist circumference, insulin resistance, levels of fasting glucose, triglycerides and liver function tests, as well as an improvement in liver histology in patients with NASH^[122].

Pharmacological treatment should be initiated only when there is no change in the course of disease after adequate lifestyle changes have been undertaken. The problem is that appropriate diet and physical activity, in addition to behavioral modifications, are not always successful, particularly in very obese NAFLD patients. A pilot study, which included ten obese NASH patients treated with weight-loss drug orlistat (inhibitor of pancreatic and gastric lipase) for 6 mo, showed that 10% or greater consequent body weight reduction leads to improvement in aminotransferase levels, liver steatosis and fibrosis^[123].

Bariatric surgery is considered to be the best therapeutic modality in NAFLD patients with severe obesity or with concomitant obesity-associated morbidities, like sleep apnea syndrome^[124]. There are different surgical approaches to morbidly obese patients: malabsorptive procedures, such as jejunio-ileal bypass and biliopancreatic diversions, and restrictive procedures, which include gastric bypass and gastroplasty (gastric banding). Jejunio-ileal bypass, as the more 'classical' procedure, has been virtually replaced by 'newer' procedures such as proximal gastric bypass and biliopancreatic diversion, mostly due to the high frequency of postoperative complications^[125,126]. Those included progression of liver disease, although, occasional cases of NASH progression and subacute liver failure have also been reported with 'newer' methods. Several recent trials reported that moderate or even massive weight loss with consequent mild to moderate malnutrition after gastroplasty in severe obese NASH patients resulted in improvement in diabetes mellitus, liver function tests and liver histology (inflammation and fibrosis)^[124,127-130]. Similar results were reported after gastric bypass surgery^[20]. Even though these promising results give a new perspective on treatment of severely obese NAFLD patients, the decision to perform surgery should still be individual.

The role of smoking and minimal to moderate alcohol intake in pathogenesis and potential progression of NAFLD has not been widely investigated; therefore, specific recommendations regarding those factors cannot be made.

Lipid-lowering agents

A one year pilot study, which evaluated a lipid-lowering

drug clofibrate in the treatment of 16 patients with hypertriglyceridemia and NASH, revealed no significant changes in levels of aminotransferases or liver histology^[132]. A controlled trial of a 4-wk treatment in 46 patients with NASH, using gemfibrozil 600 mg/d, resulted in a significant improvement in liver tests, although the study did not include liver biopsies^[133]. A total of 56 patients with NAFLD/NASH and hyperlipidemia was investigated in three separate studies and received 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitor atorvastatin (10-80 mg/d) for 6-12 mo, which lead to significant improvement or normalization in serum aminotransferase and lipids/cholesterol levels, as well as in the degree of inflammation, ballooning and Mallory bodies on liver histology^[134-136]. A small study using another HMG CoA reductase inhibitor pravastatin included 5 patients with biopsy proven NASH^[137]. After 6 mo of pravastatin treatment cholesterol levels were reduced, with normalization of liver function tests but without improvement in the fibrosis score.

Metformin

Metformin is an insulin-sensitizing agent that reportedly reversed hepatomegaly, steatosis and liver tests abnormalities in an animal model of fatty liver^[138]. First pilot study which investigated metformin treatment (500 mg three times daily) in patients with NASH suggested association of usage of this agent with improvement in liver tests and index of insulin sensitivity, as well as decrease in hepatic volume^[139]. A possible benefit of metformin in the induction of normalization of liver tests and loss of body weight was reported after 6 mo of therapy in a preliminary report of an open-label study of 15 patients^[140]. However, consequent results after 1 year of treatment showed no effect on aminotransferase levels, liver histology, or insulin sensitivity^[141]. Another randomized controlled study in patients with NAFLD reported that addition of metformin to a lipid and calorie-restricted diet *vs* diet alone for 6 mo lead to improvement in mean serum aminotransferase levels and insulin resistance. On the other hand, no statistically significant change in the severity of liver inflammation or fibrosis at the end of the treatment period was reported^[142]. Higher rates of aminotransferase normalization and improvement in liver histology and insulin sensitivity were associated with metformin treatment in comparison to vitamin E treatment or weight loss in an open-label randomized study of 110 non-diabetic patients^[143].

Thiazolidinediones

Thiazolidinediones (pioglitazone, rosiglitazone), peroxisome proliferator-activated receptor (PPAR) gamma ligands, are insulin-sensitizing drugs involved in glucose and lipid metabolism with suggested anti-inflammatory and anti-fibrotic properties^[144]. They are a new class of antidiabetic agents investigated recently as a potential treatment modality for patients with NAFLD/NASH. PPAR γ agonist pioglitazone prevents the activation of hepatic stellate cells *in vitro*, and improves hepatic steatosis and prevents liver fibrosis *in vivo*^[145]. In another study with animals 1 wk treatment with pioglitazone inhibited hepatic

fat accumulation and decreased levels of TNF α , while 4 wk treatment lead to improvement in hepatic fibrosis with a decrease in the expression of procollagen, α -smooth muscle actin, and TGF- β 1^[146]. In the first of prospective human studies, 48 wk of pioglitazone treatment (30 mg daily) of nondiabetic patients with biopsy-proven NASH improved the degree of insulin sensitivity with normalization of aminotransferase levels and histological improvement in hepatic steatosis, cellular injury, parenchymal inflammation, Mallory bodies, and fibrosis^[147]. MRI confirmed a marked decrease in liver fat and liver volume, but interestingly, increase in body weight and total body fat was observed. In another controlled study combination treatment with pioglitazone (30 mg daily) and vitamin E (400 IU daily) normalized aminotransferase levels, but the effect was also seen in the control group treated with vitamin E alone^[148]. However, only combination therapy induced a significant effect on histological findings (decrease in steatosis, hepatocyte ballooning, Mallory's bodies and pericellular fibrosis), with improvement in metabolic disturbances (increase in metabolic clearance of glucose and a decrease in fasting free fatty acid and insulin). A recent study proposed that improvements seen on liver histology after pioglitazone therapy may be the effect of change in adiponectin levels^[149]. In another study of rosiglitazone in 25 NASH patients of whom half had diabetes or impaired glucose tolerance, 1-year therapy was associated with improvement in liver function tests, insulin sensitivity and degree of fibrosis^[150]. Opposite to these promising results, the latest meta-analysis of 42 trials with rosiglitazone found that the drug was associated with significant increase in the risk of myocardial infarction^[151]. Considering all this, recommendations about use of thiazolidinediones in NAFLD treatment can not be yet established.

Losartan

A role for angiotensin II in pathogenesis of hepatic stellate cell activation, hepatic inflammation and fibrogenesis has been postulated^[152-156]. Given the potential therapeutic effects of angiotensin II receptor antagonists, studies with losartan were performed in patients with NASH and arterial hypertension^[157-159]. Reduction in levels of blood markers of hepatic fibrosis, transforming growth factor- β 1 (TGF- β 1) and ferritin concentration was reported, with improvement in serum aminotransferase levels. Reduction of hepatic necroinflammation, fibrosis and iron hepatocyte deposition was detected in the majority of liver biopsy specimens after 48 wk of treatment. Results suggest anti-fibrotic effect of losartan through inhibitory effect on hepatic stellate cell activation. These promising initial results justify further studies of angiotensin II receptor antagonists in treatment of NAFLD patients.

Antioxidants

Oxidative stress, along with the insulin resistance, plays one of the essential roles in NAFLD pathogenesis. Therefore, treatment with different antioxidants (vitamin E, vitamin C, betaine, iron depletion) has been studied in this group of patients. A study with vitamin E administration (300 mg/d during 1 year) confirmed improvement in liver tests

with reduction of plasma levels of TGF- β 1, but revealed no change in degree of steatosis, fibrosis and inflammation on follow-up liver biopsy^[160]. A placebo-controlled trial of a combination of vitamin E (1000 IU/daily) and vitamin C (1000 mg/d) during 6 mo showed no statistically significant difference between vitamin and placebo groups in liver enzyme levels, degree of steatosis and inflammatory activity, or fibrosis score, although an improvement in fibrosis was noted in the vitamin group^[161]. Given the suggested protective effect of betaine against steatosis in rats (through increase of S-adenosylmethionine levels), a pilot study was performed in 8 patients with NASH^[162]. After one year treatment with betaine (20 mg daily), a significant improvement or normalization in serum aminotransferase levels and liver histology was noted. Another placebo-controlled study included 191 patients with NAFLD treated for 8 wk with combination of betaine glucuronate (300 mg/d), diethanolamine and nicotinamide ascorbate^[163]. Significant improvement was noted in liver tests and degree of steatosis (evaluated by ultrasonography) in the treated group. Further controlled trials are needed for confirmation of these promising results. It has been hypothesized that iron induces oxidative stress by catalyzing production of ROS (reactive oxygen species) and increased hepatic iron deposition could be a part of the pathogenesis of NAFLD^[164]. In a few pilot studies in NASH patients, quantitative phlebotomies were performed with induction of iron depletion and reduction in serum ferritin levels^[165-167]. Results of these studies suggest that iron reduction therapy by phlebotomy can lead to improvement in aminotransferase levels; unfortunately, follow-up liver biopsies were not performed.

Ursodeoxycholic acid

Ursodeoxycholic acid (UDCA) could potentially act as a hepatoprotective agent by minimizing toxicity of hydrophobic bile acids and leading to a decrease in oxidative stress and hepatocyte injury. Initial small pilot-studies evaluated therapeutic effect of UDCA alone or in combination with low-fat diet or lipid-lowering agents in patients with NASH^[132,135,168-170]. Results suggested potential benefit of UDCA treatment with reported normalization/improvement in liver function tests, degree of hepatic steatosis and serum markers of fibrosis. However, consequent larger, randomized double-blinded placebo-controlled trial found no detectable benefit of UDCA treatment: similar degree of improvement in biochemistry and histology was detected in both study groups^[171]. Given the lack of effectiveness of UDCA alone as a therapeutic option in NASH, one recent study considered combination of UDCA with vitamin E. Significantly diminished levels of serum aminotransferases were observed, with improvement in histological activity index, mostly as a result of regression of steatosis^[172].

CONCLUSION

Non-alcoholic fatty liver disease is currently the object of significant scientific and clinical interest, and is to remain so in the following years. Larger studies with firm inferences are rather scarce, and their small number

reflects the difficulties in setting-up and performing clinical trials in NAFLD. Among the most important obstacles that researchers are confronted with are slowly progressive nature of the disease requiring long-term follow-up, variability in liver biopsy specimens and their interpretation, various associated conditions and multiple medication use that are common in these patients. Although clinicians dispose in theory with a wide array of possible therapies, few have been shown to have consistent effects and can therefore be firmly recommended in treatment of NAFLD.

Abstract

Capsule endoscopy (CE) is a safe, non invasive diagnostic modality for the evaluation of small bowel lesions. Obscure gastrointestinal bleeding (OGIB) is one of the most important indications of capsule endoscopy. Capsule endoscopy has a very high diagnostic yield especially if the bleeding is ongoing. This technique appears to be superior to other techniques for the detection of suspected lesions and the source of bleeding. Capsule endoscopy has been shown to change the outcome in patients with obscure gastrointestinal (GI) bleed.

INTRODUCTION

Visualization of the small bowel presents a great challenge to the practicing physician and is considered the final frontier in luminal endoscopy. Newer technologies are constantly being developed towards the goal of better, safer, and complete evaluation of the small intestine. Capsule endoscopy (CE) is a major technological advance in this direction. Its non invasive nature, safety profile, capability of imaging the entire small bowel and its ability to store images makes CE the investigation of choice for the evaluation of small bowel lesions. Obscure gastrointestinal bleeding (OGIB) both in the overt and

occult forms is one of the most important indications for CE^[1]. The widespread acceptability and utility of CE in OGIB is evident from the fact that the number of publications in peer reviewed journals have steadily increased since the first publication in 2000^[2]. The present article attempts to review the progress made in the last decade with special emphasis on the use of capsule endoscopy in obscure gastrointestinal (GI) bleeding.

Diagnostic yield of CE

Evaluation of the current status of CE in OGIB requires assessment of the efficacy and accuracy of the procedure. The diagnostic yield of CE in OGIB is extremely variable^[3-9], from > 70% in small studies (< 20 patients) to < 60% in larger studies (> 50 patients). In reality, the overall positive diagnostic yield of CE in OGIB is around 50%. Subgroup analysis shows that the diagnostic yield is much higher, reaching 92.3% in patients with ongoing overt GI bleeding compared with 44.2% in obscure occult bleeding and 12.9% in past OGIB. Current data suggests that the timing of the procedure is very important in optimizing the yield of CE in OGIB^[10]. The ICCE consensus meeting on OGIB recommended that CE should be performed early (preferably within 2 wk) in the workup of patients with OGIB^[11].

Comparison of CE with other modalities

The second issue is whether CE is superior to other diagnostic tests in the evaluation of OGIB^[12-16]. A meta-analysis compared CE with other modalities in patients with OGIB^[17], and showed that the diagnostic yield of CE was superior to push enteroscopy, small bowel radiography, CT enteroclysis, mesenteric angiography and small bowel MRI. Recently, several studies have compared CE with Double Balloon Enteroscopy (DBE). The detection rate of potential bleeding source was significantly better with CE than DBE^[18]. However these two procedures should be considered complimentary and not competitive. The usefulness of repeat CE in OGIB has been reported. In a retrospective study, repeat CE in patients with OGIB showed additional findings in 75% patients^[19]. However this data needs further validation with prospective studies.

The role of CE in iron deficiency anaemia

The role of CE in the evaluation of iron deficiency anaemia is still evolving. In two recent studies, the yield of CE in iron deficiency anemia using strict diagnostic criteria varied from 57% to 80%^[20,21]. These results

are encouraging and suggest a definite role of CE in documented iron deficiency anaemia.

Impact of CE on clinical outcome

Although several studies have assessed the yield of CE in OGIB, the exact significance of the lesions identified and their impact on clinical outcome has not been adequately examined. When we consider outcome in clinical practice, the emphasis should be on meaningful and positive results. In the case of OGIB, a positive outcome should either be stoppage of bleeding or resolution of anemia. The majority of studies on CE in OGIB discuss change in management rather than a change in the outcome. Pennazio *et al* determined the outcome in 56 patients, with a mean follow up of 18 mo. Complete resolution of bleeding was seen in 86.9% patients with ongoing overt GIB, 69.2% in occult OGIB and 41.4% in past OGIB. Other studies have assessed the change in clinical decision making after CE, with figures varying from 22% to 88% in patients with OGIB. In a multicentre study, Alberts *et al* assessed the impact of CE on clinical outcomes based on 247 capsule studies^[22]. A specific intervention or change of management was implemented in about 2/3rd of the patients who had a definite diagnosis on CE. In another recent study, 70% patients underwent definitive treatment based on CE results. On the other hand, Rastogi *et al* reported a positive clinical outcome in only 16% patients.

It is difficult to draw definite conclusions from these conflicting results. The variations in outcome may be explained by the differences in study population, the lack of a standardized approach to management, and different policies at different medical centers. However there is no doubt that CE plays a definite role in planning the management of patients with OGIB.

Cost effectiveness of CE

Not many studies have addressed the issue of cost effectiveness of CE in OGIB. One study examined the cost effectiveness of several approaches including initial DBE, CE followed by DBE if a lesion was detected, push-enteroscopy, intraoperative-enteroscopy, angiography and no treatment for the diagnosis and management of small bowel angiectasia, in patients with transfusion dependent obscure/occult bleeding. DBE was found to be the most cost effective strategy; however CE followed by DBE was more cost effective if the probability of angiectasia at DBE was less than 59%^[23]. Prospective clinical studies are needed to clarify as to when to use DBE or CE as the initial study.

CONCLUSION

Despite its limitation of being a purely diagnostic modality, CE is an important tool in the evaluation of OGIB. The technology is improving at a fast pace. The development of new software has reduced considerably the reading time of CE images. Many new capsule endoscopes are under development. CE is clearly a giant technological leap in GI endoscopy. In the near future, the technological qualities of capsule endoscope are likely to improve. A capsule

endoscope capable of not only localizing, but also treating a suspected lesion is a distinct possibility.

Abstract

AIM: To investigate the expressions of PTEN, PPM1A and P-Smad2 in hepatocellular carcinoma (HCC) and their significance.

METHODS: The expressions of PTEN, PPM1A and P-Smad2 in 31 HCC tissues, 25 adjacent liver tissues and 13 non-tumor liver tissues were detected by using Envision immunohistochemical technique.

RESULTS: The positive expression (64.52%) and staining intensity (4.19 ± 3.31) of PTEN in the cytoplasm of HCC were significantly lower and weaker than those in the adjacent or non-tumor liver tissues (97.37%, 7.88 ± 0.93 ; 100%, 7.77 ± 0.93 , respectively) ($P < 0.05$), and its staining intensity in the cytoplasm of HCC, which belongs to Edmondson pathologic grades II-III and above, was also lower than that of grade I and I-II. Furthermore, its location in the nucleus or cytoplasm of liver cells was negatively correlated with the progression of liver disease ($r = -0.339$, $P = 0.002$); most of PPM1A might be only expressed in the nucleus of adjacent liver tissues, non-HCC tissues or Edmondson grade I and I-II HCC, but it was mainly expressed in the cytoplasm of HCC with Edmondson grade \geq II, weakly or negatively expressed in the nucleus ($P < 0.05$), and its location was negatively correlated with the progression of liver disease ($r = -0.45$, $P = 0.0000$). P-Smad2, which was

mostly located in the nucleus and cytoplasm of grade I and I-II HCC, surrounding or non-tumor liver tissues, was only in the nucleus of HCC with Edmondson grade II and above ($P < 0.001$), and its location was positively correlated with the disease progression ($r = 0.224$, $P = 0.016$). Spearman correlation analysis revealed that P-Smad2 was significantly negatively correlated with PTEN and PPM1A ($r = -0.748$, $P = 0.000$; $r = -0.366$, $P = 0.001$, respectively); and PTEN and PPM1A were positively correlated with HCC carcinogenesis ($r = 0.428$, $P = 0.000$).

CONCLUSION: The aberrant location of expression and staining intensity of PTEN, PPM1A and P-Smad2 in HCC and their relationship might have an impact on the pathogenesis of HCC.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the 5th most common solid tumor worldwide and accounts for about 110 000 deaths each year in China, with the 2nd most common cause of mortality among all malignant tumors^[1]. The pathogenesis of HCC is not clearly elucidated so far; hence, the exploration of the key genes and pathways involved in hepatocarcinogenesis and novel therapeutics strategies is very crucial. Many data indicated that TGF- β /Smads pathway significantly acted on the pathogenesis of HCC^[2,3]. Recent studies showed persistent accumulation of phosphorylated Smads (P-Smads) in the nucleus of HCC may be associated with the development of HCC. But its dephosphorylation regulation remains unknown^[4]. Lin *et al*^[5] identified PPM1A as a protein serine/threonine phosphatase which can dephosphorylate and promote nuclear export of TGF- β -activated Smad2/3, and implied that dual specific phosphatases (DUSPs) also catalyze dephosphorylation of pS/Ts. Phosphatase and tensin

homolog deleted on chromosome ten (PTEN) is the first tumor suppressor gene which can encode a dual specificity phosphatase (protein phosphatase and lipid phosphatase), its deletion or mutation may impact on the development and prognosis of HCC and other tumors^[6-8]. In the present study, we investigated the expressions of PTEN, PPM1A and P-Smad2 in HCC with different Edmondson pathological grades by using immunohistochemical technique and analyzed their possible relationship associated with the pathogenesis of HCC.

MATERIALS AND METHODS

Materials

This study included 31 HCC and 25 corresponding paracancerous tissues and 13 non-tumor liver tissues (5 liver cirrhosis, 3 hepatitis and 5 normal liver tissues) obtained from Tongji Hospital from 1997 to 1998 and 2003 to 2004. Among 31 HCC cases, 27 were males and 4 were females, with age ranged from 24-78 (mean, 43.45 ± 10.77) years. None of the cases had distant metastases and received any chemotherapy and radiotherapy. According to Edmondson Grading System, 10 cases belonged to grade I and I-II, 7 cases grade II and 14 cases > grade II. In addition, among 25 cases of paracancerous liver tissues, 11 cases had intrahepatic vascular embolism and 14 cases had not. All tissue samples were fixed in formalin and imbedded in paraffin, and cut into 4- μ m thick sections.

Antibodies

Rabbit anti-phosphorylated Smad2 (P-Smad2) monoclonal antibody (1:100 dilution), mouse anti-PPM1A monoclonal antibody (1:25 dilution) and rabbit anti-human PTEN polyclonal antibody (1:400 dilution) were purchased from CellSignaling Technology Company, Abcam and Zhongshan Biotechnology Company, Beijing. DAKO Envision kit was purchased from DAKO Company.

Immunohistochemistry

Immunohistochemical staining was performed by using DAKO Envision (DAKO, Carpinteria, CA) kit according to the manufacturer's instructions. Briefly, each section was deparaffinized, rehydrated and incubated with fresh 3 mL/L hydrogen peroxide in methanol for 30 min at room temperature and then washed in phosphate-buffered saline (PBS). Sections were incubated with normal goat serum for 30 min to block the nonspecific antibody binding. Sections were then incubated with primary antibody against P-Smad2 or PTEN or PPM1A overnight at 4°C, washed three times in PBS, followed by incubation with respective secondary antibody for 30 min at room temperature. Then 3, 3'-diaminobenzidine tetrachloride (DAB) was used for color development and the sections were counterstained with hematoxylin. Primary antibody was substituted by PBS for negative control.

Evaluation of PTEN, PPM1A and P-Smad2 expression

The degree of staining was categorized by the extent and intensity of the staining; the staining results were assessed according to Detre *et al*^[9]. Briefly, the cells staining positively throughout the section were assigned

scores from 1 to 6 as follows: 1 = 0%-4%; 2 = 5%-19%; 3 = 20%-39%; 4 = 40%-59%; 5 = 60%-79%; and 6 = 80%-100%. The average intensity, corresponding to the presence of negative, weak, intermediate, and strong staining, was given a score from 0 to 3, respectively. The positive cell score was added to the average intensity to form an additive quickscore. A positive cut-off quick score was ≥ 3 .

Statistical analysis

Data analyses were performed with the SPSS (version 12.0) statistical package on a personal computer. Significant differences between variables were assessed by Student's *t* test, Chi-square test or Fisher's exact probability test, when appropriate. The correlation between factors was evaluated by using Spearman rank correlation coefficient test. A *P* value less than 0.05 was considered statistically significant.

RESULTS

Expression of PTEN protein in HCC, paracancerous and non-tumor liver tissues

The expression of PTEN was localized generally in the nucleus, cytoplasm and cell membrane of liver cells (Figure 1), but its distribution and staining intensity in HCC, paracancerous or non-tumor liver tissues (including normal liver tissues, hepatitis tissue and cirrhotic liver tissues) were different. As shown in Table 1, 20 of 31 (64.52%) HCCs tissues were positive for PTEN, mainly expressed in the cytoplasm and cell membrane. PTEN expression was strongly positive in 13 of 17 HCCs with Edmondson grade I and I-II, but weakly positive in 8 of 14 HCC with grade II-III and above. Furthermore, PTEN was stained strongly in the cytoplasm, nucleus and/or cell membrane of 24 of 25 paracancerous and 13 non-tumor liver tissues compared with HCC tissues ($P < 0.05$).

In addition, compared with the group without intrahepatic vascular embolism (85.71%, 12/14), PTEN was weakly positive in HCC with intrahepatic vascular embolism (45.45%, 5/11). Spearman rank correlation analysis showed that PTEN expression was negatively correlated with intrahepatic vascular embolism ($r = -0.428$, $P = 0.033$).

Expression of PPM1A in HCC, paracancerous and non-tumor liver tissues

We found that PPM1A staining was mainly localized in the nucleus and cytoplasm of different type liver tissues (Figure 2), but its distribution and staining intensity were different. PPM1A was strongly expressed in the nucleus of non-tumor liver tissues, paracancerous liver tissues and grade I and I-II HCC, with weak or negative expression in the cytoplasm; whereas strongly expressed in the cytoplasm of HCC with grades II-III and above, with weak expression in the nucleus, thereby showing a significant difference in distribution and staining intensity ($P < 0.001$). However, Spearman rank correlation analysis showed that the location and staining intensity of PPM1A in HCC were not correlated with intrahepatic vascular embolism ($r = -0.038$, $P = 0.821$) (Table 2).

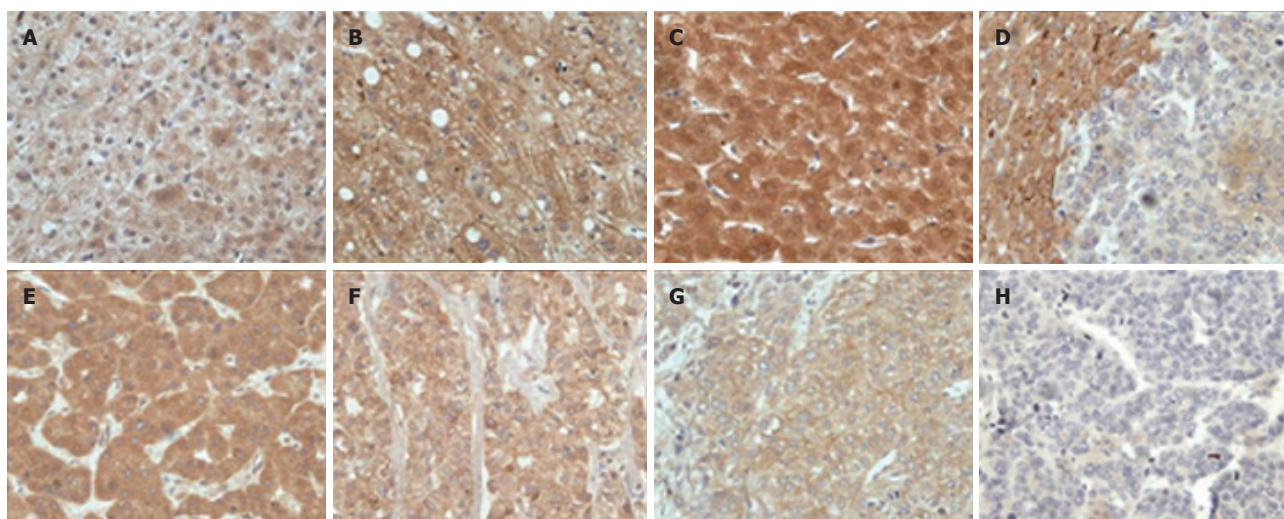

Figure 1 Expression of PTEN in hepatocellular carcinomas, paracancerous tissues and non-tumor liver tissues (Envision, x 200). **A:** Expression of PTEN in the nucleus, cytoplasm and membrane of normal liver tissues; **B:** Expression of PTEN in the cytoplasm and membrane of hepatitis tissue; **C:** Expression of PTEN in the nucleus, cytoplasm and membrane of cirrhotic liver tissues; **D:** Expression of PTEN weakly in the cytoplasm of HCC, strongly in the cytoplasm and membrane of paracancerous tissues; **E:** Strong expression of PTEN in the cytoplasm of HCC with Edmondson grade I; **F:** Expression of PTEN in the cytoplasm and membrane of HCC with grade II; **G:** Weak expression of PTEN in the cytoplasm and membrane of HCC with Edmondson grade II-III; **H:** Negative expression of PTEN in HCC with Edmondson grade III-IV.

Table 1 Expression of PTEN in hepatocellular carcinomas, paracancerous tissues and non-tumor liver tissues

Parameters	Cases (n)	Positive cases	Mean score of PTEN staining (mean \pm SD)		
			Nucleus	Cytoplasm	Cell membrane
HCC (Edmondson grading system)	31	20 ^{a,c}	0 ^{a,b,c}	4.19 \pm 3.31 ^{a,b,c}	4.77 \pm 3.92

Expression for P-Smad2 in HCC, paracancerous and non-tumor liver tissues

P-Smad2 staining was mostly localized in the nucleus and its surrounding cytoplasm (Figure 3), with different pattern of its distribution in different types of liver tissues (Table 3). P-Smad2 was expressed in the nucleus and the surrounding cytoplasm of non-tumor liver tissues, paracancerous liver tissues and HCC $<$ grade II, and only in the nucleus of \geq grade II HCC. Although its staining intensity in the nucleus was not significantly different between HCC and paracancerous tissues, P-Smad2 expression was stronger in the nucleus and weaker in the cytoplasm of HCC than those of non-tumor liver tissues ($P < 0.05$). In addition, the expression of P-Smad2 in HCC was not associated with intrahepatic vascular embolism ($r = 0.052$, $P = 0.775$).

Relationship among PTEN, PPM1A and P-Smad2 in HCC

The expressions of PTEN, PPM1A and P-Smad2 in

HCC were not related with age and gender, but might be associated with progression of liver disease. With liver pathology developing from non-tumor liver tissues, adjacent cancerous tissues to HCC, the location of PTEN shifted from the nucleus to the cytoplasm or cell membrane, even some negative staining. Most of PPM1A also shifted from the nucleus to the cytoplasm. But P-Smad2 was translocated from the nucleus and cytoplasm to the nucleus accumulation. Spearman rank correlation analysis suggested that the staining location of PTEN and PPM1A in liver cells was negatively correlated with progression of liver disease ($r = -0.339$, $P = 0.002$; $r = -0.45$, $P = 0.0000$, respectively), but P-Smad2 was positively correlated ($r = 0.228$, $P = 0.015$) (Table 4). As shown in Table 5, with progression of tumor Edmondson grades, the expression of PPM1A in the nucleus was decreased ($r = -0.322$, $P = 0.029$), but P-Smad2, in more cases, was accumulated in the nucleus ($r = 0.459$, $P = 0.003$), implying that although the location of PTEN was

positively correlated with that of PPM1A in HCC ($r = 0.428$, $P = 0.000$), the expression and location of P-Smad2 were significantly negatively correlated with those of PTEN and PPM1A ($r = -0.748$, $P = 0.000$; $r = -0.366$, $P = 0.001$, respectively).

DISCUSSION

Phosphatase and tensin homolog deleted on chromosome ten (PTEN) was discovered as a tumor suppressor gene in 1997. It could regulate normal cell growth by negatively regulating the phosphatidylinositol 3-kinase (PI3K) signaling pathway which is an important driver of cell proliferation and cell survival, and its deletion, mutation or otherwise inactivation was frequently correlated with the development and progression of many human tumors^[6,7,10]. In this study, we detected the expression of PTEN in 31 HCCs, 25 paracancerous tissues and 13 non-tumor liver tissues by using immunohistochemical technique. Our results showed that the positive rates of PTEN in HCC, paracancerous and non-tumor liver tissues were

61.29%, 97.37% and 100%, respectively. Furthermore, the staining intensity of PTEN in the cytoplasm of HCC was significantly weaker than that of paracancerous and non-tumor liver tissues. In addition, the staining intensity of PTEN in the cytoplasm of HCC with grade \geq II-III was weaker compared to HCC with grade I and I - II. Also, PTEN expression in HCC was correlated with intrahepatic vascular embolism. These results are in agreement with previous studies^[8,11] and imply that the expression and intensity of PTEN maybe related to the malignant and invasive potential of HCC, and its deletion and weak expression would result in tumorigenesis and development of HCC.

In this study, we also observed that PTEN was localized in the nucleus, cytoplasm or cell membrane of non-tumor or paracancerous liver tissues, but mainly localized in the cytoplasm or cell membrane of HCC, and the nuclei were almost negative, suggesting that its location was closely correlated with the progression of liver disease. However, whether this phenomenon is connected with the role of PTEN in tumor suppression needs to be further studied.

Table 4 Relationship of PTEN, PPM1A and P-Smad2 with HCC, paracancerous and non-tumor liver tissues

Types	Cases (n)	PTEN		PPM1A		P-Smad2	
		Cytoplasm	Nucleus	Cytoplasm	Nucleus	Cytoplasm	Nucleus
HCC	31	20	0	26	20	8	31
Paracancerous tissue	25	24	17	7	25	25	25
Non-tumor liver tissue	13	13	12	0	13	11	13

The location of expression of PTEN vs PPM1A vs P-Smad2 in the cytoplasm or nucleus of different liver diseases was significantly different ($P < 0.001$).

PPM1A is a member of the PP2C family of Ser/Thr protein phosphatases which are known to be negative regulators of cell stress response pathways, such as p38 and JNK kinase cascades. This phosphatase can also dephosphorylate cyclin-dependent kinases, thus may be involved in cell cycle control. Over-expression of the phosphatase is reported to activate the expression of the tumor suppressor gene *TP53/p53*, which leads to G2/M cell cycle arrest and apoptosis^[12]. In this experiment, we examined the expression of PPM1A in HCC, paracancerous liver tissues and non-tumor liver tissues. The results showed

that PPM1A was located in the nucleus and cytoplasm of liver cells. With the progression of liver disease, most of PPM1A shifted from the nucleus to the cytoplasm and the staining intensity was obviously different, suggesting that its expression location was negatively correlated with liver pathological type ($r = -0.45$, $P = 0.0000$) and implying that the location shift of PPM1A may have impact on the carcinogenesis and progression of HCC.

TGF- β /Smads signaling is an important regulator of cell growth pathway, which modulates diverse cellular processes including cell proliferation, differentiation,

Table 5 Relationship of PPM1A and P-Smad2 with different Edmondson grades of HCC

Pathological type	Cases (n)	PPM1A		P-Smad2	
		Cytoplasm	Nucleus	Cytoplasm	Nucleus
HCC (Edmondson grade)	31	26	20	8	31
Grade I and I - II	10	5	9	7	10
Grade II	7	7	6	1	7
Grade II-III and above	14	14	5	0	14

The location expression of PPM1A vs P-Smad2 in the cytoplasm or nucleus of HCC of different Edmondson grades was significantly different ($P < 0.05$).

adhesion, extracellular matrix remodeling, apoptosis and immunomodulation. Smad2 is an essential intracellular transducer for TGF- β signals. In response to TGF- β stimulation, it is phosphorylated by TGF- β I receptor and forms a complex with Smad3, Smad4 and transported into the nucleus, where Smads cooperates with specific DNA-binding transcription factor CRB/P300 and activates TGF- β signals to regulate gene transcription, inhibit cell growth and promote apoptosis. Xu *et al*^[13] reported that Smad2 phosphorylation or dephosphorylation would play a key role in regulation TGF- β signaling^[13]. A recent study showed that phosphorylated R-Smad2 was accumulated in the nucleus of hepatoma cell which might be correlated with hepatocellular tumorigenesis and development^[4]. In this study, we found phosphorylated Smad2 was strongly expressed in the nucleus and cytoplasm of non-tumor liver tissues, paracancerous liver tissues and HCC with Edmondson grade I and I - II. However, P-Smad2 was only located in the nucleus of HCC \geq grade II, implying that accumulation of P-Smad2 in the nucleus was closely correlated with liver pathological type and progression of hepatocarcinogenesis and may play an important role in HCC development.

Spearman rank correlation analysis results suggested that the expression location of PTEN and PPM1A in the nucleus or cytoplasm of HCC was negatively correlated with P-Smad2. Lin *et al*^[5] demonstrated that PPM1A/PP2C can dephosphorylate the SXS motif of Smads, and nucleus-to-cytoplasm shift of PPM1A would result in P-Smad2 accumulation in the nucleus and TGF- β signaling termination^[5]. Hence, we presumed that PTEN, which is dual specific phosphatases (DUSPs), may also catalyze dephosphorylation of pS/Ts of Smad2 in the nucleus or cooperate with PPM1A, and its nucleus-to-cytoplasm shift, or weak or negative expression would block TGF- β signaling, deregulate hepatocellular growth and promote tumorigenesis and development of HCC. However, further studies are needed to clarify it.

In conclusion, deletion or weak expression or nucleocytoplasmic shift of PTEN and PPM1A and accumulation of P-Smad2 in the nucleus of hepatoma cells might be associated with the tumorigenesis and progression of primary hepatocellular carcinoma.

comparable in patients infected with genotypes B and C when CH-B occurred at < 30 years old. However, CH-B patients infected with genotype C showed poor prognosis if they were 30-49 years old and were positive for HBeAg. Age-specific natural course of CH-B should be considered when patients with CH-B are treated with antiviral drugs.

Abstract

AIM: To investigate the different impact of genotypes B and C on the development of liver cirrhosis (LC) among different age groups of patients with chronic hepatitis B (CH-B).

METHODS: We examined the outcome of 121 patients with CH-B, divided by age and genotype. Univariate analyses were used to compare different groups. The Cox proportional hazard model was employed to evaluate factors affecting the development of LC.

RESULTS: In patients < 30 years old, there were no significant predictors for development of LC. However, in patients ≥ 30 years old, genotype C was the only significant predictor. In the genotype C group, 8 of 12 patients who progressed to LC were 30-49 years old at initial diagnosis of chronic hepatitis (7 patients were positive for HBeAg). In the genotype B group, 4 of 8 patients who developed LC were ≥ 50 years old at initial diagnosis and were HBeAg-negative.

CONCLUSION: The rate of development of LC was

INTRODUCTION

Hepatitis B virus (HBV) is a double-stranded DNA virus. Chronic HBV infection is associated with different forms of liver diseases, encompassing inactive carrier, chronic hepatitis (CH), liver cirrhosis (LC) and hepatocellular carcinoma (HCC)^[1].

It has been recently reported that HBV genotypes influence disease severity and clinical outcome of HBV infection^[2-6]. HBV genotypes are classified into 8 groups, from A to H, based on a sequence difference greater than 8%, and are variously distributed in the world^[2,5,7-14]. In Japan, genotypes B and C are predominant, as in other Asian countries, but > 90% of chronic carriers have genotype C^[3,5,8,15].

We previously reported that HBeAg seroconversion rate in genotype B was significantly higher compared with genotype C^[6]. Moreover, it has been reported that progression to LC is more frequently seen in genotype C patients than in genotype B patients^[2-6]. Therefore, it seems that infection with genotype C is associated with a poor prognosis.

However, our previous study^[16] and another study^[17] showed that association of genotype C with advanced

liver disease was not seen in patients over 50 years old. Therefore, the influence of HBV genotype on the prognosis of CH may vary depending on the age groups.

The aim of the present study was to investigate the different impact of HBV genotypes B and C on the development of LC among patients with chronic hepatitis B (CH-B) belonging to different age groups.

MATERIALS AND METHODS

From January 1977 to January 2005, we enrolled 145 consecutive patients with CH-B who were admitted to our institute and related facilities followed for more than 6 mo, i.e. for 7 to 207 mo (mean \pm SD: 79.8 \pm 48.4). In 124 patients, diagnosis of CH was made by liver biopsy after written informed consent, and histological classification was carried out according to standard criteria^[18]. The degree of hepatic inflammation and the stage of fibrosis were scored by a modified Knodell histological index^[19]. The inflammation score (grading) was obtained by combining the scores for the first three components of the index: portal, periportal, and lobular inflammation. The score could range from 0 to 18. The degree of inflammation was graded as 4 to 8, mild; 9 to 18, moderate to severe. The fibrosis score (staging) was graded as 0 to 1, no-mild; 2 to 3, moderate-severe. In the remaining 21 patients, diagnosis of CH was made clinically and was characterized by persistent alanine aminotransferase (ALT) elevation over for at least 6 mo and by ultrasound findings using a cirrhosis score (< 8 points)^[20]. Diagnosis of LC was made mainly by clinical assessment including serial determination of serum ALT levels, platelet count, ultrasound examination (using the above mentioned cirrhosis score, ≥ 8 points)^[20] and computed tomography. For the diagnosis of HCC, we added the measurement of serum alpha-fetoprotein to the above diagnostic criteria for LC. Patients positive for antibodies to hepatitis C virus (HCV), antibodies to hepatitis D virus (HDV) and with a history of alcohol or drug abuse were excluded from the study. Patients treated with antiviral drugs (lamivudine or interferons) were also excluded from this study. Patients were observed every 1 to 3 mo or more frequently if required. Routine follow-up studies included clinical evaluation, conventional liver function tests for ALT, aspartate aminotransferase (AST), and γ -glutamyl transpeptidase (γ GTP) and serological markers of HBV infection including hepatitis B e antigen (HBeAg) and antibodies to HBeAg (anti-HBe). Ultrasound examination and computed tomography were done every 6-12 mo or more often if necessary. Hepatitis B surface antigen (HBsAg), HBeAg, and anti-HBe antibody were tested using commercially available enzyme immunoassays (EIA) (Enzygnost, Behring, Germany). Anti-HCV was assayed by a second-generation EIA (Ortho Diagnostics, Raritan, USA). Anti-HDV was examined by a commercially available EIA (Dinabot, Tokyo, Japan). HBV genotype was determined by the restriction fragment length polymorphism (RFLP) method on an S-gene sequence amplified by polymerase chain reaction (PCR) with nested primers, as previously described by Mizokami *et al.*^[21].

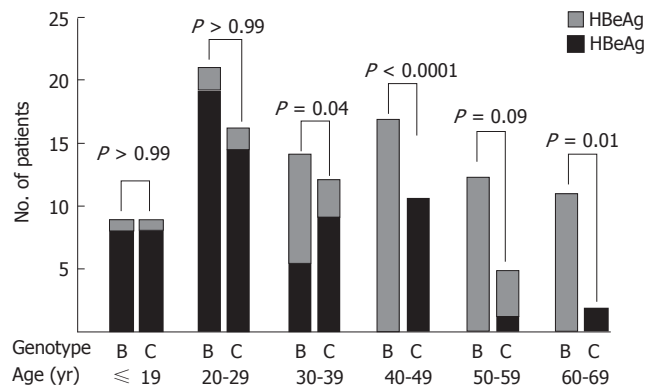

Figure 1 Age-specific HBeAg status at entry in the study in chronic hepatitis type B (CH-B)-infected patients with genotype B or C. Black box, HBeAg-positive patients; gray box, HBeAg-negative patients. Among the ≥ 30 yr old group, there are significantly more HBeAg-negative patients of genotype B than those of genotype C. In contrast, there are more HBeAg-positive patients in both groups, among the < 30 yr old group.

Statistical analysis

The chi-square test, Fisher's exact test, and Student's *t*-test were used to compare differences between groups, when appropriate. Cumulative developing rates of LC were calculated by the Kaplan-Meier method and differences were determined by the log rank test. In a multivariate analysis, the Cox proportional hazard model was employed to evaluate factors affecting development of LC. Statistical comparisons were done using SPSS for Windows version 11 package (SPSS Inc., Japan). All analyses were two sided, and *P*-values less than 0.05 were considered statistically significant.

RESULTS

Figure 1 shows age-specific HBeAg status at entry in the study for patients with CH-B infected with genotype B or C. For patients < 30 years old, most individuals were HBeAg-positive, and no difference was seen in HBeAg-positive rate between patients infected with genotype B and those infected with genotype C. However, for patients ≥ 30 years old, the majority of genotype C patients were positive for HBeAg, whereas most patients infected with genotype B were HBeAg-negative: no patient infected with genotype B showed a positive reaction for HBeAg in the age group greater than 40 years old. In addition, for patients > 50 years old, the percentage of patients infected with genotype B was increased. Since the proportion of patients positive for HBeAg was different between the group < 30 years old and that ≥ 30 years old, we divided the subjects into 2 groups (< 30 years old and ≥ 30 years old) to compare the natural course of CH-B in patients infected with genotypes B *vs* C (Table 1). There were no differences in LC development rates between genotypes B and C among the group < 30 years old using the Kaplan-Meier method and the log rank test ($P = 0.48$, Figure 2). In addition, when using the Cox proportional hazard model, which included HBeAg, gender, degree of fibrosis and genotype as associated variables, there was no significant

Table 1 Characteristics of patients with genotypes B and C

	< 30-yr-old group		≥ 30-yr-old group	
	Genotype B	Genotype C	Genotype B	Genotype C

^b $P < 0.0001$ vs genotype B in ≥ 30-yr-old group.

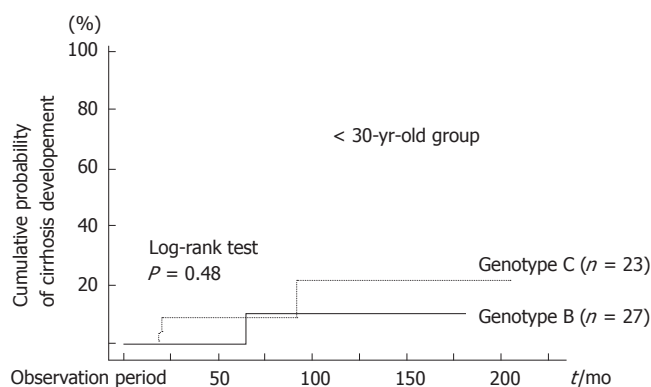

Figure 2 Comparison of cumulative probabilities of cirrhosis development between patients of genotypes B and C in the < 30 yr old group ($P = 0.48$, log-rank test). Multivariate analysis identified no significant predictors.

predictor for development of LC (Table 2). On the other hand, in the group ≥ 30 years old, only genotype was found to contribute to LC development by the Kaplan-Meier method: in fact, the rate was higher in patients infected with genotype C than in those infected with genotype B ($P = 0.002$, Figure 3). The Cox proportional hazard model also indicated that HBV genotype C was the only significant predictor of the development of LC (Relative risk 5.75; 95% CI: 0.033-0.916, $P = 0.039$, Table 2).

Patients who progressed to LC during the observation period are shown in Table 3. Eight patients progressed to LC in patients infected with genotype B. Five of these 8 patients were ≥ 40 years old at initial diagnosis, and all these 5 patients were HBe Ag-negative. Three patients < 30 years old who progressed to LC showed a positive reaction for HBeAg at enrollment. All 3 patients experienced a severe hepatic flare during the observation period and thereafter progressed to LC. However, following development of LC, they followed a benign clinical course of burn-out hepatitis: disappearance of HBeAg and persistently normal or nearly normal ALT levels. On the other hand, in the genotype C group, 8 of 12 patients who progressed to LC were 30-49 years old at initial diagnosis of CH, and 7 of the 8 patients were HBeAg-positive. These 8 patients rapidly progressed to LC within 2 to 8 years, and all of them were less than 50

LC: Liver cirrhosis.

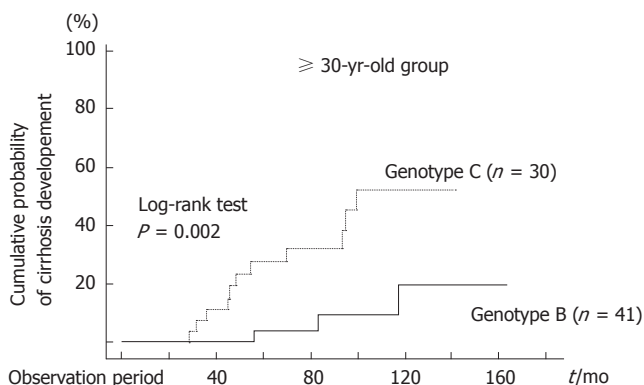

Figure 3 Comparison of cumulative probabilities of cirrhosis development between patients with genotypes B and C in the ≥ 30 yr old group ($P = 0.002$; log-rank test). A Cox proportional hazards analysis also indicated that genotype C was the only significant predictor (relative risk 5.75; 95% confidence intervals: 0.033-0.916, $P = 0.039$).

years old at the development of LC. Three of 8 patients died from HCC or liver failure shortly after development of LC, with periods ranging from 1 to 7 years.

DISCUSSION

In East Asia, most of HBV carriers are infected with genotype B or C^[2,5,22]. HBV genotype C is the predominant genotype in Japan, accounting for approximately 70% of HBV carriers living in Japan^[5].

The island Okinawa prefecture is located south-west of the main Japanese islands. Although people living in the Okinawa prefecture are Japanese, two-thirds of HBV carriers are infected with genotype B. In Okinawa prefecture, prevalence of HBsAg among blood donors is 3.5%, which is twice the average for all areas of Japan (1.5%), and is the highest in Japan (from the annual report of the Japanese Red Cross Center). In contrast, mortality rates due to cirrhosis and HCC associated with HBV infection are the lowest in Japan^[23,24]. This paradoxical phenomenon may be due to the fact that the majority of HBV carriers in Okinawa are infected with genotype B, and carriers of genotype B have a more benign clinical

M: Male; F: Female; e+: HBeAg-positive; e-: HBeAg-negative; LC: Liver cirrhosis; HCC: Hepatocellular carcinoma.

phenotype than those with genotype C (the predominant genotype in Japan).

In the present study, in the group < 30 years old, the majority of patients with CH-B were positive for HBeAg and the rate of positivity for HBeAg was not significantly different between patients infected with genotypes B and C. However, HBeAg was not detected in the majority of patients infected with genotype B in the group ≥ 30 years old. In contrast, most patients infected with genotype C were positive for HBeAg in the group ≥ 30 years old.

It has been reported that the seroconversion rate of HBeAg was higher in CH patients infected with genotype B than those infected with genotype C^[6,25,26]. However, in this study, LC development rate were not significantly different between patients with genotypes B and C in the group < 30 years old. Only one CH patient infected with genotype C progressed to LC during the observation period, whereas LC developed in 3 patients infected with genotype B. Therefore, prognoses of CH patients infected with genotypes B and C were comparable in the group < 30 years old. In contrast, LC development rate among CH patients infected with genotype C was significantly higher than that of genotype B in the group ≥ 30 years old. These patients progressed to LC within a short period of time after diagnosis of CH. In the group ≥ 30 years old, there was a significant difference in prevalence rates of HBeAg between patients infected with genotypes B and C. Therefore, it was presumed that difference in LC developing rate between genotypes B and C was responsible for differences in HBeAg positive rates. However, only genotype C was a significant predictor for development of LC using the Cox proportional hazard model, while HBeAg was not a significant predictor.

Among the 55 patients infected with genotype B in the group ≥ 30 years old, 5 were HBeAg positive at initial

diagnosis of CH. These 5 patients didn't progress to LC during the observation period (data not shown). Further stratification of the patients according to HBeAg status showed that development of LC was more frequently seen in patients infected with genotype C than in those with genotype B in the group ≥ 30 years old. As mentioned above, difference in prognosis between genotypes B and C was significantly different. In particular, prognosis was very poor if patients were infected with genotype C, were positive for HBeAg, and were ≥ 30 years old. Therefore, we believe that antiviral therapy (lamivudine, adefovir dipivoxil or entecavir) is beneficial if patients are ≥ 30 years old, positive for HBeAg and infected with genotype C.

Kao *et al.*^[26] reported that among 270 chronic HBV carriers in Taiwan, 53% belonged to genotype B and 32% to genotype C. Genotype C was significantly more common in patients with LC and/or HCC who were older than 50 years, when compared to age-matched inactive carriers, suggesting that genotype C was associated with more severe liver diseases. However, genotype B was more frequently seen in younger patients (< 35 years old) with HCC, most of whom did not have LC. While Kao *et al.* showed that genotype C was associated with poor prognosis in older age groups, as confirmed in our study, the predominance among younger patients with HCC in genotype B was quite different. These discrepancies may be responsible for differences in subgenotypes among patients infected with genotype B between Taiwan and Okinawa. Sugauchi *et al.* determined subgenotypes among 274 carriers of HBV infected with genotype B and reported that all 177 genotype B isolates from the carriers living in Asian countries other than Japan belong to the genotype Ba^[27,28]. On the contrary, they also reported that of the 97 carriers infected with genotype B living in Japan, only 7 (7%) possessed genotype Ba, and that the remaining majority was of genotype Bj without recombinations. In addition, it has been reported that loss of HBeAg occurs earlier and is more frequent in carriers of genotype Bj than genotype Ba or genotype C, particularly after they have reached 30 years or older^[27,28]. In this study, not all patients with genotype B were subgenotyped, but approximately 80% of them were infected with genotype Bj. Therefore, it is possible to speculate that differences in subgenotypes of HBV genotype B isolates may be responsible for differences in the natural course of patients infected with genotype B between Taiwan and Okinawa.

In this study, development of LC was commonly seen in patients with genotype B, and the majority of patients were HBeAg-negative at initial diagnosis of CH. Most of HBV carriers infected with genotype B seroconverted from HBeAg to anti-HBe under 30 years old and became HBeAg-negative inactive carriers^[5,16]. Status of HBeAg and anti-HBe antibody correlated with mutations in pre-core lesions^[29,30]. Most patients infected with genotype B showed the pre-core mutation before 30 years old, stopping HBeAg production, followed by reduction in HBV-DNA level^[5]. However, after clearance of HBeAg, CH occurred in some patients, and occurrence was associated with increase in serum HBV-DNA level. HBeAg-negative CH was more frequently seen in patients

infected with genotype B compared with genotype C. LC developed in some patients with genotype B, the majority of whom were ≥ 40 years old at diagnosis of CH. Therefore, CH-B has to be treated in consideration of the above described natural course of HBV infection. We believe that antiviral therapy (lamivudine, adefovir dipivoxil or entecavir) is highly recommended for the following patients: (1) HBeAg-positive CH infected with genotype C aged ≥ 30 years; (2) HBeAg-negative CH infected with genotype B aged ≥ 40 years, especially if showing advanced fibrosis (F2 or F3).

In conclusion, when HBeAg-positive CH-B was diagnosed in the group ≥ 30 years old, the rate of development of LC was higher in patients infected with genotype C than in those with genotype B. Therefore, we believe that these cases should be treated with antiviral drugs. In addition, development of LC is not rare in patients infected with genotype B if HBeAg-negative CH occurs at ≥ 40 years of age.

ACKNOWLEDGMENTS

We thank Dr. Hiroki Nakasone for his helpful discussion and suggestions.

COMMENTS

Background

Chronic infection by hepatitis B virus (HBV) causes various liver diseases. HBV genotypes are classified into 8 groups, from A to H. Genotypes B and C are predominant in Asia and > 90% of chronic carriers show genotype C, which is associated with poor prognosis. However, prior studies showed that association of genotype C with advanced liver disease was not seen in patients over 50 years old.

Research frontiers

HBV genotypes, distributed differently in the world, influence disease severity and clinical outcomes. Therefore, studies of genotypes have been thoroughly investigated to improve disease outcomes.

Innovations and breakthroughs

Prior studies showed that infection with genotype C was associated with poor prognosis. This study has focused on different age groups of chronic hepatitis B for different influences of genotype B and C and unveiled the age-specific natural course of the disease.

Applications

This study has clearly shown the age-specific natural course of the chronic hepatitis B with genotype B and C in Japan. These results should be helpful for determining the indication of antiviral drugs.

Terminology

HBV genotype: HBV genotypes are classified into 8 groups, from A to H, according to differences in base sequences greater than 8%, and are differently distributed in the world. In Japan, genotypes B and C are predominant as in other Asian countries, but > 90% of chronic carriers show genotype C.

Peer review

This population study by Maeshiro and colleagues describes the natural history of chronic hepatitis B of genotypes B and C. A moderate number of patients were seen over a long time period of 28 years and an even lower number of 121 patients was included in the analysis. Nevertheless, the study shows strong evidence for a higher progression rate towards cirrhosis for patients infected with HBV genotype C. This phenomenon was associated with a lower HBe conversion rate in genotype C patients.

Abstract

AIM: To establish an ideal model of multiple organ injury of rats with severe acute pancreatitis (SAP).

METHODS: SAP models were induced by retrograde injection of 0.1 mL/100 g 3.5% sodium taurocholate into the biliopancreatic duct of Sprague-Dawley rats. The plasma and samples of multiple organ tissues of rats were collected at 3, 6 and 12 h after modeling. The ascites volume, ascites/body weight ratio, and contents of amylase, endotoxin, endothelin-1 (ET-1), nitrogen monoxidum (NO), phospholipase A₂ (PLA₂), tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6) in plasma were determined. The histological changes of multiple organs were observed under light microscope.

RESULTS: The ascites volume, ascites/body weight ratio, and contents of various inflammatory mediators in blood were higher in the model group than in the sham operation group at all time points [2.38 (1.10), 2.58 (0.70), 2.54 (0.71) *vs* 0.20 (0.04), 0.30 (0.30), 0.22 (0.10)

INTRODUCTION

Severe acute pancreatitis (SAP) is an acute clinical disease, featuring acute onset, rapid progression, high incidence of complications and high mortality. Its pathogenesis has still not been fully elucidated till now. There is also no ideal therapy. It is quite worthwhile to rely on a SAP animal model to strengthen the study of pathogenesis and treatment of SAP. There are many requirements on an ideal SAP experimental animal model. There should be simple and reliable methods, and a low cost and high achievement ratio. The pathological changes, progression and response to treatment of the model also should be similar to those of the human body. In this study, SAP animal models were induced by retrograde injection of 3.5% sodium taurocholate into the biliopancreatic duct of

Sprague-Dawley (SD) rats. The feasibility and significance of the model were studied. And the preparation methods for an ideal model of SAP rats with multiple organ injury were established.

MATERIALS AND METHODS

Experimental animals

Ninety clean grade healthy male SD rats with a body weight of 250-300 g were purchased from the Experimental Animal Center of Zhejiang Medical School.

Experimental drugs and reagents

Sodium taurocholate and sodium pentobarbital purchased from USA Sigma Company. Dexamethasone injection purchased from Zhejiang Xinchang Pharmaceutical Company. The full automatic biochemical analyzer was used to determine the plasma amylase level (U/L). Plasma endotoxin tachypleus amebocyte lysate kit was purchased from Shanghai Yihua Medical Science and Technology Corporation (Institute of Medical Analysis in Shanghai), the calculation unit for content is EU/mL. The serum nitrogen monoxidum (NO) kit was purchased from Nanjing Jiancheng Bioengineering Research Institute, the calculation units for content is $\mu\text{mol/L}$. TNF- α ELISA kit was purchased from Jingmei Bioengineering Corporation, the calculation unit for content is pg/mL (ng/L). The serum secretory phospholipase A₂ enzyme Assay ELA kit (phospholipase A₂) was purchased from R&D system Ins and the calculation unit for content is U/mL. The serum Endothelin-1 ELA kit (Endothelin-1) was purchased from Cayman chemical company (Catalog Number: 583151) and the calculation unit for content is ng/L (pg/mL). The above determinations were all operated according to the instructions of the kits.

Experimental methods and groups

The experimental rats were randomly assigned to the model group and control group (45 rats/group). The Aho's method was adopted and the SAP rats of model group were prepared by retrograde injection of 3.5% sodium taurocholate into biliopancreatic duct through segmental eqidural catheter *via* duodenal papilla. Another 45 rats were assigned to the sham operation group where only exploratory laparotomy was performed. The above-mentioned groups were then divided into 3, 6 and 12 h group, with 15 rats in each group. The following steps were performed at 3, 6 and 12 h after operation: (1) Rat mortality of all groups was observed. Then the rats were sacrificed in batches. The ascites/body weight ratio was observed. (2) The samples of pancreas, lung, liver, kidney, terminal ileum, ileocecal junction lymphonode, thymus, myocardium and brain were collected and their pathological changes were observed. (3) After collecting blood from the heart, the ascites volume, ascites/body weight ratio and contents of amylase and endotoxin in plasma and contents of endothelin-1 (ET-1), nitrogen monoxidum (NO), phospholipase A₂ (PLA₂), tumor necrosis factor- α (TNF- α) and IL-6 in serum were determined.

Animal model preparation

Fasting with water restraint was imposed on all rat groups 12 h prior to the operation. The rats were anesthetized by intraperitoneal injection of 2% sodium pentobarbital (0.25 mL/100 g) after which lay and fixed the rats, and performed the routine shaving, disinfection and draping.

Model group: after entering abdomen *via* median epigastrium incision, confirmed the bile-pancreatic duct and hepatic hilus common hepatic duct, disclosed the pancreas, identified the duodenal papilla inside the duodenum duct wall, and then used a No. 5 needle to drill a hole in the mesenterium avascular area. After inserting a segmental eqidural catheter into the duodenum cavity *via* the hole, inserted into the bile-pancreatic duct toward the direction of papilla in a retrograde way, used the microvascular clamp to nip the catheter head temporarily and meanwhile used another microvascular clamp to temporarily occlude the common hepatic duct at the confluence of hepatic duct. After connecting the eqidural catheter end with the transfusion converter, transfused 3.5% sodium taurocholate 0.1 mL/100 g by retrograde transfusion *via* the microinjection pump at the speed of 0.2 mL/min. Stayed for 4 min after injection and removed the microvascular clamp and epidural catheter. After checking for bile leakage, sutured the hole in the duodenum lateral wall. Used the disinfected cotton ball to absorb up the anesthetic in the abdominal cavity and close the abdomen.

Statistical analysis

The statistical analysis was conducted to the arranged experimental results by applying the SPSS11.5 software. The Kruskal-Wallis test or variance analysis (only applied to PLA₂) was applied to the two-group comparison. The Bonfferoni test was also applied to comparison. There are statistical significances when $P \leq 0.05$.

RESULTS

Survival

Model group: Mortality respectively was 0% (0/15), 0% (0/15) and 13.33% (2/15) at 3, 6 and 12 h. The sham operation group survived at all time points with 100% survival.

Comparison of ascites volume

The volume was higher in model group than in sham operation group at all time points ($P < 0.001$) (Table 1).

Comparison of ascites/body weight ratio

The coefficient was higher in model group than in sham operation group at all time points ($P < 0.001$) (Table 2).

Comparison of amylase and endotoxin in plasma and NO, PLA₂, TNF- α and IL-6 in serum

The contents were higher in model group than in sham operation group at all time points ($P < 0.001$) (Table 3).

Comparison of serum ET-1 contents

The content was higher in model group than in sham operation group at all time points ($P < 0.01$) (Table 3).

Pathological changes of multiple organs

Pathological changes of pancreas: (1) Sham operation group, Gross changes: Pancreas, fat surrounding pancreas and epiploon were normal at all time points after operation. Changes under light microscope: Most cases were normal. Mild interstitial edema was found in very few cases and neutrophil infiltration was seen by chance. There was no necrosis and hemorrhage of acinar cell and fat (Figure 1 A1). (2) Model group, Gross changes: The level of gross pathological changes and changes under light microscope was higher in pancreas tail than in pancreas head. The severity of all pathological changes aggravated with time after modeling. Edema, hemorrhage and necrosis appeared in the pancreas 5 min after inducing models. There were small amounts of ascites, slightly hemorrhagic in most cases, congestion and edema of the pancreas, and hemorrhage and necrosis in some cases at 3 h. The ascites was hemorrhagic in most cases at 6 and 12 h. And the average volume was higher at 6 and 12 h than that at 3 h. The severity of edema, hemorrhage and necrosis was higher at 6 and 12 h than at 3 h, with many saponification spots in epiploon and peritoneum surrounding pancreas, gel like change and contour disappearance of pancreas, and significant hemorrhage and necrosis (Figure 1 B1). Changes under light microscope: The severity of all pathological changes aggravated with time after modeling.

There were visible interstitial congestion and edema, mild inflammatory cell infiltration, focal necrosis and mild interstitial hemorrhage in pancreas at 3 h, with lamellar necrosis and hemorrhage in some cases. There were interstitial congestion and edema, focal or lamellar necrosis and hemorrhage, more inflammatory infiltration in pancreas at 6 h. There were interstitial edema and hemorrhage, massive necrosis and hemorrhage, damaged lobule contour and massive inflammatory cell infiltration in pancreas at 12 h.

Pathological changes of lung: (1) Sham operation group: Gross changes: The color and morphous of both sides of lung were normal without bleeding point on surface or effusion in thoracic cavity. Changes under light microscope: The structure was normal in most part of lung. There were mild interstitial edema and mild inflammatory cell infiltration in a very small part. (2) Model group: Gross changes: 3 h: There were congestion and edema in pulmonary lobes of both sides, madder red bleeding points on surface of local pulmonary lobes, mild amber effusion in thoracic cavity; 6 and 12 h: There were pathological changes of both sides of lung aggravating with time after molding, prunosus plaque on lung surface, more hemorrhagic effusion in thoracic cavity. Changes under light microscope: There was edema of the lung interstitium and alveolar space, broadened alveolar wall interstitium, inflammatory cell infiltration, telangiectasis and congestion of alveolar wall, and broadened alveolar septum; 6 and 12 h: There were increased range of pathological changes of pulmonary lobes and effusion in alveolar space, edema and hemorrhage of interstitium and alveolar space, broadened alveolar septum, inflammatory cell infiltration, and lucent kytoplasm of epithelial cell in local tunica mucosa bronchiorum (Figure 1 A2 and B2).

Pathological changes of liver: (1) Sham operation group: Gross changes: The color of liver was normal without visible swelling. Changes under light microscope: There were normal hepatic tissue, mild inflammatory cell infiltration in portal area, normal morphous of hepatic cell in most cases, acidophilia denaturation in some cases, and mild dilation and congestion of sinus hepaticus in few cases (Figure 1 A3). (2) Model group: Gross changes: 3 h: There were mild liver swelling, local gray plaque in local liver of individual rats, obscure boundary; 6 and 12 h: There were pale and muddy color and congestion of

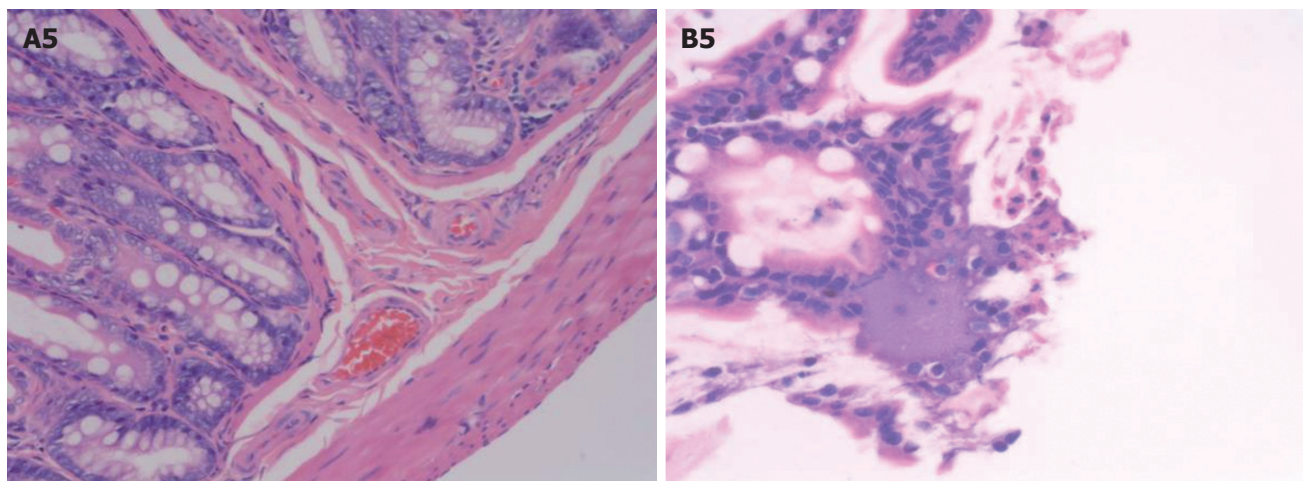

Figure 1 A1: Normal pancreas, HE, × 200; B1: Hemorrhage and necrosis of pancreatic acinus and fatty tissue, HE, × 400; A2: Normal lung in sham operation group at 12 h, HE, × 400; B2: Lung (effusion in alveolar space) in model group at 12 h, HE, × 200; A3: Normal liver, HE, × 400; B3: Massive necrosis of hepatic cell, HE, × 200; A4: Normal kidney, HE, × 400; B4: Scattered necrosis in epithelium of renal tubule, HE, × 200; A5: Normal ileum, HE, × 400; B5: Flossy necrosis of intestinal mucosa, HE, × 400.

the liver, irregular gray plaque or necrosis in local area. Changes under light microscope: 3 h: There were hepatic cell swelling or acidophilia denaturation, inflammatory cell infiltration in portal area, dilation and congestion in sinus hepaticus, scattered spotty necrosis in hepatic lobule; 6 h: There were visible hepatic cell swelling, increased range and area of hepatic cell necrosis, focal or massive hemorrhagic necrosis, inflammatory cell infiltration in necrotic focus, congestion in partial sinus hepaticus, bile duct proliferation in portal area and scattered necrosis of single cell (condensation and break of nucleus); 12 h: There were damaged hepatic lobule structure, further increased range and area of hepatic cell necrosis, inflammatory cell infiltration in lobule and/or portal area, congestion in sinus hepaticus (Figure 1 B3).

Pathological changes of kidney: (1) Sham operation group: Gross changes: The morphous of the kidney was normal without swelling, with no bleeding points on surface of renal cortex. Changes under light microscope: There were normal structure of renal glomerulus, tubule and interstitium in most rats, and blurry boundary of epithelial cell of renal tubule (especially proximal tubule), stegnosis and atresia of lumens, congestion of renal glomerulus and interstitial edema in few rats (Figure 1 A4). (2) Model group: Gross changes: There was no gross change in kidney at 3 h. There were kidney swelling, tension of renal envelope, scattered bleeding points on surface of renal envelope of rats, and slightly hemorrhagic urine in pelvis in severe cases at 6 and 12 h. Changes under light microscope: 3 h: There were capillary congestion of renal glomerulus, swelling, scattered necrosis and blurry boundary of renal tubule epithelial cell, stegnosis or atresia of lumens, visible protein cast, interstitial edema and inflammatory cell infiltration. 6 and 12 h: There were capillary congestion of renal glomerulus, swelling and scattered necrosis of epithelial cell of renal tubule, interstitial edema and inflammatory cell infiltration. The floss and red cell with eosinophilic staining were found in renal glomerulus and so was homogen or red cell cast with

eosinophilic staining in renal tubule. There were lumens dilation of medulla renal tubule and atrophica of epithelial cell. The pathological changes aggravated with time. There was lamellar necrosis of epithelial cell of renal tubule in few rats (Figure 1 B4).

Pathological changes of ileum: (1) Sham operation group, Gross changes: There was no intestinal dilation or congestion or edema of intestinal wall. The surface of intestinal mucosa was smooth without pathological changes such as hemorrhage and ulcer. Changes under light microscope: The structure of epithelium and microvillus of intestinal mucosa was integrated without exfoliation or necrosis. Edema of proper layer, submucous layer and placenta percreta was found in few cases. Focal necrosis of mucosa and inflammatory cell infiltration of proper layer, submucous layer and placenta percreta were found in very few cases (Figure 1 A5). (2) Model group, Gross changes: There was no intestinal change at 3 h. Visible intestinal dilation was found at 6 and 12 h with retention of certain amount of gas and liquid, congestion and edema of intestinal wall and bleeding points on surface of intestinal mucosa. Small focus of mucosal ulcer was found in severe cases. Changes under light microscope: Focal necrosis of ileum mucosa and inflammatory cell infiltration in various mucosa layers were found in most rats. There were visible congestion edema of proper layer of intestinal mucosa, dilation of central chyle vessel, exuviations of microvillus top of epithelium of intestinal mucosa and disordered structure arrangement at 6 and 12 h (Figure 1 B5).

Pathological changes of lymphonode: The morphous and structure of lymphonode were normal in sham operation group and swelled in model group with lymphonode swelling, dilation of follicle germinal center of lymphonode and lymphatic sinus, sinus cell hyperplasia, and frequently spotty necrosis in germinal center of folliculus lymphaticus. Infiltration of neutrophil and plasmocyte was found only in few cases.

Pathological changes of thymus: (1) Sham operation group: The histological findings of thymus at 3, 6 and 12 h were consistent. There were normal structure of thymus, clear boundary between cortex and medulla, about 2-1:1 of thickness ratio of cortex and medulla, visible lobule, integrated envelope, “starry sky” changes in few epithelial cells of cortex, and condensed dark purple blue nucleus. There were more epithelial reticular cell slightly stained in medulla, in star shape and with many prominences, large nucleus and rich kytoplasm. The structure was looser in medulla than in cortex. Slightly stained nucleus of epithelial cell was found only in few cases and epithelial cell was “vacuole” in individual cases. (2) Model group: The cortex was gradually thinned and expanded compared with medulla at 3, 6 and 12 h. There were “starry sky” epithelial cell, nuclear fragmentation and reduced amount of lymphocytes. The nucleus of epithelial cell in medulla was slightly stained. There were more “vacuole” epithelial cells in model group than in normal group.

Pathological changes of myocardium: (1) Gross changes: Normal manifestation and no visible change of appearance in all groups. (2) Changes under light microscope: The transverse striation of cardiac muscle fiber was clear in all cases. There was no abnormal cardiac muscle fiber in sham operation group. The fiber was normal in most cases of model group. But one case of blurry transverse striation of cardiac muscle fiber occurred at 3 h in model group. Granulation or lyses of muscle plasma of cardiac muscle fiber was found in 2, 3, 5 rats respectively at 3, 6 and 12 h. Mild inflammatory cell infiltration of myocardium interstitium and epicardium was found in one case of each group respectively at 3 h.

Pathological changes of brain: (1) Gross changes: Normal manifestation and no visible change of appearance in all groups. (2) Changes under light microscope: The pathological changes were almost invisible. The mild swelling of neuron was found in 2, 2, 3 rats of model group at 3, 6 and 12 h. Other rats were normal.

DISCUSSION

At present, preparation of SAP animal model is still the main method for study of SAP pathogenesis and evaluation of therapeutic effects of drugs. Therefore, many researchers have designed and carried out a great deal of animal experiment studies. The most commonly used living SAP animals are induced by puncture injection of biliopancreatic duct^[1-4], injection under capsula pancreatic^[5], ligation of pancreatic duct^[6], loop close of duodenum^[7], biliopancreatic duct injection in combination with intravenous infusion^[8] and intraperitoneal injection^[9-11]. In addition, the drugs most frequently used to induce SAP model are sodium taurocholate^[12,13] that is most popular, glycodeoxycholic acid, bombesin combined with lipopolysaccharide^[14,15], and L-arginine^[16-18]. The rat

is most frequently used. Although the above methods and drugs can successfully induce SAP model, they cannot sufficiently control the severity of pathological changes of pancreas and injury of non-pancreas organs. Therefore, it is difficult for them to accommodate the therapeutic effects and mechanism of drugs evaluated. In addition, the experimental result also will be influenced by the inconsistency of severity and range of pathological changes in pancreas and multiple non-pancreas organs in SAP models induced by the same method. Sometimes a completely opposite conclusion will be obtained. Therefore, it is necessary to establish a reliable and stable SAP model with high achievement ratio that should correctly reflect the pathological changes in pancreas and multiple non-pancreas organs during SAP and aid the evaluation of therapeutic effects.

Aho *et al*^[1] first reported the SAP rat induction by retrograde injection of 5% sodium taurocholate through puncture of biliopancreatic duct in 1980. The method is a classic model preparation method extensively applied^[19-21]. The principle of its preparation is based on the theory of bile reflux. The rat SAP will be induced directly by injuring pancreatic tissue or activating endogenous pancreatin after retrograde injection of sodium taurocholate into biliopancreatic duct. Compared with other models, this method can induce the pathological changes including blood supply disturbance of microcirculation, edema, hemorrhage and necrosis of pancreatic tissue, quite similar to the pathological features of human bile reflux pancreatitis. However, it was found in our experiment that this method could cause serious surgical trauma, blood loss and high mortality. There were also problems including unsatisfactory model induction and insensitivity to medicine intervention due to biliary fistula in biliopancreatic duct, *etc.*

Therefore, in our experiment, SAP rats were induced by retrograde minipump injection of 3.5% sodium taurocholate *via* duodenal papilla using segmental eqidural catheter, which was based on Aho method. The “reflux” of sodium taurocholate due to injection using common injector has been reduced in this experiment where segmental eqidural cathete with diameter consistent with that of biliopancreatic duct was applied. The degree and range of edema, hemorrhage and necrosis due to minipump injection of sodium taurocholate are similar to those of human since this method with even pressure can distribute sodium taurocholate in rat pancreatic tissue evenly. The pancreatic injury due to sodium taurocholate, a cytotoxic substance, is dose dependent. Acute pancreatitis models of various severities can be prepared by controlling the concentration of the drug. 5% concentration of inducing dosage was most frequently used in past reports. After years of study, we found relatively severe pancreatitis models would be induced and many pathological changes of multiple organs were irreversible under this concentration, resulting in short survival time, high mortality and insensitivity to SAP medications or other therapies. Therefore, 3.5% sodium taurocholate

(0.1 mL/100 g) was adopted in our study. Certain mortality was observed in model group. The contents of amylase, ascites volume and various inflammatory mediators in plasma were higher in model group than in sham operation group at 3, 6 and 12 h ($P < 0.01$). Various severities of multiple organ injury were also found in model group. The severity was time dependent. The pathological changes were most significant and severe at 12 h in model group but these reversible changes could be significantly changed after medication. It can be used to simulate the multiple organ injury complicated with SAP patients.

Therefore, this model with pathogenesis, pathological changes, etc similar to clinical SAP is helpful for studies on pathogenesis and therapy of multiple organ injury. This rat SAP inducing method that can induce ideal animal models for empirical studies features small trauma, convenient operation and high achievement ratio. The multiple organ injury occurring at early stage of rat SAP is not severe and reversible. It can be used for evaluation of therapeutic effect. We hope this method could be brought into full play by other researchers.

COMMENTS

Background

Severe acute pancreatitis (SAP) is an acute disease, but there is no ideal therapy. It is quite worthwhile to rely on SAP animal model to strength the study on pathogenesis and treatment of SAP.

Research frontiers

There are many requirements on an ideal SAP experimental animal model. There should be simple and reliable methods, low cost and high achievement ratio. The pathological changes, progression and response to treatment of the model also should be similar to those of human body.

Innovations and breakthroughs

In this study, the feasibility and significance of the SAP animal model were studied. And the preparation methods for an ideal model of SAP rats with multiple organ injury were established. This model with pathogenesis, pathological changes, etc similar to clinical SAP is helpful for studies on pathogenesis and therapy of multiple organ injury.

Applications

This rat SAP inducing method that can induce ideal animal models for empirical studies features small trauma, convenient operation and high achievement ratio. The multiple organ injury occurring at early stage of rat SAP is not severe and reversible. It can be used for evaluation of therapeutic effect. We hope this method could be brought into full play by other researchers.

Terminology

Severe acute pancreatitis (SAP) is a fatal systemic disease featuring acute onset, serious conditions, high incidence of complications and 20%-30% of mortality.

Peer review

This is a very interesting paper. Title reflects the major contents of the article. Abstract gives a clear delineation of the research background, objectives, materials and methods, results (including important data) and conclusions. Methods are innovative and systemic. The statistical methods used are appropriate. The results provide sufficient experimental evidences. Discussion is well organized and an overall theoretical analysis is given. The conclusions are scientifically reliable and valuable.

Abstract

AIM: To evaluate whether a higher prevalence of *Giardia lamblia* infection is associated with an increase in irritable bowel syndrome (IBS) prescriptions at the county level in Michigan.

METHODS: The Michigan Disease Surveillance System (MDSS) was used to ascertain both the numbers of *Giardia lamblia* infections as well as the total number of foodborne illnesses per population by county in Michigan during 2005. This was compared with Blue Cross Blue Shield (BCBS) of Michigan numbers of drug prescriptions for IBS per one thousand members per county in 2005. These data were also analyzed for associations with per capita income by county and the number of refugees entering each county in 2005.

RESULTS: There were a total of 786 confirmed cases of *Giardia lamblia* reported to MDSS in 2005. During the same time period, the number of prescriptions for IBS varied from 0.5 per 1000 members up to 6.0 per 1000 members per month. There was no trend towards higher numbers of IBS prescriptions in the counties with more *Giardia lamblia* infections. Per capita income was not associated with either IBS prescriptions or Giardiasis. There was a significant linear association between the number of refugees entering each county, and the number of *Giardia lamblia* cases per 100 000 population.

CONCLUSION: In this ecological study, there was no association found between BCBS prescriptions for IBS and *Giardia lamblia* infections in Michigan counties. Our findings may have been influenced by the disparate number of refugees admitted per county.

INTRODUCTION

Giardia lamblia is a multi-flagellate protozoa which can cause symptoms of abdominal discomfort, bloating, diarrhea and mucus, but not blood in the stools^[1]. The cyst form is resistant to cold weather and chlorination^[2]. It is spread by the fecal-oral route, and is most commonly diagnosed in young children, especially in day-care centers, where the prevalence has been found to be as high as 35%^[1]. The incidence is also increased in men who have sex with men, and in immigrants from developing countries^[3]. The FDA (Food and Drug Administration) estimates a probable 2% annual Giardiasis attack rate in the United States (US) population^[4] although substantially fewer infections are diagnosed. The Center for Disease Control (CDC) recorded 18 126 infections in 2005 in the US as a whole^[5], for an incidence of approximately 0.006%. This would imply that the vast majority of infections are asymptomatic, symptomatic but not brought to the attention of the medical community, or symptomatic and misdiagnosed.

Irritable bowel syndrome (IBS) is a diagnosis of exclusion. The Rome criteria specify three months of abdominal discomfort, unrelated to a physiologic or biologic cause, which can be associated with bloating, constipation, diarrhea or mucus^[6]. These symptoms overlap with many other gastrointestinal illnesses, such as inflammatory bowel disease, lactose intolerance, gastrointestinal cancers and parasitic diseases^[6], including Giardiasis, which also can become chronic.

By definition, patients with IBS do not have a physiologic cause for their illness, but some studies have shown that a significant number of patients who have been

given the diagnosis of IBS do indeed have infection with *Giardia lamblia*^[7-9]. Likewise, a study of 100 consecutive patients in an outbreak of Giardiasis in Italy found that 82% of these patients met the Rome criteria for IBS, including the chronicity of symptoms^[10]. Other authors have described a syndrome of post-infectious IBS due to either bacterial or parasitic etiologies^[11,12]. Recent research has shown a similar association between the initiation of celiac disease, and the number of previous rotavirus infections in children^[13]. Further evidence of a possible connection between parasitic disease and IBS is that treatment with metronidazole, an anti-parasitic medication, has been shown to decrease symptoms of IBS^[14-16].

The current study was undertaken to determine whether there might be a causal relationship between current or past *Giardia lamblia* infection and the prevalence of IBS. To test this, we assessed whether a higher county level prevalence of IBS prescriptions is associated with a higher incidence of *Giardia lamblia* infections in Michigan counties.

MATERIALS AND METHODS

Michigan initiated an electronic surveillance system for communicable diseases in 2004, called the Michigan Disease Surveillance System (MDSS). Local health departments, the Michigan Bureau of Laboratories, and some of the larger private laboratories enter data directly into the system over the internet. Giardiasis is a reportable disease in Michigan, and the local health departments use MDSS to track their cases. This system ensures that MDSS captures all of the reported cases of *Giardia lamblia* in Michigan. The aggregate information is made available to the CDC, as well as to the local health departments. The number of cases can be analyzed by time, demographics and geographic location. The date of onset of illness was used for inclusion when available, and the date of referral was used when date of onset was not known. Only the confirmed, completed cases in 2005 were counted. The rate per 100 000 people was obtained by dividing the number of cases per county, by population in each county, obtained from the 2005 United States census estimates.

Blue Cross Blue Shield (BCBS) of Michigan maintains a record of all prescriptions filled for its members, which includes the address and county of each member. Information on the number of members over a particular time period is also available, broken down by county. This was used to obtain a rate of prescriptions per 1000 members per month in 2005. Three medications were included in this study, dicyclomine (Bentyl), tegaserod (Zelnorm) and alosetron (Lotronex). These three medications were chosen because their only approved indication is the treatment of IBS. Prescription information was used in lieu of IBS diagnoses because there is no current registry of IBS patients in Michigan.

Per capita income data were obtained from the US census for 2000. Refugee numbers were provided by the Office of Refugee Services of the Michigan Department of Human Services.

A database was constructed containing information on *Giardia lamblia* cases by county. This was linked with

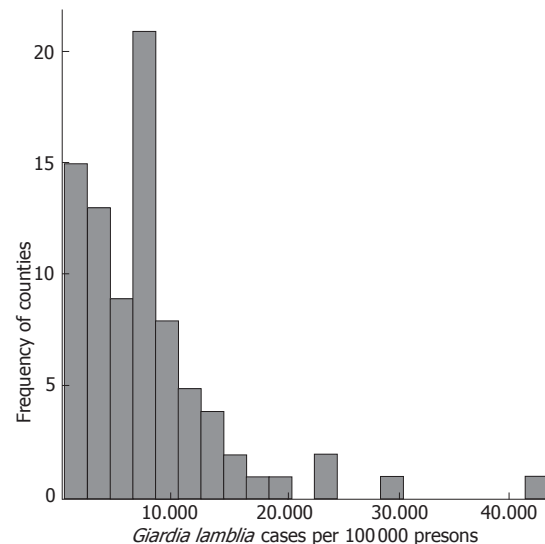

Figure 1 Frequency of Michigan counties by *Giardia lamblia* incidence in 2005.

information on the population of each county, to obtain a rate per 100 000 people. Next, the IBS prescription rates by county were added to the database, followed by per capita income and numbers of refugees admitted. Finally, the rate of foodborne illness by county was placed in the database, which was then cleaned and coded.

Descriptive statistics were used to assess frequencies and distributions of variables. Univariate regression was performed to assess relationships between IBS prescriptions and foodborne illness, IBS prescriptions and per capita income, and between *Giardia lamblia* and IBS prescriptions, refugees, foodborne illness, and per capita income. SPSS version 11.5 was used for all data analyses.

RESULTS

The total number of *Giardia lamblia* cases in Michigan, which has 83 counties, was 786 in 2005, which was down from 980 in 2000, but up from 733 in 2004, the year MDSS was introduced. Ingham County had 121 cases of Giardiasis in 2005, which gave it the highest incidence of 0.043%, which is about seven times the national average. Fourteen counties had no cases reported in 2005. The mean number of cases per county was 9.6, and the median was 3. The graph of incidence for each county by frequency was right-skewed (Figure 1). There were 362 (46%) female cases and 420 (53%) male cases with 4 unknown. One hundred and thirty-eight cases were children ≤ 4 years, and 89 were children between 5 and 9 years, for a total of 227 (29%) of the cases. There was another spike between ages 30 and 44 with a total of 184 (23%) cases. The number of cases gradually decreased after age 44 (Figure 2). The majority (51%) of cases were among 402 European Americans, with only 57 (7%) African Americans, 31 (4%) Asian Americans and 3 (< 1%) Native Americans. Race was not specified for 293 (37%) cases. Of the 393 whose ethnicity was known, 37 (9%) were Latino, and 356 (91%) were non-Latino.

The number of BCBS prescriptions for IBS per 1000 members per month in 2005 was much less variable

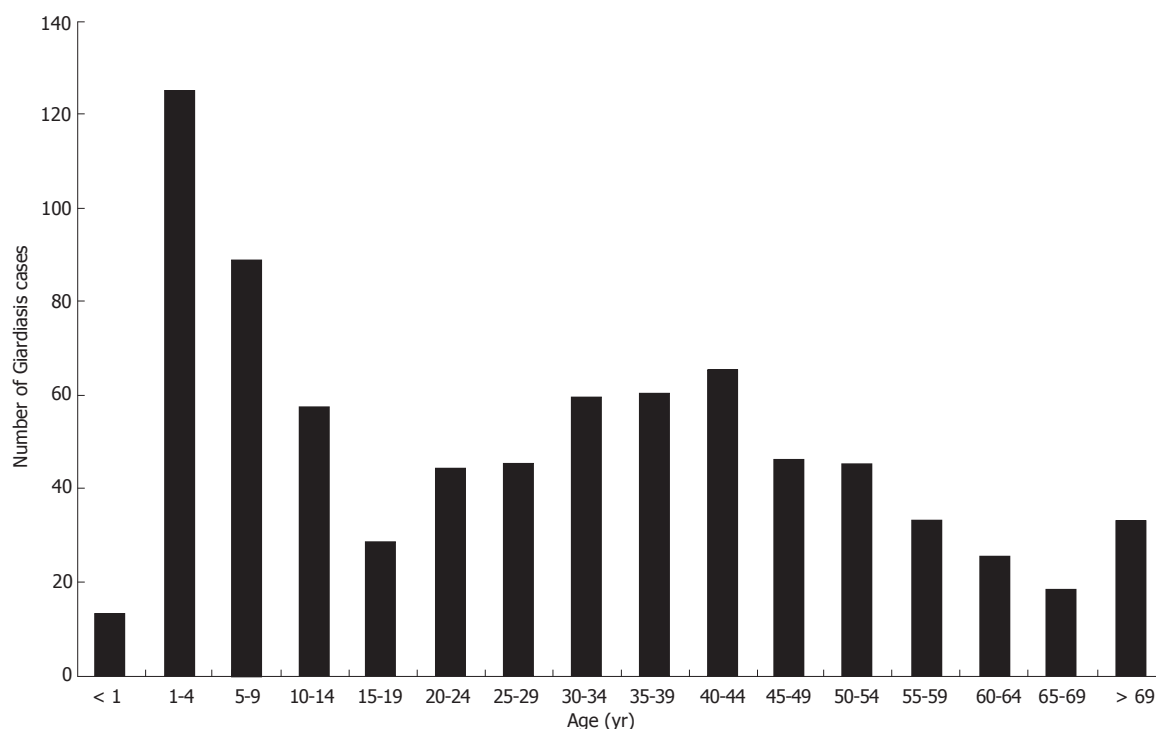

Figure 2 Michigan *Giardia lamblia* cases by age in 2005.

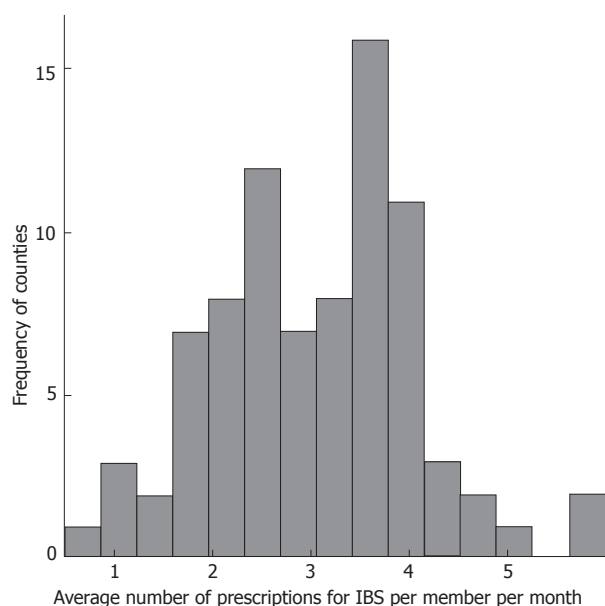

Figure 3 Frequency of counties by Michigan BCBS prescription incidence for 2005.

between counties. It ranged between 0.5 and 6.0, with a statewide total average of 3.3 (Figure 3). All six of the counties with rates above 4.3 were in the BCBS “western” region, and four of those counties were contiguous. There was no linear association between IBS prescriptions and per capita income by county.

There were 868 refugees admitted to Michigan in 2005. Of those, 342 were from Africa, 187 from the former Soviet Union, 167 from East Asia, 93 from the Middle East, 67 from Cuba, and 14 from Bosnia. Ingham County accepted 349 (40%) refugees. Thirteen other counties accepted at least one refugee. Sixty-nine counties did not

Table 1 *Giardia lamblia* incidence by refugees admitted per county in 2005

County	<i>Giardia lamblia</i> cases	Incidence per 100 000	Refugees admitted
Calhoun	7	5	12
Genesee	12	3	45
Ingham	121	43	349
Kent	86	15	236
Macomb	32	4	17
Oakland	72	6	117
Saginaw	15	7	11
Saint Clair	14	9	10
Wayne	77	4	53

receive any refugees that year. Of the nine counties that took at least 10 refugees, the number of *Giardia lamblia* cases ranged from 7 to 121, and the incidence was between 0.003% and 0.043% (Table 1).

Graphing the number of *Giardia lamblia* infections versus the number of IBS prescriptions revealed no linear relationship (Figure 4). The simple linear regression estimate provided an R-square of 0.001. Similarly, looking at total foodborne illness versus IBS prescriptions, no significant linear association was seen.

Per capita income was not significantly linearly associated with either Giardiasis or IBS prescriptions. The number of refugees admitted did show an association with the incidence of *Giardia lamblia* by county in 2005 (R-square = 0.221, $P < 0.001$).

DISCUSSION

This study examined the evidence for an association between the parasite *Giardia lamblia* and IBS, but found

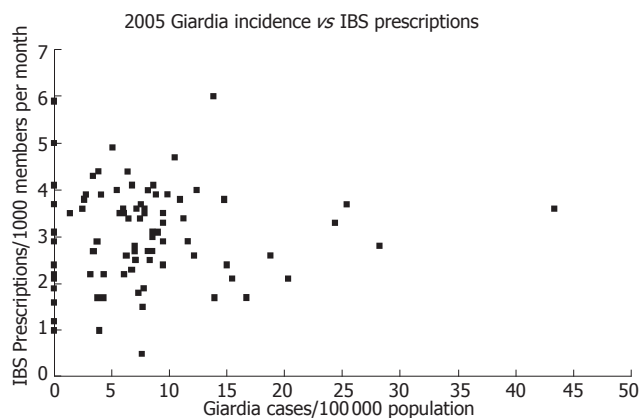

Figure 4 Michigan *Giardia lamblia* incidence versus BCBS prescriptions for IBS.

none. This lack of association is contrary to multiple previous studies linking acute infectious gastroenteritis with IBS and is therefore notable. There were 786 cases of Giardiasis reported in Michigan in 2005, which is a rate of 7.8 per 100 000 people. In comparison, in 2005, Ohio had a rate of 7.1, and Wisconsin had 13.0 per 100 000^[5]. The rate of cases among different counties in Michigan varied from zero up to 43 per 100 000 (Figure 5). In the US as a whole, the incidence in 2005 was 6.1 per 100 000 people^[5]. Ingham County had the highest activity in Michigan, and also the highest number of refugees admitted in 2005, when it received 349 of the 868 total refugees that entered the state (Personal communication, Al Horn, Director of the Office of Refugee Services of the Michigan Department of Human Services). There was a positive linear association between the incidence of Giardiasis by county and the number of refugees admitted in 2005 ($P < 0.001$). This supports the previously described increased risk of Giardiasis in immigrants from developing countries^[3].

Previous studies have posited a causal link between *Giardia lamblia* and IBS through inflammation of the mucosal lining of the gut^[10,12]. *Giardia lamblia* is also known to cause disaccharide intolerance for up to 6 mo after infection^[4]. This increases intestinal gas, causing painful distention of the colon, which could be misdiagnosed as IBS. These theoretical mechanisms need not be restricted to *Giardia lamblia*. Other parasites have been studied in relation to IBS, including *Entamoeba histolytica*^[17], *Dientamoeba fragilis*^[18], and *Blastocystis hominis*^[19-21], but none of these are reportable diseases in Michigan. Likewise acute bacterial gastroenteritis epidemics with *Salmonella enteritidis*, *Escherichia coli*, and *Campylobacter jejuni* have been shown to increase subsequent levels of IBS in those populations exposed^[22,23]. It might be expected, however, that Giardiasis alone, or foodborne illnesses in total, could act as a proxy for the myriad of parasitic and bacterial illnesses which are associated with IBS, since conditions which lead to high prevalence of one foodborne illness are likely to lead to increases in others as well. This study does not support such an association between *Giardia lamblia*, or foodborne illness in general, and IBS. It is possible that this lack of association is due to the relationship between high refugee numbers and the incidence of *Giardia lamblia* in Michigan.

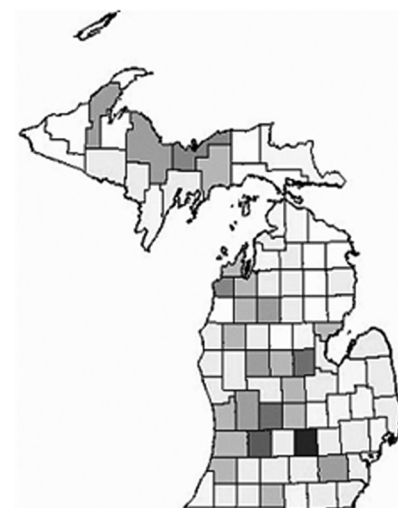

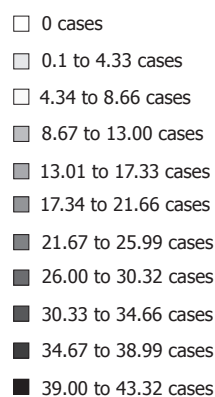

Figure 5 Map of Michigan counties by incidence of *Giardia lamblia* cases per 100 000 persons: Michigan Department of Community Health, unpublished data.

The refugee population may not have full access to regular health care, and so may be unlikely to receive a diagnosis of IBS, even if they meet the diagnostic criteria. There may also be a lag time between the onset of IBS and the use of disease-specific medication, and if this is true, then the large influx of refugees with Giardiasis in 2005 might not show up as an increase in IBS prescriptions until 2006 or later.

One limitation of this study is that BCBS prescription numbers may not accurately define the prevalence of IBS, nor do they distinguish between recent onset IBS and chronic disease. Also, although Giardiasis is a reportable disease, the collection of cases is by passive and not active surveillance, and the percentage of infections diagnosed and reported may vary greatly between counties. It seems reasonable, however, that these under-estimates in prevalence of IBS and incidence of *Giardia* might average out over the state as a whole. Finally, the 2005 Michigan population data, used to determine incidence, was necessarily an estimate, since the US census is only done every ten years. Despite these limitations, this ecological study is a first step in attempting to go beyond case reports and small clinical studies to define the true association between a parasite and IBS.

The lack of a known etiologic factor for IBS, the similarity of symptoms between IBS and Giardiasis, and the large number of undiagnosed *Giardia lamblia* infections make it tempting to look for a causal link between these two diseases, but at present, there is not enough evidence to prove one exists. Prospective studies, in a young, healthy, population at risk for IBS, with routine examination of stools for parasites, and collection of IBS symptom data, would make a tremendous contribution in this area.

COMMENTS

Background

This article concerns the possible link between an acute parasitic illness, *Giardia lamblia*, and subsequent development of a chronic disease, irritable bowel syndrome (IBS). *Giardia* is a common parasite, transmitted through ingestion of

the cyst form, which causes symptoms of diarrhea, bloating, mucus and abdominal discomfort in its victims.

Innovations and breakthroughs

Previous research has suggested associations of Giardia, other parasites, and some bacteria, with IBS. Mearin *et al* (*Gastroenterology* 2005; 129: 98-104) found a relative risk of IBS at one year after acute infection with *Salmonella enteritidis* to be 7.8 times that of the unexposed population. Two or three years after presumed infection with *Escherichia coli* 0157:H7 or *Campylobacter jejuni* gastroenteritis, Marshall *et al* (*Gastroenterology* 2006; 131: 445-450) found a rate of IBS 4.8 higher than expected. An earlier study of newly diagnosed Giardia cases in Italy by D'Anchino, Orlando and DeFeudis (*Journal of Infection* 2002; 45:169-172) noted that 82% of the patients had had at least six months of IBS symptoms before Giardia was diagnosed, suggesting that IBS predisposes patients to being symptomatic during Giardia infestation, and not that Giardia causes IBS. Whether Giardia and other intestinal infections actually cause IBS, or whether patients with IBS are simply more likely to be symptomatic during episodes of gastrointestinal infection has important implications for the diagnosis and treatment of IBS.

Applications

This study looked at rates of prevalence of IBS by county in Michigan, and compared that to incidence of newly diagnosed Giardia cases. No association was found, which implies that Giardia does not cause a significant number of cases of IBS.

Peer review

This is an important and interesting topic but were concerned that the ecological methodology of the study made the conclusions weaker than they would otherwise be.

Abstract

AIM: To evaluate the prognostic value of percentage of ^{13}C -phenylalanine oxidation (^{13}C -PheOx) obtained by ^{13}C -phenylalanine breath test (^{13}C -PheBT) on the survival of patients with chronic liver failure.

METHODS: The hepatic function was determined by standard liver blood tests and the percentage of ^{13}C -PheOx in 118 chronic liver failure patients. The follow-up period was of 64 mo. Survival analysis was performed by the Kaplan-Meier method and variables that were significant ($P < 0.10$) in univariate analysis and subsequently introduced in a multivariate analysis according to the hazard model proposed by Cox.

RESULTS: Forty-one patients died due to progressive liver failure during the follow-up period. The probability of survival at 12, 24, 36, 48 and 64 mo was 0.88, 0.78, 0.66, 0.57 and 0.19, respectively. Multivariate analysis demonstrated that Child-Pugh classes, age, creatinine and the percentage of ^{13}C -PheOx (HR 0.338, 95% CI: 0.150-0.762, $P = 0.009$) were independent predictors of survival. When Child-Pugh classes were replaced by all the parameters of the score, only albumin, bilirubin, creatinine, age and the percentage of ^{13}C -PheOx (HR 0.449, 95% CI: 0.206-0.979, $P = 0.034$) were found to be independent predictors of survival.

CONCLUSION: Percentage of ^{13}C -PheOx obtained by ^{13}C -PheBT is a strong predictor of survival in patients with chronic liver disease.

INTRODUCTION

The identification of patients with poor prognosis is of crucial importance, especially since liver transplantation has emerged as an important therapy for patients with advanced cirrhosis^[1]. The exact prediction of survival for an individual patient with cirrhosis is not easy. This may be one of the reasons to explain why so many studies have investigated factors which predict survival of these patients^[2-4].

In recent years, growing interest has been devoted to the quantitative liver function tests, as they are expected to increase the accuracy of estimating the severity of liver disease; however, several studies on their prognostic value have shown contradictory results^[5-8].

C-phenylalanine oxidation (^{13}C -PheOx) is a valuable indicator of liver function. It represents the cytosolic enzyme activity, is a non-invasive test, easy to perform and distinguishes patients with various degrees of liver disease from otherwise healthy persons. Some studies have shown that the severity of liver cirrhosis correlates with the suppression of $^{13}\text{CO}_2$ recovery after a dose of phenylalanine; other studies have reported that as liver function worsens, as defined by the Child-Pugh (CP) score, so does the phenylalanine metabolism^[9-14]. Nowadays, the CP score is still the most widely used tool to estimate the severity of liver disease in patients with cirrhosis and to predict survival.

The prognostic value of ^{13}C -phenylalanine breath test (^{13}C -PheBT) for survival in patients with chronic liver disease is yet to be established. Therefore, the aim of this study was to evaluate the prognostic value of percentage of ^{13}C -PheOx obtained by ^{13}C -PheBT for the survival of patients with chronic liver failure.

MATERIALS AND METHODS

Patients

Consecutive patients with chronic liver failure were studied at the Laboratory of Gastro-Hepatology of Centro Médico Nacional Siglo XXI. The study was approved by the Ethical Committee of the hospital. Patients were included according to the following criteria: age above 18 years, both genders; diagnosis of chronic liver failure based on history, clinical and biochemical findings combined with ultrasonographic results, plus liver biopsy when possible; and written informed consent of patients when entering the study. Exclusion criteria were pulmonary alterations, neurologic diseases different to encephalopathy; participation in other studies during the preceding thirty days of this study; and presence of other diseases conditioning a short prognosis by themselves (e.g. carcinoma). According to these criteria, 121 patients were selected from a group of 136 patients with chronic liver disease after having excluded 9 patients with hepatocellular carcinoma, 5 patients because of their unwillingness to participate and one patient with a percentage of ^{13}C -PheOx > 17 .

The etiology was defined on the basis of the history obtained from patients and their relatives and serological tests for viruses. The cause of liver disease was chronic alcohol consumption (≥ 30 g/d for 2 years or more) in 23 (19.5%) patients, chronic type-C hepatitis/HVC in 56 (47.5%), mixed (viral + alcohol) in 8 (6.8%) and other causes (cryptogenic, autoimmune, Budd Chiari syndrome, primary biliary cirrhosis, chronic type-B hepatitis/HBV-related cirrhosis and idiopathic) in 31 (26.3%). No patients had hemochromatosis or Wilson's disease.

Methods

All patients were studied following the same protocol with data collected by the laboratory staff and were followed up either as outpatients or inpatients when necessary, according to general medical practice. Survival time was accounted until March 2005. The hepatic function was evaluated by ^{13}C -PheBT and standard liver blood tests. All patients were classified by the CP score as class A (5-6 points), class B (7-9 points) or class C (10-15 points)^[15]. This classification comprises albumin, total bilirubin (TB), prothrombin time (PT), ascites and encephalopathy. Ascites was classified as "absent" or "present" according to clinical examination and ultrasonographic findings. The clinical diagnosis and degree of encephalopathy were determined according to the West-Haven criteria^[16]. Other tests were alanin transaminase (ALT), aspartate transaminase (AST), alkaline phosphatase (AP), creatinine and glucose. Biochemical data were evaluated by standard clinical chemical methods (Dimension, ARXL-Max DADE[®], Boehringer, Germany).

^{13}C -PheBT was measured following an overnight fast without control of prior dietary intake. A 100-mg oral dose of L-[1- ^{13}C] phenylalanine-isotopic purity 99% ^{13}C (Isotec[®] Inc, Ohio, USA)-dissolved in 50 mL water was administered. Alveolar breath samples were collected while in resting position and following a normal exhalation. At each sample time, patients were asked to blow directly into a 10-mL exstainer tube (Labco Limited[®], Buckinghamshire,

U.K.) through a straw. Duplicate breath samples were taken before administration of the ^{13}C -phenylalanine dose (basal), and every 10 min thereafter until completion of 1 h. Enrichment of $^{13}\text{CO}_2$ was determined by isotope ratio mass spectrometry (BreathMat-plus[®] Finnigan Bremen, Germany). The rate of hepatic ^{13}C -phenylalanine oxidation at each time point was calculated from the appearance of $^{13}\text{CO}_2$ on exhaled air, assuming a CO_2 production rate of 300 mmol/m² body surface area per hour, as described by Shneider *et al*^[17]. The analytical data were expressed as percentages of the ^{13}C -phenylalanine dose metabolized per hour (percentage of ^{13}C -phenylalanine oxidation/ ^{13}C -PheOx)^[10-12]. The day when patients first presented for the registration of clinical and laboratory data and the measurement of ^{13}C -PheBT was considered as "zero time" for the follow-up period of observation.

Statistical analysis

Results were expressed as percentages and mean \pm SD. Receiving operating characteristic (ROC) analysis was used to define the optimal percentage of ^{13}C -phenylalanine oxidation cut-off point with the highest sensitivity and specificity among thresholds. The analysis was carried out in two steps. To identify independent prognostic variables, a univariate analysis was performed with the Kaplan-Meier statistics. The curves were compared using the log-rank test. During the first stage, covariates analyzed for inclusion in the model were age, sex, etiology, pharmacologic treatment, previous hemorrhage, creatinine, glucose, ^{13}C -phenylalanine oxidation, CP score and complications. Variables that were significant ($P < 0.10$) in the univariate analysis were subsequently introduced in a multivariate analysis. Then each chosen covariate was reconsidered and eliminated if $P > 0.05$. The procedure was performed stepwise until no further covariates could be added or removed according to the afore-mentioned criteria.

In a second step, the same Cox model analysis was performed substituting the CP score with the five variables (albumin, bilirubin, prothrombin time, ascites and encephalopathy) that define the score.

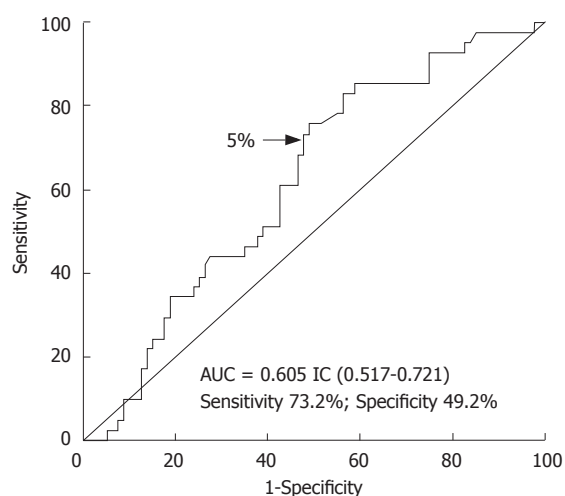

To check the proportionality of the hazard in time for the different functional classes, log of the cumulative hazard was plotted against time, demonstrating a parallel behavior in patients with low and high values for the selected predicting covariates when inspected. The goodness of fit of the model was investigated by a partial likelihood function and the Akaike's information criterion (AIC). The decision to include or to exclude the respective regressor variables was based on a χ^2 test^[18-20]. Statistical analysis was carried out by using the STATA V 8.0 statistical package (StataCorp LP, College Station, Tex).

RESULTS

One hundred and twenty-one consecutive patients with chronic liver failure were included. Cirrhosis was confirmed by liver biopsy in 35 (28.9%) cases, and the constellation of typical physical signs, such as ascites, oesophageal varices, upper gastrointestinal bleeding, and

typical laboratory findings, was accepted as evidence of chronic liver failure in the other 86 (71.0%) patients. During the follow-up period, 44 (20 males, 24 females) patients died. Causes of death were liver failure in 9 (7.6%) patients, upper gastrointestinal bleeding in 10 (8.5%), ascites in 6 (5.1%) and encephalopathy in 8 (6.8%) associated to liver failure, hepatorenal syndrome in 4 (3.4%) and hepatocellular carcinoma in 4 (3.4%), whereas 3 patients died of other causes (accident, transplant surgery and gastric cancer). These three patients were excluded from the further analysis.

Table 1 depicts the demographic and clinical data, biochemical features and liver function tests of patients. The ROC curves showed that the optimal percentage of

**Figure 2** Kaplan-Meier statistics for survival probability. **A:** All patients; **B:** Percentage of ¹³C-phenylalanine oxidation; **C:** Percentage of ¹³C-phenylalanine oxidation adjusted for covariables (age < 60 years and \geq 60 years, albumin, total bilirubin and creatinine). *P* values are given by nonparametric log-rank test.

¹³C-PheOx cut-off value for predicting survival in liver disease patients was 5.0% (sensitivity 73.2%; specificity 49.3%) (Figure 1). Serum albumin, total bilirubin and PT were clustered on the basis of the CP score. Ascites and encephalopathy were clustered as “absent” or “present”. The median probability of survival after entering the study in all the included patients was 1316 d (Figure 2A). The correlation between the percentage of ¹³C-PheOx (< 5.0% and \geq 5.0%) and survival was highly significant ($P < 0.006$; Figure 2B). Likewise, the results of this study confirmed that percentage of ¹³C-PheOx was correlated with the CP score ($r = -0.255$, $P = 0.005$).

Eleven of the twenty investigated variables showed an independent association to poor prognosis in the univariate analysis. The variables: albumin ($P < 0.000$), total bilirubin ($P < 0.000$), prothrombin time (%) (PT) ($P < 0.000$), creatinine ($P < 0.000$), ascites at follow-up ($P < 0.000$),

Table 2 Variables with an independent prognostic value, as indicated by two Cox's models in patients with chronic liver failure ($n = 118$)

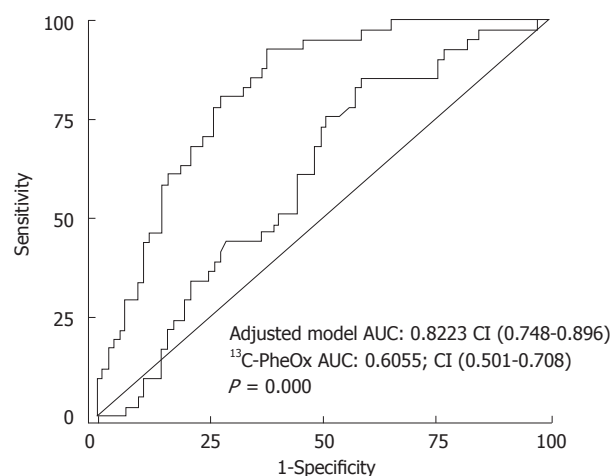

Variables	Coefficient	Hazard ratio ¹	SE	95% CI	P value

complications at follow-up ($P < 0.000$), encephalopathy at follow-up ($P = 0.012$), upper gastrointestinal bleeding at follow-up ($P = 0.015$), age ($P = 0.034$) AST ($P = 0.081$) and ascites when entering the study ($P = 0.042$). The variables with no independent association to prognosis: ALT ($P = 0.135$), patients' entry to the hospital at follow-up ($P = 0.146$), AP ($P = 0.198$), treatment of portal hypertension ($P = 0.213$), history of encephalopathy ($P = 0.424$), gender ($P = 0.437$), history of upper gastrointestinal bleeding ($P = 0.464$), etiology ($P = 0.478$) and alcohol consumption ($P = 0.804$).

The multivariate analyses demonstrated that the Child-Pugh classes, age (< 60 years and ≥ 60 years), creatinine and the percentage of ¹³C-PheOx were independent predictors of survival. When the Child-Pugh classes were replaced by all the parameters of the score, only albumin, bilirubin, creatinine, age < 60 years and ≥ 60 years, and the percentage of ¹³C-PheOx were found to be independent predictors of survival. Etiology of liver disease, gender, history of gastrointestinal bleeding, ascites, encephalopathy and prothrombin time were not significant predictors of survival after adjusting for the other explanatory variables on the model. Statistical parameters for the variables included in the final Cox model are depicted in Table 2. The first Cox's model included significant variables contained in Child-Pugh score and the second model included Child-Pugh classes.

A prognostic index (PI) predicting death was derived from the best model as: $PI = \exp(-0.798 \times ^{13}C\text{-PheOx}) + (0.765 \times \text{age}) + (-1.25 \times \text{albumin}) + (0.149 \times \text{bilirubin}) + (0.510 \times \text{creatinine})$. We attributed a value of 0 for ¹³C-PheOx < 5% and 1 for ¹³C-PheOx ≥ 5%, 0 for male sex and 1 for female sex, 0 for age < 60 years and 1 for

**Figure 3** (ROC) curve for percentage of ¹³C-phenylalanine oxidation and percentage of ¹³C-phenylalanine oxidation adjusted for age (age < 60 years and ≥ 60 years), albumin, total bilirubin and creatinine in predicting mortality ($n = 118$).

age ≥ 60 years. The relationship between PI due to the best adjusted model and risk of death were compared with a PI for percentage of ¹³C-PheOx (Figure 2C). The ROC curve for PI of adjusted model for predicting death from liver failure always depicted a better performance than that obtained from percentage of ¹³C-PheOx alone (Figure 3). Areas under the curve were also significantly larger (AUC = 0.822, 95% CI: 0.748-0.896 *vs* AUC = 0.605; 95% CI: 0.501- 0.708, $P = 0.000$).

DISCUSSION

This study shows that the percentage of ¹³C-PheOx is an important prognostic factor of long-term survival in patients with chronic liver failure. In fact, values lower than 5.0% for the percentage of ¹³C-PheOx were associated with an elevated probability of dying and values over 5.0% were associated with a better outcome (probability 0.26 *vs* 0.69 at 48 mo and 0.00 *vs* 0.37 at 64 mo). In addition, predictive value was conserved even after adjusting for covariates (Figure 2B-C). Furthermore, percentage of ¹³C-PheOx added new prognostic information to that obtained by CP classification or the common clinical and biochemical data included in the CP score. The results of this study additionally confirm that percentage of ¹³C-PheOx correlates inversely with the CP score ($r = -0.2550$, $P = 0.0053$). These data are consistent with other studies showing that ¹³C-PheBT correlates with parameters reflecting the severity of hepatic diseases, including albumin, total bilirubin, PT and CP score^[12,21-24].

Additionally, some studies have documented that percentage of ¹³C-PheOx values are significantly lower in patients with liver cirrhosis than in healthy adults^[12,14,23]. It has also been suggested that the decreased ability of decompensated livers to oxidize phenylalanine may be the result of progressive liver damage, individual cellular function; low activities of phenylalanine hydroxylase (PAH) and p-hydroxyphenylpyruvate hydroxylase; the severity or the course of liver disease that produced a decrease

in the total number of cells and the functioning liver cell mass with a consequent reduction in phenylalanine metabolism^[10,12,14,23]. Likewise, the percentage of ^{13}C -PheOx in patients with cirrhosis was estimated to be 20% of the normal value, suggesting that reduced enzyme levels account for a decreased metabolism in phenylalanine^[13]. Hehir *et al.*^[9] described that the fractional clearance rates of aromatic amino acids in plasma of patients with acute fulminant liver disease are 2 to 10 times lower than those in normal subjects.

Other authors have demonstrated that ^{13}C -PheBT is used to monitor the clinical course of patients with chronic liver failure^[13,25], as a clinical predictor to assess postoperative early complications in patients undergoing hepatectomy^[26] or to evaluate the restoration of the plasmatic phenylalanine clearance to normal during the postoperative period that is attributed to the ability of the new liver to catabolize this amino acid^[9]. In an experimental model, ^{13}C -PheBT was used to monitor the hepatic dysfunction associated with obstructive jaundice^[27]. However, there is scarce information on the prognostic value of ^{13}C -PheBT with regard to the survival of patients with cirrhosis. Our study suggests that the percentage of ^{13}C -PheOx adds new prognostic information to that obtained by the CP score or the common clinical and biochemical data included in the CP score. Nevertheless, discrepant results were recently obtained by Koeda *et al.*^[24] who could not demonstrate a correlation of ^{13}C -PheBT with mortality. They examined 23 patients with liver cirrhosis, 6 of them died of hepatic dysfunction in a follow-up period of 816 d. The lack of significance of ^{13}C -PheBT in their study may have probably related, at least in part, to the fact that less end-points were analyzed. It has been clearly established that the number of end-points heavily influences the ability to detect significant effects^[24,2].

In contrast to previous reports, ^{13}C -PheOx constituted an important prognostic index in our series. In fact, mortality due to liver-related causes was best predicted by a prognostic index containing albumin, bilirubin, creatinine, age, and ^{13}C -PheBT than by a prognostic index containing the CP score, creatinine, age and ^{13}C -PheBT, as assessed by a partial likelihood function and the Akaike's information criterion (AIC). However, there are no more data available on the prognostic value of ^{13}C -PheOx.

A limitation in our study could be that it was not possible to calculate a model for end-stage liver disease (MELD)^[28] because we did not perform the international normalized ratio of prothrombin time (INR) in all patients. MELD score is superior to CP score as a predictor of intermediate mortality is unclear^[29].

Even when the use of ^{13}C -breath tests with various substrates is not a novelty in hepatology, the clinical usefulness of these tests that explore the hepatocellular subfunctions (microsomal, cytosolic or mitochondrial) as well as the superiority of some quantitative prognostic liver function tests compared with the CP score are still unclear^[30,31].

Aminopyrine breath test (ABT) has been used to predict short-term prognosis and mortality in patients with alcoholic hepatitis. There are contradictory results of ABT

for predicting survival in patients with cirrhosis. Some studies showed that ABT is better than the Child-Turcotte score, whilst others demonstrate that ABT is not better. However, some other studies seem to provide additional prognostic information to the CP score^[31-34].

Galactose elimination capacity (GEC), a valuable indicator of liver function, is dependent on hepatic blood supply and inhibited by alcohol consumption. It has been demonstrated that GEC adds some more prognostic information when the CP score is not included; whereas, other studies reported that, GEC is unable to improve the prognostic ability of GEC^[8,35-37].

The caffeine breath test (CBT) represents a valid indicator of plasma caffeine clearance (CC) and correlates with the varying degrees of liver dysfunction. However, both tests do not appear to add prognostic information beyond that provided by the CP classification. CBT and CC may decrease with increasing age, cigarette smoking and disease state^[38-40].

Indocyanine green elimination (IGC) provides some prognostic information related to survival of patients with cirrhosis, but does not improve the predictive ability of clinical information considered for the CP score. It is also sensible to hepatic blood flow, and adversely affected by cardiovascular drugs (calcium channel blockers) and is significantly reduced after portosystemic shunting^[6,8,41,42].

On the other hand, the interest in search for accurate prognostic tests for patients with chronic liver disease is still of utmost importance since the emergence of liver transplantation is an important therapy for patients with advanced cirrhosis^[1].

In conclusion, ^{13}C -PheBT is a strong predictor of survival in patients with chronic liver failure that adds information which may not be available from the common clinical and biochemical data included in the CP score for the assessment of the risk of death due to liver disease. Should these data be confirmed in other studies and different settings, the ^{13}C -PheBT could prove to be a useful clinical tool to routinely evaluate the prognosis of patients with chronic liver disease in addition to the common clinical and biochemical data, because of its non-invasiveness and safety.

COMMENTS

Background

In recent years, there has been a growing interest in quantitative liver function tests, including breath tests, since they are expected to increase the accuracy of estimating the severity of liver disease. L-[1- ^{13}C] phenylalanine breath test ^{13}C -PheBT distinguishes patients with various degrees of liver disease from healthy persons. However, the prognostic value of ^{13}C -PheBT for survival of patients with chronic liver disease is yet to be established.

Research frontiers

Even when the use of ^{13}C -breath tests with various substrates is not a novelty in hepatology, the clinical usefulness of these tests that explore the hepatocellular subfunctions (microsomal, cytosolic or mitochondrial) and measure of hepatocyte

functional capacity in liver diseases as well as the prognostic value of ^{13}C -breath tests compared with the Child-Pugh (CP) or model for end-stage liver disease (MELD) are still unclear.

Innovations and breakthroughs

The current study provides evidence that ^{13}C -PheBT is a strong predictor of survival in patients with chronic liver failure and adds information which may not be available from the common clinical and biochemical data included in the CP score for the assessment of the risk of death due to liver disease.

Applications

^{13}C -PheBT could prove to be a useful clinical tool to routinely evaluate the prognosis of patients with chronic liver disease in addition to the common clinical and biochemical data, because of its non-invasiveness and safety.

Terminology

L-[1- ^{13}C] phenylalanine breath test measures hepatocyte functional capacity by estimating the oxidation of L-[1- ^{13}C] phenylalanine and represents the hepatic cytosolic enzyme activity.

Peer review

This manuscript describes the prospective evaluation of ^{13}C -phenylalanine breath test in the evaluation of prognosis in cirrhotic patients.

Abstract

AIM: To evaluate the effect of the natural diterpenoid, hypoestoxide (HE) on the growth of established colon cancer in mice.

METHODS: The CT26.WT mouse colon carcinoma cell line was grown and expanded *in vitro*. Following the expansion, BALB/c mice were inoculated s.c. with viable tumor cells. After the tumors had established and developed to about 80-90 mm³, the mice were started on chemotherapy by oral administration of HE, 5-fluorouracil (5-FU) or combination.

RESULTS: The antiangiogenic HE has previously been shown to inhibit the growth of melanoma in the B16F₁ tumor model in C57BL/6 mice. Our results demonstrate that mean volume of tumors in mice treated with oral HE as a single agent or in combination with 5-FU, were significantly smaller (> 60%) than those in vehicle control mice (471.2 mm³ vs 1542.8 mm³, $P < 0.01$). The significant reductions in tumor burden resulted in pronounced mean survival times (MST) and increased life spans (ILS) in the treated mice.

CONCLUSION: These results indicate that HE is an effective chemotherapeutic agent for colorectal cancer in mice and that HE may be used alone or in combination with 5-FU.

INTRODUCTION

The clinical usefulness of chemotherapy against advanced solid tumors is limited by host toxicity and tumor resistance. Combination chemotherapy is an approach to meeting this challenge. Colorectal carcinoma is the second most common cause of cancer deaths in the United States and is responsible for the deaths of over 55 000 patients annually^[1]. 5-fluorouracil (5-FU) has long been recognized as standard chemotherapy for colorectal cancer^[2] and has been used either alone or in combination with newer chemotherapeutics such as irinotecan and oxaliplatin^[3]. Both these drugs are believed to increase efficacy but also cause more toxicity. The predominant side effects of 5-FU are diarrhea, anorexia, enteritis, hand-foot syndrome and myelosuppression. While the combination of other drugs with 5-FU has improved overall patient survival, it has also been associated with more severe side effects^[4]. Modalities that include low doses of 5-FU and combination with low doses of an effective nontoxic drug which decrease or eliminate toxicity and at the same time enhance overall efficacy, would greatly advance the treatment for colorectal cancer and other malignancies. To this end, HE is an ideal candidate.

HE is a novel natural diterpenoid with anti-tumor^[5], anti-inflammatory^[6], and anti-parasitic activities^[7]. We examined the effect of HE alone or in combination with a very low dose (25 mg/kg) of 5-FU and a low dose of HE (1 mg/kg) upon efficacy in 5-FU therapy for CT26, a mouse colon cancer model.

MATERIALS AND METHODS

Experimental animals

Female BALB/c mice were purchased from Charles River Laboratories, Wilmington, MA. The thirty-five female 6-8 wk old mice were maintained on a standard laboratory chow and under pathogen-free conditions according to institutional regulations in facilities approved by the American Association for Accreditation of Laboratory Animal Care.

Reagents

HE was prepared in our laboratory with modifications, as previously reported^[8]. 5-FU was purchased from Sigma-

5-FU	25 \times 1	911.1 \pm 144	48.0 \pm 3.6	40
5-FU	100 \times 1	486.7 \pm 171	59.7 \pm 4.8	75
5-FU + HE	(5-FU) 25 \times 1 + (HE) 1 \times 10		57.7 \pm 4.0	69

PBS/DMSO: phosphate buffered saline/dimethyl sulfoxide; MST: mean survival times; ILS: increased life spans. MST: 75.0 \pm 3.8 (HE-treated mice at 5 mg/kg \times 10) *vs* Vehicle control (30.0 \pm 4.1), ILS: 150% (HE-treated mice) *vs* 0% (Vehicle control mice), $P < 0.01$.

Aldrich (St. Louis, MO). Phosphate buffered saline (PBS), Dulbecco's minimal essential medium (DMEM), and other culture media components were purchased from Irvine Scientific (Irvine, CA).

Cell line

CT26.WT mouse colon carcinoma cell line was purchased from ATCC, Manassas, VA. The cell line was grown as monolayer in DMEM culture medium containing 10% FBS and 1% L-glutamine. Full grown monolayer cultures were trypsinized for 15 min (0.25% trypsin-EDTA), harvested and passaged several times for expansion.

Experimental procedure

Following the growth and expansion of the cell line *in vitro*, trypsinized cells were harvested, washed, counted by trypan blue dye exclusion method and cell density was adjusted to 10×10^6 /mL in PBS. A suspension of 2×10^6 viable tumor cells in 0.2 mL PBS was inoculated s.c. into the left flanks of 35 mice. After tumors developed to about (80-90) \pm 10 mm³ volume, the mice were randomized into seven groups as depicted on Table 1. They were treated with varying doses of HE alone, 5-FU alone or combination of lower doses of HE (1 mg/kg) and 5-FU (25 mg/kg) *via* oral administration with a gavage needle attached to a 1.0 cc syringe.

Statistical analysis

A student *t* test was used to determine significance of difference between tumor burdens in vehicle control mice and mice treated with HE as a single agent or in combination with 5-FU. Survival data are presented in days as mean \pm SE.

RESULTS

Mice receiving varying doses of HE, 5-FU or combination experienced significant tumor growth inhibition as compared to controls. Mean % tumor growth inhibition obtained for HE was 65%; 5-FU, 55%; and HE + 5-FU, 82% relative to vehicle control. The additive effect of HE + 5-FU combination resulted in 69% ILS as compared

to 25% ILS for HE and 40% ILS for 5-FU when tested alone at each of their respective lowest doses (Table 1). Treatment was started when tumors had a mean volume of 80-90 mm³. Five female BALB/c mice were allocated to each group. Tumor volume at the start of treatment (d 0) and on d 18 after tumor implantation is shown. MST and ILS (%) were calculated for each group. MST was calculated from the period between tumor implantation and the day of death. ILS (%) was calculated using MST for each drug-treated mouse as follows:

ILS (%) =

$$\frac{[\text{MST of drug-treated mouse} - \text{MST of vehicle control}]}{\text{MST of vehicle control}} \times 100$$

This experiment was conducted twice with similar results.

DISCUSSION

HE is a novel and unique nonsteroidal antiinflammatory drug (NSAID) because it does not inhibit cyclooxygenase (COX) activity^[6]. The mechanism of action that defines NSAIDs as a class is their ability to inhibit COX activity^[9,10]. Several studies have established that numerous NSAIDs such as sulindac, aspirin, celecoxib, piroxicam and ibuprofen inhibit or prevent colorectal neoplasia in rodents and humans because of their ability to inhibit COX activity^[9-11]. HE has been shown in this report to be effective at reducing tumor burden in mice with colorectal cancer and it is thus similar to sulindac sulfide, a metabolite of sulindac sulfoxide, an NSAID which has also been shown to be effective against murine and human colorectal cancer without inhibitory effect on COX activity^[10,12]. The various mechanisms by which HE inhibits tumor growth include its ability to arrest cell cycle at G₂-M phase by interference with actin assembly, inhibit angiogenesis, vascular endothelial growth factor (VEGF)-induced cell proliferation and endothelial cell migration^[5]. All of these mechanisms have been shown to contribute to the treatment of colon cancer^[10-14]. Conversely, 5-FU is known to trigger apoptosis by depleting thymidine, partially through inhibition of thymidine synthase and partially through direct incorporation into RNA and DNA^[15,16]. Because HE lacks alkylating properties^[6], toxicity^[5], and uses several other aforementioned mechanisms, it is therefore consistent that the combination of low doses of HE with low doses of 5-FU enhances the anti-tumor responses of 5-FU.

Interestingly, consumption of the dried leaf powder of *Hypoestes rosea* (the parent plant of HE), as a dietary supplement, resulted in the elimination of existing intestinal polyps in human subjects (Nchekwube, unpublished results).

Collectively, these results indicate that HE may be a promising chemotherapeutic agent either alone or in combination with 5-FU against colorectal cancer.

COMMENTS

Background

Plants and their products have been used for medicinal purposes for thousands of years. Drugs from natural bio-resources have often been discovered on the basis of ethno-botanical information provided by herbalists living in regions of the world rich in bio-resources. Hypoestoxide is an investigational new drug isolated from the plant *Hypoestes rosea* (Acanthaceae) which is indigenous to the rain forest

regions of Nigeria. The natives have long used the *H. rosea* leaf extracts in folk medicine to treat various ailments. In this article, old world and new world medicine are brought together.

Research frontiers

The findings in this article relate well to the present state of the field in regard to the use of natural products as pharmaceutical agents. Artemisinin is an example of a natural product isolated from the Chinese plant, *Artemisia annua*. Currently, Artemisinin is used for the treatment of malaria. Interestingly, Hypoestoxide has also been found to possess anti-malarial activity. Curcumin, a polyphenolic antioxidant from a dietary spice is in clinical development for anti-cancer and anti-inflammatory activities. Vincristine is another example of a natural product (isolated from the rose periwinkle flower) which is used as a standard anti-cancer agent.

Innovations and breakthroughs

The findings are significant and novel because Hypoestoxide is an investigational new drug for which new indications are being sought. This is the first report on both the chemotherapeutic effect of Hypoestoxide on colon cancer and its additive effect with a standard chemotherapeutic agent, 5-Fluorouracil.

Applications

Future applications of the findings in this article will be in the areas of single and combination drug therapies for colorectal cancer. The findings also lend support to the use of NSAIDs such as Hypoestoxide, as anti-cancer agents. NSAIDs have long been associated with tumor chemoprevention and inhibition of the growth of established tumors.

Terminology

NSAIDs are anti-inflammatory drugs that are not steroids. Anti-angiogenesis is the process by which a drug inhibits the growth of an established tumor by shutting off the blood supply to the tumor. CT26 is an N-nitroso-N-methylurethane (NNMU)-induced, undifferentiated colon carcinoma cell line. It was cloned to generate the cell line CT26.WT (ATCC CRL-2638).

Peer review

The paper is well written. Using the simple and reliable methods, the authors studied the effect of hypoestoxide (HE) on mouse colon adenocarcinoma, and give us a definite conclusion: HE is an effective chemotherapeutic agent for colorectal cancer in mice and that HE may be used alone or in combination with 5-FU. The conclusion will help us to deeply understand HE's value in the treatment of colorectal cancer.

Abstract

AIM: To investigate the safety and outcome of gastrectomy for patients with gastric cancer and non-uremic renal failure (NURF).

METHODS: One hundred forty-seven patients who underwent gastrectomy for carcinoma were retrospectively divided into two groups: a group with Ccr values of ≥ 50 mL/min (Group 1; $n = 110$), and one with Ccr values of ≥ 20 to < 50 mL/min (Group 2; $n = 37$). Preoperative patient characteristics, intraoperative parameters (including operation time and blood loss), and postoperative management and complications were evaluated.

RESULTS: There were no statistically significant differences between the two groups in operation time (297.9 min vs 272.6 min, $P = 0.137$) or blood loss (435 mL vs 428 mL, $P = 0.078$). The differences in postoperative complications and hospital stay between the groups were not statistically significant. None of the patients in Group 2 required dialysis therapy, and no patients died due to gastrectomy or gastrectomy-related causes. The overall 4-year survival rates in Groups 1 and 2 were 86.6% and 81.8%, respectively ($P = 0.48$), and the corresponding 4-year disease-free survival rates for stage I, II, and III patients were 88.7% and 83.5%, respectively ($P = 0.65$).

CONCLUSION: Gastrectomy can be performed as safely in patients with NURF similar to patients with normal renal function.

INTRODUCTION

Gastric cancer is the most common cancer in Japan, and the prognosis of affected patients has been improving^[1,2]. The surgical procedure for gastric cancer consists of gastrectomy, with regional and extended lymph node dissection. Although advances in surgical techniques and management have made it possible to perform gastrectomy safely, renal dysfunction remains a major risk factor for perioperative management.

Renal dysfunction is classified into non-uremic and uremic stages. Patients with non-uremic renal failure (NURF) are defined as having impaired renal function but are dependent on their own kidneys. Patients with NURF require special attention to prevent deterioration of renal function and avoid the need for dialysis therapy when undergoing gastrectomy. Recently, due to the increase of the aged population and the incidence of diabetes mellitus, patients with gastric cancer associated with NURF have been increasing^[3]. However, there have been no published reports focusing on gastrectomy in such patients. In the present study, we retrospectively evaluated the results of pre-, intra-, and postoperative management and the outcome of gastrectomy in patients with gastric cancer associated with NURF to assess the safety of gastrectomy in such patients.

MATERIALS AND METHODS

A total of 147 patients who underwent gastrectomy for carcinoma between January 2003 and December 2005 were included in this study. In all patients, renal dysfunction was evaluated by the creatinine clearance test. NURF was defined on the basis of a creatinine clearance rate (Ccr) of > 20 to < 50 mL/min according to the New York Heart Association criteria^[4,5].

The patients were divided into two groups based on the Ccr value: a group with a Ccr of > 50 mL/min (Group 1; normal renal function: $n = 110$) and a group with a Ccr of > 20 to < 50 mL/min (Group 2; NURF: $n = 37$). The characteristics of the patients are shown in Table 1.

Our treatment strategy for gastric carcinoma in patients

Table 1 Preoperative patients' characteristics

	G1	G2	P-value
Number	110	37	
Sex (male/female)	80/30	27/10	$P = 0.98 (\chi^2)$
Age	66.6 ± 9.4	73.2 ± 9.4	$P < 0.001$
BMI	22.2 ± 3.3	21.5 ± 3.6	$P = 0.24$
BUN (mg/dL)	13.5 ± 4.0	17.0 ± 4.6	$P < 0.001$
Cr (mg/dL)	0.7 ± 0.2	0.9 ± 0.2	$P < 0.001$
Ccr (mL/min)	82.5 ± 15.9	38.1 ± 8.8	$P < 0.001$

Statistical analyses were performed by Mann-Whitney *U* test, except sex. χ^2 : Chi-square test.

with NURF is to perform gastrectomy with regional lymph node dissection to the same extent as that for patients with normal renal function. We do not reduce the extent of lymph node dissection in patients with NURF. If patients have metastases in organs such as the liver and lung (Stage IV), removal of gastric cancer by distal gastrectomy or total gastrectomy without regional lymph node dissection is performed.

Our management strategy for patients with NURF is to maintain intraoperative and postoperative urine volume at more than 1 mL/kg per hour. To obtain this target, adequate fluid infusion and administration of diuretics are employed.

For adjuvant chemotherapy, we use oral administration of fluorouracil, and for patients whose clinical stage is more advanced than stage III, an intravenous infusion of the anti-neoplastic agents fluorouracil and cisplatin is given.

Patients' preoperative characteristics including serum blood nitrogen urea (BUN) and creatinine (Cr), surgical methods, TNM classification, surgery-related data such as operation time, blood loss, and postoperative complications, were compared between Groups 1 and 2. Postoperative increase of BUN and Cr was calculated

Table 4 TNM classification *n* (%)

	G1	G2
Stage I A	45 (40.9)	7 (18.9)
I B	20 (18.2)	8 (21.6)
Stage II	10 (9.1)	5 (13.5)
Stage III A	13 (11.8)	7 (18.9)
III B	5 (4.5)	1 (2.7)
Stage IV	17 (15.5)	9 (24.3)

Table 5 Perioperative data

	G1	G2	P-value
Operation time (min)	279 (139-643)	259 (130-521)	0.14
Operative blood loss (mL)	324 (26-2314)	250 (42-3251)	0.048 ¹
Operative urine volume (mL/kg per hour)	0.92 (0.25-7.31)	0.71 (0.17-3.03)	0.17
Postoperative complications (%)	18.2	16.2	0.79
Postoperative hospital stay (d)	15 (11-73)	15 (11-80)	0.78

¹Statistically significant.

by dividing the maximum postoperative value by the preoperative value, and multiplying by 100.

The data are expressed as mean \pm SD or median value (minimum-maximum). Statistical analyses for means and medians were performed by Mann-Whitney *U* test. Statistical analyses of surgical procedures, lymph node dissection, and TNM classification were performed using the chi-squared test. The 4-year survival and the 4-year disease-free survival rates were analyzed by the Kaplan-Meier method, and statistical analysis was performed by log-rank test. For the calculation of 4-year disease-free survival, only patients whose clinical stages were I, II, and III in Groups 1 ($n = 93$) and 2 ($n = 28$) were included. Differences at $P < 0.05$ were considered to be significant.

RESULTS

Preoperative clinical data are shown in Table 1. The mean patient age was higher in Group 2 (73.2 ± 9.4 years) than in Group 1 (66.6 ± 9.4 years). Higher Cr and BUN values were observed in Group 2 than in Group 1, and the differences were statistically significant. The Ccr value was significantly lower in Group 2 (38.1 ± 8.8 mL/min) than in Group 1 (82.5 ± 15.9 mL/min).

Table 2 and Table 3 shows details of the surgical procedure and the extent of lymph node dissection. There were 6 cases of remnant gastrectomy in Group 1 and no such cases in Group 2. Also there was one case of partial gastrectomy in Group 2 and no such case in Group 1. However, there were no significant differences in the surgical procedure between the two groups.

The details of the TNM classification are shown in Table 4. The incidence of advanced gastric cancer exceeding stage II was significantly higher in Group 2 than in Group 1 (Group 1; 40.9%, Group 2; 59.5%, $P < 0.05$).

Table 5 shows the operative data. Operation times in Groups 1 and 2 were 279 (139-643) min and 259 (130-521)

Table 6 Postoperative percentile increases in BUN and Cr

	G1	G2	P-value
BUN	19.5% (-55.6-180)	11.5% (-47.6-166.7)	$P > 0.05$
Cr	9.0% (-20.5-700)	0.0% (-20-42.9)	$P > 0.05$

Table 7 Postoperative complications

	G1	G2
Pneumonia	6	3
Pancreatitis	4	0
Anastomotic leakage	4	1
Drain infection	3	0
Catheter infection	2	1
Ileus	1	0
Others	3	3

min, respectively ($P = 0.14$), and operative blood losses were 324 (26-2314) mL and 250 (42-3251) mL, respectively ($P = 0.048$). There were no significant inter-group differences in intraoperative urine volume, occurrence of postoperative complications, or median postoperative hospital stay.

Postoperative percentage increases in BUN and Cr are shown in Table 6. There were no significant increases in BUN and Cr after surgery in either group. Furthermore, none of the patients in either group were placed on hemodialysis after gastrectomy.

Details of postoperative complications are shown in Table 7. The incidences of these complications did not differ between the two groups. No patients died as a result of the gastrectomy procedure or of gastrectomy-related causes.

The 4-year survival rates in Groups 1 and 2 were 86.6% and 81.8%, respectively ($P = 0.48$) (Figure 1A), and the 4-year disease-free survival rates were 88.7% and 83.5%, respectively ($P = 0.65$) (Figure 1B).

DISCUSSION

The critical factor to consider when performing curative gastrectomy for patients with NURF is to perform the procedure safely to prevent deterioration of renal function and avoid the need for dialysis therapy. Patients with NURF have several risk factors for major surgery. It is known that renal dysfunction is frequently associated with cardiac dysfunction, a condition known as a cardio-renal syndrome^[6]. In cardio-renal syndrome, activation of the renin-angiotensin-aldosterone system, imbalance of reactive oxygen species, and irritation of the sympathetic nervous system result in acceleration of coronary sclerosis, cardiac hypertrophy, impairment of cardiac microcirculation, and hypertension^[7]. It is also known that renal anemia is a solid risk factor for cardiovascular dysfunction (cardio-renal anemia syndrome)^[8]. Therefore, when performing major surgery in patients with NURF, careful evaluation of the cardiovascular system is essential.

Patients with NURF have impaired blood-coagulation function^[9]. Increased perioperative bleeding is the main

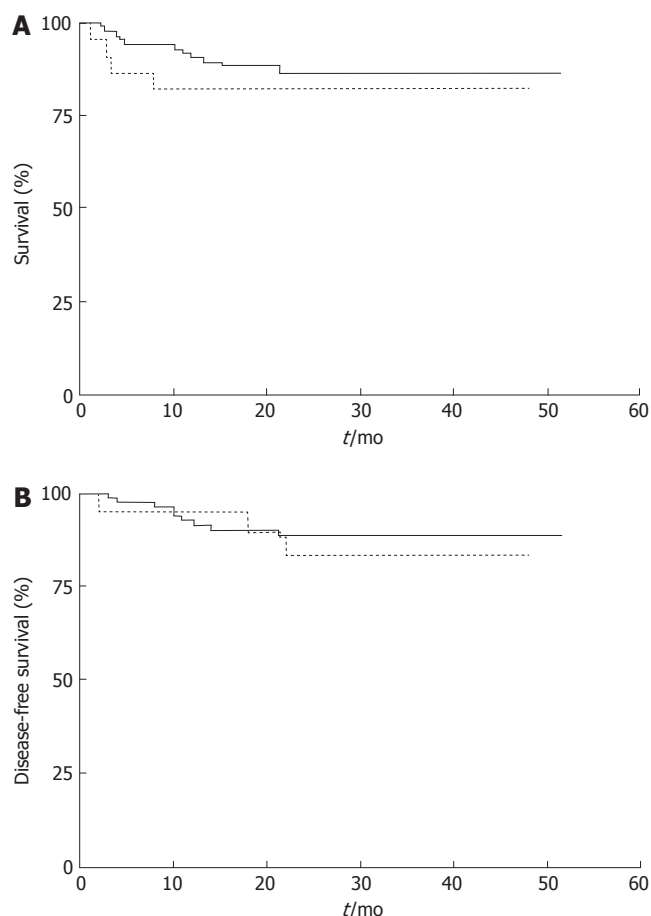

Figure 1 Outcomes of gastrectomy for carcinoma in patients with NURF. **A:** The 4-yr survival rates of patients with normal renal function (solid line) and NURF (dotted line) were 86.6% and 81.8%, respectively ($P = 0.48$); **B:** The 4-yr disease-free survival rates of patients with normal renal function (solid line) and NURF (dotted line) were 88.7% and 83.5%, respectively ($P = 0.65$).

cause for the deterioration of perioperative renal function, and often results in other postoperative complications. However, in the present study, intraoperative blood loss was significantly higher in Group 1 than in Group 2, regardless of the fact that there were no significant differences in the surgical procedures, and the more extensive lymph node dissection in Group 2 than in Group 1 (Table 2 and Table 3). Proper intraoperative hemostasis makes it possible to perform gastrectomy safely for patients with NURF.

There was no significant difference in the postoperative morbidity rates between the two groups. Postoperative complications included pneumonia, pancreatitis, anastomotic leakage, drain infection, catheter infection, ileus, and others, but none of these complications are unique to patients with NURF. The median postoperative hospital stay was 15 d in both groups, and there was no statistically significant difference between them.

Patients with renal failure are immunocompromised, and the occurrence of perioperative infection is higher than in the normal population^[10]. However, in this study, there was no significant difference in postoperative infection between the two groups. We routinely use cephalosporin-antibiotics for 3 d after surgery, and the dose of antibiotics was the same in both groups,

no cases of drug-induced renal function deterioration being observed in either of them. In terms of the TNM classification, the frequency of advanced gastric cancer above stage II was significantly higher in Group 2 than in Group 1 (Table 4). The immunocompromised state of patients with NURF may be the reason why more advanced-stage gastric cancers were present in Group 2 than in Group 1.

Previous reports have suggested that impaired innate and acquired immunity in patients with end-stage renal disease increases the incidence of cancer, the rate of recurrence after surgery, and decreases the survival rate^[11-14]. In one study, relative risks of gastric cancer in patients with end-stage renal disease in Australia, New Zealand and America were 1.2^[15]. In our study, the survival and disease-free survival rates for gastric cancer after curative surgery in patients with NURF were the same as those in patients with normal renal function. Thus, removal of gastric cancer with a sufficient normal stomach, associated with extended lymph node dissection, enables patients with NURF to achieve a satisfactory outcome.

In conclusion, with accurate preoperative evaluations, appropriate operative procedures and perioperative management, gastrectomy for carcinoma including extended lymph node dissection in patients with NURF can be performed as safely as in patients with normal renal function.

COMMENTS

Background

Renal dysfunction is classified into non-uremic and uremic stages. Patients with non-uremic renal failure (NURF) are defined as having impaired renal function but dependent on their own kidneys. Crucial issue in the surgery for the patients with NURF is to prevent deterioration of renal function and avoid the need for dialysis.

Research frontiers

We retrospectively evaluated the results of pre-, intra-, and postoperative management and the outcome of gastrectomy in patients with gastric cancer associated with NURF to assess the safety of gastrectomy in such patients.

Innovations and breakthroughs

With accurate preoperative evaluations, appropriate operative procedures and perioperative management, gastrectomy for carcinoma including extended lymph node dissection in patients with NURF can be performed as safely as in patients with normal renal function.

Applications

Malignant diseases occur likely in patients with NURF and within 2 years of the introduction of hemodialysis. Findings of the present study fascillitate the aggressive surgery in such patients.

Terminology

Non-uremic renal failure (NURF): patients having impaired renal function but dependent on their own kidneys.

Peer review

This is an unique study and as such worthy of acceptance. It is well written and presented. I think it would benefit if the authors made more of their management in maintaining urinary output both during and after the operation.

cancer specimens with the prognosis of the patients, and found a tendency of favorable prognosis and low BNIP3 expression.

CONCLUSION: High levels of *BNIP3* expression cannot be used as one of the predicting factors for gemcitabine chemosensitivity, and some yet to be known factors will have to fill the gap for the accurate prediction of pancreatic cancer chemosensitivity to gemcitabine. However, BNIP3 expression may have an impact on prediction of prognosis of patients with pancreatic cancer.

Abstract

AIM: To evaluate the significance of BNIP3 in the pathogenesis of pancreatic cancer, we analyzed the relationship between the expression of BNIP3 and survival rate of the patients with pancreatic cancer, or chemosensitivities in pancreatic cancer cell lines, particularly for gemcitabine, the first-line anti-tumor drug for pancreatic cancer.

METHODS: To compare the expression level of BNIP3 with the resistance to gemcitabine, eight pancreatic cancer cell lines were subjected to gemcitabine treatment and the quantitative real-time RT-PCR method was used to evaluate *BNIP3* expression. Immunohistochemical analysis was also performed using 22 pancreatic cancer specimens to study relationship between BNIP3 expression and survival rate.

RESULTS: Although no significantly positive association between *BNIP3* mRNA level and gemcitabine chemosensitivity was observed, pancreatic cancer cell lines that were sensitive to gemcitabine treatment tended to show high levels of *BNIP3* expression. The converse, an absence of *BNIP3* expression, was not correlated with gemcitabine resistance. We further compared the BNIP3 expression profiles of resected primary pancreatic

INTRODUCTION

Pancreatic adenocarcinoma is a common cancer with an extremely poor prognosis around the world because of its aggressive invasive capacity, early metastasis, resistance to existing chemotherapeutic agents and radiation therapy, and lack of specific symptoms that help in finding patients at early stages for curative operation. To improve the horrible prognosis, we need to find novel approaches to both diagnosis and treatment that are more efficient than currently available techniques.

BNIP3, the hypoxia-inducible proapoptotic gene belonging to the *BCL2* family, was originally identified as the gene encoding a protein that interacts with adenovirus E1B 19-kDa protein^[1]. The expression of *BNIP3* is increased under hypoxic conditions by a transcription factor, hypoxia-inducible factor 1 α (*HIF1* α)^[2,3], and leads to cell death by two different pathways; (1) heterodimerization with the anti-apoptotic protein *BCL2*, and (2) opening the mitochondrial permeability transition pores by direct contact with its outer membrane. Thus, *BNIP3* is considered to be a key regulator

of hypoxia-induced cell death^[4,5,6].

Hypoxia is a common phenomenon in solid tumors and has been proven to occur in pancreatic cancer, but *BNIP3* expression was shown to be decreased in pancreatic cancer compared with normal pancreas due to the hypermethylation of its promoter^[7]. On the other hand, high expression of *BNIP3* in pancreatic cancer cell lines has been reported to be associated with the chemosensitivity to gemcitabine 2', 2'-difluorodeoxycytidine (Gemzar, Eli-Lilly, Indianapolis, IN), a novel pyrimidine nucleoside analogue^[8]. It was expected that downregulation of proapoptotic *BNIP3* might contribute to chemoresistance, survival and progression of pancreatic cancer in a hypoxic environment. In the present study, we analyzed the expression of *BNIP3* in several pancreatic cancer cell lines to explore the association with chemosensitivity in pancreatic cancer.

MATERIALS AND METHODS

Pancreatic cancer cell lines and cell culture

Two human pancreatic cancer cell lines (CFPAC1 and SUIT2) were obtained from Cancer Research UK Research Services (London, UK). PK-1, PK-8, PK-9, PK-45, and PK-59 were established at Tohoku University from patients with pancreatic cancer^[9,10]. PANC-1 was obtained from Cell Resource Center for Biomedical Research, Institute for Development, Aging, and Cancer, Tohoku University (Sendai, Japan). All cells were maintained in RPMI 1640 containing 10% fetal bovine serum under an atmosphere of 5% CO₂ with humidity at 37°C.

MTT (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide) assay

To assess cell proliferation, the MTT test was used as described previously^[11]. Cells were resuspended in fresh medium and seeded in 96-well plates at concentration of 5×10^3 cells/well. Cells were incubated for 24 h at 37°C, and then gemcitabine was added to each well at various concentrations. Each plate was incubated at 37°C for 72 h. An aliquot of 10 μ L of 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (2.5 mg/mL) was added to each well, and the plate was incubated at 37°C for 2 h. The absorbance was measured at 560 nm using a microplate reader.

Quantitative real-time reverse transcription PCR

Total RNAs were extracted from the harvested cells using an RNeasy mini kit (QIAGEN, Tokyo, Japan) according to the supplier's instructions. Each purified RNA was dissolved in RNase-free water, and its concentration was measured by optical absorbance at an aliquot of 10 μ g total RNA and Super Script II Reverse Transcriptase (Invitrogen, Carlsbad, CA) by the methods described previously^[12]. The synthesized cDNA was used for a quantitative real-time PCR analysis using an ABI PRISM 7000 Sequence Detection System (Applied Biosystems, Foster City, CA) following the manufacturer's instructions. Specific primers and common probe were designed by using the Primer Express software (Applied Biosystems), and their nucleotide sequences are: 5'-tggacggagtagctcc

aagagc-3' (forward primer), 5'-agaagccctgttggtatcttg-3' (reverse primer), 5'-tctcactgtgacagtccacctcgc-3' (TaqMan probe). These primers were purchased from Nihon Gene Research Laboratories (Sendai, Japan). Expression of the β 2-microglobulin (*B2M*) gene was monitored as an internal control, and the nucleotide sequences for the primers and the probe were described previously^[13]. Amplifications were carried out in the reaction mixture in 25 μ L containing 5 μ L of cDNA samples and 12.5 μ L of 2 \times ABsolute QPCR ROX Mix (ABgene, Epsom, UK), and the final concentration of 0.2 μ mol/L of each primer pair and 0.4 μ mol/L of the probe were added in a program comprised of 2 min at 50°C, 15 min at 95°C, followed by 40 cycles consisting of 15 s at 95°C and 1 min at 60°C. The expression ratio of *BNIP3*/*B2M* was calculated and used. Each experimental reaction was performed in triplicate.

Tissue samples and immunohistochemical analysis

Pancreatic cancer specimens were obtained from 22 patients between 1995 and 2004. All the patients had undergone surgery at Tohoku University Hospital. Stages were defined according to the general rules of the Japan Pancreas Society^[14]. These patients underwent either pancreaticoduodenectomy or distal pancreatectomy with nodal dissection followed by similar chemotherapy including gemcitabine treatment. All of the patients' prognoses until 2005 were also determined. Twelve patients were male and 10 patients were female, and the mean age of operation was 64.0 years old. Specimens for immunohistochemistry were fixed in 10% formalin and embedded in paraffin for histological analysis. Research protocols for this study were approved by the Ethics Committee of the Tohoku University School of Medicine. Antigen retrieval was performed by boiling the slides in 10 mmol/L citrate buffer twice for 10 min. Peroxidase was quenched with a 3% H₂O₂ solution in 30% methanol. After an overnight incubation with mouse anti-BNIP3 antibody clone Ana 40 (Sigma-Aldrich, St. Louis, MO) at 4°C, slides were washed with PBS supplemented with 0.05% Tween-20 and exposed to the HRPO-linked anti-mouse secondary antibody for 45 min at room temperature. Color reaction was carried out by incubation for 4 min with liquid DAB+ substrate and counterstaining by Mayer's hematoxylin solution. Staining patterns were divided into three groups following the report by Erkan *et al*^[15]; punctate perinuclear staining, diffuse cytoplasmic staining, and negative/faint staining.

Statistical analysis

All experiments were done in duplicate or triplicate. A two-tailed Student's *t*-test was applied for statistical analysis of comparative data. Overall survival curves were generated according to the Kaplan-Meier method. *P* < 0.05 was considered statistically significant.

RESULTS

Efficacy of cytotoxicity induced in pancreatic cancer cell lines by gemcitabine exposure

The response of eight pancreatic cancer cell lines to gemcitabine treatment was investigated using the MTT

Table 1 Classification of the Cell Lines by IC50

	IC50 ($\mu\text{g/mL}$)	Cell lines
Sensitive group	< 0.1	PK-9, SUI2
Intermediate group	0.1-100	CFPAC1, PK-1, PK-8, PK-45
Resistant group	> 100	PK-59, PANC-1

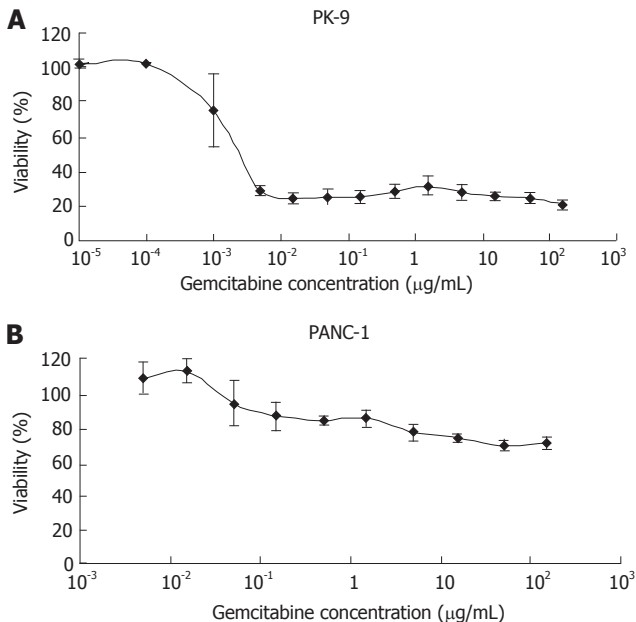

Figure 1 Response to gemcitabine in pancreatic cancer cell lines. Dose-response curves for gemcitabine in PK-9 (A) and PANC-1 (B). These are representative gemcitabine-sensitive and -resistant cell lines, respectively. Each bar represent a standard deviation (SD).

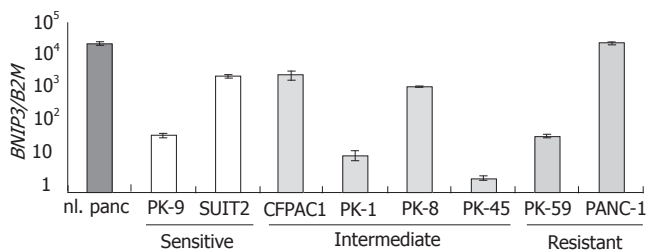

Figure 2 Relative expression levels of *BNIP3* in eight pancreatic cancer cell lines. *BNIP3* expression in pancreatic cancer cell lines as determined by quantitative real-time RT-PCR, and the expression of *B2M* was monitored as the internal control. The cell lines are arranged by IC50 for gemcitabine. No significant correlation was observed between the expression level of *BNIP3* and IC50.

assay. Representative dose-response curves are shown in Figure 1; PANC-1 is a representative resistant cell line, whereas PK-9 is a representative sensitive cell line. The pancreatic cancer cell lines were divided into three groups according to their IC50 values as shown in Table 1. Judging from the IC50 value, two cell lines (PK-9 and SUI2) showed high sensitivities to gemcitabine; less than 30% of the cells survived in the presence of 0.1 $\mu\text{g/mL}$ of gemcitabine for 72 h (Figure 1A). In contrast, PANC-1 and PK-59 showed very low sensitivity; more than 50% of the cells survived even in the presence of more than 100 $\mu\text{g/mL}$ of the drug for 72 h (Figure 1B). The remaining four cell lines (CFPAC1, PK-1, PK-8 and

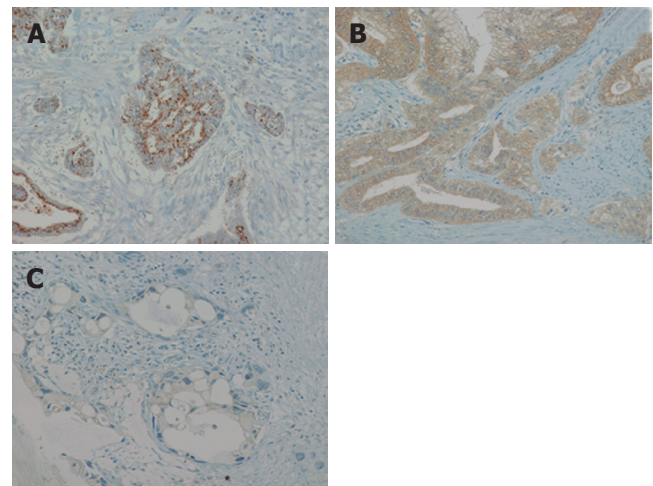

Figure 3 Immunohistochemical analysis of *BNIP3* in primary pancreatic cancer specimens. A monoclonal anti-*BNIP3* antibody (clone Ana 40) was used. A: Punctate perinuclear staining; B: Diffuse cytoplasmic staining; C: Negative/faint staining.

PK-45) showed moderate sensitivity (IC50 values 0.1-100 $\mu\text{g/mL}$) and were classified as intermediately sensitive cell lines.

***BNIP3* expression level is not associated with chemosensitivity of pancreatic cancer to gemcitabine**

The expression of *BNIP3* mRNA was examined in all the pancreatic cancer cell lines by quantitative real-time RT-PCR. Among the cell lines analyzed, *BNIP3* expression levels varied by 10^4 fold, as shown in Figure 2. Cell lines were arranged by their IC50 values from left to right. PANC-1 showed the level of *BNIP3* expression comparable to normal pancreas, but PK-45 and PK-1 showed highly suppressed levels of expression. No significant correlation was observed between the expression level of *BNIP3* and the IC50 for gemcitabine.

Next we examined the expression level of *BNIP3* before and after gemcitabine treatment to see if gemcitabine affects the *BNIP3* expression. After administration of 1 $\mu\text{g/mL}$ of gemcitabine to PANC-1, PK-45, PK-9, and SUI2, the cells were harvested on d 0, 1, 2, and 3. No significant alterations in *BNIP3* expression were observed in these cell lines (data not shown).

Expression level of BNIP3 in pancreatic cancer tissue and correlation with patient survival

To explore the question of whether the expression level of *BNIP3* affects the prognosis, we performed immunohistochemical analyses of resected tumor tissues. The staining patterns of *BNIP3* were divided into three groups^[15]. Representative examples are shown in Figure 3. Among the 22 evaluated specimens, four patients were classified as negative, 11 patients displayed diffuse cytoplasmic staining and 7 showed the punctate perinuclear pattern. The groups were comparable in terms of tumor morphology, stage, and year of treatment including usage of gemcitabine. Although significant differences were not calculated, a tendency between long survival of the patients and negative/faint *BNIP3* expression was observed (Figure 4).

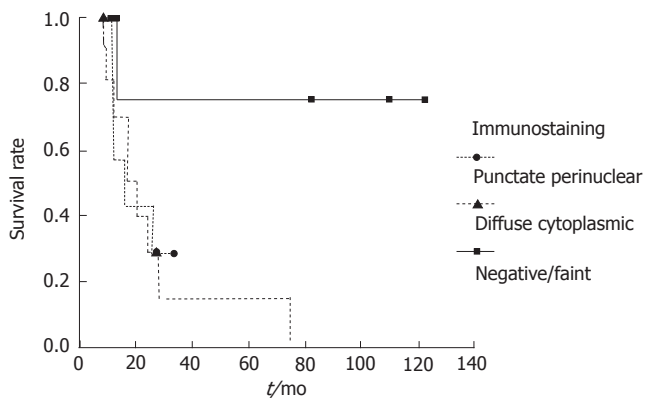

Figure 4 Kaplan-Meier analysis of the patients with pancreatic cancer by BNIP3 immunostaining patterns. The mean survival time of patients with punctate perinuclear staining group was 20 mo, diffuse cytoplasmic staining group was 26 mo, and negative/faint-staining group was 95 mo. Each group was comparable in terms of tumor stage and adjuvant therapies.

DISCUSSION

Recent studies have reported that *BNIP3* expression is silenced in pancreatic cancer by hypermethylation of its promoter and that loss of *BNIP3* expression contributes to chemoresistance and worsened prognosis^[7,8,15]. Furthermore, siRNA-mediated knockdown of *BNIP3* caused chemoresistance to gemcitabine^[8]. The information was supposed to give us some clues to finding some efficient novel methods for treatment of pancreatic cancer patients. As the first step for invention of such an efficient method for treatment, we tried to confirm these reported results by comparing *BNIP3* expression levels and gemcitabine chemosensitivity in several pancreatic cancer cell lines. However, our results did not support the previous report by Akada *et al*^[8]. The expression levels of *BNIP3* in our series of pancreatic cancer cell lines, which were basically the same as used in the previous study, did not reproduce the previous results; the chemosensitivities of pancreatic cancer cell lines to gemcitabine were quite different. Representative gemcitabine sensitive cell lines (CFPAC1 and SUIT2) and the representative resistant cell line (PK-59) were used in both studies, but PK-9, which was previously scored as moderately sensitive to gemcitabine, was actually classified as the most sensitive cell line in our study. PANC-1, which was reported also as “moderate” was the most resistant cell line. In addition, PK-8, which was not tested in the previous study, showed resistance to gemcitabine even with high expression of *BNIP3*. The cause of these discrepancies of the gemcitabine sensitivity between the two studies is unclear; the difference of the methods used in these studies, different culture media, and, probably, cell density, may have caused the discrepancy to some extent. Our immunohistochemical studies also showed results opposite to those reported by Erkan *et al*^[15]; loss of *BNIP3* expression seemed to correlate with better survival of patients.

In our present study, we could not detect any clear relationship between *BNIP3* expression and chemosensitivity that might associate with a favorable patient survival rate. *BNIP3* is a proapoptotic protein that was considered to have some effect on the chemosensitivity

and growth of the pancreatic cancer cell in itself, so it is not difficult to think that overexpression of *BNIP3* leads to cell death and that inhibition of *BNIP3* leads cells survive longer. Our present results by immunostaining supported this idea, albeit no significant difference was obtained. As the number of cases increases, a significant difference will probably be observed. However, pancreatic cancer involves very complicated molecular changes, and those *BNIP3*-positive cancer cells that appear to be weak to the cytotoxic effect and less aggressive may have other genetic and epigenetic changes which can compensate for the proapoptotic effect of *BNIP3* and eliminate the differences between *BNIP3*-positive and -negative cancer cells with regard to chemosensitivity and survival. Furthermore, chemosensitivities can be caused by factors other than those we have discussed so far, such as upregulation of the transportation system to eliminate the drugs from the cells or upregulation of metabolism. Any association between chemosensitivity and *BNIP3* expression may yet give us a clue to find a way to invent efficient methods for treatment; further studies are necessary to explain the discrepancy.

Abstract

AIM: To investigate the relationship among gastric xanthomatosis (GX), *H pylori*, dyslipidemia, and gastritis in Korea, a well-known *H pylori* endemic area.

METHODS: A total of 771 patients who had undergone gastroduodenoscopy by one endoscopist were included in this study. Among them, 54 patients with GX were assessed for *H pylori* infection and their endoscopic characteristics and serum lipid profiles. The findings were compared with 54 age- and sex-matched control subjects without GX.

RESULTS: The prevalence of GX was 7% (54/771) with no sex difference. GX was mainly single (64.8%) and located in the antrum (53.7%). The mean diameter was 7 ± 3 mm. Mean body mass index (BMI) of patients with GX was 23.1 ± 2.8 and no one was above 30. Compared with the controls, lipid profiles of GX group showed significantly lower HDL-cholesterol (48.8 ± 12.3 vs 62.9 ± 40.5 , $P = 0.028$) and higher LDL-cholesterol (112.9 ± 29.9 vs 95.9 ± 22.4 , $P = 0.032$). The level of total serum cholesterol, triglyceride and the existence of dyslipoproteinemia were not related to the presence of GX. However, GX showed a close relationship with endoscopically determined atrophic gastritis and histologic severity (24/53, 44.4% vs 8/54, 14.8%, $P = 0.0082$). *H pylori* infection and bile reflux gastritis were not significantly related with GX.

CONCLUSION: The prevalence of GX is 7% and it may be an increasing entity in Korea. Moreover, dyslipidemia and atrophic gastritis are found to be related to GX, but *H pylori* infection is not.

INTRODUCTION

Xanthomatosis is a yellow tumor-like lesion of the skin or deeper structure characterized by the presence of lipid-containing histiocytes. Its presence may be a manifestation of a metabolic disturbance, such as hyperlipidemia, although it usually represents an isolated phenomenon. Many clinicians believe that yellowish plaque in the gastric mucosa is a benign lesion, and it has no clinical significance. Feyrter^[1] reported the first recorded observation of a small yellow macule in the gastric mucosa representing a fatty deposit. Since gastric xanthomatosis (GX) was first named in 1929 by Lubarsch and Borchardt^[2] as a gastric lipid island, a variety of possible causes, such as an abnormality of the lipid metabolism or inflammatory changes in the gastric mucosa, have been suggested^[3-5]. However, the detailed developmental mechanism remains unknown.

H pylori is the most important etiologic factor of peptic ulcer disease and chronic active gastritis. Chronic gastritis is thought to be involved in the gastric glandular atrophy and intestinal metaplasia sequence, which is considered a precursor of gastric cancer. Recently, Hori and Tsutsumi^[6] found *H pylori* infection on the surface of foveolar cells in 48% of biopsy samples of GX. Isomoto *et al*^[7] also reported a close relationship among *H pylori* infection, GX, and atrophic gastritis, and GX may be provoked by *H pylori* infection.

Since GX has received little attention in the Korean literatures, we undertook this study to evaluate the prevalence and the clinical significance of GX endoscopically, and to investigate the relationship among GX, *H pylori* infection and dyslipidemia.

MATERIALS AND METHODS

Patients

From August 2003 to March 2004, a total of 771 patients (398 males and 373 females) who had undergone gastroduodenoscopy by one endoscopist were included in this study. Subjects' age ranged from 17 to 88 (mean 60) years. Of these 771 patients, 54 cases (27 men and 27 women; mean age 54 and range 33-77 years) had GX. Of these 54 patients, chronic gastritis was diagnosed in 41, gastric ulcer in 4, duodenal ulcer in 4, gastric polyp in 3, gastroesophageal reflux disease (GERD) in 3, Mallory-Weiss syndrome in 1, gastric cancer in 1, congestive gastropathy in 1, and normal gastric mucosa in 2. Among them, 6 cases were

Table 1 Serum lipid profiles of gastric xanthomatosis and age- and sex-matched controls (mean \pm SD)

	GX (n = 54)	Control (n = 54)	P
Total cholesterol (mg/dL)	188.7 \pm 32.8	189.2 \pm 30.9	NS
LDL-cholesterol (mg/dL)	112.9 \pm 29.9	95.9 \pm 22.4	0.032
HDL-cholesterol (mg/dL)	48.8 \pm 12.3	62.9 \pm 40.5	0.028
TG	125.9 \pm 71.0	119 \pm 67.8	NS

NS: Not significant. TG: Triglyceride; HDL: High-density lipoprotein; LDL: low-density lipoprotein.

combined with chronic gastritis; those were gastric polyp in 2, gastric ulcer in 2, duodenal ulcer in 1 and GERD in 1.

There were no systemic signs of xanthomatosis in GX patients. Fifty-four age- and sex-matched individuals without GX served as controls. During endoscopy, six biopsy specimens had been obtained, two from GXs, two from the antrum, and two from corpus specimens. The two biopsy specimens were available from the area of the xanthomatosis and these were stained with hematoxylin and eosin (HE) for histologic examination. The one antrum and one corpus samples were used for the rapid urease test (CLO test, double chamber: Chongkeundang Co., Seoul, Korea), and stained with HE for evaluation of the activity of gastritis and *H. pylori* positivity. Anti-*H. pylori* IgG antibody was measured by enzyme-linked immunosorbent assay (ELISA) with a commercial kit (Hel-p test, Amrad Co, Melbourne, Australia) before endoscopy. Patients were classified as *H. pylori*-positive if at least two of above tests were positive or as *H. pylori*-negative if all tests were negative.

Endoscopic assessment

GX, a white-yellow nodule measuring less than 10 mm, was observed on the wall of stomach. Enterogastric or bile reflux gastritis was defined as the presence of bile-stained mucosa and a collection of bile juice on endoscopic examination.

Histologic evaluation

The histologic appearance of lipid islands was that the lamina propria was occupied by large ovoid to polygonal histiocytes having an abundant, finely vacuolated (foamy) cytoplasm staining lightly with eosin. The foam cell nuclei were regular, round to ovoid, and occupied a small portion of the cell area. No mitoses were observed. To confirm that foamy cells were present in the GX and derived from macrophages, immunohistochemical study was performed. The foamy cells were positive for the human macrophage marker (HAM-56, DAKO, Carpinteria, CA) and negative for cytokeratins (AE 1/3, Biogenix, San Roman, CA), supporting the diagnosis of xanthomatosis.

Histologic examination of the other biopsy specimens of the mucosa taken at a distance from lipid islands was also done. Biopsy specimens stained with HE and Giemsa were used to detect *H. pylori*. The histologic degree of activity (neutrophil infiltration), inflammation (mononuclear cell infiltration), glandular atrophy, and intestinal metaplasia were classified as none, mild, moderate, and severe in accordance with the updated Sydney System^[8]. Atrophy of

the gastric mucosa is defined as loss of glandular tissue. The observer should attempt to evaluate one feature at the time using a new visual analogue scale that was provided to assist in grading^[9]. Two independent observers evaluated the histologic examination without prior knowledge of the diagnosis or experimental results.

Statistical analysis

Statistical analysis was performed using the Chi-square test, Student's *t* test, and Mann-Whitney *U* test, when appropriate. A *P* value less than 0.05 was considered statistically significant. Data were expressed as mean \pm SD. SPSS 11.0 version software was used to analyze the data.

RESULTS

In this present study, the prevalence of GX was 7% (54/771). Of these 54 GX patients, 27 were men and 27 women, with mean age of 54 (range 33-77) years.

Endoscopic characteristics of GX

The mean number of GX was 1.7 ± 1.1 , and 64.8% (35/54) of cases had a single xanthoma. GX was located at the antrum in 53.7% (29/54), at the body in 35.2% (19/54), and at the fundus in 11.1% (6/54) of cases. The mean size of GX was 7 ± 3 mm, and none of the GX exceeded 10 mm in diameter.

Clinical characteristics of patients with GX

Distribution of BMI: The mean BMI of the GX group was 23.1 ± 2.8 (range, 18.0-28.2), with none over 30, which was similar to the control group (mean 24.1 ± 2.4 , range, 18.5-29.7). No correlation was found between abnormal BMI and the presence of GX.

Lipid profiles: Results of lipid profiles are shown in Table 1. When a normal HDL-cholesterol level of 30 mg/dL was selected as the lower cut-off value, 11 (20.4%) GX cases had HDL-cholesterol level lower than the cut-off value. Hypertriglyceridemia was found in 11 GX patients. However, no difference was found in the serum total cholesterol and triglyceride levels between the GX and control groups. In contrast, GX patients had lower mean HDL-cholesterol and higher mean LDL-cholesterol levels than the controls (*P* = 0.032 and *P* = 0.028, respectively).

Lipoprotein electrophoresis analysis was performed in 32 GX patients. Abnormal patterns were exhibited by only 2 (6.3%) patients, and both of them were dyslipoproteinemia type IV. No correlation was observed between the presence of dyslipoproteinemia and GX.

Underlying diseases: The underlying diseases were diabetes mellitus in 3 (5.5%), essential hypertension in 7 (12.9%), fatty liver in 3 (5.5%), chronic liver disease in 2 (3.7%), and malignancies in 6 (11.1%) GX patients. GX was not significantly correlated with any special underlying diseases.

Endoscopic findings and histologic severity

Table 2 shows the endoscopic findings of the GX patients

Table 2 Comparison of endoscopic distribution of atrophic gastritis in GX patients and controls

	Predominant distribution		
	Antrum	Corpus	Pangastritis
GX patients (24/54, 44.4%) ^b			
Mild (n = 10)	2	1	7
Moderate (n = 8)	3	0	5
Severe (n = 6)	2	0	4
Control (8/54, 14.8%)			
Mild (n = 6)	3	1	2
Moderate (n = 1)	1	0	0
Severe (n = 1)	1	0	0

The distribution and severity of atrophic change in GX patients significantly differed from that in controls (^b $P = 0.0082$).

and controls. The endoscopic distribution and severity of atrophic gastritis were determined in 24 of 54 (44.4%) GX patients as follows: mild form in 10, moderate in 8, and severe in 6. The distribution and severity of atrophic change were significantly higher in GX patients as compared with the controls in terms of both the antral distribution and the pangastritis ($P = 0.048$ and $P = 0.0082$, respectively).

Enterogastric reflux gastritis was noted in only 2 of 54 (3.7%) GX patients without other mucosal injury and in 1 of 54 (1.9%) controls. There was no significant relationship between GX and the presence of enterogastric reflux.

Prevalence of *H pylori* in GX

The positive rate of *H pylori* infection in GX patients (63%, 34/54) was similar to that of the controls (69.2%).

DISCUSSION

Gastric xanthomatosis, once considered a rare lesion, is being reported more frequently. Many reports^[1,3-5,10-12] about GX have shown its frequency of 0.018%-0.8%. Of 7816 patients who had undergone gastroduodenoscopy from January 2001 to August 2002, GX was detected in 76 (0.97%) patients, which is similar to the findings of previous studies^[11,12]. In the present study, the prevalence was found to be 7%, which is very much higher than that reported in Western countries^[12]. This finding indicates that GX is a relatively common disease entity as an increasing trend in Korea, although its etiology remains unclear. This may be associated with an increased awareness and selection bias of endoscopists; however, a large-scaled prospective study is needed in the future. In a Chinese series of 3870 patients, a moderate predominance of male over female (male:female = 3.3:1) was reported^[11], but GX showed no sex predilection in the present study.

Xanthogranulomatous gastritis is characterized by an inflammation of the gastric wall by foamy histiocytes, inflammatory cells, multinucleated giant cells, and fibrosis. The occurrence of this nodular growth in the gastric mucosa is manifested by the presence of lipid-laden macrophages containing cholesterol and natural fats in the lamina propria. The relationship between serum lipid and gastric mucosal injury due to bile reflux has been more clearly defined. After subtotal gastrectomy (Billroth II operation), GX occurred in 6.3% at 1 to 3 years after surgery,

in 35.7% at up to 15 years, and in 43.9% after 20 years^[12,13]. Isomoto *et al*^[7] reported a close relationship between atrophic gastritis or bile reflux gastritis and GX endoscopically. Several studies have shown that xanthoma is associated with gastritis, carcinoma, intestinal metaplasia of the gastric epithelium, or peptic ulcer diseases^[5,14,15]. In the present study, a close relationship was found between atrophic gastritis and GX but there was no correlation between GX and enterogastric reflux.

Endoscopically, a single GX was detected in a majority (64.8%) of GX patients, all GX were less than 10 mm in size, and most of the lesions (88.9%) were located at the antrum and body, which is in agreement with a previous study^[16]. The clinical significance of GX remains unknown and the presence of GX *per se* is probably of little clinical significance. Basic metabolic analysis to assess for hyperlipidemia or hypercholesterolemia should also be considered. Etiologically, these conditions may be associated with a primary dyslipoproteinemic state, such as diabetes, nephrosis, obesity or cholestasis. Chang *et al*^[17] reported lower mean HDL-cholesterol and higher mean triglyceride levels in GX subjects in comparison with the controls. In the present study, abnormal BMI (≥ 30) was not correlated with the presence of GX, while the lower mean HDL-cholesterol and higher mean LDL-cholesterol levels in GX subjects than controls seems statistically interesting ($P = 0.028$ and $P = 0.032$, respectively). Elevated triglyceride levels among GX patients have been occasionally mentioned in a small number of case studies^[18-20]. The present study showed insignificantly higher mean triglyceride level in GX subjects than controls. Abnormalities of lipid metabolism seem to play a role in presence of GX. The higher serum lipid content in GX patients may be partly derived from circulating lipids. Since excessive concentrations of oxygen-free radicals may result in accelerated LDL-cholesterol oxidation and the formation of GX^[7], the plasma levels of LDL-cholesterol and of oxidized LDL-cholesterol are important factors in the pathogenesis of atherosclerosis. GX cases in the present study showed no systemic signs of xanthomatosis and no significant differences were observed between GX patients and controls in the incidences of other conditions, such as diabetes, hyperlipidemia, or hypertension.

Chronic persistent infection with *H pylori* is believed to result in the development and to influence the extent of atrophic gastritis. Korea is one of the well-known *H pylori* endemic countries in the world. Some studies found a close association between *H pylori* infection and GX^[6,7]. Moreover, bacterial infection-induced foamy cell infiltration was observed in the small bowel lesions of Whipple disease^[21]. Therefore, it is possible that macrophage transformation into foamy cells may be secondary to phagocytosis caused by *H pylori* that have penetrated into the lamina propria, as suggested by Hori *et al*^[6]. In the present study, we examined *H pylori* infection by CLO test, histologic examination, or serologic test, and found that the prevalence of *H pylori* was similar in GX patients and controls, suggesting no correlation between GX and *H pylori* infection. This may be associated with high prevalence of *H pylori* infection in Korean adult population. Although the prevalence of *H pylori* infection was similar in GX patients and controls, atrophic gastritis was more frequently ob-

served in GX patients. Although atrophy of stomach was highly related to *H pylori* infection, there was no absolute correlation between atrophy and *H pylori* in some endemic area like Korea^[22]. Also atrophy could be induced by some other reasons, such as autoimmune, idiopathic, reactive, drug-associated, or other gastric irritant-induced causes.

In conclusion, although the reasons remain unclear, GX is an increasing entity in Korea. In addition, GX is associated with dyslipidemia and atrophic gastritis. However, there is no relation between *H pylori* infection or entero-gastric reflux gastritis and GX. It remains to be clarified whether dyslipidemia and atrophic gastritis observed among GX patients play any role in its etiology.

COMMENTS

Background

Xanthomatosis is yellow tumor-like lesion of the skin or deeper structure characterized by presence of lipid-containing histiocytes. This yellowish plaque in gastric mucosa (gastric xanthomatosis, GX) is a benign lesion, and it has no clinical significance. But a variety of possible causes, such as an abnormality of the lipid metabolism or inflammatory changes in the gastric mucosa, have been suggested. The aim of this study was to evaluate the prevalence and the clinical significance of GX endoscopically in Korea, and to investigate the relationship among GX, *H pylori* infection and dyslipidemia.

Innovations and breakthroughs

Although the reasons remain unclear, GX is an increasing entity in Korea. The present study showed the lower mean HDL-cholesterol and higher mean LDL-cholesterol and higher mean triglyceride levels in GX subjects than the controls. Abnormalities of lipid metabolism seem to play a role in presence of GX. However, there was no relation between *H pylori* infection or enterogastric reflux gastritis and GX. Although the prevalence of *H pylori* infection was similar in GX patients and controls, atrophic gastritis was more frequently observed in GX patients.

Applications

Even though GX is benign disease entity, it is definitely related with dyslipidemia and atrophic gastritis. If the patient has GX in endoscopic examination, it needs to evaluate the severity of atrophic gastritis and the level of lipid profile. It remains to be clarified whether dyslipidemia and atrophic gastritis observed among GX patients play any role in its etiology.

Terminology

GX was first named in 1929 by Lubarsch and Borchardt as a gastric lipid island. A variety of possible causes, such as an abnormality of the lipid metabolism or inflammatory changes in the gastric mucosa, have been suggested. The histologic appearance of GX was that the lamina propria was occupied by large ovoid to polygonal histiocytes having an abundant, finely vacuolated (foamy) cytoplasm staining lightly with eosin.

Peer review

It is an interesting and well written paper. The authors investigated the relationship among GX, *H pylori*, dyslipidemia, and gastritis in Korea. They conclude that the prevalence of GX is 7% and it may be an increasing entity in Korea. Moreover, dyslipidemia and atrophic gastritis are related to GX, but *H pylori* infection is not.

Abstract

AIM: To evaluate whether the prevalence of overweight and obese conditions is increased in gastro-esophageal reflux disease (GERD) patients (with 24-h pathological pH recordings) in comparison to general population.

METHODS: A total of 196 consecutive patients (103 females, age range 18-83 years) with symptoms of gastro-esophageal reflux (GER) and 24-h pathological esophageal pH-metry. Body mass index (BMI) of the patients was calculated and its distribution (%) was compared with that of the Italian general population as assessed by National Bureau of Census (ISTAT). To evaluate the association of GERD with weight categories, the binomial test was employed. $P < 0.05$ was considered statistically significant.

RESULTS: In males, overweightedness (BMI 25-25.9) was present in 43% of GERD patients *vs* 41.8% of Italian population (IP) (ns), obesity (BMI ≥ 30) in 10.9% *vs* 9.1% (ns). In females overweight was present in 34.9% of GERD patients *vs* 25.7% of IP ($P < 0.01$), obesity in 13.6% of GERD patients *vs* 9.1% of IP ($P < 0.01$). No statistically significant differences were noted in different age classes.

CONCLUSION: In comparison to the Italian general population, the prevalence of overweightedness and obesity is increased in female but not in male patients with ascertained gastro-esophageal reflux disease.

World J Gastroenterol 2007; 13(34): 4602-4605

<http://www.wjgnet.com/1007-9327/13/4602.asp>

INTRODUCTION

Increased body weight has often been considered one of the most important risk factors for gastro-esophageal reflux disease (GERD). A recent meta-analysis concluded that overweightedness and obesity are the risk factor for GERD^[1]. However, only three of the nine examined studies^[2-10] showed the relationship between obesity and GERD symptoms^[2].

Other studies have been performed only on patients with an exceedingly high body mass index (BMI), or even on patients requiring surgical^[11-15] or intragastric balloon^[16] treatment with no comparison with a normal BMI population.

Only two studies assessed the gastro-esophageal reflux (GER) by means of 24-h pH-metry but made no comparison with a reference population. Of these two studies, one was performed only on obese patients requiring intragastric balloon treatment^[16], the other was performed on 70 patients, 79% of whom had abnormal BMI, indicating a biased patient selection^[17].

Attempts to evaluate an improvement in gastro-esophageal reflux, or related symptoms following weight loss, in overweight and obese patients, have not led to a better understanding of the relationship between these two conditions since the data obtained are controversial^[16,18,19].

MATERIALS AND METHODS

A total of 196 patients (103 females, age range 18-83 years; 93 males, age range 24-74 years) referred to our GI unit for GERD symptoms (including typical and atypical symptoms), were included in this study.

In all 196 patients, the presence of pathological gastro-esophageal reflux, according to DeMeester score, was established after a 24 h pH-metry assessment [Ingold 440 M3 glass electrode, Genesi2 RAM 8Kb LEM Electronics recorder, Casalecchio di Reno (BO), Italy]. Weight and height were measured in each patient, and their BMI was calculated [weight (kg)/ height (m²)].

Patients were then assigned to one of the four categories, according to their BMI, following the 1995 World Health Organization criteria, in which distinction

between males and females is no longer considered: BMI < 18.5: underweight, BMI = 18.5-24.9: normal, BMI = 25-29.9: overweight, BMI > 30: obesity. The distribution (%) of the 196 GERD patients was compared with that of the Italian general population used, for this purpose, the data obtained in a National Bureau of Census (ISTAT) survey^[20].

To evaluate the association of GERD with weight categories, we employed the binomial test, to calculate the probabilities of the estimated proportion of GERD patients in the overweight Italian population. The expected proportion of overweight individuals, in the population, was obtained from the above-mentioned ISTAT survey, based on approximately 50000 people. This test was also performed stratifying the data according to sex and age-class. $P < 0.05$ was considered statistically significant. The association between smoking habit and presence of GERD was evaluated using the χ^2 test.

Informed consent was obtained from patients at beginning of the study.

RESULTS

Of the patients presenting with pathological gastro-esophageal reflux, 45.9% had a normal BMI which was lower than that in the general population (53.8%) while 38.8% and 12.2% overweight and obese GERD patients had a normal BMI (exceeding 33.4% and 9.1%, respectively, in the general population) (Figure 1A).

If the data on sex were considered, although the greater prevalence of BMI was still present in male GERD patients, the difference in the general population was less evident (overweight: 43% *vs* 41.8; obese: 10.8% *vs* 9.1%) (Figure 1B).

Conversely, the prevalence of overweightedness and obesity in female GERD patients was considerably greater than that in the general population (overweight: 34.9% *vs* 25.7% $P < 0.01$; obese: 13.6% *vs* 9.1% $P < 0.01$) (Figure 1C).

If the overweight and obese female patients were considered together, the total percentage reached 48.5% *vs* 35% in the general female population ($P = 0.005$).

No statistically significant differences were found in the analysis comparing different age classes. Likewise, statistical analysis failed to show any relationship between smoking habit and gastro-esophageal reflux in our patient population.

DISCUSSION

The most relevant finding of this study is that the prevalence of overweightedness and obesity was increased in female, but not in male Italian patients with ascertained gastro-esophageal reflux disease. Previous population-based studies considered GERD patients as those referring heartburn and acid regurgitation only^[1-5] and did not assess any objective pH-metric evidence of GER.

By using typical GER symptoms as entry criteria, these studies excluded subjects with atypical GER symptoms and pathological GER and, on the other hand, included subjects with functional heartburn and no GER. It is

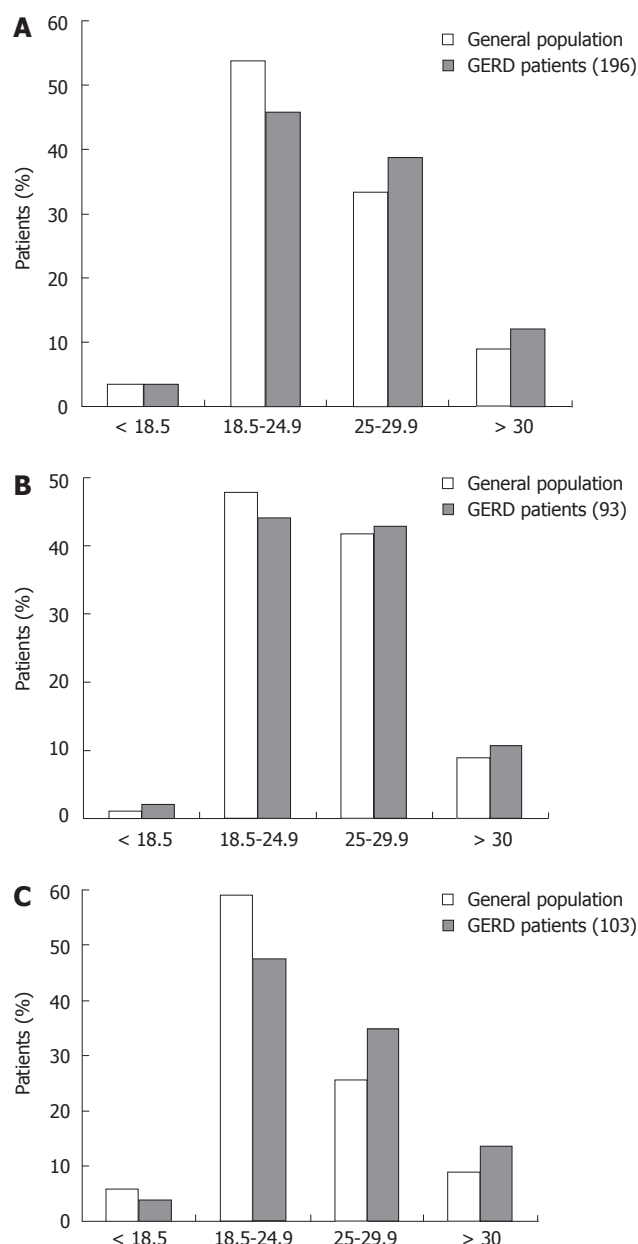

Figure 1 Distribution of BMI in general GERD patients (A), in male GERD patients (B), and in female GERD patients (C) after 24h esophageal pH-metry.

estimated that about 10% of patients complaining of heartburn have functional heartburn, namely heartburn in endoscopy-negative, pH-metry negative patients not responding to proton pump inhibitors^[21]. The prevalence of functional heartburn in patients recruited from our center is 16.5%^[22]. It is also likely that the prevalence of functional heartburn is increased in obese subjects since elevated psychosomatic score is associated with reflux symptoms^[10]. Moreover, some authors have advanced the hypothesis that esophageal mucosa is more sensitive in patients with functional heartburn and obese patients^[23].

These limitations were not encountered in the present study which assessed BMI in patients in whom pathological gastro-esophageal reflux was confirmed by 24-h pH-metry according to DeMeester score, independently of typical or atypical GER symptoms.

Almost 45% of the Italian population have an increased BMI. Although the percentage of overweight subjects is steady, if compared with data from the

ISTAT survey in 1994, the number of obese subjects has increased by 25% in the last 8 years. Elevated BMI, when accompanied with a greater intra-abdominal adipose mass, like other pathological conditions (constipation, cough and dysuria), may increase the abdominal-thoracic gradient favoring gastro-esophageal reflux episodes.

When the relationship between overweightedness or obesity and gastro-esophageal reflux is considered, it should be borne in mind that the eating habits of subjects with increased BMI values are often different from those of normal individuals, in terms of quality (particularly as lipids are concerned) and quantity of the nutrient intake. It is known that fatty foods produce a prolonged inhibitory effect on the lower esophageal sphincter (LES), particularly following intra-duodenal lipid perfusion^[24]. This inhibitory effect would appear due to a cholecystokinin-mediated action on LES^[25]. An epidemiological study revealed that overweightedness, but not excess fatty food intake, increases the risk of hospitalisation for GERD^[26]. Gastric distension following a copious meal produces a transient increase in LES relaxation which is directly correlated to the distension volume^[27] and could thus be another important factor favouring gastro-esophageal reflux. Variables such as eating habits and lifestyle were not considered in this study. The analysis of smoking failed to show any significant difference between the smoker and non-smoker groups.

Albeit, the role of LES pressure in obese patients with GERD is still controversial, and recent data^[28] show that gastro-esophageal pressure gradient but not LES pressure, plays a relevant pathogenetic role in GERD patients with elevated BMI.

All the above mechanisms secondary to overweightedness and obesity would equally affect both genders and cannot explain the association between GER and overweight and obesity in females only.

The role of sex in GERD has not been clearly defined since available data from the literature are not homogeneous. In most epidemiological studies, the prevalence of GERD is greater in males than in females among symptomatic patients^[29-31]. Some studies assessed the prevalence of sex primarily upon endoscopic esophagitis disregarding NERD patients, and found that low grade esophagitis is more frequent in females and high grade esophagitis in male patients^[32,33]. Moreover, one study showed that longer GERD duration is correlated with the male sex^[34]. It is widely known that Barrett's esophagus is far more frequent in males^[35-37].

The present study seems to indicate an association between BMI increase and gastro-esophageal reflux in female patients. Other authors have observed analogous results when studying the prevalence of male or female sex in overweight or obese patients with GERD. In fact, an association between obesity and GERD in females has been reported in some studies in which the authors are of the opinion that higher oestrogen concentration may cause more frequent transient lower esophageal sphincter relaxations^[9,38].

Since high levels of circulating free oestrogens occur in obese and overweight females due to decreased concentration of oestrogen binding globulin and a concomitant increased production of oestrone from the

fatty tissue, the hormonal effect can be indicated as a possible cause of GER. Although differences in gender fat distribution have not been considered, no data suggest a major risk of GER in males and a cardiovascular or metabolic risk of obesity in females. In addition, in this study the analysis of BMI and GER according to different age classes, failed to identify any significant difference, indicating that female postmenopausal distribution of visceral fat, similar to male one^[39], has the same but not relevant effect on GER of the premenopausal fat distribution.

However, it can be hypothesized that the hormonal effect of increased adipose tissue increases the GER risk in overweight and obese females and makes it comparable to the GER risk in males.

In conclusion, findings of the present study suggest that overweightedness and obesity are related with an increased risk of gastro-esophageal reflux in females.

Abstract

AIM: To discuss about the perioperative problems encountered in patients with internal biliary fistula (IBF) caused by cholelithiasis.

METHODS: In our hospital, 4130 cholecystectomies were carried out for symptomatic cholelithiasis from January 2000 to March 2004 and only 12 patients were diagnosed with IBF. The perioperative data of these 12 IBF patients were analyzed retrospectively.

RESULTS: The incidence of IBF due to cholelithiasis was nearly 0.3%. The mean age was 57 years. Most of the patients presented with non-specific complaints. Only two patients were considered to have IBF when gallstone ileus was observed during the investigations. Nine patients underwent emergency laparotomy with a pre-operative diagnosis of acute abdomen. In the remaining three patients, elective laparoscopic cholecystectomy was converted to open surgery after identification of IBF. Ten patients had cholecystoduodenal fistula and two patients had cholecystocholedochal fistula. The mean hospital stay was 13 d. Two wound infections, three bile leakages and three mortalities were observed.

CONCLUSION: Cholecystectomy has to be performed in early stage in the patients who were diagnosed as cholelithiasis to prevent the complications like IBF which is seen rarely. Suspicion of IBF should be kept in mind, especially in the case of difficult dissection during cholecystectomy and attention should be paid in order to prevent iatrogenic injuries.

INTRODUCTION

A biliary fistula is an abnormal passage or communication from the biliary system to an organ, cavity, or free surfaces. Fistula are classified as external (biliary-cutaneous) or internal (biliobiliary, bilioenteric, bronchobiliary)^[1]. Internal biliary fistula (IBF) is associated with chronic cholelithiasis in 90% of the cases.

Preoperative diagnosis of IBF is difficult^[2]. As the symptoms of IBF include abdominal pain, fever, nausea, vomiting, flatulence, fat intolerance, diarrhoea and weight loss, which are all non-specific and seen in most gastrointestinal pathologies, the diagnosis is often not suspected preoperatively^[3]. The diagnosis is usually made peroperatively^[4-6].

MATERIALS AND METHODS

A total of 4130 cholecystectomies were carried out for symptomatic cholelithiasis in Ankara Numune Teaching and Research Hospital, Ankara, Turkey from January 2000 to March 2004 and only 12 patients were diagnosed with IBF. The preoperative and peroperative findings as well as postoperative course of the patients with IBF were evaluated from their hospital records.

RESULTS

Pre-operative findings

Of 4130 cholecystectomies, 12 patients (5 women and 7 men) were diagnosed as IBF. The mean age of these 12 patients was 57 years and 8 of these patients were above 60 years. Five of the 12 patients were previously diagnosed cases of cholelithiasis.

Tenderness in the right hypochondrium was the most frequent physical finding presented in 10 of the 12 (83.3%) patients. One case presented with abdominal pain in the right lower quadrant, with nausea, vomiting and abdominal distension, that was preoperatively diagnosed as acute appendicitis.

Preoperative diagnosis of IBF was achieved in only two patients with gallstone ileus and based primarily on plain abdominal X-ray. The consistent findings were air-

Table 1 The characteristics of the patients

No.	Age/sex	Pre-operative diagnosis	Peri-operative findings	Operation	Hospital stay (d)	Morbidity during postoperative course
1	69/F	Gallstone ileus	Double CDF + gallstone ileus + iatrogenic sigmoid perforation	Cholecystectomy + enterolithotomy + T-tube + primary sutures to duodenal wall + Bogota bag + primary colon repair	45	Bile leakage
2	80/M	Acute abdomen, Acute appendicitis? Ileus?	Gallstones, CDF + jejunal mass + gallstone ileus	Cholecystectomy + choledochotomy + T-tube + primary sutures to duodenum + tube duodenostomy + appendectomy + jejunotomy + removal of stone	16	Myocardial infarction, death
3	60/M	Obstructive jaundice	CCDF	Partial cholecystectomy + repair of common bile duct over T-tube	20	Wound infection
4	22/M	Cholecystocholedocholithiasis	Adhesions, conversion to laparotomy, CDF, acute cholecystitis	Cholecystectomy + T tube insertion + primary sutures to duodenal wall	10	NC
5	67/F	Cholelithiasis	Adhesions, conversion to laparotomy, CDF	Cholecystectomy + primary sutures to duodenal wall	8	NC
6	54/F	Acute abdomen	CDF	Cholecystectomy + choledochotomy + T-tube insertion + primary sutures to duodenal wall	8	NC
7	71/M	Choledocholithiasis	Mirizzi's syndrome, CDF	Cholecystectomy + choledochotomy + T tube insertion + primary sutures to duodenal wall	6	NC
8	30/F	Cholelithiasis	CDF	Cholecystectomy + primary sutures to duodenal wall	4	NC
9	66/M	Cholelithiasis	Adhesions, conversion to laparotomy, CDF	Cholecystectomy + T-tube insertion + primary sutures to duodenal wall	8	Wound infection

11	62/M	Acute abdomen, gallbladder perforation	CDF, perforation of gallbladder, pleural effusion	Cholecystectomy + T-tube insertion + primary sutures to duodenal wall + chest tube insertion ¹	28	GI bleeding, bile leakage, sepsis, death
12	70/F	Acute cholecystitis, obstructive jaundice	CCDF, acute cholecystitis	Cholecystectomy + Hepaticojejunostomy	25	Bile leakage

CDF: Cholecystoduodenal fistula; CCDF: Cholecystocholedochal fistula; NC: No complications. ¹This is the primary operation performed. Patient also underwent repeated procedures due to bile leakage.

fluid levels, distended small bowel loops and a radio-lucent stone outside the biliary tree.

Endoscopic retrograde cholangiopancreatography (ERCP) performed in two patients due to obstructive jaundice and choledocholithiasis failed to show any fistulous opening in any of them.

Among four patients diagnosed preoperatively as acute abdomen, two patients had serious coronary failure and other two had history of chronic obstructive pulmonary disease.

Nine of the 12 patients with IBF underwent emergency laparotomy with the pre-operative diagnosis of acute abdomen. In remaining three patients, elective laparoscopic cholecystectomy was converted to open surgery after identification of IBF.

Peroperative findings

In the 12 patients with IBF, peroperative findings were dense adhesion around gallbladder requiring of sharp dissections, fibrosed and contracted gallbladder, encountering difficulty in identifying cystic duct, cystic artery and common bile duct.

Intra-operative cholangiography (IOC) had to be performed only in 4 of the 12 patients in order to prevent iatrogenic injuries due to the aforementioned findings. Nevertheless, IOC was useful in identifying IBF in only one patient. The fistula tract was identified after sharp dissection in the remaining 8 patients. Regarding the types of fistulas, cholecystoduodenal fistula (CDF) and cholecystocholedochal fistula (CCDF) were found in 10

and 2 patients, respectively.

The fistula orifice in the common bile duct was usually closed by T-tube placement after exploration of the common bile duct for stone retrieval. The fistula orifice in the duodenum was primarily repaired and T-tube was inserted with the aim of biliary decompression in the patients with CDF. Cholecystectomy plus fistula repair, enterotomy and removal of the gallstone (enterolithotomy) were performed in two patients with cholecystoduodenal fistula (CDF) plus gallstone ileus. The operative details and other details are shown in Table 1.

Postoperative course

The mean (range) hospital stay was 13 (4-45) d. Two wound infections, three bile leakages and three mortalities were observed in postoperative period. Thus, the mortality rate was 25% (3/12) and morbidity rate was 42% (5/12).

One death occurred due to myocardial infarction on the 16th postoperative day after cholecystectomy + choledochotomy and T-tube insertion + repair of fistula + tube-duodenostomy + jejunotomy and removal of stone. The second death occurred due to acute respiratory distress syndrome (ARDS) on the 18th postoperative day after cholecystectomy + T-tube insertion + primary closure of the duodenum. The third death occurred following repeated procedures (abdominal lavage for intra-abdominal interloop abscess + T-tube reinsertion) due to septic complications caused by bile leakage on the 28th d after cholecystectomy + T-tube insertion + primary closure of the duodenum.

One of the two patients had bile leakage after being discharged from the hospital with T-tube and T-tube was extracted after one month later. External biliary fistula was observed in the other patient and the fistula was closed after 20 d.

DISCUSSION

Internal biliary fistula (IBF) occurs due to acute inflammation with obstruction of the cystic duct resulting in adhesions of the gallbladder to the adjacent viscus, usually to the duodenum; and repeated attacks of inflammation including gangrenous changes of the gallbladder wall and the wall of the adherent viscus, with eventual erosion and fistula formation^[1]. The common causes of IBF include cholelithiasis, peptic ulceration, malignant neoplasm (gallbladder, bile duct, duodenum, pancreas, or stomach), Crohn's disease of the duodenum and paraduodenal abscess^[1,7,8]. In this study, IBF due to cholelithiasis was evaluated.

Our data showed the IBF incidence of 0.29% (12/4130) and all fistula were secondary to cholelithiasis, which is less than the previous reports^[9,10].

Our patients with IBF usually presented with non-specific signs or symptoms of biliary fistula. Hence, the preoperative accurate diagnosis was made only in 16.6% (2/12) patients in the present study, which is in agreement with the previous study^[3]. In the present study, gallstone ileus was suspected on plain abdominal X-ray in only one patient, which was confirmed by operative findings and stone was removed by enterotomy. However, some classical findings on plain abdominal radiography include pneumobilia, intestinal obstruction, aberrantly located gallstone and change of location of a previously observed stone^[1,3]. Although ultrasonography is extremely useful in detecting a fistula, pneumobilia, impacted stones and the presence of residual cholelithiasis and/or choledocholithiasis^[11], none of the IBF in our patients was detected preoperatively by ultrasonography.

As the symptoms of IBF include abdominal pain, fever, nausea, vomiting, flatulence, fat intolerance, diarrhoea and weight loss, which are all non-specific and seen in most gastrointestinal pathologies, the diagnosis is often not suspected preoperatively^[3]. Preoperative diagnosis according to the symptoms was not possible in any of the our cases. Jaundice secondary to common bile duct obstruction was reported to be a common finding in patients with cholecystocholedochal fistula (CCDF)^[9,12]. Although two patients in our study presented with jaundice and underwent ERCP, we were unable to detect any fistulous opening.

Most studies report that the fistulas are detected incidentally or unsuspectedly during ERCP or other radiologic examinations performed for investigation of biliary or pancreatic diseases^[13]. Although ERCP failed to detect IBF in one patient in the present study, ERCP is the principal tool for diagnosis of IBF^[4]. It can easily show the fistula orifice, fistula tract, and communication with the biliary tree, as well as the etiology. ERCP has therapeutic potential by endoscopic sphincterotomy

Table 2 Data on diagnosis and management of internal biliary fistula in literature

Authors	Case number	Peri-operative findings	Procedure
Silecchia ^[18]	5	CCDF, Type II Mirizzi syndrome	NA
Carlei ^[19]	5	CDF	LC + repair
Angrisani ^[6]	34	CDF, CJF, CCF	LC + repair in 14 patients, Conversion to laparotomy in 20 patients
Moreno Ruiz ^[20]	17	14 CDF, 3 CCF, 2 CGF	LC + repair

NA: Surgical data not available; LC + repair: Laparoscopic cholecystectomy + fistula repair; CDF: Cholecystoduodenal fistula; CCDF: Cholecystocholedochal fistula; CCF: Cholecysto-colic fistula; CGF: Cholecystogastric fistula; CJF: Cholecystojejunal fistula.

and choledocholithotomy^[14]. CT is the most appropriate imaging test for further evaluation because sonographic diagnosis is often difficult^[15]. Pickhardt *et al*^[16] reported that MRCP might be useful in selected cases to confirm the diagnosis^[16].

In our study, all fistulas were diagnosed intra-operatively. Suspicion of IBF should be kept in mind, especially in cases of difficult dissection during cholecystectomy due to small, contracted, chronically inflamed and densely adherent gallbladder, and attention should be paid in order to prevent iatrogenic injuries. Moreover, intra-operative cholangiogram through the gallbladder help to identify any existing fistulous tract.

Cholecystoduodenal fistula (CDF) is the most frequent type (70%-90%) of IBF, followed by cholecystocolonic (10%), choledochoduodenal, choledochogastric, cholecystogastric, and duodeno-left hepatic duct fistulas^[1,17]. Similarly in this study, cholecystoduodenal fistula (CDF) and cholecystocholedochal fistula (CCDF) were found in 10 (83.3%) and 2 (16.6%) patients, respectively. Two of our patients with cholecystoduodenal fistula had gallstone ileus (20%).

The standard treatment of IBF is cholecystectomy and repair of the fistulous opening; however, it was performed in only two cases in our study^[2]. Common bile duct exploration, T-tube insertion, choledochoduodenostomy, tube duodenostomy, enterolithotomy and hepaticojejunostomy were also used as an additional procedure when indicated.

It was initially reported that when the IBF was diagnosed during laparoscopic cholecystectomy, it carried a higher rate of conversion to laparotomy^[6,18] (Table 2). Nowadays, as the surgeon is skilled in advanced laparoscopic procedures, such as duodenal mobilization and intracorporeal suturing and knotting, the rate of conversion is low, CDF is no longer considered a contraindication for laparoscopic treatment^[19-21]. Although the procedure was started laparoscopically in three cases in the present study, it was converted to the open due to technical difficulties.

The mortality rate of IBF was 25% (3/12) in our study, which is slightly higher than that reported in literature (i.e. 15% to 22%)^[1,9]; this might be explained as the patients underwent emergency operation for acute abdomen without enough preoperative evaluation.

In conclusion, cholecystectomy has to be performed in the early stage in the patients who were diagnosed as cholelithiasis to prevent the complications like IBF which is seen rarely. Suspicion of IBF should be kept in mind, especially in case of difficult dissection during cholecystectomy and attention should be paid in order to prevent iatrogenic injuries.

COMMENTS

Background

Internal biliary fistula (IBF) is seen rarely and it is a complication of chronic cholelithiasis. Preoperative diagnosis of IBF is difficult because of non-specific signs or symptoms. Although ultrasonography and ERCP are extremely useful in detecting a fistula, the diagnosis of IBF is usually made peroperatively.

Research frontiers

This study showed high morbidity, mortality rate and the peroperative problems encountered in patients with IBF.

Innovations and breakthroughs

Even though IBF is seen rarely, it must be remembered in the patients with chronic cholelithiasis and IBF should be diagnosed during USG and ERCP. Currently, treatment of IBF may be performed during laparoscopic cholecystectomy, but in this case the surgeon must be very skilled in advanced laparoscopic procedures.

Applications

Cholelithiasis has to be treated in early stage to prevent IBF. Suspicion of IBF should be kept in mind, especially in cases of difficult dissection during cholecystectomy due to small, contracted, chronically inflamed and densely adherent gallbladder.

Terminology

Cholecystectomy: Removing of gall bladder *via* operation. Choledocholithiasis: The position of existing one or more stones in bile ducts. Choledochotomy: Incision which is performed on ductus choledochus. Duodenostomy: Surgical fistula which is performed between duodenum and another anatomic area. Enterolithotomy: Removing of stone from intestine. Hepaticojejunostomy: Anatomises which is performed between ductus hepaticus and proximal jejunum.

Peer review

The authors investigated the occurrence of internal biliary fistula seen among the patients receiving cholecystectomy due to cholelithiasis. They concluded that laparoscopic cholecystectomy has to be performed in early stage in the patients who were diagnosed as cholelithiasis to prevent from complications like IBF which is seen rarely. IBF suspicion should be remembered during difficult dissection encountered in peroperative period and attention should be paid in order to prevent iatrogenic injuries.

Abstract

AIM: To investigate the role of gastric mucosa at the secretion of sTREM-1 in peptic ulcer.

METHODS: Seventy two patients were enrolled; 35 with duodenal, 21 with gastric ulcer and 16 with chronic gastritis. Patients were endoscoped and gastric juice was aspirated. Patients with duodenal and gastric ulcer underwent a second endoscopy post-treatment. Biopsies were incubated in the absence/presence of endotoxins or gastric juice. Supernatants were collected and sTREM-1 and TNF α were measured by enzyme immunoabsorbent assays. Scoring of gastritis was performed before and after treatment according to updated Sydney score.

RESULTS: Patients with duodenal and gastric ulcer and those with chronic gastritis had similar scores of gastritis. sTREM-1 was higher in supernatants of tissue samples of *H pylori*-positive than of *H pylori*-negative patients with gastric ulcer. Median (\pm SE) sTREM-1 was found increased in supernatants of patients with gastric ulcer before treatment (203.21 ± 88.91 pg/1000 cells) compared to supernatants either from the same patients post-treatment (8.23 ± 5.79 pg/1000 cells) or from patients with chronic gastritis (6.21 ± 0.71 pg/1000 cells) ($P < 0.001$ and < 0.001 , respectively). Similar differences for sTREM-1 were recorded among LPS-stimulated tissue samples of patients ($P = 0.001$). Similar differences were not found for TNF α . Positive correlations were found between sTREM-1 of supernatants from patients with

both duodenal and gastric ulcer before treatment and the degree of infiltration of neutrophils and monocytes.

CONCLUSION: sTREM-1 secreted by the gastric mucosa is an independent mechanism connected to the pathogenesis of peptic ulcer. sTREM-1 was released at the presence of *H pylori* from the inflamed gastric mucosa in the field of gastric ulcer.

INTRODUCTION

Many aspects of the mechanisms implicated in the pathogenesis of peptic ulcer disease remain unclear^[1]. Research has been focused more on derangements of mechanisms of protection and repair of the mucosa of the stomach and duodenum^[2]. It appears that most cases of both gastric and duodenal ulcer occur in the setting of infection by *H pylori*. Evidence is mounting in support of *H pylori* as a necessary ingredient in the ulcerative process, similar to acid and pepsin. It is not known whether the bacteria or the accompanying inflammation is the most important factor in the pathophysiology of peptic ulcer disease^[3].

Triggering receptor expressed on myeloid cells (TREM)-1 is a recently discovered receptor expressed on the surface of neutrophils and monocytes. Engagement of TREM-1 has been reported to stimulate the synthesis of proinflammatory cytokines^[4]. A soluble form of TREM-1, named sTREM-1, was observed and identified at significant levels in serum samples of patients with diseases affecting the gastrointestinal tract^[5].

sTREM-1 has been found elevated in the gastric juice

of patients with peptic ulcer. Since its levels were positively correlated to the degree of infiltration of the gastric mucosa by neutrophils, leading thus to the hypothesis that sTREM-1 might be a sign of an inflammatory reaction taking place in the gastric mucosa^[6]. The latter hypothesis might be strengthened by the lack of expression of TREM-1 on cell membranes of macrophages of healthy intestinal lamina propria^[7].

Based on the latter evidence, it is questioned whether sTREM-1 might be produced from the gastric mucosa in the event of peptic ulcer disease. The current study was designed to investigate a role of gastric mucosa for the release of sTREM-1. Furthermore it was investigated whether anti-ulcerative treatment was accompanied by any change of the ability of the mucosa for the secretion of sTREM-1.

MATERIALS AND METHODS

Study group

The study was approved by the Medical and Ethics Committee (6th/11.30.05/26962) of General Hospital "Sismanoglion", Athens, Greece. A total of 72 patients, 54 men and 18 women, aged 58.92 ± 16.52 (mean \pm SD) years were enrolled; 56 patients with peptic ulcer disease and 16 patients with chronic gastritis without peptic ulcer. Admitted patients were divided into three groups based on endoscopic findings, as follows: group A: consisting of 35 patients with duodenal ulcer; group B: consisting of 21 patients with gastric ulcer; and group C, consisting of 16 patients with chronic gastritis.

Informed consent was obtained from all participants. Indications for endoscopy in these patients were abdominal pain or discomfort, epigastric pain with nausea and vomiting, and dyspepsia. All endoscopies were done by the same endoscopist. Peptic ulcer was defined as a circumscribed break in the mucosa in the duodenum (DU) or in the stomach (GU) with apparent depth covered by an exudate, as previously described^[8]. All patients with peptic ulcer disease belonged to the Forrest III score^[9]. *H. pylori* infection was defined by the presence of the bacterium both at the histopathologic findings of each biopsy and after a gastric biopsy culture at the proper growth medium^[10]. Exclusion criteria for the study were: recent upper GI bleeding, gastric carcinoma, diabetes mellitus, liver cirrhosis, acute or chronic renal failure and the ingestion of any antimicrobial or antisecretory medication for at least 15 d prior to endoscopy.

Interventions and study design

All patients were examined by upper GI endoscopy. Among patients with duodenal and gastric ulcer disease two endoscopies were performed; the first before treatment and the second 15 d after the end of the treatment. Among patients with chronic gastritis only one endoscopy was done; at each endoscopy biopsies were collected. Gastric juice was aspirated immediately after the entrance of the endoscope into the gastric lumen. At the time of endoscopy, three biopsy specimens were obtained from adjacent areas of the gastric antrum. When each biopsy

specimen was taken, the forceps were fully opened and aimed at right angles to the gastric lumen to the extent possible to obtain uniformly sized biopsies. Biopsies were obtained from endoscopically intact mucosa distant from focal lesions such as ulcers and erosions. Each biopsy was used for *in vitro* culture.

After diagnosis of peptic ulcer disease or gastritis, esomeprazole 20 mg twice daily was prescribed. It was administered for four weeks in patients with duodenal ulcers, for eight weeks in patients with gastric ulcers and for four weeks in patients with chronic gastritis. For patients with infection by *H. pylori*, clarithromycin 500 mg bid and amoxicillin 1000 mg bid for 10 d were also added. The above treatment was administered according to international guidelines^[11,12].

In brief, gastric antral mucosal biopsy tissues were weighed and cultured on a culture insert over wells containing RPMI 1640 medium with 10% heat inactivated fetal bovine serum in a 5% CO₂ incubator for 18 h^[13]. Biopsies were positioned on the insert with mucosal surfaces up. The first biopsy tissue was left unstimulated and served as control; the second was stimulated with 10 ng/mL of lipopolysaccharide of *Escherichia coli* O144:H4 (LPS), and the third with 30 μ L of gastric juice of each patient. The total volume of the added growth medium was 2.4 mL; when gastric juice was added it represented 1.25% of the total well volume. At the end of the incubation, the plates were centrifuged for ten minutes at 1400 g; then supernatants were collected from the wells and stored at -70°C, until assayed for estimation of sTREM-1 and TNF α . Results were correlated with histopathological findings.

Estimation of sTREM-1

Estimation of sTREM-1 was performed by a home-made enzyme immunoabsorbent assay in samples of supernatants. Capture antibody of sTREM-1 (R&D Inc, Minneapolis, USA) was diluted to 4000 ng/mL and distributed in a 96-well plate at a volume of 0.1 mL per well. After overnight incubation at 25°C, wells were thoroughly washed with a 0.05% solution of Tween in PBS (Merck) (pH: 7.2-7.4). Then 0.1 mL of standard concentrations of sTREM-1 (15.1-4000 pg/mL, R & D Inc) diluted with Reagent diluent (1% BSA in PBS, pH 7.2-7.4, 0.2 micron filtered) serving as a buffer or of supernatants was added in wells. After incubation for two hours, wells were washed thrice, and 0.1 mL of one 400 ng/mL dilution of sTREM-1 detection antibody (R&D Inc) was added per well. The plate was then incubated for two hours, and attached antibodies were signalled by streptavidin. Concentrations of sTREM-1 to each well were estimated by the optical density detected at 450 nm after addition of one 1:1 solution of H₂O₂: tetramethylbenzidine as a substrate (R&D Inc). sTREM-1 was expressed in pg/g of tissue. The lowest limit of detection for sTREM-1 was 3.91 pg/g of tissue. All determinations were performed in duplicate; the inter-day variation of the assay was 5.23%.

Estimation of TNF α

Tumor necrosis factor alpha (TNF α) was measured in samples of supernatants with an enzyme immunoabsorb-

Table 1 Demographic characteristics of patients enrolled in the study. Updated Sydney scores are given

Parameters	Pre treatment	Post treatment	Chronic gastritis

bent assay (EIA, Amersham, London, UK). Lowest limits of detection were 6.25 pg/g of tissue. All measurements were performed in duplicate and cytokine concentrations were expressed as pg/g of tissue.

Histopathology

Formalin-fixed, paraffin-embedded tissue samples were routinely cut at 3–4 μ m and stained with haematoxylin and eosin alcian blue PAS (Periodic Acid Schiff) (at pH: 2.5) and Giemsa. Immunohistochemistry was performed for *H. pylori* detection with 1:100 dilution (Biocare Med., California, USA).

The presence of gastritis was evaluated in each biopsy sample after separate scoring for each of the following parameters: (a) disease activity as mucosal infiltration by neutrophils; (b) chronic inflammation expressed as infiltration by monocytes and lymphocytes; (c) degree of mucosal atrophy; and (d) intestinal metaplasia. Each parameter was scored from 0 to 3 (0: absent, 1: mild, 2: moderate, 3: marked). In the case of intestinal metaplasia scores indicated the following findings: 0: absence; 1: complete or type I; 2: incomplete or type II; and 3: incomplete or type III. As a consequence total Sydney score of gastritis ranged between 0 and 15, according to previously reported criteria of the updated Sydney System^[14]. The extent of gastric inflammation in the antrum, corpus or both was also recorded. The density of *H. pylori* was also evaluated semiquantitatively by the same criteria^[15]. Specimens were classified by one pathologist who was unaware of the corresponding laboratory findings.

Statistical analysis

Patients of three groups were further divided into subgroups according to the absence or presence of *H. pylori*. Concentrations of sTREM-1, and TNF α were expressed by their median \pm 95% confidence intervals (CI) or range. Updated Sydney classification scores were given by their means (\pm Standard Deviation, SD). Comparison between groups was made by Mann-Whitney *U* test with a correction according to Bonferroni; for qualitative data comparisons were performed by χ^2 test. Correlations between sTREM-1, and TNF α and the gastritis score or the density of *H. pylori* were performed according to Spearman's rank of order. Any *P* value less than 0.05 was considered as significant.

RESULTS

Patients' characteristics are given in Table 1. All patients suffering from duodenal ulcers had presence of *H. pylori* on tissue biopsy.

No differences were recorded between patients with duodenal and gastric ulcer disease before treatment and patients with chronic gastritis regarding histological parameters of gastritis according to updated Sydney score. Differences in total updated Sydney score, and several parameters of chronic gastritis before and after treatment among patients with peptic ulcer disease and patients with chronic gastritis are shown in Table 1.

Concentrations of sTREM-1 and of TNF α in supernatants of samples of gastric mucosa taken from patients with either duodenal ulcer disease or gastric ulcer disease or chronic gastritis pre-treatment are shown in Table 2. sTREM-1 was higher in supernatants of tissue samples of *H. pylori*-positive than of *H. pylori*-negative patients with gastric ulcer. That was also found when mucosa samples were stimulated by LPS. Respectively, similar differences were not found for TNF α . They were also not found for both sTREM-1 and TNF α between *H. pylori*-positive and *H. pylori*-negative patients with chronic gastritis.

In the above subgroups of patients, concentrations of sTREM-1 were higher in supernatants of gastric mucosa of *H. pylori*-positive patients with gastric ulcers than of mucosa of *H. pylori*-positive patients with duodenal ulcer after stimulation by LPS (*P* < 0.05). Concentrations of sTREM-1 were also higher in supernatants of gastric mucosa of patients with duodenal ulcer than of patients with gastritis either without or with stimulation by LPS (*P* of comparisons: < 0.01 and < 0.01, respectively). Similar differences for sTREM-1 were found between gastric ulcer and chronic gastritis for *H. pylori*-positive patients (*P* of comparisons < 0.01 and < 0.01, respectively). No changes were found when gastric juice was added in cultures. Respective differences in concentrations of TNF α were not observed.

Comparisons of concentrations of sTREM-1 and TNF α between supernatants in unstimulated, and LPS-stimulated samples of gastric mucosa in patients with duodenal and gastric ulcer pre and post treatment respectively, are shown in Table 3. In the presence of LPS, TNF α was increased in supernatants of biopsies taken from *H. pylori*

Table 2 Concentrations of soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) and tumor necrosis factor- α (TNF α) of supernatants of tissue samples taken from patients with either duodenal or gastric ulcer disease or chronic gastritis at pre-treatment

Parameters	Duodenal ulcer		Gastric ulcer		Chronic Gastritis

negative patients with gastric ulcer before treatment and with chronic gastritis ($P < 0.05$ and < 0.05 , respectively).

Correlations of sTREM-1 and TNF α between supernatants of patients with duodenal and gastric ulcer pre treatment and of patients with chronic gastritis when cultured in the absence/presence of LPS and parameters of gastritis score are shown in Table 4. In the absence of LPS sTREM-1 concentrations were significantly correlated with monocytes infiltration in *H pylori* positive patients with

gastric ulcer. In the presence of LPS sTREM-1 was significantly correlated with both monocytes and neutrophils infiltration in *H pylori* positive patients with gastric ulcer; respectively, significant correlations were also observed between sTREM-1 and monocytes infiltration in *H pylori* positive patients with duodenal ulcer. Respectively, both in the absence/presence of LPS TNF α concentrations were significantly correlated with monocytes and neutrophils infiltration in *H pylori* positive patients with and gastric ulcer; respectively, significant correlations were also observed between TNF α and monocytes infiltration in *H pylori* positive patients with duodenal ulcer. No significant correlation was found between any of the latter scores and sTREM-1 or TNF α of supernatants of biopsies taken from patients post-treatment.

DISCUSSION

Among patients suffering from chronic active gastritis only a minority evolves to peptic ulcer disease^[15], rendering the question what might be the underlying mechanism leading several patients with gastritis to peptic ulcer and others not. Recent data revealed that sTREM-1 was found increased in the gastric juice of patients with peptic ulcer disease compared to patients with chronic gastritis^[7]. That finding might lead to the hypothesis that sTREM-1 might constitute an independent factor leading from gastritis to peptic ulcer.

The present study applied a unique design. It is the first time, to our knowledge, in the literature where the ability of

the gastric mucosa for the release of sTREM-1 and TNF α was studied among patients with either duodenal ulcer or gastric ulcer or chronic gastritis without signs of peptic ulcer disease. Supernatants of biopsies taken from the enrolled patients were stimulated with LPS and gastric juice of patients. It is known that *H pylori* as a Gram negative bacterium secretes LPS that mediates to the gastric inflammation^[16]. As described by others, cell loss and apoptosis of gastric mucous cells was enhanced by *H pylori* LPS with less potency compared to the same effect by *E. coli* LPS. The low immunological potency of *H pylori* LPS may contribute to low-grade gastritis^[17]. In an attempt to simulate the latter process cultured biopsies were stimulated with LPS. Inflammation of the gastric mucosa was significantly reduced after treatment whereas *H pylori* was also eradicated (Table 1). Although the proper treatment was administered in patients with chronic gastritis second endoscopy was not performed; the latter was thought to be of no significance because sTREM-1 concentrations were already minimal pre treatment.

Results revealed that gastric mucosa of *H pylori* positive patients with both duodenal and gastric ulcer disease was potent to secrete sTREM-1. The potency for secretion of sTREM-1 was lost post-treatment. The release of sTREM-1 was higher by *H pylori* infected gastric mucosa than by gastric mucosa not infected by *H pylori*. The effect of *H pylori* on the release of sTREM-1 by mucosa of patients with duodenal ulcer could not be assessed since all patients with duodenal ulcer in the studied cohort were *H pylori*-positive.

Similar kinetics to sTREM-1 were not found for TNF α . TNF α was found increased in strict correlation with the degree of mucosal inflammation independently from the underlying pathogenetic status. The latter was highlighted by the fact that TNF α was increased post treatment when gastric mucosa was stimulated by LPS (Table 4).

The main assumption revealed from the presented study was that sTREM-1 was secreted by the activated inflammatory cells that infiltrate the gastric mucosa; inflammatory cells were immigrated to the inflamed gastric mucosa attracted by *H pylori* or its components. The treatment of inflamed gastric mucosa and the eradication of *H pylori* ceased the secretion of sTREM-1. It is of great importance that the latter assumption exists only in the status of gastric and duodenal ulcer disease. The release of sTREM-1 was independent from the density of mucosal inflammation at patients with no evidence of peptic ulcer. The pattern of release of sTREM-1 by the activated inflammatory cells and probably their intracellular activity should be further investigated.

The independent contribution of sTREM-1 release in the pathogenesis of gastric ulcer is further aggravated by the observation that gastric juice could not influence the activity of the inflamed mucosa per se. Stimulation of inflamed gastric mucosa with gastric juice was not lead to a significant increase to the release of sTREM-1 and TNF α (Table 4).

The present study revealed for the first time in the literature that sTREM-1 secreted by the gastric mucosa is an independent mechanism connected to the pathogenesis of gastric and duodenal ulcer. sTREM-1 was released at the

presence of *H pylori* from the inflamed gastric mucosa in the field of gastric ulcerative process. The exact pathogenetic mechanisms needs to be further clarified.

Abstract

AIM: To investigate the inhibitory effect of kallistatin (KAL) on angiogenesis and HCT-116 xenograft tumor growth.

METHODS: Heterotopic tumors were induced by subcutaneous injection of 2×10^6 HCT-11 cells in mice. Seven days later, 2×10^{11} rAAV-GFP or rAAV-KAL was injected intratumorally ($n = 5$ for each group). The mice were sacrificed at d 28, by which time the tumors in the rAAV-GFP group had grown to beyond 5% of the total body weight. Tumor growth was measured by calipers in two dimensions. Tumor angiogenesis was determined with tumor microvessel density (MVD) by immunohistology. Tumor cell proliferation was assessed by Ki-67 staining.

RESULTS: Intratumor injection of rAAV-KAL inhibited tumor growth in the treatment group by 78% ($171 \pm 52 \text{ mm}^3$) at d 21 after virus infection compared to the control group ($776 \pm 241 \text{ mm}^3$). Microvessel density was significantly inhibited in tumor tissues treated with rAAV-KAL. rAAV-KAL also decreased the proportion of proliferating cells (Ki-67 positive cells) in tumors compared with the control group.

INTRODUCTION

Advanced colorectal cancer (CRC) is a critical health concern in the world; overall survival is highly dependent upon the stage of disease at diagnosis. The estimated 5-year survival rates range from 85% to 90% for patients with stage I disease to < 5% for patients with stage IV disease. Over 50% of patients with colorectal cancer presenting with metastatic or locally advanced disease experience local recurrence or develop distant metastases after potentially curative surgery. The most important treatment currently available for patients with stage IV disease is systemic chemotherapy. Although there have been recent advances in the field, with randomized trials confirming the activity of irinotecan, oxaliplatin and capecitabine, median survival remains at only 15-18 mo. There is, therefore, a critical need for more effective and better-tolerated therapies.

With the role of angiogenesis in tumor growth and progression firmly established, considerable efforts have been directed to antiangiogenic therapy as a new modality to treat human cancers. Clinical trials have provided strong evidence that antiangiogenic agents, such as bevacizumab (avastin, anti-VEGF humanized monoclonal antibody), may play a meaningful role in colorectal anticancer therapy, with an optimistic increase of 20%-30% in survival. Based upon the results of these randomized studies^[1,2], bevacizumab has now been approved by the FDA for the first-line treatment of metastatic colorectal cancer in

combination with chemotherapy.

Despite the enthusiasm and promising early results, there are still several problems to resolve in evaluating the activity of antiangiogenic agents, which are predominantly cystostatic rather than cytotoxic, and the clinical results are still disappointing according to internationally accepted RECIST criteria. Antiangiogenic gene therapy strategy holds great promise in advancing antiangiogenesis as an effective cancer therapy to be evaluated in clinical trials in the future. Several lessons can be learned from early clinical trials in antiangiogenic therapy. (1) Prolonged use of angiogenesis inhibitors is envisioned for cancer patients. Because antiangiogenic agents stabilize tumor growth but do not reduce tumor burden, constitutive expression of an antiangiogenic protein even at lower concentrations than bolus doses may be more effective than the intermittent peaks associated with repeated delivery of a recombinant protein. Preclinical experiments have shown that a constant level of these inhibitors in the circulation provides more effective anti-cancer therapy than intermittent peaks of inhibitor in mice^[3]. Therefore, in the future, antiangiogenic gene therapy may be important for protein angiogenesis inhibitors. (2) The angiogenic switch has become recognized as a critical step in tumor propagation and progression^[4]. Multiple angiogenic pathways are involved in the balance between endogenous stimulators and inhibitors. From this perspective, the body may harbor many in situ tumors, yet the tumors do not progress to lethal tumors unless there is an imbalance between a tumor's pro-angiogenic output and the body's total angiogenic defense^[5]. Gene therapy offers a strategy whereby an individual could boost their endogenous angiogenic defenses and tip the balance favorably, because multiple therapeutic genes can be engineered into one vector. (3) The production of functional proteins can be expensive, and repeated usages will not be affordable for patients. Gene therapy offers the opportunity for patients to become their own source of production, i.e., an endogenous factory for antiangiogenic protein production.

Among the identified endogenous inhibitors of angiogenesis, kallistatin (KAL) is one of the best choices because of its broad-spectrum characteristics^[6]. It is capable of inhibiting vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) mediated angiogenesis [unpublished data], as well as preventing tumor invasion *via* the activation of metalloproteinases by inhibiting tissue kallikrein activity.

Gene transfer vectors based on adeno-associated virus (AAV) are of particular interest as they are capable of inducing transgene expression in a broad range of tissues for a relatively long time without stimulation of a cell-mediated immune response. Perhaps the most important attribute of AAV vectors is their safety profile in phase I clinical trials ranging from cystic fibrosis (CF) to Parkinson's disease. The utility of AAV vectors as a gene delivery agent in cancer therapy is showing promise in preclinical studies. With the identification of different serotypes and recent progress in the improvement of AAV vectors, such as dual vectors to overcome the limited packaging capacity, self-complementary vectors to

increase the level and onset of transgene expression, and capsid modifications to mediate cell specific transduction, it will be possible in the future to design more specific and efficient therapies for use in the cancer treatment arena^[7]. Therefore, an approach whereby the KAL gene is delivered to tumors in a form enabling stable and long-term gene expression has become increasingly attractive. Our recent laboratory work revealed that KAL could be a suitable candidate for hepatocellular carcinoma (HCC) therapy [unpublished data]. In the present study, an anti-angiogenic approach by transfer of the KAL gene through an AAV vector was employed to treat colon cancer in a mouse model.

MATERIALS AND METHODS

Plasmid construction

The full-length cDNA fragments of human KAL were amplified from human liver first-stranded cDNA by PCR. Specific primers were designed from the nucleotide sequence of human KAL published in NCBI (accession number L19684), Kalli-F (5'-AAGAATTTCGAGGATGCATCTTATCGAC) and Kalli-R (5'-AAGGTACCAAGCTTCTATGGTTTCGTGGGGTC). Restriction enzyme sites (underlined) were introduced into primers for subcloning. The conditions of PCR were 45 s each at 94°C, 50°C and 68°C for 36 cycles. The PCR fragments were sequenced and subcloned into the AAV-2 vector, which has been described previously^[8,9]. The cDNA fragments of KAL were generated by PCR and were confirmed by DNA sequencing. The sequence of KAL matched that published in NCBI except for two nucleotides. The differences were at nucleotides 1145 and 1146, which resulted in a sense mutation in amino acid sequence. The residue threonine (ACG) at codon 382 was changed into a serine (AGC) residue.

To attain a constitutive and high-level expression of KAL, the KAL cDNA was inserted into the AAV vector between the inverted terminal repeats (ITRs) under the control of cytomegalovirus (CMV) enhancer/chicken β -actin promoter. A woodchuck hepatitis B virus post-transcriptional regulatory element (WPRE) was inserted into constructs immediately after the inserted genes, in order to boost transgene expression^[10].

Generation of rAAV vectors

AAV particles were generated by a three plasmid, helper-virus free packaging method^[8,15]. The viral titre was determined by real-time PCR analysis as described previously^[11].

Fifty-thousand human embryonic kidney (HEK) 293 cells were seeded into 6-well plates and were grown overnight. The medium was replaced by complete medium with reduced fetal bovine serum (FBS) (2%). A total of 5×10^9 vector genome rAAV-GFP particles were incubated with cells for 8 h. Two days later, the ability of the virus to infect and transduce the cell line was assessed by fluorescent microscopy.

Cell lines, animals and antibodies

The HEK 293 cell line and the colon adenocarcinoma

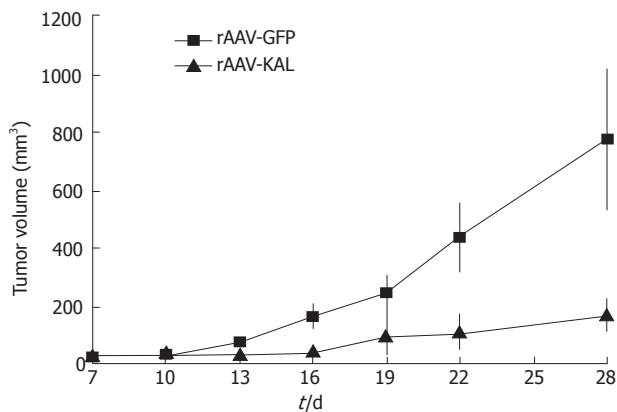

Figure 1 Tumor growth suppression curve: tumor volumes of the rAAV-KAL group versus the rAAV-GFP group on the indicated days.

cell line HCT-116 were purchased from American Type Culture Collection (ATCC). The cells were cultured in Dulbecco's Modified Eagle's Medium (DMEM) (Invitrogen, Grand Island, NY) supplemented with 10% FBS (Gemini, Sacramento, California), 100 unit/mL penicillin and 100 µg/mL streptomycin (Invitrogen). Six- to eight-week-old male BALB/c mice were obtained from the Laboratory Animal Unit of the University of Hong Kong. All surgical procedures and care administered to the animals were approved by the University Ethics Committee and performed according to institutional guidelines. The anti-CD34 (clone MEC 14.7), anti-Ki-67 (clone B56) and anti-rat polyclonal antibodies and anti-mouse polymer conjugate were purchased from Santa Cruz (Santa Cruz, CA), Pharmingen (San Jose, CA), BD Biosciences (San Jose, CA) and Zymed (South San Francisco, CA), respectively.

Tumor model

Tumors were established by subcutaneous inoculation of 2×10^6 HCT-116 cells into the dorsal skin of mice using 25-G needles. Seven days later, 2×10^{11} rAAV-GFP or rAAV-KAL was injected intratumorally ($n = 5$ for each group). The mice were sacrificed at d 28, by which time the tumors in the AAV-GFP group had grown to beyond 5% of the total body weight.

Tumor growth was monitored for 4 wk by measuring two perpendicular diameters. Tumor volume was calculated according to the formula $0.52 \times a \times b^2$, where a and b are the largest and smallest diameters, respectively.

Evaluation of microvessel density

Microvessel density (MVD) was assessed by the method defined by Weinder and co-workers^[12] after CD34 staining. The mean value of the three hot spots was taken as the MVD, which was expressed as the absolute number of microvessels (0.7386 mm² per field).

Quantitation of Ki-67 proliferation index

Positive and negative stained cells were counted on a minimum of 10 randomly selected $\times 400$ high-power fields from representative sections of tumors. The Ki-67 proliferation index (the fraction of proliferating cells) was

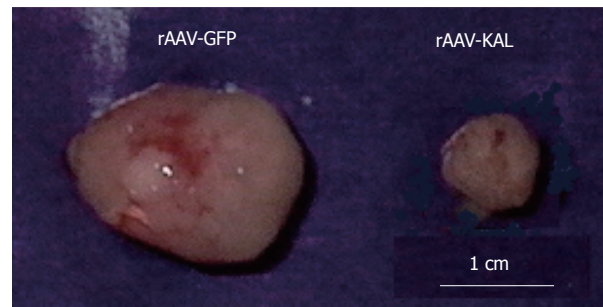

Figure 2 Representative photographs of a tumor at 21 d for mice injected with rAAV-GFP and rAAV-KAL intratumorally.

calculated from the number of Ki-67 positive cells divided by the total cell count.

Statistical analysis

Comparisons of tumor volume between groups were made with the Student's *t*-test where indicated and were considered statistically significant if the *P* value was less than 0.05.

RESULTS

KAL suppressed growth of HCT-116 tumors in vivo

Tumor formation was detected in all of the mice. Tumor growth was significantly slower in the rAAV-KAL group than in animals injected with rAAV-GFP (Figure 1). At d 21 after virus infection, tumor growth was reduced by 78% (171 ± 52 mm³) in the treatment group compared to the control group (776 ± 241 mm³, $P < 0.01$). Representative photographs of the tumor at 21 d for both groups are shown in Figure 2.

Evaluation of angiogenesis by CD34 staining

We found that delivery of KAL could significantly reduce growth of tumors, demonstrating that the treatment method was effective. Since KAL is an antiangiogenic inhibitor, in order to determine whether the suppression of tumor growth in the mice injected with rAAV-KAL was related to the antiangiogenic ability of the transgene product, the tumor blood vasculature was examined by staining for endothelial cell antigen CD34 (Figure 3). A significant reduction in microvessel density was observed in rAAV-KAL [73 ± 29 vessels/high power field (hpf), $P < 0.01$] compared with control mice (236 ± 67 vessels/hpf).

Assessment of cell proliferation by Ki-67 staining

Tumor growth retardation could also be a result of reduction in cell proliferation. To quantitatively compare the proliferation index of tumors in different groups, tumor sections were stained for expression of Ki-67. Ki-67 is strictly expressed in proliferating cells and is commonly used as a marker for cell proliferation. Treatment with rAAV-KAL decreased the proportion of proliferating cells (Ki-67 positive cells) in tumors compared with the control group. Based on the counting of 10 randomly selected microscopic fields, the proliferation index was significantly

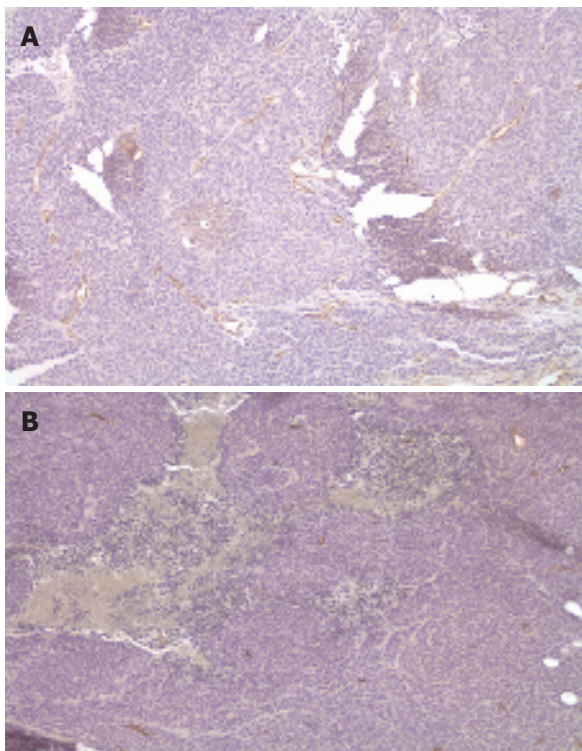

Figure 3 Evaluation of microvessel density at 21 d after intratumor injection of rAAV-GFP (A) and rAAV-KAL (B) (x200).

decreased from $63\% \pm 9\%$ in the control group to $41 \pm 6\%$ in the rAAV-KAL group ($P < 0.01$).

DISCUSSION

Our present data showed that the application of the angiogenic inhibitor KAL suppressed angiogenesis and resulted in growth retardation of colon tumors. CD34 staining of the HCT-116 tumors revealed a significant direct correlation between MVD in histological sections of cancer and size of the tumor. This finding demonstrated that continuous release of KAL in mice could successfully decrease the MVD in HCT tumors, thereby blocking angiogenesis effectively. Ki-67 protein is widely known as an appropriate and useful marker of the proliferating fraction within a given cell population. Since Ki-67 expression provides information on the proliferating status of the tumor cells, it should give good insight into the effect of treatment. The success of the current treatment method lays an important foundation, not just for colon tumor treatment, but also for anti-angiogenic gene therapy.

Miao *et al* found that human KAL significantly inhibits both VEGF and bFGF induced proliferation, migration, and adhesion of primary cultured human endothelial cells in vitro, and attenuates both VEGF and bFGF induced increases in capillary density and hemoglobin content in subcutaneously implanted Matrigel plugs *in vivo*^[6]. KAL is also a heparin binding protein. The major heparin-binding domain was identified in the region between the H helix and C2 sheet of KAL, which contains clusters of positively charged residues. KAL may act by competing with VEGF and bFGF binding to heparan-sulfate proteoglycans, a low affinity-binding site, and thus suppressing VEGF-

and bFGF-binding activity and the angiogenesis signaling cascades induced by VEGF and bFGF.

As a broad-spectrum angiogenesis inhibitor, KAL inhibits angiogenesis mediated by its heparin-binding activity, which is similar to that of endostatin^[13]. It has become clear that various growth factors and lymphokines are required to bind to two distinct classes of cell surface receptors to elicit a signal^[14]. In many ligand-receptor systems, ligands bind first to an abundant low-affinity receptor, which draws the ligand onto the cell surface and then links it to a second, high-affinity receptor that transduces the signal into cells. In addition, KAL is a specific serine proteinase inhibitor (serpin) for human tissue kallikrein. Like plasmin, tissue kallikrein may have a role in degrading extracellular matrix to promote tumor invasion. Our study results confirmed KAL's multifunction purpose for tumor inhibition.

With the role of angiogenesis in tumor growth and progression firmly established, considerable efforts have been directed to antiangiogenic therapy as a new modality to treat human cancers. There is much enthusiasm for the role that antiangiogenic agents may play in preventive therapy. Nevertheless, it is still unclear whether KAL can regress a tumor completely, even after prolonged treatment. Many leaders in the field of angiogenesis now believe that some of the most important future cancer therapies may not completely eradicate all tumor cells in an individual, but instead, may turn cancer into a chronic manageable disease^[5]. Gene therapy strategies leading to increased production of endogenous angiogenesis inhibitors would seem perfectly suited to support such an approach by tipping the balance toward a more antiangiogenic state.

Antiangiogenic approaches should be greatly encouraged, since the FDA has recently approved the angiogenesis inhibitor avastin and the SFDA approved endostatin. Because of the difficulties and high costs of manufacturing numerous endogenous inhibitors of angiogenesis, and because of the need for chronic administration of these agents, gene therapy remains an exciting strategy to circumvent these difficulties.

AAV based vectors are now being used for clinical gene transfer for cystic fibrosis, hemophilia, and Canavan's disease. Although recombinant adenoviral vectors have been utilized for a majority of both preclinical and clinical trials in cancer gene therapy, studies in animal models have suggested therapeutic benefits for tumor treatment using AAV vectors^[7]. T-cell mediated cytotoxicity to AAV vectors has not been observed even though AAV vectors can induce strong humoral immune responses. AAV can initiate long-term transgene expression and this transduction is attributed to episomal concatamer formation without integration into the host chromosome. Therefore, AAV vectors appear to be less mutagenic than other virus vectors. With new serotypes and the potential to develop targeting vectors, AAV holds great promise as a viral vector delivering therapeutic genes such as immune regulation and antiangiogenesis genes for cancer gene therapy.

In addition to AAV studies, the understanding of tumor development at the biological and molecular biological level will lead to the discovery of strong, efficient, and specific enhancers/promoters in tumor cells.

Utilization of regulatory systems will avoid the undesired side effect of systemic transgene expression delivered by AAV vectors for immune-modulation and antiangiogenesis. As better vectors are developed, combination strategies continue to evolve, and there is increased understanding of the complex role that endogenous angiogenesis inhibitors play in tumor growth. Antiangiogenic gene therapy will certainly be evaluated in future clinical trials.

COMMENTS

Background

Colon cancer is one of the most common cancers in the world, with a high propensity to metastasize. Surgical resection currently remains the only curative treatment for colon cancer. Since the majority of deaths with colon cancer result from metastatic disease, inhibition of growth and metastasis of colon cancer is expected to become an effective treatment.

Research frontiers

Antiangiogenesis strategies have been increasing and have been proven to be an attractive strategy for colon cancer therapy, as they are less toxic than conventional chemotherapy and they have a lower risk of drug resistance. Antiangiogenesis strategies can also transiently 'normalize' structure and function of tumor vasculature to make it more efficient for drug delivery and increase the efficacy of conventional therapies. Encouragingly, recent studies have demonstrated it is feasible to complete inhibition of neovascular growth in tumors by attacking multi-angiogenesis mechanisms.

Innovations and breakthroughs

There is growing evidence linking KAL to a role in the inhibition of angiogenesis. In contrast to previous reports that antiangiogenic inhibitors inhibited endothelial cells only, the results of this study clearly showed that KAL not only significantly inhibited VEGF and bFGF induced proliferation, migration, and adhesion of endothelial cells, but also suppressed the proliferation of tumor cells. The multi characteristics of KAL suggest that it is a promising candidate for a colon tumor angiogenesis inhibitor.

Applications

rAAV-mediated expression of KAL inhibits the growth of xenograft colon cancer by 78% compared with controls. Lack of toxicity may favor the clinical use of rAAV-KAL, thus demonstrating its potential in a range of clinical applications of therapy. Furthermore, rAAV-KAL may provide an effective form of therapy for other cancers in future. Elucidating the suppression of proliferation of tumor cells by KAL will provide a better understanding of the mechanism of cancer therapy.

Terminology

Tumor angiogenesis: the proliferation of a network of blood vessels that penetrates into cancerous growths, supplying nutrients and oxygen and removing waste products. Tumor angiogenesis actually starts with cancerous tumor cells releasing molecules that send signals to surrounding normal host tissue.

Peer review

This paper provides sufficient and new data of KAL's unique advantage for colon tumor treatment, and that a KAL based gene therapy has great potential therapeutic value.

Abstract

AIM: To further elucidate the possible molecular biological activity of wild type K-ras2 gene by detecting changes in wild type K-ras2 gene-induced gene-expression profiles of colon carcinoma cells using cDNA microarray techniques.

METHODS: Total RNA was isolated from peripheral blood of health volunteers. Reverse transcription of RNA and polymerase chain reaction were used to synthesize wild type K-ras2 cDNA. K-ras2 cDNA fragment was cloned into a T easy vector and sequenced. A eukaryotic expression vector pCI-neo-K-ras2 was constructed and transfected to Caco2 cell line using the liposome method. Finally, mRNA was isolated, reverse-transcribed to cDNA from pCI-neo-K-ras2 or pCI-neo blank vector-transfected Caco cells, and analyzed by cDNA microarray assay.

RESULTS: Restriction enzyme analysis and DNA sequencing verified that the constructed expression vector was accurate. High-quality RNA was extracted and reverse transcribed to cDNA for microarray assay. Among the 135 genes, the expression was up-regulated in 24 and down-regulated in 121. All these differentially expressed genes were related to cell proliferation, differentiation, apoptosis and signal transduction.

CONCLUSION: Differentially expressed genes can be successfully screened from wild type K-ras2-transfected colon carcinoma cells using microarray techniques. The results of our study suggest that wild type K-ras2 is related to the negative regulation of cell proliferation, metabolism and transcriptional control, and provide new clues to the further elucidation of its possible biological activity.

INTRODUCTION

Carcinogenesis and progression of human colon carcinoma result from abnormal expression of many tumor-associated genes. Activation oncogenes and deactivation antioncogenes are known as one of their important mechanisms^[1,2]. Ras gene which is closely related to carcinogenesis and progression of colon carcinoma consists of three members: Hras1, Nras and K-ras2^[3,4]. It is traditionally believed that activated Ras gene plays a dominant role as an oncogene in the pathogenesis of colon carcinoma. About 30% of tumors display mutations of Ras gene members, the most frequent mutation is found in K-ras2^[5,6], and the relatively high frequency of K-ras2 mutation is observed in colon, pancreas and lung carcinomas^[7-9]. Recent studies indicate that frequent loss of wild type Ras gene occurs in human and mouse lung adenocarcinomas, thus questioning the dominant role of Ras gene in the pathogenesis of tumors^[10]. Loss of heterozygosity on chromosome 12p12-13 in K-ras2 gene has also been found in non-small-cell lung cancer^[11,12]. We have reported that frequent loss of heterozygosity occurs in this domain during carcinogenesis and progression of colon carcinoma^[13]. By observing the changes in growth curve and cell cycle of colon carcinoma cells transduced with wild type K-ras2 gene, we found that wild type K-ras2 gene could step down the growth and cell cycle of colon carcinoma cells manifested as significantly increased stage G0-G1 cells and decreased stage G2-M cells, suggesting that resting cells with proliferation activity are inhibited to advance into proliferating cell cycle^[14]. In the present study, in order to study the biological activity of wild type K-ras2 gene, we constructed a eukaryotic expression vector of wild type K-ras2 gene phenotype, screened differentially expressed genes of colon carcinoma cells transfected by wild K-ras2 gene with cDNA microarray, and detected the effect of wild K-ras2 on the gene-expression profiles

of colon carcinoma and its function *in vivo*. The results provide new clues to the exploration of the pathogenesis of colon carcinoma and the functions of K-ras2 gene.

MATERIALS AND METHODS

Cells and cDNA array

Human colon adenocarcinoma cell line Caco-2 was obtained from the ATCC. DMEM, FBS, Trizol RNA isolation kit, pCI-neo mammalian expression vector and Lipofectamine2000 were purchased from Invitrogen (Carlsbad, CA). A commercial human expression cDNA array was obtained from Shanghai Biochip Company (Shanghai, China). The array includes 8568 known genes, which can be categorized into cell division, cell signaling, cell structure, gene and protein expression, metabolism and pseudogene, *etc.*

Transfection of Caco-2 cells

Total RNA was isolated from peripheral blood of health volunteers using Trizol RNA isolation kit. Reverse transcription of RNA and polymerase chain reaction were used to synthesize the full-length sequence of wild K-ras2 cDNA. Primers containing *Mul*1 and *Sal*1 restrictions (Y1: 5'-ACCCACGCGTATGACTGAATATAAAC-3'; Y2: 5'-AACGTCGACTTACAT AATTACACACT-3') were synthesized by Shanghai Ouke Biotech Company (Shanghai, China). The PCR products were inserted into pGEM-T Easy vector (Promega) to generate pGEM-T-Ras, and positive clones were identified by blue/white color screening followed by sequencing. pGEM-T-Ras and pCI-neo eukaryotic expression vector were digested in *Mul*1 and *Sal*1 restriction enzymes and ligated using T4 DNA ligase (Promega) to produce pCI-neo-K-ras2. The recombinant pCI-neo-K-ras2 and empty pCI-neo-K-ras2 were transfected into Caco-2 cells (ATCC) using Lipofectamine2000 according to the manufacturer's instructions, and the positive clones were selected from G418 (Amresco).

cDNA microarray analysis

Total RNA was extracted from pCI-neo-K-ras2 (transfection group) and empty pCI-neo-K-ras2 (control group) using Trizol RNA isolation kit. The purity of RNA was confirmed by agarose gel electrophoresis and absorbance (A) ratio (A₂₆₀/A₂₈₀). To make cDNA probes, approximately 5 µg of total RNA was labeled with Cy3-dUTP (control) or Cy5-dUTP (transfection group) by reverse transcription. The probes were precipitated using ethanol and dissolved in 5 × SSC + 2 g/L SDS at 20°C. The microarray and probes were denatured in 95°C water bath for 5 min. Hybridization was performed at 60°C for 15-17 h. Microarray was washed with 2 × SSC + 2 g/L SDS and 1 × SSC + 2 g/L SDS for 10 min respectively and dried at room temperature. Scanning was performed with ScanArray3000 (General Scanning, Inc.). The acquired image was analyzed using ImaGene 3.0 software (BioDiscovery, Inc.). The intensities of Cy3-dUTP and Cy5-dUTP were normalized by a coefficient according to the ratio of housekeeping genes. The positively expressed

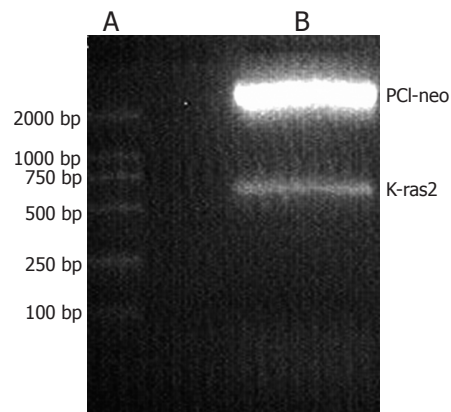

Figure 1 Restriction enzyme analysis of PCI-neo with K-ras2 genes showing a 576 bp K-ras2 gene and a 5600 bp carrier.

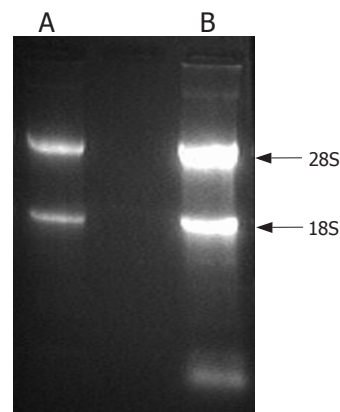

Figure 2 Electropherogram of total RNA from control (A) and transfection (B) groups.

genes were as follows: Cy5-dUTP: Cy3-dUTP signal ratio > 2.0, red fluorescent displaying up-regulated expression; Cy5-dUTP: Cy3-dUTP signal ratio < 0.5, green fluorescent displaying down-regulated expression.

Statistical analysis

Data on gene expression were analyzed by Student's *t* test using SPSS 10.0 software and *P* < 0.05 was considered statistically significant.

RESULTS

Validation of wild type K-ras2 and RNA

Restriction enzyme analysis and nucleotide sequencing of eukaryotic expression vector pCI-neo-K-ras2 showed that its sequence containing an integrity open reading frame was accurate (Figure 1). A 260/A₂₈₀ of total RNA ranging from 1.9 to 2.1 and 28S/18S of about 2 indicated that RNA was not degraded and could be used for preparation of hybridization probe (Figure 2).

Results verified by microarray hybridization system

To monitor the whole process of microarray hybridization, we set up 6 negative controls and 10 positive controls. Scanning of hybridization array and report of array detection showed that hybridization array and sample RNA were intact with good background value and well-distributed noise. The hybridization reaction system was normal and the results were reliable. To compare gene profiles between transfection and control groups, a scatter

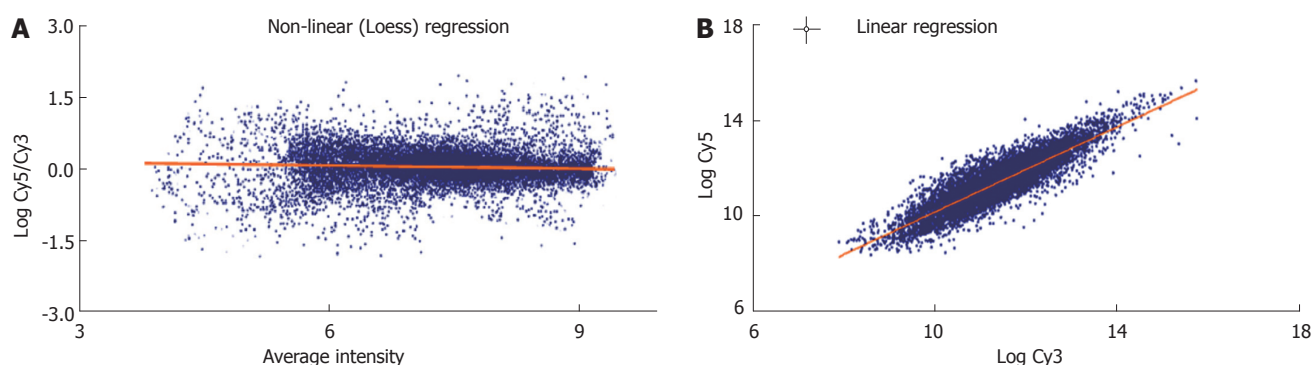

Figure 3 Scatter bar of gene-expression profiles of Caco2 cells transfected (A) and non-transfected (B) with wild-type K-ras2 gene.

Table 1 Biological function of genes with down-regulated expression

Gene	Chromosomal localization	Biological function	Cy5/Cy3
NDP	Xp11.4	Cross-cell signal transmission, signal transduction, NS development	4.509
SSX4	Xp11.23	Transcription regulation, immunoreaction	4.044
CASP1	11q23	Positive regulation of I-kappaB kinase/NF-kappaB cascade reaction, signal transduction, apoptosis	3.754
HPRT1	Xq26.1	Cytolysis, lymphocyte proliferation, purine nucleotide synthesis	3.715
TM4SF2	Xp11.4	ECM	3.554

SERPINA7	Xq22.2	ECM, transport of TH	2.833

profile was plotted for the probe signal values, showing that most genes were distributed around the regression line, and their expression in two tissue samples was similar, but a few genes had a different expression. When the difference in gene expression increased, the number of differently expressed genes decreased (Figure 3). The data were confirmed by the low hybridization signal of these genes. Cy5 fluorescein (red) and Cy3 fluorescein (green) were used to mark the probes of experimental and control groups, and the difference in color was expressed as the difference in gene expression between the two groups. Yellow indicated no expression difference. According to the experimental protocol, the expression of 24 genes with their $cy5/cy3 \geq 2$ (Table 1) was up-regulated, accounting for 17.76% of all the differentially expressed genes, and the expression of 121 genes with their $cy5/cy3 \leq 0.5$ was down-regulated, accounting for 89.63% of all the differentially expressed genes. The top 30 down-regulated genes are listed in Table 2.

Biological function classification of differentially

expressed wild type K-ras2 genes Biological function classification of differentially expressed wild type K-ras2 genes was performed based on the biological classification of genes in Affymetrix gene ontology database. Eleven subtypes were found to be closely related to carcinogenesis (Table 3).

DISCUSSION

Carcinogenesis and progression of colon cancer represent its phases from normal mucosa to atypical hyperplasia (including intestinal metaplasia) of adenoma and adenocarcinoma, involving multiple genes and factors^[15]. K-ras2 gene plays a dominant role as an oncogene in promoting carcinogenesis because of point mutation^[16,17]. In the present study, in vitro experiments demonstrated that carcinogenic agents used in the treatment of loss of heterozygosity in mice with wild type K-ras2 gene facilitated the development of cancer but not in those with normal wild phenotype K-ras2 gene. Moreover, the

Table 2 Biological function of genes with up-regulated expression

Gene	Chromosomal localization	Biological function	Cy5/Cy3
SZF1	3p21	Transcriptional control	0.181

PAX8	2q12-q14	Organ-formation, transcription control, metanephros development, mRNA synthesis	0.442

size of poorly-differentiated adenocarcinoma in mice with loss of heterozygosity was significantly larger than that of adenoma in mice with abnormal wild phenotype K-ras2 gene. It was reported that cell lines activated by wild type K-ras2 gene-transfected ras can inhibit cell growth, clone formation and tumorigenesis in nude mice, indicating that wild type K-ras2 gene may be a potential anti-oncogene^[9,18]. Changes in gene-expression of Caco2 cells induced by wild type K-ras2 gene were found in our study, showing the possible biological activity of wild type K-ras2 gene.

In our study, genes related to signal transduction, transcription control and cell differentiation were dominant, accounting for 33.33% of the total up-regulated genes. The top 30 down-regulated genes related to cell proliferation accounted for 24.79% of the total up-regulated genes. The expression of genes related to cell metabolism, cell cycle and transcription control was up-regulated. Wild type ras may inhibit cell proliferation by promoting differentiation. In fact, it has long been known that Ras proteins can induce differentiation of some cell types, such as neurons, under certain conditions^[19]. Our findings suggest that K-ras2 can negatively regulate cell proliferation, metabolism and transcription control, and inhibit the growth of colon carcinoma.

The expression of NDP is most significant. As a genetic locus, its mutation may give rise of genetic-correlated Norrie disease caused by two molecular defects in NDP gene. One is 265 C>G missense mutation in the

Table 3 Functional classification of differentially expressed genes

Type of gene	Down-regulated genes (n)	Rate of down-regulated genes (%)	Up-regulated genes (n)	Rate of up-regulated genes (%)
Metabolism-associated	18	14.88	3	12.50
Cell proliferation	30	24.79	3	12.50
Cell cycle	16	13.22	0	0
Signal transduction	18	14.88	8	33.30
Cytoskeleton	8	6.61	1	4.17
Transcription control	18	14.88	4	16.67
Cell adhere	11	9.09	1	4.17
Cell apoptosis	8	6.61	2	8.33
Cell differentiation	14	11.57	4	16.67
Immune-associated	14	11.57	2	8.33
ECM	6	4.96	1	4.17

97th codon by changing arginine into proline, the other is excision in 3'-non-translated region of the third exon^[20]. It was reported that patients with gene excision present relatively severe symptoms, whereas patients with gene mutation display relatively mild symptoms^[21]. The SSX4 gene (a member of the node point protein family) whose expression was significantly up-regulated in our study, can inhibit cell transcription, cause humor- and cell-mediated immune reaction, and may be a very valuable target for vaccine therapy of tumors^[22]. Caspase-1 encoding

apoptosis-associated thioesterase (a member of the caspase family) can lead to proteolysis and activate pro-IL-1, thus playing an important role in cell apoptosis^[23]. Its up-regulated expression in wild-type K-ras2-transduced cells may be related to apoptosis of tumor cells, suggesting that caspase-1 is one of the human p53-dependent cell modulators^[24].

The myc gene whose expression was most significantly up-regulated in our study, is closely related to tumors. It is adjusted by many factors, and can promote cell mitosis and make target cells proliferate and immortalize. This gene involving cell apoptosis is related to tumorigenesis and progression of diverse tumors^[25]. Amplification of correlated sequence of myc has been observed in diverse human tumor cell lines including cell lines of granulocytic leukemia, retinoblastoma, neuroblastoma, breast and lung cancer, as well as in human colon carcinoma cell line^[26,27]. The *MMP14* gene (MT1-MMP) is a member of the matrix metalloprotease family. Its function is modified and regulated by O-glycosylation, interaction with CD44, internalization and recycling, depending on its proper expression on the cell surface^[28]. It can invade tumors by activating MMP2 protein. It was reported that up-regulated expression of MMP2 and MT1-MMP is related to invasion of glioblastoma^[29], while the expression of MT1-MMP is related to local invasion of and metastasis to lymph nodes of oral squamous cell carcinoma^[30], supporting its function in colon carcinoma LoVo cells^[31]. The WIT-1 gene is localized in the upstream of Wilm's tumor gene sharing the same promoter. Methylation of the WIT-1 gene is related to chemotherapy-resistant tumors and acute leukemia^[32]. The EPHB4 gene whose expression was remarkably down-regulated in our study is a member of the biggest receptor tyrosine kinase (RTK) family. Its encoding protein, a receptor of ephrin-B2, promotes microvascular endothelial cell migration and/or proliferation, thus playing an important role in angiogenesis of tumors^[33]. It has been shown that EPHB4 expresses in diverse tumors such as prostate carcinoma and astrocytoma, and involves phenotype transformation post-metastasis^[34,35].

In summary, K-ras2 seems to have a dual function. On the one hand, it promotes cancer development as a gain of function oncogene. On the other hand, it inhibits cancer as a loss-of-function tumor suppressor gene. There are some interesting parallels between the Trp53 tumor suppressor gene and the unfolding story of K-ras2. Trp53 was initially described as an oncogene carrying point mutations in tumors. Later, it was found that it is in fact the wild type copy of the gene that functions as a tumor suppressor gene and is capable of reducing cell proliferation. In this case, the Trp53 mutation may, in a sense, also be considered an activating (but not necessarily gain-of-function) mutation in that it produces a dominant-negative effect over the wild type p53 protein. The two major players in human cancer have more in common than they were previously thought^[18].

only induces tumors but also inhibits tumor growth. We have reported that loss of heterozygosity on chromosome 12p12-13 K-ras2 gene occurs in colon carcinoma and wild type K-ras2 gene can effectively inhibit its growth. This study was to construct a eukaryotic expression vector of the wild type K-ras2 gene phenotype, screen differentially expressed genes of colon carcinoma cells transfected by the wild K-ras2 gene with cDNA microarray, and detect the effect of wild K-ras2 gene on the gene-expression profiles of colon carcinoma and its function *in vivo*.

Research frontiers

Based on the results of recent studies, it is hypothesized that K-ras gene plays a role both in carcinogenesis and in inhibition of cancer. It is a proto-oncogene in normal physiological conditions. However, when mutations occur, the activated K-ras2 gene changes into an oncogene and wild type K-ras2 gene becomes an anti-oncogene. This is what we want to prove in this study.

Innovations and breakthroughs

Since the inhibitory effect of wild type K-ras2 gene on tumors was reported by Zhong-Qiu Zhang, its role in suppressing long cancer has been extensively studied by foreign scholars. This is the first time to study the inhibitory effect of wild type K-ras2 gene on colon carcinoma in China.

Applications

The possible molecular pathway of K-ras2 gene in suppressing tumor cell proliferation found in this study may contribute to finding the genes closely related with colon cancer.

Peer review

This interesting paper investigated the importance of K-ras cascade at mRNA level. The major finding of this study is that wild-type K-ras results in both complex induction and more common inhibition of several genes, and may have a dual role in carcinogenesis. The new association elucidated herein may provide further insight into the carcinogenesis and may identify potentially important therapeutic targets.

Y, Zhang X. Matrix metalloproteinase-9-1562C>T polymorphism may increase the risk of lymphatic metastasis of colorectal cancer. *World J Gastroenterol* 2007; 13(34): 4626-4629

<http://www.wjgnet.com/1007-9327/13/4626.asp>

Abstract

AIM: To explore the role of the matrix metalloproteinase-9 (*MMP-9*) polymorphism in colorectal cancer (CRC) in a northeast Chinese population.

METHODS: Genotyping of *MMP-9*-1562C>T and 279R>Q polymorphisms was carried out on blood samples from 137 colorectal cancer patients and 199 controls using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP). Multivariate logistic regression models were used to calculate adjusted odds ratios (OR) and 95% confidence intervals (95% CI).

RESULTS: The distribution of *MMP-9* -1562C>T and 279R>Q genotype was not significantly associated with the risk of CRC. However, the risk of lymph node metastasis of CRC was increased in patients with the -1562T allele (OR = 2.601; 95% CI = 1.160-5.835; *P* = 0.022). The frequency of *MMP-9* 279RR + RQ genotype was higher than the QQ genotype among CRC patients younger than sixty years old (OR = 0.102; 95% CI = 0.013-0.812; *P* = 0.012).

CONCLUSION: Our results indicated that the *MMP-9*-1562C>T polymorphism affects lymph node metastasis of CRC. In addition, the *MMP-9* 279R allele may lead to a younger age of onset of colorectal cancer.

INTRODUCTION

Matrix metalloproteinases (*MMPs*) are a family of zinc-binding proteases that process growth factors, growth factor binding proteins, and cell surface proteins^[1]. They also degrade extracellular matrix (ECM) components and thereby play a central role in tissue remodeling associated with various pathological processes, such as cancer invasion and metastasis^[2].

MMP-9 is a member of the *MMP* family that is also known as gelatinase B or type IV collagenase. (92 kDa). *MMP-9* possesses proteolytic activity against type IV collagen, a major component of the basement membrane, and has been shown to facilitate vascular smooth muscle cell migration^[3]. The expression of *MMP-9* is up-regulated in various types of human cancer, such as esophageal carcinogenesis^[4], breast cancer^[5], and gastric carcinoma^[6]. *MMP-9* expression is also significantly increased in CRC tissues^[7]. Further, over-expression of *MMP-9* represents an early event in colorectal carcinogenesis and may possibly have prognostic value^[8].

The regulation of *MMP-9* expression may be at the transcription level. Growing evidence indicates that genetic variants in the promoters of the *MMP-9* gene may result in differential expression in different individuals^[9]. A promoter variant, -1562C>T, a polymorphism due to a C to T substitution results in the loss of the binding site of a nuclear protein to this region of the *MMP-9* gene promoter^[10]. Polymorphisms in coding regions may also have altered function; a coding region polymorphism, 279R>Q, which is located in the catalytic domain, leads to substitution of arginine by glutamine.

We hypothesized with respect to the role of the two polymorphisms, speculating that they may contribute to CRC risk and metastasis. We thus conducted a case-control study to examine the relationship between *MMP-9* polymorphisms and CRC.

MATERIALS AND METHODS

Study population

The subjects for this case-control study of risk factors

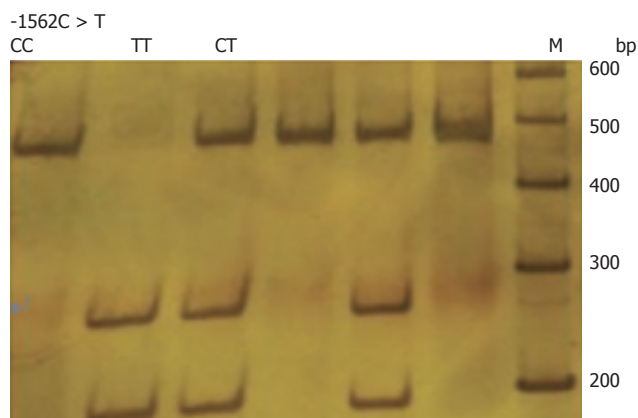

Figure 1 Genotyping of *MMP-9* -1562C>T polymorphism by PCR-RFLP.

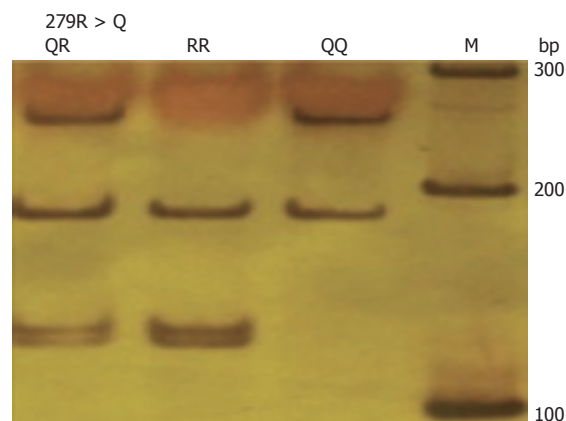

Figure 2 Genotyping of *MMP-9* 279R>Q polymorphism by PCR-RFLP.

for CRC were unrelated and from Shenyang in northern China. The trial recruited 137 CRC patients and 199 healthy control subjects. The patients were comprised of 71 men and 66 women, median age 61.29 years, with a histologically confirmed new diagnosis of CRC, made at the First Affiliated Hospital of China Medical University and Shenyang Anal Hospital, between 2005 and 2006. The CRC patients were grouped according to TNM-classification (UICC) on the basis of postoperative histopathological evaluation.

The controls, 104 men and 95 women, with a median age of 60.65 years, were randomly selected among people admitted to the same hospital during the same period. These control subjects had no history of any cancer.

All subjects gave informed consent for the study, and allowed their blood samples to be analyzed. Detailed information on risk factors including tobacco (smokers were defined as the population who intake more than one cigarette per day; all others were non-smokers), alcohol intake (drinkers were defined as the population who intake more than 50 g alcohol per day), and BMI were obtained with a baseline questionnaire. This study used the suggested WHO BMI cutoff points for Asians to assess several variables; respondents whose BMI was < 23 kg/m² were categorized as normal weight and respondents whose BMI was ≥ 23 kg/m² were categorized as overweight and obese.

DNA extraction

Five milliliters of venous blood was extracted from each subject. Genomic DNA was extracted using proteinase K digestion, followed by a salting out procedure.

Genotyping of *MMP-9* polymorphisms

MMP-9 -1562C>T genotypes were determined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) assay. The primers used were 5'-GGCACATAGTAGGCCCTTTAA-3'(forward) and 5'-TCACTCCTTTCTTCCTAGCCA-3'(reverse)^[11]. PCR was performed with a 20 μL volume containing 20 ng DNA template, 2.0 μL 10 × PCR buffer, 0.5 U Taq DNA polymerase, 20 pmol of each primer and 1.6 μL 2.5 mmol/L dNTP. Amplification was for 1 min at 94°C, followed by 35 cycles of 30 s at 94°C, 30 s at 57°C, and 30 s at 72°C, and a final step at 72°C for 1 min. PCR products were digested with *Sph*I (Takara) and separated on 8%

polyacrylamide gel electrophoresis. After electrophoresis, the homozygous C allele was represented by a DNA band at 442 bp, whereas the homozygous T allele was represented by a DNA band at 264 and 178 bp, and heterozygotes at 442, 264 and 178 bp (Figure 1).

279R>Q genotypes were determined using a PCR-RFLP assay, as previously described. The primers used were 5'-GAGAGATGGGATGAACTG 3'(forward) and 5'-GTGGTGGAAATGTGGTGT-3'(reverse)^[12]. PCR products were digested with *Msp*I (Takara) and separated by electrophoresis on 8% polyacrylamide gels. The 279R allele has two restriction sites, represented by DNA bands at 187, 129 and 123 bp; the 279 Q allele has only one restriction site, represented by DNA bands at 252 and 187 bp (Figure 2).

Statistical analysis

Odds ratios (ORs) and 95% confidence intervals (CIs) were estimated by logistic regression analyses from comparison of genotypes between CRC patients and healthy controls, using SPSS version 13.0 (SPSS, Chicago, IL, USA), adjusting for the potential confounders such as age, sex, tobacco use, alcohol use, and BMI. Association of the genotype with clinicopathological parameters was evaluated by Fisher's exact test. The χ^2 test was used to assess Hardy-Weinberg equilibrium. In all cases, $P < 0.05$ was considered statistically significant.

RESULTS

Characteristics of the study population and the association with CRC are presented in Table 1. There were no significant differences in terms of distribution for age and gender between cases and controls ($P = 0.325$ and 0.951 , respectively). However, cases tended to have a higher BMI ($P < 0.001$), and were more likely to smoke cigarettes ($P < 0.001$).

The *MMP-9* -1562C>T and 279R>Q polymorphisms genotype and allele distribution in cases and controls are shown in Table 2. The distribution of *MMP-9* 279R>Q and -1562C>T polymorphisms in cases and controls were all consistent with a Hardy-Weinberg equilibrium. In addition, there was no linkage disequilibrium between -1562C>T and 279R>Q polymorphisms ($R^2 = 0.009$, $D' = 0.376$).

The frequency of *MMP-9* -1562C>T and 279R>Q

genotypes did not differ significantly between cases and controls (-1562CT+TT vs CC: OR=0.877; 95% CI = 0.527-1.462; $P = 0.615$; 279RQ vs QQ: OR = 0.936; 95% CI = 0.410-2.138; $P = 0.875$; RR vs QQ: OR=0.961; 95% CI = 0.424-2.177; $P = 0.924$). We examined the combined effects of the two polymorphisms among cases and controls, using 279R and -1562T as risk alleles. We found that neither the genotypes containing one or two risk alleles, nor those containing more than two risk alleles were associated with increased risk of CRC.

We also estimated the association between the -1562C>T and 279R>Q genotypes and clinicopathological findings among CRC patients (Table 3). Logistic regression analysis revealed that CRC patients with the -1562CT + TT genotype showed increased risk of lymph node metastasis (CT+TT vs CC; $P = 0.022$). Age, sex, TNM classification and external membrane invasion were not correlated with the -1562 C>T genotype. There was no significant difference between the 279R>Q polymorphism and clinicopathological features. However, the frequency

of the *MMP-9* 279RR + RQ genotype was higher than the QQ genotype among CRC patients aged < 60 years.

DISCUSSION

Increased levels of *MMP-9* have been found to be associated with CRC susceptibility^[13]. However, despite of the strong rationale for this study, our results showed that the two *MMP-9* polymorphisms did not enhance susceptibility to the development of CRC, although we did find that the *MMP-9* -1562C>T polymorphism was associated with lymph node metastasis of CRC.

Consistent with this finding is a previous report of an absence of an association between the -1562C>T polymorphism and gastric cancer susceptibility; that report also found the -1562T allele to be associated with the invasive phenotype of gastric cancer^[14]. Similarly, a Chinese study has suggested that the -1562C>T genotype distribution in CRC cancer patients and healthy controls was comparable, but an association between the -1562C allele and the invasive capability of CRC was not observed^[15]. To explain this discrepancy, two points warrant consideration. First, the difference may be due to the different populations; all our subjects were drawn from a population pool in the northern part of China, whereas their subjects were not.

Second, the association between the -1562C>T polymorphism and the risk of lymph node metastasis of CRC is consistent with the biological function of *MMP-9*. *MMP-9* is up-regulated in various human cancer types. The over-expression of *MMP-9* is positively correlated with the depth of invasion, lymphatic and venous invasion, and lymph node metastasis, such as in CRC^[7], gastric carcinoma^[16], and prostate cancer^[17]. Lymph node metastasis is considered as the most important prognostic factor of CRC^[18,19]. In addition, the 5-year survival rate of patients with CRC with lymph node metastasis is worse than that in those without lymph node metastasis^[20]. We postulated that the promoter polymorphisms could increase the risk of lymph node metastasis by affecting the expression of *MMP-9*.

The -1562 C>T polymorphism is located within an important regulatory element that appears to be a binding site for a transcription repressor protein. DNA-protein interaction is abolished by the C-to-T substitution at the polymorphic site, which results in a higher promoter activity of the T-allelic promoter^[21]. It is suggested that the *MMP-9* promoter-1562C>T polymorphism appears to regulate gene expression in an allele-specific manner.

A surprising finding was that the frequency of the *MMP-9* 279RR + RQ genotype was higher than that of the QQ genotype among patients younger than 60 years ($P < 0.05$). The results indicate that the *MMP-9* 279R allele may lead to a younger age of onset of CRC. The 279R>Q polymorphism is located in the catalytic domain of the *MMP-9* gene, and within one of the fibronectin type-II like repeats required for binding the enzyme to its substrate elastin^[22]. The polymorphism led to the substitution of a positively charged amino acid (arginine) by an uncharged amino acid (glutamine). These factors may contribute to the mechanism of our findings.

The major limitation of our study is the relatively small sample size, which could have resulted in a less precise estimation of the association between *MMP-9* polymorphisms and CRC susceptibility. Another weakness is that the study population was limited to native northern Chinese in Shenyang city, Liaoning province, and thus the results may not apply to other populations.

In conclusion, our study provides evidence of a connection between *MMP-9* -1562C>T polymorphisms and increased risk of developing CRC. Our results are consistent with a report of the multiple functions of *MMP-9* in cancer^[23], and especially with its role in tumor cell migration and invasion^[24].

Abstract

AIM: To investigate the hotspots, direction, and the time course of evolution of hepatitis A virus in the process of consecutive cell culture passage in human KMB17 diploid cells.

METHODS: Wild type hepatitis A virus H2w was serially propagated in KMB17 cells until passage 30, and the full-length genomes of H2w and its six chosen progenies were determined by directly sequencing RT-PCR products amplified from viral genomic RNA. Alignment comparison of sequences from H2w with its six progenies and phylogenetic analysis of the whole VP1 region from H2w, progenies of H2w, and other cell culture adapted hepatitis A virus were then carried out to obtain data on the molecular evolution of hepatitis A virus in the process of consecutive passage in KMB17 cells.

RESULTS: Most of the mutations occurred by passage 5 and several hotspots related to adaptation of the virus during cell growth were observed. After that stage, few additional mutations occurred through the remaining duration of passage in KMB17 cells except for mutation in the virulence determinants, which occurred in the vicinity of passage 15. The phylogenetic analysis of the whole VP1 region suggested that the progenies of H2w evolved closely to other cell culture adapted hepatitis A virus, i.e. MBB, L-A-1, other than its progenitor H2w.

CONCLUSION: Hepatitis A virus served as a useful model for studying molecular evolution of viruses in a given environment. The information obtained in this study may provide assistance in cultivating the next generation of a seed virus for live hepatitis A vaccine production.

INTRODUCTION

The mechanism of molecular evolution is often used by epidemiologists to acquire information about the direction of an epidemic, velocity of dissemination, site of the origin of the epidemic, and even predictions concerning future epidemics^[1,2]. These methods are helpful in visualizing molecular events of viruses that have evolved in a known environment, i.e. consecutive propagation of viruses in a given cell line under given temperature and nutritional conditions. However, only a few studies had been carried out to fulfill this objective. Research of this type can provide virologists important information on the evolutionary history of viruses, as well as the virulent gene in the virus.

Our group has accumulated several years of technical expertise in the cultivation of hepatitis A virus (HAV) in the human KMB17 diploid cell line, which originated from human embryonic lung tissue^[3]. The aim of the present study was to employ HAV as a model virus to investigate the evolution of the virus in the course of consecutive cell culture passage in human KMB17 diploid cells. In the present study, we serially propagated wild type HAV H2w in KMB17 cells to obtain 30 consecutive progenies, applied cold adaptation at passage 15 to 20 to investigate the conditions resulting in mutation within virulence determinants, and acquired virus samples at the end of every 5 passages from serial progenies for genome-wide sequence analysis. The resulting 5th (H2K5), 10th (H2K10), 15th (H2K15), 20th (H2K20), 25th (H2K25), and 30th (H2K30) progenies were obtained and analyzed. We have attempted to summarize the time course of molecular events that occur in the process of consecutive passage of HAV in human KMB17 diploid cells, as well as the hotspots and the direction of the evolution of HAV in given conditions. We hope that the information obtained from this study will help explain the conditions which promote the development of mutations pertaining to viral virulence determinants, and provide help in the development of a seed virus for the production of live virus vaccine.

MATERIALS AND METHODS

Cells and viruses

The KMB17 cell line which originated from human embryonic lung^[4] is now widely used for vaccine production in China^[3]. The KMB17 cells were grown in Dulbecco's modified Eagle's medium (Invitrogen), supplemented with 10% newborn calf serum (Invitrogen).

The H2w strain of HAV was isolated directly from feces obtained from hepatitis A patients^[5]. The KMB17 cells-adapted viruses were retrieved from cell substrate as follows: cells were first suspended in 6 mL phosphate saline buffer (pH 7.0) and treated with three cycles of freeze-thawing/sonication. The supernatant was obtained after centrifugation at 8000 r/min for 30 min and then extracted three times with chloroform. The virus in the supernatant was precipitated by the addition of polyethylene glycol 6000 to obtain a final concentration of 10% (wt/vol) and sodium chloride to give 0.4 mol/L solution^[6]. The virus pellet was collected by centrifugation at 12000 r/min for 30 min and was used directly in HAV RNA extraction.

Consecutive passage of HAV in KMB17

10⁵ 50% tissue culture infectious doses (TCID₅₀) of H2w were inoculated into 80% confluent monolayers of KMB17 cells in a 25 cm² flask (Costar). After 2 h of adsorption, the cells were washed three times and incubated at 35°C for 45 d to fulfill the first passage in the cell line^[3]. When harvested, the cells were suspended in 6 mL phosphate saline buffer (pH 7.0) and treated as described in the “cells and viruses” section above to obtain the 1st progeny virus in the supernatant. One ml of the supernatant was then inoculated into KMB17 cells to perform the 2nd passage. In this passage, the cells were kept at 35°C for 28 d. Consecutive passages from 3rd to 30th passage were carried out using the same technique as for the 2nd passage. All the passages were carried out at 35°C except for six passages from 15th to 20th, which were performed at 32°C.

Design of PCR primers

The HAV genome was divided into ten overlapping fragments, the size of about 1000 bp, and primers specific to both ends of the fragments were designed. To facilitate the process of sequencing and to ensure reproducibility of the results, we added a universal adapter from T7 promoter primer or M13 reverse sequencing primer to the routine primers used in specific amplification of HAV genome (Table 1). Our design of PCR primers allowed us to sequence PCR products with universal primers, which ensured maintaining the same reaction system for sequencing different PCR fragments, thus providing more reproducible results.

Nucleotide sequence analysis

HAV RNA was extracted from virus pellets using Trizol (Promega) according to the manufacturer's instruction. cDNA was synthesized using primers complementary to HAV nt 1567 to 1549, 3098 to 3080, 4549 to 4530, 6027 to 6008 or 3' RACE primer with AMV reverse transcriptase

(Promega). PCR amplifications were performed using 10 pairs of primers specific for HAV genome (Table 1) with Taq polymerase (Promega) based on the routine operation of PCR amplification. Sequences of PCR fragments were determined by directly sequencing the gel-purified PCR fragments on an ABI Prism 3730XL automated sequencer using T7 Promoter primer or M13 reverse sequencing primer. At least three reactions of the same PCR fragment were performed to ensure reliable results. The nucleotide sequence of the full-length HAV genome was obtained by splicing sequences from 10 overlapping RT-PCR fragments. Pair wise comparison of sequences from H2w and its six progenies was performed with Lasergene software package. The number of mutations in the nucleotide occurring in every 5 passages was calculated, and the mutation events as well as mutations in the deduced amino acid were summarized to provide information on hotspots and the time course of mutations of HAV during consecutive cell culture passages.

Subgenotype analysis of progeny viruses

Subgenotype analysis was performed by pair wise comparison of sequences from 168 bp VP1/2A junction at nt 3024 to nt 3191 according to the method of Robertson *et al.*^[7]. HM175 and LA were used as reference strains for IB and IA subgenotypes respectively. Divergence less than 7.5% in comparison with the reference strain was used as a criterion for distinguishing different subgenotype.

Phylogenetic assay of cell culture derivatives of H2w with other cell culture adapted HAV

Phylogenetic and molecular evolutionary analyses were conducted to evaluate the direction of evolution of HAV in consecutive passages in KMB17 cells. According to the

Table 2 Divergence of H2w and its progenies compared to reference strains in VP1/2A region (%)

	H2w	H2K5	H2K10	H2K15	K2K20	H2K25	H2K30
HM175	10.1	3.6	3.6	3.6	3.6	3.6	3.6
LA	4.8	7.7	7.7	7.7	7.7	7.7	7.7

method described by Costa-Mattioli *et al*^[8], the entire VP1 nucleotide sequences of H2w and its chosen progenies were aligned to other cell culture adapted HAV or reference strains, LA/wt^[9], GBM/wt, GBM/FRhK, GBM/HFS^[10], HM175/wt^[11], HM175/HAV7^[12], HM175/18F, HM175/24A, HM175/43C^[13], L-A-1^[14] and MBB^[15], by the CLUSTAL W program^[16]. Matrix distances for the Kimura two-parameter model were calculated from the resulting alignment output^[17] and used to plot neighbor-joining phylogenetic trees. These methods were implemented by using MEGA software package version 3.1^[18].

GenBank accession numbers

Sequences of several HAV strains were drawn from the GenBank for phylogenetic analysis. These included LA/wt (K02990), GBM/wt (X75215), GBM/FRhK (X75214), GBM/HFS (X75216), HM175/wt (M14707), HM175/HAV7 (M16632), HM175/18F (M59808), HM175/24A (M59810), HM175/43C (M59809), L-A-1 (AF314208) and MBB (M20273).

RESULTS

Nucleotide sequences of full-length HAV genomes

Our design allowed us to sequence the PCR products with a high degree of efficiency and reproducibility. All the three reactions of the same PCR fragment gave the same result, with excellent readability. The individual sequences from PCR fragments were spliced to obtain seven nearly full-length genomic sequences, which were deposited in GenBank with accession numbers: H2w (EF406357), H2K5 (EF406358), H2K10 (EF406359), H2K15 (EF406360), H2K20 (EF406361), H2K25 (EF406362) and H2K30 (EF406363).

Conversion of subgenotype during cell culture-adaptation

After pair wise comparison of H2w and its six cell culture derived progenies with HM-175 and LA, a divergence 3.6% of progenies to reference IB strain (HM175) other than 10.1% of the parent H2w was obtained. Often divergence less than 7.5% to the reference strain was a criterion for distinguishing different subgenotype, therefore, cell culture-adaptation switched the subgenotype of progenies from 1A to 1B (Table 2), which was not a common phenomenon in cell culture study of HAV conducted by other workers^[12,19].

Hotspot mutations in the course of consecutive cell passage

After alignment comparison of nearly full-length genomic sequences from H2w and its six cell culture derived progenies, we summarized hotspot mutations accumulated in the course of every 5 passages in the KMB17 cell line

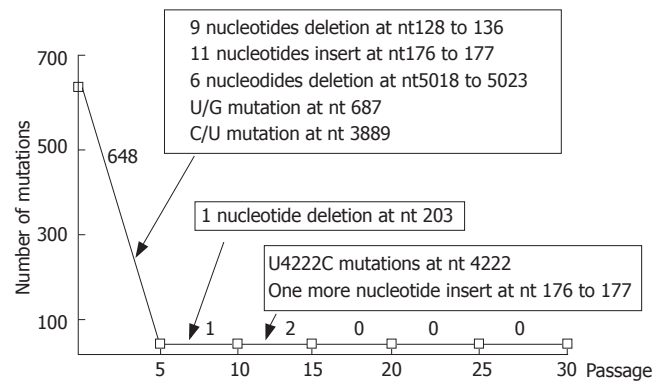

Figure 1 Summary of hotspots and time course of mutations in the process of consecutive passage of HAV in human cell line KMB17. The numbers on the curve indicate total mutations occurring at every 5 passages. Text in the boxes describes hot mutations occurring at the stage of cell culture passage.

(Figure 1). Within the first 5 passages, 648 mutations occurred throughout the genome, out of which forty were amino acid mutations. Among these 648 mutations, 9 nucleotides deletion at nt 128 to 136, 11 nucleotide insert at nt 176 to 177, 6 nucleotide deletion at nt 5018 to 5023, U/G mutation at nt 687 and C/U mutation at nt 3889, are possible hotspot mutations common to cell culture adapted HAV, or specific to HAV when adapted to grow in the KMB17 cell line^[12,19], which played crucial role in ensuring that the virus grew efficiently in human cell line KMB17. In the course of the next 5 passages, there was only one nucleotide deletion at nt 203, which was common to cell culture adapted HAV as described by other authors^[12]. A U/C mutation at nt 4222 occurred during the third 5 passages, which has been shown to be a virulence-related mutation^[20]. In the remaining consecutive passages, no new mutations were observed.

Time course of mutations pertaining to cell culture adaptation

Cell culture of HAV has been studied for many years. Several authors have reported their findings on hotspots related to changes in the HAV genome after cell-culture adaptation in different cell lines^[12,19,21-25]. Among these findings, C/U mutation at nt 3889 of 2B region^[23] was the most important in cell culture adaptation of HAV, regardless of the cell line origin. Other events, such as insertion mutation in 5' NCR and deletions at the beginning of the 3A region, have been suggested as cell line specific phenomena^[19,25]. In the present study, we found that almost all the events related to the adaptation of HAV in cell culture appeared to have been completed as early as passage 5 (Figure 1). These events included deletions near nt 131, insert at nt 176 to 177, U/G mutation at nt 687, C/U mutation at nt 3889 along with deletions near nt 5020. All the new mutations were stable during the remainder of the consecutive passage in KMB17 cells. Another mutation common in cell culture adapted HAV^[12], was deletion of 1 nucleotide at nt 203, which occurred before passage 10.

Time course of mutations within virulence determinants

It is difficult to identify mutations responsible for the

attenuation of HAV. Several studies have examined the virulence determinants of HAV through chimeric viruses constructed from wt HM175 and an attenuated derivative HAV/7^[20,26,27]. According to the studies conducted by Emerson *et al.*^[20], six nucleotides (HAV nt 3025, nt 3196, nt 4043, nt 4087, nt 4222, nt 4563) may be involved in the attenuation of HAV during cell culture adaptation. When we compared H2w and its cell culture derivatives, only nt 4222 of the six nucleotides mentioned above was found to have mutated from U to C in the long term consecutive cell culture adaptation. We thus extrapolated that in our study, nt 4222 was the main determinant for the virulence of HAV. In present study, we carefully compared H2w and its six chosen derivatives from cell culture at nt 4222, and summarized the time course of mutations related to virulence determinants of HAV. The virulence determinant did not mutate before the 10th passage in KMB17 cell line. Mutation of virulence determinant occurred between passage 11 and passage 15, and these mutations were stable throughout the remainder of the consecutive passage in KMB17 cell line (Figure 1).

Direction of evolution of HAV in prolonged cell culture passage

The complete VP1 nucleotide sequences from H2w and its six progenies were determined and aligned with those of cell culture adapted HAV strains taken from the GenBank. A phylogenetic tree was produced using Kimura two-parameter distance and the neighbor-joining method (Figure 2), which was implemented using the MEGA software package. The results showed that the six progenies of H2w were clustered more closely to MBB, a HAV adapted to human hepatocellular carcinoma cell line^[15], and L-A-1, another live attenuated HAV developed in the human diploid cells^[14], whereas the progenitor H2w clustered in another group with LA, the reference strain of HAV IA subgenotype. The situation was very different when derivative viruses from HM175 and GBM were examined. The derivatives from HM175 or GBM were clustered closely only with their progenitor virus. The phylogenetic tree suggested that progenies of H2w evolved closely to other cell culture adapted HAV rather than its progenitor virus regardless of the origin of the wild progenitor or the method used for adapting the virus.

DISCUSSION

In the present study, we used HAV as a model virus to investigate the molecular evolution of HAV in the course of prolonged consecutive passage in KMB17 cells. We obtained a good understanding of the overall time course of molecular events that occur during prolonged consecutive cell culture passage by genome-wide sequence comparison of HAV selected from serial cell culture-derived progenies. After assessing the data on the hotspot mutations at different stages of the consecutive cell culture passage, we concluded that nearly all the mutations occurred before passage 5 and these mutations remained stable throughout the remainder of the prolonged passage in KMB17 cells; several of the hotspot mutations

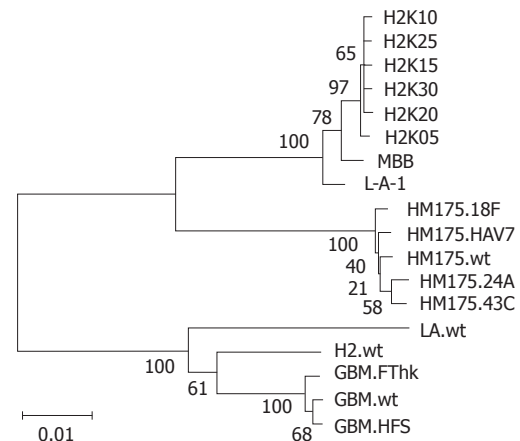

Figure 2 Phylogenetic analysis of the complete VP1 region using MEGA software package version 3.1. The numbers at nodes indicate bootstrap percentages after 1000 replications of bootstrap sampling. The bar indicates genetic distance.

played crucial roles in determining the ability of HAV to grow in cells other than hepatocytes. After this stage, no new mutations were observed except for mutations in the virulence determinants during the remainder of the consecutive passage. If the velocity of mutation is taken into account, our results were different from those described by other workers. Graff *et al.*^[19] noted that the GBM strain did not mutate its 5' non-coding region (NCR) before the 8th passage in a human cell line, and before the 20th passage in a rhesus kidney derived cell line. The main factors influencing the velocity of mutation remain unclear. Perhaps the cell substrate plays a critical role in determining the process of mutation. As the phylogenetic analysis of the whole VP1 region from H2w and its derivative progenies with other cell culture derived HAV indicates, cell culture derived progenies of H2w evolve closely to other cell culture derived HAV, i.e., MBB and L-A-1, which were successfully adapted to grow in human cells, despite the origin of the wild type progenitor or the method for adapting the virus. It is possible that the determinant factor for the direction of the evolution may be the cell substrate used, since MBB, L-A-1 and progenies of H2w were all produced in cell lines originating from human tissue.

Only a few studies have examined the time course of mutations within the virulence determinants of HAV, as well as the conditions for the occurrence of the mutations. The information obtained from this evolution study should help explain when and why the virus needed to mutate its virulence gene. In the present study, a U/C mutation at nt 4222 of 2C region with Phe/Ser conversion in amino acid occurred in H2K15, which was crucial for the attenuation of HAV, according to the identification of the virulent gene by Emerson *et al.*^[20]. Therefore, HAV may evolve its main virulence determinants in the vicinity of passage 15 in KMB17 cells. Cold adaptation was a common technique used to attenuate the virus^[28]. We therefore, hoped that this technique would mutate the virulence determinants of HAV. In our study, after the passage of virus was repeated 14 times at 35°C, we lowered the temperature from 35°C to 32°C for the following 6 passages in order to mutate the

virulent gene. The temperature was returned to the normal 35°C after completing the 20th passage so as to obtain the mutants accustomed to the higher temperature. Because U/C mutation at nt 4222 had occurred in H2K15, which was produced at lower temperature, we presumed that this mutation was temperature related. Recently, we sequenced a fragment of H2K14, the 14th progeny virus produced at the normal 35°C, and discovered that the U/C mutation at nt 4222 had already occurred (Data not shown). Therefore, cold adaptation may not influence the mutational process of virulence determinants of HAV. Perhaps, prolonged cell culture adaptation in an appropriate cell line is the real determinant for the occurrence of mutations of the virulent gene. By contrast, a study by Konduru *et al*^[29] showed that the wild type HM175 displayed no mutations during 9 passages in human hepatoma Huh7 cells.

Genetic stability is a major concern in the development of any live viral vaccine. Because of the quasispecies nature of the RNA viruses, it is believed that these viruses are heterogenous in their genome and mutations occur nonspecifically across the genome. In the case of live hepatitis A vaccine, few systematic studies have been carried out to determine the genetic stability of cell culture adapted HAV genome. In the present study, we investigated the genetic stability of cell culture adapted HAV genome after careful observation of the molecular evolution of HAV during prolonged consecutive passage in KBM17 cells. To ascertain that there would be few genetic changes during consecutive passages in KBM17 cells after completion of mutations regarding cell culture adaptation and virulence, we performed alignment analysis of genome-wide sequences from H2w and its progenies resulting from consecutive cell passage. Our results showed that no mutation occurred throughout the whole genome and none of the virulence determinants were affected by prolonged passage in KBM17 cells after the 15th passage. We concluded that the cell culture adapted genome of HAV was very stable during the course of consecutive cell culture passage in human diploid cells.

The data obtained from analyzing the molecular events during prolonged consecutive passage of HAV in KBM17 cells may provide information and technical assistance in monitoring the genetic stability of virulence determinant of seed virus used in live vaccine production, as well as the genetic stability of the live virus vaccine. Our observations may help establish an optimized design for cultivating seed virus for live vaccine production, which depends upon the knowledge of when and why the virus evolved its virulent gene, and the overall time course of mutations during consecutive passage in a given cell line. We hope that our findings are useful in breeding a seed virus for other live vaccine production, i.e., influenza, Japanese encephalitis, *etc.* In conclusion, HAV is an effective model for identifying hotspots, as well as the time course and direction of evolution of the virus in given conditions. The mechanism and possible implications of this type of evolution merits further investigation. Studies utilizing other viruses should be carried out to further evaluate this type of evolution.

Abstract

AIM: To study the postoperative complications in patients with preoperative portal vein thrombosis (PVT) undergoing liver transplantation (LT) and to evaluate the complications with Doppler ultrasonography.

METHODS: Retrospective studies were performed on 284 patients undergoing LT (286 LT) with respect to pre- and postoperative clinical data and Doppler ultrasonography. According to the presence and grade of preoperative PVT, 286 LTs were divided into three groups: complete PVT (c-PVT), partial PVT (p-PVT) and non-PVT, with 22, 30 and 234 LTs, respectively. Analyses were carried out to compare the incidence of early postoperative complications.

RESULTS: PVT, inferior vena cava (IVC) thrombosis, hepatic artery thrombosis (HAT) and biliary complications were found postoperatively. All complications were detected by routine Doppler ultrasonography and diagnoses made by ultrasound were confirmed by clinical data or/and other imaging studies. Nine out of 286 LTs had postoperative PVT. The incidence of the c-PVT group was 22.7%, which was higher than that of the p-PVT group (3.3%, $P < 0.05$) and non-PVT group (1.3%, $P < 0.005$). No difference was found between the p-PVT and non-PVT groups ($P > 0.25$). Of the 9 cases with postoperative PVT, recanalizations were achieved in 7 cases after anticoagulation under the guidance of ultrasound, 1 case received portal vein thrombectomy and 1 case died of acute infection. Ten LTs had postoperative IVC thrombosis. The c-PVT group had a higher incidence of IVC thrombosis than the non-PVT group (9.1% vs 2.6%, $P < 0.05$); no significant

difference was found between either the c-PVT and p-PVT groups (9.1% vs 6.7%, $P > 0.5$) or between the p-PVT and non-PVT groups ($P > 0.25$). Nine cases with IVC thrombosis were cured by anticoagulation under the guidance of ultrasound, and 1 case gained natural cure without any medical treatment after 2 mo. HAT was found in 2 non-PVT cases, giving a rate of 0.7% among 286 LTs. Biliary complications were seen in 12 LTs. The incidence of biliary complications in the c-PVT, p-PVT and non-PVT groups was 9.1%, 3.3% and 4.3%, respectively ($P > 0.25$ for all), among which 2 stenosis led retransplantations and others were controlled by relative therapy.

CONCLUSION: C-PVT patients tend to have a higher incidence of PVT and IVC thrombosis than non-PVT patients after LT. The incidence of postoperative complications in p-PVT patients does not differ from that of non-PVT patients. A relatively low incidence of HAT was seen in our study. Doppler ultrasonography is a convenient and efficient method for detecting posttransplant complications and plays an important role in guiding treatment.

INTRODUCTION

Portal vein thrombosis (PVT) is a common complication of chronic liver disease and malignant liver tumors. The incidence of PVT in patients undergoing liver transplantation (LT) ranges from 4.9% to 10.6%^[1-4]. In the past, technical difficulties and the potential risk of vessel reconstruction, as well as the higher rate of postoperative complications made PVT a contraindication of LT^[1,5].

However, improvement of operative management and advancement of postoperative care have meant that PVT is no longer a contraindication of LT^[6]. Only a few studies have looked in detail at the actual impact of preoperative PVT on postoperative complications. The understanding of pretransplant PVT still remains a problem. Since 1999, our center has begun to perform LT, and a portion of LT recipients have suffered from preoperative PVT. The aim of this study was to analyze the probable impact of preoperative PVT on postoperative complications, and to discuss the value of Doppler ultrasonography on monitoring the complications and guiding treatment by comparing results of LT in patients with and without PVT.

MATERIALS AND METHODS

Patients

Between February 1999 and April 2006, 302 patients received cadaveric liver transplantations. The inclusion standard was as follows: records of clinical data and ultrasonographic exams were complete. Exclusion standard was as follows: postoperative routine Doppler ultrasonography studies were not performed. Of the entire population, 284 patients (286 LT) were included in our study, with 284 primary grafts and 2 regrafts due to biliary stenosis after the primary graft. Patient group characters were as follows. There were 237 males and 47 females with an age range of 4-65 years (mean age, 43.7). The number of LTs was used as the frame of reference in our study.

Primary disease and previous surgery were as follows. There were 131 malignant liver tumors (2 regrafts), among which 8 had hepatic segment excision, 6 had splenectomy and 1 had transjugular intrahepatic portosystemic shunt (TIPS). One hundred and forty-eight cases had chronic liver disease, among which 8 had splenectomy and 3 had splenic artery embolization. Four patients had hepatic hydatidosis, 1 patient had congenital Caroli's disease, 1 patient had acute hepatic failure after liver contusion, and 1 patient had fulminant hepatitis. Orthotopic liver transplantations were performed on all patients including 284 full-size and 2 reduced-size grafts.

PVT patients: Of 286 LTs, 52 (18.2%) had preoperative PVT, with 48 males and 4 females ranging in age from 28 to 65 years (mean age, 44.3). Primary disease and previous surgery were as follows. There were 46 malignant liver tumors, with 1 liver segment excision and 3 splenectomies; 6 patients had cirrhosis, with 1 splenectomy and 2 splenic artery embolizations. PVT was confirmed by Doppler ultrasonography, contrast-enhanced CT and/or surgery as follows; there were 44 cases with tumor thrombosis and 8 with thrombus. All 52 PVT patients received full-size grafts. Portal vein (PV) reconstruction was as follows. Forty-seven patients accepted end-to-end PV anastomosis, 3 accepted porto-caval hemitransposition, 1 accepted PV to mesenteric vein anastomosis and 1 accepted PV to renal vein anastomosis.

According to the presence and grade of PVT, 286 LTs were divided into three groups. (1) Complete PVT (c-PVT) group: 22 cases, all with complete main portal vein (PV) thrombosis and 15 of them had PV branch thrombosis, 3

Table 1 Postoperative complications according to presence or absence of PVT and PVT grade

Postoperative complications	c-PVT <i>n</i> = 22 (%)	p-PVT <i>n</i> = 30 (%)	non-PVT <i>n</i> = 234 (%)
PVT	5 (22.7)	1 (3.3)	3 (1.3)
IVC thrombosis	2 (9.1)	2 (6.7)	6 (2.6)
BC	2 (9.1)	1 (3.3)	10 (4.3)
HAT	0	0	
	0	0	2 (0.9)

with superior mesenteric vein (SMV) thrombosis, 2 with splenic vein (SPV) thrombosis, and 2 with both SMV and SPV thrombosis. (2) Partial PVT (p-PVT) group: 30 cases, including 2 with partial main PV thrombosis and 28 with PV branch thrombosis. (3) Non-PVT group: 234 cases, which were the control group.

Ultrasound examination

An Agilent Sonos 4500 (HP, USA), Logiq 500 (GE, USA) and HDI 5000 (ATL, USA) were utilized in our study. The probe frequency was 2-5 MHz. Preoperative ultrasound scan included etiology of the liver, presence of PVT, and grade and extent of PVT. Postoperative ultrasound scan included size, configuration and echo of graft, the diameter of the hepatic vein, the PV and hepatic artery, anastomotic stoma, presence of thrombosis, blood flow and spectrum, presence of biliary obstruction, presence of perihepatic space effusion, and hydrothorax and ascites. Examination intervals were on the operation day and then daily or every 2 d during the first week. If any complications occurred, a scan was performed daily or according to the clinical situation.

Our study focused on early postoperative complications, which was defined as having been diagnosed within the initial hospital stay^[7].

Statistical analysis

Statistical analysis was performed with SPSS 10.0 (Chicago, IL, USA). A probability value less than 0.05 was considered significant. Differences in incidence between c-PVT, p-PVT and non-PVT groups were determined by Chi-square analysis.

RESULTS

Postoperative complications included PVT, inferior vena cava (IVC) thrombosis, hepatic artery thrombosis (HAT) and biliary complications (BC). Postoperative complications of the three groups are listed in Table 1.

PVT

Postoperative PVT was observed in 9 cases (3.1%), among which 6 were rethrombosis (11.5%). Five PVTs were found in the c-PVT group (22.7%), 1 was found in the p-PVT group (3.3%) and 3 were found in the non-PVT group (1.3%). The grades of PVT were 3 complete main PVT (Figure 1A and B), 1 partial main PVT and 5 PV branch thromboses. Nine PVTs were confirmed clinically as thrombus, appearing on 2-11 d, among which

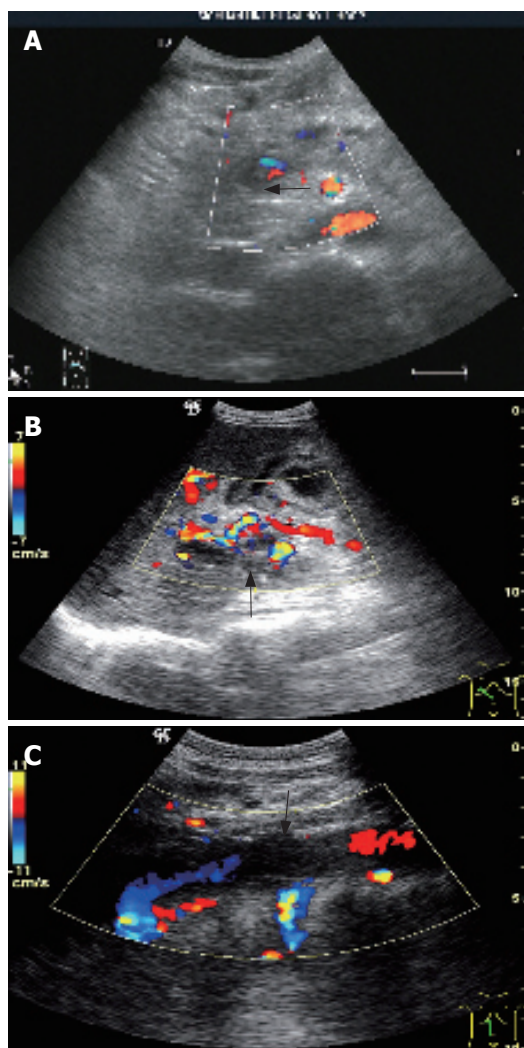

Figure 1 A 32-year-old male underwent LT due to posthepatic cirrhosis. **A:** Preoperative c-PVT; **B:** Postoperative main PV (arrow) and right branch thrombosis. Collateral circulation near PV was clearly showed also; **C:** Postoperative IVC (arrow).

recanalizations were achieved in 7 after anticoagulation, 1 received portal vein thrombectomy on the 5th d and 1 died of acute rejection on the 12th d postoperatively.

IVC thrombosis

IVC thrombosis was seen in 10 cases on 5-13 d postoperatively. All were subhepatic IVC thrombosis (Figure 1C), with 4 complete and 6 partial thromboses. Recanalizations were obtained in 9 cases after anticoagulation. One case with partial thrombosis got natural cure after 2 mo.

HAT

HAT was seen in 2 non-PVT patients on d 3 and 5. Thrombectomy was successfully performed on 2 patients. BC.

Thirteen cases suffered from BC postoperatively. Four of these were stenosis, leading to cholangioplasty in 2 cases and retransplantation in the other 2 cases. Two cases had cholangitis and were cured with drainage and anti-infective treatment. Four cases had evanescent dilation of

the intrahepatic duct. One case had biliary fistula and a repair operation was necessary. One case had secondary biliary obstruction.

The incidence of postoperative PVT in the c-PVT group was higher than in the p-PVT ($P < 0.05$) and non-PVT groups ($P < 0.005$), and there were no significant differences found between the p-PVT and non-PVT groups ($P > 0.25$). The c-PVT group had more IVC thromboses than the non-PVT group ($P < 0.05$) and did not differ from the p-PVT group ($P > 0.5$). There was no difference for IVC thromboses between the p-PVT and non-PVT groups ($P > 0.1$). Among the three groups, the incidence of BC between every two groups was not different ($P > 0.25$ for all groups).

DISCUSSION

Preoperative PVT and LT

PVT is a common preoperative complication in patients undergoing LT. In China, posthepatic cirrhosis and advanced malignant liver cancer form the majority of primary diseases in the LT population^[8], which results in an even higher incidence of PVT in LT patients. In our series, the incidence of PVT was 18.2%, which is higher than reports elsewhere^[1-4,6,16]. Gayowski *et al*^[5] also found an extremely high incidence of PVT (26%) in a predominantly male group of patients mostly with postnecrotic cirrhosis. Our study is consistent with the finding in that most of our cases were male and primary diseases were posthepatic cirrhosis and liver cancer accompanied with cirrhosis.

In past years, PVT has been taken a contraindication for LT. With improvement of surgical techniques and enhancement of posttransplant care, the outcomes of PVT patients are very close to those of non-PVT patients. The one-year survival rate of PVT patients is reported to be 81%^[6], and 1-, 2- and 4-year survival rates are not significantly different in patients with or without PVT^[5]. However, several reports confirmed that PVT had a substantial impact on increased blood loss, a higher mortality rate, a higher graft loss and more posttransplant complications^[1,5,9,10]. The mortality rate of patients with PVT and extensive splanchnic venous thrombosis undergoing LT is as high as 33%^[10]. As shown by Zhou *et al*^[11], PV tumor thrombosis is one of two major prognostic factors of HCC after LT. Therefore, strict preoperative screening and efficient postoperative examinations such as laboratory examinations, Doppler ultrasound, CT, MRI, and angiography when needed should be executed on PVT recipients^[4,12]. In addition, such surgeries should be handled by an experienced transplantation center.

Postoperative complications of PVT patients undergoing LT

PVT is a common postoperative complication of LT. Especially in children, PVT is the top transplant vascular complication^[13]. The clinical presentations include intractable ascites, variceal bleeding, shrunken livers, splenomegaly, and hepatic failure^[1-3]. It's widely

accepted that risk factors of posttransplant PVT include severe pretransplant portal hypertension, experience of treatment for portal hypertension (e.g., TIPS, portocaval shunt, splenectomy, and splenic vein embolization) and preoperative PVT^[4,14-16]. The incidence of postoperative PVT in our study was 3.1%, which is similar to 1%-3% of other reports^[2,4,17,18]. The incidence of rethrombosis in LT recipients with native PVT has been reported to range from 5% to 21%^[2,4,10,16]. A significantly increased incidence compared to the whole group of rethrombosis (11.5%) was also seen in our study, which is much higher than 1.3% of non-PVT recipients ($P < 0.005$). Although Settmacher *et al*^[16] associated splenectomy during LT with an increased incidence (10.5%) of PV complications, none of our patients endured splenectomy during LT.

In the study by Yerdel *et al*^[4], PVT was classified into four grades as follows: grade 1; $< 50\%$ PVT \pm minimal obstruction of SMV, grade 2; grade 1 but $> 50\%$ PVT, grade 3; complete PVT and proximal SMV thrombosis, and grade 4; complete PVT and entire SMV thrombosis. By Yerdel's research, postoperative complications of grade 1 did not differ from those of non-PVT, while grades 2, 3 and 4 exceeded non-PVT. We only divided the PVT patients into the p-PVT and c-PVT groups instead of classifying the recipients as in the study by Yerdel *et al* because there were too few grade 3 and 4 patients to perform statistical analysis. Our results also revealed the impact of grade and extent of PVT on postoperative complications. Retrombosis of c-PVT recipients was 22.7%, which was higher than that of p-PVT and non-PVT groups.

With regard to the probable cause of posttransplant PV complications, Settmacher *et al*^[16] took pathological changes of the vessel wall for an important reason, because all cirrhosis patients may have experienced partial or complete PVT and pathological changes of the vessel wall may increase the incidence of PV complications to 17.9%. In our study, PV branch thrombosis was predominant in the p-PVT group, which had a minute influence on PV reconstruction, while blood vessel pathological changes caused by partial thrombosis of main PV were relatively milder than c-PVT. We attribute these probable reasons to the lower incidence of postoperative PVT in p-PVT than c-PVT and similar incidences of postoperative complications between p-PVT and non-PVT groups. With regard to LT in children, postoperative PVT is much more common with the incidence ranging from 8% to 33%, which is attributed to donor/recipient portal vein diameter mismatch and application of graft veins^[7,13,19]. One of the patients with postoperative PVT in our study was a 4-year child without preoperative PVT. However, it is difficult to reach a conclusion that mismatch of donor/receptor vein diameter may lead to posttransplant PVT due to too few child cases.

IVC thrombosis

IVC thrombosis occurred in 3.5% of our series (10/286), with more in the c-PVT group than in the non-PVT group and adjacent occurrences were seen between p-PVT and non-PVT groups. Donor/recipient vessel mismatch and

recurrence of the underlying disease (e.g. Budd-Chiari syndrome) account for the majority of complications of the vena cava, while unknown causes account for the minority^[16]. At this time we can not explain the higher incidence of IVC thrombosis in c-PVT.

HAT

HAT is a common posttransplant complication, which is associated with operation techniques^[20]. In our center, vascular anastomoses are accomplished by a vascular surgeon with microsurgical techniques, which remarkably improves the quality of vascular reconstruction, especially on small vessels like the hepatic artery. Thus, posttransplant HAT in our center has been decreased to an ideal extent, which is much less than in other centers^[18,21].

BC

Biliary stenosis, biliary fistula and cholangitis account for most of the postransplant BC, for which technical failure or local ischemia are major causes^[22]. BC occurred after 13 LTs (4.5%), affecting 11 recipients in our series. No difference was found between groups with or without PVT. Biliary cirrhosis caused by biliary obstructions in two recipients led to retransplantations in the 7th and 12th mo, which suggests that BC may be the main reason for late retransplantation.

Vascular complications after LT may be more prone for placing the patient and allograft in jeopardy than BC, but they rarely necessitate retransplantations with early management^[18,23]. In our study, although 2 patients suffering from postoperative HAT endured re-exploration and thrombectomy, and 1 patient with postoperative PVT died of acute rejection, no retransplantations were caused by PVT or IVC thrombosis if early diagnosis and treatment were administered. Settmacher *et al*^[16] studied 1000 LTs and demonstrated that more than half of the patients suffering from PV complications did not require any treatment at all and treatment became necessary only when additional complications such as arterial occlusion or bile duct injuries occurred.

Doppler ultrasonography in postransplant evaluation of PVT recipients

In China, cirrhosis and unresectable liver cancer forms the majority of primary disease in LT recipients, among which PVT has a high incidence. Preoperative PVT should have the requirement for pretransplant screening and postoperative monitoring of a high quality. Since Doppler ultrasonography is rapidly available, inexpensive and provides reasonable accuracy, it is predominant in pre-, intra- and posttransplant evaluations^[4,21,24]. Accurate diagnosis of vascular abnormalities helps to determine the operation agenda^[4]. Early detection and management of postoperative complications, especially clinically unsuspected vascular complications, can satisfactorily reduce the mortality rate and avoid retransplantation^[2,21]. Conventional Doppler ultrasound provides an ideal specificity on diagnosing PVT ranging from 97% to 100%^[4,24,25]. In our series, Doppler ultrasonography detected all of the complications and

got confirmation of clinical presentations and other image examinations. In our center, if anticoagulation is essential when the posttransplant patient suffers from PVT or IVC thrombosis, a daily ultrasound examination will be performed to observe dissolution of thrombosis. Termination of treatment is thrombosis dissolution and vessel recanalization determined by ultrasound examination.

In a previous study by Hom *et al*^[25], diagnostic validity of contrast-enhanced ultrasound (CEUS) was comparable to that of angiography, and CEUS shortened study time markedly. In addition, we are currently working on CEUS on posttransplant patients and will have results when more cases are studied.

In conclusion, the incidence of PVT after LT in our study was higher in the c-PVT group than in the p-PVT and non-PVT groups. Compared to non-PVT patients, c-PVT patients are more likely to suffer from IVC thrombosis postoperatively. The incidence of BC did not differ between c-PVT, p-PVT and non-PVT groups. In our center, postoperative HAT is relatively uncommon. Doppler ultrasonography provides an accurate diagnosis of complications after LT, plays a very important role in posttransplant monitoring and is essential in guiding treatment.

Abstract

AIM: To investigate if the nucleoside analogue lamivudine (LAM), a potent inhibitor of HBV replication, could restore the function of dendritic cells derived from patients with chronic hepatitis B (CHB) in an Asian population.

METHODS: Dendritic cells (DCs) derived from mononuclearcytes of patients with chronic HBV infection were cultured in the presence of IL-4, granulocyte-macrophage colony-stimulating factors (GM-CSF) and gradient concentrations of LAM (0-2 mmol/L). Cell morphology was observed under light microscopy. Cell surface molecules, including HLA-DR, CD80, CD83, and CD1 α , were analyzed with flow cytometry. The concentrations of IL-6 and IL-12 in the supernatant were assayed by ELISA. T cell proliferation was assayed by methyl thiazolyl tetrazolium (MTT).

RESULTS: The expression of CD1 α on DC treated with 0.5 mmol/L LAM (LAM-DC 0.5 mmol/L) was significantly higher than that of DC untreated with LAM (54.1 ± 4.21 vs 33.57 ± 3.14 , $P < 0.05$), and so was the expression of CD83 (20.24 ± 2.51 vs 12.83 ± 2.12 , $P < 0.05$) as well as the expression of HLA-DR (74.5 ± 5.16 vs 52.8 ± 2.51 , $P < 0.05$). Compared with control group, LAM-DC group (0.5 mmol/L) secreted significantly more IL-12 (910 ± 91.5 vs 268 ± 34.3 pg/mL, $P < 0.05$), had lower levels of IL-6 in the culture supernatant (28 ± 2.6 vs 55 ± 7.36 pg/mL, $P < 0.05$), markedly enhanced the stimulatory capacity in the allogeneic mixed leukocyte reaction (MLR) (1.87 ± 0.6 vs 1.24 ± 0.51 , $P < 0.05$).

INTRODUCTION

More than 300 million people worldwide are chronically infected with hepatitis B virus (HBV), and the majority of them are in Asia, especially in China. One of the important mechanisms resulting in the immune tolerance by chronic hepatitis B (CHB) is the impaired function of dendritic cells (DCs) derived from patients with CHB^[1]. DCs are antigen-presenting cells (APC) responsible for initiating immunity and play an important role in the induction of antiviral immune responses^[2]. Recently there has been considerable interest in using DCs as adjuvants to enhance host immunity against viral infection^[3].

Lamivudine (LAM), a nucleoside analogue, is a potent and selective inhibitor of HBV replication. LAM specifically inhibits hepadnaviral DNA polymerase by competing with the corresponding dNTPs for incorporation into nascent DNA acting as a chain terminator after incorporation^[4]. In addition to anti-HBV replication, the potential role of LAM in the regulation of immune response in HBV patients has been noticed recently. LAM treatment can restore T cell responsiveness in chronic hepatitis B^[5]. Furthermore, it has been reported that LAM could up-regulate major histocompatibility complex class II (MHC-II) expression and restore impaired allostimulatory function of mononuclear cell-derived DC in the Caucasian patients with HBV infection^[6]. In China, the influence of LAM on function of DC has not been investigated. We, therefore, HBsAg-pulsed DCs derived from the mononuclear cells

of patients with chronic HBV infection with different LAM concentrations (0-2 mmol/L) *in vitro* and observed whether LAM could enhance DCs function. We attempted to explore a new approach to combine LAM and dendritic cell-based immunotherapy for CHB infection.

MATERIALS AND METHODS

Materials

rhGM-CSF, rhIL-4, mouse anti-human HLA-DR-PE, CD80-FITC, CD1 α -FITC, CD83-PE were purchased from BioLegend. RPMI-1640 was purchased from GIBCO (USA), and fetal calf serum (FCS) from Hangzhou Sijiqing Biological Engineering, China. Ficoll-Hypaque density gradient separate solution was purchased from Tianjin Jinmai Gene Biotechnology Co., China. rhIL-6, IL-12 ELISA Kit (Peprotech) were purchased from Shanghai Shengxiong Technology Company, China. LAM was purchased from GlaxoSmithKline Company.

Subjects

Fifteen outpatients with HBeAg-positive CHB infection participated in this study. Written informed consent was obtained from all the patients and the study protocol was approved by the Ethics Committee of Zhengzhou University.

Preparation of dendritic cells

Peripheral blood mononuclear cells (PBMCs) were prepared from CHB patients. Briefly, PBMCs were washed and resuspended at 2×10^6 cells/mL. The cells were cultured in RPMI 1640 media containing 100 mL/L autologous serum, 100 U/mL penicillin, 100 μ g/mL streptomycin. After incubation for 2 h at 37°C, non-adherent cells were removed; the adherent cells were cultured with RPMI 1640 media with recombinant GM-CSF and IL-4 in a 24-well culture plate at 37°C in a humidified atmosphere containing 50 mL/L CO₂. Mononuclear cells were assigned to two groups on d 3: LAM-treated group (experimental group), and non-LAM-treated group (control group). The experimental group was further divided into subgroups according to the different concentrations (0.125, 0.25, 0.5, 1, 2 mmol/L) of LAM. Half of the medium was replaced with fresh medium every other day. DCs were harvested on the 8th d.

Analysis of DCc morphology and flow cytometry (FACS)

DCs were observed on an inverted microscope dynamically, and the phenotypes of DCs, such as CD1 α , CD80, CD83 and HLA-DR, were analyzed by FACS on the 8th day. FITC-labelled mouse anti-human CD1 α , CD80 monoclonal antibody (mAb) and phycoerythrin-conjugated mouse anti-human CD83, HLA-DR mAb were used. Staining was performed as described previously^[7].

Allogeneic mixed leukocyte reaction

To clarify whether the antigen-presenting capacity of LAM-treated DCs (LAM-DC) was different from that of non-LAM-treated DCs (non-LAM-DC), mononuclear cells were isolated from the peripheral blood of healthy

subjects. After incubation for 2 h, the non-adherent cells were collected as lymphocyte cells. DCs were collected as stimulator cells at a concentration of 1×10^5 /mL and added into a 96-well culture plate. DCs were incubated with mitomycin C (50 μ g/mL) for 30 min, and then lymphocytes were added as responder cells at a concentration of 1×10^6 /mL; each group was set to triple wells. After being cultured for 3 d, absorbance at 570 nm (A_{570}) was assayed by MTT and the stimulator index (SI) was calculated using a formula: $SI = A_{\text{experiment}} / (A_{\text{responder cells}} + A_{\text{stimulator cells}})$.

Evaluation of IL-12 and IL-6 in supernatant of DC

Levels of IL-12 and IL-6 in the supernatant of DC were determined using an enzyme-linked immunosorbent assay (ELISA) kit following the manufacturer's instructions. Samples of each group were set to triple wells.

Statistical analysis

Data were analyzed with SPSS10.0 statistical software. The significant difference between groups was determined by one-way ANOVA test. Two-sided $P < 0.05$ was considered statistically significant.

RESULTS

Morphology analyses

After being cultured for 24 h, DCs began to grow as fully differentiated swarm cells as observed under a microscope; 3 d later there was an increase in size and in numbers of DCs; 6 d later much salience on the surface of DCs was observed; many nebulous substance floating among culture media were also found on the 8th day. However, the LAM-DC at low doses had no distinct difference in morphology from control group (Figure 1A and B). There was an increase in number of grainy substance in culture media of the LAM-DC at a high dose on the 2nd day (Figure 1F), which might be cell debris resulted from the medication toxicity.

Phenotype of dendritic cells

The phenotypes of DCs were determined by FACS on the 8th day. The expressions of phenotype molecules in DCs diversified among groups treated with different concentrations of LAM. The expressions of CD1 α on LAM-DC (0.5 mmol/L) was significantly higher than those in naïve controls and other groups ($P < 0.05$), and so was the expression of CD83 ($P < 0.05$) and the expression of HLA-DR ($P < 0.05$); there was no difference in CD80 expression between LAM-DC (0.5 mmol/L) group and control group. The results demonstrated that HBsAg-pulsed DCs with LAM at certain concentration can enhance the capacities of antigen-presentation (Table 1).

Stimulatory capacity of the LAM-DC on lymphocyte proliferation

In the allogeneic mixed leukocyte reaction (MLR), the lymphocyte proliferation reflected the stimulatory function of DCs. The stimulatory capacity of the LAM-DC (0.5 mmol/L) in the allogeneic mixed leukocyte reaction

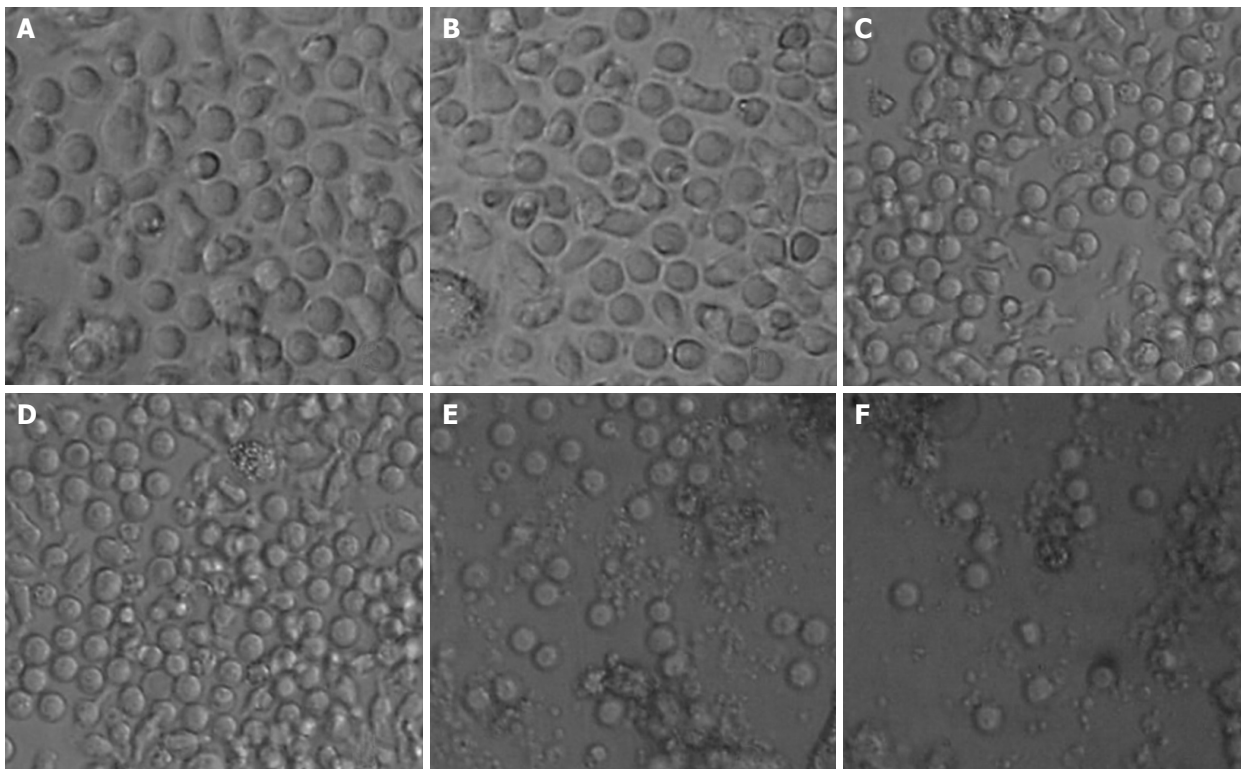

Figure 1 Morphology of DCs treated with lamivudine (LAM) at different concentrations on the 8th d (× 400). **A:** Non-LAM-treated DC; **B:** DC + LAM (0.125 mmol/L); **C:** DC + LAM (0.25 mmol/L); **D:** DC + LAM (0.5 mmol/L); **E:** DC + LAM (1 mmol/L); **F:** DC + LAM (2 mmol/L).

(MLR) was markedly enhanced as compared with control group (*P* < 0.05). On the contrary, there was no significant difference between LAM-DC (0.125 mmol/L) and control group (Table 2).

Secretion of IL-12 and IL-6 by DCs

The concentrations of IL-12 in the supernatant of LAM-DC (0, 0.125, 0.25, 0.5, 1, 2 mmol/L) were 268 ± 34.3, 380 ± 51.2, 500 ± 89.4, 910 ± 91.5, 255 ± 73.1, 138 ± 27.9 pg/mL, respectively. The concentrations of IL-6 in the supernatant of LAM-DC (0, 0.125, 0.25, 0.5, 1, 2 mmol/L) were 55 ± 7.36, 47 ± 5.2, 32 ± 2.7, 28 ± 2.6, 69 ± 8.7, 67 ± 8.4 pg/mL, respectively. The secretion of IL-12 significantly increased in the LAM-DC (0.5 mmol/L)

Table 2 The stimulatory ability of DCs treated with LAM in allogeneic mixed leukocyte reactions (mean ± SD, *n* = 15)

	Control group	LAM (mmol/L)				
		0.125	0.25	0.5	1	2

group in comparison with control group (*P* < 0.05). However, LAM-DC (0.5 mmol/L) group produced a lower level of IL-6 as compared with control group (*P* < 0.05) (Figure 2).

DISCUSSION

Experimental data from HBV-transgenic mice demonstrate that the immune system plays a key role in HBV clearance^[8]. After HBV infection, the body starts a series of non-specific immunology responses, including activation of natural-killing cells and secretion of interferon. However, the complete clearance of HBV relies on the activation of HBV-specific T lymphocytes^[2]. The body can produce HBV antigen-specific CTL response to kill target cells related to HBV. DCs are professional antigen-presenting cells that link innate and adaptive immunity, and are essentially involved in the initiation of primary immune responses and in the establishment of peripheral tolerance^[9,10]. The infection of CHB relates to the impairment of immunity by the mechanism resulting from the deficiency of DC function^[11]. Selective modification of DC function and promotion of HBV-

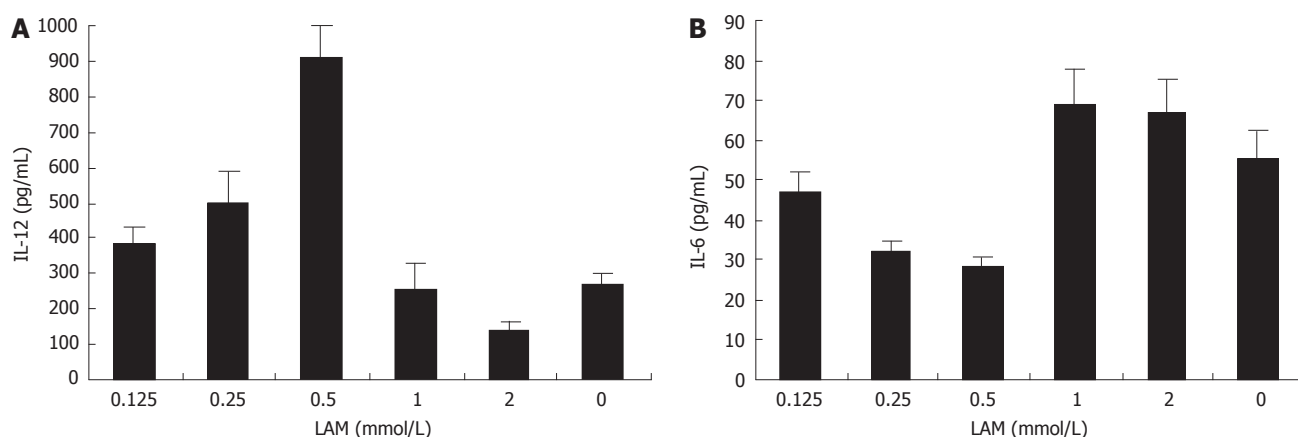

Figure 2 Modulation of cytokine secretion from DCs by LAM treatment. Bars indicate the levels of IL-12 (A) and IL-6 (B) in culture media of DCs treated with LAM at different concentrations (mean \pm SD, $n = 15$).

specific immune responses during CHB treatment have shown therapeutic significance^[12].

DCs could be assigned to two groups by their immunocompetence: mature DCs and immature DCs. Mature DCs have already encountered antigens, whereas immature DCs are able to internalize antigens, process them in the extranuclear compartment, and convert them on the cell surface in the compound of MHC-antigen peptides and present antigenic peptides to T cells. It activates the antigen-specific T cells and initiates immune response with the help of costimulatory molecules binding the corresponding T cell receptors^[13]. In the present study, we detected the expression of CD1 α , CD80, CD83 and HLA-DR on DCs. CD1 α is the specific sign of DC's function; the more CD1 α expresses on DCs, the strong function DCs have. CD83 is a mature sign of DCs; HLA-DR, one of the MHC II molecules, mostly takes part in the process of antigen presentation; CD80, one of the costimulatory molecules, promotes T cell activation *via* combining the corresponding T cell receptors^[14,15].

Beckebaum *et al*^[6] proposed that LAM could facilitate the maturation of DCs isolated from Caucasian patients with HBV infection by increasing the expression of HLA-DR and further promote DCs function. In the present study, the expression of CD1 α , CD83 and HLA-DR on DCs derived from Chinese patients with CHB infection incubated with LAM (0.5 mmol/L) *in vitro* could be enhanced; however, the increase of CD80 was not statistically different as compared with that of control group. Here we found that the lower expression of phenotypic molecules and impaired allogeneic mixed lymphocyte reaction function of DCs from patients with HBV infection could be restored *in vitro* by incubation with LAM. The present study demonstrated that LAM did promote DCs maturation and enhance DCs function.

DCs regulate Th0 cell proliferation towards Th1 cells and Th2 cells through the secretion of IL-6, IL-12 and IFN- γ ^[16]. IL-12 secreted by mature DCs regulates Th0 cells proliferation towards Th1 cells, promotes the secretion of IL-2, IFN- γ and participates in the cellular immune response. IL-6 from immature DCs drives Th0 cells to proliferate towards Th2 cells, restrains the cellular

immune and induces the immune tolerance^[17]. In the current experiment, we found that the secretion levels of IL-12, IL-6 by DCs could be affected by LAM *in vitro*. The secretion of IL-12 increased in the LAM-DC. LAM-DC produced lower levels of IL-6 as compared with non-LAM-DC. These results indicate that DCs treated with LAM at certain concentrations can promote T cell proliferation and enhance the cellular immunity.

The present data confirmed that the defect of DC function could be partially restored by LAM *in vitro* as marked by the enhanced expression of CD1 α , CD83 and HLA-DR on DCs and increased secretion of IL-12, reduced secretion of IL-6 in DCs, and enhanced mixed lymphocyte reaction ability. This indicates that, in addition to its potent anti-HBV replication role, LAM is able to modify the biological activities of DCs derived from patients with CHB infection. Therefore, LAM can be a potential candidate as an immunoregulatory therapeutic remedy used in the treatment of patients with CHB infection. Since treatment with LAM can overcome T cell hyporeactivity^[5] and restore DCs function, combination of LAM with DCs may be an effective therapeutic strategy to obtain eradication of chronic HBV infection.

COMMENTS

Background

Hepatitis B virus (HBV) infection is a global public health problem. The immune response of the host plays an important role in the pathogenesis of chronic HBV infection.

Research frontiers

One of the important reasons responsive for the immune tolerance in chronic hepatitis B (CHB) is impaired function of dendritic cells (DCs) which cannot efficiently present HBV antigens to host immune system.

Innovations and breakthroughs

DC-based therapeutic vaccine has recently been a potential approach to treat CHB. Lamivudine (LAM), a nucleoside analogue, specifically inhibits the hepadnaviral DNA polymerase.

Applications

The present study provides a new support for the application of LAM and DC-based immunotherapy in clinical practice of CHB therapy.

Peer review

This is a good paper indicating that combining LAM with DCs may be an effective therapeutic approach to obtain eradication of chronic HBV infection.

Abstract

Patients with inflammatory bowel disease have normal life expectancy and, due to modern immunosuppressive therapies, also a normal quality of life. Since mostly young people are affected, their social behaviour suits this environment. Alcohol bingeing is an increasingly disturbing factor among young people. We describe a patient with Crohn's disease, treated with azathioprine, who developed peliosis hepatitis after three episodes of alcohol bingeing. Liver toxicity was not observed previously during the course of the treatment. Azathioprine-induced peliosis hepatitis is thought to be idiosyncratic in humans. From animal studies, however, it is clear that hepatic depletion of glutathione leads to azathioprine toxicity to the sinusoidal endothelial cells. Damage of these cells causes peliosis hepatitis. Since alcohol bingeing leads to hepatic glutathione depletion, we conclude that in our patient the episodes of bingeing have reduced liver glutathione content and therefore this has increased azathioprine toxicity causing peliosis hepatitis. The problem of alcohol bingeing has not yet been addressed in IBD patients undertaking immunosuppressive therapy. This should be reviewed in future considerations regarding patients advice.

INTRODUCTION

Patients with inflammatory bowel disease (IBD) have normal life expectancy and, due to modern immunosuppressive therapies, also a normal quality of life^[1,2]. Since young people are often affected, their social behaviour suits this environment^[3]. Alcohol bingeing is an increasingly disturbing factor among young people^[4] and also occurs in treated IBD patients. However, there is little information about the toxicity of drugs used in IBD patients during alcohol bingeing. Azathioprine is frequently used as immunosuppressant in IBD. Adverse effects occur in 15% to 30% of patients^[5]. Hepatotoxicity is a rare but important complication of this drug. In the liver, three syndromes can be grouped: hypersensitivity, idiosyncratic cholestatic reaction, and endothelial cell injury. Liver endothelial cell injury presents with portal hypertension caused by venoocclusive disease or peliosis hepatitis^[6]. Here we describe a patient with IBD who developed peliosis hepatitis during azathioprine therapy most likely due to concomitant alcohol bingeing.

CASE REPORT

In 1996, the diagnosis of Crohn's disease was made in a 37-year-old male after a right hemicolectomy with resection of the terminal ileum. He was treated with mesalazine. In September 2005, the patient presented us with an incomplete intestinal cutaneous fistula originating from the anastomosis. He was treated with metronidazole and immunosuppression was begun with steroids (prednisolon 60 mg/d) and azathioprine (2.5 mg/kg body weight per day), mesalazine was stopped. The fistula disappeared and steroids were tapered to zero in the course of the following weeks. In April 2006, liver enzymes were within normal limits, as were white and red blood counts under azathioprine medication. At the end of July, the patient experienced an episode of ethanol bingeing at a local festival with intake of 800 g alcohol (11 g/kg body weight) over 3 d. The consumption of comparable amounts of alcohol had been uneventful in the former years. In August, he had two episodes of bingeing with intake of 20 g per day (0.3 g/kg body weight). At the end of October, he developed progressive fatigue, abdominal discomfort and pruritus. Laboratory values showed pancytopenia [WBC $2.1 \times 10^3/\mu\text{L}$ (normal range $3.6-9.6 \times 10^3/\mu\text{L}$), platelets $66 \times 10^3/\mu\text{L}$ (normal range $150-400 \times 10^3/\mu\text{L}$), erythrocytes $2.53 \times 10^6/\mu\text{L}$ (normal range $4.5-5.9 \times 10^6/\mu\text{L}$)] and elevated gammaglutamyltransferase (121 U/L, normal value < 66

Figure 1 Ultrasonography of the liver.

U/L), alkaline phosphatase (220 U/L, normal value < 129 U/L) and total bilirubin (4.03 mg/dL, normal value < 1.10 mg/dL). Transaminases were normal. Thiopurine-methyltransferase (TMA) activity was 44 nmol/g Hb × h (normal value > 20 nmol/g Hb × h). Hyaluronic acid levels were 166 ng/mL (normal value < 100 ng/mL). Ultrasound showed an enlarged liver with a macronodular surface (Figure 1) and an enlarged spleen. The diagnosis of cholestatic hepatitis with portal hypertension and related pancytopenia was made. Viral, autoimmune and hereditary causes of liver disease were serologically excluded, chronic alcohol intake was negated. Simultaneously the patient developed signs of small bowel obstruction with the presence of dilated jejunal loops. Steroid pulse therapy was administered and azathioprine was stopped. A liver biopsy was performed, which showed a sinusoidal ectasia in zone II and III without venous obliterations, minimal portal tract fibrosis without bile duct alterations (Figure 2). No cirrhotic change was noted. Thus, a diagnosis of peliosis hepatis was made. After withdrawal of azathioprine, the patient's condition improved, pancytopenia disappeared and bilirubin values returned to normal. A liver biopsy to document histological resolution was not performed.

DISCUSSION

Azathioprine-induced peliosis hepatis is thought to be idiosyncratic in humans. Possible risk factors are male gender, renal transplantation and intake of steroids^[7,8]. From our observation, we conclude that alcohol bingeing is an additional risk factor. Peliosis hepatis is a consequence of sinusoidal endothelial cell damage^[9]. This damage is demonstrated in our patient by the elevation of serum hyaluronic acid levels^[10]. *In vitro* studies with murine sinusoidal endothelial cells and hepatocytes exposed to azathioprine have suggested that the mechanism of hepatotoxicity is sinusoidal endothelial damage associated with glutathione depletion. In this model, azathioprine toxicity was selective to sinusoidal endothelial cells and hepatocellular damage was likely due to subsequent ischemia rather than direct toxicity to hepatocytes. Reducing intracellular glutathione levels in sinusoidal endothelial cells increased azathioprine toxicity. Glutathione levels in sinusoidal endothelial cells play an essential role in azathioprine detoxification^[9]. Since ethanol

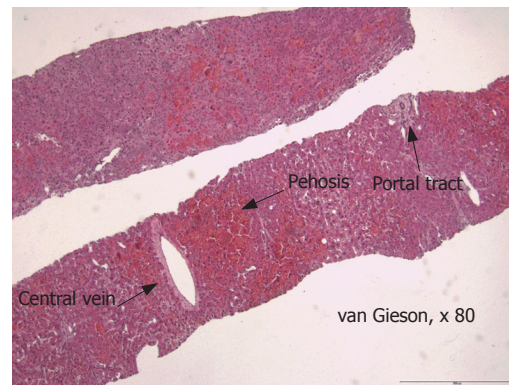

Figure 2 Peliosis hepatis with sinusoidal ectasia in Zone II and III (Elastica von Gieson stain, x 80).

bingeing depletes hepatic glutathione by 60% and therewith increases the toxicity of paracetamol to sinusoidal endothelial cells^[11], we hypothesize from our observation that the alcohol binges of the patient led to glutathione depletion in endothelial cells, thereby increasing the susceptibility to azathioprine toxicity and leading to peliosis hepatis with portal hypertension.

The observed pancytopenia was a consequence of the hypertension rather than a direct myelotoxic effect since TMA activity was normal in our patient. High TMA activity has been associated with hepatotoxicity and refractoriness on therapy^[12], while a diminished activity increases the risk of developing myelotoxicity (e.g. leucopenia or thrombocytopenia)^[13].

Of interest is also the appearance of the liver during sonography. Peliosis hepatis can be a focal, segmental or diffuse dilatation of hepatic sinusoids. According to this, imaging findings are quite variable^[14]. Cirrhotic appearance as in our patient without histological signs of fibrosis or cirrhosis has not been described so far.

The problem of alcohol bingeing has not yet been addressed in IBD patients undertaking immunosuppressive therapy. This should be reviewed in future considerations regarding patients advice.

Abstract

Watery diarrhea, hypokalemia and achlorhydria (WDHA) syndrome caused by vasoactive intestinal polypeptide (VIP) -producing tumor only rarely occurs in patients with nonpancreatic disease. A 49-year-old woman was referred for evaluation of a right adrenal tumor incidentally diagnosed by abdominal ultrasound during the investigation of chronic watery diarrhea. Laboratory findings showed hypokalemia and excessive production of VIP and catecholamines. After surgical resection of the tumor, diarrhea subsided and both electrolytes and affected hormone levels normalized. Immunohistochemical examination confirmed a diagnosis of pheochromocytoma, which contained VIP-positive ganglion-like cells. We herein present the clinical and histogenetic implications of this rare clinical entity, with literature review.

INTRODUCTION

A rare syndrome of watery diarrhea associated with

hypokalemia and achlorhydria (WDHA) was first described by Verner and Morrison in 1958^[1], and has been assumed to be due to hypersecretion of vasoactive intestinal polypeptide (VIP)^[2]. In adults, this syndrome is most commonly associated with pancreatic islet cell tumors, but rarely can be caused by nonpancreatic tumors, such as bronchogenic carcinoma, medullary thyroid carcinoma, retroperitoneal histiocytoma and adrenal pheochromocytoma^[3]. In this report, we describe a woman who presented with chronic watery diarrhea and hypokalemia due to a right adrenal pheochromocytoma, which was immunohistochemically confirmed to contain immunoreactive VIP. After surgical resection of the tumor, symptoms completely disappeared and the preoperatively elevated plasma VIP level normalized.

CASE REPORT

A 49-year-old woman was referred to our hospital for evaluation of a right adrenal tumor. For several years, she had experienced protracted episodes of watery diarrhea, up to 6 times in 24 h, without blood or mucus. In the course of evaluating the diarrhea, an abdominal ultrasound was performed by her primary physician and a right adrenal tumor was incidentally discovered. She had no history of headache, palpitation, perspiration or hypertension. She also had no relevant familial history of endocrine disease. Her height was 150 cm and weight 46.8 kg. Physical examination showed blood pressure of 110/67 mmHg and regular heart rate of 70 beats/min. Laboratory tests showed hypokalemia of 3.1 mEq/L. Fasting blood sugar was 179 mg/dL and a 75-g oral glucose tolerance test (75-g OGTT) showed a pattern indicating diabetes mellitus. Results of complete blood cell count and other routine biochemical tests were within normal ranges. An abdominal computed tomography (CT) scan demonstrated a mass measuring 6 cm in diameter in the right adrenal region, but there was no apparent abnormality in the pancreas (Figure 1A). Magnetic resonance imaging (MRI) of the pituitary fossa was normal.

We then performed an endocrinological evaluation. Examination of plasma hormone levels demonstrated elevated concentrations of VIP, epinephrine, norepinephrine and dopamine (Table 1). In addition, 24-h urinary catecholamines were also highly elevated, confirming the presence of a pheochromocytoma. Plasma cortisol, gastrin, glucagon, adrenocorticotrophic hormone, prolactin, luteinizing hormone, follicle-stimulating hormone, growth

Stained cells were scattered throughout the tumor tissue (× 300).

Table 1 Pre- and post-operative hormone levels

	Pre-operative	Post-operative
Plasma VIP, pg/mL (100)	225	7
Plasma catecholamines, ng/mL		
Epinephrine (0.070)	2.22	0.028
Norepinephrine (0.06-0.46)	1.81	1.53
Dopamine (0.014)	0.609	0.03
24-h urinary catecholamines, ng/d		
Epinephrine (1-29)	4890	4
Norepinephrine (26-230)	920	154
Dopamine (310-1140)	209000	474

Normal range is given in parentheses.

hormone, thyroxine, parathyroid hormone and calcitonin levels were within normal ranges.

Based on these results, the patient was diagnosed as having an adrenal pheochromocytoma with excessive catecholamine production and WDHA syndrome due to the excessive secretion of VIP, probably produced by the pheochromocytoma.

She subsequently underwent surgical resection of the tumor. At laparotomy, the tumor was found above the upper pole of the right kidney and was separated from the pancreas. Right adrenalectomy was accomplished without complications except for a transient elevation of systolic blood pressure up to 190 mmHg during manipulation of the tumor.

The patient had an uneventful postoperative course. The diarrhea soon subsided, and the laboratory data demonstrated normalization of plasma potassium level and improvement in glucose tolerance. The postoperative plasma levels of VIP and catecholamines as well as the 24-h urinary excretion of catecholamines were markedly decreased (Table 1). At follow-up 12 mo after surgery, the patient was well without any signs of recurrence.

The tumor weighed 65 g and measured 6 cm × 7 cm. It

was encased in a brownish capsule and contained a normal adrenal cortex attached to the upper part. The cut surface showed variegated white and red-brown areas, typical of a pheochromocytoma (Figure 1B). Histologically, large polygonal cells with eosinophilic granular cytoplasm were arranged in alveolar and anastomosing trabecular patterns invested by a fine fibrovascular stroma. Tumor cells showed prominent nucleoli and were strongly positive for chromogranin A on immunohistochemistry (Figure 1C). There were no ganglioneuromatous figures. We then looked for the presence of VIP-positive cells. VIP immunoreactivity was found in some of the ganglion-like cells scattered among the predominant neoplastic cell population (Figure 1D). Since pheochromocytes did not show staining for VIP, it was assumed that VIP eventually released from these scattered cells could be responsible for the WDHA syndrome presented by the patient.

DISCUSSION

The WDHA syndrome is, although rare, a well-defined clinicopathologic entity that occurs most often in association with VIP-producing tumor. VIP is a 28-amino acid peptide that stimulates intestinal water and electrolyte secretion by activating adenylate cyclase and cyclic AMP in intestinal cells^[4]. It is physiologically distributed in the digestive tract, the central and peripheral nervous systems, as well as in the adrenals^[5]. VIP also inhibits gastric acid secretion, promotes hepatic glycogenolysis and hyperglycemia, and dilates peripheral systemic blood vessels^[6]. When it is secreted in large amounts from endocrine tumors, the patient typically experiences massive secretory diarrhea, dehydration, flushing and weight loss^[6]. Characteristic laboratory abnormalities include hypokalemia, achlorhydria, hypercalcemia, hyperglycemia and metabolic acidosis^[6,7]. Unfortunately, we did not perform gastric analysis for acid secretion in our patient. However, it is now known that achlorhydria

is not necessarily part of the WDHA syndrome and that hypochlorhydria or even normal acid secretion may occur^[6,8].

To our knowledge, fifteen cases of pheochromocytoma associated with the WDHA syndrome have been reported since the first report in 1975 by Loehy *et al*^[9]. Ten cases were histologically diagnosed as pheochromocytoma^[6,7,9-16], while five cases were diagnosed as mixed pheochromocytoma-ganglioneuroma^[17-21]. In the cases of mixed pheochromocytoma-ganglioneuroma, immunoreactive VIP was confined to the ganglion cells of the ganglioneuroma component, whereas the pheochromocytes did not show staining for VIP. Eeckhout *et al*^[16] documented a pheochromocytoma in which VIP was seen only in scattered cells among pheochromocytes, as in our case. In contrast, other investigators have found VIP-positivity in the pheochromocytes themselves^[7,13,15].

The differences in these immunohistochemical findings have been partly explained by the neuronal differentiation of neoplastic cells. Both chromaffin cells and ganglion cells are derived from the neural crest and have in common a number of histochemical and biosynthetic characteristics, including amine precursor uptake and decarboxylation (APUD)^[22]. Sano *et al*^[23] suggested that tumor cells of hormone-producing neurogenic tumors can be divided into at least two cell populations: adrenergic neuron-related cells containing catecholamine and somatostatin, and cholinergic neuron-related cells containing VIP. Matsuoka *et al*^[24] demonstrated in an experimental study that some factors in glioma-conditioned medium induced the cholinergic neuronal differentiation of rat pheochromocytes. Mendelsohn *et al*^[25] immunohistochemically identified isolated VIP-containing cells that showed distinct ganglion cell differentiation in two of four pheochromocytomas without associated diarrhea. However, since pheochromocytes lacking ganglionic differentiation features may stain for VIP, it has been postulated that neoplastic transformation might elicit VIP synthesis by the tumor cells^[13]. This could be consistent with the knowledge that neoplastic growth of APUD cells may produce several polypeptides or amines, which are characteristic not only of their specific differentiated cell types but also of associated APUD cells derived from the common neuroectoderm^[6,26].

An interesting feature of this case was the absence of any hypertensive symptoms characteristic of pheochromocytoma. Most patients with pheochromocytoma complicated by WDHA syndrome remain normotensive despite high catecholamine levels. A certain proportion of patients with pheochromocytoma are indeed clinically "silent"^[27], but, in our case, it is conceivable that VIP might have masked the symptoms of catecholamine overproduction by either its vasodilator effect or subsequent induction of secretory diarrhea and dehydration.

This case is an unusual presentation of pheochromocytoma in which diarrhea was the principal clinical sign. We suggest that, in a patient with chronic diarrhea of unknown etiology, it is important to perform not only gastrointestinal investigations but also abdominal ultrasound and/or CT scan to determine if a mass is present. When an adrenal mass is discovered,

determination of catecholamines, as well as VIP is essential for a precise diagnosis even if the clinical symptoms are not characteristic of pheochromocytoma.

ACKNOWLEDGMENTS

We acknowledge the contributions of Dr. Kurimoto to the diagnosis and management of this patient.

Abstract

A 3-year-old boy developed transient protein-losing gastroenteropathy associated with cytomegalovirus (CMV) infection. Both IgG and IgM antibodies to CMV were positive in a serologic blood test. Upper gastrointestinal endoscopy showed multiple erosions throughout the body of the stomach, without enlarged gastric folds. Histological examination of the biopsy specimens indicated eosinophilic gastroenteritis and CMV infection. The patient had complete resolution without specific therapy for CMV in four weeks. An allergic reaction as well as CMV infection played important roles in the pathogenesis of this case.

INTRODUCTION

Eosinophilic gastroenteritis (EG) is a chronic inflammatory disorder of the gastrointestinal (GI) tract characterized by the infiltration of eosinophils. Klein *et al*^[1] proposed classification of EG based on the depth of eosinophilic infiltration; mucosal, muscular and serosal. The mucosal disease tends to present with protein-losing gastroenteropathy (PLG). As for pathogenesis, an allergic mechanism has been implicated in many cases^[2,3]. A viral etiology has also been suggested in several cases^[4]. In this

report, we present a case of PLG caused by allergy- and cytomegalovirus (CMV)-related EG in a 3-year-old boy.

CASE REPORT

A 3-year-old boy was referred to our hospital for evaluation of hypoproteinemia and edema. He had experienced allergic reactions to milk, soybeans, shrimp and pork. His initial symptoms of diarrhea and edematous swelling of the eyelids developed during one week before admission. Physical examination revealed periorbital and pretibial edema. His abdomen was slight distended. The liver and spleen were not palpable. Abdominal ultrasound detected a small amount of ascites and mild swelling of the mesenteric lymph nodes. On laboratory examination, the white blood cell count was 11 300/mm³, with 24% eosinophils. Total serum protein concentration was 3.2 g/dL, with an albumin concentration of 1.8 g/dL. Serum IgE level was within normal limits (24 IU/mL). RAST for specific IgE antibodies and skin prick test failed to reveal reactions to common food antigens. The results of a serological test for CMV were positive for IgM and IgG. Stool samples showed normal flora on culture and the absence of blood, *H pylori* antigen, ova and parasites. Enteric protein loss was confirmed by a fecal α_1 -antitrypsin clearance of 68.8 mg/d (normal, < 20 mg/d). We excluded urinary protein loss as a cause of the hypoalbuminemia. Upper GI endoscopy showed multiple erosions with abundant whitish mucus throughout the gastric body. Enlarged gastric folds were not observed. The esophagus exhibited no remarkable change and the duodenum appeared mildly reddened. A sigmoidoscopy showed mucosa with a normal vascular pattern and a mild lympho-nodular appearance. Histological examination of the gastric mucosa revealed neutrophilic and eosinophilic infiltrates with focal clustering of eosinophils in the lamina propria and regenerative epithelial changes. We also observed a small number of cells with intranuclear and intracytoplasmic inclusions that were immunohistochemically positive for CMV. *H pylori* was not detected. Duodenal and colonic biopsies showed increased numbers of eosinophils in the lamina propria. Histological diagnosis was compatible with EG.

The patient was treated with transfusions of albumin, oral famotidine, oxatamide and cromoglicic acid, but not corticosteroid or a specific therapy for CMV. There was a gradual recovery from edema with a concomitant increase in the serum protein level to 6.8 g/dL and a normalization of the eosinophil count over the next four

weeks. The endoscopic abnormalities also subsided after four weeks of hospitalization. Histological assessment of the mucosal biopsy specimens demonstrated clearing of the eosinophilic infiltration. He had no recurrences in the subsequent 36 mo.

DISCUSSION

CMV infection in the GI tract is unusual in an immunocompetent person. Primary infection with CMV is generally asymptomatic and usually remains latent for life. If host immune defenses are impaired, latent CMV may be activated and produce symptoms of overt disease. GI tract infection with CMV usually occurs in immunocompromised patients by activation of the latently infectious virus. On the other hand, there are several reports of CMV infection in normal healthy persons and the important role of CMV in the acute gastrointestinal disease has been emphasized^[5]. In our case, evidence of gastric CMV involvement was shown by histological findings of characteristic inclusion bodies and by the immunohistochemical detection of viral antigens. It was likely that mucosal disruption due to allergic mechanism facilitated the CMV infection, which then led to further injury. As well, CMV infections in the GI tract might be locally cytopathogenic, possibly allowing mucosal penetration of allergens that then stimulated the allergic reaction.

Allergy has been suggested as the cause of transient PLG in children^[6]. However, the target allergens in our patient were unclear; serum RAST and skin prick tests against common food allergens were all negative. Lin *et al*^[7] suggested that a localized IgE-mediated response could cause the gastrointestinal symptoms seen in skin-prick test-negative and serum IgE antibody-negative patients with suspected food allergy.

EG may present with a wide variety of clinical and endoscopic findings. However, the multiple erosions throughout the body of the stomach seen in our patient are unusual for EG; commonly endoscopic findings of EG are edema, erythema and erosions in the antrum of the stomach. Only one case of EG with similar endoscopic features has been reported^[8]. Additionally, the clinical course of our case was unusually benign and short for

EG; patients with EG usually have a prolonged course of relapse and remission and for control may require therapy with steroids.

Menetrier's disease is another common cause of PLG. Allergic phenomena and CMV infection have been implicated in pediatric cases^[6,9], and the course of the disease in children, unlike that in adults, is usually benign and short^[9]. EG and Menetrier's disease exhibit several common features in childhood, leading to the assumption that they may represent a continuum of gastroenteropathy associated with allergic mechanism.

Although our patient remains well, he requires long-term follow-up since the natural history of this condition remains unclear. Kristopaitis *et al*^[10] reported a case of EG in a 24-year-old female, who had experienced infantile EG, that recurred after a long period of dormancy.

Abstract

Liver pseudocysts are a very rare complication in acute pancreatitis with only a few cases previously described. The lack of experience and literature on this condition leads to difficulties in the differential diagnosis and management. We report herein a case of acute pancreatitis who developed multiple intrahepatic pseudocysts. After complete imaging evaluation, the diagnosis was still unclear and the patient was operated on. The presence of liver lesions in patients with acute pancreatitis should raise the possibility of intrahepatic pseudocysts.

<http://www.wjgnet.com/1007-9327/13/4655.asp>

INTRODUCTION

Pancreatic pseudocysts are a common complication of acute pancreatitis, defined as a collection of pancreatic juice enclosed by a wall of nonepithelialized granulation tissue or fibrotic capsule^[1,2]. Most pseudocysts are located around the pancreatic gland, but they have also been described at a great distance from the pancreas; and the mediastinum to the scrotum, when the fluid dissects through tissue planes^[3,4].

A very rare location for a pseudocyst during acute pancreatitis is in the liver with only about 30 cases previously described^[5]. The lack of experience with pseudocysts located in the liver makes it difficult to establish a clear diagnosis and choose the appropriate management.

We report here a case of a patient who developed several intrahepatic lesions after an episode of acute pancreatitis. Despite a complete imaging study, the definitive diagnosis was still unclear and the patient was therefore operated on. Diagnosis and pathophysiological mechanisms were discussed herein.

CASE REPORT

A 68-year-old male with no history of hepato-biliary or pancreatic diseases or alcoholic ingestion was admitted to our hospital with abdominal pain and nausea. Physical exploration revealed moderate upper abdominal pain without tenderness or rebound and normal bowel sounds, as well as a slight conjunctival jaundice. Laboratory parameters showed 12300 white blood cells/mm³ (80% neutrophils), normal hemoglobin, 3291 IU/L serum amylase (normal value < 115 IU/L), 4003 IU/L serum lipase (normal value < 190 IU/L), 461 U/L AST (normal value < 37), 389 U/L ALT (normal value < 41) and 238 mU/mL alkaline phosphatase (normal value < 300). Abdominal ultrasound demonstrated cholelithiasis without inflammatory signs in the gallbladder wall or common bile duct dilation. The APACHE II score at admittance was 5. The patient recovered uneventfully after a few days of hospitalization, but a computed tomography (CT) scan revealed a scarcely enlarged, almost normal pancreas and an ill-defined hypodense lesion (4.5 cm × 3.5 cm) located in the left hepatic lobe of unclear etiology (Figure 1). Accordingly, liver and cholangiopancreatography magnetic resonances were carried out confirming the lesion in segment II and describing a new lesion (3 cm in diameter) located in segment III (Figure 2), and showing a normal common bile duct. The masses found were of unclear nature with a mixture of liquid and solid content. Eventually, a US-guided fine needle aspiration (FNA) cytology was performed, yielding an unspecified leukocyte infiltration without malignant cells.

Since the patient had mild acute biliary pancreatitis and cholecystectomy was indicated, we decided to proceed with the operation, despite the lack of a definitive diagnosis based on the liver lesions.

Upon operation, three soft cystic tumors were located in the left lobe of the liver with a very dense and necrotic content on exploration with intraoperative

Figure 1 CT scan showing a hypodense lesion located in the left hepatic lobe of unclear etiology.

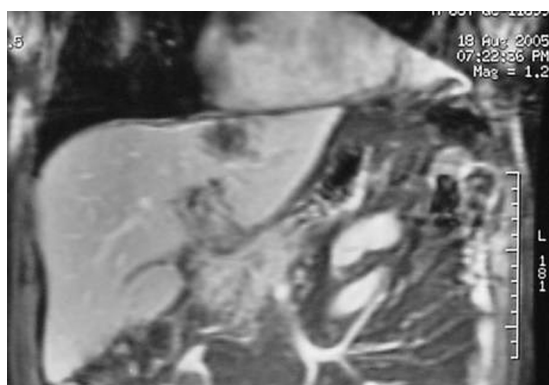

Figure 2 Magnetic resonance of the liver and bile duct showing a lesion in segments II and III and a normal common bile duct.

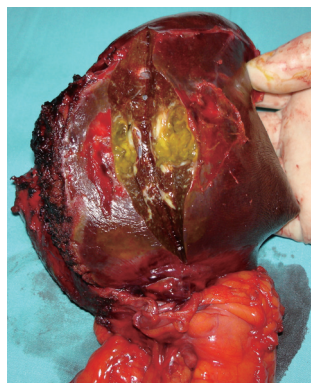

Figure 3 Left lobectomy demonstrating a lesion in segment III.

ultrasonography. There were no other lesions in the right lobe or anywhere else in the abdominal cavity. Cholecystectomy with intraoperative cholangiography was performed with the liver lesions excised by a left lobectomy (Figures 3 and 4). The pseudocysts were full of debris with a very small amount of juice. Microbiologic cultures of the content in the cysts were negative. Pathological examination confirmed the pseudocystic nature of the three subcapsular lesions by proving nonepithelialized tissue of the wall (Figure 5). There were no postoperative complications and the patient was discharged 6 d after surgery. Eight months later, the patient was completely recovered and disease free.

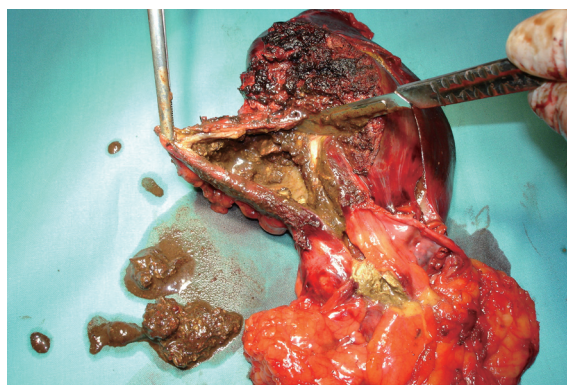

Figure 4 Cystic lesion in segment II showing the continuity with the lesser omentum and necrotic material from the pseudocyst.

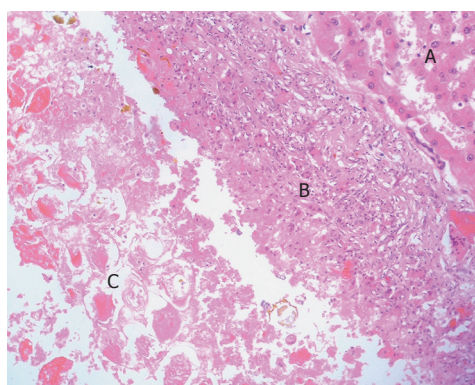

Figure 5 Microscopically the liver pseudocystic lesion is surrounded by a wall formed by macrophages and inflammatory cells (HE, x 20). A: Normal liver tissue; B: Pseudocystic wall; C: Intracystic necrotic debris.

DISCUSSION

The interest in this case presented here relies on the very rare location of the pseudocysts, the atypical evolution for the formation of a pseudocyst and the difficulties to achieve a definitive diagnosis.

So far there are only about 30 cases describing pseudocysts located in the liver, most of them are single involving the left lobe^[5]. Our case indeed involved the left lobe, but the fact that there were three pseudocysts clearly separated in the surgical specimen increases the rarity of the case^[6].

Two pathophysiological mechanisms have been proposed trying to explain the liver location of pseudocysts^[7-10]. The first suggests a release of pancreatic juice towards the lesser sac and from there towards the left lobe of the liver along the lesser omentum or gastrohepatic ligament. Nearby the liver and due to the proteolytic effect of pancreatic juice, it may dissect the liver capsule leading to formation of subcapsular collections. When another peripancreatic fluid collection or a pancreatic pseudocyst is not associated, a direct disruption or erosion on the hepatic capsule may occur. The second mechanism proposes the propagation of pancreatic juice from the head of pancreas to the porta hepatis along the hepatoduodenal ligament resulting in formation of intraparenchymal collections. The anatomic location of the case presented here seems to be better

explained by the first mechanism.

An important point of our case is the unusual evolution of liver pseudocysts. The ultrasonography performed upon admission did not detect any lesions in the liver, but the CT scan performed 6 d later vaguely identified a mass-cystic forming image. Usually a pancreatic pseudocyst requires a minimum of time, between 4 and 6 wk, to form the well-defined wall, a main characteristic of it. However, the time span between admission and identification of our patient's liver lesions was extremely short. It can be argued that the patient suffered from a previous pancreatitis and that the present episode might in fact be a relapsing pancreatitis, but this possibility should be rejected after thoroughly questioning both the patient and his family. Hence perhaps pseudocysts in the liver might not take as long to develop as in the abdominal cavity or near the pancreas. Unfortunately, this suggestion cannot be clarified from the scarce literature on liver pseudocysts.

The third point is the difficult diagnosis even with a complete radiological study and FNA. During the evaluation of this case, we were always concerned about an incidental neoplasia, although unseen in the first ultrasonography exploration, we never thought of a liver pseudocyst secondary to the inflammatory pancreatic process. In fact, the patient was sent to the operating room without a clear diagnosis of hepatic lesions, which was eventually established by the pathologist. The atypical radiological appearance of the pseudocysts full of debris may have contributed to the difficult diagnosis.

In conclusion, the presence of liver lesions in patients with acute pancreatitis should raise the possibility of intrahepatic pseudocysts, even when they are not associated with intraabdominal collections or pancreatic

pseudocysts. The atypical radiological imaging or short clinical evolution cannot rule out this complication.

Abstract

Lynch syndrome, or hereditary nonpolyposis colorectal cancer (HNPCC), is the most common genetic disorder predisposing to colorectal cancer. As regular colonoscopic surveillance has been shown to reduce the incidence of colorectal cancer, this strategy is recommended worldwide. Recently, several advances in colonoscopic techniques have improved detection rates of neoplasia in Lynch syndrome. In this nationwide survey, we evaluated current surveillance colonoscopy practices for Lynch syndrome in the Netherlands and the extent to which advanced techniques have been adopted in routine clinical practice.

TO THE EDITOR

Lynch syndrome, or hereditary nonpolyposis colorectal cancer (HNPCC), is caused by germline mutations in mismatch repair (MMR) genes. HNPCC is the most common hereditary disorder predisposing to colorectal cancer (CRC), accounting for up to 5% of cases. Carriers of MMR gene mutations are recommended to undergo surveillance colonoscopy once every 1-2 years starting

at the age of 20-25, a strategy which has been shown to reduce CRC mortality^[1,2]. Despite this approach, which is internationally recommended^[3-5], interval cancers can be encountered^[6]. Therefore, the identification of high-risk precursor lesions in Lynch syndrome is considered critically important. It is well known that conventional colonoscopy has a confirmed miss rate for colorectal neoplasms of up to 20%, especially small adenomas^[7]. This is of particular importance in Lynch syndrome patients since even in adenomas as small as 5-7 mm, high-grade dysplasia can be encountered^[8]. Recently, chromoendoscopy using indigo carmine was reported to increase the diagnostic yield in HNPCC patients^[9,10]. Also, several improvements involving endoscopic such as magnifying endoscopy (ME) and narrow-band imaging (NBI) techniques have recently been introduced^[11]. The role of these techniques in the clinical arena, especially in the management of Lynch syndrome patients, is still unclear. In this study, we evaluated adherence to the current guidelines for HNPCC surveillance in the Netherlands. We also surveyed the current use of new diagnostic colonoscopic techniques.

All Lynch syndrome families registered at the Netherlands Foundation for the Detection of Hereditary Tumors were reviewed. The physicians that had undertaken responsibility for these families were sent a questionnaire in which they were asked to provide data on the frequency of colonoscopic surveillance and the age at which surveillance was initiated. The current use of advanced endoscopic techniques such as chromoendoscopy, ME and NBI were also evaluated along with the physicians' expectations regarding the use of these techniques in the near future. Reimbursements for regular colonoscopic surveillance in Lynch syndrome subjects are generally authorized in the Netherlands.

Of the 446 questionnaires sent out, 228 were returned (51%). 221 out of 228 physicians (97%) adhered to the recommendation of performing surveillance colonoscopy every 1-2 years, with most physicians preferring a 2-year interval. Most physicians indicated they initiated surveillance when subjects at risk were between 25-30 years of age. The majority of physicians (196, 86%) used only conventional videocolonoscopes in their current surveillance management. The remainder of the consulted physicians regularly used advanced colonoscopic techniques, most often magnifying or high-resolution endoscopy (6%), followed by chromoendoscopy (5%) and narrow-band imaging (3%). Interestingly, 50% of the physicians expected to alter their endoscopic surveillance practices in the near future. In most cases, physicians

intended to use chromoendoscopy with indigo carmine as their standard endoscopic technique with this patient group.

In summary, there is excellent adherence to published guidelines on colonoscopic surveillance management in Lynch syndrome patients in the Netherlands. Most physicians presently use a conventional colonoscope for their regular surveillance colonoscopies. The recent introduction of new endoscopic techniques, especially chromoendoscopy, will probably be incorporated into surveillance management of this patient group in the near future. Whether Lynch syndrome patients really benefit from the introduction of these techniques, by a reduction in incidence of colorectal neoplasia, remains to be determined.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (WJG, *World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, etc., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/index.jsp>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (<http://www.wjgnet.com/wjg/help/instructions.jsp>) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5

line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, etc. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: <http://www.wjgnet.com/wjg/help/11.doc>

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P*<0.05, ^b*P*<0.01 should be noted (*P*>0.05 should not be noted). If there are other series of *P* values, ^c*P*<0.05 and ^d*P*<0.01 are used. Third series of *P* values can be expressed as ^e*P*<0.05 and ^f*P*<0.01. Other notes in tables or under

illustrations should be expressed as 1F , 2F , 3F ; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, etc. in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed>). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (<http://www.wjgnet.com/cgi-bin/index.pl>)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as γ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p*(B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 $24.5 \mu\text{g/L}$; CO₂ volume fraction, 50 mL/L CO₂ not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The author about how to accurately write common units and quantum is at: <http://www.wjgnet.com/wjg/help/15.doc>

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kpn I*, etc.

Biology: *H pylori*, *E coli*, etc.

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision.

(1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please download CAF from <http://www.wjgnet.com/wjg/help/9.doc>.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to *WJG* all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The *WJG* requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1) direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3) supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The *WJG* does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to *WJG* if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: <http://www.wjgnet.com/wjg/help/13.doc>

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: <http://www.wjgnet.com/wjg/help/10.doc>

How labile is gastric infection with *H pylori*?

M Hobsley, FI Tovey, J Holton

M Hobsley, FI Tovey, J Holton, Departments of Surgery and Medical Microbiology, Royal Free and University College Medical School, United Kingdom

Abstract

It is known that patients infected with *H pylori* can spontaneously become free from infection, and that the reverse change can occur. The time-scale of these conversions is expressed as percentages per year. Since they have been investigated in terms of serology, the changes are called sero-reversion and sero-conversion respectively. Using serological evidence to investigate these phenomena is open to the criticisms that positive serology can be present in the absence of all other evidence of infection, and that a time-lag of 6-12 mo or longer can occur between eradication of the infection and sero-reversion. Investigations using direct evidence of current infection are sparse. The few that exist suggest that some individuals can seroconvert or sero-revert within six to twelve weeks. If these findings are confirmed, it means that some patients have an ability that is variable in time to resist, or spontaneously recover from, *H pylori* infection. Evidence suggests that the deciding factor of susceptibility is the level of gastric secretion of acid.

Key words: *H pylori*; Lability of infection; Serology; Conversion; Reversion

Hobsley M, Tovey FI, Holton J. How labile is gastric infection with *H pylori*? *World J Gastroenterol* 2007; 13(35): 4665-4668

<http://www.wjgnet.com/1007-9327/13/4665.asp>

EVIDENCE OF LABILITY OF *H PYLORI* INFECTION

Evidence from indirect tests: Spontaneous seroconversion and seroreversion

In papers concerned with human infections of the

gastroduodenum with *H pylori*, it is usually tacitly assumed that infection is stable, i.e., that a subject infected at any one moment will remain infected until the organism is eradicated with pharmacological agents. There is considerable evidence based on serological studies that *H pylori* infection can be more labile, with subjects undergoing spontaneous sero-reversion as well as sero-conversion. Reports from countries where the prevalence of *H pylori* infection is moderate (40%-60%) show that spontaneous cures may occur even more frequently than fresh infections, and more often in children and teenagers than in adults^[1-14]. The question is, do these figures adequately reflect the rates of the changes?

In children, of a total of 1134 children who were *H pylori* negative, 92 had converted to *H pylori*-positive in periods ranging from 9 to 14 years^[2-6]. The percentage conversion rates differed from 40 percent after 10 and 14 years to 5% or less after 2, 10 and 14 years. The same publications documented that of a total of 141 *H pylori*-positive patients 58 reverted to *H pylori* negative over the same periods. The sero-reversion rates in the five studies varied between 15% at 14 years and 80% at 10 years.

In these reports of children, there is no evidence that the length of follow-up is related to sero-conversion or sero-reversion rates. The lack of evidence of a link between the rates and the length of follow-up may be due to the (necessarily) small range of follow-up in an age group defined as children and teenagers. The salient feature of these results is that the sero-conversion rate overall was 92/1134 (8.1%), while the sero-reversion rate was 58/141 (41%). A small tendency for children to develop the infection as time passed was considerably outweighed by a five-fold tendency towards natural cure.

In adults, there is strong evidence that both sero-conversion and sero-reversion rates increase with the duration of follow-up. Eight publications^[7-14] yielded the following statistical results. Over a time-interval of 3-32 years, 94 (2.7%) of 3489 subjects sero-converted; regression analysis indicated that the number converting increased by 0.311 per cent per annum ($r^2 = 0.836$, $P = 0.0015$). The corresponding figures for sero-reversion were 109 (6.04%) of 1806 subjects; the regression values were an increased rate of reversion of 0.676 per cent per annum ($r^2 = 0.747$, $P = 0.0056$). In adults, therefore, conversion rates per annum were outweighed by a doubled rate of sero-reversion.

Comparisons between the two rates in adults and the two in children are strictly impossible because of the lack of correlation in children with length of follow-up. However, if one is prepared to accept that the yearly rates in children (in whom the average length of follow-up was

about 11 years) were, for sero-conversion $8.1/11 = 0.74\%$, for sero-reversion $41/11 = 3.73\%$, it is clear that infection status derived from antibody information in children is more labile in both directions than it is in adults.

The evidence from countries with a high prevalence of infection with *H pylori* is scanty. There are only three papers^[15-17] from Japan where, on the published evidence, the prevalence is variable (36%-87%), and only one^[15] of these papers gives data for children; and two from Brazil where the prevalence is very high (80%) - one for children^[18] and one for adults^[19]. Regression analysis to determine whether length of follow-up is related to the conversion rates is inappropriate. However, it is clear that in Japan sero-conversion rates are only slightly lower than sero-reversion rates, 5/86 (5.8%) versus 2/22 (8.1%) in children and 66/1038 (6.4%) versus 149/2103 (7.1%) in adults, whereas in Brazil the rates of sero-conversion are high 5/78 (6.41%) in less than 2 years in children, 5/46 (10.87%) in 3 years in adults, while in children there was a zero reversion rate and in adults only 1 of 173 *H pylori*-positive subjects reverted.

There seems little doubt that the sero-conversion rate rises with the overall prevalence of the infection in the population, that where the prevalence is moderate the tendency to spontaneous cure overtakes the rate of new infections, but where the prevalence is high there is practically no spontaneous cure. These conclusions depend on the assumptions that sero-positivity means the presence of infection, sero-negativity means its absence.

The time periods of the quoted studies range from 20 mo to 32 years. It is tacitly assumed by the authors that sero-reversion and sero-conversion rates represent the averages of a slow, single rate in each direction. However, it is also conceivable that during these times changes in infection status might have occurred several times in both directions.

These reports seem to assume that serological evidence of the presence or absence of antibodies to *H pylori* indicates the presence or absence of the infection. The fact is that the presence of antibodies indicates exposure to the infecting organism in the past, but does not indicate current infection. Indeed, there are reports of positive serology in the absence of other positive tests for infection^[20-23]. Moreover there is a known time lag of 6-12 mo^[24-27] or even longer between eradication of infection and reversion of serology to normal^[20-23].

Evidence from direct tests: Histology and urea breath test

Only a few reports base their opinions on direct methods such as the urea breath test (UBT) or histology. There are two reports of children showing changes either way within 3 mo^[28,29] and one reporting such changes within 6 mo in both children and adults^[30] using the urea breath test. There are two reports based on histology in adult patients, one showing 5/39 patients becoming *H pylori* negative over a ten year period^[31], and another reporting 9% of patients becoming positive and 9% becoming negative over a 6 years period^[32]. However, there is some direct evidence that infection can be even more labile than the above evidence suggests, There is one significant report

in a Master of Surgery Thesis^[33] involving adults. Some aspects of this study have been reported^[34]. Two hundred and eight patients undergoing endoscopy for dyspepsia were categorized as *H pylori*-positive or -negative, using the biopsy-rapid urease, culture and polymerase chain reaction tests. The patients received no anti-*H pylori* treatment. The first hundred of these patients to volunteer (14 duodenal ulcer, 5 gastric ulcer, 16 oesophagitis, 46 non-ulcer dyspepsia (NUD) and 19 Others) were examined between 6 and 12 wk later and re-categorized as positive or negative, using a non-invasive ¹³C-urea breath test. Of 42 patients positive for *H pylori* at endoscopy, 8 (19%) had become negative at the later breath test; and of 58 patients negative at endoscopy, 15 (26%) had become positive at the later breath test. The results suggest that *H pylori*-status in the adult can alter in both directions within a few weeks. The PCR test was done at the time of the endoscopy but, at the time of the follow-up, because it was not clinically justifiable to repeat endoscopy, the UBT was used.

It may be criticised that the results from two different tests may not be comparable. There is considerable evidence, however, that PCR and UBT vie with each other as the gold standard for *H pylori*-status, and therefore are highly unlikely to give divergent results^[24-26,35-40]. Indeed, it has been shown that PCR results can be used to determine the optimal cut-off point for the breath test results^[41], and that both tests can be used to determine not only the presence of, but also the weight of infection with, the organism^[42]. The evidence from the later breath tests can, therefore, be relied on as at least as satisfactory as that from the PCR tests at the time of endoscopy. It follows that in this study during a period of 6 to 12 wk there was a 20%-25% change of *H pylori*-status in both directions.

The possible effect of gastric pH on *H pylori* infection

One possible explanation is that the ability of *H pylori* to colonize the stomach (and gastric-type epithelium in the duodenum) is dependent on the local luminal pH. Extremes of pH in either direction kill the organism^[43,44]. The patients with peptic ulcer (whether gastric or duodenal), with reflux oesophagitis, and some of those with other lesions would have received acid-suppression agents during the period between the two examinations, and this fact might explain why patients negative at endoscopy later became positive. There is evidence that acid-suppression promotes gastritis associated with *H pylori* infection^[45]. For movements in status in the opposite direction, in patients given a clean bill of health (NUD) or those in the group with diagnoses that did not seem related to gastric hyperacidity, the later withdrawal of acid-suppressing agents given prior to the endoscopy that excluded an ulcer might be the cause of the reversion from positive to negative. It is interesting to recall that, when Marshall^[46] in 1985 swallowed a culture of *H pylori*, he took 600 mg of cimetidine 3 h before to reduce the acidity. Thereafter, stomach acidity would have returned to normal and, whilst stomach biopsies taken one week later were positive for *H pylori*, those taken at two weeks had become negative.

CONCLUSION

The above findings show that the *H pylori*-status of adults can alter in both directions in a matter of a few weeks and that the infection is much more labile than previously realised. The known time lag of 6-12 mo^[22-25] between eradication of infection and reversion of serology to normal compared with 6 wk for UBT^[22], and the unknown time lag between the inception of infection and seroconversion, are features that cast some doubt on whether serology could have demonstrated this lability.

Abstract

The highly increasing prevalence of obesity and type 2 diabetes mellitus in the general population makes nonalcoholic fatty liver disease the most common diagnosis in every-day practices. Lifestyle changes (mainly exercise withdrawal and weight gain) have probably heightened the prevalence of nonalcoholic fatty liver disease. Mortality in patients with Nonalcoholic Fatty Liver Disease is significantly higher when compared with that of the same age-gender general population. Hepatologists claim to bear a new burden, being Nonalcoholic Fatty Liver Disease strongly linked to systemic diseases.

SCENARIO

Nonalcoholic fatty liver disease (NAFLD) has recently emerged as the most common cause of abnormal laboratory liver tests (LLTs) seen in patients presented to practicing hepatologists, with the overall prevalence of NAFLD in the developed world estimated to be between 20% and 30%. Changes in lifestyle have resulted in a dramatic increase in the prevalence of NAFLD. Apoptosis and insulin resistance (IR) play an important

role in the disease development and progression. Our current knowledge of the natural history of NAFLD can be summarized as follows: elevated body mass index (BMI) plays a key role; simple steatosis NAFL (Fatty liver, FL) does not generally progress to Non-Alcoholic SteatoHepatitis (NASH); patients with NASH progress, in relatively many cases, to cirrhosis; older age and advanced fibrosis are risk factors for hepatocellular carcinoma (HCC) in NASH; up to a third of patients develop liver-related morbidity or mortality. It is extremely important that physicians diagnose NASH accurately and perform appropriate treatments, because it represents an illness mirroring a systemic process, and an adjunctive cardiovascular disease (CVD) risk^[1]. A great deal of research highlight the need for surrogate serum markers for diagnosing NASH. Among them, serum cytokeratin 18 has captured certain interest^[2].

COULD NAFLD BE CONSIDERED A FURTHER EXPRESSION OF METABOLIC SYNDROME?

NAFLD and NASH are conditions gaining increasing recognition, obesity being (mainly of high grade) one of the more important risk factors. But, do other aspects of metabolic syndrome (MS) play a role? To answer this question, a prospective study was conducted in 127 consecutive obese patients (62% female, mean age 40 ± 11 years, mean BMI 42 ± 6 kg/m²) undergoing gastric bypass over a 20-month period. The report highlighted that arterial hypertension was present in 52 patients (41%) and type 2 diabetes mellitus (DM) in 18 (14%). However, NAFLD was confirmed in 80 patients (63%). Of them, 47 (37%) had FL, and 33 (26%) had NASH. Cirrhosis was found in 2 patients corresponding to 1.6% of the total population. For multivariate analysis, elevated HOMA independently predicted only NASH, (OR 4.18, 95% Confidence Interval, CI, 1.39-12.49). That NAFLD was frequently found, it is easy to deduce that the NAFLD presence coupled with obesity (visceral) and hypertension could be used as criteria to label the patients with MS^[3].

ARE PATIENTS' AGE OR LONGEVITY OF ILLNESS A CRITERION TO INFER NASH PRESENCE?

To characterize the spectrum of NAFLD in morbidly

obese adolescents, a cross-sectional study correlated in 41 adolescent subjects' (mean age, 16 years, 61% female, 83% non-Hispanic white, mean BMI 59 kg/m², undergoing bariatric surgery) liver histology with clinical features and compared data with those of the adults. The Authors wondered if NAFLD would be less severe as a result of younger age and shorter duration of obesity and which grade of portal inflammation and fibrosis would be present. Eighty-three percent had NAFLD: 24% FL, 7% isolated fibrosis with steatosis, 32% non-specific inflammation and steatosis, and 20% NASH. Twenty-nine percent had fibrosis; none had cirrhosis. Abnormal ALT was more prevalent in NASH. Mean fasting glucose was higher in NASH, but the percentage of MS was not different. The researchers concluded that NAFLD was very prevalent in morbidly obese adolescents, but severe NASH was uncommon. In contrast to morbidly obese adults, lobular inflammation, significant ballooning, and perisinusoidal fibrosis were rare, whereas portal inflammation and portal fibrosis were more prevalent, even in those who did not meet criteria for NASH. Presence of MS in morbidly obese adolescents did not distinguish NASH from FL. Conclusively; the answer is... yes it is^[4].

Could being overweight (not necessarily obese) be considered a risk factor for the NAFLD progression?

The realization that a proportion of patients with NAFLD can progress through NASH and fibrosis to full-blown cirrhosis and HCC has recently focused the attention of the liver-disease scientific community on this condition, previously considered to be benign. Although several studies have been performed on risk factors (presented in a single or combined way) and natural course of NASH, it seems that NASH is inclined to be more than a disease confined to classic boundaries. The objective of a recent study was to assess the clinical features and risk factors for NASH patients in an Iranian population. Fifty three patients (21 female, mean age 37.8 ± 11.3 years) with histologically confirmed NASH entered the study. Twenty-six patients (55.3%) were overweight, 15 (31.9%) obese, 40 (75.5%) dyslipidemic, and three patients (5.7%) were diabetic. Liver histology showed mild steatosis in 35.7%, moderate steatosis in 53.6%, and severe forms in 10.7%. In 80.2% of patients, portal inflammation was present, and 9.4% had cirrhosis. The amount of increase in LLTs bore no relationship with fibrosis, portal inflammation, and degree of steatosis. The interesting point of this research dwells with the overweight, not the obese, as having a risk factor for NASH. Obviously, a careful history was taken regarding alcohol intake^[5].

And what is the role of visceral fat?

NAFLD is increasing rapidly in the population of the Asia-Pacific region, representing a good model of study. The aim of an up-to-date research was to define the anthropometric, metabolic and histological characteristics of patients with NAFLD in these countries. Seventy-five patients with persistently raised LLTs and/or FL detected on ultrasonography (US) with exclusion of other liver disorders were prospectively enrolled (39 men, mean

age 47.0 ± 12.2 years). Fifty eight patients (77.3%) had visceral obesity, 29 (38.7%) were diabetic and 15 (20.0%) had impaired glucose tolerance (IGT). Insulin resistance was diagnosed in 62 out of 64 (96.9%) patients. FL, NASH and cirrhosis were diagnosed in three (4.3%), 59 (84.3%) and eight (11.4%) of 70 patients, respectively. The complete histological spectrum of NAFLD was seen in these patients. The majority of them were characterized by IR, central obesity and had either type 2 DM or IGT^[6].

Is isolated portal fibrosis the link between FL and NASH?

NASH is a progressive form of NAFLD that can lead to hepatic fibrosis and cirrhosis. Until now, portal fibrosis in the absence of NASH, called isolated portal fibrosis (IPF), has received less attention and has not been classified as a spectrum of NAFLD, but, when found in patients with HCV-related chronic hepatitis it is considered to be a key feature of viral infection. Liver biopsies from 195 morbidly obese subjects who underwent bariatric surgery after excluding all other causes of liver disease were analyzed. The prevalence of fatty liver (FL) only, IPF, and NASH was 30.3%, 33.3%, and 36.4%, respectively. Again, hyperglycemia was the only metabolic parameter associated with NASH (OR, 5.4; 95% CI, 2.4-12) and IPF (OR, 2.8; 95% CI, 1.2-6.5). MS was identified in 78.5% of subjects, and a significant trend for the clustering of MS criteria was observed across the spectrum of FL, IPF, and NASH^[7].

Is the exact prevalence of NASH in the severely obese known?

NAFLD has been consistently associated with every grade of obesity and IR. As previously stated, NASH is a histological entity within NAFLD that can progress to cirrhosis. The prevalence of NASH in morbidly obese patients is a crucial point of study, because they represent a well-defined population. It is unclear whether differences in insulin sensitivity exist among subjects with NASH and FL. To evaluate the prevalence and correlates of NASH and consequently liver fibrosis in this distinctive cohort of ninety-seven subjects, a recent study was employed. Thirty-six percent of subjects had NASH and 25% had fibrosis. No cirrhosis was diagnosed on histology. Markers of IR and MS, but not BMI were associated with the presence of NASH. Forty-six percent of patients suffering from NASH had normal transaminases. Subjects with NASH had more severe IR when compared to those with FL. In conclusion, NAFLD is associated with MS rather than excess adipose tissue in the severely obese^[8].

Are laboratory liver tests worth using to screen NAFLD?

A fascinating study was conducted to determine whether the current liver screening program for NAFLD has sufficient evidence to justify its continued implementation. The LLTs program to detect NAFLD was performed on 411 Japanese workers utilizing serum ALT, AST, and gammaglutamyl transpeptidase (GTP). Subjects with viral and alcohol hepatitis were excluded from the evaluation. The diagnosis of NAFLD was based on US findings. The program was evaluated by efficacy and effectiveness in comparison with the BMI. Effectiveness, based on

the efficacy determinations, was assessed by means of the positive predictive value (PPV) test performance, the disease characteristics, and the program cost. The diagnostic performances of ALT and BMI were far from excellent. The areas under the curves of the two indices were 0.69 and 0.63, respectively. The PPV ranged from 15 to 28% where the prevalence of fatty liver was 12.3%. The cost of the program was estimated at \$4 U.S. dollars per person based on the medical reimbursement fee rate. The efficacy of the liver screening program was found to be insufficient and, therefore, revealed that BMI monitoring may provide a more suitable and inexpensive alternative. The authors challenge the effectiveness of the LLTs, considering the high price of the program^[9].

What is the risk of cancer in patients with NAFLD?

The relation between NAFLD and cancer risk is poorly understood. Using the population-based National Registry of Patients, some Authors examined the incidence of cancer in 7326 patients discharged with a diagnosis of NAFLD from a Danish hospital during 1977-1993. Overall, 523 cancers were diagnosed during 47 594 person-years of follow-up, yielding a 1.7-fold increased risk (95% CI, 1.6-1.9) compared with the Danish general population. The risk of primary liver cancer was markedly elevated in patients with alcoholic liver disease (ALD) as well as NAFLD with a standardized incidence ratio of 9.5 (95% CI, 5.7-14.8) and 4.4 (95% CI, 1.2-11.4), respectively. Patients with ALD also had substantially increased risks of several types of cancer associated with alcohol and tobacco use (cancers of the lung, pharynx, larynx, esophagus, and stomach) and a moderately increased risk for cancers of the colon and breast. Among patients with NAFLD, an increased risk of some alcohol- and tobacco-related cancers was seen, and there was also an increased risk of colon and pancreas cancer^[10].

Then, what is the natural history of NAFLD in the community?

Authors sought to determine survival and liver-related morbidity among community-based NAFLD patients. Four hundred twenty patients diagnosed with NAFLD in Olmsted County, Minnesota, between 1980 and 2000 were identified using the resources of the Rochester Epidemiology Project. Overall survival was compared with the general population of the same age and sex. Overall, 53 of 420 (12.6%) patients died. Survival was lower than the expected survival for the general population ($P = 0.03$). Higher mortality was associated with age (hazard ratio per decade 2.2; 95% CI 1.7-2.7) and impaired fasting glucose (hazard ratio 2.6; 95% CI 1.3-5.2). Liver disease was the third leading cause of death (as compared with the thirteenth leading cause of death in the general population), occurring in 7 (1.7%) subjects. Twenty-one (5%) patients were diagnosed as being affected by cirrhosis, and 13 (3.1%) developed serious complications^[11].

And what about NAFLD in atopic/non-atopic children?

NAFLD in non-obese Japanese children was observed in 3.2% of non-atopic children and in 17.6% of patients

with atopic dermatitis or suffering from bronchial asthma, allergic rhinitis, in 2000. NAFLD was studied by abdominal US scans. The prevalence of NAFLD was increasing annually, and it reached 12.5% in non-atopic children, 13.1% in patients with bronchial asthma, 13.7% in patients with allergic rhinitis, or 33.9% in patients with atopic dermatitis, in 2003. Since NAFLD in childhood may be a risk factor for lifestyle-related diseases in future, care should be taken to prevent it^[12].

It would have been interesting to know how many of those subjects were on steroid therapy.

Could polyunsaturated fatty acids be used to improve an immunological disease and an apparently distant illness of liver, i.e., NAFLD?

The higher incidence of inflammatory diseases in Western countries might be related, in part, to a high consumption of saturated fatty acids and n-6 polyunsaturated fatty acids (PUFA) and an insufficient intake of n-3 fatty acids. In an intriguing study, Balb/C mice were fed for 3 wk either n-6 or n-3 PUFA-fortified diets. After inducing a contact or an atopic dermatitis, immunological parameters were analyzed by the authors to evaluate the anti-inflammatory potential of these n-3 PUFA. Accordingly, n-3 PUFA lessened innate and specific immune responses through inhibition of TH1 and TH2 responses, increase of immunomodulatory cytokines such as IL-10, and regulation of gene expression. Furthermore, reduction in edema, leukocyte infiltration, and enhancement of antioxidant defenses in the inflamed ears of mice from both models proved n-3 PUFA efficacy. Authors' data suggest that dietary fish oil-derived n-3 fatty acids could be useful in inflammatory disorders^[13].

On the other hand, is obesity a chronic low-grade inflammatory process or not? Because eicosapentaenoic acid, docosahexaenoic acid, and gamma-linolenic acid have anti-inflammatory, as well as lipid-modifying properties, the effects of supplement mixtures of these PUFA should have received much more attention by researchers in the field of NAFLD treatment.

What have two peculiar syndromes to do with NAFLD?

NAFLD and polycystic ovary syndrome (PCOS) are both associated with IR. Thus, women with PCOS may have an increased prevalence of NAFLD, including NASH. To determine the prevalence and characteristics of NASH and abnormal ALT in women with PCOS were retrospectively studied 200 women with PCOS, diagnosed with irregular menses and hyperandrogenism. Fifteen percent (29 out of 200) had AST and/or elevated ALT. Women with aminotransferase elevations had lower high-density lipoprotein (HDL), $P = 0.006$, higher triglycerides ($P = 0.024$), and higher fasting insulin ($P = 0.036$) compared with women with normal aminotransferases. Six women had NASH with fibrosis. The authors concluded that abnormal aminotransferase activity is common in women with PCOS and suggest a reflection of whether to screen PCOS women for liver disease at an earlier age than is currently recommended for the general population^[14].

Recently, obstructive sleep apnea (OSA) has been proposed as an independent risk factor for IR. The

objectives of this study were to document the prevalence of SOSA in patients with NAFLD and to determine whether prevalence rates for SOSA differ in NAFL versus NASH patients. The prevalence of OSA was similar in both biochemically ($P = 0.66$) and histologically ($P = 0.11$) defined NAFL and NASH patients. Other risk factors for NAFLD such as BMI, cholesterol and triglyceride levels, and prevalence of diabetes were also similar in the two groups. Approximately one-half of NAFLD patients, whether NAFL or NASH, have OSA^[15].

Could abnormalities in the estradiol to testosterone ratio (increased androgens and decreased estrogens) lead to insulin resistance and NASH?

Recently, the fourth case has been presented of an adult man (29 years old) affected by aromatase deficiency resulting from a novel homozygous inactivating mutation of the CYP19A1 (P450-aromatase) gene. The patient showed also a complex dysmetabolic syndrome characterized by IR, type 2 DM, acanthosis nigricans, NASH, and signs of precocious atherogenesis. The analysis of the effects induced by the successive treatment with high doses of testosterone, alendronate, and estradiol allows further insight into the roles of androgens and estrogens in several metabolic functions. High doses of testosterone treatment resulted in a worsening of IR and type 2 DM. Estrogen treatment resulted in an improvement of acanthosis nigricans, IR, and NASH, coupled with a better glycemic control and the disappearance of two carotid plaques. Data from this case provided new insights into the role of estrogens in glucose, lipid, and liver metabolism in men^[16].

CONCLUSION

For many years, research concerning acute and chronic liver diseases have been mostly confined to few areas of Medicine, i.e., virology and immunology. Vice versa, for the first time in decades, the liver comes back to have a pivotal role in Health Sciences, embracing endocrine, cardiovascular and oncological diseases, so the answer to the initial question, "Should nonalcoholic fatty liver disease be regarded as a hepatic illness only?," is... It should not!

Abstract

Distinct from hereditary haemochromatosis, hepatic iron overload is a common finding in several chronic liver diseases. Many studies have investigated the prevalence, distribution and possible contributory role of excess hepatic iron in non-haemochromatotic chronic liver diseases. Indeed, some authors have proposed iron removal in liver diseases other than hereditary haemochromatosis. However, the pathogenesis of secondary iron overload remains unclear. The High Fe (*HFE*) gene has been implicated, but the reported data are controversial. In this article, we summarise current concepts regarding the cellular role of the *HFE* protein in iron homeostasis. We review the current status of the literature regarding the prevalence, hepatic distribution and possible therapeutic implications of iron overload in chronic hepatitis C, hepatitis B, alcoholic and non-alcoholic fatty liver diseases and porphyria cutanea tarda. We discuss the evidence regarding the role of *HFE* gene mutations in these liver diseases. Finally, we summarize the common and specific features of iron overload in liver diseases other than haemochromatosis.

INTRODUCTION

Iron is an essential element for living cells because it is

a cofactor for enzymes of the mitochondrial respiratory chain and it co-ordinates the binding of oxygen by myoglobin and haemoglobin. However, excess iron is toxic, causing increased oxidative stress; the production of reactive oxygen species is thought to be responsible for the observed oxidation of lipids, proteins and nucleic acids. Thus, iron overload can cause serious damage to organs including the liver, heart, joints and endocrine glands.

Hereditary haemochromatosis (HH) is the paradigm of heavy iron overload which can eventually lead to multiple organ failure. HH is an inherited disease of iron metabolism^[1]. Absorption of dietary iron is inappropriately high in relation to body iron stores. This leads to increased deposition of iron, predominantly in parenchymal cells of the liver, heart, joints, pancreas and other endocrine organs. Undiagnosed and untreated, iron deposition can cause hepatocellular injury, activation of hepatic stellate cells (HSCs) and increased production of collagen and other components of the extracellular matrix^[2]. The liver is the major site for storage of excess iron, which probably explains the increased risk of hepatocellular carcinoma (HCC) in HH^[3].

In non-haemochromatotic liver diseases, hepatic iron may worsen liver injury or hepatic fibrosis. This has been investigated in common chronic liver diseases (CLDs) such as chronic hepatitis C (CHC) and alcoholic and non-alcoholic fatty liver diseases. In these CLDs, the progression towards end-stage liver disease is often unpredictable; many cofactors have been proposed to explain this variability. Iron overload has been proposed as such a cofactor, but its exact role remains unclear^[4]. Iron has also been implicated in the progression of hepatitis B virus (HBV) infection^[5], but this has not been widely studied. Other conditions that may cause CLD and that have been associated with iron overload include porphyria cutanea tarda (PCT) and insulin resistance-associated hepatic iron overload (IR-HIO) syndrome^[6,7]. The IR-HIO syndrome encompasses iron overload with hyperferritinaemia and normal transferrin saturation, type 2 diabetes mellitus and non-alcoholic steatohepatitis (NASH). In these forms of secondary (acquired) iron overload, however, the hepatic iron concentration is generally lower than that seen in HH. Although major advances have been made in understanding the pathogenesis of primary iron overload in HH, the mechanism(s) whereby pre-existing CLD may lead to iron overload remain unclear. In HH, there is a strong relationship with missense mutations in the *HFE* (High Fe) gene^[8]. In non-haemochromatotic diseases, several studies have investigated the possible role of *HFE* mutations in the pathogenesis of hepatic

iron overload, with somewhat discordant results. This review aims to describe the prevalence and role of *HFE* mutations in secondary iron overload. It will discuss the effects of moderate iron excess on the natural history and its possible relevance to therapeutic approaches in CLDs other than HH.

NOMENCLATURE OF IRON OVERLOAD

Hereditary, or primary, haemochromatosis is an inherited iron storage disease. Secondary iron overload is acquired as a result of another disease. The nomenclature and classification of iron overload states is shown in Table 1. Primary haemochromatosis may be due to mutations in the *HFE* gene, or to mutations in genes other than *HFE*. The main causes of acquired iron overload are haemolytic anaemias and CLDs. Untreated HH may develop severe iron overload, whereas in secondary iron overload due to CLDs, minimal to modest iron overload is usually seen^[2].

GENETICS OF PRIMARY IRON OVERLOAD

There are two common mutations of the *HFE* gene. The first results in a change of cysteine at position 282 to tyrosine (C282Y); the second results in a change of histidine at position 63 to aspartate (H63D). Numerous studies have shown that homozygosity for C282Y is associated with typical phenotypic HH in Caucasians. C282Y homozygosity ranged from 64% of Italian haemochromatosis cases up to 100% of cases in Australia^[9-11]. A recent study of almost 100 000 North American primary care patients analysed the distribution of *HFE* mutations in a racially diverse group^[12]. It confirmed that homozygosity for C282Y is most common in whites, consistent with the hypothesis that this mutation originated in a Caucasian “founder” individual. Individuals who are compound heterozygous for C282Y and H63D may also have iron overload in the range diagnostic for haemochromatosis, although the penetrance of this genotype is lower than for C282Y homozygosity^[13-15]. The H63D mutation is variably distributed worldwide. It is more prevalent than the C282Y mutation: approximately one in five of the European population are estimated to be H63D heterozygotes^[9,16]. The C282Y/H63D compound heterozygous and H63D homozygous genotypes have mostly been associated with only biochemical evidence of mild iron overload. The clinical penetrance of these genotypes is low although there have been reports of varied phenotypic presentation^[15,17].

A third point mutation (S65C) of the *HFE* gene was also identified. It was originally considered to be a neutral polymorphism, not associated with increased transferrin saturation^[18]. However, other evidence implicated the mutation in mild iron overload^[19,20]. Other, rare mutations have been described. Two missense mutations in exon 2 of the *HFE* gene (I105T and G93R) were detected in haemochromatosis patients with atypical *HFE* genotypes, such as heterozygosity for C282Y, H63D or S65C^[21]. A splice-site *HFE* mutation (IVS3+1G/T) that prevented normal mRNA splicing was identified in a patient with classical HH who was heterozygous for the C282Y muta-

Table 1 Nomenclature for iron overload states

Primary iron overload-hereditary haemochromatosis (HH)
<i>HFE</i> -associated HH
1 C282Y homozygosity
2 C282Y/H63D compound heterozygosity
3 Other mutations
Non <i>HFE</i> -associated HH
1 Juvenile haemochromatosis
2 Tfr2-related haemochromatosis
3 Autosomal dominant haemochromatosis
Secondary iron overload-acquired
Iron-loading anaemias
1 Thalassaemia major
2 Sideroblastic anaemia
3 Chronic haemolytic anaemias
Chronic liver diseases
1 Hepatitis C
2 Alcoholic liver disease
3 Non-alcoholic steatohepatitis
4 Porphyria cutanea tarda
5 IR-HIO
6 Post-portacaval shunting
7 Transfusional and parenteral iron overload
8 Dietary iron overload
Miscellaneous
1 Iron overload in sub-Saharan Africa
2 Neonatal iron overload
3 Acaeruloplasminaemia
4 Congenital atransferritinaemia

tion. This highlighted the possibility that other rare *HFE* mutations could explain the classical HH phenotype, particularly in C282Y heterozygotes with iron overload^[22]. In this review, we will consider only the two most frequent *HFE* mutations, C282Y and H63D. The other mutations are rare, thus they are unlikely to play a major role in CLDs other than HH.

HH has been described as the most common monogenic disorder in Celtic populations. Certainly, homozygosity for the C282Y mutation occurs in about 1 in 300 people of Northern European origin, with an estimated carrier (heterozygote) frequency of 1 in 10^[8]. However, the C282Y homozygous genotype has incomplete penetrance: not all patients with this genotype show an iron overload-related phenotype. The penetrance of HH is influenced by a variety of factors. Increasing age increases the penetrance, as the body has no means of active iron excretion, so iron accumulation progresses with time. Male gender also increases the penetrance, as women may be partially protected against iron overload by iron losses incurred in childbirth and menstruation. Dietary iron content may also influence penetrance. There has been considerable debate regarding the penetrance of HH. The “biochemical penetrance” of the C282Y homozygous state is generally agreed to be high, particularly in older males, but disease-related morbidity is less frequent. A study of almost a third (3011) of the residents of Busselton, Australia showed that four (all males) of the 16 C282Y homozygotes detected had fibrosis and/or cirrhosis. If attributable to iron overload, this equates to a disease-related morbidity of 25%^[23]. In contrast, recent large studies have reported lower penetrance. Beutler and colleagues studied over

40 000 individuals attending a health appraisal clinic, where expression of haemochromatosis was investigated by questionnaire. The results for C282Y homozygotes were compared with the control group who were wild type for C282Y and H63D. The clinical penetrance of ill health or shortened lifespan in C282Y homozygotes was reported to be less than 1%^[24]. Various factors, such as the exclusion of most patients who had a previous diagnosis of haemochromatosis from the assessment of ill health, would have tended to decrease this calculated clinical penetrance of C282Y homozygosity^[25]. Despite this, a similar, low value was obtained in a survey of about 1 000 000 individuals in two health authority regions in South Wales. It was concluded that a diagnosis of haemochromatosis had been made for only 1.2% of adult C282Y homozygotes. When only male homozygotes older than 45 years were considered, the diagnosis rate rose to 2.8%^[26]. Thus, the “severity” of the definition of penetrance (disease related morbidity or clinical expression as ill health/shortened life span) is an important factor influencing the observed value. It seems that the clinical penetrance of C282Y homozygosity is low.

HFE PROTEIN AND CELLULAR IRON HOMEOSTASIS

The predicted HFE protein has sequence homology to the major histocompatibility complex (MHC) class I molecules, a family of transmembrane glycoproteins of the immune system, which present peptide antigen to T cells^[8]. Like the class I proteins, HFE is made up of three extracellular loops (α_1 , α_2 , α_3)^[27], a transmembrane domain and a short cytoplasmic C-terminal region. Two disulphide bridges stabilize the tertiary structure of the HFE protein. One of these gives rise to the α_3 loop, that is crucial for interaction with β_2 -microglobulin and for translocation to the cell surface^[28,29]. The C282Y mutation prevents formation of this disulphide bond, thereby inhibiting correct cell surface expression of HFE^[8]. The H63D mutation causes a histidine to be replaced by aspartate in the α_1 domain^[8]. H63D is generally considered to have a milder effect on body iron stores than C282Y.

The role of HFE in cellular iron homeostasis remains only partially understood. Co-immunoprecipitation experiments showed that the HFE- β_2 -microglobulin complex interacted with transferrin receptor 1 (TfR1) in human placental membrane preparations^[30] and in human embryonic kidney cells over-expressing wild type HFE^[31]. Immunohistochemical studies of human duodenum showed that TfR1 staining overlapped that of HFE in the crypt cell enterocytes, consistent with the co-trafficking of these proteins^[32] (Figure 1). These studies provided a link between HFE and the transferrin-mediated endocytosis pathway of iron uptake into cells. Under conditions of iron excess, circulating iron-saturated transferrin is understood to bind the TfR1-HFE- β_2 -microglobulin complex on the cell surface, which is internalised within an endosome. At the acidic endosome pH, iron dissociates from transferrin and enters an intracellular chelatable iron pool. The transferrin-TfR1 complex recycles to the cell

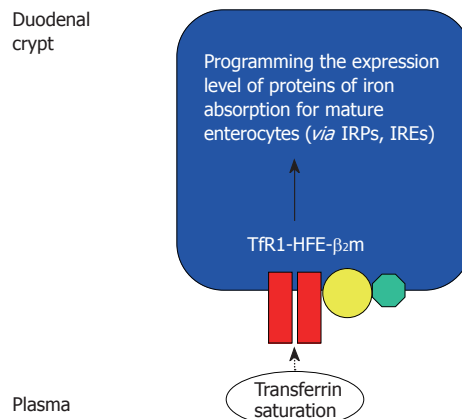

Figure 1 The duodenal “crypt cell hypothesis” of HFE function^[36]. HFE at the basolateral membrane of duodenal crypt cells co-localizes with β_2 -microglobulin and TfR1. The saturation of circulating transferrin, which reflects body iron stores, was proposed to be “sensed” by the TfR1-HFE- β_2 -microglobulin complex, through transferrin-mediated endocytosis. Wild type HFE was proposed to facilitate transferrin-mediated iron uptake. In haemochromatosis, deficiency of functional HFE would therefore decrease the iron pool within the crypt cell, despite increased body iron stores. This would increase the activity of iron responsive proteins (IRPs), leading to increased expression of genes involved in iron absorption, such as DMT1 and ferroportin. This could contribute to the iron overload seen in HH^[27,34,35]. However, recent evidence suggests that HFE may play more important roles in influencing iron metabolism in the liver.

surface, where transferrin dissociates at the pH of blood, around pH 7.4^[27,33].

However, investigations of the HFE-TfR1 interaction and its potential effect on iron metabolism in transfected cell lines gave conflicting results. Several studies indicated that overexpression of HFE may ultimately reduce iron uptake into cells *via* transferrin-mediated endocytosis^[34]. Biosensor- and radioactivity-based assays indicated that HFE competes with transferrin for binding to TfR1^[35]. Conversely, in stably transfected Chinese hamster ovary cells, HFE increased the rate of TfR1-mediated iron uptake and cellular iron concentrations, but only when co-transfected with β_2 -microglobulin^[36]. Also, in primary macrophages from haemochromatosis patients, transfection of the wild type HFE gene increased uptake of ⁵⁵Fe-transferrin and accumulation of ⁵⁵Fe in the ferritin iron pool^[37]. These latter studies are consistent with the observation that in haemochromatosis, duodenal enterocytes are paradoxically iron-deficient^[38].

Several hypotheses have been advanced to model the possible roles of HFE in the regulation of iron metabolism. It was originally proposed that the TfR1-HFE- β_2 -microglobulin complex on the basolateral surface of the duodenal crypt cell may sense the transferrin saturation (Figure 1). Where wild type HFE was present, the transferrin saturation was proposed to determine the crypt intracellular iron concentration, thereby setting the activity of iron responsive proteins 1 and 2 and ultimately the expression levels of key proteins of iron absorption in the mature enterocyte^[36]. The pathway of iron absorption in the mature enterocyte is shown in Figure 2. Duodenal cytochrome b ferric reductase (Dcytb) is expressed on the luminal surface of the enterocyte and reduces dietary ionic iron from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state.

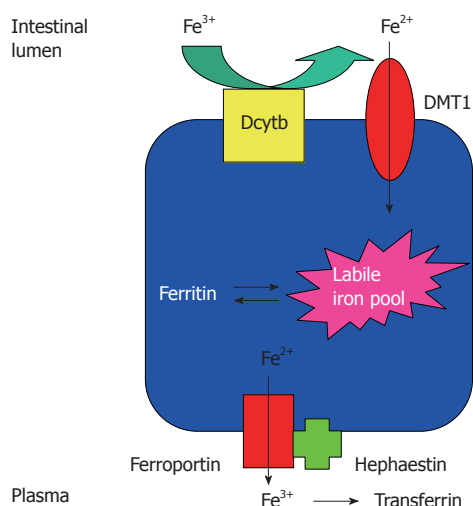

Figure 2 The pathway of iron absorption in the mature duodenal enterocyte. Dietary ferric iron is reduced to the ferrous state by ferric reductase(s), for example duodenal cytochrome b (Dcytb), which is expressed on the luminal surface of the enterocytes. Ferrous iron is taken up via DMT1 into the labile iron pool. Iron may be stored within the cell as ferritin or transferred across the basolateral membrane to the plasma by ferroportin. The exported iron is oxidized to the ferric state by hephaestin; ferric iron is then avidly bound by circulating transferrin^[39].

The ferrous iron is then taken up by the apical transporter, divalent metal transporter 1 (DMT1). Iron may be stored within the cell as ferritin or exported across the basolateral membrane by ferroportin. The exported iron is re-oxidized to the ferric state by hephaestin. Upon exiting the villus enterocyte, ferric iron can be avidly bound by circulating transferrin^[39].

The discovery of the peptide hormone hepcidin^[40-42] revived an alternative hypothesis, that the liver may be central to the regulation of iron metabolism^[43-46]. Hepatocytes act as a storage reservoir for iron, taking up dietary iron from the portal circulation and, in iron deficiency, releasing iron into the hepatic circulation. The liver is also the site of high expression of hepcidin, *TfR2* and haemojuvelin, three genes which when mutated result in HH.

Hepcidin is produced in the liver in response to dietary iron loading^[42]. Mutation of the hepcidin gene results in juvenile haemochromatosis, characterised by early onset and a rapid rate of iron loading^[47]. As in hepcidin-related haemochromatosis, inappropriately low hepcidin levels in relation to body iron stores are also seen in haemochromatosis resulting from mutation of the *HFE*, *TfR2* and haemojuvelin genes, suggesting that hepcidin may be the common pathogenic mechanism in haemochromatosis^[43,48]. Therefore, *HFE*, *TfR2* and haemojuvelin proteins may all be involved in the pathway sensing iron overload that leads to hepcidin synthesis. Experiments using cultured cells indicated that hepcidin may act by interaction with ferroportin, causing its degradation and reducing cellular iron export^[49]. The overall effect would be to “trap” iron within enterocytes, hepatocytes and macrophages. However, other studies, using parenteral injection of hepcidin into mice and analysis of iron absorption in tied off lengths of duodenum, found that hepcidin inhibited the uptake

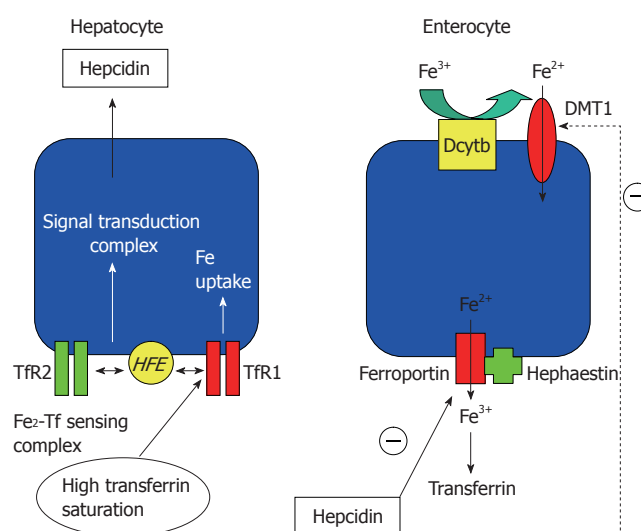

Figure 3 Current concepts regarding hepatic regulation of iron metabolism. Left panel, hepatocyte. At normal transferrin saturation, TfR1 may sequester HFE^[19]. At increased transferrin saturation, diferric transferrin competes with HFE for binding to TfR1^[55]. Freed HFE is proposed to bind TfR2; the complex conveys transferrin saturation status via a cytoplasmic signal transduction complex, leading to synthesis and secretion of hepcidin. In HH, mutations in the genes encoding HFE, TfR2, haemojuvelin or hepcidin may all disrupt this sensing system, leading to deficient hepcidin production and iron overload^[53]. Right panel, enterocyte. Circulating hepcidin may reduce iron absorption by interacting with ferroportin, causing its internalization and degradation^[49] and/or by reducing DMT1 expression^[50].

step of iron absorption. This did not require HFE. In this study, hepcidin did not influence the proportion of iron transferred into the circulation^[50]. Therefore it is not yet clear whether hepcidin acts at ferroportin in the enterocyte basolateral membrane, at DMT1 in the apical membrane, or both (Figure 3).

Because hepcidin is synthesised in hepatocytes, they have been proposed as the site of an iron sensing mechanism. TfR2 is expressed mainly in hepatocytes, haematopoietic cells and crypt cells of the duodenum, which are all also sites of HFE expression^[51,52]. Recent expression studies of intact HFE and TfR2 proteins in cultured cells showed interaction between these two proteins^[53]. It was proposed that when transferrin saturation is in the normal range, TfR1 may sequester HFE^[54]. At increased serum transferrin saturation, diferric transferrin has been shown to compete with HFE for binding to TfR1^[55]. Freed HFE is proposed to act as an iron sensor, binding TfR2 and conveying transferrin saturation status via TfR2 and a cytoplasmic signal transduction complex, leading to the synthesis of hepcidin (Figure 3). Haemojuvelin may form part of the signal transduction system. In HFE-, TfR2- or haemojuvelin-related haemochromatosis, mutations may disrupt this sensing system, leading to the observed deficiency of hepcidin; iron loading would therefore result^[53]. Thus, latest ideas propose that HFE-TfR2 interaction in hepatocytes may sense transferrin saturation, as an index of body iron status, determining production of hepcidin, which governs iron absorption^[53].

IRON AND *HFE* MUTATIONS IN CHRONIC HEPATITIS C

CHC remains a major health problem with around 200 million individuals affected worldwide^[56]. The natural course of CHC is characterised by progressive fibrosis in the inflamed liver with cirrhosis and haemodynamic changes which may be followed by end-stage complications^[57]. The progression of fibrosis in CHC is highly variable. Several factors may favour progression, including alcohol, young age at the time of infection and male gender. The role of iron in the pathogenesis of CHC has been debated. An association between iron and viral hepatitis was first described by Blumberg and colleagues^[5]. Following those observations, several studies noted elevated serum iron indices in CHC^[58-60]. Iron has been proposed as a cofactor that may both promote the progression of liver disease and reduce the response to antiviral therapy^[56,61,62]. Mechanisms proposed include production of reactive oxygen species, increased fibrogenesis through activation of HSCs and impairment of the host immune response^[63]. Several studies of CHC reported hepatic iron deposits in HSCs, which may contribute to liver damage^[64,65]. Many studies have also tried to investigate the pathogenesis of iron overload in CHC. Necroinflammation due to ongoing viral infection is considered the most important cause of iron overload. Additionally, the viral infection *per se* or the associated activation of cytokines have been proposed to modify iron metabolism in liver cells^[60,66]. A recent study showed that TfR1 expression was increased in CHC hepatic tissue irrespective of the degree of hepatic iron overload. This might, therefore, contribute to the accumulation of hepatic iron in CHC^[67]. Viral genotype may be another factor. In a large study of 242 patients, one of us analyzed the relationship between hepatitis C virus (HCV) genotypes and liver iron deposits in CHC^[68]. We found a higher prevalence of hepatic iron deposits in HCV-3 infected cases, concluding that hepatic iron deposition is HCV-genotype dependent. Indeed, the distribution of hepatic iron was mostly parenchymal in HCV-3 cases, while in non-HCV-3 patients, hepatic iron deposits were more frequently detected in the reticuloendothelial cells. These findings support the hypothesis that the expression of HCV-3 proteins in infected hepatocytes might cause specific metabolic changes resulting in enhanced oxidative stress. The non-HCV-3 cases had more severe fibrosis. Therefore their lesser hepatic iron deposits might reflect a more advanced stage of liver inflammation. A further relationship between viral genotype and iron was found in another study: Izumi and colleagues reported higher hepatic iron concentrations in HCV-1b compared with HCV-2 infected cases^[69].

A role of proteins that are involved in iron homeostasis has also been hypothesized. In a detailed histopathological study, Corengia and colleagues investigated *HFE* genotypes and hepatic iron score in hepatitis C^[70]. They found a significant relationship between *HFE* genotypes and iron deposition in hepatocytes. This suggested that some iron accumulation in CHC derives from increased iron absorption due to mutated *HFE* protein. Hecpudin has also been implicated. A study by Aoki and colleagues

evaluated the possible role of hepcidin in determining iron overload in hepatitis C^[71]. In patients with HCV, they demonstrated that hepatic hepcidin mRNA correlated with hepatic iron concentration (HIC). This suggested that iron stores regulate hepcidin expression normally; iron loading in CHC is not due to inappropriate hepcidin expression.

Serum iron indices are frequently abnormal in patients with CHC. Elevation of the serum ferritin concentration has been reported in 20%-60% of patients with chronic hepatitis C^[59,68,72,73]; stainable hepatic iron deposits were detected in 3%-38%. Furthermore, many cases of CHC, including those with elevated serum ferritin, elevated transferrin saturation, or both, showed no significant increase in HIC^[59,61,68,73-74]. In most of these studies, hepatic iron overload was generally mild to moderate and often not sufficient to be hepatotoxic *per se*^[61,75,76]. Elevated serum ferritin concentration in CHC may be explained by several associated conditions, in the absence of iron overload. Serum ferritin could be elevated as an acute phase protein because of the cytolytic necroinflammation that is common in hepatitis C. Moreover, hepatic steatosis is frequent in patients with hepatitis C^[77,78] and has been associated with raised levels of serum ferritin^[79,80]. A recent study suggested that increased serum ferritin in CHC may be mainly due to diabetes mellitus, which is commonly associated with CHC^[81]. In contrast, other observations from one of us suggested that elevated serum ferritin in CHC may be mostly multifactorial^[82].

The distribution of iron has been examined in several studies, with some discrepancies. Some studies reported iron deposits mostly in hepatocytes^[70,83,84], others in reticuloendothelial cells^[85-87] and others reported a mixed distribution^[68,88,89]. This is a notable difference with HH where, until iron loading is severe, hepatic iron deposition is almost exclusively parenchymal.

The role of *HFE* mutations as a risk factor for iron overload in CHC has been studied in different populations, with somewhat discordant results (Table 2). Piperno and colleagues studied 110 Italian patients with chronic B or C viral hepatitis; they found that all male heterozygotes for the C282Y mutation had iron overload. The H63D mutation was significantly more frequent in patients with marked hepatic siderosis than in those with mild or no siderosis and in controls^[73]. A study of 137 CHC patients from the North of England reported that patients who carried the C282Y mutation had higher serum iron indices and more frequently had stainable hepatic iron, together with more advanced fibrosis or cirrhosis, than patients without the C282Y mutation^[90]. Similar results were obtained in other studies which correlated the presence of *HFE* mutations with increased serum iron indices, hepatic iron deposits and severe hepatic fibrosis^[70,91-94]. In an Austrian study of 184 patients with CHC versus 487 controls, Kazemi-Shirazi and colleagues found that serum iron indices were increased in patients carrying *HFE* mutations. In contrast with other studies, however, there was no evidence for more hepatic siderosis or advanced fibrosis in patients with *HFE* mutations^[95]. Other studies reported no relationship of *HFE* mutations with hepatic iron deposits and severe hepatic fibrosis^[83,89]. In a Scottish study, Thorburn and colleagues prospectively investigated

164 consecutive patients with HCV infection. They did not find a role for *HFE* mutations in the accumulation of iron or the progression of liver disease^[89]. Overall, only a few studies have suggested an increased prevalence of *HFE* mutations in CHC patients, with respect to the general population^[90,92,95]; this observation was not confirmed in other studies^[73,91,94].

A role for the H63D mutation in the iron overload of CHC was proposed in a few of the studies. Lebray and colleagues found that the histological hepatic iron score was higher in patients who were homozygous or heterozygous for H63D; this was surprisingly associated with an increased response rate to antiviral therapy^[96]. Another study reported increased hepatic iron deposits in male patients carrying the H63D mutation^[97]. Thus, the role of the H63D mutation is unclear and, as observed in HH, is minor with respect to the C282Y mutation.

Several studies suggested that higher levels of serum ferritin or HIC were associated with a diminished likelihood of response to antiviral therapy^[84,85,97]. Data from a recent Italian multicenter study indicated that iron removal by phlebotomy improved the rate of response to interferon^[98]. The influence of *HFE* mutations on the outcome of antiviral treatment has been investigated in a few studies. Chapman and colleagues suggested that a single mutation in the *HFE* gene had no impact on the outcome of interferon treatment; this was confirmed by subsequent reports^[99-101]. However, a study of 242 patients found that presence of the C282Y mutation was positively correlated with sustained response in a multivariate analysis^[88]. The reports by Lebray *et al* and Distant *et al* suggest that *HFE* may be part of a pattern of host genes which together influence response to antiviral therapy^[88,96]. Indeed, clearance of HCV is believed to be associated with different HLA alleles; the C282Y mutation of the

HFE gene is part of an extended founder haplotype which includes the HLA region on the short arm of chromosome 6^[101]. The positive effect of the C282Y mutation may reflect linkage disequilibrium between the *HFE* mutated allele and alleles at other loci implicated in the virological response, close to the *HFE* gene on chromosome 6. Several MHC class I and II loci have been shown to be associated with a sustained virological response to interferon treatment^[102-105]. Similarly, an American study investigated the role of iron overload and *HFE* mutations in the response to antiviral therapy in over 1000 patients with advanced CHC^[97]. The authors found that *HFE* mutations correlated with histological hepatic iron score in CHC. Subjects harbouring *HFE* mutations, particularly H63D, had significantly higher likelihood of both on-treatment virological responses (at 24 and 48 wk) and sustained virological responses (24 wk after the end of lead-in therapy) to re-treatment with pegylated interferon alpha-2α plus ribavirin. Again, both the *HFE* mutation and/or associated genetic variants were considered as possible causes of the improved response to therapy.

In conclusion, elevation of serum iron indices and hepatic iron deposits are a common feature in CHC. Hepatic iron overload is generally mild to moderate and it rarely reaches the severity seen in HH. In contrast to HH, the intrahepatic iron accumulation is generally mixed, with both parenchymal and reticuloendothelial distribution. The exact mechanism of hepatic iron accumulation in hepatitis C is still not clear. The pathogenesis is likely to be multifactorial and viral and host factors have been evaluated. The viral factors suggested by several studies include necroinflammation due to viral infection, direct influence on iron homeostasis mediated by cytokines, or HCV genotypes. Among the host factors, a role for *HFE* mutations has been proposed and extensively evaluated. On the basis of current knowledge, we conclude that *HFE* mutations may have a role in the elevation of serum iron indices and hepatic iron deposition observed in CHC, but they do not fully explain the observed abnormalities of iron homeostasis. Iron may also contribute to the rate of response to antiviral therapy.

IRON AND *HFE* MUTATIONS IN CHRONIC HEPATITIS B

Chronic hepatitis B (CHB) remains a serious global health concern. Approximately 350 million people are chronically infected, and 500 000 to 1.2 million deaths per year are attributed to HBV-associated complications^[106]. Among patients with active viral replication, cirrhosis will develop in 15%-20% within five years^[107]. For patients with cirrhosis, acute exacerbation can occur and the disease may progress to end stage complications^[107]. The histopathological pathway of progressive liver disease is characterised by fibrosis leading to increasing distortion of the hepatic architecture, that is the hallmark of evolution to cirrhosis. Liver fibrosis is the result of chronic injury and plays a direct role in the pathogenesis of hepatocellular dysfunction and portal hypertension. The progression of liver fibrosis is due to many viral and host

factors. In CHC it has been proposed that iron may be a cofactor, but data for patients with CHB are more scarce. An association between iron and hepatitis B was first described by Blumberg and colleagues^[5]. They found that serum iron indices were higher in patients who developed chronic hepatitis than in those who eliminated the virus. The same team also observed that haemodialysed patients with higher serum iron indices were less likely to achieve spontaneous recovery after acute hepatitis B^[108]. Other authors, assessing the presence of hepatic iron in Kupffer cells of patients with CHB, deduced that it is derived from hepatocytes destroyed by the virus^[109,110]. Zhou and colleagues studied 40 patients with hepatocellular carcinoma, 80% of whom were hepatitis B surface antigen (HBsAg) positive. They found a significant correlation between the presence of hepatitis B core antigen (HBcAg) and iron in hepatic tissue, suggesting that iron may accumulate predominantly in the hepatocytes in which HBV replication takes place^[111]. More recently, Martinelli and colleagues evaluated the prevalence of serum iron biochemical abnormalities and iron deposits in the liver of CHB patients^[112]. They found elevated transferrin saturation in 27.1% and liver iron deposits in 48.7% of cases. Patients with liver iron deposits presented with higher scores of necroinflammatory activity and fibrosis. The authors found no relationship between *HFE* mutations and elevation of serum iron indices or liver iron.

The effect of iron on the outcome of interferon alpha therapy in patients with CHB has been investigated by very few studies. In chronic viral hepatitis, Van Thiel and colleagues reported that low hepatic iron content may predict response to interferon therapy^[61]. More recently, a Polish group investigated iron metabolism and prognostic factors in interferon therapy in children with CHB. They showed that seroconversion for hepatitis Be antigen (HBeAg) was more frequently observed in children with lower iron and ferritin values^[113].

In conclusion, only a few studies have evaluated the prevalence and the physiopathological significance of iron overload in CHB. It has been suggested that iron deposits may occur mostly in hepatocytes. It seems that patients with higher levels of serum iron indices are less likely to achieve spontaneous recovery after acute hepatitis B. No role for the *HFE* gene mutations in iron overload has been detected. Iron could influence the response to antiviral therapy, but there is not sufficient evidence to permit a definitive conclusion.

IRON AND *HFE* MUTATIONS IN ALCOHOLIC LIVER DISEASE

Alcoholic liver disease (ALD) is one of the leading causes of end-stage CLD. It is well established that only a minority of heavy drinkers, estimated at between 10 and 30%, will ever develop advanced ALD; the risk increases with cumulative alcohol intake^[114,115]. Hence, in addition to alcohol, other factors are deduced to act synergistically to enhance its hepatotoxic effects. Patients with ALD commonly have elevation of transferrin saturation and serum ferritin concentration; significant hepatic iron

NA: not available; HI: hepatic iron; ALD: alcoholic liver disease (histological and/or biochemical evidence).

deposition is not infrequent^[116-118]. However, most patients with ALD have normal or slightly elevated HIC, with a mixed parenchymal and reticuloendothelial pattern of distribution^[119,120]. There is growing evidence that a mild degree of iron overload is sufficient to enhance alcohol-induced liver injury. The paradigm of synergy between iron and alcohol is HH. Patients with HH and significant alcohol consumption have a higher incidence of cirrhosis and hepatocellular carcinoma than those without heavy alcohol consumption or a history of alcohol abuse^[121,122]. In ALD, stainable hepatic iron was positively correlated with fibrosis in a multivariate analysis of risk factors in 268 French alcoholic patients^[123].

There are several potential causes for hepatic iron overload in alcoholic liver disease, including increased ingestion of iron, increased intestinal iron absorption, up-regulation of hepatic TfR1, secondary anaemia due to haemolysis, hypersplenism, ineffective erythropoiesis, hypoxaemia due to intrapulmonary shunts and portosystemic shunts^[4,124,125]. Increased iron absorption could arise through three main mechanisms: an increase in the reduction of luminal iron to the ferrous state; up-regulation of DMT1 in duodenal enterocytes; upregulation of ferroportin in duodenal enterocytes. The latter mechanism may be influenced by the down-regulation by ethanol of the hepatic production of hepcidin^[126].

Several studies suggested a genetic component to disease susceptibility. Significant associations have been reported between ALD risk and polymorphisms of the genes encoding cytochrome P450 and tumour necrosis factor (TNF) α ^[126,127]. Few studies assessed the possible role of *HFE* mutations as genetic cofactors in the development of ALD (Table 3). Lauret and colleagues found a significant association between carriage of the C282Y mutation and elevation of serum iron indices, but another study did not replicate this finding^[120,128]. One study found a relationship between *HFE* mutations and hepatic iron deposits^[120] but this observation was not confirmed by others^[119]. Moreover, none of these studies found that *HFE* mutations influenced the severity of ALD^[119,120,128,129].

In conclusion, patients with ALD tend to show mild increases in hepatic and serum measures of iron status. Iron is thought to play a role in worsening the course of ALD, although the mechanisms responsible are not resolved. To date, evidence from the literature does not

suggest a role for *HFE* mutations in determining iron overload or in influencing the course of ALD.

IRON AND *HFE* MUTATIONS IN NON-ALCOHOLIC FATTY LIVER DISEASE

Non-alcoholic fatty liver disease (NAFLD) is increasingly recognized as the most prevalent liver disease, at least in the West. In the adult population of the USA, 31% of men and 16% of women were found to have NAFLD^[130]. The disease has a spectrum ranging from fatty liver alone to steatohepatitis, and progressive steatofibrosis. Although fatty liver alone is considered non progressive, up to 20% of patients with non-alcoholic steatohepatitis (NASH) may develop cirrhosis, liver failure and HCC^[131]. Many cases of cryptogenic cirrhosis may be end-stage forms of NASH^[132]. The pathogenesis of NAFLD and the reasons why some patients with fatty liver develop NASH and have progressive liver disease are not entirely understood. A “two-hit” hypothesis has been proposed, involving the accumulation of fat in the liver (“first hit”), together with a “second hit” that gives rise to increased oxidative stress. Hepatic steatosis has been recognised as the first of two hits in the pathogenesis of NASH, since the presence of oxidisable fat within the liver is enough to trigger lipid peroxidation^[133]. However, many patients with fatty liver do not progress to steatohepatitis. Potential second hits for the development of NASH include all mechanisms contributing to the development of inflammation and fibrosis. Increased expression of ethanol-inducible cytochrome P450 2E1 (CYP2E1) and an increase in the intrahepatic concentration of free fatty acids could result in oxidative stress via peroxisomal oxidation^[134]. TNF α has also been implicated, since administration of anti-TNF α antibody ameliorated liver damage in animal models^[135].

There is controversial evidence that hepatic iron may play a role in the pathogenesis of NASH. It has been proposed that iron, in relatively low concentrations, could synergize with lipid overload and induction of CYP2E1 to increase oxidative stress in hepatocytes^[136]. Elevation of serum iron indices has been found in several studies^[126,127]. In most cases hepatic siderosis was mild and HIC was only rarely elevated^[137-140]. The distribution of hepatic iron was mixed parenchymal and sinusoidal^[79]. Strong support for an important role of iron in NAFLD and NASH was recently provided by studies on iron-depletion therapy, which improved both serum aminotransferases and insulin sensitivity^[141,142].

The role of iron has been re-evaluated since the discovery of the strict pathogenetic link between NASH and insulin resistance^[143]. Iron has been proposed to contribute to the development or exacerbation of insulin resistance, which is the most important risk factor for development of NAFLD and NASH^[79,80]. Mendler and colleagues reported a new syndrome characterized by mild to moderate hepatic iron overload and features of insulin resistance; the new syndrome was named insulin resistance-hepatic iron overload (IR-HIO). In their study, liver steatosis and NASH were present in 25% and 27% of IR-HIO cases, respectively^[7,144]. A subsequent study confirmed the high prevalence of NAFLD (59.7%) in patients with

insulin resistance-associated iron overload^[145]. Moreover, as in NASH, phlebotomy allows for normalization of body iron stores in IR-HIO^[146]. Indeed, IR-HIO shares some features with NASH, such as hyperferritinemia with mostly normal transferrin saturation. However, not all patients with IR-HIO have hepatic steatosis. It is likely that NASH and IR-HIO share some pathogenetic mechanisms. It has been proposed that IR-HIO may represent one end of the spectrum of NASH in which HIC is increased. Another point of view is that IR-HIO may represent a coincidental convergence of hepatic iron overload with a very common liver disorder in the general population^[128].

Genetic factors have also been proposed to play a role in the pathogenesis of NASH. Investigations of the possible contribution of *HFE* mutations in the pathogenesis of NASH have given sometimes discordant results (Table 4). George and colleagues reported increased intrahepatic iron (Perls' grade > 1) in 41% of cases; 23% of patients had HIC above the upper limit of normal^[138]. The increased HIC was attributed to the higher prevalence of homozygotes and heterozygotes for C282Y in these Australian patients with NASH versus control subjects (31% *vs* 13%, respectively). No significant difference in the prevalence of the H63D mutation was reported. A subsequent study by Bonkovsky and colleagues reported a significantly increased prevalence of H63D heterozygosity in patients versus controls (44.4% *vs* 26.4%)^[147]. Heterozygosity for C282Y was not statistically different between the two groups. Fargion and coworkers also reported an increased prevalence of *HFE* mutations in patients with respect to controls (65% *vs* 26%). Patients carrying *HFE* mutations did not present with increased serum iron indices, but showed increased HIC^[79]. In contrast to these results, other investigators have failed to observe significant associations between hepatic iron accumulation, *HFE* mutations and the severity of liver disease in patients with NASH^[139,140,80,148-151]. Angulo and colleagues found that HIC was normal in patients with NASH and abnormal serum iron indices^[139]. Another study by Chitturi and colleagues did not find any correlation

between HIC and any features of NASH, including the severity of fibrosis^[151]. The authors did not find any increase in stainable hepatic iron in the majority (90%) of liver biopsies from patients with NASH. Although they, like others, found a higher prevalence of C282Y heterozygosity in patients with NASH, no relationship with fibrotic severity was identified. Other studies did not find either significant abnormalities of serum and liver iron or an increased frequency of *HFE* mutations^[80,148,149].

Explanations for discrepant results include ascertainment bias, varied power of the studies and possible ethnic differences in the study populations. It should be underlined that elevation of serum iron indices in NASH, especially serum ferritin, may be due to insulin resistance, steatosis and inflammation, rather than to iron overload. Indeed, the discrepancies could be partially attributed to the differences between databases: the patients could be selected among subjects with hepatic iron overload or among population routinely attended a gastroenterology outpatient clinic. The association between NASH and *HFE* mutations has been described mainly in Australian and North American Caucasians^[138,147]. This hypothesis is supported by a recent study by Chitturi and colleagues that found an increased frequency of C282Y heterozygosity in NASH only in Anglo-Celtic patients^[151]. However, studies showing a positive correlation may have come from tertiary centres with an interest in iron storage disorders.

An increased prevalence of C282Y and H63D mutations has also been reported in patients with IR-HIO, but this finding was not connected with increased iron burden^[7]. A recent study of ours described four cases of H63D homozygosity associated with hyperferritinemia, macrovesicular steatosis, mild parenchymal and sinusoidal hepatic siderosis, with a granular pattern that could be related to NASH. Furthermore, three of the cases had one or more metabolic disorders which are part of the insulin resistance syndrome. The study could be consistent with proposals of a possible biological effect of the H63D mutation in IR-HIO and/or fatty liver^[152].

In conclusion, NAFLD has a heterogeneous spectrum of disease. It can progress to NASH and to end-stage liver disease, but the exact mechanism of fibrosis progression is not completely clear. A “two hits” hypothesis has been proposed and iron has been evaluated as a potential “second hit” that can cause progression of simple fatty liver to NASH. The available data are discordant about prevalence and effect of iron overload in NAFLD and NASH. Patients with coexisting NASH and hepatic iron stores undoubtedly exist, but the discordant data of the literature suggest that iron overload in NASH may be an epiphenomenon rather than have a main causative role. Insulin resistance syndrome has emerged as a key player in NAFLD and in the development of NASH. Iron may exacerbate insulin resistance; although iron overload is fairly common in NAFLD, its amount is rarely clinically significant when considered in isolation. A possible role of *HFE* mutations in NASH has been described in two studies from countries with predominantly Caucasian populations. However, this was not confirmed in subsequent studies of more heterogeneous populations. *HFE* mutations may be part of a genetic pattern

contributing to the progression of NASH in populations of Celtic origin.

IRON AND *HFE* MUTATIONS IN PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda (PCT) is the most common of the human porphyrias. It is caused by deficient activity of hepatic uroporphyrinogen decarboxylase. Most cases of PCT are acquired; the major risk factors are CHC, alcohol abuse, iron overload and oestrogen use. The familial form of the disease is observed in 20%-25% of patients^[4]. Both sporadic and familial PCT are iron-dependent disorders. The association of PCT with iron overload has been recognized for decades. Independent of the cause of liver disease, the majority of patients with sporadic PCT have biochemical evidence of iron overload, liver siderosis and increased body iron stores. However, hepatic siderosis is generally mild or moderate, reaching the lower end of the haemochromatosis range in less than 10% of cases^[153-154]. The causes of iron overload in patients with PCT appear to be heterogeneous. Indeed, altered iron status may be secondary to cofactors such as alcohol and chronic infection with HCV, that are frequently associated with sporadic PCT^[4]. Clinical and experimental data suggest that an iron-dependent process reversibly inactivates uroporphyrinogen decarboxylase^[155]. Indeed, as initially observed by Lundvall, venesection therapy may induce remission of cutaneous lesions and an improvement of liver function tests, whereas replenishment of iron stores leads to relapse^[156,157]. Phlebotomy may also be beneficial in patients without biochemical or histological evidence of iron overload^[157]. Altered iron homeostasis, even in the absence of systemic iron overload, could reduce uroporphyrinogen decarboxylase activity^[158].

Several studies have investigated the possible association between PCT and mutations of the *HFE* gene (Table 5). Investigators from UK reported that 44% of patients with PCT *vs* 11% of the control group carried the C282Y mutation, whereas no significant difference was found for the H63D mutation^[159]. Similar results were

reported by Stuart and colleagues in Australian patients and by Bonkovsky and colleagues in patients from North America^[160,161]. A detailed study comprising 108 US patients with PCT reported a C282Y frequency of 30% compared to 6% in controls^[162]. HIC, transferrin saturation and serum ferritin were highest in PCT patients who were homozygous for the C282Y mutation. The authors also reported a high frequency of comorbidity due to factors such as alcohol and hepatitis C. They concluded that homozygosity for the C282Y mutation and HCV infection, especially with heavy alcohol consumption, are the strongest risk factors for PCT. Martinelli and colleagues reported an association between C282Y and PCT with respect to controls (17.4% *vs* 4%) in a population of Southern European ancestry^[143]. Similar results were obtained in two studies of French patients^[164,165]. In a large study of 190 sporadic PCT cases from Germany the C282Y and H63D mutations were found in 39% and 45%, respectively^[166]. C282Y was significantly more frequent in patients than controls. Serum iron, transferrin saturation, ferritin concentration, HIC and liver enzymes did not differ significantly between patients with or without *HFE* mutations. Investigators from South Africa determined the frequency of *HFE* mutations in a racially-mixed group of patients with PCT in Cape Town^[167]. They found that both the C282Y and H63D mutations were highly prevalent in South Africans of European origin. In cases of mixed or Asian origin, the H63D mutation was common but the C282Y mutation was very rare. Neither mutation was found in any African subject. They concluded that both mutations were associated with PCT, but the association was dependent on the ethnic origin of the patient. Interestingly, one study from Italy reported a strong association of PCT with the H63D mutation, which was present in half of the patients. The presence of the H63D mutation was not related to the iron status of patients. However, a subtle abnormality of iron metabolism induced by this mutation could escape detection by the standard parameters of iron status^[168]. Some major factors may account for some differences between these studies. Firstly, the C282Y mutation is more frequent in cases of Celtic ancestry, although the prevalence of this mutation appears to be lower in Southern European countries^[9,11]. Secondly, the distribution of factors predisposing for PCT also shows relevant geographical differences. In Italy and other Mediterranean countries, hepatitis C is present in 70%-90% of PCT patients while it is rare in Northern European countries, where alcohol is the prevalent aetiological agent for CLD associated with PCT^[169]. Stolzel and colleagues investigated the relationship between *HFE* gene mutations and response to chloroquine in PCT patients^[170]. Chloroquine therapy was accompanied by clinical remission and reduced urinary porphyrin excretion in 39% of patients without *HFE* mutations versus 56% of *HFE* heterozygous patients. Interestingly, all patients homozygous for the C282Y mutation had high serum iron, transferrin saturation and serum ferritin concentration, and failed to respond to chloroquine treatment.

In conclusion, PCT is frequently associated with elevated serum iron indices and sometimes with hepatic iron overload. The pathogenesis of altered iron

homeostasis in PCT is not completely understood, although iron is thought to reduce the activity of uroporphyrinogen decarboxylase. Venesection therapy may be beneficial in PCT patients. Several cofactors have been proposed to play a role in the impairment of iron homeostasis observed in PCT, such as alcohol and CHC. A role of *HFE* mutations has also been reported. The available data support a role for the C282Y mutation in many cases of PCT, especially the C282Y homozygous genotype. This is particularly true in Celtic ancestry cases, thus confirming that the importance of *HFE* mutations as modifiers of disease varies according to the ethnic group. Most studies did not detect a relationship between *HFE* mutations and serum and hepatic iron overload. This suggests that *HFE* mutations, particularly C282Y, may contribute to the pathogenesis of PCT either through immunological mechanisms that could be iron-independent, or via subtle changes in hepatic iron metabolism that may act in concert with other co-factors to inhibit the activity of uroporphyrinogen decarboxylase.

IRON AND *HFE* MUTATIONS IN HEPATOCELLULAR CARCINOMA OCCURRING IN CLDS OTHER THAN HH

HCC is a common cause of death in patients with compensated cirrhosis^[171]. European studies have reported HCC as the cause of liver-related deaths in 54%-70% of cases of compensated cirrhosis of varied aetiology and in 50% of cases with cirrhosis due to HCV^[172]. The annual incidence of HCC in patients with liver cirrhosis has been estimated at 3%-5%^[173,174]. Thus, it is important to identify patients at high risk of HCC, to increase the rate of early detection. Several risk factors for the development of HCC have been identified in Western patients with cirrhosis, including male sex, age, persistently raised serum α -fetoprotein levels, severity of cirrhosis and genetic background^[173]. A possible carcinogenic role for iron has been suggested by *in vitro* studies. Iron may promote cellular oxidative stress through the production of reactive oxygen species. These have the potential to cause lipid peroxidation as well as damage to other cellular components, including proteins and nucleic acids^[151]. *In vitro* studies showed that iron can reduce the levels of two systems that normally protect against reactive oxygen species, vitamin E and superoxide dismutases^[175-176]. Furthermore, *in vivo* studies in mammals showed that tumor growth is enhanced by iron supplementation and inhibited by iron deficiency^[175,177]. Finally, neoplastic cells highly express TfR1 and can synthesize their own transferrin^[177].

Apart from the experimental evidence, the role of iron in the step by step process that leads to HCC in CLDs other than HH is controversial. A report of 133 cases by Boige and colleagues did not find any difference in the grade of hepatic iron staining between cirrhotic patients with and without HCC^[178]. This finding was also in keeping with a previous study where no significant relationship was observed between the hepatic iron score and the occurrence of HCC in alcoholic and HCV-related

cirrhosis^[179]. A role of *HFE* mutations as part of a genetic pattern promoting carcinogenesis has been evaluated in some studies, with somewhat discordant results. In a German study, C282Y heterozygosity was significantly more common in 137 HCC cases with no history of HH versus 107 cirrhotic patients without HCC and 126 healthy controls. C282Y heterozygote HCC patients had significantly increased hepatic iron score in both HCC and non-tumorous tissue^[180]. Other studies reported that the prevalence of C282Y heterozygosity was increased above control levels in patients with HCC and alcoholic and virus-related liver disease^[129,182]. An excess of the C282Y mutation, mostly in the heterozygous genotype, has also been reported in patients with HCC developed in non cirrhotic liver. In that study, Blanc and colleagues showed that mild iron overload is frequent (54%) and that in patients with HCC in non cirrhotic liver and iron overload, C282Y mutations are frequent (36.8% of cases) and significantly increased compared to HCC in non cirrhotic liver without iron overload^[183]. In contrast with the above results, some studies did not find a relationship between HCC and mutations in the *HFE* gene. Cauza and colleagues evaluated the prevalence of *HFE* mutations in patients with HCC developed on cirrhosis of viral and alcoholic aetiology. The authors found that, except for C282Y homozygotes, *HFE* mutations did not increase the risk of HCC in patients with cirrhosis^[184]. A prospective study of 133 consecutive cirrhotic patients without HH did not find an increased prevalence of *HFE* mutations in cirrhotic patients who developed HCC compared to cases without HCC^[178]. Similarly, a study from Italy found that in patients with HCC in the absence of HH, the frequency of *HFE* mutations was not increased, compared to the controls. The authors concluded that mutations of the *HFE* gene do not play a significant role in the pathogenesis of HCC^[185].

In conclusion, iron has a clear pathogenetic role in the development of HCC in HH. The carcinogenic role of iron is deduced to be mediated through production of reactive oxygen species leading to lipid peroxidation and damage of proteins, nucleic acids and other cellular components in hepatocytes. However, similar results have not been obtained for other CLDs. The available studies about the role of *HFE* mutations in HCC in liver diseases other than HH indicate that C282Y heterozygosity may play a role in liver iron deposition and could contribute to hepatocarcinogenesis, possibly by playing a part in the immunogenetic pattern of the patient or through subtle changes in iron metabolism acting together with other cofactors.

HIGHLIGHTS

Apart from HH, a number of CLDs cause hepatic iron overload. These include hepatitis C and B, alcoholic and nonalcoholic steatohepatitis and PCT. Secondary iron overload due to CLD presents with some clinical, histological and genetic differences with respect to HH. Since the occurrence of HH is clearly related to the presence of specific genetic patterns, the role of mutations

Table 6 Secondary iron overload: common features and differences

Common features	
1	Mixed distribution of hepatic iron (parenchymal and reticuloendothelial)
2	Mild to moderate iron overload in most cases, rarely severe iron overload
3	Phlebotomy possibly improves the course of disease and response to therapy
Differences	
1	C282Y: accepted role in PCT, possible cofactor in CHC and NAFLD (especially in populations of Northern European descent)
2	H63D: unclear role in NAFLD and PCT
3	No role for <i>HFE</i> mutations in ALD or CHB

PCT: porphyria cutanea tarda; CHC: chronic hepatitis C; NAFLD: non-alcoholic fatty liver disease; ALD: alcoholic liver disease; CHB: chronic hepatitis B; CLDs: chronic liver diseases.

of the gene most commonly responsible for HH has been investigated in liver diseases other than HH. Liver diseases that cause secondary iron overload share some common features, but they also show differences (Table 6). The evidence in the literature regarding secondary iron overload in comparison to HH are consistent in showing that: (1) in HH iron overload is widespread in many organs while in secondary iron overload due to CLDs, iron is confined to the liver; (2) in HH the histological distribution of iron is mostly parenchymal while in secondary iron overload due to CLDs, iron shows mostly a mixed distribution, with both reticuloendothelial and parenchymal localization; (3) point mutations in the *HFE* gene are the most common genetic factor underlying HH; their prevalence varies according to geographic area and ethnic group. In secondary iron overload, data are controversial. When present, the penetrance of *HFE* mutations may be more influenced by cofactors, since the aetiology of CLDs is multifactorial; (4) in HH, genetics is the “primum movens” of the disease while in secondary haemochromatosis it has been proposed as a cofactor that may increase the severity of disease expression. Evidence from the literature suggests that the C282Y mutation may play a role in NASH, PCT and possibly CHC in cases of Celtic ancestry. The importance of *HFE* mutations as modifiers of disease, therefore, varies between different ethnic groups. H63D has been reported by few authors as having a role in some cases of mild iron overload in NAFLD and PCT, although any effect is generally minor, in agreement with the findings in HH. *HFE* mutations do not seem to determine iron overload or to influence the course of ALD and CHB. Iron may contribute to the rate of response to antiviral therapy in CHC and to chloroquine in PCT and a positive influence of *HFE* mutations has been suggested in CHC.

Abstract

Non-HFE hereditary haemochromatosis (HH) refers to a genetically heterogeneous group of iron overload disorders that are unlinked to mutations in the HFE gene. The four main types of non-HFE HH are caused by mutations in the *hemojuvelin*, *hepcidin*, *transferrin receptor 2* and *ferroportin* genes. Juvenile haemochromatosis is an autosomal recessive disorder and can be caused by mutations in either *hemojuvelin* or *hepcidin*. An adult onset form of HH similar to HFE-HH is caused by homozygosity for mutations in *transferrin receptor 2*. The autosomal dominant iron overload disorder ferroportin disease is caused by mutations in the iron exporter ferroportin. The clinical characteristics and molecular basis of the various types of non-HFE haemochromatosis are reviewed. The study of these disorders and the molecules involved has been invaluable in improving our understanding of the mechanisms involved in the regulation of iron metabolism.

INTRODUCTION

After the identification of the *HFE* gene in 1996^[1] it became apparent that not all cases of haemochromatosis are caused by mutations in *HFE*. HFE-associated HH (HFE-HH) or type 1 HH is the most common form,

especially in populations of Northern European origin, where the C282Y mutation has a high allele frequency^[2]. Haemochromatosis that is unrelated to mutations in the *HFE* gene are collectively referred to as non-HFE haemochromatosis. Non-HFE haemochromatosis occurs in populations world wide and makes up a larger proportion of HH cases in areas where the C282Y mutation is less common, such as Southern Europe^[3] and Asia^[4]. Non-HFE HH can be further differentiated according to the gene mutated. There are four main types of non-HFE HH. The molecules mutated in all forms of HH are related in pathways involved in the regulation of iron homeostasis. Hpcidin the central regulator of iron homeostasis and hemojuvelin are mutated in juvenile or type 2 HH^[5,6]. Transferrin Receptor 2 is mutated in type 3 HH^[7] and the iron exporter ferroportin is mutated in the autosomal dominant type 4 HH or ferroportin disease^[8,9]. The genetic, clinical and laboratory features of the various types of HH are outlined in Table 1. This review will describe in detail the four main types of non-HFE HH and review the current literature in this area.

JUVENILE HAEMOCHROMATOSIS (TYPE 2)

An early onset form of juvenile haemochromatosis (JH), distinct from the typical HFE-HH has been recognised for some time^[10]. As with HFE-HH, JH or type 2 HH is an autosomal recessive disorder, and is characterised by elevated serum iron indices and iron deposition in parenchymal cells. JH usually presents before the age of 30 years and has a more rapid and severe course than HFE-HH. Unlike HFE-HH both sexes are affected equally^[10]. Cardiomyopathy and hypogonadism are more prominent features of JH, hypogonadism being the most common symptom at presentation^[11]. The rapid accumulation of iron in patients with JH can often be fatal, death usually resulting from heart failure^[11].

When the *HFE* gene was identified in 1996, it became apparent that JH was indeed a disorder genetically distinct from the typical HFE-HH. Linkage to the *HFE* gene region on chromosome 6 was ruled out, in a study utilising microsatellite markers in five Italian JH families^[12]. This was followed by a genome wide search that identified linkage to the chromosome 1q21 region in nine JH families. Subsequently a subset of families who did not have linkage to 1q21 were found to have mutations in the *hepcidin* (*HAMP*) gene on chromosome 19^[5]. This subset of JH has been termed type 2B HH and is described in more detail later. The chromosome 1 form of JH has been termed type 2A HH.

Table 1 Genetic, clinical and laboratory features of the various types of Hereditary Haemochromatosis

HH Type	Gene	Inheritance	Clinical features	Laboratory findings	Liver pathology	Functional consequences of mutations
1	<i>HFE</i>	Autosomal recessive	May include: fatigue, lethargy, arthropathy, skin pigmentation, liver damage, diabetes mellitus, endocrine dysfunction, cardiomyopathy, hypogonadotropic hypogonadism	↑ serum ferritin, ↑ transferrin saturation	Hepatocyte iron loading, fibrosis, cirrhosis	Impaired hepcidin regulation by iron, leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
2A	<i>Hemojuvelin (HJV)</i>	Autosomal recessive	As for HFE. Earlier onset (< 30 yr). Cardiomyopathy and hypogonadism more prevalent.	↑ serum ferritin, ↑ transferrin saturation	Hepatocyte iron loading, fibrosis, cirrhosis	Loss of hepcidin regulation, leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
2B	<i>Hepcidin (HAMP)</i>	Autosomal recessive	As for HFE. Earlier onset (< 30 yr). Cardiomyopathy and hypogonadism more prevalent.	↑ serum ferritin, ↑ transferrin saturation	Hepatocyte iron loading, fibrosis, cirrhosis	No/inactive hepcidin, leading to maximal iron absorption and release of iron from reticuloendothelial cells
3	<i>Transferrin Receptor 2 (TfR2)</i>	Autosomal recessive	As for HFE.	↑ serum ferritin, ↑ transferrin saturation	Hepatocyte iron loading, fibrosis, cirrhosis	Impaired hepcidin regulation by iron, leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells
4	<i>Ferroportin (Fpn), SLC40A1, IREG1, MTP1</i>	Autosomal dominant	Typical presentation: as for HFE, except generally milder. May have mild anaemia and lower tolerance to venesection. Atypical: as for HFE	↑ ↑ serum ferritin, normal transferrin saturation ↑ serum ferritin, ↑ transferrin saturation	Predominant Kupffer cell iron loading, fibrosis Predominant hepatocyte iron loading, fibrosis, cirrhosis	Reduced ferroportin iron transport ability, leading to accumulation of iron in reticuloendothelial cells Loss of ferroportin regulation by hepcidin, leading to increased intestinal iron absorption and release of iron from reticuloendothelial cells

HEMOJUVELIN-ASSOCIATED HAEMOCHROMATOSIS (TYPE 2A)

The gene responsible for the chromosome 1 form of JH was identified in 2004^[6]. Fine mapping of the JH locus was performed in 12 JH families of Greek, Canadian and French origin. Sequencing of genes in this region revealed a novel gene that was mutated in all affected individuals^[6]. The gene originally named *HFE2* encodes hemojuvelin (HJV), a protein with homology to the repulsive guidance molecule (RGM) family of proteins. Six mutations were initially identified in the affected individuals either in the homozygous or compound heterozygous state. One mutation G320V was present in nine of the 12 families^[6]. Since the identification of *HJV*, numerous mutations have been identified in JH families worldwide^[6,13-24]. An Italian study identified 16 more mutations among 34 JH patients from various European backgrounds^[13]. Figure 1 illustrates the structure of hemojuvelin and position of disease-causing mutations. Most mutations are private and were detected in single families. A few have been detected in more than one population. One mutation in particular (G320V) is significantly more frequent and has been reported in JH patients in many populations^[6,13,16-20,24].

Patients with HJV-HH were shown to have low levels of urinary hepcidin^[6]. This suggested that HJV may be involved in regulating hepcidin expression in response to iron. The generation of mouse knockouts confirmed that HJV was critical for the regulation of iron homeostasis and the induction of hepcidin^[25,26]. Recent studies have suggested that HJV regulates hepcidin expression through signalling pathways involving bone morphogenic proteins (BMPs)^[27].

HEPCIDIN-ASSOCIATED HAEMOCHROMATOSIS (TYPE 2B)

While most cases of juvenile haemochromatosis have been linked to a locus on the long arm of chromosome 1 (1q21) and mutations in *HJV*, a small number of families have been described with a JH-like disorder unlinked to 1q21^[28]. This subset of patients was found to have mutations in the *hepcidin (HAMP)* gene. Two consanguineous families of Italian and Greek origin were originally reported with linkage to a region on chromosome 19, encompassing the region containing the *hepcidin* gene^[5]. Homozygosity for mutations in the *hepcidin* coding sequence was detected in both families. One family harboured a one base pair deletion (93delG), causing a frameshift and an abnormal extended protein (T31fsX180). The other family carried a single base pair substitution (166C>T) causing the replacement of an arginine with a stop codon (R56X), in the predicted cleavage site for prohormone convertases. Both of these mutations severely affect the protein sequence and would result in the absence of any mature hepcidin peptide^[5].

Hepcidin mutations remain a rare cause of JH. However, since the first report, other cases and mutations have been described^[5,29-37]. Mutations described in the *hepcidin* gene are shown in Figure 2. These include mutations affecting two of the eight highly conserved cysteine residues (C70R and C78T), important for the complex disulphide bonded structure of mature hepcidin^[33-35]. A mutation in the 5'UTR of the *hepcidin* mRNA (-25G>A) has been described in two Portuguese families^[36,37]. This mutation creates a new initiation codon upstream from the original

ATG. Measurement of urinary hepcidin in a patient homozygous for this mutation, suggests that steady state transcription of *hepcidin* from the original ATG codon does take place. But there is loss of upregulation of *hepcidin* transcription in response to iron^[37]. In another study it was shown *in vitro* that the out of frame upstream initiation codon was functional and prevented normal transcription from the original ATG^[38].

DIGENIC INHERITANCE AND MODIFIERS OF HFE

The remaining mutations in *hepcidin* have been detected in the heterozygous state in patients carrying *HFE* mutations. Merryweather-Clarke *et al*^[29,30] described patients with haemochromatosis who carried mutations in both *HFE* and *hepcidin*. One patient carried a four base pair deletion in *HAMP* (Met50del IVS2+1(-G)) and had a JH-like phenotype. Another family carried the G71D mutation in combination with either heterozygous or homozygous C282Y, and adult-onset iron overload. This was the first description of iron overload due to digenic inheritance of mutations in two separate genes. Two studies have detected *hepcidin* mutations in large cohorts of patients with HFE-HH. Jacolot *et al* detected *HAMP* mutations in five individuals from a cohort of 392 C282Y homozygotes and found that these were among the more iron-loaded. In addition, four of 31 subjects with iron overload, but at least one chromosome lacking an *HFE* mutation also carried a *HAMP* mutation. This supports the concept that digenic inheritance of *HFE* and *HAMP* mutations can lead to iron overload. Biasiotto *et al*^[30] also screened for *hepcidin* mutations in iron overload patients carrying the C282Y allele and detected sequence variations in some. They concluded that a novel substitution in the *hepcidin* promoter (-72C>T) may aggravate iron loading in patients with *HFE* mutations.

HJV mutations have also been detected in patients with HFE-HH. Two studies suggested that heterozygosity for *HJV* mutations may aggravate the phenotype in HFE-

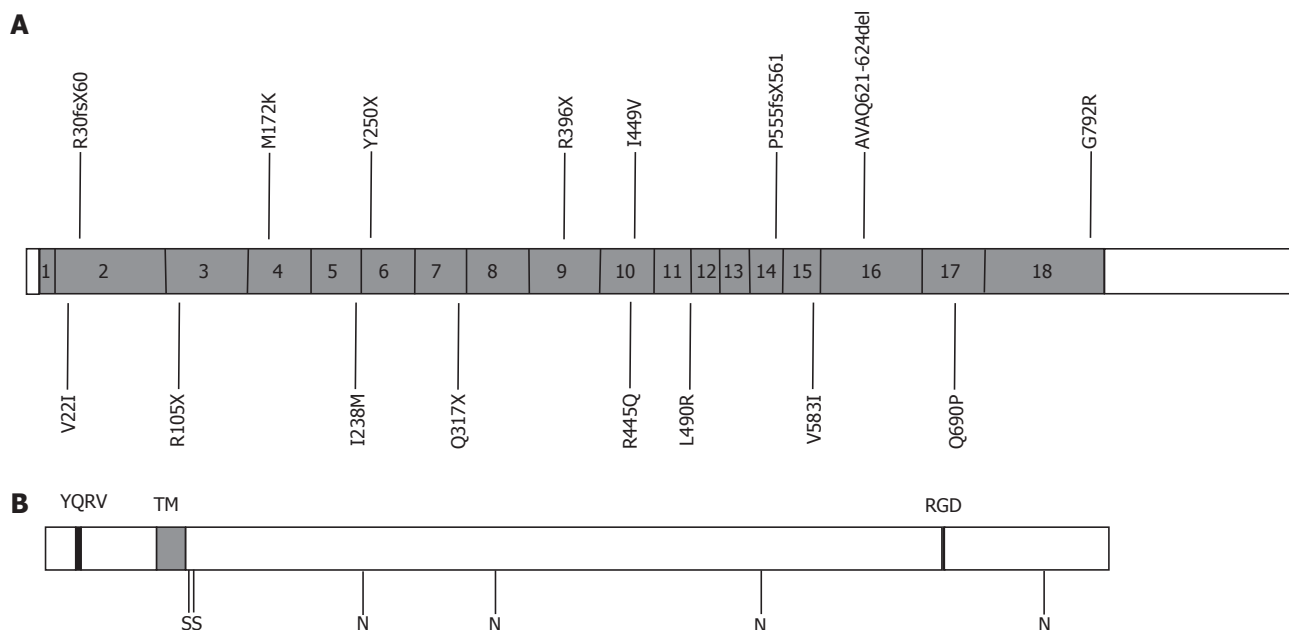

Figure 3 Structure of human transferrin receptor 2 (TfR2) and positions of mutations. **A:** The exon structure of human *TfR2* is shown with positions of known mutations marked^[7,30,40-52]. The frameshift mutations R30fsX60 and P555fsX561 are also known as E60X and V561X respectively. G792R may be associated with R396X; **B:** Predicted structure of TfR2 protein. YQRV, endocytosis signal; TM, transmembrane domain; RGD, RGD motif; S, predicted interchain disulphide bonds; N, potential N-linked glycosylation sites.

HH^[30,39]. Le Gac *et al.*^[39] reported nine of 310 C282Y homozygous patients with additional *HJV* mutations. Eight of the nine patients appeared to have a more severe phenotype, suggesting that heterozygosity for mutations in *HJV* were having a modifying effect. A similar effect of *HJV* mutations was reported by Biasiotto *et al.*^[30], the N196K mutation being associated with abnormally high iron indices in a C282Y/H63D compound heterozygote. The effect of *HJV* mutations on phenotypic expression of HFE-HH is small, and has not been detected in all studies. Lee *et al.*^[24] did not detect any *HJV* mutations in a group of 49 C282Y homozygotes. Wallace *et al.*^[7] reported a G320V heterozygous relative of a JH patient, who was also a C282Y/H63D compound heterozygote, but with normal iron indices.

TRANSFERRIN RECEPTOR 2-ASSOCIATED HAEMOCHROMATOSIS (TYPE 3)

Transferrin Receptor 2 (TfR2)-HH was first described in 2000^[7]. This was the first HH syndrome to be attributed to non-HFE mutations. Mutations in *TfR2* were first detected in six members of two Sicilian families. The defect was linked to a region on the long arm of chromosome 7 (7q22), and affected individuals were found to be homozygous for a nonsense mutation (Y250X) in *TfR2*^[7]. Affected individuals had iron overload with a similar phenotype to HFE-HH. TfR2-HH is a rare condition; however, several mutations have been reported worldwide associated with haemochromatosis^[7,30,40-52]. Mutations reported in *TfR2* are illustrated in Figure 3.

TfR2 is a homologue of the classical transferrin

receptor (TfR1)^[53], the molecule responsible for the uptake of transferrin-bound iron into cells. Unlike the ubiquitous expression of TfR1, TfR2 expression and activity is restricted almost exclusively to the liver^[54]. Rather than being involved in the uptake of transferrin bound iron, it appears that the main function of TfR2 is as a sensor of iron levels and regulator of hepcidin. In both patients and animal models with TfR2-HH hepcidin levels are low in relation to iron stores^[55-57].

The clinical features of TfR2-HH resemble that found in HFE-HH. Onset is usually in adulthood and is associated with increased serum iron indices and iron accumulation in parenchymal cells. Clinical features reported in patients with TfR2-HH include abnormal liver function, liver fibrosis, cirrhosis, arthritis, diabetes, hypogonadism, cardiomyopathy and skin pigmentation^[41,44]. All of these features are typical of HFE-HH. A direct comparison of phenotype between HFE-HH and TfR2-HH is difficult, due to the low prevalence of *TfR2* mutations and small number of reported cases. It appears, however, that TfR2-HH may have a more severe phenotype. Early onset of disease has been reported in a number of cases. Two adolescent siblings homozygous for the R105X mutation were reported with elevated transferrin saturation^[51]. However, the serum ferritin in both cases was normal and liver biopsy was not performed. Two unrelated cases, presenting at ages 3 and 16 years were reported, homozygous for the Y250X mutation^[40]. Both had raised serum iron, transferrin saturation and hepatic iron. The 16-year-old, who presented with fatigue, also had raised serum ferritin. Other cases suggestive of an earlier onset and more severe phenotype than HFE-HH have also been reported^[42, 44].

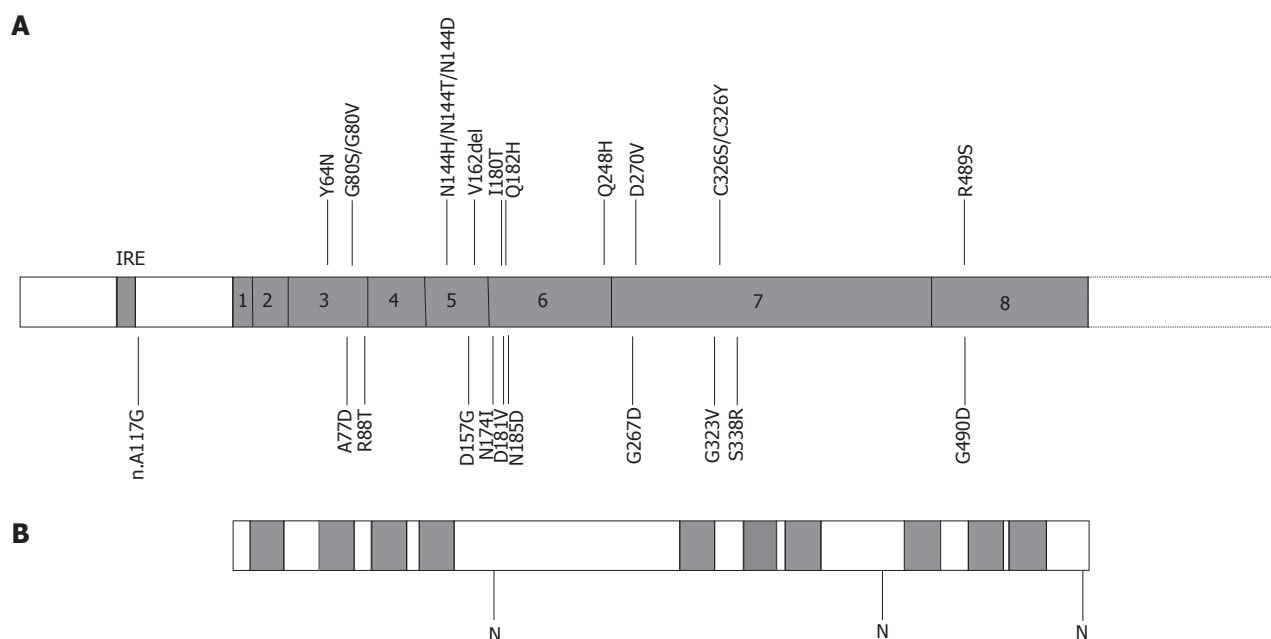

Figure 4 Structure of human *ferroportin* and positions of mutations. **A:** The exon structure of human *ferroportin* is shown with positions of known mutations marked^[8,9,60-85]. IRE, iron response element; **B:** Predicted structure of *ferroportin* protein. Predicted transmembrane domains are shaded; N, potential N-linked glycosylation sites.

Pietrangelo *et al*^[52] recently reported an unusual family with both adult and juvenile onset haemochromatosis. Two siblings presented in their early twenties with features typical of JH. These included hypogonadotropic hypogonadism, cardiomyopathy and cirrhosis. Both were found to be homozygous for a mutation Q317X in *TfR2*. In addition compound heterozygosity for *HFE*-C282Y/H63D was also present. A brother who had a less severe adult onset phenotype was homozygous for the Q317X *TfR2* mutation, but had wild type *HFE* sequence. This is the first and only report of juvenile haemochromatosis due to mutations in two genes normally associated with adult-onset haemochromatosis^[52]. This observation suggests that defects in either *HFE* or *TfR2* can be compensated to some extent by the other. Homozygosity for mutations in either one can lead to appreciable iron overload with onset normally in adulthood. The combination of mutations in both genes has an additive effect on iron loading, leading to an earlier onset and JH-like phenotype. Both *HFE* and *TfR2* are thought to regulate hepcidin expression in the liver through as yet unidentified signalling pathways. It is possible that *HFE* and *TfR2* work through either parallel or converging signalling pathways resulting in the induction of hepcidin. This would explain why the loss of one can be compensated to some extent by the other. The loss of both, however, would lead to complete loss of regulation of hepcidin by iron, as occurs in JH. Further studies will be needed to clarify the relationship between *HFE* and *TfR2*, and the signalling pathways they are involved in.

FERROPORTIN DISEASE

Ferroportin disease differs from other genetic iron overload disorders in that it is inherited in an autosomal dominant pattern. An autosomal dominant form of

haemochromatosis was first reported in 1990, in a Melanesian pedigree from the Solomon Islands^[58]. In a large 96 member pedigree, 31 of 81 members tested were affected in at least three generations. All affected individuals had raised transferrin saturation and serum ferritin levels. Liver biopsies in 19 individuals showed a pattern of iron staining consistent with *HFE*-HH, with iron present in hepatocytes and Kupffer cells. Some degree of fibrosis or cirrhosis was present in the majority of cases. This study was performed before the identification of the *HFE* gene; hence, analysis of *HFE* mutations could not be performed. However, linkage to the *HFE* locus on chromosome 6 was excluded, by HLA typing of affected and non-affected family members^[58]. Another large pedigree with multiple affected individuals, but without pathogenic mutations in the *HFE* gene was described in 1999^[59]. This Italian family consisted of 53 living members, with 15 affected across three generations. Linkage to the *HFE* region on chromosome 6 was excluded by typing of microsatellite markers.

Mutations in *ferroportin*, associated with autosomal dominant haemochromatosis were first described in 2001. An asparagine to histidine mutation (N144H) was identified in a large multi-generation family from the Netherlands^[9]. At the same time an alanine to aspartate mutation (A77D) was reported in the large Italian pedigree described previously^[8]. Since these first reports, many more *ferroportin* mutations have been described in association with autosomal dominant haemochromatosis^[60-85]. Figure 4 shows the mutations reported in the literature to date. *Ferroportin* mutations have been reported in populations throughout the world. Most of the reported *ferroportin* mutations are private and restricted to single families. Some mutations, however, are more common and have been reported in diverse populations. The most prevalent is the deletion of one of a group of three valine residues

(V162del). This mutation has been reported in families from Australia, the UK, Italy, Greece, Sri Lanka and Austria^[61-66]. It has been proposed that this mutation has occurred independently, several times, due to slippage mispairing in a repeat sequence. Other mutations reported in multiple populations include A77D (Italy and Australia)^[8,60] and Q248H^[75-79]. It is unclear whether Q248H is a mutation or polymorphism. It has been reported at high frequencies in African and African-American populations, in both controls and individuals with iron overload, where it can occur in the heterozygous or homozygous state. There is suggestive evidence that it may contribute to slightly higher serum ferritin levels^[76-79], but this effect is very small compared to other *ferroportin* mutants. There are three mutations affecting asparagine 144, suggesting that this residue is important for the functioning of ferroportin. In the original Dutch family reported by Njajou *et al*^[9], it was mutated to a histidine (N144H)^[9], in an Australian family to an aspartate (N144D)^[71] and in a Solomon Island patient to a threonine (N144T)^[67]. Whether this mutation is responsible for the autosomal dominant Solomon Island iron overload syndrome reported by Eason *et al*^[58], remains to be determined.

The phenotypic features of most cases of ferroportin disease differ significantly from that of HFE-HH. The typical features are an early elevation in serum ferritin, with normal transferrin saturation, and iron accumulation preferentially in the Kupffer cells of the liver. With increasing age, iron stores increase, and iron is seen in hepatocytes as well as Kupffer cells, and the transferrin saturation can be elevated. In these cases liver damage is minimal, with fibrosis occurring in some individuals. Venesection therapy is not always tolerated, with anaemia developing, especially in early cases when the transferrin saturation is low. It is now apparent that some cases of ferroportin disease differ from this typical pattern. A second atypical phenotype has been proposed, with features that more closely resemble HFE-HH. Atypical features include an early rise in transferrin saturation, and iron accumulation preferentially in hepatocytes, with some Kupffer cell iron apparent in some cases. Venesection therapy in these cases is usually tolerated well, but liver damage would appear to be more prevalent, with two reports of cirrhosis^[71,80].

The heterogeneity of ferroportin disease has led to the suggestion that mutational differences account for the phenotypic variation observed in patients. In general each mutation can be classified as leading to either the typical or atypical ferroportin disease phenotype. It has been proposed that particular mutations affect the function of ferroportin in different ways. The *ferroportin* gene, also referred to as *IREG1*, *MTP1*, *SLC11A3* and *SLC40A1*, encodes a multiple transmembrane domain iron transporter, highly expressed in duodenum, liver and reticuloendothelial cells. It is responsible for iron transport across the basolateral surface of enterocytes into the blood and recycling of iron in the reticuloendothelial system. Mutations such as A77D and V162del lead to the typical phenotype of reticuloendothelial iron storage, with relatively low transferrin saturation. A non-functional

ferroportin molecule would be predicted to lead to this phenotype. Heterozygosity for a non-functional mutant would be predicted to lead to haploinsufficiency for ferroportin, with only half the amount of functional ferroportin present on the surface of cells at any one time. In the reticuloendothelial system, where the vast majority of daily iron turnover occurs, this would be predicted to cause a blockage in the release of iron back into the circulation. Hence, iron would accumulate in the reticuloendothelial macrophages, and serum iron concentrations would be relatively low. These low levels of circulating iron would in turn lead to an increase in iron absorption in the duodenum, possibly involving sensors in the liver, such as HFE and Tfr2 and signalling *via* the hepcidin pathway. The turnover of iron in the reticuloendothelial system far outweighs that in the duodenum. Hence, the ferroportin required to transport iron across the basolateral surface of enterocytes would probably be sufficient to transport more iron into the body, even if a non-functional mutant was present. Over a long period of time body iron stores would increase to a point where the capacity of the reticuloendothelial cells to store iron would be reached, and iron would accumulate in parenchymal cells such as hepatocytes. This is seen in advanced typical ferroportin disease and is usually accompanied by an increase in the transferrin saturation.

It was recently reported that ferroportin expression on the cell surface can be regulated by hepcidin^[86]. It was shown that hepcidin could bind to ferroportin on the cell surface and induce its internalisation and degradation. In this way hepcidin could rapidly reduce iron absorption in the intestine and release of iron from the reticuloendothelial system, resulting in a reduction in serum iron. It has been proposed that the mutations which cause the atypical ferroportin disease phenotype affect the ability of hepcidin to internalise ferroportin. Failure to internalise would lead to a permanently “switched on” ferroportin molecule. This would lead to increased iron absorption in the duodenum and release from reticuloendothelial cells, resulting in high serum iron levels and storage of iron in parenchymal cells. Having a permanently “switched on” ferroportin molecule would effectively be the same as having hepcidin deficiency, as they both result in the same end point. This explains why the atypical form of ferroportin disease phenotypically resembles other forms of haemochromatosis, which all result from hepcidin deficiency.

CONCLUSION

There are four main genes implicated in non-HFE haemochromatosis. Mutations in these genes occur in populations world wide and account for the majority of HH cases not linked to HFE. The study of these disorders has led to a greater understanding of how the body regulates iron homeostasis. All the genes implicated in the different forms of haemochromatosis are involved in the regulation and maintenance of iron homeostasis. Hepcidin is at the centre of the iron regulatory pathway. Its expression in the liver can be regulated by the activities of HFE, Tfr2 and HJV. Hepcidin itself can regulate the activity of the iron

exporter ferroportin. Mutations in any one of these genes can disrupt the regulation of iron homeostasis and lead to iron overload. Further study of these molecules, their relationships to each other, and signalling pathways they are involved in will further illuminate our understanding of iron metabolism and its regulation.

Abstract

There are several cofactors which affect body iron metabolism and accelerate iron overload. Alcohol and hepatic viral infections are the most typical examples for clarifying the role of cofactors in iron overload. In these conditions, iron is deposited in hepatocytes and Kupffer cells and reactive oxygen species (ROS) produced through Fenton reaction have key role to facilitate cellular uptake of transferrin-bound iron. Furthermore, hepcidin, antimicrobial peptide produced mainly in the liver is also responsible for intestinal iron absorption and reticuloendothelial iron release. In patients with ceruloplasmin deficiency, anemia and secondary iron overload in liver and neurodegeneration are reported. Furthermore, there is accumulating evidence that fatty acid accumulation without alcohol and obesity itself modifies iron overload states. Ineffective erythropoiesis is also an important factor to accelerate iron overload, which is associated with diseases such as thalassemia and myelodysplastic syndrome. When this condition persists, the dietary iron absorption is increased due to the increment of bone marrow erythropoiesis and tissue iron overload will thereafter occurs. In porphyria cutanea tarda, iron is secondarily accumulated in the liver.

INTRODUCTION

In hereditary hemochromatosis, patients having HFE trait are more susceptible to iron overload when cofactors such as alcohol, hepatitis viruses, and abnormal porphyrin metabolism are present. Even in the absence of hereditary hemochromatosis, there are several conditions associated with secondary iron overload in which iron deposition is rather mild^[1]. For example, in alcoholics and patients with chronic hepatitis C, intrahepatic iron is increased and liver injury is accelerated, followed by development of fibrosis, cirrhosis and hepatocellular carcinoma (HCC). In addition, abnormal copper metabolism and several causes for iron-loaded anemia are also important cofactors which influence the background iron overload. Furthermore, there is accumulating evidences that fatty acid accumulation without alcohol and obesity itself modifies insulin resistance through iron^[2] and fibrogenesis of the liver^[3]. In this review, the role of cofactors on iron overload will be discussed in three categories such as alcohol, hepatitis C virus infection and steatosis with obesity, the most common cofactors in liver iron overload.

COFACTORS AFFECTING BODY IRON METABOLISM AND IRON OVERLOAD

There are several factors which affect body iron metabolism and accelerates iron overload. Table 1 lists cofactors and disease conditions which are known to accelerate hepatic iron accumulation independent from responsible genes for hereditary hemochromatosis. Alcoholic and hepatic viral infections are the most typical examples for clarifying the role of cofactors in iron overload. In addition, abnormal copper metabolism and several causes for iron-loaded anemia such as thalassemia and myelodysplastic syndrome are also important factors which influence the background iron overload. When this condition persists, the dietary iron absorption is increased due to the increment of bone marrow erythropoiesis^[4] and tissue iron overload will occur thereafter. These patients are usually anemic in spite of increased body iron stores (iron-

loaded anemia), and require frequent blood transfusions, which further exaggerate secondary iron overload, in which conditions of **new oral iron chelators are effective**^[5]. In patients with ceruloplasmin deficiency, anemia and secondary iron overload in liver and neurodegeneration are reported^[6]. Furthermore, there are accumulating evidences that fatty acid accumulation without alcohol and obesity itself modifies iron overload states. Ineffective erythropoiesis is also an important factor to accelerate iron overload. This condition is associated with diseases such as thalassemia, aplastic anemia, and myelodysplastic syndrome. In porphyria cutanea tarda, iron is secondarily accumulated in the liver and phlebotomy and oral iron chelators are effective as well as in hemochromatosis.

ALCOHOL

Alcohol is one of the most important cofactors to modify or enhance iron accumulation in the liver. Excess intake of alcohol induces alcoholic liver diseases (ALD) such as fatty liver, fibrosis, hepatitis, and cirrhosis, in which iron overload is frequently associated^[7]. By **Perls' iron stain**, excess iron accumulation was found in hepatic tissues with ALD, but not in any normal hepatic tissues^[8]. In ALD, iron is deposited in both hepatocytes and reticuloendothelial (Kupffer) cells. In advanced cases of ALD, which is also called as "alcoholic siderosis", the reticuloendothelial iron deposition is dominant. In earlier stages of ALD such as fatty liver and fibrosis, iron deposition is mild and is preferentially present in hepatocytes **rather than in** Kupffer cells, which finding is more frequently observed in Japanese patients who have mild clinical phenotype comparing with those in US^[9].

The **reactive oxygen species (ROS) produced play** an important role in the development of ALD^[10]. The expression of 4-hydroxy-2-nonenal (HNE)-protein adducts, which is a lipid peroxidative product is **increased** in oxidized hepatocytes^[11]. Chronic alcohol ingestion in experimental animals is associated with oxidative stress as reflected by increased hepatic levels of lipid peroxidation products such as malondialdehyde and HNE, both of which have been implicated in hepatic fibrogenesis in the intragastric ethanol infusion model^[12]. Furthermore, lipid peroxidation products induce gene expression of procollagen α -1 (I) and increase collagen production by several folds in cultured hepatic stellate cell^[13]. In human ALD, there is a positive correlation between iron deposition and histological intensity of HNE-protein adduct^[14]. As shown in Figure 1, the **distribution of** HNE-protein adducts and iron granules appeared to be

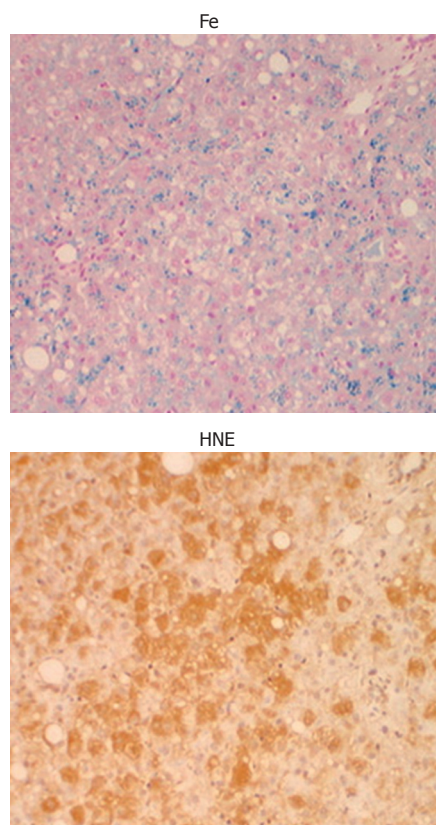

Figure 1 Iron staining and immunohistochemical staining of 4-hydroxy-2-nonenal-modified protein (HNE-protein) adducts in human alcoholic liver disease. The localization of HNE-protein adducts and iron in hepatocytes appeared to be identical (from ref. 14 with some modifications).

identical, suggesting that iron may be associated with the production of HNE-protein adduct. As hepatic iron is **visualized by Perls' reaction as an insoluble protein-bound iron** such as hemosiderin, this form of iron may be inactive for the production of ROS. But, the free iron responsible for Fenton reaction should be present close to the protein-bound iron, and may be involved in the production of HNE-protein adducts. There are two pathways to generate ROS through ethanol metabolism. Oxidation of ethanol by alcohol dehydrogenase to form acetaldehyde, which is subsequently oxidized to acetate and ultimately carbon dioxide and water. During the oxidation process of acetaldehyde involving aldehyde oxidase and xanthine oxidase, superoxide (O_2^-) is produced^[15]. In addition, cytochrome P450 is involved in the metabolism of ethanol, in which ROS are also generated in microsomes^[16]. Among ROS, hydroxy radical (OH) is most potent, which is produced via Fenton reaction in the presence of free iron and the resulted OH can easily cause **cell damage by oxidizing lipid, proteins, and nucleic acids**. In an intragastric infusion mouse model of ALD, supplementation of carbonyl iron advanced peri-venular fibrosis to bridging fibrosis and cirrhosis^[17]. **Oxidative stress arising from hepatocytes and macrophage activates** hepatic stellate cells by increasing the production of cytokines such as transforming growth factor- β (TGF β), directly or indirectly. The **dietary iron supplementation was** associated with increased NF- κ B activation^[18], and the up

regulation of NF- κ B responsive proinflammatory genes such as IL-1 β , TNF α , and MIP-1^[19].

In advanced cases of ALD, iron is accumulated more prominently in Kupffer cells than in hepatocytes, mainly due to repeated endotoxemia and hyper-cytokinemias of TNF α and IL-1 β ^[20]. These cytokines induced hepatic uptake of transferrin iron *in vitro*^[21] and *in vivo*^[22]. In mild cases of ALD, iron is preferentially stained in hepatocytes, rather than in Kupffer cells, suggesting that hepatocyte is the main site of early iron storage in the liver. However, it is not clear why iron is accumulated in liver parenchymal cells of alcoholics in such conditions. Two possibilities can be drawn: one is the increased uptake of iron in hepatocytes, and another is the increased iron absorption through hepcidin, which is a newly found antimicrobial peptide, and is a negative regulator of iron absorption and reticuloendothelial iron releases^[23]. Hepatocytes have several pathways for iron uptake. Iron in serum is usually bound to transferrin and iron-bound transferrin is taken up via transferrin receptor (TfR) with high affinity or via other unknown mechanism with greater capacity, but low affinity independent of high affinity receptor^[24]. There are two molecules of transferrin receptor: transferrin receptor 1 (TfR1) and transferrin receptor 2 (TfR2). TfR1 has a high affinity to serum transferrin and considered to be functional, while the function of TfR2 is not clear yet, even though the TfR2 gene is responsible for genetic hemochromatosis^[25]. In normal hepatocytes, TfR2 is constitutively expressed. But, TfR1 is down-regulated, suggesting that TfR1 does not contribute to the steady state hepatic iron uptake. Recently, Wallace *et al*^[26] reported that homozygous TfR2 knockout mice had no TfR2 associated with typical iron overload, and there was no upregulation of hepcidin mRNA, suggesting that TfR2 is required to iron regulated expression and is involved in a pathway to HFE and hemojuvelin. In addition, DMT1 may be involved when serum iron concentration exceeds transferrin iron binding capacity^[27]. It is noteworthy that TfR1 is regulated by cellular iron levels or oxidative stresses post-transcriptionally and it is possible that ethanol may augment TfR1 expression by producing oxidative stresses. According to immunohistochemical investigation, TfR1 expression was increased in hepatocytes in 80% of hepatic tissues with ALD, but was not detected in any normal hepatic tissues^[28]. It is noteworthy that the mean duration of abstinence of patients who demonstrated positive TfR1 expression in hepatocytes was significantly shorter than that of patients who demonstrated negative TfR1 expression.

Ethanol exposure in the presence of iron to the primary cultured-hepatocytes demonstrated an increase of TfR expression, and this augmentation was suppressed by the inhibitor of alcohol dehydrogenase, 4-methoxy pyrazole, but enhanced by a inhibitor of acetaldehyde dehydrogenase, cyanamide, suggesting that ethanol metabolite acetaldehyde itself is involved for the induction of TfR1 by ethanol^[29]. By functional uptake assay using ⁵⁹Fe-transferrin, the additional ethanol exposure increased transferrin-iron uptake into hepatocytes, while non-transferrin-bound iron (NTBI) uptake^[30] was not increased. It has been reported that TfR1 expression was

Table 2 Speculated effects of iron on HCV

1	Immunological modification (Immunological escape of HCV)
	Decrease of Th1 activity
	Impaired function of macrophage and Kupffer cells
	Decrease of innate immunity (Natural resistance macrophage protein 2)
2	Increase of liver toxicity by iron-mediated radical formation
	Reactive oxygen production through fenton reaction
	Induction of apoptosis
	Acceleration of fibrinogenesis
	DNA damage and carcinogenesis
3	Effect on cell signalling
	Decrease of interferon responsiveness by NF κ B activation
4	HCV proliferation
	Activation of translation initiation factor 3 (eIF3)
	Suppression of HCV RNA polymerase (NS5B) activity

up-regulated both transcriptionally^[31] and posttranscriptionally^[32]. This regulation is induced either by iron deficiency state or oxidative stress such as H₂O₂ and nitric oxide via iron regulatory protein, IRP^[33]. In addition to the direct cell toxicity, acetaldehyde produces free radicals^[34] and free radicals modify IRP activity^[35,36].

Body iron homeostasis is strictly regulated by a balance between the processes such as dietary iron absorption in enterocytes, iron transport by transferrin in circulation, iron utilization and storage in bone marrow and liver. The increase of intestinal iron absorption was one of the mechanisms of the hepatic iron deposition in alcoholics^[37]. In patients with hereditary hemochromatosis, serum pro-hepcidin is lower than that of normal controls, suggesting that iron absorption is increased in spite of high iron storage^[38]. It is speculated that down-regulation of hepcidin might be one of important factors for pathogenesis of iron overload in ALD^[39]. Serum pro-hepcidin concentration in ALD was significantly lower than that in healthy subjects, and pro-hepcidin/ferritin ratios in ALD were lower than healthy subjects^[40]. In the ethanol-loaded mouse model which has a mild steatotic change, the hepcidin mRNA and protein expression were significantly lower than that of control. In addition, alcohol-loading might disrupt the sensing signal of inflammatory cytokines, and then down-regulate hepcidin expression, following the increased iron absorption from small intestine. Recently, the mechanism of hepcidin downregulation by alcohol has been elucidated: a decreased hepcidin expression in mouse liver is accompanied with an increase of DMT1 and ferroportin1, and a decrease of hepcidin promoter activity and DNA-binding activity of CCAAT/enhancer-binding, protein α (C/EBP α)^[41].

HEPATITIS C VIRUS INFECTION

Hepatitis C virus infection is one of the most common disorders in liver diseases involving chronic hepatitis, cirrhosis, and hepatocellular carcinoma (HCC). Table 2 summarizes the effect of iron on hepatitis C virus infection. In the Third National Health and Nutrition Examination Survey, HCV infection is significantly associated with higher serum levels of ferritin and iron in the US population^[42]. The mean serum levels of

ferritin and iron were significantly higher among subjects with HCV infection than among subjects without liver disease^[43]. In addition, serum ferritin levels were directly and significantly correlated with serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and γ -glutamyl transpeptidase, whereas platelet counts were inversely correlated with serum ferritin. It is also found that lipid peroxidative products such as malondialdehyde are increased in hepatic tissues with CH-C^[44]. In 1994, an initial report was published that phlebotomy was effective in improving the serum ALT level in patients with CH-C^[45] and a national prospective study confirmed the results^[46]. Since then, it was reported that hepatic iron accumulation in CH-C predict a response to interferon (IFN) therapy^[47], and phlebotomy before and during IFN therapy improved virological and histological response to short-term IFN therapy evaluated at the end-of-treatment^[48]. This observation is reasonable considering the finding that oxidative stress impairs interferon alpha signal by blocking JAK-STAT pathway^[49]. The standard therapy for hepatitis C is now a combined therapy of interferon- α and ribavirin, in which patients with viral response to treatment seemed to develop higher soluble transferrin receptor levels^[50] with decline in serum iron and ferritin than non-responders, revealing intracellular reduction of iron store depending on the result of treatment including hemolytic reaction by ribavirin^[51]. This is an interesting observation that decrease of iron status may be an additional effect of the combination therapy with interferon and ribavirin. Moreover, HFE mutations are also associated with increased sustained virologic responses by antiviral long-term treatment, while it is well known that HFE mutations are associated with increased iron loading^[52]. However, some reports suggest that iron depletion was unable to trigger interferon response, so that there are conflicting data. It should be further investigated whether hepatic iron content modify the response to interferon^[53,54].

From these observations, iron and related molecules seem to be key factors in the hepatocytes to influence the disease condition of CH-C, and also development of cirrhosis and maybe hepatocellular carcinoma. Clinical data on phlebotomy on CH-C generally indicates that phlebotomy does not influence the viral load in vivo. On the other hand, in vitro study on HCV replication is controversial: iron promotes HCV translation by up-regulating expression of the translation initiation factor eIF3 by reporter assay^[55], whereas iron suppresses HCV replication by inactivating the RNA polymerase NS5B^[56].

As previously described, hepatocytes have two iron uptake systems, transferrin-mediated and nontransferrin-bound iron-mediated pathway. Transferrin and TfR1 are molecules involved in the classical pathway of cellular iron uptake, but are faintly expressed in normal hepatocytes, and is down-regulated in iron-loaded hepatic tissues with hemochromatosis. Concerning the post-transcriptional regulation of TfR1, two mechanisms are postulated through the activity change of IRP which is already mentioned. In CH-C, TfR1 expression was up-regulated and DMT1 expression was down-regulated in the condition of hepatic excess iron accumulation, suggesting that regulation of DMT1 expression is iron-

dependent, but that of TfR1 expression is iron-independent in CH-C^[57]. In patients with CH-C, serum values of inflammatory cytokines such as IL-1 β , IL-6, and TNF α have been reported to be high in comparison with those in normal controls. In addition, TfR1 was up-regulated by IL-1 β , IL-6, and TNF α in HepG2. Administration of IL-6 augments hepatic uptake of transferrin-bound iron (⁵⁹Fe), and this is mainly mediated through hepatocytes, but not through Kupffer cells. These results suggest that the up-regulation of TfR1 expression in CH-C might be caused by increase of inflammatory cytokines that proceeded from HCV infection, although there is a possibility that the components of HCV themselves may induce TfR1 expression directly or indirectly.

Like wise, the up-regulated TfR1 might act as a key molecule for hepatic excess iron accumulation in CH-C; however, there are several candidate molecules which cause this condition. For instance, each mutant of HFE, TfR2, hepcidin, hemojuvelin and ferroportin1 (also known as Ireg1 or MTP1) with substitution of amino acid causes the similar phenotype of hemochromatosis. That is, these facts indicate that at least 5 molecules are involved in the familiar hemochromatosis^[58]. In hepatocytes, TfR2 predominantly expresses in the normal condition^[59] and the disruption of TfR2 gene caused the hepatic iron overload, a phenotype of hemochromatosis, suggesting that TfR2 should also have important role in hepatic iron metabolism^[60]. This receptor might act as a sensor of iron status because hepatic TfR2 protein level was increased in iron loaded rats and was decreased in iron deficient rats. Recently, Takeo *et al*^[61] reported that in CH-C TfR2 protein expression is increased parallel with ferroportin1, although the meaning of this TfR2 elevation is still to be elucidated^[62].

In addition, there was a significant correlation of hepcidin mRNA expression in the liver with hepatic iron concentration and serum ferritin, but did not correlate with ALT, AST, HAI, or viral load. In inflammatory conditions, hepcidin is regulated transcriptionally by IL-6^[63] and IL-1 β ^[64] independent of liver iron content. It is noteworthy that, in contrast to other inflammatory states, hepcidin mRNA expression in the liver was independent of markers of inflammation in hepatitis C, suggesting that iron stores in patients with hepatitis C regulate hepcidin expression, and that iron loading in chronic hepatitis C is not due to inappropriate hepcidin expression^[65]. However, there is still a controversial result concerning the hepcidin metabolism in chronic hepatitis C that serum pro-hepcidin is down-regulated^[66]. The role of hepcidin in chronic hepatitis C seems to need further consideration.

The role of iron on the hepatocellular carcinoma (HCC) development in patients with chronic hepatitis C is another major concern. In primary hemochromatosis, iron could be involved in the development of HCC in associated with cirrhosis, suggesting a strong link between heavy iron overload and HCC development. In cases of chronic hepatitis C, it is also known that HCC are developed 20 to 30 years after the infection of hepatitis C virus through the progression of the disease from chronic hepatitis and cirrhosis. In Long-Evans Cinnamon (LEC) rat, an animal model of human Wilson

disease which spontaneously developed hepatitis and liver fibrosis, HCC is frequently developed after the rats have recovered from initial fulminant hepatitis and subsequent liver fibrosis. This is considered to relate to progressive iron accumulation in the animal^[67], and iron depletion prevents their development of hepatic cancer^[68]. Even though the iron deposition in chronic hepatitis C is mild compared with that in hemochromatosis, iron may be an independent factor on the risk of HCC. It is reported that liver fibrosis is a favorable environment of proliferation of cancer cells by releasing transforming growth factor β , and there is a strong link between liver fibrosis and liver iron deposition. In clinical trials of phlebotomy, the hepatic content of 8-OH deoxyguanosine is decreased and fibrotic score is improved. An important issue in hepatocarcinogenesis in chronic hepatitis C is the closely related sustained production of ROS during inflammation and fibrosis. Moriya *et al*^[69] reported that HCC developed in HCV core transgenic mice after the age of 16 mo, and showed high hepatic lipid peroxidation levels in old (more than 16 mo) core transgenic mice, than in control. However, the association of HCV transgenic mice, and HCC development disappeared with advanced passaging of animals, suggesting that HCC development in HCV transgenic mice cannot be simply explained by HCV infection, but requires additional cofactors. A recent study by Furutani *et al*^[70] clearly showed that hepatic iron overload induces HCC in transgenic mice expressing HCV polyprotein. Transgenic animal carrying full length polyprotein-coding region (core to NS5B, nts 342-9378) by using pAlb promoter/enhancer was fed with excess iron diet. After 6 mo feeding, the transgenic mice showed marked steatosis and increased 8 hydroxy-2'deoxyguanosine content in association with the hepatic iron accumulation. Twelve months after feeding, 45% of transgenic mice developed hepatic tumors including HCC. It is noteworthy that the steatosis does not accompany with inflammation but a remarkable ultrastructural alteration of mitochondria associated with decreased degradation activity of fatty acids.

STEATOSIS AND INSULIN RESISTANCE

Nonalcoholic steatohepatitis (NASH) is a clinical entity characterized by the development of histopathological changes in the liver that are nearly identical to those induced by excessive alcohol intake, but in the absence of alcohol abuse; the presence of macrovesicular steatosis and mixes inflammatory infiltrate associate with varying amounts of Mallory's hyaline, glycogenated nuclei, and focal hepatocyte ballooning degeneration. Clinical features of NASH include obesity, hyperlipidemia, diabetes mellitus, and hypertension. In US population, approximately 25% is obese, and at least 20% of the obese individuals have hepatic steatosis. Thus, non-alcoholic liver disease (NAFLD) is the most common cause of liver dysfunction, and it is believed that NASH becomes a cause of cryptogenic cirrhosis and hepatocellular carcinoma (HCC). In patients with homozygote of HFE-related hemochromatosis, obesity and steatosis affect liver disease progression, and will be cofactors for iron overload. There

is one study of Australia that showed that the prevalence of abnormal genotype of HFE in NASH is 31% compared to a normal prevalence of 13% in the general population, suggest that excess iron might be important. A study on North American subjects showed similar results that the prevalence of the HFE gene mutation associated with hereditary hemochromatosis are increasing in patients with NASH^[71]. In the study dealing Japanese NASH patients, who had no HFE gene mutations, a significant staining of liver iron and increased level of thioredoxin, a marker of oxidative stress in addition to the increase of serum ferritin, was observed.

As diabetes and obesity were background conditions of NAFLD, and is thought to be a initial triggering factor, insulin resistance is now considered the fundamental operative mechanism. Insulin resistance is probably the "first step" in NASH, and a close correlation between insulin resistance and iron is speculated. Even though it is not still clear whether secondary iron accumulation increases insulin resistance, or vice versa, oxidative stress may be the elusive "second" hit of possibly multiple steps in the progression of steatosis to fibrosing steatohepatitis^[72]. This may be due to the activation of stellate cells^[73].

Because hepatic iron promotes oxidative stress, it seems that iron is a contributory cofactor in NASH. This proposal is strengthened by an association with hepatic fibrosis with NASH^[74] and was confirmed by measuring serum markers of oxidative stress^[75-77]. Excess hepatic iron also occur in insulin resistance-associated iron overload (IRHIO), characterized by hyperferritinemia with normal to mild increases in transferrin saturation. There is an interesting clinical study that venesections and restricted diet are effective in patients with IRHIO^[78]. As in IRHIO, restriction of dietary calories, fat and iron improved NAFLD in addition the decrease of levels of serum aminotransferases and ferritin^[79]. It seems that the simultaneous disorder of iron and glucose and/or lipid metabolism, in most cases associated with insulin resistance, is responsible for persistent hyperferritinemia and identifies patients at risk for NASH^[80]. However, it is still unclear why iron is deposited in IRHIO and NAFLD. There is an interesting report by Bekri *et al*^[81] that there is an increase of hepcidin in adipose tissue of the severely obese but of liver, suggesting that severe obesity itself cause hypoferrremia due to the overproduction of hepcidin in the adipocytes. This finding may explain the hypoferrremia in severe obese patients, but does not show the mechanism of hepatic iron deposition in IRHIO and NASH. Further studies are needed to clarify this issue, including an increase of transferrin iron influx into hepatocytes in NAFLD.

In patients with NASH, increased transferrin saturation correlated positively with the severity of fibrosis in univariate analysis, although it became insignificant when age, obesity, diabetes, and AST/ALT ratio were controlled. A recent study showed improvement in insulin sensitivity with the use of venesection in 11 patients with NASH. Biweekly phlebotomy until serum ferritin concentration became lower than or equal to 30 ng/mL reduced mean serum ALT activity without a significant change of

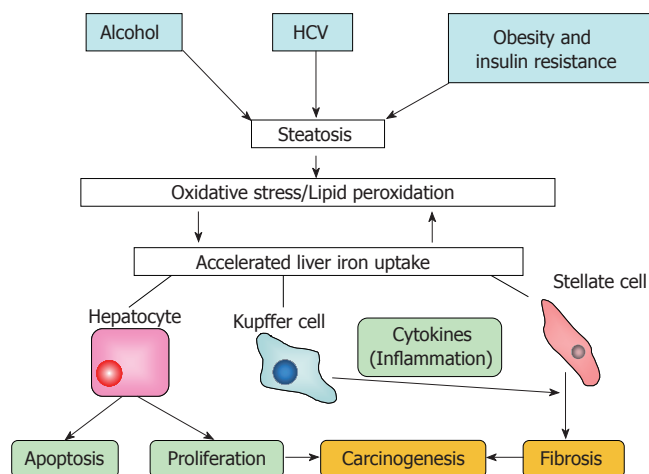

Figure 2 Postulated schema of liver damage occurred by alcohol, HCV infection, obesity and insulin resistant. A common pathway through steatosis/oxidative stress may be responsible for the development of liver fibrosis and carcinogenesis by iron.

body weight, suggesting that iron reduction therapy by phlebotomy will be one of the promising therapies for NASH^[82], although this approach cannot be implemented without extensive review.

The natural history of NASH is still unclear, but some patients follow advanced liver fibrosis progressing to cirrhosis and sometimes HCC^[83]. It is also known that diabetes increases the risk of hepatocellular carcinoma in US^[84]. Further studies are needed to clarify this issue, especially the relation between hepatocarcinogenesis from mild iron accumulation in NASH.

As shown in Figure 2, a common pathway through steatosis/oxidative stress may be present for the development of liver fibrosis and carcinogenesis by iron.

Abstract

Progress in the characterization of genes involved in the control of iron homeostasis in humans and in mice has improved the definition of iron overload and of the cells affected by it. The cell involved in iron overload with the greatest effect on immunity is the macrophage. Intriguing evidence has emerged, however, in the last 12 years indicating that parenchymal iron overload is linked to genes classically associated with the immune system. This review offers an update of the genes and proteins relevant to iron metabolism expressed in cells of the innate immune system, and addresses the question of how this system is affected in clinical situations of iron overload. The relationship between iron and the major cells of adaptive immunity, the T lymphocytes, will also be reviewed. Most studies addressing this last question in humans were performed in the clinical model of Hereditary Hemochromatosis. Data will also be reviewed demonstrating how the disruption of molecules essentially involved in adaptive immune responses result in the spontaneous development of iron overload and how they act as modifiers of iron overload.

THE TWO IMMUNITIES

The last decade has seen a growing understanding of the

numerous functions of the immune system beyond the two classical attributes of adaptive immunity: antigen specificity and memory. The key effector cell of adaptive immunity is the lymphocyte, a cell no longer known from its two principal origins in mammals, the thymus (T) and bone marrow (B), but with several subtypes characterized by different function and cytokine production profiles^[1]. “Behind” adaptive immunity lays a complex world of cells and molecules involved in less antigen-specific tasks collectively dedicated to the function of innate immunity. Two competing models have sought to explain innate immunity. One where evolutionary conserved features of pathogens are recognized by pattern recognizing receptors^[2] known generally as toll-like-receptors (TLRs). A second model, known as the danger model, is based on the assumption that products from damaged or stressed cells provide a danger signal to the host, thus evoking an innate immunity response^[3]. The effector cells of innate immunity are mostly myeloid cells and lymphocytes whose interaction with target cells does not depend on the recognition of the Major Histocompatibility Complex (MHC). A third cell, the dendritic cell (DC), was first described by Steinman and Cohn in 1973^[4]. DCs have been described most elegantly as “the nexus for translating signals from innate recognition into cells guiding adaptive immune function”^[5].

One hallmark of immune system cells, whether involved in innate or adaptive immunity, is their capacity to circulate and migrate from the blood compartment into lymphoid and non-lymphoid tissues (innate immunity cells) from non-lymphoid into lymphoid tissues (DCs) and from the blood into the lymph through the peripheral lymphoid organs (lymphocytes). The other is their role in protection from pathogen infections. Since early descriptions of immune cell functions in iron overload^[6] knowledge of the reciprocal interactions between immune cell responses, intracellular iron load and response to micro-environmental changes in iron levels has increased considerably. A decisive contribution to this understanding was the clarification of the genes involved in iron homeostasis. Reviews of the functions of such genes and their link to the reticuloendothelial system and immunity have been published recently^[7,8]. The present review will focus on the evidence that the cells of the immune system are equipped to modulate iron homeostasis through the expression of several iron related genes and proteins, and how do innate and adaptive immune cells respond in conditions of iron overload. In addition, the reader will be reminded of the evidence indicating that defective immune system models, particularly experimental models,

Table 1 Relevant genes/proteins involved in iron homeostasis and iron overload, and their related immunological functions

Genes/Proteins	Main role in iron homeostasis	Related immunological functions
Lactoferrin	Iron binding, transport and storage Iron chelator	Bactericidal and antiviral ^[13,14] . Immunoregulatory effects on Th1/Th2 cell activities ^[15]
Transferrin	Iron transporter	Present in monocyte/macrophages and T lymphocytes ^[16] Required for early T-cell differentiation ^[17]
Transferrin receptor 1	Cellular iron uptake	Iron uptake by activated lymphocytes and required for DNA synthesis and cell division of T lymphocytes ^[18]
Ferritin	Iron storage	Synthesised by macrophages and T lymphocytes ^[19,20]
Nramp1 (<i>SCLA11</i>)	Iron transfer in late phagolysosome	Resistance to infection with intracellular pathogens ^[21,22]
Nramp2/DMT-1	Iron uptake and transfer in late phagolysosome	Resistance to infection with intracellular pathogens ^[21,22]
Ferroportin 1 (IREG1)	Cellular iron exporter	TLR4 mediated downmodulation in infection ^[23]
Lipocalin	Unknown	Limits bacterial growth by sequestering the siderophore ^[24]
Regulators and modifiers of iron overload		
Hepcidin	Key regulator of iron homeostasis ^[25] . Gene disruption results in hemochromatosis ^[26] . Mutations associated with severe Juvenile Hemochromatosis (JH) ^[27]	Liver derived antimicrobial peptide ^[28] . TLR4 mediated expression in myeloid cells in response to bacterial pathogens ^[23]
Hemojuvelin	Regulation of hepcidin expression ^[29,30] . JH associated gene ^[31]	Unknown
IL-6 and IL-1	Involved in iron deprivation during infection and inflammation, through hepcidin induction and ferroportin down-modulation ^[32,33]	Derived from macrophages during infection and inflammation ^[32,33]
Heme-oxygenase 1	Required for mammalian iron reutilization. Targeted <i>Hmox1</i> mutations induce spontaneous iron overload ^[34]	High CD4:CD8 ratios with activated CD4+ cells in <i>Hmox1</i> deficient mice ^[34]
HFE	Hereditary Hemochromatosis associated gene ^[35] . HFE gene knockout produces mouse model of hereditary hemochromatosis ^[36]	Non-classical MHC-class I molecule ^[37]
β2-Microglobulin	β2m deficiency induces spontaneous iron overload and modifies the phenotype of HFE deficient mice ^[38,39]	Critical to the folding of MHC-class I molecules and selection of MHC class I molecule-associated peptides ^[40]
MHC-class I	MHC-class I deficient mice develop hepatic iron overload ^[41]	Critical molecule for viral peptide presentation ^[42]

are associated with the spontaneous development of iron overload^[9]. The mechanisms underlying what could be called the “reverse” side of this same coin, i.e. immunity and iron overload are less well understood. However, taking into account that practically all cells of the immune system express iron related genes their contribution to systemic iron homeostasis should no longer be ignored.

IRON AND INNATE IMMUNITY

As a critical element of cellular activity, iron plays a pivotal role in the fight for survival between mammalian hosts and their pathogens, each displaying a wide range of mechanisms for controlling iron acquisition and utilization. Micro-organisms have developed a large number of strategies to acquire iron from the environment and to transport the element to sites of incorporation into biologically important molecules^[10,11]. On the other side, the host has developed the capacity to modulate cellular iron metabolism, not only for its optimal utilization as a catalyst for the generation of reactive oxygen species acting as strong antimicrobial molecules, but also in order to make iron less available for the micro-organisms^[11,12]. A number of genes and proteins primary involved in iron homeostasis, namely in iron binding, transport and storage are now recognised to display related immunological functions. These are summarized in Table 1^[13-24]. In addition, it is becoming clear that the cells of the innate immune system, as part of a non-specific defense against

infection, are equipped to express genes and proteins that can modulate iron homeostasis both at the cellular and the systemic levels (see also Table 1)^[25-42]. One central player in this modulation is hepcidin, first described as a liver derived antimicrobial peptide^[28], and now well recognised as a key regulator of iron homeostasis and the anaemia of inflammation, at the interface of innate immunity and iron metabolism^[43]. Liver-derived hepcidin is strongly induced during infection and inflammation, causing intracellular iron sequestration and decreased plasma iron levels, a process mediated by the inflammatory cytokine cascade, namely macrophage derived IL-6 and IL-1^[32,33]. The mechanism underlying intracellular iron sequestration is mediated by the hepcidin-induced internalization and degradation of ferroportin, the only known iron exporter^[44]. The reduction in extracellular iron concentrations is believed to limit iron availability to invading microorganisms, thus contributing to host defense. Recently, hepcidin has been shown to be endogenously expressed by innate immune cells, i.e. macrophages and neutrophils, capable of migrating from the blood to a site of infection, constituting a newly recognised component of the local innate immune response to bacterial pathogens^[23]. Myeloid endogenous hepcidin mRNA expression in response to bacterial pathogens was shown to be dependent on the specific activation by the toll-like receptor 4 (TLR-4), the key pattern recognition receptor for LPS^[45]. This activation also produces down-regulation of the iron exporter

ferroportin. Endogenous myeloid hepcidin production is not stimulated by iron, pointing to different pathways of hepcidin activation in response to infection or iron overload^[23]. The mechanisms underlying the differential stimulatory effects of infection and iron overload on hepcidin are still not understood. Interestingly, it was recently shown that hepcidin levels in fish also respond both to iron overload and infection, demonstrating the evolutionary conservation of hepcidin's dual function^[46].

In addition to the demonstrated role of neutrophils and macrophages on hepcidin gene activation and ferroportin down-modulation, other iron genes and proteins involved in iron transport from the human phagosome into the cytosol also play critical roles in TLR-4 mediated innate immunity. The natural resistance-associated macrophage protein 1 (Nramp1) is expressed in circulating phagocytes, and is recruited from the lysosomal compartment to the phagosome membrane where it functions as an efficient antimicrobial through a mechanism of iron deprivation^[22]. Nramp1 mutations in mice are shown to cause susceptibility to infection with various intracellular pathogens including *Salmonella*, *Mycobacterium* and *Leishmania*^[21]. Mutations in the human homologue of the gene, NRAMP1, were also shown to strongly affect the susceptibility to tuberculosis^[47]. Nramp2, also known as the divalent metal transporter 1 (DMT1) is another important iron transporter in mammals^[48,49] and, as Nramp1, it is also induced by infection with intracellular pathogens, namely *Mycobacterium*^[50]. In addition, it is suggested to play an important role in recycling iron from RBC-containing phagosomes to the cytoplasm^[51]. The amount of available iron in the phagosome is also decreased by the entry in macrophages of neutrophil derived lactoferrin (Lf), another well known potent iron chelator found recently to have also a bridging role between innate and adaptive immunity. Both *in vitro* and *in vivo* studies showed that Lf is able to stimulate the proliferation and differentiation of T lymphocytes from their immature precursors into the Th1 or the Th2 phenotypes thus having an immunoregulatory effect on Th1/Th2 activities^[15].

Finally, lipocalin 2 has been recently described as a pivotal component of the innate immune system and the acute phase response^[52]. Upon infection the toll-like receptors on immune cells stimulate the transcription, translation and secretion of lipocalin 2 which then limits bacterial growth by sequestering the iron-loaded siderophore^[24].

INNATE IMMUNITY AND IRON OVERLOAD

If one or all of the above described iron related immune response genes either fail or the cells are overwhelmed by continuous iron overloading such as seen in transfusional iron overload, one consequence is the development of infection. Infections including rare microorganisms^[53] are among the major complications in patients with thalassemia, a group of common genetic disorders of hemoglobin synthesis clinically characterized by severe anemia and blood transfusion-dependent iron overload. Besides the well-known risks of blood borne viral infections associated with multiple transfusions, the

increased susceptibility of these patients to infection is known to be associated with a wide spectrum of immune abnormalities which are, at least in part, due to the effect of iron overload, including defective chemotaxis and phagocytosis by neutrophils and macrophages and decreased natural killer cell activity^[54].

In contrast with the findings in transfusional iron loading, patients with severe iron overload due to Hereditary Hemochromatosis (HH) do not show evidence of increased susceptibility to infections or iron loading of macrophages. HH is a common genetic disorder of iron overload, the majority of HH patients being homozygous for the C282Y mutation in *HFE*, a gene encoding a protein of the Major Histocompatibility Complex class I (MHC class I). The C282Y mutation disrupts the correct folding of the $\alpha 3$ domain of the protein, interfering with its interaction with $\beta 2$ -microglobulin ($\beta 2m$) and consequently abolishing the cell surface expression of the molecule^[35]. The surface expression of *HFE* was shown to have a prominent role in the regulation of iron export from macrophages^[55,56].

Monocyte/macrophage abnormalities in HH

Anomalies in monocyte/macrophage cells have been consistently described in HH patients, including low TNF- α production by peripheral blood macrophages upon stimulation with lipopolysaccharide^[57] and a significant increase in iron regulatory protein (IRP) activity in monocytes^[58], an anomaly that was corrected after phlebotomy treatment. Interestingly, subjects with a tissue iron burden similar to HH patients, but due to secondary iron overload have an IRP activity significantly decreased suggesting that the increased IRP activity in iron overload is specific to the *HFE* related hereditary form of hemochromatosis^[58]. In addition, a study that investigated the release of erythrocyte-derived iron from purified human monocytes obtained from controls and HH patients showed that although HH monocytes phagocytosed less than half the number of erythrocytes taken up by control monocytes, they released twice as much iron in the form of LMW-Fe complex than controls^[59]. More recently, increased iron content was described in macrophages from HH patients transfected with wt *HFE* when compared with HH macrophages transfected with an empty vector^[56]. These observations are consistent with previously reported observations in macrophage cell lines derived from C282Y mutated HH patients, where *HFE* was shown to lose its ability to inhibit iron release leading to a relative macrophage iron deficiency^[55]. Interestingly, *Mycobacterium tuberculosis* (*M.tb*) residing within phagosomes of macrophages from HH patients exhibit a profound defect in their ability to acquire iron from exogenous transferrin and lactoferrin relative to *M.tb*-infected macrophages from normal controls^[60]. Moreover, macrophages from HH patients failed to induce Nef-mediated iron and ferritin accumulation upon HIV-1 infection in contrast to macrophages expressing wild-type *HFE*^[61], thus suggesting that *HFE* mutated macrophages may be better equipped to protect from HIV-1 infection, compatible with the description of a long survival in a patient with AIDS

and hereditary hemochromatosis^[62]. One must therefore wonder whether the failure of macrophages from C282Y *HFE* HH patients to hold on to the iron is the expression of a putative selective advantage protecting from infection brought by the appearance and the establishment of such a mutation.

Iron and the dendritic cells

Very little work has addressed the interaction between iron loading and dendritic cell (DC) function. There is, however, recent evidence indicating that, upon endotoxin induced maturation, DCs increase significantly the expression of Tfr1 and down regulate expression of the export molecule ferroportin^[63], an observation compatible with an earlier finding of Kramer *et al*^[64] who reported that DCs generated under iron deprivation conditions were phenotypically undifferentiated and could not stimulate T cells.

IRON OVERLOAD AND ADAPTIVE IMMUNITY

The postulate that the immunological system could have a role in monitoring tissue iron toxicity, as part of its surveillance function, was first advanced in 1978, based on studies on lymphocyte traffic and positioning^[65-67]. It was implicit in that postulate that the lymphomyeloid system, and its circulating components participate in the recognition and binding of metals as a protective device against metal toxicity, and the preferential use of indispensable metals, such as iron, by bacteria or transformed cells. While a vast number of studies have clarified the reciprocal interactions between myeloid innate immunity cells and iron metabolism, fewer studies addressed this question in lymphocyte populations. Lymphocyte activation and expansion depend on the expression of transferrin receptors, required for DNA synthesis and cell division^[18] and both activated and non-activated T lymphocytes synthesize ferritin^[19,20]. Lymphocytes could, therefore, act as a “mobile” and easily “mobilizable” iron-storage compartment protecting from iron-mediated toxicity^[65]. This hypothesis motivated the study of lymphocyte function in iron overload^[68]. The influence of iron on the expansion of different T-cell subsets was demonstrated both *in vitro*^[69] and *in vivo*, namely in patients with thalassemia^[70]. Results in this clinical model, however, are difficult to interpret due to the inseparable effects of blood transfusion, splenectomy, iron chelation therapy and infection. Imbalances of the relative proportions of CD4+ and CD8+ T lymphocytes, with abnormally high CD4/CD8 ratios were later reported in HH patients^[71,72], a clinical model where iron overload is not complicated by the effects of transfusion, splenectomy or desferrioxamine. Curiously, in one experimental model of iron overload seen in mice generated with targeted *Hmox1* mutations, high CD4:CD8 ratios have been seen in the splenic cell populations of older mice aged 50 wk^[34]. These mice also exhibited numerous activated CD4+ cells. Hepatic inflammatory cell infiltrates were seen in the mice, a finding similar to that reported by Rodrigues *et al*^[73] in

aging *Hfe* deficient mice.

T lymphocyte abnormalities in HH

Abnormalities in the relative proportions of the two major T lymphocyte subpopulations have been consistently described in HH patients. Reimão and co-workers first described that patients with abnormally high CD4/CD8 ratios displayed a faster re-entry of iron into the serum transferrin pool after intensive phlebotomy treatment than patients without those abnormalities^[71]. It was shown later that the amount of iron mobilized by phlebotomy correlated significantly with the number of CD8+ T cells, but not with CD4+ T cells^[72,74]. An independent study examining patients homozygous for the C282Y mutation showed that the low percentages of CD8+ T cells seen in the peripheral blood of HH patients were associated with low numbers of the same cells in the liver and with higher levels of hepatic tissue iron^[75]. HH patients had been shown earlier to have reduced percentages of CD8+ CD28+ T cells in peripheral blood^[76]. No anomalies of CD28 expression were found in the CD4+ subset. The apparent failure of the CD8+ CD28+ T cell population to expand coincided with an expansion of CD8+ CD28- T cells in peripheral blood of HLA-A3+ but not HLA-A3-HH patients^[76]. Although the described abnormalities in lymphocyte populations were systematically found in the sub-population of CD8+ T lymphocytes, the association with total body iron stores is also reflected in the total lymphocyte counts. Low total lymphocyte counts were found associated significantly with a higher degree of iron overload in *HFE*-linked HH, but not in African iron overload^[77]. More recently, Barton *et al*^[78] also described a significant inverse relationship of total blood lymphocyte counts and severity of iron overload in hemochromatosis probands with *HFE* C282Y homozygosity. Fabio *et al*^[79] confirmed that the presence of low numbers of total lymphocyte counts and CD8+CD28+ T cells in C282Y homozygous patients was inversely related to the transferrin saturation. In addition, they found low numbers of CD4+ T and NK cells, and a major increase in IL-4 and IL-10 production in the CD3+ CD8+ T cell subset^[79]. A study of the V α / β T cell receptor (TcR) repertoire in a population of C282Y homozygous HH patients showed that the frequency of V α / β TcR expansions within the CD8+ pool in the group of HH patients was significantly higher in those with iron overload related pathology (9/16) than in patients (1/16) without pathology^[80]. In the same study it was found that control subjects heterozygous for the C282Y mutation had an absence of expansions of the V β 5.2 and V β 12 chains in the CD8+ pool, suggesting that *HFE* could have an effect in the shaping of T cell receptor repertoire.

Functional abnormalities in CD8+ T lymphocytes were also described in HH patients. The level of autophosphorylation of the CD8-associated p56lck as well as its phosphotransferase activity, as determined by phosphorylation of an exogenous substrate, was significantly reduced by two- to three-fold in HH patients relative to a control population of healthy donors^[81]. By contrast, the level of CD4-p56lck activity did not show an

overall decrease relative to controls. The decreased CD8-p56lck activity seen in patients was not corrected by iron depletion. A significantly higher percentage of HLA-DR+, but not CD45RO+ cells was also found within the peripheral CD8+ T cell subset in HH patients relative to controls^[76]. Moreover, functional studies showed that CD8+ cytotoxic T lymphocytes (CTL) from HH patients exhibited a diminished cytotoxic activity when compared with CD8+ CTL from healthy controls^[76].

The finding of a significant association of abnormally low CD8+ T lymphocytes with a more severe clinical expression of hemochromatosis in HH patients^[72,82] raises the obvious question: are if these anomalies the follow or precede the development of iron overload. The fact that those abnormalities are remarkably stable in each individual patient, that they are not corrected by phlebotomy treatment, and that they are observed in asymptomatic patients at young ages, favors the hypothesis that they are intrinsic to the genetic defect and not a consequence of the progressive iron overload. More recently it was shown that the numbers of CD8+ T lymphocytes are genetically determined, in association with other genetic determinants at the MHC class I region close to HLA and HFE^[83,84]. It is, therefore, conceivable that the inherited abnormalities in CD8+ T lymphocytes in HH are modifiers of the clinical expression of the disease as proposed by Cruz *et al.*^[82] or genetically located close to a yet unidentified modifier gene of iron metabolism.

THE REVERSE TOPIC: ADAPTIVE IMMUNITY AND IRON OVERLOAD

Genetically manipulated animal models have, therefore, become wonderful and decisive tools to address the questions of the effect on iron overload of a specific gene or protein at the systemic level. Several animal models of spontaneous iron overload were described that illustrate the influence of proteins of the adaptive immunological system on iron homeostasis, all pointing to the putative importance of the MHC class I region.

The $\beta 2m$ -microglobulin deficient ($\beta 2m^{-/-}$) mice constitute the first described model of spontaneous iron overload^[38,85,86]. These mice develop a hepatic iron overload with a distribution similar to that seen in HH liver pathology, i.e., mainly in the liver parenchyma with no evidence of iron loading in the Kupffer cells^[38,86]. These mice present severe decreased cell surface expression of the MHC-class I molecules and consequently almost no CD8+ T lymphocytes^[87,88]. Intestinal uptake of ferric iron and the subsequent transfer into the plasma is inappropriately increased in $\beta 2m^{-/-}$ mice^[86]. Upon treatment with hematopoietic cells derived from normal mice fetal liver iron overload is attenuated and shifted from the parenchymal to the Kupffer cells^[86,89]. However, TfSat and intestinal iron absorption remain high, suggesting that the primary defect of iron overload is not corrected. With the discovery of the HFE gene and the demonstration that the C282Y mutated form failed to bind to $\beta 2m$ ^[35] it was assumed that the earlier findings in $\beta 2m^{-/-}$ were due to an impaired HFE function. However, several subsequent studies showed that this was not sufficient to explain the

pathology of $\beta 2m$ deficient mice. In contrast to $Hfe^{-/-}$, the $\beta 2m^{-/-}$ mice display increased expression of the duodenal iron transporters DMT1 and ferroportin1, implicating a broader role of $\beta 2m$ in mammalian iron overload^[90]. More recently, Rodrigues *et al.*^[73] described results of a comparative study of these two models in older mice. The results confirmed that the $\beta 2m^{-/-}$ old mice present a more severe hepatic iron overload than the $Hfe^{-/-}$ counterparts. $\beta 2m^{-/-}$ old mice which also showed liver steatosis, probably as a reflection of the higher hepatic iron content causing lipid peroxidation. Earlier Levy *et al.*^[91] had reported the finding that in mice lacking both the Hfe and the $\beta 2m$ molecules, liver iron deposition is observed in greater levels than in mice lacking Hfe alone.

The $\beta 2m^{-/-}$ - $Rag1^{-/-}$ double knock out mice lack mature T and B lymphocytes as well as MHC-class I and Hfe expression. $Rag1$ is required for normal T and B lymphocyte development. $\beta 2m$ is required for correct folding and cell surface expression of MHC-class I like proteins. These mice present a more severe body iron overload than each of the single knock out models^[39]. Besides liver iron deposition in the parenchymal cells, the $\beta 2m^{-/-}$ - $Rag1^{-/-}$ also showed iron deposition in pancreas and heart. Older mice under an iron-enriched diet develop heart fibrosis, which could be prevented by treatment with normal fetal liver hematopoietic cells. To determine whether the effect of the $\beta 2m$ deficiency in the $\beta 2m^{-/-}$ - $Rag1^{-/-}$ double knock out mouse was only due to lack of Hfe expression, double knock out mice for Hfe and $Rag1$ were generated^[92]. $Hfe^{-/-}$ - $Rag1^{-/-}$ double knock out mice showed increased liver iron overload compared to each of the single knock out, or the $\beta 2m^{-/-}$ - $Rag1^{-/-}$. The distribution of the iron loading in $Hfe^{-/-}$ - $Rag1^{-/-}$ mice did not recapitulate the iron loading of the $\beta 2m^{-/-}$ - $Rag1^{-/-}$, since they did not present heart or pancreas iron loading.

The δ TCR^{-/-} mice lack the $\gamma\delta$ intraepithelial lymphocytes. Following the administration of an iron supplemented diet, these mice showed an increased liver iron accumulation in relation to control mice^[93]. In addition, δ TCR^{-/-} mice had a marked reduction of tumor necrosis factor alpha (TNF- α) production by intraepithelial lymphocytes when compared with controls suggesting a role for this cytokine in intestinal iron regulation.

Finally, mice deficient in the MHC class I molecules H2K^b and D^b have a strong reduction in CD8+ T-lymphocyte numbers^[94]. These mice present a spontaneous increase of iron content in the liver preferentially in hepatocytes with occasionally Kupffer cells iron staining^[41]. The liver iron content in this model was shown to correlate directly with the number of residual CD8+ T lymphocytes (Cardoso E and M de Sousa, unpublished observations).

The above described double knockout mouse models provide a good illustration of the modifier effect of the components of the adaptive immune system, namely a MHC class I dependent effect, on the iron overload phenotype, a conclusion also reached separately by Muckenthaler *et al.*^[90] in a study of differential gene expression in $\beta 2m$ deficient mice. Altogether the results described in animal models of hemochromatosis may help to explain why immunological anomalies

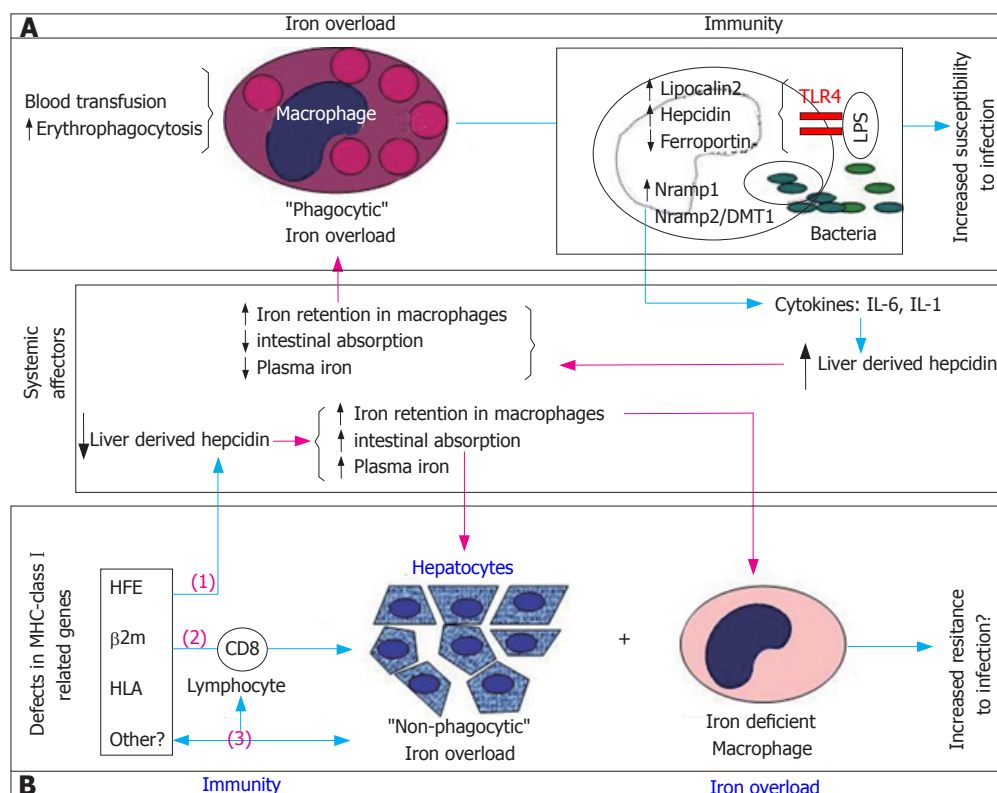

Figure 1 A model illustration of the two topics addressed in this review: how innate immunity is affected and affects “phagocytic” iron overload (Box A) and the evidence that defective immune system models, namely natural and experimental defects in MHC-class I related genes (*HFE*, β 2-microglobulin and *HLA*) are associated with the spontaneous development of “non-phagocytic” or parenchymal iron overload (Box B). **A:** Macrophages “overwhelmed” by continuous iron overloading as seen in conditions of chronic transfusion and increased erythrophagocytosis are compromised in their function of surveillance of bacterial growth resulting in increased host susceptibility to infection. As part of the natural response to bacterial infection macrophages modulate the expression of a number of genes involved in the regulation of cellular iron metabolism. By activating the cytokine cascade they induce up-regulation of liver hepcidin synthesis with further increase in macrophage iron retention and perpetuation of this cycle; **B:** A “non-phagocytic” or parenchymal iron overload is observed in hepatocytes of several defective immune system models associated with a relative iron deficiency in macrophages, recapitulating the findings observed in the human model of Hereditary Hemochromatosis. The mechanisms underlying the spontaneous development of iron overload in these models are not yet understood. Three possible (not mutually exclusive) mechanisms are represented in this figure: (1) the fact that both *Hfe* and β 2m knockout mouse models lack the liver hepcidin response to iron overload^[80,97,98] may support the notion of a liver-derived, systemically induced iron overload. The involvement of liver hepcidin in the development of iron overload in mice deficient in the MHC-class I molecules *H2K^b* and *D^b* (*HLA*) was never tested; (2) the iron overload seen in the β 2m^{-/-} *Rag1^{-/-}* and *Hfe^{-/-} Rag1^{-/-}* mouse models support the involvement of lymphocytes themselves as modifiers of the severe parenchymal iron overload phenotype seen in those mice^[39]; (3) finally, the recent demonstration of a strong link between the MHC-class I region and the genetic transmission of low CD8⁺ T lymphocyte numbers in humans and the association of total lymphocyte numbers with a more severe iron overload phenotype in patients with Hereditary Hemochromatosis^[78,82,83] opens a new possibility that another, still unidentified MHC-class I associated gene(s) may simultaneously regulate CD8⁺ T lymphocyte numbers and influence the development of parenchymal iron overload^[84].

modify the severity of iron overload in Hereditary Hemochromatosis^[82,95].

CLOSING REMARKS

The growing knowledge and availability of genetic techniques dissecting the fine components of the host response to the challenge of infection have strengthened the opportunity of revising the topic “iron and immunity”. When the main concern for this topic resided in the effects of iron deficiency on the immune response, Weinberg pioneered the opposite concern for iron overload and infection^[12]. Today it is evident that in response to infection numerous innate immunity components display metal chelating properties, including synthesis and release of lactoferrin, lipocalin and hepcidin, as discussed above. The cells involved in that response are neutrophils and macrophages. But, during evolution the macrophage, particularly the splenic macrophage, assumed the key

physiological role of recognizing senescent red blood cells and recycling the iron in hemoglobin^[96]. Exhaustion of that pool *in vivo* leads to “phagocytic” iron overload, such as seen in transfusional iron overload, with the expected consequences in the development of infection. If on the other hand the macrophage fails, it is to be expected that “parenchymal” iron overload will develop. This is the case in *HFE*-Hereditary Hemochromatosis. Therefore, iron overload must not be seen as one entity, but two separate entities with different relationships to immunity (Figure 1). Evidence was provided in this review that innate immunity is affected and affects “phagocytic” iron overload. On the reverse side, defective immune system models, namely natural and experimental defects in MHC-class I related genes (*HFE*, β 2-microglobulin and *HLA*) are associated with the spontaneous development of “non-phagocytic” or parenchymal iron overload.

The large new question looming in the horizon of this topic with which we wish to close this brief review is: does

the MHC class I region harbor, in addition to *HFE*, other gene or genes that besides regulating lymphocyte numbers also influence the development of “non-phagocytic” or parenchymal iron overload? The search for the answer to this question will probably guide many research interests for years to come.

Abstract

Iron is an essential trace metal in the human diet due to its obligate role in a number of metabolic processes. In the diet, iron is present in a number of different forms, generally described as haem (from haemoglobin and myoglobin in animal tissue) and non-haem iron (including ferric oxides and salts, ferritin and lactoferrin). This review describes the molecular mechanisms that co-ordinate the absorption of iron from the diet and its release into the circulation. While many components of the iron transport pathway have been elucidated, a number of key issues still remain to be resolved. Future work in this area will provide a clearer picture regarding the transcellular flux of iron and its regulation by dietary and humoral factors.

INTRODUCTION

Iron is an essential trace metal for all organisms. In humans it plays numerous biochemical roles, including oxygen binding in haemoglobin and as an important catalytic centre in many enzymes, for example the

cytochromes. In normal healthy adults, some 0.5-2 mg of iron is lost each day due to blood loss and the constant exfoliation of iron-containing epithelial cells that line the gastrointestinal and urinary tracts, skin and hair. Therefore, the same amount of iron from dietary sources is required each day to replace the lost iron and maintain body iron homeostasis. Even though iron is an essential metal in human metabolism, it is highly toxic to cells and tissues if present in elevated levels. Perversely, humans do not possess the necessary machinery to rid the body of excess iron and, therefore, the absorptive process must be tightly regulated within defined physiological limits to avoid pathologies associated with both iron deficiency and overload.

Dietary iron is found in two basic forms, either as haem-found in meat and meat products-or non-haem iron-present in cereals, vegetables, pulses, beans, fruits *etc* in a number of forms ranging from simple iron oxides and salts to more complex organic chelates. Non-haem iron predominates in all diets comprising some 90%-95% of total daily iron intake. The absorption of both haem and non-haem iron takes place almost exclusively in the duodenum and the bioavailability of iron from these sources is influenced by a number of variables, e.g. the iron content of foods, the type of iron present, i.e. haem or non-haem, and other dietary constituents. Importantly, absorption is also regulated in line with metabolic demands that reflect the amount of iron stored in the body, and the requirements for red blood cell production. These humoral mechanisms are further reviewed in this volume^[1].

Despite accounting for only 5%-10% of dietary iron in western countries, haem is the most bioavailable source of iron amounting to is some 20%-30%^[2]. In contrast, the bioavailability of non-haem iron is low-only 1%-10% of the dietary load is absorbed-and is profoundly influenced by other dietary components that can enhance or inhibit non-haem iron bioavailability. The most potent enhancer is ascorbic acid (vitamin C), which acts by reducing ferric iron to the more soluble and absorbable ferrous form. Phytates found in cereal products and polyphenolic compounds found in all plant products are the most potent dietary inhibitors of non-haem iron absorption. However, it is important to note that on an equimolar basis the pro-absorptive action of dietary ascorbic acid can counteract the inhibitory effect of phytates and polyphenols^[3].

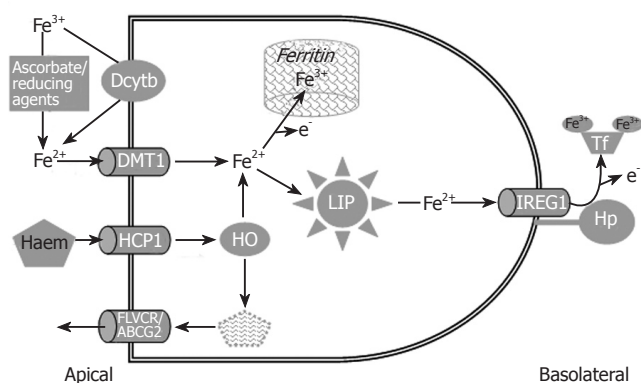

Figure 1 The cellular mechanisms involved in intestinal iron absorption. Dietary non-haem iron (mostly ferric) is reduced by the actions of the ferric reductase Dcytb and reducing agents in the diet to yield Fe^{2+} , which subsequently enters the enterocytes via DMT1. Haem is absorbed via HCP1, broken down by haem oxygenase 1 (HO) to liberate Fe^{2+} (this joins a common pool with iron from the non-haem pathway) and bilirubin (which might be removed from the cell by the efflux proteins FLVCR and ABCG2). If body iron stores are high, iron may be diverted into ferritin and lost when the cell is shed at the villus tip. Alternatively, iron passes into the labile iron pool (LIP) and is subsequently processed for efflux via IREG1 (as Fe^{2+}). The exiting iron is re-oxidized to Fe^{3+} through hephaestin (Hp) to enable loading onto transferrin (Tf).

MECHANISMS INVOLVED IN INTESTINAL IRON TRANSPORT

In recent years our understanding of the mechanisms involved in dietary iron absorption by duodenal enterocytes has increased dramatically. Both haem and non-haem iron are taken up in this proximal region of the small intestine, though their transport across the apical membrane of the enterocytes occurs through totally independent pathways (Figure 1).

Ferrous iron

The majority of dietary non-haem iron enters the gastrointestinal tract in the ferric form. However, Fe^{3+} is thought to be essentially non-bioavailable (see below) and, therefore, it must first be converted to ferrous iron prior to absorption. There are numerous dietary components capable of reducing Fe^{3+} to Fe^{2+} , including ascorbic acid^[4], and amino acids such as cysteine^[5] and histidine^[6]. It is believed that the action of these dietary reducing agents takes place in the acidic environment of the gastric lumen. Indeed the essential requirement for an acid environment in iron absorption is exemplified by the fact that achlorhydria is commonly associated with iron deficiency anaemia^[7,8]. However, ferric iron reaching the duodenal enterocytes may still be reduced by the cells endogenous reducing activity. A number of studies have demonstrated that the brush-border surface of duodenal enterocytes and cultured intestinal cells possess ferric reductase enzymic activity^[9-11]. Using a subtractive cloning strategy designed to identify intestinal genes involved in iron absorption, Dcytb (for duodenal cytochrome b), a homologue of cytochrome b_{561} , was identified as the enzyme responsible for this process^[12]. Like cytochrome b_{561} , Dcytb is a haem-containing protein with putative binding sites for ascorbate and semi-dehydroascorbate. The protein is expressed on

the brush border membrane of duodenal enterocytes, the major site for the absorption of dietary iron. Moreover, antibodies raised against Dcytb block the endogenous ferric reductase activity of the duodenal brush border membrane, providing further evidence for a functional role in dietary iron processing^[12].

Intriguingly, a recent study has reported that the targeted disruption of the *Cybrd1* gene in mice (which encodes Dcytb) does not lead to an iron deficient phenotype^[13], implying that Dcytb is not necessary for intestinal iron absorption in mice. However, an important caveat to this study is the fact that mice are able to synthesize significant quantities of ascorbic acid-unlike humans who are reliant on dietary vitamin C to satisfy their requirements-and may, therefore, have less need for a duodenal surface ferric reductase.

Following reduction either by Dcytb or dietary reducing agents, the resulting Fe^{2+} becomes a substrate for the divalent metal transporter, DMT1-also known as the divalent cation transporter, DCT1^[14], and natural resistance associated macrophage protein, Nramp2^[15]. The relatively low pH of the proximal duodenum together with the acid microclimate present at the brush border membrane^[16,17] stabilises iron in the ferrous form and provides a rich source of protons that are essential for driving iron uptake across the apical membrane of the intestinal epithelium^[14,18].

The role of this transporter in intestinal iron homeostasis has been highlighted by a number of studies. Our work^[18] and that of others^[19] have shown that antibodies to DMT1 can significantly inhibit iron absorption. Furthermore, targeted disruption of DMT1 in mice has revealed the essential role of this transporter in both intestinal iron absorption and in erythroid precursor development^[20]. In addition to these biochemical and molecular manipulations, two rodent models, the *mk/mk* mouse^[15] and the Belgrade (*b*) rat^[21], which possess a spontaneous mutation (G185R) in the DMT1 gene, exhibit defective intestinal iron uptake and microcytic anaemia. More recently a number of mutations in human DMT1 have also been identified^[22-25] which in turn lead to the development of microcytic anaemia.

The molecular identity of the functional DMT1 isoform in intestinal epithelial cells has been the subject of recent debate. At least four isoforms exist through alternate splicing in exon 16^[26] and the presence of two transcription start sites-named exon 1A and 1B^[27]. Exon 16 splicing gives rise to two variants which differ in their terminal 19-25 amino acids and their 3' untranslated sequence (UTR). Interestingly one of these variants contains an iron responsive element in its 3' UTR^[26]. The significance of this is discussed later in this review. All four isoforms can be detected at varying levels in intestinal epithelial cells^[27], but the exon 1A/IRE-containing variant has been suggested to be the major functional isoform in absorptive enterocytes.

Ferric iron

We stated earlier that Fe^{3+} is thought to be non-bioavailable. However, some workers have proposed that Fe^{3+} might be absorbed by intestinal enterocytes *via* a

mechanism that is distinct from DMT1 (reviewed in^[28]). In this model, ferric iron, which is insoluble at physiological pH, is released from the food matrix in the acidic environment of the stomach, and is chelated by mucins on the duodenal brush border surface, which maintain the iron in the ferric state. Fe³⁺ enters the enterocyte across the apical membrane via interaction with β_3 -integrin and mobilferrin (a calreticulin homologue). In the cytosol, this complex combines with flavin monooxygenase and β_2 -microglobulin to form a larger conglomerate (approximately 520 kDa) known as paraferitin, which has ferric reductase activity resulting in the conversion of the absorbed Fe³⁺ to Fe²⁺. Recent evidence suggests that the paraferitin complex may also contain DMT1^[29], which may permit the delivery of ferrous iron to intracellular organelles.

Ferritin

In animal and plant tissues, the major iron storage protein is ferritin. Most nutrition texts focus only on haem and non-haem iron, and generally ignore the possibility that ferritin may be an important nutritional source of iron. While the issue of ferritin bioavailability is still controversial, a number of studies have shown that both plant and animal ferritin sources are absorbed in humans^[30-32] with a bioavailability equivalent to that of ferrous sulphate. The ferritin iron uptake mechanism is yet to be determined. One possibility is that ferritin is broken down by protease activity in the upper gastrointestinal tract and the released iron is absorbed *via* the Dcytb/DMT1 route. However, studies have shown that ferritin is largely resistant to high temperature, low pH and protein denaturing agents^[33,34]. Therefore, it is possible that ferritin may be absorbed intact and broken down intracellularly (in the lysosomes) to liberate its iron load. In support of this latter possibility, one study has reported that iron and ferritin protein are both taken up by the intestinal Caco-2 cell line^[35]. Such a mechanism would require the presence of a ferritin receptor on the apical membrane of intestinal enterocytes. While the presence of ferritin receptors has been postulated on liver^[36] and placental^[37] plasma membranes, none has yet been identified in intestinal tissue. Taken together this evidence suggests that the molecular identity of at least one important intestinal iron transport gene may remain to be discovered.

Lactoferrin

In breast-fed infants, a major proportion of iron is bound to the human milk protein lactoferrin, an iron-binding protein capable of binding two ferric ions^[38]. Specific receptors for lactoferrin have been identified on the brush border surface of foetal enterocytes^[39] and subsequent studies have shown that these receptors mediate the uptake of lactoferrin-bound iron in intestinal epithelial cell cultures^[40]. Interestingly, a recent study looking at ontogenic changes in the expression of iron transport proteins in mouse small intestine, has suggested that the lactoferrin receptor may be the principal iron transport pathway in early life^[41]. Intriguingly, a recent human volunteer study has indicated that the nutritional importance of lactoferrin

may not be limited to infants since it is also a bioavailable source of iron (with equivalent bioavailability to ferrous sulphate) in young adult females^[42].

Haem

Non-vegetarian diets provide an additional and important source of iron in the form of haem (largely from haemoglobin and myoglobin). While haem comprises only approximately 10% of dietary iron intake, because it is more bioavailable than non-haem iron, it may contribute as much as half of the total iron absorbed from western meat-rich diets^[43]. Despite the wealth of information available on the uptake of non-haem iron, the mechanisms involved in haem iron absorption are only just beginning to emerge. Early work on intestinal absorption suggested that haem binds to the duodenal brush border membrane and is absorbed as an intact molecule^[43,44]. In support of this proposed mechanism, workers have reported the existence of haem binding proteins on pig enterocytes^[45,46] and intestinal Caco-2 cells^[47]. More recently, a number of candidate haem binding proteins have been identified in the intestinal epithelial cells including the ATP-binding cassette protein, ABCG2^[48], the feline leukaemia virus C receptor protein, FLVCR^[49] and the haem carrier protein, HCP1^[50]. Of these candidate haem transporters, ABCG2 and FLVCR mediate haem efflux and only HCP1 acts as a haem import protein. The high duodenal expression of HCP1 suggests that it may be the protein involved in haem uptake from the diet. However, the precise role of HCP1 in iron metabolism remains to be fully elucidated. This issue has been complicated by recent data indicating that HCP1 may also function as a proton-coupled folate transporter, independent from its haem transporting properties^[51].

Following absorption, haem is detectable in membrane-bound vesicles within the cytoplasm^[52,53]. Within these vesicles, it is thought that the iron contained within the protoporphyrin ring is excised by the action of haem oxygenase 1^[54] yielding ferrous iron which enters a common intracellular pool along with the iron absorbed via the non-haem transport pathways. Digestion appears to be complete within the enterocytes since a number of studies have failed to detect intact haem efflux across the basolateral membrane^[44,47]. One intriguing possibility is that the efflux proteins ABCG2 and FLVCR, also expressed in the duodenum, may act to remove bilirubin formed as a by-product of haem degradation from the enterocytes.

Intracellular storage and translocation of iron

At this stage, the absorbed iron has two fates depending on the body's requirements. If the body stores are replete, and there is no increased erythropoietic drive, a significant amount of newly absorbed iron will be stored in the enterocytes as ferritin. Because duodenal enterocytes turnover very rapidly (their lifespan is approximately 3-4 d) and the majority of enterocytes contributing to absorption lie in the mid/upper villus region, this intracellular ferritin iron is quickly lost into the intestinal lumen as the ageing cells are sloughed off at the villus tip. Interestingly, in human subjects there is a positive correlation between

dietary iron bioavailability and faecal ferritin content which supports the above mechanism^[55,56]. Indeed it is likely that this is a very important mechanism for controlling the release of iron into the circulation.

The mechanism by which iron is translocated from the apical pole of the enterocytes so that it becomes available for export across the basolateral membrane is poorly understood. A body of evidence has emerged from studies in Caco-2 cells for a vesicular transport pathway that co-ordinates the transcellular movement of iron. Central to this mechanism is apo-transferrin (apo-Tf) which when added at the basolateral surface of the Caco-2 cell monolayer stimulates transepithelial iron flux in a dose-dependent manner^[57-59]. Interestingly, in Caco-2 cells apo-Tf and Fe-Tf, once taken up from the basolateral medium, appear to be directed into distinct endosomal vesicular fractions^[59,60]. The apo-Tf containing endosomes are routed towards the apical pole of the cell where they co-localise with vesicles containing DMT1^[61]. It is proposed that the iron entering the cell along with DMT1 is transferred to apo-Tf within these endocytic vesicles, and is subsequently exocytosed into the basolateral medium as Fe-Tf. Using a combination of biochemical inhibitors to disrupt this vesicular network, it is estimated that this pathway may count for as much as 50% of the transepithelial iron flux in Caco-2 cells^[62,63].

While on the face of it, the above studies provide compelling evidence for a co-ordinated mechanism for the transcellular routing of iron, a number of caveats must be taken into consideration. (1) This model requires the expression of both DMT1 on the apical surface and transferrin receptors (TfR) on the basolateral membrane of the same enterocytes. While this requirement holds for Caco-2 cells^[64], the evidence from rat and mouse intestine suggests that TfR are predominantly expressed in the proliferating crypt and lower villus enterocytes^[65-69] while dietary iron uptake through apical membrane DMT1 occurs in the upper villus enterocytes^[70-73]. (2) Recent studies have shown that intestinal-specific inactivation of IREG1 (the basolateral iron transporter) results in anaemia confirming the essential role of this pathway in iron homeostasis^[74]. (3) Caco-2 cells, while an excellent model of the intestinal epithelium, exhibit some non-enterocyte properties including the ability to synthesize and secrete transferrin^[75-76]. Taken together, all of these studies highlight the need for further investigation into the transcellular iron transport mechanisms and their role in maintaining body iron homeostasis.

Iron export

Efflux of iron across the basolateral surface of enterocytes is achieved through the co-ordinated action of a transport protein IREG1^[77]-also known as ferroportin^[78] and MTP1^[79]-and a ferrioxidasase, hephaestin^[80]. Studies in which IREG1 was expressed in *Xenopus laevis* oocytes indicate that this is a unidirectional efflux transporter of ferrous iron^[77,78]. Interestingly, this efflux function is up-regulated in the presence of ceruloplasmin, a copper binding ferrioxidasase, plus transferrin to bind the newly liberated iron^[77]. This suggests that while ferrous iron is released through IREG1 it must be oxidised to ferric iron to

facilitate its loading onto transferrin for onward transport in the circulation. Interestingly studies with the yeast ceruloplasmin homologue, Fet3p, have highlighted the requirement for ferrioxidasase activity in iron accumulation by transferrin^[81,82].

As stated above, the use of knockout mice has elegantly demonstrated the essential role of IREG1 in basolateral iron efflux^[74]. In addition, a second genetic mutant mouse model-the sex-linked anaemia (sla) mouse-has highlighted the critical requirement for oxidation of iron leaving the enterocytes for normal iron homeostasis. The sla mouse develops a moderate to severe microcytic hypochromic anaemia^[83]. It has been shown subsequently that these mice exhibit normal uptake of iron into enterocytes^[84], but the subsequent release of iron into the circulation is diminished^[85]. As a result, iron accumulates in enterocytes, and is lost when these cells are sloughed at the villus tip^[86]. While the *in vitro* studies described earlier^[77] used the ferrioxidasase activity of ceruloplasmin to drive iron efflux, in the intestine the oxidation of iron is achieved by a ceruloplasmin homologue, hephaestin, which is also a multicopper ferrioxidasase^[87]. In the sla mouse, the hephaestin gene is defective leading to a truncated form of the protein^[80], which is mislocalised within the enterocytes^[88] and has reduced ferrioxidasase activity^[87].

REGULATION OF INTESTINAL IRON TRANSPORT

The regulation of intestinal iron absorption is complex and relies on mechanisms which sense dietary iron content as well as iron storage levels in the body and erythropoietic iron requirements (Figure 2). The iron regulatory hormone hepcidin is likely to be an important intermediate in signalling the storage and erythroid requirements and this aspect of iron homeostasis will be dealt with in an accompanying review^[1].

Basal transporter expression

In the healthy physiological state intestinal transporter expression will reflect body iron status exemplified by the circulating levels of iron bound to transferrin. Cells in the duodenal crypts of Lieberkühn express both Hfe^[89,90], the protein mutated in more than 80% of haemochromatosis patients^[91], and TfR on their basolateral surface. It is believed that Hfe binds to TfR regulating the rate at which transferrin-bound iron can enter the cell^[92,93]. One suggestion is that the cellular iron concentration established as a result of this interaction ultimately determines the basal level of expression of the proteins involved in iron absorption in the mature absorptive cells in the upper third of the villus. Importantly, in a modification to this hypothesis, we propose that in response to humoral signals, such as hepcidin, iron transport^[94] and transporter expression^[95] in mature epithelial cells, can be modified rapidly without the need to re-programme the crypt cell sensing mechanism.

The role of dietary iron

Rapid regulation of intestinal transporter expression in

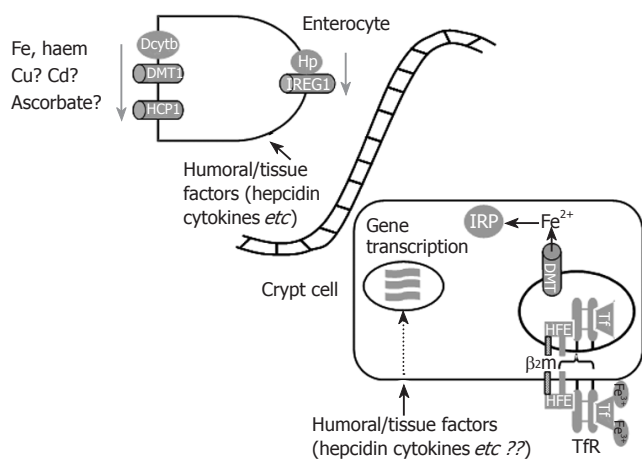

Figure 2 The regulation of intestinal iron transport. The duodenal crypt-villus axis represents a differentiation pathway that can be influenced by the dietary and humoral signals that ultimately regulate iron absorption. Immature proliferating cells in the crypt take up transferrin from the circulation via transferrin receptors (TfR). This process is governed by interactions between Hfe, β_2 microglobulin and TfR. The crypt cells are thus sensitive to the circulating levels and the iron-saturation of Tf. Iron regulatory proteins (IRP) recognise the cellular iron content and regulate iron responsive mRNAs posttranscriptionally. In addition, transcription control of iron metabolism may be exerted by a number of humoral and tissue-derived factors, such as hepcidin or cytokines interacting with their individual specific receptors. Together, these processes set the basal level of iron transporter protein expression in enterocytes as they mature and travel up the villus. Importantly, this basal level of transporter expression can be modified rapidly in mature enterocytes in response to changes in the levels of dietary factors (e.g. the iron content of the diet, other metals etc) and humoral and local tissue mediators (especially hepcidin and pro-inflammatory cytokines). This combination of basal programming in the crypts and fine tuning in villus enterocytes permits tight control of intestinal iron transport.

response to dietary factors is probably sensed by the villus enterocytes. More than half a century ago the “mucosal block” hypothesis was formulated following studies which demonstrated that a large oral dose of iron could reduce the absorption of a smaller dose administered several hours later^[96,97]. It was argued that due to the short time interval between doses, the initial dose must be having a direct effect on the mature enterocytes rather than the crypt cells. Whether such a phenomenon occurs with meaningful dietary iron levels is not clear but this may be a considerable problem with supplemental iron levels^[98]. Using the Caco-2 cell model, we have addressed the issue of whether non-haem iron can regulate iron transporter expression within a timescale and at concentrations that are consistent with digestion and absorption of a meal. We found that DMT1 (the IRE-containing isoforms) protein expression on the apical surface of these cells is decreased by iron concentrations as low as 20 $\mu\text{mol/L}$ ^[64]. The decrease in DMT1 transporter expression was rapid, occurring within 1-4 h following the exposure to iron^[99]. Further analysis revealed that DMT1 protein was internalised and targeted towards a late endosomal/lysosomal compartment. Interestingly, these iron-dependent effects were restricted to the apical uptake pathway-IREG1 protein expression was unaltered and were fully reversible (DMT1 protein levels returned to their original basal levels within 4-8 h) following the removal of iron^[99]. Our findings in this pertinent cell

culture model are consistent with those observed in rats following oral gavage with an iron bolus^[100-102] suggesting that the redistribution of DMT1 between different cellular compartments may be important physiologically for optimising iron absorption from a meal so that it matches better the body's metabolic requirements.

Iron regulatory proteins and iron responsive elements

In addition to trafficking of iron transport proteins, a number of intestinal iron metabolism genes can be regulated post-transcriptionally through interactions between cytosolic iron regulatory proteins (IRP) which bind to iron responsive elements (IRE), stem loop structures in either the 3' or 5' untranslated region (UTR) of several mRNA species, under conditions of cellular iron deficiency. TfR mRNA contains five IREs in its 3' UTR, and is stabilised following IRP binding as this blocks a target site for endonuclease activity^[103-106]. Interestingly, two isoforms of DMT1 contain a single IRE in the 3'UTR^[26]. While the DMT1 IRE can bind IRP *in vitro*^[107,108], its role in regulating DMT1 expression remains to be fully determined.

In contrast to the reported role of the 3'IRE sequences in conferring mRNA stability, the expression of mRNAs possessing 5'IREs, such as ferritin, are poorly translated with cellular iron low. But, expression is increased by high iron levels in duodenal enterocytes^[109]. This is because IRP/IRE binding blocks the association of the eukaryotic initiation factor complex to the 43S ribosomal unit^[110]. Interestingly, IREG1 mRNA contains a single IRE in the 5'UTR^[77,79]. However, the role of IRP/IRE interactions in the regulation of IREG1 transporter expression is even more controversial than its role in regulating DMT1 expression. Evidence suggests that the response to changes in iron status is tissue-specific-IREG1 expression in the liver^[79] and lung^[111] and in macrophages^[112] is up-regulated by high iron whereas in the intestine expression is elevated by iron deficiency^[77]. This may indicate that transcriptional, translational and post-translational processing of IREG1 varies between cell types^[113]. Clearly, the mechanisms involved in iron-dependent regulation of IREG1 in the intestine require further attention.

Local tissue factors

While the majority of this review has focussed on the transport pathways in the enterocytes it is important to bear in mind that the intestinal cell population is a highly heterogeneous affair. It is likely, therefore, that cross-talk between the epithelial cells and other cell types, such as macrophages, neutrophils, intraepithelial lymphocytes etc will be important in the overall regulation of intestinal iron transport. One intriguing hypothesis in this regard is the possible physiological role of the pro-inflammatory cytokine TNF α in regulating intestinal iron transport. TNF α is not only synthesized by peripheral blood monocytes and macrophages in response to inflammatory stimuli, but is also released by intraepithelial lymphocytes (IEL) that reside within the intestine in response to high iron intakes^[114]. These findings led to the formation of a hypothesis (named the piggyback-sensor model^[115])

which suggested that interaction between Hfe in the developing enterocytes with specific epitopes on the IELs was essential for regulating local TNF α production. Once released, TNF α leads to iron deposition within intestinal enterocytes *via* a TNF receptor 2-dependent mechanism^[116]. Further studies by our group^[117] and others^[118,119] have shown that TNF α has a direct influence on intestinal iron transporter expression and iron transport. These studies have opened the way for further investigations into the role of cell to cell cross-talk and the role of local tissue factors in regulating intestinal iron transport.

SUMMARY AND FUTURE DIRECTIONS

Clearly, our understanding of the molecular components of the intestinal iron transport pathway has increased exponentially in the last decade. However, there are still a number of important questions that remain unanswered: (1) How is iron shunted across the enterocytes from the apical pole to the basolateral membrane? There is some evidence for the presence of a tubulovesicular pathway. But, this work has largely been carried out in cell lines, and needs to be explored further in “normal” intestinal tissue. A role for calreticulin, a proposed component of the paraferitin pathway, remains a possibility though is still unproven. (2) What are the relative contributions of ferritin (and possibly lactoferrin) to iron nutrition? Could these iron sources be exploited for new supplemental therapies to treat iron deficiency? (3) Is there a role for cross-talk between enterocytes and other intestinal cell types in the local regulation on intestinal iron transport? If so, what are the cellular mechanisms involved? Are local tissue factors (such as TNF α) relevant physiologically in the control of iron absorption? (4) Hcpidin - how does it regulate intestinal iron transport? Is it an important physiological regulatory or is its main role in iron-related pathologies such as iron deficiency anaemia, haemochromatosis and anaemia of chronic disease?

ACKNOWLEDGMENTS

The authors would like to thank the Biotechnology and Biological Research Council for continued financial support for their work on iron metabolism.

Abstract

The liver plays a central role in iron metabolism. It is the major storage site for iron and also expresses a complex range of molecules which are involved in iron transport and regulation of iron homeostasis. An increasing number of genes associated with hepatic iron transport or regulation have been identified. These include transferrin receptors (TFR1 and 2), a ferrireductase (STEAP3), the transporters divalent metal transporter-1 (DMT1) and ferroportin (FPN) as well as the haemochromatosis protein, HFE and haemojuvelin (HJV), which are signalling molecules. Many of these genes also participate in iron regulatory pathways which focus on the hepatic peptide hepcidin. However, we are still only beginning to understand the complex interactions between liver iron transport and iron homeostasis. This review outlines our current knowledge of molecules of iron metabolism and their roles in iron transport and regulation of iron homeostasis.

INTRODUCTION

Iron is an essential trace element for almost all forms of

life. However, under physiological conditions, the free form of iron is practically insoluble and potentially toxic. Thus, iron is always found bound to specific ligands in such a way as to render it both soluble and non-toxic. The toxicity of iron stems from its ability to redox cycle. The release of an electron from ferrous iron, if uncontrolled, may result in the formation of highly reactive oxygen species capable of oxidising lipids, proteins and DNA^[1] causing damage to the structures and processes in which they are involved. However, many catalytic and other biological processes rely on the redox properties of iron; hence, iron must be available in a form which allows it to donate and accept electrons without causing non-specific damage.

In mammals, iron is transported around the plasma bound mainly to the glycoprotein transferrin, although other forms are also present in small amounts. In normal human plasma, transferrin has a concentration of between 25 and 50 $\mu\text{mol/L}$, and is usually about one-third saturated with iron. The remaining, unoccupied, binding sites on transferrin provide a large buffering capacity in case of an acute increase in plasma iron levels, an important consideration given the toxicity of free iron. Following uptake by the tissues, iron is transferred into a cytosolic pool (the "transit pool") from where it is distributed to ferritin for storage or to iron-requiring moieties, such as haem or iron-sulphur clusters. The majority of hepatocellular iron is contained in ferritin (80%) with 2%-3% present as haem; the remainder is either bound to transferrin or present in the transit pool^[2].

The liver plays a central role in iron metabolism. It is responsible for approximately 8% of plasma iron turnover in humans^[3], most of which is mediated by hepatocytes^[4,5] and it has long been known that it is the major site for storage of iron. Histologically, iron is distributed around the periportal regions of the liver with a decreasing gradient towards the centrilobular regions. In iron overload disorders, this gradient becomes more pronounced^[6], involving mainly hepatocytes with the resident liver macrophages, Kupffer cells, leading to a much lesser extent^[7].

More recently, it has been shown that the liver expresses a complex range of molecules which regulate iron homeostasis. The liver and, more specifically, hepatocytes, also express the vast majority of genes that have been associated with hereditary iron disorders. Our understanding of these disorders as well as the normal function of the liver in iron homeostasis is, as yet, incomplete. This review focuses on iron metabolism in hepatocytes, with a specific section on the role of Kupffer

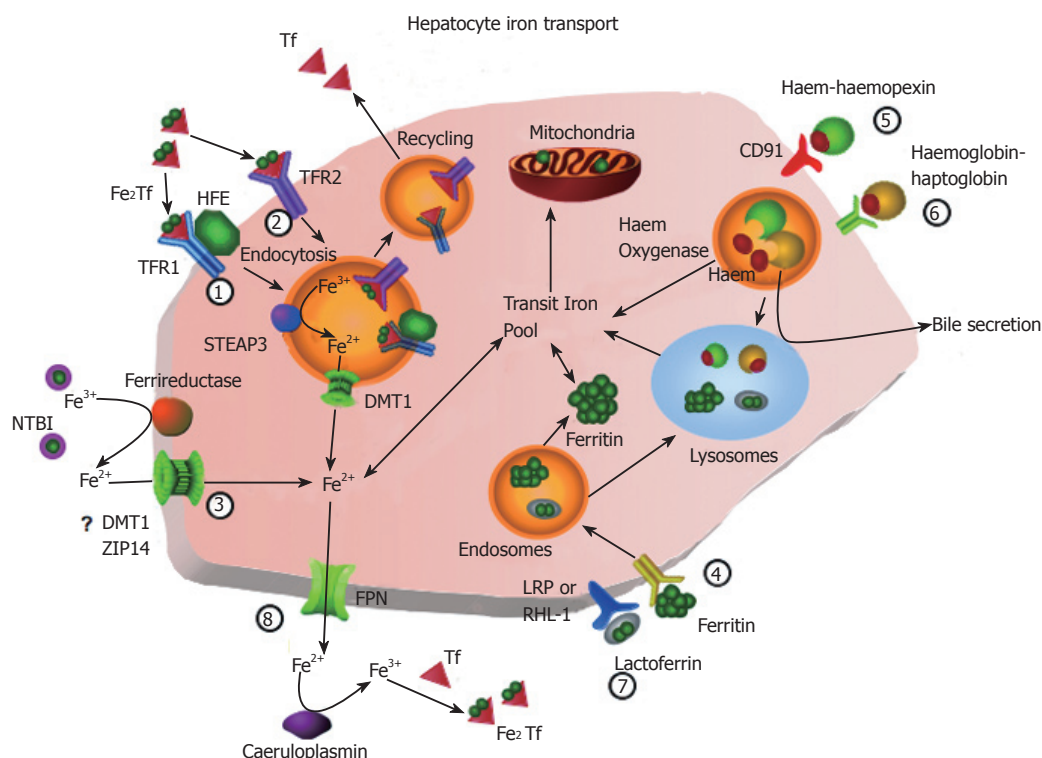

Figure 1 Hepatocyte iron transport. (1) TFR1-mediated uptake of diferric transferrin. Diferric transferrin binds to its specific receptor and is endocytosed. The endosome is acidified and Fe^{3+} is reduced by STEAP3. The iron is released and transported out of the endosome via DMT1 and apotransferrin is exocytosed. (2) TFR2-mediated uptake of transferrin. This mechanism is similar to the TFR1-specific mechanism except that transferrin binds to TFR2. (3) Uptake of NTBI. Iron is reduced and is transported into the cell via a carrier-mediated process. (4) Uptake of ferritin. Ferritin binds to its specific receptor and is endocytosed. The endosome is directed to lysosomes and the iron is transferred to the transit pool or endogenous ferritin. (5) Uptake of haem-haemopexin. The haem-haemopexin complex binds to its specific receptor CD91 and is endocytosed. Haem is removed and is degraded by haem oxygenase. (6) Uptake of haemoglobin-haptoglobin. The haemoglobin-haptoglobin complex binds to a specific receptor. Following endocytosis, the complex may be directed to the canalicular membrane for release into the bile or to the lysosomes for degradation. (7) Uptake of lactoferrin. Lactoferrin binds to LRP or RHL-1 and is endocytosed and targeted to the lysosomes for degradation. (8) Iron release. Iron is released by FPN and oxidised by caeruloplasmin and binds to apotransferrin. TFR1, transferrin receptor 1; TFR2, transferrin receptor 2; STEAP3, six-transmembrane epithelial antigen of the prostate 3; DMT1, divalent metal transporter 1; NTBI, non-transferrin bound iron; ZIP14, zinc-regulated transporter and iron-regulated transporter-like protein 14; LRP, low-density lipoprotein receptor-related protein; FPN, ferroportin.

cells, and on the molecules known to be involved in iron metabolism in the liver and their role in our current understanding of liver iron transport.

TRANSFERRIN RECEPTOR 1 (TFR1)-MEDIATED UPTAKE OF TRANSFERRIN

TFR1-mediated uptake of diferric transferrin is, perhaps, the best described process of iron uptake (Figure 1, pathway 1). Briefly, transferrin binds to TFR1 and is endocytosed^[2,5]. At the pH of the extracellular fluid, diferric transferrin is bound preferentially, the affinity of the receptor being higher for diferric transferrin than for either monoferric- or apo- transferrin^[7-10]. Following formation of the endosome, it is acidified which results in a decrease in the affinity of transferrin for iron and subsequent detachment of the metal^[11,12]. The affinity of the receptor for the (now) apotransferrin is increased by the acidic environment^[7] and apotransferrin remains bound to the receptor as the endosome returns to and fuses with the plasma membrane. At the higher extracellular pH, the affinity of the receptor for apotransferrin decreases^[7] and apotransferrin is released back into the circulation^[2]. The entire process takes between 3.8 and 15 min^[13-15].

TFR1

TFR1 expression is regulated by iron primarily by a post-transcriptional mechanism. The transcript contains five iron-responsive elements (IRE) in its 3' untranslated region (UTR) along with a number of instability elements that facilitate breakdown of the message^[16-19]. Under low-iron conditions, iron regulatory proteins (IRP) bind to the IREs, placing an inhibition on the instability elements^[18,19], increasing the half-life of the mRNA and, hence, increasing translation. When iron is abundant, IRPs do not bind IREs, resulting in a decrease of the stability of the transferrin receptor message. Two isoforms of IRP have been identified. The first (IRP1) is an iron-free form of cytosolic aconitase^[20-22]. The second (IRP2) does not exhibit any aconitase activity^[23] and appears to be the physiologically active IRP since it can respond to iron under conditions of low oxygen tension^[24], a situation which occurs in the liver *in vivo*.

TFR1 is also regulated by other mechanisms. The gene contains an hypoxia response element in its promoter region which mediates up-regulation of transcription in the presence of hypoxia-inducible factor 1^[25-27]. Transcription is also up-regulated by cytokines, such as interleukin-2, mitogens and growth factors^[28-30]. Furthermore, *TFR1*

expression is increased in proliferating cells and reduced in quiescent cells^[31-33], consistent with cellular demand for iron during periods of growth.

HFE

A mutation in HFE was the first to be shown to be causative for the iron overload disorder, haemochromatosis^[34]. HFE is a major histocompatibility complex-like protein and was originally designated HLA-H. The gene is widely expressed, with highest expression in the liver and small intestine. HFE requires the protein β 2-microglobulin for its correct localisation to the cell surface^[35].

Despite this knowledge, the normal function of the protein has been difficult to elucidate. The crystal structure of the transferrin-TFR1 complex^[36] indicates that the C-lobe of transferrin interacts with the helical domain of one of the TFR1 monomers. In contrast, the N-lobe of transferrin appears to interact partially with the helical domain, partially with the protease-like domain and, unusually, with the stalk connecting the extracellular region of TFR1 to its transmembrane region. HFE also interacts with the helical domain of TFR1^[37,38], competing with transferrin for its binding site^[39,40]. The resulting inhibition causes a reduction in transferrin-bound iron uptake in a variety of cell types^[41-44], suggesting that HFE is involved in the regulation of iron uptake by TFR1, possibly by limiting the amount of iron released from transferrin^[44]. HFE cycles with TFR1^[44], but its effect on cycling is controversial, with different groups reporting no effect^[44], a reduction in endocytosis^[45] or a reduction in exocytosis^[43].

The physiological consequences of the HFE-TFR1 interaction are difficult to ascertain given that the affinity of TFR1 for HFE is one to two orders of magnitude lower than for diferric transferrin^[46], implying that, at normal transferrin concentrations, almost no HFE would be associated with the receptor. However, these measurements were conducted on isolated proteins, so it is possible that, *in vivo*, the local environment of these proteins changes their interactions leading to a shift in the balance of competition between HFE and transferrin.

STEAP3

Following endocytosis and vesicle acidification, iron is reduced to its ferrous form prior to being transferred across the endosomal membrane. It was suggested some years ago that the transferrin receptor appeared to facilitate detachment of iron from transferrin in the endosome^[47]. More recently, it was shown that, at endosomal pH, the reduction potential of ferric iron co-ordinated by transferrin is increased when diferric transferrin is complexed to TFR1^[48], confirming the earlier observation and suggesting that reduction of iron occurs prior to release from transferrin. However, purely chemical reduction is unlikely to result in the highly efficient process of iron uptake seen in biological systems.

Despite evidence of endosomal ferrireductase activity^[49], it wasn't until recently that a candidate ferrireductase was identified^[50]. The gene *STEAP3* ("six-

transmembrane epithelial antigen of the prostate 3") is one of four genes wholly or partially deleted in the *nm1054* iron deficiency anaemia mouse. Under normal conditions, it is highly expressed in the liver, and its product is a protein which co-localises in endosomes with TFR1 and DMT1 (divalent metal transporter 1; see below). It is predicted to be a haemoprotein containing an N-terminal flavin-NADH binding domain. Most importantly, ferrireductase activity and iron uptake were lower in reticulocytes obtained from *nm1054* and *steap3* knockout mice and overexpression in HEK293T cells resulted in increased ferrireductase activity. A follow-up paper from the same group^[51] showed that the remaining three members of the Steap family (STEAP1, 2 and 4) were also ferri- and cupric- reductases. The four genes are ubiquitously expressed; however, different members are expressed more highly in some tissues than others. Foetal liver expresses all four transcripts, but adult liver expresses predominantly STEAP3 with a small amount of STEAP1^[50,51]. Like STEAP3, the other Steap proteins co-localise, at least partially, in an endosomal compartment with transferrin and TFR1.

Divalent metal transporter 1 (DMT1)

The released ferrous iron is transported from the interior of the endosome to the cytosol by DMT1 (also known as "natural resistance-associated macrophage protein 2", NRAMP2, "divalent cation transporter 1", DCT1, or "solute carrier family 11 member 2", SLC11A2). This protein is a transmembrane glycoprotein with 12 predicted transmembrane helices^[52,53] although there is no structure currently available to confirm this.

There are four known isoforms of DMT1, resulting from splice variation at the mRNA level. Alternative first exons (1 A or 1 B) give rise to the first level of variation^[54]. Secondly, each of the 5' splice variants may contain one of two 3' splice variations^[55]. The first of these contains an IRE in its 3'UTR. The second results in replacement of the final 18 codons of the open reading frame with a different sequence of 25 codons and a different 3'UTR, which, importantly, does not contain an IRE^[55]. The predominant form in the liver is the exon 1B + IRE form, although a small amount of the 1B-IRE form may also be present^[54].

Studies comparing the variants of DMT1 have indicated that the +IRE isoform is localised predominantly to the plasma membrane, exhibits slower internalisation kinetics than the -IRE isoform, and is targeted to lysosomes. In contrast, the C-terminal region of the -IRE isoform contains peptide signals which are required for efficient endocytosis and subsequent targeting to recycling endosomes^[56,57]. Thus, it is possible that the +IRE isoform is predominantly involved in iron transport across the plasma membrane whereas the -IRE isoform is involved in endosomal transport.

Evidence that DMT1 is the endosomal transporter is supported by the finding that DMT1 co-localises with TFR1^[58-60] and cycles through the endosomal compartment, appearing in acidic endosomes^[61]. DMT1 transports iron optimally at pH 5.5^[62], consistent with its presence in acidic endosomes and suggesting the energy for iron transport may be provided by a proton gradient. However, considerable transport also occurs at pH 7.4,

and a model for metal transport by DMT1 has been proposed which is consistent with symport of Fe^{2+} and H^+ from acidic endosomes and uniport of Fe^{2+} from a neutral environment^[63].

DMT1 appears to be regulated by iron levels with protein expression increased in iron loaded liver, lower in control liver, and not detected in iron deficient livers^[64]. Similar results have been obtained with the HepG2 hepatoma cell line^[65]. These findings are inconsistent with an IRE located in the 3'UTR of the transcript, which would be expected to result in a decrease in mRNA stability in iron loading with a concomitant decrease in protein expression. However, regulation of DMT1 is complex, and it is possible that the 5'UTR of the transcript or the N-terminal domain of the protein may modify the regulatory effects of the IRE in a tissue-specific manner^[54]. Additionally, regulation based around the stability of the protein cannot be ruled out.

LOW AFFINITY TRANSFERRIN UPTAKE

A second transferrin-mediated route of iron uptake (Figure 1, pathway 2) has been recognised in hepatocytes for many years^[14,66,67] and is probably responsible for the bulk of iron uptake by hepatocytes since, at the concentrations of transferrin present in the plasma, TFR1 would be saturated^[15,66,68]. The mechanism of uptake is similar to that of the TFR1-mediated pathway^[5,14,69]. After binding to the low affinity binding site, transferrin is endocytosed and iron is removed following acidification of the vesicle. Iron is sequestered away from the vesicle and apotransferrin is exocytosed^[69].

Transferrin receptor 2 (TFR2)

In 1999, Kawabata and colleagues^[70] reported the cloning of transferrin receptor 2 (TFR2), a type II transmembrane protein which shared significant sequence similarity to TFR1. It is currently the best candidate gene to code for the low-affinity binding site, with which it shares many similarities. TFR2 binds diferric transferrin specifically in a pH-dependent manner with an affinity 25-30 times lower than TFR1^[38,71]. In the liver, it is expressed predominantly in hepatocytes^[70,72,73] and mediates cellular transferrin and iron uptake^[70,73].

Regulation of TFR2 is different from regulation of TFR1. TFR2 mRNA does not contain any iron-responsive elements and cellular iron levels do not appear to change TFR2 mRNA or protein expression. Dietary and pathological iron loading do not result in decreased hepatic expression of TFR2 mRNA and neither does iron deficiency result in increased hepatic expression^[74]. Instead, TFR2 appears to be regulated at the protein level by cell cycle, with proliferating cells expressing approximately twice as many receptors as stationary cells^[75] and by the presence of diferric transferrin. Diferric transferrin causes an upregulation of receptor number and a redistribution of the protein to the cell surface in liver and hepatoma cells^[72,76]. The upregulation is caused by an increase in the half-life of the receptor conferred by its binding diferric transferrin. Removal of diferric transferrin results in a return to baseline expression^[77]. Consistent with these

findings, TFR2 protein levels were decreased with iron deficiency, and increased with iron loading in genetic models of iron overload, such as haemochromatosis, but not in the atransferrinaemic mouse which has impaired transferrin synthesis^[76]. Evidence suggests that TFR2 is a sensor of transferrin saturation and controls iron metabolism by regulating hepcidin expression^[78,79]. However, it is still not known whether changes in levels of TFR2 expression are correlated with changes in transferrin-bound iron uptake by the liver.

Given the similarities between TFR1 and TFR2, it was thought that, like TFR1, TFR2 may bind HFE. Co-localisation studies suggested an interaction in the duodenum. TFR2 was shown to co-localise with wild-type HFE in an early endosomal compartment whereas, in the presence of HFE^{C282Y}, the mutation predominantly associated with haemochromatosis type 1, TFR2 was distributed mainly to basolateral membrane^[80]. Despite this, initial *in vitro* binding studies indicated that there was no detectable interaction between soluble HFE and the soluble TFR2 ectodomain^[38]. More recently, an interaction has been demonstrated between the full-length, membrane-anchored HFE and TFR2 proteins^[81] suggesting that HFE may, indeed, be involved in TFR2-mediated iron uptake and TFR2-dependent regulation of hepcidin.

It has also been shown that TFR2, unlike TFR1, is present in lipid rafts and binding of diferric transferrin to TFR2 can activate the ERK1/2 and p38-MAPK signalling pathways^[82]. However, any connection of this to the hepcidin signalling pathway has yet to be demonstrated.

NON-TRANSFERRIN-BOUND IRON UPTAKE

The liver is one of the major sites of accumulation of iron delivered as low molecular weight chelates (Figure 1, pathway 3)^[83,84]. The pathophysiological relevance of such a process is apparent in diseases of iron overload such as hereditary haemochromatosis^[85]. The form of this low molecular weight plasma pool is likely to comprise several species; however, citrate appears to be the major component in both normal^[86,87] and haemochromatotic^[88] sera. In experimental situations, hepatocytes and their derivatives have been shown to take up iron from a variety of chelators^[89-105]. Iron taken up from these chelators has been shown to be distributed to haem and ferritin in hepatocytes^[90,101,103].

NTBI uptake by hepatocytes is linear for at least the first 15 to 60 min of incubation^[91,94,101,104]. It is also concentration dependent, with both ferrous and ferric iron, delivered as a variety of low molecular weight chelates, showing saturation kinetics^[95,97,106-108], indicating that this process is carrier-mediated. Uptake of iron as ferric citrate has been shown to be most efficient in normal rat hepatocytes at neutral pH^[92].

DMT1 as a major transporter of NTBI

NTBI uptake is increased in cells in which DMT1 mRNA and protein expression are upregulated^[109,110]. Furthermore, NTBI uptake appears to share at least one common pathway with TBI uptake since diferric transferrin has

consistently been shown to competitively inhibit uptake of NTBI^[93,102,111]. These observations, together with findings that DMT1 is active at neutral pH^[62], are consistent with DMT1 being a major transporter of NTBI in hepatocytes.

The specificity of NTBI uptake has been investigated by a number of groups and it has been generally observed that Cd, Co, Cu, Mn and Zn decrease iron uptake by normal and transformed hepatocytes^[97,104,108,109,112,113]. These observations match the range of divalent metals transported by DMT1^[53,114], adding further credence to the suggestion that DMT1 is a transporter of NTBI. Indeed, Mn and Cd appear to be transported by DMT1 with higher affinity than Fe^[114]. Although this observation is probably not relevant under normal physiological conditions, where the concentration of Fe is considerably higher than either Mn or Cd, it may become important in pathological conditions such as heavy metal poisoning in which competition for the transporter may result in a reduction in iron uptake. The alternative N and C termini conferred by the splice variants do not appear to affect the metal transport abilities^[62].

Certain inconsistencies in the data showing that some metals cause inhibition in some cell types, but not others have led to the suggestion of a family of transporters for iron and other transition metals^[101,111,115]. Several candidate transporters have been identified including calcium channels and specific transporters of other metals such as the zinc transporter, ZIP14 (zinc-regulated transporter and iron-regulated transporter-like protein 14).

ZIP14

ZIP14 (SLC39A14) is a transmembrane protein with eight predicted transmembrane helices^[112,113]. It is highly expressed in the liver, and is localised to the plasma membrane^[112]. There are two splice variants of the transcript; however, the biological functions of these two forms are yet to be determined. Originally shown to transport zinc, ZIP14 has also been shown to transport non-transferrin bound iron^[112,113,116]. But, it is not currently known whether ZIP14 is involved in hepatic iron loading. Importantly, ZIP14 has also been shown to be upregulated by interleukin-6^[112], which also upregulates hepcidin during inflammation^[117].

Calcium channels

The role of calcium channels in uptake of NTBI by the liver remains unclear. It has been suggested that L-type calcium channels are responsible for a significant component of ferrous iron uptake by cardiomyocytes, particularly under iron loaded conditions^[118,119]. However, information about any role for calcium channels in liver iron uptake is scant. Available evidence indicates that the transcripts coding for calcium channel subunits are expressed at low levels in the liver^[120], suggesting their participation in iron uptake by the liver is likely to be minor. However, levels of mRNA do not take into account any post-transcriptional modifications or functional regulation such as gating. Hence, the contribution of calcium channels to iron uptake by the liver requires further investigation.

It has also been suggested that calcium itself plays a functional role in NTBI uptake; however, this, too, needs

further clarification. Some studies have reported stimulation of NTBI uptake in cell types including hepatocytes^[99,101,104,121], whilst other studies have reported inhibition^[122] or no effect^[92]. It is possible that this spectrum of observations is due to variable chelation of calcium by the variety of chelators used to solubilise the iron^[123].

TRANSPORT OF OTHER IRON COMPLEXES

A number other forms of iron are recognised as being cleared from the circulation by the liver; however, these are likely to be mechanisms of clearance for their respective ligands rather than for uptake of iron, *per se*.

Specifically, these are ferritin, lactoferrin, the haem-haemopexin complex and the haemoglobin-haptoglobin complex. Circulating ferritin contains very small amounts of iron^[124-126] and, as such, it is not a major source of iron in the normal human. Nevertheless, the liver clears ferritin by a method involving binding to a specific ferritin receptor^[127-129] followed by endocytosis (Figure 1, pathway 4). There are several possible fates for endocytosed ferritin including catabolism of the protein in lysosomes^[130-132], excretion in the bile or inclusion in the endogenous ferritin pool^[133]. Any iron released is distributed to the mitochondria and endogenous ferritin^[130,132].

The uptake of the haem-haemopexin complex is mediated by its specific receptor, CD91 (Figure 1, pathway 5)^[134]. Following endocytosis, haem is degraded by haem oxygenase. Like transferrin, haemopexin was thought to be recycled back to the circulation^[135-137]; however, this fate has recently been questioned with evidence suggesting that it is substantially degraded in lysosomes^[134].

The haemoglobin-haptoglobin complex also binds to a high-affinity specific receptor and is endocytosed (Figure 1, pathway 6)^[138]. However, from this point, two possibilities exist for the fate of the complex. Both haemoglobin and haptoglobin may be directed to lysosomes for degradation^[139] or transported to the canalicular membrane of hepatocytes where haemoglobin is released into the bile and the receptor is recycled to the sinusoidal membrane^[140]. Clearance of the haemopexin and haptoglobin complexes by the liver is of importance in haemolytic states, especially those associated with intravascular haemolysis.

Lactoferrin is an iron-binding protein similar to transferrin which is present mainly in milk. Two lactoferrin binding sites have been reported on hepatocytes, although neither is specific for lactoferrin. The first is low-density lipoprotein receptor-related protein (LRP)^[141] and the second is the major (RHL-1) subunit of the asialoglycoprotein receptor^[142]. Lactoferrin appears to be cleared *via* receptor-mediated endocytosis regardless of its binding site (Figure 1, pathway 7)^[141,142]. Most of the internalised lactoferrin is directed to lysosomes for degradation^[143].

IRON RELEASE

Ferroportin (FPN)

The transporter, ferroportin (FPN; “solute carrier family 40 member 1”, SLC40A1; IREG1 or “metal transporter protein-1”, MTP1) was reported independently by three groups in 2000^[144-147] and appears to be the sole mediator

of iron release from hepatocytes (Figure 1, pathway 8)^[148]. Although it has not been shown directly, FPN appears to transport ferrous iron. Evidence comes from the apparent requirement of transport for ferroxidase activity. Caeruloplasmin knockout mice exhibit impaired hepatocellular and reticuloendothelial iron efflux which can be rescued by injection of caeruloplasmin^[149]. Similarly, mice with mutations in the membrane-bound ferroxidase, hephaestin, also exhibit impaired iron efflux^[150]. Further, iron efflux was stimulated in *Xenopus* oocytes over-expressing FPN in the presence of caeruloplasmin^[147]. There have been no reports to date indicating whether FPN-mediated iron transport is linked to transport of any other ion or whether there is any energy requirement for the process.

The structure and membrane topology of FPN is currently unclear with various models predicting between nine and twelve transmembrane helices^[151-153]. However, both the N- and C-termini appear to be located intracellularly^[153,154], which precludes an odd number of transmembrane segments. Similarly, the quaternary structure of FPN has been the subject of debate. Initial reports suggested that FPN was oligomeric^[155,156], but later reports cast doubt on this, suggesting a monomer^[152,157]. Recently, a comprehensive study by de Domenico *et al*^[154], demonstrated that FPN was most likely a dimer.

The quaternary structure of FPN may have important implications for regulation of iron homeostasis. Under the oligomeric model, the dominant negative phenotype of FPN-associated haemochromatosis (type 4) can be interpreted as interaction between wild-type and mutant forms of the protein interfering with its normal function^[155,156]. The alternative interpretation, haploinsufficiency, is less likely given that mice heterozygotic for a FPN knockout demonstrated a very mild phenotype and homozygotic knockout mice died *in utero*^[148]. Also, the majority of reports of human FPN-associated haemochromatosis with demonstrable iron loading involve heterozygotic point mutations which are at least partially functional^[156,158,159].

Like ferritin, FPN mRNA contains a functional IRE in its 5'-UTR^[144,147,160] indicating that translation should be augmented when iron is abundant. This has been shown to be true in HepG2 and Kupffer cells but not in the duodenum^[144,160,161] suggesting that regulation of FPN is cell-specific and one or more other regulatory mechanisms may be involved.

OTHER MOLECULES INVOLVED IN IRON HOMEOSTASIS

Hepcidin

Hepcidin is a 25 residue peptide containing four internal disulphide bonds which is produced in hepatocytes under conditions of iron sufficiency^[162-164]. It is created as a pre-pro-peptide which undergoes post-translational cleavage^[163], and its expression is regulated by inflammation and hypoxia as well as iron levels^[164,165]. It appears to be the focal point of an iron-regulatory pathway involving HFE, TFR2 and HJV, since disruption of these genes in haemochromatosis results in decreased hepcidin expression^[166-168]. Its expression is enhanced by cytokines such as interleukin-6 (IL-6)^[117].

In 2004, it was shown that FPN was a receptor for hepcidin^[169]. In HEK293 cells, the peptide was shown to bind to FPN and induce its internalisation in a dose-dependent manner. The complex was targeted to lysosomes for degradation^[169]. This is consistent with results that show increased FPN in the duodenum under conditions of iron deficiency, when hepcidin levels would be low^[144], and offers a mechanism for hepcidin-mediated anaemia of inflammation^[117,170] in which FPN levels are decreased resulting in a reduction of iron efflux to the plasma. The N-terminus of hepcidin is necessary for binding and internalisation of FPN, and the disulphide bonds appear to be necessary for its stability in the plasma^[171]. It is unclear whether hepcidin acts *in vivo* as an autocrine hormone, signalling to FPN in hepatocytes or as a paracrine hormone, signalling to FPN in Kupffer cells.

Haemojuvelin (HJV)

HJV is a protein known to play a very important role in hepatic iron homeostasis although its exact function and whether it plays a role in iron transport have yet to be ascertained. It is expressed in adult skeletal muscle, and foetal and adult liver in the periportal hepatocytes^[168,172]. Both soluble and membrane anchored forms have been demonstrated in Hep3B cells^[173]. Identified as the protein mutated in many cases of juvenile haemochromatosis^[168], human HJV shares 48% sequence identity with repulsive guidance molecules which are important in retinal development^[174]. Absence of functional HJV results in increased plasma transferrin saturation and ferritin in humans^[175,176] and studies in HJV knockout mice demonstrate decreased hepatic hepcidin expression and increased liver iron loading^[172,177]. The major function of HJV appears to be regulation of hepcidin levels, and it has been shown that HJV can bind bone morphogenic protein-2 (BMP-2), a member of the TGF- β superfamily of cytokines and activate hepcidin transcription *via* SMAD-4^[178,179]. This pathway is independent of HFE, TFR2 and IL-6^[180].

KUPFFER CELLS

Kupffer cells are the resident macrophages of the liver. Their main function in iron metabolism appears to be as a clearing house for iron from phagocytosed red blood cells^[181]. Haem breakdown is catalysed by haem oxygenase, and the products are ultimately excreted in the bile^[182]. Iron can be stored in Kupffer cells as ferritin. But, much of it is released back into the circulation^[183]. Consistent with this, Kupffer cells have been shown to strongly express both FPN transcript and protein^[184,185]; indeed, FPN is more highly expressed in Kupffer cells than hepatocytes^[144,184,186].

No functional studies on the role of FPN in iron release by Kupffer cells have been carried out. However, a number of studies have been undertaken using bone marrow-derived macrophages or macrophage cell lines. Following erythrophagocytosis or experimentally induced iron loading, the expression of many genes involved in iron metabolism, including FPN and haem oxygenase 1, are upregulated^[185,187]. In these cells, FPN is localised to intracellular vesicles, redistributing to the cell surface

following erythrophagocytosis^[188]. The upregulation of FPN results in an increase in iron release and its down-regulation results in a decrease in iron release^[189], consistent with involvement in iron recycling by Kupffer cells.

That FPN has been observed localised to intracellular vesicles in the absence of hepcidin suggests that FPN may play a role in intracellular redistribution of iron within Kupffer cells^[190] as well as in iron export. Addition of hepcidin resulted in rapid disappearance of FPN from the cell membrane, and subsequent degradation of the protein^[188], suggesting that in the absence of hepcidin, FPN may be able to cycle to intracellular compartments as necessary.

Kupffer cells also express TFR1^[191] indicating that they can obtain iron from transferrin if necessary. Interestingly, Kupffer cells also express high levels of HFE^[192]; however, they appear to be spared the level of iron loading associated with hepatocytes in HFE-associated haemochromatosis^[7]. This may indicate a difference in regulation of HFE in macrophages compared to hepatocytes or simply that iron loading of Kupffer cells is partially negated by the high level of iron exported from these cells^[183]. A recent report has suggested that GAPDH functions as a transferrin receptor in macrophages^[193]. However, the affinity of the interaction was extremely low and its importance is yet to be determined.

LIVER IRON TRANSPORT IN DISORDERS OF IRON METABOLISM

In the absence of any relevant genetic defects, an increase in plasma iron would result in an increase in transferrin saturation followed by a rise in the concentration of NTBI. Gene expression in the liver would change to sequester the iron in a non-toxic form, and signal to the duodenum to reduce iron absorption. In primary iron overload disorders, such as hereditary haemochromatosis, mutations in HFE, HJV or TFR2 result in a decrease in hepcidin production, and subsequent misregulation of iron absorption by the duodenum (as, of course, does a lack of functional hepcidin)^[194]. The mechanistic consequences of this for the liver are difficult, if not impossible, to dissect out from the resulting iron overload. This leads to the paradox of TFR2, an iron transporter which is sub-functional in type 3 haemochromatosis, resulting in hepatic iron overload^[71,195] rather than hepatic iron deficiency. This apparent paradox is probably the most telling demonstration of the liver's repertoire of iron transport and regulatory mechanisms.

Secondary iron overload is often a consequence of blood transfusions required for the treatment of certain types of anaemia such as β -thalassaemia or sideroblastic anaemia. The source of the excess iron is haem from transfused erythrocytes which are broken down in the normal way with the haem being catabolised, *inter alia*, by Kupffer cells. As with primary iron overload disorders, gene expression in secondary iron overload will change to reflect the cellular iron loading and the increase in plasma transferrin saturation and NTBI concentration despite the underlying anaemia.

Iron deficiency may be caused by a number of factors

including genetic disorders, pregnancy, an increased requirement for iron during growth, or simply by lack of dietary iron intake. The initial stage of iron deficiency corresponds to mobilisation of storage iron from the liver with decreases in hepatocyte ferritin, and an increase in iron uptake proteins such as TFR1^[196]. Plasma NTBI is generally considered to be non-existent or at very low levels in iron deficiency^[85].

CONCLUSION

Iron transport by the liver is, of necessity, tightly regulated because of the liver's myriad of transport pathways, and its role in iron homeostasis. The explosion of information in the past ten years describing many of the genes involved in liver iron transport has not only provided insight into the mechanisms involved, but also confirmed the complexities evident from the literature from previous decades. Nevertheless, much work remains to be done in piecing together this information in order to fully understand how the pathways of iron transport, the distribution of iron in the liver and the regulatory pathways interact and how they contribute to iron homeostasis.

ACKNOWLEDGMENTS

We are grateful to the National Health and Medical Research Council (Australia) and the Fremantle Medical Research Foundation for funding and to Miss Nicole McCoy for assistance with preparation of the manuscript.

Abstract

The human body requires about 1-2 mg of iron per day for its normal functioning, and dietary iron is the only source for this essential metal. Since humans do not possess a mechanism for the active excretion of iron, the amount of iron in the body is determined by the amount absorbed across the proximal small intestine and, consequently, intestinal iron absorption is a highly regulated process. In recent years, the liver has emerged as a central regulator of both iron absorption and iron release from other tissues. It achieves this by secreting a peptide hormone called hepcidin that acts on the small intestinal epithelium and other cells to limit iron delivery to the plasma. Hepcidin itself is regulated in response to various systemic stimuli including variations in body iron stores, the rate of erythropoiesis, inflammation and hypoxia, the same stimuli that have been known for many years to modulate iron absorption. This review will summarize recent findings on the role played by the liver and hepcidin in the regulation of body iron absorption.

INTRODUCTION

Intestinal epithelial cells or enterocytes take up the predominating ferric iron from the diet through the combined action of an iron reductase (duodenal

cytochrome B or DcytB is a strong candidate) and a ferrous iron transporter known as divalent metal-ion transporter (DMT1) on the brush border membrane^[1,2]. Heme iron, on the other hand, appears to be absorbed through a separate system, and a recently identified apical membrane protein, HCP1, has emerged as a candidate heme transporter^[3]. Irrespective of the form in which iron crosses the brush border, enterocytes export iron into the circulation by the combined action of an iron reductase, hephaestin, and a basolateral membrane iron transporter, ferroportin (FPN). The newly absorbed iron is then bound to circulating transferrin which distributes it around the body to sites of utilization and storage.

The amount of iron transported across the enterocytes is ultimately influenced by body iron requirements. Thus, for example, when body iron levels are low or when erythropoietic demand is increased, iron absorption is elevated. The factors that alter iron absorption exert their effects by influencing the duodenal expression of the major iron transport molecules, particularly DMT1, Dcytb1 and ferroportin^[1,2,4]. Early kinetic studies suggested that it was the efflux of iron out of the enterocytes and into the circulation that was rate limiting for absorption^[5], and more recent molecular studies have provided support for this concept^[6,7]. In particular, this work suggested that basolateral iron transfer by ferroportin was most likely the primary regulatory step. But, how signals from distant sites modulate iron release from enterocytes has until recently remained poorly understood. The missing link in this regulatory pathway has now emerged as the liver-derived peptide hormone hepcidin, and thus we know that the liver plays a central role in the regulation of body iron homeostasis. Hepcidin regulates plasma iron levels by controlling the cell surface expression of ferroportin, and this in turn limits the efflux of iron from enterocytes, macrophages and a number of other cell types.

HEPCIDIN

Hepcidin was first discovered as an antimicrobial peptide in human blood ultrafiltrate^[8] and urine samples^[9]. The gene encoding hepcidin (*HAMP*) is very strongly expressed in the liver. But, weak expression has also been detected in heart, spinal cord, stomach, intestine and lungs^[8-10]. The first evidence linking hepcidin to iron metabolism came almost simultaneously from two groups. One group, using suppressive subtractive hybridization, demonstrated that the levels of the hepcidin transcript were greatly increased in the livers of iron loaded mice^[10]. The other group

Figure 1 Sequence alignment of hepcidin from various species.

inadvertently engineered a mouse strain with negligible hepcidin expression (considered in more detail below), and found that these animals accumulated high levels of body iron^[11]. *HAMP* was mapped to human chromosome 19, and it encodes an 84 amino acid pre-pro-peptide^[9,10]. Pre-pro-hepcidin is ultimately processed into several smaller peptides that consist of the 20, 22 or 25 C-terminal amino acids^[9]. The 25 amino acid peptide has eight cysteine residues forming four intramolecular disulfide bonds, and is the biologically active form of hepcidin^[9,12]. The eight cysteine residues are highly conserved among species from zebra fish to humans (Figure 1). Two-dimensional nuclear magnetic resonance (NMR) spectroscopy showed that hepcidin forms a distorted hairpin-like structure, and NMR diffusion studies demonstrated that the 25 residue peptide forms aggregates involving the first five N-terminal residues^[13]. The 20 and 22 amino acid forms, that lack the N-terminal residues, do not form aggregates and have much reduced iron regulatory capacity^[12,13]. Removal of individual disulfide bonds did not reduce the hepcidin function significantly *in vitro*. However, serial deletions of the N-terminal residues progressively reduced hepcidin activity^[12].

The first animal model describing the relationship between hepcidin and iron homeostasis came serendipitously from the knockout of an adjacent gene encoding upstream stimulatory factor 2 (USF2)^[11]. The USF2 knockout mice of this strain (Paris USF2) had very low levels of hepcidin transcript in the liver and developed multi-organ iron overload (but with relative sparing the spleen) and high transferrin saturation, a phenotype consistent with the human iron loading disease hereditary hemochromatosis^[11]. These results provided the first indication that hepcidin was a negative regulator of iron uptake from the intestine and of iron release from macrophages. Another USF2 knockout mouse strain (Houston USF2)^[14] had normal hepcidin levels, and showed no aberrations in iron metabolism^[15], indicating that the Paris USF2 knockout phenotype was due to hepcidin deficiency. Since these original studies, a specific hepcidin knockout mouse has been generated, and it also shows an iron loading phenotype^[16]. In contrast, mice over expressing hepcidin display decreased body iron levels and a microcytic hypochromic anaemia typical of severe iron deficiency^[15]. The majority of these mice die within a few hours after birth suggesting that hepcidin also inhibits placental iron transport^[15]. A similar situation has been described in humans, and patients with hepatic adenomas producing abnormally high levels of hepcidin suffer from a severe iron refractory anaemia that only resolved after resection of the tumour^[17]. As might be expected from these results, injection of synthetic hepcidin peptide into mice leads to inhibition of intestinal iron absorption and consequently hypoferrremia^[18].

Taken together, these data provide strong evidence that hepcidin is the central regulator of body iron levels.

In humans, mutations in the *HAMP* gene result in a severe form of iron loading disease that presents at early age, and is aptly named juvenile hemochromatosis (JH). *HAMP*-associated JH is inherited in an autosomal recessive manner, and two mutations have been described (93delG and C166T) that are associated with iron loading when present in the homozygous state^[13,19]. While heterozygosity for these mutations alone does not lead to iron loading, compound heterozygosity between two other *HAMP* mutations (Met50del IVS2+1(-G) and G71D) and C282Y, the most common mutation in patients with HFE-associated iron loading, has been reported to result in hemochromatosis^[20]. Thus *HAMP* mutations may act as modifiers of the HFE-associated hemochromatosis phenotype.

Clearly hepcidin plays a major role in the regulation of intestinal iron absorption. But, how does it exert its effects? Soon after the link between hepcidin and iron was recognised, a close inverse correlation between *HAMP* expression and iron absorption and the expression of duodenal iron transporter transcripts was described^[21]. It was suspected that hepcidin interacted with a receptor on the basolateral surface of the enterocytes, thereby activating one or more signal transduction pathways that ultimately led to changes in the expression of the iron transport genes. The truth turned out to be elegantly simple. Hepcidin acts by directly binding to the sole basolateral iron export molecule, ferroportin, and causing its internalisation and subsequent degradation^[22]. Thus ferroportin is the hepcidin “receptor”. This loss of ferroportin on the cell surface reduces iron export from the cells leading to intracellular iron accumulation. As ferroportin is responsible for iron export from both enterocytes and macrophages, loss of this protein will result in reduced supply of iron to the plasma and, hence, will cause hypoferrremia and, ultimately, anaemia. Consistent with this mechanism is the observation that mice lacking hepcidin show decreased iron in the spleen, an organ rich in macrophages, in the face of increased hepatic iron^[15]. Similarly, J774 mouse macrophages treated with hepcidin peptide showed decreased levels of ferroportin and reduced the efflux of iron^[23]. Hepcidin likely acts on iron export from other cell types, such as hepatocytes, in a similar fashion, and this can explain its key role in regulating iron traffic into and around the body.

Since hepcidin interacts with FPN, it might be expected that mutations in FPN that alter this interaction could essentially mimic hepcidin deficiency. This has been found to be the case. Two classes of FPN mutations have been identified in human subjects and both lead to iron loading.

However, there are subtle differences in the phenotypes, with one being consistent with reduced iron transport by the protein and, the other consistent with impaired interaction with hepcidin^[24].

SYSTEMIC FACTORS THAT REGULATE HEPCIDIN

Consistent with its role as a central regulator of body iron metabolism, hepcidin levels are modulated by the same factors that alter iron homeostasis. Changes in body iron stores, the rate of erythropoiesis, inflammation and hypoxia all influence iron absorption and iron release from macrophages and these are the major systemic factors that regulate *HAMP* mRNA levels in the liver.

Hepcidin levels are increased in response to oral and parenteral iron loading and decreased under iron deficient conditions^[10]. This inverse relationship is seen with chronic changes in body iron status. But, it can also occur quite quickly, and *HAMP* mRNA levels in the liver can decrease within days of transferring rats from a control to iron deficient diet^[21]. The regulation of hepcidin by body iron levels acts as a feedback mechanism to allow sufficient iron to enter the plasma when demand is high, but to limit iron intake/release in times of iron sufficiency. How hepcidin responds to changes in body iron levels is incompletely understood. Since hepcidin expression is largely restricted to the liver, it is highly likely that the hepatocyte is the site of action of the regulatory stimulus. But, whether hepatocyte iron levels per se play a primary role or whether an external signal is involved is unclear. This will be considered in more detail in the following section.

Interestingly, *in vitro* loading of hepatocyte cell lines and primary hepatocytes with iron decreases *HAMP* mRNA expression, the opposite effect to that seen *in vivo*^[25]. Why this is the case has proved difficult to resolve. One possibility is that the iron supplied to the cultured cells is of a different form to that presented to the liver *in vivo*. This may be the case, but the *in vitro* reduction in hepcidin expression is seen when both iron salts and transferrin-bound iron is presented to the cells. A second possibility is that during the isolation and culture procedure liver-derived cells lose some factor that is critical for their normal physiological response to iron. Since the same effect is seen on freshly isolated primary hepatocytes this appears unlikely. But, it remains possible. Potentially the most satisfying explanation for the observations is that the response of the liver to iron *in vivo* requires the interaction of two or more types of cells, and that this interaction is lost after the cells are isolated. The liver macrophages or Kupffer cells are strong candidates for cells that might interact with hepatocytes to regulate iron homeostasis. But, several studies have now shown that when animals are depleted of macrophages (including Kupffer cells) their livers respond normally by increasing hepcidin expression in response to iron^[26,27]. Thus it appears that macrophages are not required for hepcidin regulation in the liver in response to iron *in vivo*. A final possibility is that reduced expression of hepcidin is the normal physiological response of hepcidin to iron, and that the *in vivo* situation is complicated by a range of interacting stimuli that

influence expression of the *HAMP* gene. Further work is required to resolve this issue.

The largest single sink for iron in the body is haemoglobin in the red blood cells, and consequently iron demand is closely linked to the rate of erythropoiesis. Thus when erythropoiesis is stimulated, following phenylhydrazine-induced hemolysis for example, hepcidin expression is suppressed to allow increased iron flow into the plasma and consequently to the developing red cells^[15,28]. This hepcidin response is observed only in the presence of erythropoiesis as suppression of erythropoiesis by irradiation or by post-transfusion polycythemia leads to increased hepcidin levels^[29,30]. The regulation of hepcidin mRNA levels by erythropoiesis is independent of direct erythropoietin effects^[30], and is likely to reflect several stimuli. The iron requirement of the erythroid marrow is certainly a major factor. But, hypoxia too is also likely to be important as reduced haemoglobin may reduce oxygen delivery to the tissues. The response of hepcidin to hypoxia is considered in more detail below. In a recent study by Ganz and colleagues, it was concluded that in addition to iron requirements and hypoxia, there is an erythropoiesis-specific factor that affects hepcidin expression^[30]. However, this factor has yet to be characterized.

Another situation where body iron homeostasis is perturbed is during inflammation or infection. Under these circumstances, iron absorption declines and iron is sequestered in macrophages, with the consequence that the plasma iron level is decreased (hypoferrremia). With chronic inflammation or infection, anemia may result, and this condition is often called the anemia of chronic disease^[31]. Consistent with the reduction in plasma iron is the demonstration that inflammatory stimuli positively regulate hepcidin levels^[32-35]. Increased hepcidin means decreased iron entry into the plasma. That hepcidin is responsible for the hypoferrremia accompanying inflammation has been shown by studies with *Hamp* null mice. These animals mount a standard inflammatory response to a stimulus such as bacterial lipopolysaccharide (LPS), but the expected hypoferrremia does not occur^[32].

One of the major mediators of the inflammatory response is the cytokine IL-6. IL-6 infusion in humans or administration to experimental animals leads to an increase in hepcidin production and decrease in serum iron levels within a few hours^[36]. A time course analysis in human subjects injected with LPS revealed a strong temporal correlation between increases in serum IL-6 and urinary hepcidin, and the decrease in serum iron^[34]. Similarly, IL-6, other pro-inflammatory cytokines like IL-1 α and IL-1 β and LPS stimulate hepcidin in primary hepatocytes and hepatoma cell lines^[36,37].

Many inflammatory processes have a systemic component, and these are able to influence hepcidin expression in hepatocytes. However, there is increasing evidence that hepcidin may also be relevant in the local, extra-hepatic setting. For example, in an *in vivo* murine granulomatous pouch model of infection the host animals responded to bacterial infection by upregulating hepcidin at the local level, presumably to limit availability of iron to the pathogens in the immediate vicinity^[35]. The

cells responsible for the local production of hepcidin are unknown, but may be infiltrating macrophages and neutrophils. Indeed hepcidin expression has been detected in myeloid cells in response to systemic infection^[38]. Hepcidin production also has been demonstrated in adipose tissue. But, again the responsible cell type is not known^[39].

At the whole body level, hypoxia is usually associated with a reduced amount of circulating hemoglobin, and the body's response to this deficiency is to stimulate erythropoiesis. This in turn requires an increased iron supply. It thus comes as no surprise that hepcidin levels drop 2-4 d after animals are placed in a hypoxic chamber^[32], and that luminal iron uptake is increased in the small intestine under the same conditions^[40]. Some of the *in vivo* effects of hypoxia cannot be attributed to the direct repression of hepcidin expression by low oxygen as increased erythropoiesis may reduce hepcidin levels by other mechanisms^[30]. But, the demonstration that hypoxia down regulates hepcidin mRNA levels in human hepatoma cell lines^[32] suggests that the *HAMP* gene itself may be regulated by hypoxia. In addition, hypoxia could also trigger a stress response in cells and animals, and *HAMP* is a known stress response gene^[33].

The factors that regulate hepcidin levels described above vary in their relative strength, and in certain situations, where more than one stimulus is present, one may predominate. A good example of this is in β -thalassemia. In both mice and humans with this disorder, hepcidin levels are initially low despite increased levels of storage iron, and thus the erythropoietic stimulus is predominating^[41-43]. However, as the disease advances the effect of the increasing iron stores become relatively stronger and hepcidin levels increase. A similar situation is found in hypotransferrinaemic mice^[17] and in iron loaded animals treated with PHZ to induce anaemia and erythropoiesis^[32] where the erythropoietic stimulus predominates.

THE MOLECULAR BASIS OF HEPCIDIN REGULATION

While the major physiological factors that alter hepcidin expression have been identified, how these stimuli signal the liver to alter hepcidin expression, and how the changes in expression are brought about is complex and only partially understood. Important clues in dissecting these regulatory pathways have come from the analysis of human iron loading disorders and their equivalent murine models. Patients with mutations in the *HFE*, transferrin receptor 2 (*TfR2*), hemojuvelin (*HJV*) or *HAMP* genes all show a histological pattern of iron deposition that is similar and consistent with elevated iron absorption. Furthermore, *HFE*, *TfR2* and *HAMP* all show their highest expression in the liver and *HJV* shows strong expression in this organ. These similarities suggested that the proteins these genes encode may form part of the same regulatory pathway. This has now proved to be the case.

Classical, adult onset hereditary hemochromatosis (HH) results from mutations in the *HFE* gene, and both human

patients and mouse strains with a disrupted *HFE* gene show periportal iron deposition with relative sparing of the Kupffer cells^[44,45]. *HFE* is expressed on the cell surface as a complex with β_2 -microglobulin (β_2m) and mouse models of β_2m deficiency show a similar iron loading phenotype^[46-48]. Since hepcidin expression is increased with iron loading, it was expected that disruption of the *HFE* gene would lead to enhanced hepcidin levels. When this was investigated, however, the opposite was seen. Human patients with *HFE*-associated hemochromatosis showed significantly lower levels of liver hepcidin expression than control subjects^[49]. In *Hfe* knockout mice, hepcidin levels were similar to those of wild-type animals. But, the level remained low even when the knockout animals were fed a high iron diet^[50]. Taken together, these observations show that *HFE* is an upstream regulator of hepcidin, and not a downstream target as was previously believed^[49]. Proof of this was provided by Nicolas and colleagues who showed that mice over expressing hepcidin, but null at the *Hfe* locus, did not accumulate excess iron^[51]. Despite low hepcidin levels in patients with HH, hepcidin levels still increase as the body iron load increases indicating that hepcidin regulation is not completely disrupted when *HFE* is mutated^[49,52]. This is consistent with the milder phenotype of patients with *HFE*-associated HH compared to those with mutations in the *HAMP* gene^[24].

If *HFE* acts as an upstream regulator of hepcidin, how does it respond to changes in body iron demand? The answer to this question is not clear. But, the level of circulating diferric transferrin has emerged as a potential regulator^[53,54]. *HFE* is able to bind to TfR1, the major cell-surface diferric transferrin binding protein^[55,56], and *HFE* and transferrin are able to compete for TfR1 binding. Such competition could modulate the amount of *HFE* that is not bound to TfR1 that in turn could transduce a signal to alter hepcidin expression. It is also possible that *HFE* interferes with the cellular uptake of transferrin-bound iron, and that this in turn affects *HAMP* expression^[57]. Support for diferric transferrin as a signal to alter *HAMP* expression has come from the demonstration that another transferrin binding protein, TfR2, also is involved in hepcidin regulation.

Transferrin receptor 2 encodes a protein that shares 45% identity with TfR1^[58]. However, in contrast to its widely expressed homolog, TfR2 expression is restricted to the liver, spleen, brain and heart, with highest expression in the liver^[58]. Mutations in TfR2 lead to iron overload in human patients^[59] with a clinical picture similar to classical *HFE*-associated hereditary hemochromatosis^[60]. The same phenotype is seen in TfR2 knockout and mutant mice^[61,62]. As in *HFE*-associated iron loading, hepcidin expression is decreased in the liver of TfR2 mutant mice^[62,63], and patients with TfR2-related hemochromatosis also show decreased urinary hepcidin levels^[64]. The severity of TfR2-related hemochromatosis is much less than that associated with mutations in *HAMP* or *HJV*, but is similar to *HFE*-associated hemochromatosis.

Like *HFE*, TfR2 appears to be an upstream regulator of hepcidin. But, how it exerts its effects is unknown. It has been reported that, unlike TfR1, TfR2 does not bind to *HFE*, and shows 25 times less affinity for transferrin compared to TfR1^[65] making it unlikely that TfR2 makes a

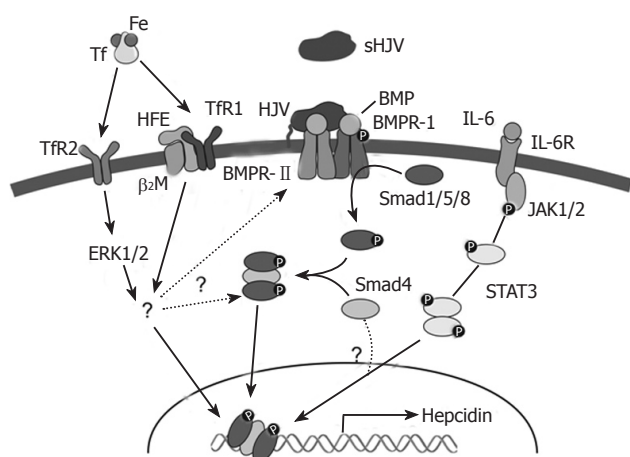

Figure 2 Signalling pathways for *HAMP* regulation.

major contribution to cellular iron uptake. Indeed, in *Tfr2* knockout mice, the liver accumulates iron very efficiently indicating that *Tfr2* is not essential for hepatic iron uptake. In contrast, a recent study has shown that when *Tfr2* and *HFE* are over expressed together in the same cells they can be co-immunoprecipitated^[66]. Whether this interaction is physiologically relevant or represents an overexpression artefact remains to be determined. Interestingly, two independent studies have demonstrated that *Tfr2* protein levels are upregulated by diferric transferrin, but do not respond to apotransferrin or non-transferrin bound iron^[67,68]. This effect of diferric transferrin is not observed at the transcript level, and appears to be post-translational^[68]. Recently, it has been reported that the interaction between diferric transferrin and *Tfr2* activates ERK1/ERK2 and p38 MAP kinase, but only when *Tfr2* is present on the lipid rafts of the exosomes^[69]. However, the precise mechanisms and signalling pathway of *Tfr2*-hepcidin axis are not yet understood and remain to be further explored.

The third important protein known to be involved in the regulation of hepcidin is hemojuvelin (HJV, RGMc). HJV, is a member of the repulsive guidance molecule (RGM) family, and shares some common features with RGMa and RGMb, including a C-terminal glycosylphosphatidylinositol-linked membrane anchor (GPI-anchor), N-terminal signal sequence, proteolytic cleavage site and partial von Willebrand factor type D domain^[70,71]. Mutations in the *HJV* gene cause severe iron overload, and lead to juvenile hemochromatosis due to greatly decreased hepcidin levels in human patients^[72] and mice^[73,74]. Moreover, knocking down HJV with siRNA in Hep3B cells leads to a decrease in hepcidin levels^[74]. Interestingly, HJV expression is strongest in heart and skeletal muscle, but also shows moderate expression in the liver^[72], where *HAMP* is most strongly expressed. Treating primary hepatocytes with soluble HJV led to a decrease in hepcidin levels suggesting that a binding competition exists between soluble and cell-associated hemojuvelin^[75]. In addition, increasing iron concentrations led to a decrease in soluble HJV (sHJV) in cells over expressing HJV^[75], indicating that iron could regulate HJV at the post-transcriptional level.

HJV acts as a co-receptor for the bone morphogenetic proteins (BMPs), in a similar fashion to other molecules of the Rgm family, and HJV mutants have impaired BMP signalling^[76]. BMPs represent a subfamily of transforming growth factor-beta (TGF- β) ligands that signal by binding to and bringing together type I and type II BMP receptors on the cell surface, and then propagating the signal through phosphorylation of the Smad proteins^[77] (Figure 2). BMPs phosphorylate receptor-regulated Smads 1, 5 and 8 that in turn form heteromers with the co-mediator Smad 4. The activated complex then translocates to the nucleus and, in combination with other factors, regulates target genes such as *HAMP*^[77]. Cells transfected with the co-receptor HJV or treated with the ligand BMP-2 showed increased levels of hepcidin, and BMP-2 induction was enhanced in the presence of HJV^[76]. Other BMPs, BMP-4 and BMP-9, have been shown to have a similar effect on hepcidin expression independent of *HFE* and *Tfr2* status^[78]. This suggests that HJV acts *via* a *HFE*/*Tfr2* independent pathway to alter *HAMP* levels. Further insight into this aspect of hepcidin regulation comes from the studies of the liver-specific Smad 4 knockout mouse. These animals showed markedly decreased levels of hepcidin, increased duodenal transporters and iron overload^[79]. Overexpression of Smad 4 led to transcriptional activation of *HAMP* due to epigenetic modification of histone H3 protein^[79]. Smad 4-deficient hepatocytes showed no increase in hepcidin levels upon treatment with BMP, iron, TGF- β or IL-6^[79]. This response to BMP is expected as Smad 4 acts downstream in the signalling pathway^[79]. However, the result with IL-6 is interesting as it indicates that the IL-6 pathway and the BMP-Smad pathway converge at some point. Overall, these data indicate that the BMP/SMAD pathway plays an important role in the regulation of *HAMP* gene expression. Whether this is the major pathway operating or other pathways are dominant remains to be determined, as the relationship between *HFE*, *Tfr2* and HJV (Figure 2).

Pro-inflammatory molecules like LPS and FCA positively regulate hepcidin expression by inducing the expression of cytokines such as IL-6. This induction of hepcidin by pro-inflammatory cytokines appears to be independent of *HFE*, β_2m and *Tfr2*^[80,81], although one study provided evidence that these proteins may play some role^[82]. The differences in these studies could be due to the difference in the timing and dosage of the treatments. IL-6 alters *HAMP* transcription through the classical JAK-STAT pathway^[83,84]. This pathway ultimately leads to activation of STAT3 that binds to an element in the proximal 100 bases of the *HAMP* promoter. The interesting observation that the IL-6 dependent stimulation of the *HAMP* gene is abrogated in Smad 4 knockout mice indicates that Smad 4 is involved in the signalling process as well. This has yet to be investigated in detail, as have the mechanisms by which other pro-inflammatory cytokines stimulate *HAMP* expression.

Although it is widely considered that the *HAMP* gene is regulated predominantly at the level of transcription, relatively few promoter analyses have been carried out. As noted above, STAT3 is known to bind to the promoter, and several other transcription factors have been

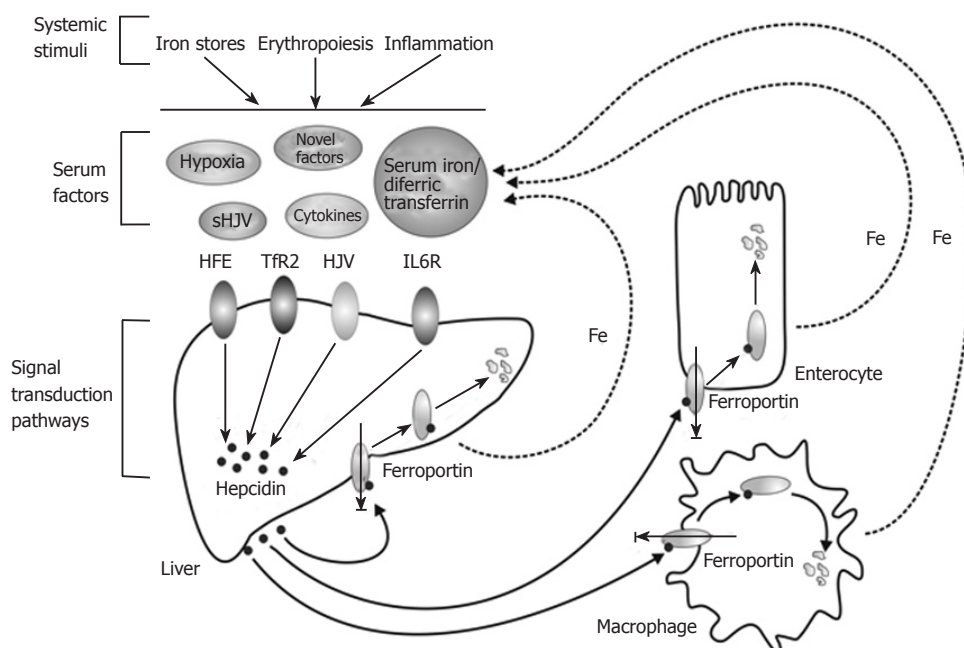

Figure 3 A model for the liver-dependent regulation of iron homeostasis.

identified. C/EBP α , a liver-enriched transcription factor, has been shown to bind the *HAMP* promoter 230-250 bp upstream of the transcription start site^[85], and may drive basal transcriptional activity of the gene. Supporting such a role, C/EBP α knockout mice showed decreased hepcidin levels and increased iron staining in their livers^[85]. In another study, the role of the basic helix-loop-helix leucine zipper (bHLH-ZIP) family of transcriptional regulators, and notably USF2, in *HAMP* transcription was studied in order to investigate the reasons behind the lack of hepcidin expression in the USF2 knock out mouse. It was demonstrated using site-directed mutagenesis, chromatin immunoprecipitation assays and mobility shift assays that USF1/USF2 and c-Myc/Max bind to E-boxes in the hepcidin promoter, and regulate its transcription^[86]. Because some genes with E-boxes show rhythmicity, it has been proposed that hepcidin might also be under pulsatile or rhythmic transcriptional control. However, the signals and cellular pathways that lead to the activation of these proteins in the context of hepcidin regulation remain to be resolved.

A MODEL FOR THE LIVER-DEPENDENT REGULATION OF IRON HOMEOSTASIS

The discussion above has highlighted various factors that regulate hepcidin, and the current knowledge about the molecular mechanisms behind their effects. We previously proposed a model to explain the regulation of hepcidin in a physiological context^[53], and present an updated version of the model here (Figure 3). In this model, signals that alter body iron homeostasis (iron stores, erythropoiesis, inflammation, hypoxia) act on the hepatocytes in the liver to modulate *HAMP* gene expression. Some of these stimuli may act directly on the liver cells (e.g. hypoxia), while others may act indirectly e.g. iron stores may act through changing the levels of diferric transferrin in the circulation. How the signals alter *HAMP* expression at the

molecular level is incompletely understood. HFE, TfR2 and HJV are clearly involved in the process and, in the case of the latter; signalling through the BMP/SMAD pathway is a likely mode of action. Pro-inflammatory cytokines such as IL-6 act through the JAK/STAT pathway to regulate *HAMP* transcription. Hepcidin secreted by the liver acts on mature enterocytes in the proximal small intestine to reduce iron export into the circulation. Thus, high hepcidin means reduced iron absorption and vice versa. Hepcidin also acts on macrophages, hepatocytes, and likely other cells in the body to regulate their release of iron, so it plays a universal role in iron homeostasis.

Hepcidin levels show a positive correlation with transferrin saturation that is independent of the liver iron content^[21] indicating that the levels of iron bound to transferrin may be a major signal that regulates the expression of hepcidin in the liver. Diferric transferrin is essential for iron delivery to the tissues making it suitable as an indicator of plasma iron status. Transferrin saturation thus decreases with iron deficiency and increases with iron loading. Diferric transferrin competes with HFE for binding to TfR1, and their binding sites overlap. But, it has a higher affinity for its principal receptor than HFE^[87], and thus out-competes HFE for binding to TfR1. This leaves HFE “free” on the cell surface to initiate a signal to stimulate hepcidin expression. Similarly, diferric transferrin binds to TfR2, although with lower affinity, and sends a signal via the proposed ERK1/2 and MAPK pathways^[69]. The signal transduction pathways driven by HFE and TfR2 that lead to the regulation of hepcidin expression are not yet clear. HFE and TfR2 may form a stable complex with each other as has been proposed^[66] or may interact with HJV/BMPRs to propagate the signalling *via* the Smad1, 5, 8/Smad4 pathway. But, the precise details have yet to be elucidated.

In iron deficiency, TfR1 and transferrin levels increase, and transferrin saturation drops. The balance shifts towards monoferric transferrin that has lower binding affinity for TfR1 compared to diferric transferrin. This

results in increased binding of HFE to TfR1, decreased signalling, and consequently lower hepcidin production. Similarly, as the plasma iron level falls, TfR1 binds residual diferric transferrin more efficiently than TfR2. This down regulates the TfR2-ERK signalling pathway, and thus hepcidin synthesis. When body iron levels are high the opposite pattern is seen, and hepcidin expression is increased. Stimulated erythropoiesis is another major stimulus for iron absorption, and at least one mechanism by which it might exert its effects on reducing hepcidin expression is *via* reduced transferrin saturation.

CONCLUSION

Recent developments in understanding the molecular mechanisms of iron homeostasis have greatly enhanced our knowledge of iron absorption in the gut. The most important advance in this area has been the recognition that the liver-derived peptide hepcidin responds to variations in body iron demand, and acts on the proximal small intestine to regulate iron efflux into the plasma. This shows that the liver plays a central role in the regulation of body iron homeostasis. Various systemic stimuli including iron stores, the rate of erythropoiesis, and oxygen levels regulate hepcidin expression, and consequently iron absorption. But, how systemic signals are received by the liver, and how these signals are transduced into changes in *HAMP* gene expression are incompletely understood. Strong evidence now suggests that signalling through the BMP/Smad pathway plays a major role in regulating hepcidin. But, how universal this pathway is has yet to be resolved.

Abstract

Iron is an essential element involved in various biological pathways. When present in excess within the cell, iron can be toxic due to its ability to catalyse the formation of damaging radicals, which promote cellular injury and cell death. Within the liver, iron related oxidative stress can lead to fibrosis and ultimately to cirrhosis. Here we review the role of excessive iron in the pathologies associated with various chronic diseases of the liver. We also describe the molecular mechanism by which iron contributes to the development of hepatic fibrosis.

INTRODUCTION

Iron, created by stellar nucleosynthesis, is the most abundant element on Earth in terms of mass, making up 35% of total planetary mass. Iron, in its ferrous (Fe^{2+}) and ferric (Fe^{3+}) forms, is critical to all life forms from the simplest filamentous algae through to the most complex multicellular organisms. Iron is an essential element mainly present within the cells in association with haemoprotein (haemoglobin, myoglobin) or within an iron-sulphur cluster of various metalloproteins (e.g., aconitase and

Rieske proteins of the respiratory chain)^[1]. Iron is involved in the redox-driven processes of oxygen transport, electron transport and various enzymatic reactions such as DNA synthesis, transcriptional regulation, catalysis as well as nitric oxide (NO) and oxygen sensing^[1]. Mammals do not have any major physiological pathway for iron excretion. Therefore, iron uptake and storage is closely regulated so as to avoid deficiency, and excess. In humans, iron deficiency is manifested as anaemia and with increasing severity can eventually result in cardiac failure. Iron overload, especially at sites of storage, enhances oxidative stress ultimately leading to lipid, nucleic acid and protein peroxidation. Within the liver, which is the major site of iron storage, enhanced oxidative stress can lead to fibrosis, cirrhosis, hepatocellular carcinoma (HCC) and death.

In this review, we outline the hepatic disease states where iron is an important factor in disease progression. We also discuss the role of iron in promoting liver fibrosis and those cells and mechanisms most important in the underlying wound healing/fibrotic processes.

HEPATIC FIBROSIS

Hepatic fibrosis is promoted by various pathogenic, mechanical and toxic insults to the liver, and is part of a physiological wound healing response. If the injurious stimuli are chronic, the degree of fibrosis worsens, leading to cirrhosis, and eventually to hepatic failure and death. The interactions between various resident hepatic cell populations and immune cells that lead to the establishment of fibrosis are complex, and not yet fully understood. However, some profibrogenic pathways and clinical outcomes are common to several disease states, and these will be briefly outlined below.

In the normal liver, a balance is struck between extracellular matrix (ECM) deposition and degradation, a process that is tightly regulated by matrix metalloproteinases (MMP) and their specific inhibitors (TIMPs)^[2]. Fibrosis is associated with major quantitative and qualitative changes in the ECM. These changes are mainly due to an increase in the expression of TIMP-1^[3] and an increase in the expression of various ECM components, which include fibrillary collagens I and III, collagen IV, fibronectin, elastin and laminin^[4].

The hepatic stellate cell (HSC) resides within the space of Disse, and is responsible for the majority of ECM deposition in the normal and fibrotic liver^[5,6]. In the normal liver the primary role of the HSC is the regulation of

vitamin A homeostasis and storage^[6]. In times of chronic injury, the HSC transdifferentiates into a myofibroblastic cell exhibiting contractile, proliferative, inflammatory and fibrogenic properties. Transdifferentiation occurs in response to soluble fibrogenic and proliferative factors released mainly by Kupffer cells (KC), (PDGF, TGF β 1) or by damaged hepatocytes (IGF-1, TNF α , EGF)^[2]. Once transdifferentiated, the HSC expresses a number of myogenic markers (including α smooth muscle actin (α SMA), c-myc and myocyte enhancer factor-2) that allows them to be readily identified by immunohistochemical techniques^[4]. In addition, HSC also express a number of neuroendocrine proteins (e.g., glial fibrillary acidic protein or GFAP, synaptophysin and nestin^[4]) and receptors for various neurotransmitters^[7]. Once activated, HSC also release TGF β 1 and PDGF-BB, thereby ensuring a self-sustained phenotypic change^[8,9]. Fibrosis was once thought to be irreversible; however, a growing body of evidence now suggests that once the underlying source of liver injury is treated, fibrosis, and even cirrhosis, to some extent, are reversible. Fibrosis resolution is known to be accompanied by HSC apoptosis, and to some degree of reversion of HSC to their original phenotype^[10].

IRON AND DISEASES OF THE LIVER

Iron is proposed to play a role in promoting hepatic fibrosis in a number of different chronic liver disease states. The evidence supporting or contradicting those propositions is outlined in the following section.

Haemochromatosis

Haemochromatosis is a term used to describe excessive iron loading of the liver leading ultimately to cirrhosis and frequently to HCC^[11]. The knowledge regarding the underlying causes of haemochromatosis is gradually expanding, and the term has now been subdivided according to the specific genetic mutation involved. Iron loading of the liver is a life long process in patients with haemochromatosis, occurring without any apparent overt inflammation or elevation of serum liver enzymes such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The symptoms associated with hereditary haemochromatosis (HH) include; hepatomegaly, malaise, insulin resistance and arthritis, to name but a few. When hepatic iron reaches the threshold concentration of 60 μ mol/g dry weight, HSC begin to exhibit the early stages of cellular activation (namely α SMA expression), a key event in the initiation of hepatic fibrosis^[12]. Evidence also suggests that there is a hepatic iron concentration threshold (about 250 μ mol/g dry weight) beyond which cirrhosis can develop in patients with HH^[13,14]. Initial iron loading of the liver occurs in hepatocytes located in Rapoport zone 1, progressively extending to hepatocytes in zones 2 and 3. In the later stages of the disease, KC also accumulate iron and it is the co-loading of both hepatocytes and KC that is, believed to allow fibrosis to become established^[15]. Patients with well established hepatic iron loading are also at a significantly greater risk of developing HCC^[11]. Phlebotomy is widely used to reduce iron burden

in patients with haemochromatosis and, is also an effective way to reverse hepatic fibrosis^[14,16], although regression of cirrhosis remains controversial^[14,16].

Transition of the iron-loaded liver from non-fibrotic to fibrotic, and then onwards to cirrhotic is not always a clear-cut process, and there is growing evidence to suggest that other factors, such as excessive alcohol consumption^[17], viral hepatitis^[18] and steatosis^[19] among others, have an important role in that transition. In fact, iron overload has been shown to be important in the pathology of other liver disease such as non-alcoholic fatty liver disease (NAFLD), alcoholic liver disease (ALD) and chronic hepatitis C.

Non-alcoholic fatty liver disease

Increase in caloric intake and an evermore sedentary lifestyle have led to a surge in the prevalence of people being overweight or obese. Current estimates suggest that as much as 60% of the over 18 age group in Australia will be overweight or obese by the year 2010^[20]. Obesity impacts the liver in the form of NAFLD, which is now recognised as the most common form of liver disease. NAFLD begins with steatosis (fat accumulation within the liver) and can remain in this state without any apparent associated pathology. In its more advanced form NAFLD is often referred to as non-alcoholic steatohepatitis (NASH). It is believed that in order for steatosis to advance to NASH a secondary liver insult is also required often termed the "second hit"^[21]. Iron is among several co-factors known to increase hepatic oxidative stress, and constitutes a "second hit" agent that is postulated to contribute to the progression of steatosis to NASH.

Several studies have highlighted mutations (C282Y and H63D) in the HFE gene that positively correlate with the presence of NAFLD/NASH^[19,22-24]. These studies suggest that while combined NASH/NAFLD and HFE mutation have a negative effect on disease severity as highlighted by serum ALT concentrations and fibrosis grade, hepatic iron concentration is not always elevated. Interestingly Mendler and colleagues also noted that patients with an elevated iron burden almost always displayed insulin resistance irrespective of liver damage^[24]. Insulin resistance is known to play a central role in the accumulation of triglycerides within the hepatocytes, and in the initiation of the inflammatory cascade ultimately leading to cirrhosis^[25]. The correlation between elevated hepatic iron and disease severity in patients with NAFLD/NASH is not always consistent. Several studies have failed to find any evidence of increased hepatic iron levels in patients with NAFLD/NASH, with histological severity being linked to the presence of ballooning hepatocyte degeneration, Mallory hyaline, older age, obesity and the presence of diabetes mellitus^[26-28]. The role of iron in the pathologies associated with NAFLD is, however, further supported by several studies that demonstrate the beneficial effects of iron depletion on serum ALT concentrations and insulin response in patients with NAFLD^[29]. How and why steatosis and iron combined lead to exacerbated fibrosis is possibly linked to the oxidative stress that both can exert.

Alcoholic liver disease

ALD is caused by high risk alcohol consumption over a number of years. Of those engaging in high risk alcohol consumption, only approximately 30% go on to develop liver cirrhosis^[21]. This would suggest that other factors influence disease severity and progression in patients with ALD. Iron is one such factor known to affect the pathogenesis of ALD. In pre-cirrhotic ALD, approximately 29% of patients demonstrate an elevated hepatic iron concentration^[30]. As the disease progresses to cirrhosis, as many as 57% of patients have iron overload ($> 25 \mu\text{mol/g}$)^[31]. It is also apparent that iron is an independent risk factor for the development of fibrosis^[32] in ALD, and higher iron concentrations also correlate with reduced survival^[33]. Alcohol has been postulated to enhance iron uptake by a number of different mechanisms, which have recently been reviewed by Brittenham^[34]. In addition, recent work by Bridle and colleagues suggest that ethanol may perturb IL-6-mediated hepcidin expression resulting in enhanced absorption of iron and hemosiderosis^[35]. This is important when one considers that mammals lack an effective mechanism by which excess iron can be eliminated from the body^[34].

Hepatitis C

Viral hepatitis encompasses a range of different entities from hepatitis A through E, which are caused by distinct viruses. Of these, hepatitis B and C are perhaps the most significant in terms of patient morbidity and mortality. Hepatitis B virus (HBV) is a member of the *Hepadnaviridae* family. Estimates suggest that between 3% and 6% of the world's population are infected with HBV, with up to one third having been previously exposed^[36]. Hepatitis C virus (HCV) is a member of the *Flaviviridae* family and is thought to infect somewhere between 150 and 200 million people worldwide. Both types of viral hepatitis contribute to the development of cirrhosis and HCC. As is common with many forms of liver disease, the severity and rate at which fibrosis progresses are influenced by a great number of external factors and in viral hepatitis these include male gender, alcohol consumption, iron status and age at infection^[37].

The association between elevated serum iron and hepatitis B was first described by Blumberg *et al* in 1981^[38]. Some years later, a link was also found between serum iron, ferritin, transferrin saturation levels and HCV infection^[39,40]. However, these results did not correlate with an increased hepatic iron concentration. Where hepatic iron was found to be elevated in association with HCV infection (in 5% of cases), it was seldom to levels deemed hepatotoxic^[39]. In HCV-infected patients, iron is deposited in hepatocytes, sinusoidal cells, and portal mesenchymal cells, with the degree of portal mesenchymal iron deposition correlating with both hepatic inflammation and fibrosis^[41]. Martinelli and colleagues demonstrated a significant correlation between liver iron scores and the number of GFAP and αSMA -positive HSC in patients with HCV. These αSMA -positive or "activated HSC" were located primarily in Rappaport zones 1 and 3^[42]. Similar findings were also reported by Rigamonti and colleagues,

who also described a correlation between hepatic iron concentration and HSC activation. They suggested that, in patients with HCV infection, iron was important in both HSC activation and fibrosis progression^[43]. Besides being directly correlated with inflammation and fibrosis, hepatic iron has also been linked to a lack of response to IFN α in chronic hepatitis C patients^[44,45]. One mechanism by which this may occur was suggested by Di Bona and colleagues, who found that oxidative stress prevented IFN α induced phosphorylation of STAT-1 & 2 and subsequent upregulation of the antiviral proteins MxA and interferon regulatory factor 9, thereby impairing the antiviral action of IFN α ^[46].

The link between iron and fibrosis in chronic hepatitis C patients has, however, been challenged by Guyader and colleagues who looked at other confounding factors also known to influence both iron overload and fibrosis^[47]. In their studies, liver iron was elevated in only 17% of patients, and correlated with age, male sex, and alcohol intake. They found no association between liver iron and fibrosis after adjusting for confounding variables, and suggested that iron should be considered more as a surrogate marker for disease severity rather than as a fibrogenic factor^[47]. Iron is still further implicated in chronic hepatitis C progression by a number of groups investigating the effects of iron depletion on HCV-associated fibrosis. Kaito and colleagues demonstrated that phlebotomy treatment of HCV-infected patients alone was enough to reduce markers of liver damage (AST and ALT values), lipid peroxidation and oxidative stress^[48]. In addition, patients treated by maintenance phlebotomy (keeping patients in a state of near iron deficiency with a serum ferritin level of 10 ng/mL) showed less inflammation and suppressed fibrosis progression^[49]. Phlebotomy has also been used to increase the therapeutic effect of IFN α treatment of chronic hepatitis C by a number of groups^[50,51]. How and why HCV should interfere with iron homeostasis is open to conjecture. However, there is some evidence to suggest that HCV infection may influence the expression of the iron homeostasis peptide, hepcidin. Nagashima and colleagues suggested that a failure in the regulation of serum prohepcidin levels (mediated by HCV) leads to elevated serum ferritin concentrations, and subsequently to progression of liver injury by iron overload in chronic hepatitis C patients^[52]. Conversely, Aoki and colleagues found hepcidin mRNA expression in the liver did not correlate with AST, ALT levels, or viral load and no differences in hepcidin mRNA were found based on viral genotype or the presence of fibrosis^[53].

MOLECULAR MECHANISMS OF IRON-INDUCED FIBROSIS

This section outlines the mechanisms by which iron is able to cause liver damage and the subsequent pathways activated that lead to hepatic fibrosis.

Role of iron in oxidative stress

In hepatocytes and KC, iron catalyses the production

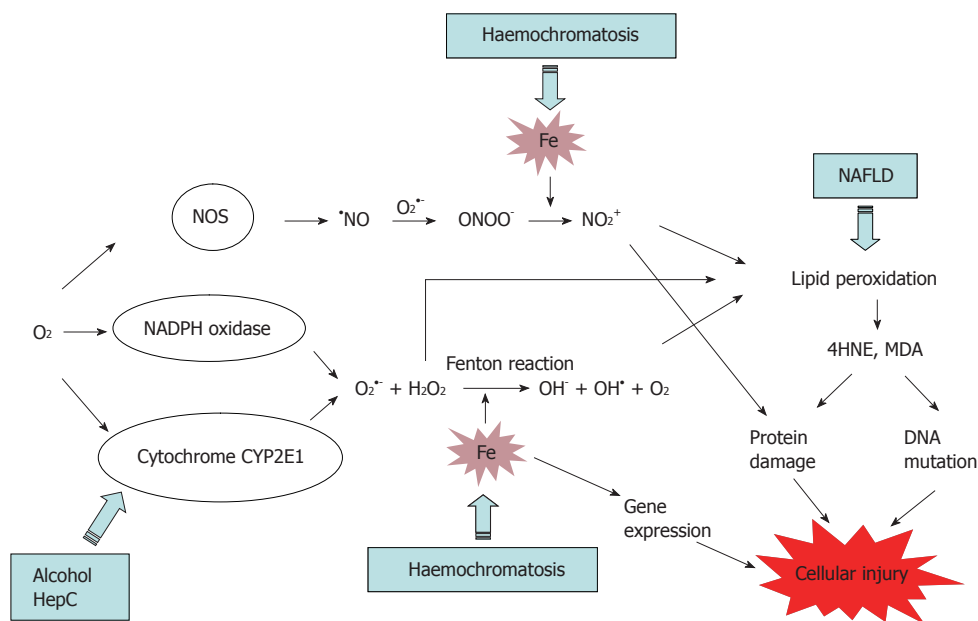

Figure 1 The involvement of iron in oxidative stress and its cytotoxic consequences. Iron catalyses the production of the reactive molecules OH^\bullet (via the Fenton reaction) and NO_2^+ , which promote lipid peroxidation and protein damage leading to cellular injury. NOS, nitric oxide synthase; NO, nitric oxide; ONOO^- , peroxynitrite; $\text{O}_2^{\bullet-}$, superoxide radical; OH^\bullet , hydroxyl radical; H_2O_2 , hydrogen peroxide; NO_2^+ , nitronium anion; Fe, iron; NAFLD, non-alcoholic fatty liver disease.

of hydroxyl radical (OH^\bullet) from reactive oxygen species (ROS), superoxide ($\text{O}_2^{\bullet-}$) and hydrogen peroxide (H_2O_2) *via* a chemical reaction known as the Fenton reaction (Figure 1). ROS are the by-products of aerobic respiration reactions by cytochrome P450 (CYP) 2E1, and are also produced by the membrane-bound NADPH oxidase complex^[54]. In addition, Fe catalyses the formation of NO_2^+ from peroxynitrite (ONOO^-). ONOO^- is formed when the cellular level of $\text{O}_2^{\bullet-}$ is elevated as this later reacts with nitric oxide (NO), produced by the constitutive and inducible nitric oxide synthase (NOS)^[55,56] (Figure 1). Interestingly, nitric oxide has also a protective effect against oxidative stress, as it can inhibit lipid peroxidation and the generation of OH^\bullet by reacting with Fe^{3+} ^[56,57]. NO_2^+ and OH^\bullet induce oxidative deterioration of biomolecules (lipid, protein and DNA), leading to tissue injury and cell death. In addition, iron can modulate gene expression in the cells leading to an alteration of cell function^[58,59].

Alteration of essential biomolecules: NO_2^+ and OH^\bullet catalyse lipid peroxidation which is the process whereby electrons are transferred from the lipids in cell membranes to the free radical, resulting in cell damage. This process proceeds by a free radical chain reaction mechanism. It affects polyunsaturated fatty acids, as they contain multiple double bonds, between which lie methylene $-\text{CH}_2-$ groups that are especially susceptible to peroxidation. Lipid decomposition leads to the generation of thiobarbituric acid (TBA)-reactants and breakdown by-products 4-hydroxynonenal (4HNE) and malondialdehyde (MDA), which are used as marker of lipid peroxidation.

Lipid peroxidation affects the plasma membrane of the cell, but also increases the membrane fragility of a number of different cell organelles, such as lysosomes, which store excess iron, mitochondria and endoplasmic reticulum, leading to impaired cell function^[2]. Lipid peroxidation of the mitochondrial membrane can lead to an increase in their permeability resulting in loss of the electrochemical gradient and release of the proapoptotic cytochrome C.

This phenomenon is called mitochondria permeability transition. Damaged mitochondria generate yet more ROS that further enhance cell damage and activate proapoptotic signals^[60].

Another consequence of lipid peroxidation is the damage of DNA and proteins, as lipid peroxidation products such as 4HNE and MDA can react with DNA bases^[61] and the ϵ - NH_2 group of lysine and histidine residues^[62]. The presence of acetaldehyde, resulting from ethanol oxidation, increases the binding of MDA and its own binding to proteins in a synergistic manner, generating new hybrid adducts called MDA-acetaldehyde adducts^[63]. These adducts may play a role in the development and progression of liver fibrosis as they have been shown to stimulate the secretion of several cytokines and chemokines by liver endothelial cells (TNF α , MCP-1, MIP-2, fibronectin) and HSC (MCP-1, MIP-2, uPA)^[64-66].

Gene expression modulation: Iron or iron-induced oxidative stress have also been found to activate cell signaling cascades triggering apoptosis and necrosis pathway *via* NF- κ B and AP-1 pathways respectively^[60]. NF- κ B promotes the synthesis and release of cytotoxic, proinflammatory and fibrogenic factors such as TNF α , IL-6 and MIP-1 that alter KC and hepatocyte function, and trigger HSC activation^[58,59]. In HSC, AP-1 transcription factors are involved in the regulation of procollagen (I)^[56]. In addition, AP-1 and NF- κ B-dependent gene products modulate hepatocyte death induced by oxidative stress^[67].

Regulation of intracellular levels of ROS: In the normal liver, hepatocytes are able to remove or neutralize oxidative molecules *via* enzymatic and non-enzymatic antioxidant processes, thereby maintaining a safe cellular level of ROS. For example glutathione (GSH) is a tripeptide that neutralizes free radicals and ROS directly *via* a chemical reaction or *via* enzymatic reactions involving glutathione-reductase or glutathione-peroxidase^[68]. Antioxidant agents such as vitamin A, C and E are also able to impair

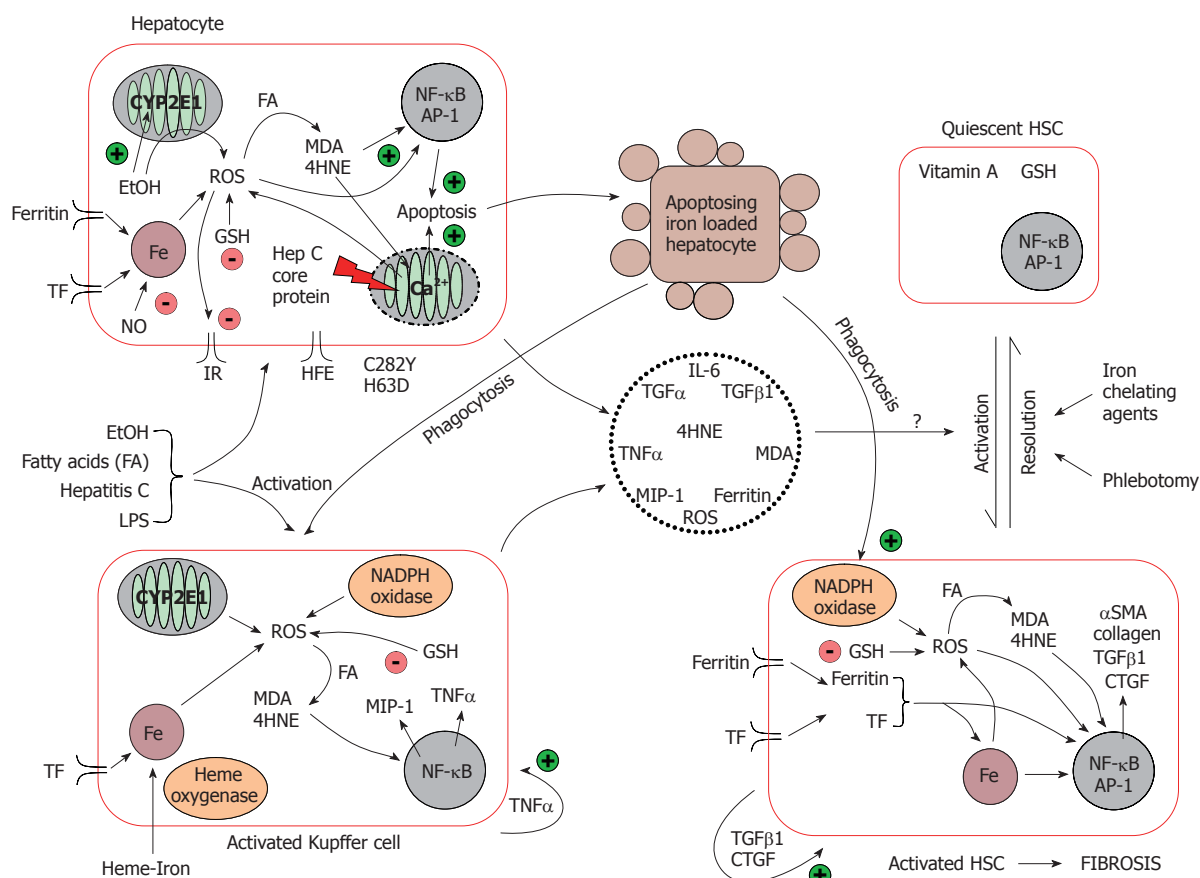

Figure 2 Mechanisms of iron-induced liver injury and fibrosis. Iron catalyses the formation of several reactive oxygen species in hepatocytes. Under normal circumstances, hepatocytes are able to effectively cope with oxidant stress. When the liver is subjected to a secondary insult that enhances hepatic oxidant stress, hepatic fibrosis begins to develop. Increased oxidative stress and other pathological modes of action of HCV, ethanol and steatosis, lead to mitochondrial dysfunction and hepatocyte apoptosis. Kupffer cell activation is achieved by phagocytosis of apoptosing hepatocytes in conjunction with the direct effects of iron, HCV infection, ethanol and steatosis on Kupffer cells. The concomitant hepatocyte damage/apoptosis and Kupffer cell activation is able to drive and maintain hepatic stellate cell activation leading to fibrosis and ultimately cirrhosis if left unchecked. Fe, iron; TF, transferrin; ROS, reactive oxygen species; FA, fatty acids; IR, insulin receptor; GSH, glutathione; TNF α , tumour necrosis factor α ; NO, nitric oxide; IL-6, interleukin 6; TGF β 1, transforming growth factor β 1; CTGF, connective tissue growth factor; α SMA, α smooth muscle actin; MDA, malondialdehyde; 4HNE, 4-hydroxynonenal; MIP-1, macrophage inflammatory protein-1; TGF α , transforming growth factor α ; NF- κ B, nuclear factor κ B; AP-1, activating protein-1.

lipid peroxidation by breaking the chain reaction. Other antioxidants can act as inhibitors of CYP2E1, such as diallylsulfide^[56]. However, when cellular defences are overwhelmed, there is an accumulation of ROS, which trigger cellular damage and apoptosis and, when this occurs in the liver, it can lead to fibrosis.

Iron driven oxidative stress promotes the development of hepatic fibrosis: Iron from the diet is absorbed into the enterocyte, and is either stored bound to ferritin or exported out into the plasma coupled to transferrin. In the liver, iron is taken up mainly by hepatocytes, and secondarily by KC. Hepatic iron uptake is mediated via HFE and the transferrin receptor, and iron is stored within the storage protein, ferritin^[69]. Macrophages phagocytose senescent blood cells, and recycle the iron back to plasma. In iron-loading disorders, although hepatocytes remain the dominant site of iron deposition, KC can also store iron^[70]. As mentioned earlier, the interplay between hepatocytes, KC and HSC and other extracellular proteins in the liver is important in the progression of hepatic fibrosis, and can be influenced by iron. Iron, as a key player in the oxidative reaction, may contribute directly and indirectly to HSC activation although the precise pathways remain

unclear (Figure 2).

Indirect activation of HSC: Hepatocytes and KC are the main cells where iron-induced oxidative damage occurred as described earlier, i.e. lipid peroxidation and activation of proapoptotic/necrotic signalling. It is proposed that HSC activation occurs as a result of soluble factors (TGF- α / β 1, TNF α , MIP-1, IL-6) produced by injured hepatocytes or KC following oxidative stress^[71-73]. Indeed, the gene expression of two markers of HSC activation, collagen type I and α SMA, is increased in studies where HSC are incubated with conditioned medium from iron loaded hepatocytes^[72,74]. Collagen upregulation was also observed when HSC were co-cultured with hepatocytes expressing CYP2E1, which is the principal cytochrome involved in the oxidation of ethanol when the concentration of ethanol is elevated^[74]. This effect was even more pronounced in the presence of iron, and was prevented by several antioxidants suggesting a oxidation mediated upregulation of these profibrogenic genes^[74].

KC have been shown to play a role in HSC activation. When KC and HSC are co-cultured, HSC proliferation is increased along with HSC expression of α SMA and collagen type I, when compared to the culture of HSC

alone^[73]. Friedman and Arthur demonstrated that KC conditioned medium activated HSC and stimulated HSC proliferation^[75]. After exposure to several stimuli such as LPS, ethanol, fatty acid, HCV infection or the phagocytosis of injured hepatocytes, KC become activated and produced ROS *via* PKC dependant activation of NADPH oxidase and *via* the CYP1E2^[55,59,76,77]. Deugnier and colleagues observed KC containing phagocytosed hepatocellular debris in hemochromatosis liver tissue^[78]. Tsukamoto and colleagues demonstrated that haeme-derived iron primed hepatic macrophages for NF- κ B activation, and enhanced the expression of the pro-inflammatory genes TNF α and MIP-1^[79]. TNF α is known to play a key role in promoting KC activation^[80], and also prevents the HSC from undergoing apoptosis^[81] thereby promoting fibrosis.

In addition to the production of profibrogenic and proinflammatory cytokines that activate HSC, KC release iron-loaded tissue ferritin that may interact with the ferritin receptor on activated HSC^[82]. Furthermore, hepatocyte and KC-generated ROS can be released from the cell, and enhance the perpetuation of HSC activation^[83]. In contrast, the role of the toxic by-products of lipid peroxidation such as MDA and 4HNE has been studied by Olynyk and others who showed that these compounds did not directly activate HSC^[84,85].

Direct activation of HSC: Activated HSC express a specific receptor for H-ferritin^[86] which appears to regulate the expression of α SMA^[82]. Ruddell and colleagues have preliminary evidence which suggest that ferritin upregulates genes involved in HSC activation via a PKC ζ dependent pathway^[87]. In addition, activated HSC are also known to express a transferrin receptor which can enhance the expression of α SMA and collagen type I within these cells^[88]. The role of free iron in the induction of HSC activation has been studied by Gardi and colleagues who demonstrated that iron can stimulate type I collagen gene expression but this was not mediated by lipid peroxidation^[89]. This is supported by other studies which rule out the involvement of intracellular lipid peroxidation in the activation of HSC^[84,85,90].

However, in other studies, intracellular oxidative stress has been shown to induce collagen expression in HSC, and that HSC lipid peroxidation can be triggered by hepatocytes^[91,92]. A recent study by Zhan and colleagues supports the role of lipid peroxidation in HSC in the upregulation of procollagen expression^[93]. They showed that HSC are able to phagocytose apoptotic bodies (i.e. injured hepatocytes), which triggers the activation of the stellate cells NADPH oxidase and its production of superoxide within and outside the cell. They also showed that the upregulation of procollagen I following the phagocytosis of apoptotic bodies was NADPH oxidase-dependent.

In conclusion, iron may have a direct effect on the activation of HSC or *via* the modulation of intracellular oxidative stress. However, this may be a minor role in the activation of the HSC when you consider that hepatocytes are the main cells that take up iron, and that quiescent HSC do not express the transferrin or ferritin

receptors^[86,88]. The inherent ability of iron to catalyse the production ROS in hepatocytes and KC appears likely the main mechanism by which it is able to influence hepatic disease progression. Iron, in conjunction with other factors, may overwhelm the liver in terms of its innate ability to cope with oxidative stress thereby causing disease.

Iron and other oxidation-related molecules

As described in Figure 1, iron is a key player in oxidative reactions that produced toxic ROS. However, the cellular level of other molecules, such as H₂O₂ and unsaturated lipids, also influence the degree of oxidation that occurs in the cells and thereby the degree of fibrosis. Indeed, the role of iron along with alcohol, steatosis and HCV in exacerbating liver injury has been the subject of fairly intensive study. The effects of feeding rats a diet supplemented with iron and alcohol was found to enhance hepatic localisation of MDA and 4HNE as well as increase serum levels of ALT and AST to two-fold that of rats fed ethanol alone^[94]. Both liver tissues and HSC isolated from rats fed ethanol and iron were also found to express elevated levels of procollagen α_1 (I) and TGF β 1 mRNA compared to those fed ethanol alone^[94]. Kato and colleagues also suggested TGF α derived from alcohol exposed hepatocytes may also contribute to hepatic fibrosis in ALD^[95]. Ethanol is known to upregulate the expression of CYP2E1^[74] which would exacerbate the potential oxidative stress exerted by iron in hepatocytes due to the catalysis of more ROS. In the same manner, accumulation of fatty acid within the cells will increase oxidative damage due to the enhanced peroxidation of lipid.

HCV alone has been shown to increase ROS generation and also lipid peroxidation in hepatocytes^[96]. It does this *via* the core protein, which is able to alter mitochondrial Ca²⁺ uptake, and also it induces endoplasmic reticulum (ER) stress and enhances ER to mitochondria Ca²⁺ transfer^[97]. Iron overload is also able to induce mitochondrial dysfunction (as visualised by ultrastructural alterations), and in mice over expressing the HCV core polyprotein, iron increases the risk of those mice going on to develop HCC^[98].

CONCLUSION

Iron plays an integral part in the progression of hepatic fibrosis, and it does this via its ability to catalyse the formation of highly reactive and damaging ROS. The damage done by ROS includes lipid peroxidation, protein and DNA modification leading ultimately to apoptosis and necrosis. However, the literature also indicates that co-factors such as steatosis, ethanol and HCV infection contribute to iron-induced hepatic injury. Antioxidant therapies have been tested in clinical trials with limited success with regards to the prevention and reversal of liver fibrosis. Iron depletion therapies have also been used with varying degrees of success to treat all four diseases of the liver outlined in this review. Continued investigation into the molecular mechanisms of iron toxicity, and how it leads to hepatic fibrosis may give a better understanding of the role of iron as a cofactor in the

progression of liver disease leading ultimately to novel anti-fibrotic therapies.

Abstract

Although progress in imaging and genetics allow for a noninvasive diagnosis of most cases of genetic iron overload, liver pathology remains often useful (1) to assess prognosis by grading fibrosis and seeking for associated lesions and (2) to guide the etiological diagnosis, especially when no molecular marker is available. Then, the type of liver siderosis (parenchymal, mesenchymal or mixed) and its distribution throughout the lobule and the liver are useful means for suggesting its etiology: HLA-linked hemochromatosis gene (HFE) hemochromatosis or other rare genetic hemochromatosis, nonhemochromatotic genetic iron overload (ferroportin disease, aceruloplasminemia), or iron overload secondary to excessive iron supply, inflammatory syndrome, noncirrhotic chronic liver diseases including dysmetabolic iron overload syndrome, cirrhosis, and blood disorders.

INTRODUCTION

Progress in molecular genetics and in liver imaging have allowed for the noninvasive diagnosis of most cases of inherited disorders of iron metabolism. However, liver pathology remains often useful to assess associated lesions—especially fibrosis—in patients with HLA linked hemochromatosis gene (HFE) and, mainly, nonHFE hemochromato-

sis, and to guide the etiological diagnosis of iron overload in the absence of a molecular marker. Moreover, because iron is more and more considered as a putative (co) factor of morbidity in patients with chronic liver diseases of various causes, iron excess must be recognized, indicated, qualified, quantified and interpreted even when it seems to be contingent upon a well established hepatic disorder.

ASSERTION OF IRON OVERLOAD

In the normal liver, iron is present at a concentration lower than 20 $\mu\text{mol/g}$ of dry weight^[1]. But, it is not histologically visible. Iron deposits are usually difficult to identify on usual stains unless they are abundant. Therefore, every liver biopsy should be routinely stained using not only hematoxylin-eosin-safron and connective stains, but also iron stain. Because it is easier and more reproducible than the Tirmann-Schmeltzer's method, Perl's staining is the most widely used, despite, it identifies Fe^{2+} only^[2].

DESCRIPTION OF IRON OVERLOAD^[2,3]

Distribution

The cellular distribution of iron deposits within hepatocytes, sinusoidal and portal macrophages, sinusoidal and portal endothelial cells, and biliary cells must be precisely described according to lobular areas in order to differentiate the following types of liver siderosis.

Parenchymal iron overload: It is related to intestinal iron hyperabsorption. Then, because it comes to the liver through the portal vein, iron deposits within hepatocytes as fine granules at the biliary pole of cells, and is distributed throughout the lobule according to a decreasing gradient from periportal to centrolobular areas. Mesenchymal iron deposits may be found at a latter stage when the amount of hepatocytic iron is high and responsible for sideronecrosis.

Mesenchymal iron overload: It corresponds to iron deposition within Kupffer cells and/or portal macrophages. Iron loaded cells are either isolated or grouped together without any lobular systematization. When associated, hepatocytic iron deposits are rough, sparse and usually located within cells close to iron loaded macrophages.

Mixed iron overload: It presents with the histological characteristics of the previous two types and corresponds usually to complex conditions or to massive iron loading.

Table 1 Histological grading of iron storage^[2]

Grade	Ease of observation and magnification required
0	Granules absent or barely discernible at × 400
1	Granules barely discernible at × 250 and easily confirmed at × 250
2	Discrete granules resolved at × 100
3	Discrete granules resolved at × 25
4	Masses visible at × 10, or naked eye

Table 2 Histological grades of iron storage from Deugnier Y and Turlin B^[3-12]

Hepatocytic iron	0, 3, 6, 9 or 12	HIS
	According granules size	0-36
	In each Rappaport area	
Sinusoidal iron	0, 1, 2, 3 or 4	SIS
	According granules size	0-12
	In each Rappaport area	
Portal iron	0, 1, 2, 3 or 4	PIS
	According to % of iron overloaded macrophages, biliary cells, and vascular walls	0-12
Total iron score		0-60

HIS: hepatocytic iron score; SIS: sinusoidal iron score; PIS: portal iron score.

It is also important to precise whether iron distribution throughout the liver is homogeneous or not, i.e. whether lobules (or, in case of cirrhosis, nodules) are equally iron loaded or not^[4,5].

Quantification

Biochemical hepatic iron concentration: Irrespective of the method used (colorimetry or atomic absorption), the biochemical determination of hepatic iron concentration (HIC) is considered as the reference method for quantifying iron in the liver^[1,6]. In normal subjects, HIC ranges from 10 to 36 μmol/g of dry weight. Iron excess is considered as mild up to 150, moderate between 150 and 300, and important above 300. Cases with HIC greater than 1000 are exceptionnal. Results obtained from fresh tissue and from deparaffinized blocks are equivalent^[7]. Therefore, determination of HIC on deparaffinized tissue should be the rule because it allows for histological control. This is especially relevant when iron distribution is heterogeneous as in the cirrhotic liver^[4,5].

Histological semiquantitative assessment: Several scoring systems have been proposed. The Scheuer's scoring system, either in its original presentation^[8] or modified according to Rowe *et al*^[9] or to Searle *et al*^[2] is widely used because it is simple (Table 1). However, it was not satisfactorily validated. The system proposed by the authors (Table 2) was well validated in both hemochromatotic^[10,11] and nonhemochromatotic iron overload disorders^[12]. But, it remains mainly used for research purposes due to its relative complexity.

ETIOLOGICAL DIAGNOSIS

Both the type of iron overload and associated hepatic

Table 3 Main causes of hepatic iron overload according to the histological type of siderosis and associated lesions

Parenchymal iron overload
With normal liver
Early genetic hemochromatosis
Nontransfused dysmyelopoiesis
Hereditary aceruloplasminemia
With cirrhosis
Iron overload secondary to cirrhosis
Mixed iron overload
With normal liver
Insulin resistance syndrome
Ferroportin disease
Transfused dysmyelopoiesis
Oral or parenteral iron supplementation
With steatosis or steatohepatitis
Insulin resistance syndrome
Chronic alcoholism
With chronic hepatitis
Hepatitis C or B
Wilson's disease
With intrahepatocytic inclusions
Porphyria cutanea tarda
With cirrhosis
Late genetic hemochromatosis
Mesenchymal iron overload
With normal liver
Inflammatory syndrome
Repeated transfusions

lesions may guide towards the right etiology (Table 3).

Genetic iron overload

Genetic hemochromatosis: Genetic hemochromatosis^[3] corresponds to 4 disorders transmitted as autosomal recessive traits, two with late onset (adult type: HFE hemochromatosis and iron overload related to mutation on the receptor transferrin 2 gene) and two with early onset (juvenile type related to mutations on the hemojuvelin or the hepcidin gene). From a histological point of view, these disorders are very similar because of a common pathophysiology consisting in an impairment of hepcidin production whose degree modulates the severity of iron burden^[13].

In early GH, iron remains located within hepatocytes, at the biliary pole of cells. It is distributed according to a decreasing gradient from periportal to centrilobular areas. This results in a typical parenchymal iron overload pattern.

With the passage of time, hepatocytic iron load increases, and then periportal sideronecrosis occurs. Sideronecrosis is responsible for macrophage activation, which leads to both development of fibrosis, and redistribution of iron towards nonparenchymal cells. In the absence of other cause of chronic liver disease, cirrhosis develops when hepatic iron concentration exceeds 400 μmol/g. GH related cirrhosis consists of large fibrous septa resembling biliary cirrhosis, while preserving the vascular architecture of the liver for a long time. This likely explains why portal hypertension and hepatic failure are rare features in GH patients. According to series, 25% to 50% of GH patients are still diagnosed at the cirrhotic stage.

Liver cancer is a frequent complication in GH^[10]. Most cases are hepatocellular carcinomas (HCC) developed in

a cirrhotic liver. However, some cases of HCC have been reported in GH patients with no cirrhosis, and frequency of cholangiocarcinoma reports is increasing^[14]. Two types of preneoplastic lesions have been reported and should be sought for at histological examination: (1) Iron-free-foci^[15] consist of sublobular nodular clusters of hepatocytes devoid of iron or with a low iron content within an otherwise iron-overloaded liver. Most often, they exhibit a proliferative pattern with either large or small cell dysplasia in 50% of cases. More than half the patients with IFF on their initial liver biopsy will develop. (2) Von Meyenburg complexes have also been reported as abnormally numerous in the surrounding liver of patients with GH complicated with cholangiocarcinoma^[14].

Nonhemochromatotic genetic iron overload

The ferroportin disease: The ferroportin disease^[16] is a dominant hereditary iron overload disorder characterized by phenotypic variability. In most cases, iron deposits are found within macrophages (mesenchymal type) with no significant fibrosis. This corresponds to the classical asymptomatic form with elevated hyperferritinemia contrasting with normal or mildly increased transferrin saturation. Rarely, iron is predominantly located within parenchymal cells, and the histological picture is similar to that of genetic hemochromatosis with, in some cases, either severe fibrosis or cirrhosis. Then, transferrin saturation is usually markedly elevated.

Hereditary aceruloplasminemia: Hereditary aceruloplasminemia^[17,18] is an exceptional disease transmitted as a recessive trait. Under the lens, iron is found predominantly in parenchymal cells. No case of liver cirrhosis has been described even in the most iron overloaded cases.

African iron overload : African iron overload^[19] is a rare disorder characterized by a mixed hepatic iron overload frequently complicated with cirrhosis. It is related to excessive iron intake, and likely underlain by nonHFE genetic factors.

Excessive iron supply

When brought parenterally: (i.e. through multiple transfusions), iron is initially localized within Kupffer cells and portal macrophages. With time, it is usually redistributed towards surrounding parenchymal cells, which results in a mixed and heterogenous pattern.

In case of excessive chronic iron intake: mixed hepatic iron overload may develop as reported in elite road cyclists^[20].

Inflammatory syndrome

It is a frequent cause of mesenchymal hepatic siderosis related to a defect of iron release from Kupffer cells due to increased production of hepcidin^[13]. Iron deposits are usually sparse and distributed throughout the lobule.

Noncirrhotic chronic liver diseases.

Dysmetabolic iron overload syndrome (DIOS): Dios

is a frequent condition corresponding to the association of an unexplained hepatic iron overload with usually normal transferrin saturation and features of metabolic syndrome^[21,22]. The histological pattern of DIOS is mixed, both mesenchymal (throughout the entire lobule) and parenchymal (predominating in periportal area)^[23]. Iron excess is usually mild and averages 100 $\mu\text{mol/g}$. However, in 30% of cases, the hepatic iron concentration to age ratio exceeds 2, a threshold previously considered as highly suggestive of GH before the discovery of the HFE gene. Either steatosis or steatohepatitis is present in 50% of cases. Bridging fibrosis or cirrhosis is found in 12% of cases. Whether iron may be involved in the development of fibrosis in DIOS patients, and its removal may be beneficial remains debated.

Alcoholic liver disease: Mixed and mild hepatic siderosis is found in 5% to 20% of chronic alcoholics, even in the absence of cirrhosis. A direct effect of alcohol on hepcidin production could be involved^[24].

Chronic hepatitis: Hepatic iron deposition is found in 35% to 56% of patients with chronic hepatitis. This was especially demonstrated in patients with chronic hepatitis C. The histological pattern is usually mesenchymal with frequent iron deposits in endothelial cells. Iron excess has been shown to be correlated with necrotico-inflammatory changes, and to decrease after interferon therapy. Moreover, iron removal before or at the time of interferon therapy could result in histological improvement, even in nonresponders^[25].

Wilson disease: Mixed iron overload is frequently found in the liver of patients with Wilson disease. Its mechanism is likely multifactorial, and involves low serum ceruloplasmin levels, hemolysis, necrotico-inflammatory changes and cirrhosis.

Cirrhosis: Significant liver siderosis is found in 35 to 78% of patients with end-stage cirrhosis, irrespective of the cause of cirrhosis^[4,5]. Iron deposits are mainly located within hepatocytes, predominate in remaining periportal areas, and, in some cases, can mimic GH. However, liver siderosis secondary to cirrhosis is distributed very heterogeneously from a nodule to another and absent from fibrous septa, biliary cells and vascular walls. This usually allows for correct diagnosis, and points to the need, in case of cirrhosis, for interpreting hepatic iron concentration according to histological findings. It is likely that nontransferrin bound iron (NTBI) plays a key role in the development of iron overload in cirrhosis^[26]. Indeed, in severe cirrhosis, serum transferrin levels are low due to hepatic failure which results in increased saturation of transferrin and, then, in the appearance of NTBI, a special form of iron that is avidly taken up by hepatocytes.

Hepatocellular carcinoma: Parenchymal or mixed iron overload is frequently present in the nontumorous part of the liver of patients with hepatocellular carcinoma (HCC), whether they have cirrhosis or not^[27]. This supports the

(co)carcinogenic role of iron suggested by numerous experimental and epidemiological studies^[28].

Blood disorders

Porphyria cutanea tarda: Mixed, heterogeneous and mild hepatic siderosis is encountered in 60% to 70% of patients with porphyria cutanea tarda (PCT). Searching for intrahepatocytic inclusions when faced with mixed iron overload is suitable, because the clinical diagnosis of PCT may be missed.

Dyserythroipoiesis: In well compensated dyserythropoietic syndromes, intestinal iron absorption is increased secondary to impairment in iron incorporation into red cell precursors. With time, severe hepatic iron overload resembling GH may develop, even in the absence of blood transfusions. Once transfusions are required, iron deposits in both parenchymal and mesenchymal cells resulting in a mixed pattern.

PLACE OF LIVER BIOPSY IN THE MANAGEMENT OF IRON OVERLOAD DISORDERS

Recent progress in both imaging and genetics have resulted in reducing the role of liver biopsy in the diagnosis of hepatic iron overload.

Positive diagnosis: MRI allows for a specific and sensitive detection and reliable quantification of excessive hepatic iron content when comprised between twice the upper limit of normal and 300 $\mu\text{mol/g}$ dry weight^[29]. Then, liver biopsy is no longer necessary to ascertain iron overload.

Aetiological diagnosis: MRI also allows for classifying iron excess as parenchymal, mesenchymal or mixed according to organ iron deposition (liver and/or spleen and/or spine)^[30]. Then it provides guidance for the aetiological diagnosis process, especially with respect to the first choice of genotyping tests. This was recently well illustrated by Pietrangelo *et al*^[31] in patients with ferroportin mutations. Moreover, in these patients, MRI contributed to establish phenotypic/genotypic correlations, and to understand the pathophysiology of the disease by demonstrating, beside the classical mixed pattern of iron accumulation, a non-classical parenchymal pattern related to the N144H ferroportin mutation^[31].

Disease severity: Once the positive and aetiological diagnosis of hepatic iron overload has been made, it is mandatory to assess the degree of hepatic damage, that is to determine whether severe fibrosis has developed or not. This will remain the major goal of liver biopsy as long as noninvasive tests for fibrosis-including biochemical markers, and elastometry-are not validated in patients with iron overload syndromes.

Currently, indication of liver biopsy can be discussed according to the phenotypic presentation of iron excess.

In case of hemochromatotic phenotype (= increased transferrin saturation with parenchymal iron deposition),

performing liver biopsy depends on HFE genotyping:

In C282Y homozygotes, liver biopsy is no longer necessary for diagnosis, but remains suitable with respect to prognosis. Guyader *et al*^[32] demonstrated that, when the liver was not clinically enlarged AND serum ferritin level was lower than 1000 ng/mL AND serum AST level was normal, there was never significant liver fibrosis (i.e. grade 3 or 4 fibrosis according to the METAVIR scoring system). On the contrary, when one, two or all these conditions were not met, there was a significant risk of fibrosis calculated as $1/(1 + \exp[-(-6.7620 + 3.2934 \text{AST}_{(\text{iu/l})} + 0.0013 \text{ferritin}_{(\text{ng/ml})} + 2.5317 \text{hepatomegaly}_{(0:1})])$. Accuracy of Guyader's algorithm was further validated in Canadian patients^[32]. Since then, other equations of prediction of (non)fibrosis have been proposed^[33,34] based upon age and serum ferritin level or serum ferritin level, serum AST level and platelets count. But, either they were not further correctly validated or they were not as simple for clinical use as Guyader's algorithm. Then, currently there is a global consensus to perform liver biopsy for fibrosis evaluation in C282Y homozygotes with either increased liver size, serum ferritin level higher than 1000 ng/mL or abnormal serum AST levels except when the diagnosis of cirrhosis is clinically obvious or when the predictive equation gives a risk close to 100%. Recently, Powell *et al*^[35] showed that obesity-related steatosis may have a role as a cofactor in liver injury-especially fibrosis-in C282Y homozygotes. This has clinically important implications, but does not modify indications of liver biopsy in these patients.

In a C282Y-H63D compound heterozygote presenting with mild increase in transferrin saturation-usually comprised between 45% and 60% and in serum ferritin-usually < 500 ng/mL and with no biochemical abnormalities and clinical liver symptoms, it can be reasonably assumed that the HFE genotype is responsible for the abnormalities in iron metabolism^[36], and that the patient is free of risk of fibrosis. Then, liver biopsy is not necessary.

In all other cases, the diagnostic procedure must be conducted irrespective of HFE genotype. Indeed, C282Y and H63D heterozygosity as well as H63D homozygosity not only are frequent (up to 1/3 of subjects in European general populations), but do not result, in a given subject, in clinically relevant perturbances of iron metabolism even if large genotyping studies^[36-39] have shown that some of them induced slight but significant increase in serum ferritin and/or transferrin saturation. Then, liver biopsy remains suitable to search for an additional cause of either iron overload or chronic liver disease. The most frequent finding is heterogeneous parenchymal iron overload complicating alcoholic or viral liver cirrhosis^[4,5,40]. Much more rarely, liver biopsy discovers marked iron overload suggesting an associated mutation on another gene involved in iron metabolism. In that case, the precise description of iron deposition, and associated lesions may participate in defining the choice of diagnostic molecular tests: mesenchymal or mixed iron deposition with no significant fibrosis is suggestive of ferroportin disease (which sometimes presents with TS > 60%) while parenchymal iron overload suggests the diagnostic

of juvenile haemochromatosis in a young adult with usually severe fibrosis (mutation on the hemojuvelin or hepcidin gene) and that of transferrin receptor 2-related haemochromatosis in an adult with or without fibrosis.

In the absence of hemochromatotic phenotype (= low, normal or slightly elevated transferrin saturation), the question is whether increased serum ferritin levels are related to iron overload or not. MRI can replace liver biopsy to answer this question, and histological examination of the liver can be restricted to patients with significant iron deposition at MRI (i.e. hepatic iron concentration > 100 µmol/g dry weight) and/or elevated serum transaminase levels and/or abnormal noninvasive predictive tests of fibrosis^[41]. In such a situation, the most frequent finding is mild and mixed iron overload with either metabolic or alcoholic steatohepatitis or chronic hepatitis C or porphyria cutanea tarda. Much more rarely, histological examination reveals marked iron overload with no significant fibrosis corresponding to ferroportin disease (mesenchymal type-normal or slightly increased transferrin saturation) or to hereditary aceruloplasminemia (parenchymal type-low transferrin saturation).

Due to the widespread use of genotyping, of MRI and of noninvasive predictive markers of hepatic fibrosis, liver biopsy is less and less performed for diagnostic and prognostic purposes in C282Y homozygous patients. Conversely, it remains often necessary in other patients in order to guide the etiological diagnosis of hepatic iron overload by describing and semi-quantifying iron excess and by assessing associated lesions.

Abstract

AIM: To investigate *in vitro* and *in vivo* therapeutic effects of histone deacetylase inhibitors NVP-LAQ824 and NVP-LBH589 on biliary tract cancer.

METHODS: Cell growth inhibition by NVP-LAQ824 and NVP-LBH589 was studied *in vitro* in 7 human biliary tract cancer cell lines by MTT assay. In addition, the anti-tumoral effect of NVP-LBH589 was studied in a chimeric mouse model. Anti-tumoral drug mechanism was assessed by immunoblotting for acH4 and p21^{WAF-1/CIP-1}, PARP assay, cell cycle analysis, TUNEL assay, and immunohistochemistry for MIB-1.

RESULTS: *In vitro* treatment with both compounds significantly suppressed the growth of all cancer cell lines [mean IC₅₀ (3 d) 0.11 and 0.05 µmol/L, respectively], and was associated with hyperacetylation of nucleosomal histone H4, increased expression of p21^{WAF-1/CIP-1}, induction of apoptosis (PARP cleavage), and cell cycle arrest at G2/M checkpoint. After 28 d, NVP-LBH589 significantly reduced tumor mass by 66% (bile duct cancer) and 87% (gallbladder cancer) *in vivo* in comparison to placebo, and potentiated the efficacy of gemcitabine. Further analysis of the tumor specimens revealed increased apoptosis by TUNEL assay and reduced cell proliferation (MIB-1).

CONCLUSION: Our findings suggest that NVP-LBH589 and NVP-LAQ824 are active against human biliary tract cancer *in vitro*. In addition, NVP-LBH589 demonstrated

INTRODUCTION

Interactions between histones and DNA are regulated by the acetylation status of histones, which in eukaryotic cells, plays a pivotal role in chromatin remodeling and in the regulation of gene expression: hyperacetylation determines transcription activation while hypoacetylation transcription repression. The balance between two classes of enzymes, histone acetyltransferases (HATs) and histone deacetylases (HDACs), can affect the acetylation status of histones. Altered HAT or HDAC activity has been identified in several cancers^[1]. HDACs have been found to be associated with aberrant transcription factors, and can mediate the function of oncogenic translocation products in specific forms of leukemia and lymphoma. They are divided into three classes: class I (HDAC 1-3, 8, 11) is generally nuclear; class II (HDAC 4-7, 9, 10) is generally tissue-dependent for the expression, and can shuttle between the cytoplasm and the nucleus; and class III requires nicotinamide adenine dinucleotide (NAD) as cofactor with substrate; they were discovered recently and are poorly characterized^[1]. To date, several structural unrelated classes of HDAC-inhibitors (HDACIs) demonstrating anti-tumor activity both *in vitro* and *in vivo* in animal models have been identified. These classes include carboxylic acids such as phenylbutyrate (PB), phenylacetate (PA), sodium butyrate (SB), AN-9 (Pivanex) and valproic acid; cyclic tetrapeptides such as trapoxin A; cyclic peptides such as depsipeptide or FK-228 and apicidine; benzamides such as MS27-275 and CI-994

(*N*-acetyldinaline); ketones such as trifluoromethyl ketone and α -ketomides; hydroxamic acids such as trichostatin A (TSA), suberoylanilide hydroxamic acid (vorinostat, SAHA), azelaic bis-hydroxamic acid (ABHA), scriptaid, oxamflatin, pyroxamide, *m*-carboxycinnamic acid bis-hydroxamide (CBHA), and the recently developed NVP-LAQ824, NVP-LBH589, and PXD101^[2]. Multiple phase I, II clinical trials are either completed or currently ongoing with several HDACIs, either as single agent or in combination with conventional chemotherapy, or biologicals. Clinical studies published so far have shown that HDACIs can be administered safely in humans and that treatment of some cancers with such agents seems to be beneficial^[3]. NVP-LAQ824 and NVP-LBH589 are a new chemical entity belonging to a structurally novel class of cinnamic hydroxamic acid compounds^[4-6] which are currently in phase I clinical evaluation in advanced refractory solid tumors and hematologic malignancies^[7-12]. However, little is known about their potential efficacy in biliary tract cancer, a rare tumor with a grim prognosis and up to now only limited treatment options. Therefore, the objectives of the current study were to investigate the efficacy of *in vitro* and *in vivo* treatment with the two novel pan-HDACIs NVP-LAQ824 and NVP-LBH589 and to evaluate the combination with gemcitabine.

MATERIALS AND METHODS

Materials

Seven biliary tract cancer cell lines - five extra-hepatic bile duct cancer cell lines (EGI-1, TFK-1, CC-SW-1, CC-LP-1, and SK-ChA-1)^[13-17] and two gallbladder cancer cell lines (Mz-ChA-1, Mz-ChA-2)^[16] were examined. All cell lines were cultured with appropriate media and incubated at 37°C in a humidified atmosphere containing 50-100 mL/L CO₂ in air, and the media were changed every three days. The HDACIs NVP-LAQ824 and NVP-LBH589 were provided by Novartis (Basel, Switzerland) and dissolved in dimethyl sulfoxide (DMSO) (10 mmol/L stock). Hoechst dye, sodium butyrate and monoclonal (mc) β -actin antibody were purchased from Sigma (Sigma-Aldrich Chemie GmbH Munich, Germany), mc p21^{WAF-1/Cip-1}, and polyclonal (pc) cleaved-poly(ADP-ribose) polymerase (PARP) antibodies from Cell Signaling (Cell Signaling Technology, Beverly, USA), mc acH4 antibody from Upstate (Upstate Biotechnology, Lake Placid, USA), mc MIB-1 antibody from Dako (Glostrup, Denmark), and gemcitabine [diluted in 50 g/L dextrose in water (D5W) and 50 mL/L DMSO] and etoposide (dissolved in normal saline to 10 mmol/L stock) from our hospital pharmacy. Six to eight-week-old female athymic NMRI nude mice were supplied from Taconic (Taconic Europe, Ry, Denmark) and held under pathogen-free conditions. Humane care was administered, and study protocols complied with the Institutional Guidelines.

Inhibition of cell growth detected by MTT assay

Cytotoxic effects of both drugs were determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma-Aldridge Chemie GmbH Munich, Germany) assay. About 1.5×10^3 cells were seeded in

triplicate in 96-well plates (100 μ L/well) and allowed to attach overnight. The medium was then replaced with medium (100 μ L) containing the designated drug or vehicle control (50 mL/L DMSO in D5W), followed by an incubation for 3 or 6 d. For the 6-d experiment, medium was changed after 3 d. Three hours before the end of the incubation period, 10 μ L of phosphate-buffered solution (PBS) containing 5 g/L MTT was added to each well. Following this, the medium was removed. The precipitate was then resuspended in 100 μ L of lysis buffer (DMSO, 100 g/L SDS). The absorbance was measured on a plate reader at 590 nm and a reference wavelength of 630 nm. Each experiment was performed in triplicate.

Immunoblotting

Cell culture monolayers were washed twice with ice-cold PBS, and lysed with RIPA-buffer containing Tris-HCl (50 mmol/L, pH 7.4), NP-40 (10 g/L), sodium-desoxycholate (2.5 g/L), NaCl (150 mmol/L), EDTA (1 mmol/L), sodium-orthovanadate (1 mmol/L), and one tablet of complete mini-EDTA-free protease inhibitor cocktail (Boehringer, Mannheim, Germany) (in 10 mL buffer). Histones for anti-acH4 immunoblotting were isolated by acid extraction [cells were lysed in ice-cold lysis buffer (HEPES 10 mmol/L; pH 7.9), MgCl₂ (1.5 mmol/L), KCl (10 mmol/L), DTT (0.5 mmol/L), PMSF (1.5 mmol/L), and additional protease inhibitor]. One molar HCl was added to a final concentration of 0.2 mol/L, followed by incubation on ice for 30 min, and centrifugation at 13000 *g* for 10 min. The supernatant was kept and dialysed against 200 mL of 0.2 mol/L acidic acid twice for 1 h and against 200 mL of H₂O overnight. Proteins were quantified by Bradford protein assay (Bio-Rad, Munich, Germany) and stored at -80°C, and 50 μ g of cell or tissue lysates were separated on SDS-polyacrylamide gels and electroblotted onto polyvinylidene difluoride membranes (Amersham Pharmacia Biotech, Freiburg, Germany). Membranes were then incubated in blocking solution [50 g/L dry milk in 10 mmol/L Tris-HCl, 140 mmol/L NaCl, 1 g/L Tween-20 (TBS-T)], followed by incubation with the primary antibody at 4°C overnight (50 g/L BSA in TBS-T). The membranes were then washed in TBS-T, and incubated with horseradish peroxidase (HRPO)-conjugated secondary antibodies for 1 h at room temperature. Antibody detection was performed with an enhanced chemoluminescence reaction (SuperSignal West Dura, Pierce, Rockford, USA).

Cell cycle analysis

Cells (2×10^5) were seeded in T-25 flasks, treated with various concentrations of NVP-LAQ824 or NVP-LBH589 or vehicle control (50 mL/L DMSO in D5W) for 72 h, washed with PBS, trypsinized, centrifuged, and fixed in 750 mL/L ice-cold ethanol/phosphate-buffered saline containing 10 g/L EDTA. DNA was labelled with 100 mL/L propidium iodide. Cells were sorted by FACScan analysis, and cell cycle profiles were determined using ModFitLT V2.0 software (Becton Dickinson, San Diego, USA). Each experiment was performed in triplicate.

Animal studies

Tumors were induced by injecting 5×10^6 Mz-ChA-2 or

EGI-1 cells in 200 μ L of PBS subcutaneously into the flank region of NMRI nude mice. Treatment was started when an average tumor volume of 150 mm³ was reached (usually after 2 wk). The verum groups intraperitoneally received either NVP-LBH589 (40 mg/kg, 5 \times weekly) or gemcitabine (5 mg/kg, 2 \times weekly) or a combination of both (NVP-LBH589 at 20 mg/kg, 5 \times weekly plus gemcitabine at 5 mg/kg, 2 \times weekly), whereas the control group received placebo (carrier solution 50 mL/L DMSO in D5W) only. Treatment was continued for 28 consecutive days, tumors were daily measured with a Vernier caliper and tumor volumes were calculated using the formula: tumor volume = $0.5 \times L \times W^2$, where *L* represents the length and *W* the width of the tumor. When treatment was finished, animals were sacrificed and tumors were excised and weighed.

TUNEL POD test

Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (*In Situ* Cell Death Detection Kit, POD) was used to detect apoptosis in paraffin sections from mouse tumor tissue. TUNEL test was carried out following the manufacturer's instructions (Roche, Penzberg, Germany) as previously described^[18]. Apoptotic cells (red) were counted under a light microscope after fluorescence signal conversion using antibody with conjugated peroxidase and the substrate for peroxidase (DAB, Roche, Penzberg, Germany). The number of positive cells was counted by an experienced pathologist in a total of 8 high-power fields (HPFs) and expressed as mean percentage of total cells in these fields of the tumor. Necrotic tumor cells were excluded from cell count.

Immunohistochemical staining

For MIB-1 staining, we used paraffin sections following a protocol that has been described elsewhere^[19]. The number of positive cells was counted in a total of 4 HPFs and expressed as mean percentage of total cells in these fields of the tumor.

Statistical analysis

Statistical calculations were performed using SPSS version 10.0 (SPSS Inc., Chicago, USA). Numeric data were presented as mean \pm SD or SEM. Inter-group comparisons were performed using Student's *t* test. *P* < 0.05 was considered statistically significant.

RESULTS

Inhibition of cellular growth by NVP-LAQ824 and NVP-LBH589

After 3 d of incubation, all tested cell lines were sensitive to NVP-LAQ824 [mean IC₅₀ (3 d) = 0.11 ± 0.06 μ mol/L] and even more to NVP-LBH589 [mean IC₅₀ (3 d) = 0.05 ± 0.05 μ mol/L]. There was no significant difference in response between the group of extra-hepatic bile duct cancer cell lines [mean IC_{50/LAQ824} (3 d) = 0.10 ± 0.07 μ mol/L and mean IC_{50/LBH589} (3 d) = 0.05 ± 0.06 μ mol/L] and the group of the two gallbladder cancer cell lines [mean IC_{50/LAQ824} (3 d) = 0.12 ± 0.03 μ mol/L and mean IC_{50/LBH589} (3 d) = 0.06 ± 0.05 μ mol/L].

Inhibition of cell growth was more pronounced if incubation time was extended to 6 d, with a mean IC₅₀ value of 0.05 ± 0.02 μ mol/L for NVP-LAQ824 and 0.02 ± 0.01 μ mol/L for NVP-LBH589. Once again, there was equal response between the group of extra-hepatic bile duct cancer cell lines [mean IC_{50/LAQ824} (6 d) = 0.05 ± 0.02 μ mol/L and mean IC_{50/LBH589} (6 d) = 0.01 ± 0.01 μ mol/L] and the group of the two gallbladder cancer cell lines [mean IC_{50/LAQ824} (6 d) = 0.06 ± 0.03 μ mol/L and mean IC_{50/LBH589} (6 d) = 0.02 ± 0.02 μ mol/L] (Figure 1 and Table 1). In addition, DMSO, the solvent of NVP-LAQ824 and NVP-LBH589, alone had no influence on cell growth (data not shown).

Mechanism of drug action

Treatment of cell lines EGI-1 and Mz-ChA-2 with 0.1 μ mol/L NVP-LAQ824 or 0.1 μ mol/L NVP-LBH589 for 24 h resulted in acetylation of histone H4 (Figure 2A). Protein extract from HELA cells that were treated with 5 mmol/L sodium butyrate served as positive control. The same treatment caused an induction of p21^{WAF-1/CIP-1} expression (Figure 2B). Cell lysate from HEK 293 cells served as positive control. A dose increase to 0.2 μ mol/L NVP-LAQ824 or 0.2 μ mol/L NVP-LBH589 corresponded with an increase of p21^{WAF-1/CIP-1} levels. Histone H4 acetylation was higher in treated Mz-ChA-2 than EGI-1 cells, whereas p21^{WAF-1/CIP-1} expression was higher in treated EGI-1 cells. Immunoblotting for cleaved-PARP was positive when cells were treated with 0.1 μ mol/L NVP-LAQ824 or 0.1 μ mol/L NVP-LBH589 for 24 h (Figure 2C, Lanes 2 and 5). PARP cleavage was more pronounced when the concentration of NVP-LAQ824 or NVP-LBH589 was increased to 0.2 μ mol/L (Figure 2C, Lanes 3 and 6). Lysate from untreated NIH-3T3 cells (Figure 2C, Lane 7) and from cells that were treated with 25 μ mol/L etoposide for 5 h [Figure 2C, Lane 8 (lane *)] served as negative control. Lysate from NIH-3T3 cells that were treated with 10 μ mol/L etoposide for 24 h [Figure 2C, Lane 9 (lane **)] served as positive control. Positive and negative controls were selected according to the recommendations of the manufacturers of antibodies. Staining with β -actin antibody confirmed equal protein loading in all immunoblots.

Treatment of cell lines EGI-1 and Mz-ChA-2 with 25 nmol/L NVP-LAQ824 or 25 nmol/L NVP-LBH589 for 72 h resulted in G2/M phase arrest. This arrest was more pronounced if the dose of NVP-LAQ824 or NVP-LBH589 was increased to 50 nmol/L. For both concentrations, the effect of NVP-LBH589 was stronger than the effect of NVP-LAQ824 (Table 2). Further increase of the NVP-LAQ824 and NVP-LBH589 concentration to 100 nmol/L and 200 nmol/L led to no further significant changes in G2/M phase arrest (data not shown). Sub-G1-peak percentage was not analyzed.

Inhibition of tumor cell growth by NVP-LBH589 \pm gemcitabine in nude mice

Tumors were induced in nude mice by subcutaneous injection of Mz-ChA-2 and EGI-1 cell lines. These cell lines were selected because they had shown the best growth capability in nude mice in our previous studies^[20,21].

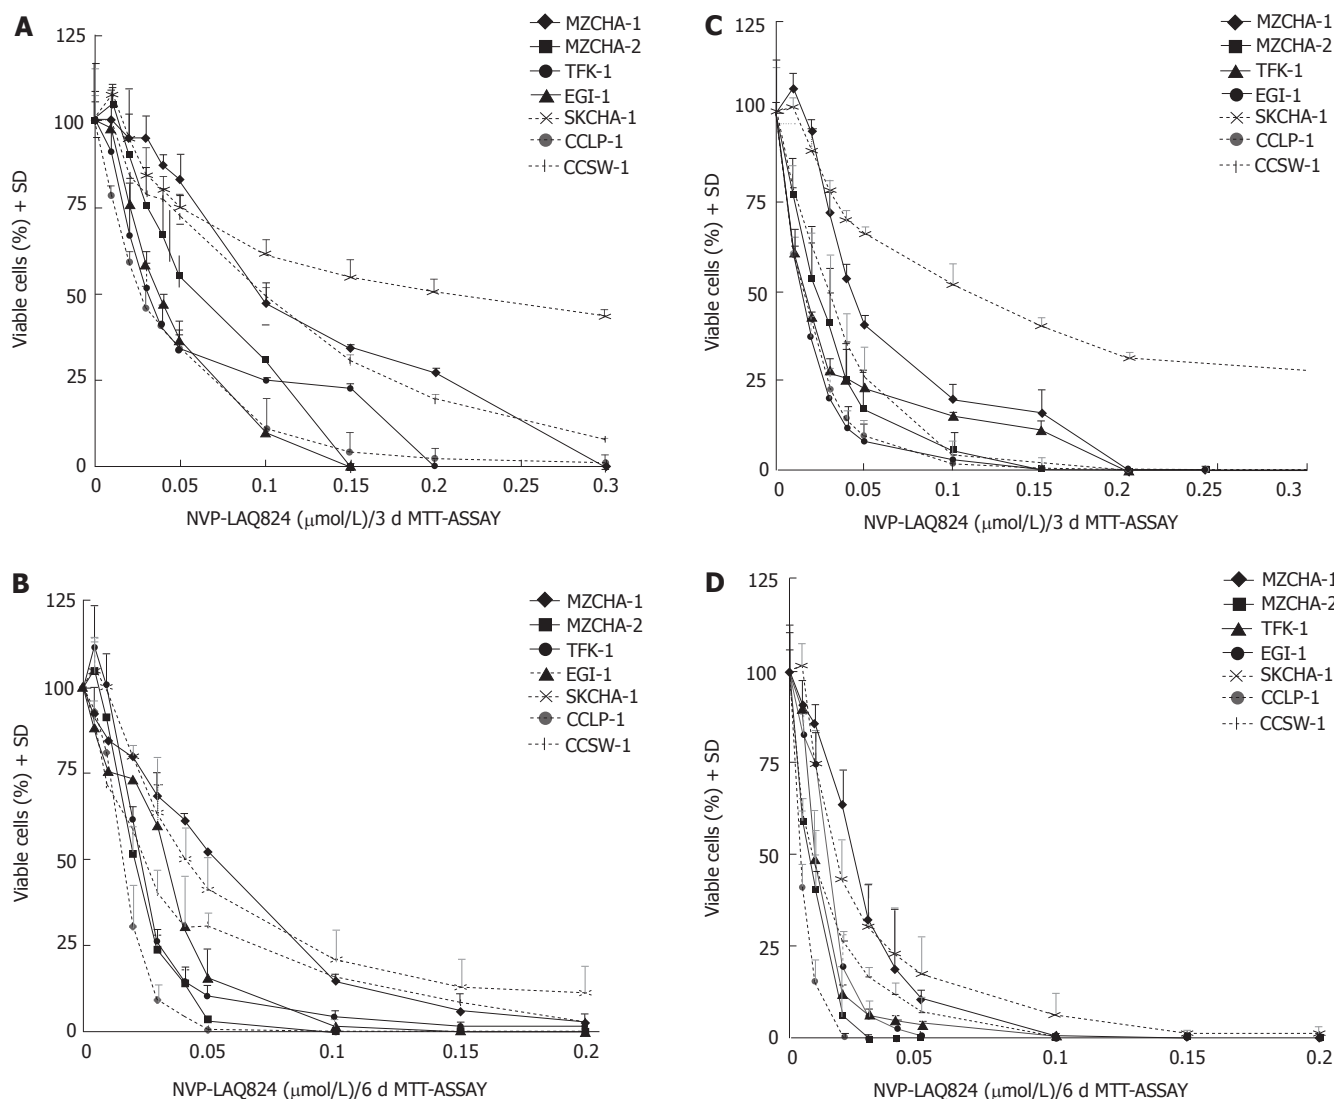

Figure 1 *In vitro* treatment of biliary tract cancer cell lines with NVP-LAQ824 and NVP-LBH589. **A:** 3-d incubation with NVP-LAQ824 ($n = 3$); **B:** 6-d incubation with NVP-LAQ824 ($n = 3$); **C:** 3-d incubation with NVP-LBH589 ($n = 3$); **D:** 6-d incubation with NVP-LBH589 ($n = 3$).

Table 1 Inhibition of cell growth by NVP-LAQ824 and NVP-LBH589

Cell line	IC ₅₀ (μmol/L)			
	NVP-LAQ824		NVP-LBH589	
	3 d	6 d	3 d	6 d
TFK-1	0.06	0.05	0.01	0.01
EGI-1	0.07	0.05	0.01	0.01
CC-LP-1	0.05	0.02	0.01	0.01
CC-SW-1	0.13	0.05	0.04	0.01
Sk-ChA-1	0.21	0.08	0.15	0.04
Mz-ChA-1	0.14	0.07	0.09	0.04
Mz-ChA-2	0.10	0.04	0.02	0.01

Since NVP-LBH589 seemed to have a higher *in vitro* activity than NVP-LAQ824 in these two cell lines (Table 1), only NVP-LBH589 was investigated *in vivo* in order to save costs. Treatment of mice consisted of intraperitoneal injections with NVP-LBH589, gemcitabine, NVP-LBH589 plus gemcitabine (COMBO) or placebo (50 mL/L DMSO in D5W). Starting at d 19, respectively at d 26, of the

experiment, EGI-1 cell tumors showed a significantly reduced volume in comparison to control after treatment with NVP-LBH589 or COMBO ($n = 7$ for each group; $P < 0.05$). The statistically significant difference was maintained until the end of the experiment. In contrast to that, treatment of mice with gemcitabine alone did not result in any significant reduction of tumor growth compared to control (Figure 3A). Treatment of Mz-ChA-2 tumors with NVP-LBH589, COMBO, or gemcitabine resulted in a significantly reduced volume in comparison to control at d 5, 5, and 8 ($P < 0.01$), respectively ($n = 7$ for each group; Figure 3B). The statistically significant difference was maintained until the end of the experiment. Regarding tumor latency (representing the time for the tumor to increase to 150% of the initial volume when treatment was initiated), the extrapolated data were as follows for EGI-1: placebo d 6, LBH d 26, COMBO d 12, and gemcitabine d 4. The data for Mz-ChA-2 were: placebo d 3, LBH d 14, COMBO "not reached", and gemcitabine d 7. At the end of the experiment at d 29, tumor mass in EGI-1 cells-bearing mice was significantly diminished as compared to placebo after

treatment with NVP-LBH589 (-66%) or COMBO (63%) ($P < 0.05$; Figure 3C). In contrast to that, treatment of mice with gemcitabine alone (-6%) did not result in any significant reduction of tumor mass as compared to control (Figure 3C). For Mz-ChA-2 cells-bearing mice, tumor mass was significantly diminished after treatment with either NVP-LBH589 (-87%), COMBO (96%), or gemcitabine (-74%), respectively ($P < 0.01$; Figure 3C). For both cell lines, EGI-1 and Mz-ChA-2, the combination of NVP-LBH589 and gemcitabine was more effective in tumor mass reduction in comparison to gemcitabine alone ($P < 0.05$ and $P < 0.01$, respectively). Moreover, for tumor

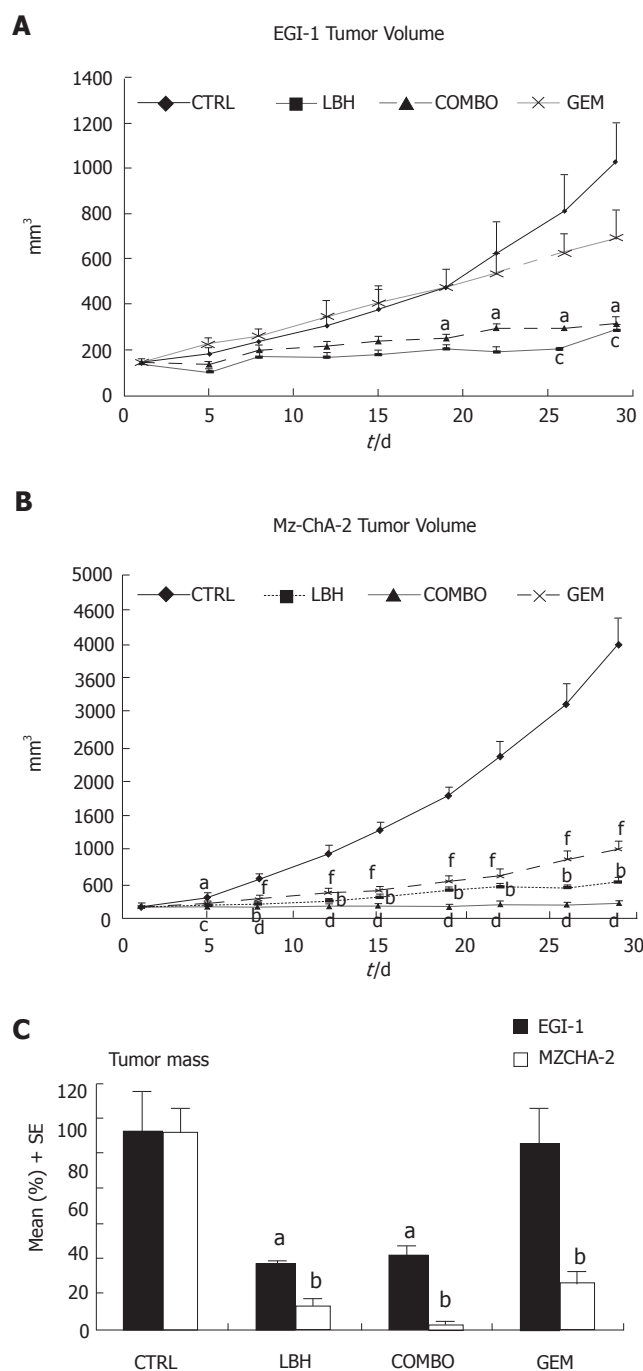

Figure 3 *In vivo* treatment with NVP-LBH589 \pm gemcitabine in chimeric mice. **A**: Effect on tumor volume of EGI-1 cells ($^aP < 0.05$, NVP-LBH589 vs control; $^cP < 0.05$, COMBO vs control); **B**: Effect on tumor volume of Mz-ChA-2 cells ($^aP < 0.05$, $^bP < 0.01$, NVP-LBH589 vs control; $^cP < 0.05$, $^dP < 0.01$, COMBO vs control; $^eP < 0.01$, gemcitabine vs control); **C**: Effect on tumor mass ($^aP < 0.05$, NVP-LBH589 or COMBO vs control; $^bP < 0.01$, NVP-LBH589 or COMBO or gemcitabine vs control).

cell line Mz-ChA-2, COMBO reduced tumor mass at a higher degree than NVP-LBH589 alone ($P < 0.05$), although NVP-LBH589 was administered at half dose in the COMBO group. Concerning side effects of the different drugs used in our experiments with EGI-1 and Mz-ChA-2 cells tumor-bearing mice, NVP-LBH589 alone (-17% and -19%, respectively) and COMBO (-7% and -10%, respectively) induced weight loss in the animals at d 29 of therapy as compared to the initial body weight, whereas

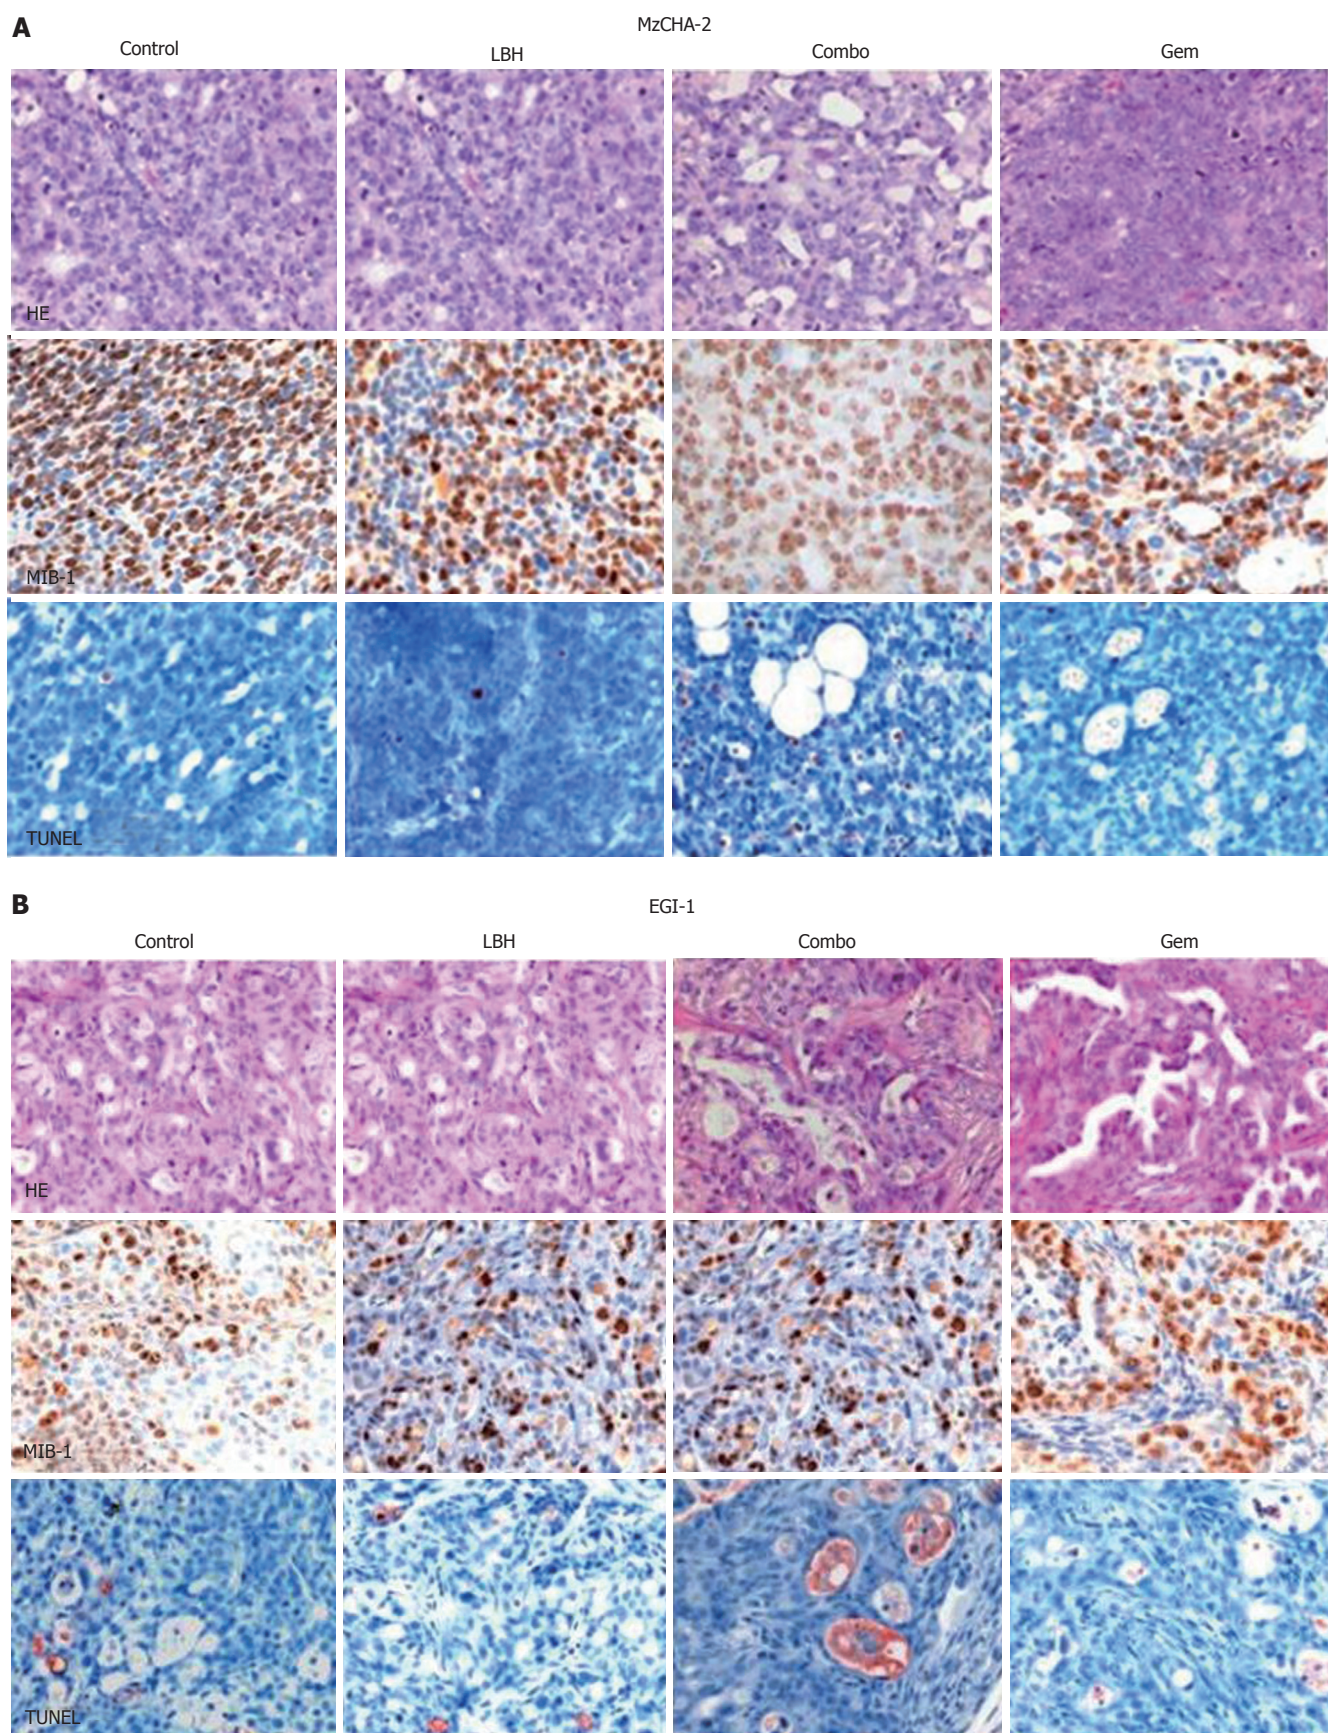

Figure 4 Hematoxylin-eosin (HE), MIB-1 (proliferation marker) and TUNEL (apoptosis marker) staining of mouse tumors (SABC, $\times 40$). **A:** cell line Mz-ChA-2; **B:** cell line EGI-1.

gemcitabine alone did not. One animal died at d 12 (EGI-1 experiment) in the COMBO group, and 2 animals died at d 22 and d 26 (Mz-ChA-2 experiment) in the NVP-

LBH589 group from significant weight loss. These three mice were replaced by back-up mice in order to guarantee equal numbers in the different groups ($n = 7$) for the

comparisons of tumor volume and tumor mass at the end of the experiment. Finally, NVP-LBH589 alone at a dose of 40 mg/kg (5 × weekly) caused diarrhea and exsiccation in the animals starting at d 16 of the experiment. We performed no further microscopic evaluation for organ damage in these animals. However, there was no macroscopic tissue damage.

In order to assess the anti-tumoral drug mechanism, paraffin sections of mouse tumors were stained with hematoxylin-eosin (HE), MIB-1 (proliferation marker) and TUNEL (apoptosis marker) (Figure 4). Treatment with NVP-LBH589, gemcitabine, and COMBO reduced proliferation (reduced MIB-1 staining) and induced apoptosis (increased TUNEL staining) (Figure 4, Table 3).

DISCUSSION

Cholangiocarcinoma (CC) is the second most common primary hepatic tumor, with increasing incidence and a high mortality^[22-24]. Tumors may occur anywhere along the biliary ductal system, and are arbitrarily defined anatomically as intra-hepatic or extra-hepatic CC as well as adenocarcinoma of the gallbladder^[25,26]. Unfortunately, the vast majority of patients with CC typically seek treatment with advanced disease, and often these patients are deemed poor candidates for curative surgery. Moreover, conventional chemotherapy and radiation therapy have not been shown to be effective in prolonging long-term survival, and although photodynamic therapy combined with stenting has been reported to be effective as palliative treatment, it is not curative^[27-30]. Thus, there is a need to develop novel therapeutic strategies for CC based on exploiting selected molecular targets that would have an impact on clinical outcome^[31,32].

One possible approach may be the use of HDACIs, perhaps in combination with conventional chemotherapy or other so called biologicals. Therefore, in our current study, we investigated the two novel cinnamic hydroxamic acid compounds NVP-LAQ824 and NVP-LBH589 for *in vitro* and *in vivo* treatment of CC. Cell-growth inhibition by NVP-LAQ824 and NVP-LBH589 was studied *in vitro* in 7 human biliary tract cancer cell lines by MTT assay. Treatment with the both compounds significantly suppressed the growth of all cancer cell lines after 3 and 6 d with a mean IC₅₀ (3d) of 0.11 and 0.05 μmol/L, and with a mean IC₅₀ (6d) of 0.05 and 0.01 μmol/L, respectively. In previous *in vitro* studies, NVP-LAQ824 exhibited a potent anti-proliferative activity against the HCT116 colon carcinoma cell line (IC₅₀ = 0.01 μmol/L), as well as against H1299 (IC₅₀ = 0.15 μmol/L) and A549 non-small cell

lung carcinoma cells (IC₅₀ = 0.15 μmol/L), DU145 (IC₅₀ = 0.018 μmol/L), PC3 prostate cancer cell lines (IC₅₀ = 0.023 μmol/L), Cal27 (IC₅₀ = 0.04 μmol/L), SCC25 (IC₅₀ = 0.095 μmol/L), SCC9 (IC₅₀ = 0.245 μmol/L), FaDu (IC₅₀ = 0.340 μmol/L) head and neck squamous carcinoma cells, and MDA-MB-435 (IC₅₀ = 0.039 μmol/L) and BT-474 (0.03 μmol/L) human breast adenocarcinoma cells after 72 h of exposure^[6,33,34]. The *in vitro* effects of NVP-LAQ824 on hematologic malignancies have been examined in several human cell lines, including AML (HL60, K562), lymphoma (Namalwa, DHL10), and multiple myeloma (IM9, 8226). Death of more than 90% of all cells was seen in all cell lines following 48 h of drug incubation, with exposures as low as 0.1 μmol/L^[35-37]. NVP-LBH589, the second investigated compound, was even more effective *in vitro* for the treatment of human chronic myeloid leukemia blast crisis K562 and LAMA-84, multiple myeloma, and acute leukemia MV4-11 cells^[5,38-40].

The *in vitro* anti-tumoral drug mechanism in our study was assessed by immunoblotting for acH4 and p21^{WAF-1/CIP-1}, PARP assay, and cell cycle analysis. Treatment with both compounds was associated with hyperacetylation of nucleosomal histone H4, increased expression of p21^{WAF-1/CIP-1}, induction of PARP cleavage, and cell cycle arrest at G2/M checkpoint. Hyperacetylation of nucleosomal histones H3 and H4 has been previously reported as the primary mechanism of action of NVP-LAQ824 and NVP-LBH589 for the treatment of HCT116, A549, MDA-MB-231, BT-474, MCF-7 (human breast adenocarcinoma), HL-60, K562, MV4-11, and multiple myeloma cells^[5,6,34,35,41]. Inactivation of tumor suppressor p14/mdm-2/p53/p21^{WAF-1/CIP-1} signaling pathway is a phenomenon that occurs frequently in CC, mostly due to p53 mutations or by up-regulation of mdm-2, an inhibitor of p53^[42]. P21^{WAF-1/CIP-1} binds to the cell division kinase (CDK) 4:cyclin D complex and prevents it from phosphorylating Rb. Therefore, the release of the bound E2F transcription factor that regulates genes encoding for proteins critical to entrance into the S-phase of the cell cycle is prevented^[25]. Up-regulation of p21^{WAF-1/CIP-1} induced by NVP-LAQ824 and NVP-LBH589 has been described for BT-474, MCF-7, MDA-MB-468 (human breast adenocarcinoma), human umbilical vein endothelial cells (HUVEC), LNCaP (prostate cancer), K562, LAMA-84, MV4-11 and multiple myeloma cells^[5,34-36,38,43,44]. P21^{WAF-1/CIP-1} is likely to be transcriptionally activated by a p53-independent mechanism, since it has been shown for NVP-LAQ824 to activate the p21^{WAF-1/CIP-1} promoter^[6]. Other commonly induced tumor suppressor genes include p53, p57 and the CDK inhibitor p27^{kip1}^[34,36,38,40].

Another mechanism of *in vitro* drug action found in our study was induction of apoptosis as shown by the increase of PARP cleavage, a process mediated by active effector caspase-3. This phenomenon, induced by NVP-LAQ824 and NVP-LBH589, has been described previously for several other cell lines^[5,34-36,39,43]. Furthermore, transcriptional up-regulation of pro-apoptotic genes such as *FAS*, *TRAIL*, *BID* or *BAX* and down-regulation of anti-apoptotic genes such as *BCL-XL* or *FLIP*, although not examined in our study, may explain apoptotic cell death induced by HDACIs, besides priming of malignant cells

for innate immune effector mechanisms^[36,45-49]. Whereas a number of different mechanisms were described for HDACi-induced cell death, including the death receptor-activated caspase cascade, usually the intrinsic apoptotic pathway, mediated by mitochondrial membrane disruption, is commonly activated, which has also been shown for NVP-LAQ824 and NVP-LBH589^[38,50]. Among several genes repressed by HDACis are cyclin D1 and thymidylate synthase. The result is a G1 or G2-M cell cycle arrest and differentiation, common mechanisms of the anti-proliferative effect of HDACis. Further potential growth inhibitory mechanisms include induction of other cell cycle regulatory genes such as GADD45 α and β and up-regulation of transforming growth factor β (TGF- β) receptor signaling, leading to repression of c-myc and cell cycle arrest. Several studies, including ours, investigating NVP-LAQ824 and NVP-LBH589, could demonstrate G2-M cell cycle arrest, induced by those compounds^[6,34,44], others detected G1-arrest^[5,35,36].

Encouraged by our *in vitro* results, we decided to test the most effective drug NVP-LBH589 *in vivo* in comparison to placebo using the chimeric mouse model. At d 29 of the experiment, NVP-LBH589 significantly reduced tumor mass in comparison to placebo and potentiated the efficacy of gemcitabine. The NVP-LBH589 dose of 40 mg/kg (5 d/wk) was selected according to a study testing different intravenous doses of NVP-LAQ824 between 5 and 100 mg/kg (5 d/wk) in a similar chimeric mouse model using the human colon cancer cell line HCT116^[6]. *In vivo* data for NVP-LBH589 were only available after completion of our study, using human prostate carcinoma cell PC-3 xenografts, being able to show tumor reduction at a dose of 10 mg/kg per day^[44]. Surprisingly, weight loss of the animals, as observed in our study, was not previously reported for NVP-LAQ824^[6]. Therefore, further studies are required to examine animals microscopically for organ damage. Unfortunately, this was not done in our experiments. Since we already experienced this phenomenon in a small pilot study with 3 animals (data not shown), we decided to have the dose of NVP-LBH589 for the combination therapy with gemcitabine. The latter drug was selected since it is a commonly used drug for CC monotherapy in the palliative setting^[30]. Even with this dose reduction of NVP-LBH589, our results do strongly support an additive effect which, however, requires further investigation. In human breast cancer cell lines SKBR-3 and BT-474, NVP-LAQ824 also enhanced taxotere-, epirubicin B-, and gemcitabine-induced apoptosis *in vitro*^[34]. For head and neck squamous carcinoma cells, the combination of NVP-LAQ824 with gemcitabine was more effective *in vitro* than a combination with docetaxel, paclitaxel, or cisplatin, especially when used in the sequence of the cytotoxic agent first for 24 h, followed by 48 h of NVP-LAQ824^[33]. There might be also a synergistic *in vitro* effect of a combination of NVP-LAQ824 and VEGFR-inhibitor PTK787/ZK222584 as demonstrated for PC3 and MDA-MB-435 cells^[41]. Similar results were observed *in vitro* for a combination of NVP-LBH589 and proteasome inhibitor bortezomib^[39], NVP-LBH589 and tyrosine kinase inhibitor AMN107^[40], and NVP-LBH589 and heat-shock protein 90 (hsp90) inhibitor

17-allyl-amino-demethoxy geldanamycin (17-AAG)^[5].

Anti-tumoral drug mechanism in our *in vivo* model was assessed by TUNEL assay, and immunohistochemistry for MIB-1, which revealed increased apoptosis (TUNEL) and reduced cell proliferation (MIB-1), confirming our *in vitro* data. Surprisingly, the calculated numbers were much smaller than expected from the *in vitro* experiments.

Finally, it should be mentioned that other mechanisms of anti-tumor activity of HDACis include anti-angiogenic properties through alteration of VEGF-, HIF-1 α -, Ang-2/Tie-2-, and survivin-signaling, down-regulation of endothelial nitric oxide synthase (eNOS), suppression of tumor invasion through negative regulation of matrix metalloproteinases expression, and depletion of several oncoproteins that are normally stabilized by binding to the hsp90 multi-chaperone complexes, including bcr-abl, ErbB2, Raf-1, or AKT (HDACis may induce acetylation of hsp90 *via* inhibition of HDAC 6, thus inhibiting chaperone activity, resulting in polyubiquitination and proteasomal degradation of the hsp90 client proteins), which was not further investigated in our study^[44,51].

In conclusion, our findings suggest that NVP-LBH589 and NVP-LAQ824 are active against human biliary tract cancer *in vitro*. In addition, NVP-LBH589 demonstrated significant *in vivo* activity and potentiated the efficacy of gemcitabine. Therefore, further clinical evaluation of NVP-LBH589 alone or its combination with gemcitabine for the treatment of biliary tract cancer is recommended.

ACKNOWLEDGMENTS

We thank Annett Kluge, Katrin Schoepp, Karen Rother, and Ines Sommerer for technical assistance and Novartis Pharma for the provision of NVP-LAQ824 and NVP-LBH589.

COMMENTS

Background

Carcinoma of the biliary tree are rare tumors of the gastrointestinal tract with worldwide rising incidence for intrahepatic cholangiocarcinoma during the last several years. At present, complete resection is the only potentially curative therapy. But, most of the patients present with already advanced disease. In the palliative setting, systemic chemotherapy (chemoradiation) has not been clearly proven to prolong survival significantly.

Research frontiers

Receptor tyrosine kinase (TKs), cyclooxygenase-2 (COX-2), mammalian target of rapamycin (m-TOR), and histone deacetylase (HDAC) inhibitors are currently under preclinical and clinical evaluation as new treatment options.

Innovations and breakthroughs

In 2006, the results of a two-stage phase I and a phase II study suggested a therapeutic benefit for EGFR blockade with erlotinib and combined erbB-1/erbB-2 signaling inhibition with GW572016 (Lapatinib) in patients with biliary cancer. In 2007, a phase II study was presented examining the combination of gemcitabine, oxaliplatin and angiogenesis inhibitor bevacizumab (GEMOX-B) in unresectable or metastatic biliary tract cancer/gallbladder cancer. Early evidence of antitumor activity was seen.

Applications

The aim of our study was to investigate the *in vitro* and *in vivo* treatment with histone deacetylase inhibitors NVP-LAQ824 and NVP-LBH589 in biliary tract cancer. Our findings suggested that NVP-LBH589 > NVP-LAQ824 are active

against human biliary tract cancer *in vitro*. In addition, NVP-LBH589 demonstrated significant *in vivo* activity and potentiated the efficacy of gemcitabine.

Terminology

Histones (positively charged proteins) are the major components of chromatin. Histone acetylation and deacetylation modulate chromosome structure and regulate gene transcription. Two families of enzymes, histone acetyltransferases (HATs) and histone deacetylases (HDACs), activate and repress gene expression, respectively. Aberrant HAT or HDAC activity is associated with various epithelial and hematologic cancers. HDACs may play an important role in human oncogenesis through HDAC-mediated gene silencing and interaction of HDACs with proteins involved in tumorigenesis. HDAC inhibition could potentially restore normal processes in transformed cells without affecting normal cells.

Peer review

This manuscript is original, interesting and well-written. It deserves to be published.

Abstract

AIM: To investigate if increased dietary fiber, in terms of kiwifruit, is effective in Chinese constipated patients.

METHODS: 33 constipated patients and 20 healthy volunteers were recruited for a 4-wk treatment of kiwi fruit twice daily. Response during wk 1-4 was defined as an increase in complete spontaneous bowel motion (CSBM) ≥ 1 /wk. Secondary efficacy included response during wk 1-4, individual symptoms and scores of bowel habits and constipation. Responses were compared with the baseline run-in period. Colonic transit time and anorectal manometry were performed before and after treatment.

RESULTS: Responder rate was 54.5% in the constipated group. The mean CSBM increased after treatment (2.2 ± 2.6 vs 4.4 ± 4.6 , $P = 0.013$). There was also improvement in the scores for bothersomeness of constipation ($P = 0.02$), and satisfaction of bowel habit ($P = 0.001$), and decreased in days of laxative used ($P = 0.003$). There was also improvement in transit time ($P = 0.003$) and rectal sensation ($P < 0.05$). However, there was no change in the bowel symptoms or anorectal physiology in the healthy subjects.

CONCLUSION: Increasing dietary fiber intake is effective in relieving chronic constipation in Chinese population.

INTRODUCTION

Functional constipation is a common problem in clinical practice. In the Western population, the prevalence was reported to be as high as 24% in elderly persons and more commonly among women^[1]. We observed a prevalence of 14% of constipation in the Hong Kong population^[2].

In mild cases of functional constipation, it has been suggested that the treatment includes general measures like increased intake of water and dietary fiber, and use of simple laxatives. A diet with enough fiber (20-35 g each day) helps form a soft, bulky stool. Sufficient dietary fiber is also needed to promote normality in bowel movement frequency over the long term^[3,4]. Colonic transit has been shown to be related to stool weight and dietary fiber intake^[5,6]. On the other hand, there are only a few studies that looked for dietary fiber intake by patients with chronic constipation^[7-9]. In addition, in a trial with a proprietary fiber product, less than a half of the patients with self-defined constipation responded^[10]. Also, anorectal physiology was not assessed in most of these studies.

Numerous anecdotal reports have suggested that kiwifruit has laxative effects, and suggested it could be an acceptable dietary supplement, especially for the elderly who often experience constipation. It has been reported that the dietary fiber in kiwifruit is about 3.4 g/100 g, thus being a good source of dietary fiber. Rush *et al*^[11] has demonstrated the laxative effect of kiwifruit in the elderly subjects.

In the current study, we aimed at assessing if increasing dietary fiber intake could improve functional constipation. We chose kiwifruit to be the source of dietary fiber in the study. In addition to constipation symptoms, we also assessed if there was any improvement in anorectal physiology after fiber intake.

MATERIALS AND METHODS

Protocol

This is a single center, age and sex-matched, case control study performed from 31 December, 2006 to 31 March, 2007, consisting of a 2-wk baseline assessment and 4-wk treatment period. Both patients and controls were given two Zespri Kiwi fruit (1 in the morning after breakfast and 1 in the evening after dinner) throughout the four-week treatment period. The kiwifruit were of the green, 'Hayward' variety, and were supplied at an optimum ripeness for consumption. The kiwi fruit was dispatched in two batches, the first on d 0 and the second at the begin-

ning of wk 3 to ensure the freshness of the fruit. All the participants were seen by the investigator on d 0 and at the end of wk 4. Bisacodyl was given as rescue medicine and patients were instructed to take it if no bowel motion for ≥ 4 d. The subjects were asked to fill in the diary during the 2-wk baseline period, and throughout the treatment period. Anorectal physiology tests including both colonic transit and anorectal manometry were performed for both the constipated patients and healthy controls before and after the treatment with kiwi fruit. The study was performed in accordance with the Declaration of Helsinki regarding informed patient consent and institutional review board approval.

Patients and controls

Thirty-five age ≥ 18 years constipated subjects were recruited for the study. They were recruited from the Gastroenterology outpatient clinic of Department of Medicine, Queen Mary hospital, Hong Kong, after assessment by a gastroenterologist, and satisfied the following criteria: constipation for 6 mo or more, with an average of less than three complete spontaneous bowel motion (CSBM) per week; and at least one of the following occurring for more than 25% of the time: straining, passage of lumpy or hard stools, and sensation of incomplete evacuation. Complete spontaneous bowel motion referred to the feeling that defecation led to complete passage of stool rather than partial or incomplete evacuation of stool without relief of symptoms. In addition, these patients also satisfied the Chinese constipation questionnaire^[12]. Patients with a previous history of constipation predominant irritable bowel syndrome using the Rome II criteria were excluded from the present study. Additional exclusion criteria were inability to understand Chinese, constipation due to secondary causes, history of malignancy and significant systemic disease. Pregnant or breast feeding women were also excluded. Patients who failed to complete the diary or if the constipation was not confirmed by diary were excluded.

Twenty age and sex matched volunteers were recruited by posters distributed at the university campus and community. All the volunteers were screened and then assessed by the same gastroenterologist. All the subjects will be asked to maintain normal diet pattern and activity during study period.

Assessment

Assessment of constipation symptoms was done in a diary format. Patients recorded their constipation symptoms in a diary throughout the 2-wk baseline and 4-wk treatment period. On a daily basis, they recorded the symptoms of CSBM, straining score (using a 3-point score: no straining/acceptable straining/too much straining), the 7-point Bristol stool scale form (range from 1, separate hard lumps, to 7, watery with no solid pieces)^[13], and the intake of Bisacodyl as rescue medicine. Final assessment included the patients' satisfaction with bowel habits over the past week (using a 5-point ordinal scale, 0 = very satisfied, 4 = not at all satisfied), and the bothersomeness of constipation (using a 5-point ordinal scale, 0 = not at all, 4 = a very great deal).

Assessment of bowel transit time

Normal and slow transit constipation were confirmed by X-ray and colonic motility studies performed in all patients. Colonic transit time was assessed through the use of radiopaque markers, as modified from the method described by Metcalf *et al*^[14] (14). In brief, 4 sets of distinctive radiopaque markers of different shapes and size (circle on d1, semi-cylinder on d 2, dot on d 3 and cylinder on d 4) were ingested by the volunteers on 4 consecutive days. X-ray of the abdomen was taken on d 5 to assess the mouth to anal transit and segmental colon transit. Transit in the right, left, and rectosigmoid colon was calculated by adding all markers seen in these regions on d 5. Slow total colonic transit was defined as > 67 h, the mean transit plus 2 standard deviations averaged from published studies.

Anorectal manometry

The manometry catheter (Zinetics Manometric Catheter, Medtronic) had a latex balloon on its tip that could be distended with air *via* a handheld syringe, and it had 8 perfusion ports spaced 0.5 cm apart beginning 2 cm below the balloon to measure pressures. The catheter was perfused with degassed water at a rate of 0.5 mL/min by a low-compliance pump (Densleeve Manometric infusion pump-16 channel E4500). The outer diameter of the catheter was 4.5 mm. Pressures were recorded and displayed using a model (Polygraph Medtronic Functional testing Software 2.05). Pressure recordings were analyzed manually.

With the patient in the left lateral position, the manometry catheter was lubricated and inserted into the rectum. It was then pulled back in 1-cm steps, and pressures were recorded at each position while the patient was instructed to relax. The peak pressure (averaged across all 8 perfusion ports) defined anal canal resting pressure. The second perfusion port was then positioned in the high-pressure zone of the anal canal, and the rectal balloon was distended with varying volumes of air (10, 20, 30, 40, 50 mL) to determine the smallest volume of distention that elicited a rectoanal inhibitory reflex (RAIR, defined as the reflex decrease in anal canal pressure that is elicited by rectal distention). Next, the rectal balloon was inflated in 20-mL steps up to 200 mL to assess the threshold for the first sensation, sensation of urge to defecate and the maximum tolerable volume. A phosphate enema was administered approximately 30 min before the anorectal manometry and balloon defecation tests.

Statistical analysis

Primary efficacy variable: The primary efficacy variable was the responder rate for CSBM during the first 4 wk of treatment. Patients with a mean increase of CSBM ≥ 1 /wk compared with the last 14 d of baseline were defined as responders, provided that they had completed at least 7 d of treatment.

Secondary efficacy variables: These included the change from baseline in scores for individual constipated symptoms (stool form, straining scores, bothersomeness of constipation, and satisfaction of bowel habit). Days of laxatives used and percentage of patients needed laxatives were assessed.

Table 1 Demographic data and constipation symptoms of the constipated patients and healthy subjects

	Treatment group (<i>n</i> = 33)	Control group (healthy subjects) (<i>n</i> = 22)	<i>P</i> value
Sex (female)	72.70%	80%	0.74
Female to male ratio	2.67:1	04:01	
Ethnicity (Chinese)	100%	100%	
Age (yr \pm SD)	49.9 \pm 12	50.8 \pm 14	0.82
Duration of constipation (yr \pm SD)	20.3 \pm 15	-	
Complete spontaneous bowel motion per week (mean \pm SD)	1.9 \pm 1	-	
Passage of hard stool	72.70%	-	
Incomplete evacuation	84.80%	-	
Straining	90.90%	-	

Tertiary efficacy variables: These included any improvement in anorectal physiology, which included the colonic transit time, simulated defecation pressure and also the rectal sensation.

Statistical analysis was performed using SPSS (SPSS, Chicago, IL, USA) statistical software. Demographics for patients and controls were summarized by calculating means (SD) (or median (range)) for continuous variables (for example, age and severity score) and proportions for categorical variables (for example, sex). Comparisons were performed with the Student's *t* test for continuous variables, and with Chi square test for categorical data. Paired *t* test was used to assess the bowel habit and anorectal physiology parameters before and after treatment within the same group. All statistical tests were two-sided, and *p* value of less than 0.05 was considered to indicate a statistically significant difference.

RESULTS

Demographic data

There were 35 patients screened, but only 33 patients were enrolled into the study. Two of them refused to participate. The demographic data, baseline constipation symptoms of both the patients and controls are summarized in Table 1. There was no difference in the demographic data as they were purposely matched. The anorectal physiology was markedly different between the constipated patients and healthy controls. These include prolonged colonic transit time and impaired rectal sensation.

Primary efficacy

The mean CSBM per week before and after treatment in patients was 2.2 ± 2.6 *vs* 4.4 ± 4.6 (*P* = 0.013). The responder rate, ie mean increase of CSBM ≥ 1 /wk, was 54.5% (18 patients). Whereas in the controls, the mean CSBM per week before and after treatment was 6.5 ± 1.6 *vs* 7.1 ± 2.2 (*P* = 0.31). There was no difference in the responder rate between those with slow and normal transit (42.9% *vs* 63.2% , *P* = 0.25).

Secondary efficacy

The scores for stool form, straining, bothersomeness of constipation, satisfaction of bowel habit, and use of

laxatives before and after treatment are summarized in Table 2. The scores for bothersomeness of constipation and satisfaction of bowel habit were significantly lower after treatment. The number of days of laxatives used, and the percentage of patients needed laxatives as rescue therapy was lower after treatment with Kiwi fruit (Table 2). There was no significant change in bowel habits or satisfaction in the control group after treatment.

Tertiary efficacy

The parameters of anorectal physiology before and after treatment are summarized in Table 3. There was marked decrease in total colonic transit time, especially in the sigmoid-rectal segment, in the constipated patients after treatment. In addition, improvement in rectal sensation, in terms of the first sensation, urge sensation and the maximum tolerable volume and the rectoanal inhibitory reflex, was seen in the constipated patients after treatment. On the contrary, there was almost no significant change in the anorectal physiology parameters in the healthy subjects after treatment.

Safety and side effects

There were no side effects reported in both the patient and control groups. None of them, including the healthy subjects, reported diarrhea.

DISCUSSION

The current study demonstrated the efficacy of increasing dietary fiber in Chinese constipated patients, with significant improvement in complete spontaneous bowel motion, decrease laxatives used, decrease bothersomeness of constipation and improved satisfaction of bowel habit. More importantly, anorectal physiology was shown to improve significantly after treatment.

It has always been suggested that increasing dietary fiber might be helpful in patients with mild constipation. However, there have been few studies done on this area, and few studies assessed the improvement objectively using the criteria of CSBM, as well as anorectal physiology.

It is interesting to note that in this study, improvement was seen not only in the constipation symptoms, but also in terms of colonic transit time and rectal sensation in the constipated patients. It has been reported that gas production from fiber metabolism may limit acceptance, which is particularly true for bran^[15] and other insoluble fibers. Despite most of the fibers in kiwifruit are insoluble fiber, none of the patients or controls reported bloating or gas, or intolerance. Voderholzer *et al*^[10] reported in their study on proprietary fiber in self-defined constipation, only 20% of slow transit patients profited from fiber, whereas more than 80% of patients without identifiable cause of their complaints had a partial or complete improvement. We observed in this study that the responder rate did not differ in both groups of patients. This is probably the first study reporting an improvement in rectal sensation: the first sensation, urge and maximal tolerable volume in constipated patients after increasing fiber intake. Despite the change in anorectal physiology parameters in constipated patients, there was no significant change observed in

Table 2 Secondary efficacy variables before and after the kiwi fruit treatment in the constipated patients and healthy subjects (mean \pm SD)

	Constipated patients			Healthy subjects		
	Before treatment	After treatment	P value	Before treatment	After treatment	P value

normal healthy subjects. The reason for the difference in anorectal physiology response in the two groups is still unknown. However, Muller-Lissner in their meta-analysis did show that the improvement in transit time in constipated patients was greater than in healthy subjects^[16].

The current study aimed at assessing the effect of increasing fiber intake in constipated subjects. However, other nutrients that are present in the kiwifruit may also contribute partly to the laxative effect. The whole fruit (minus skin) was consumed, making it difficult to isolate the mechanism. One of the novel compounds in kiwifruit that has been suggested to interact in laxation is actinidin, a proteolytic enzyme belonging to the class of thiol-proteases.

It is important to note that double blinding was impossible in this study or other studies involving dietary fiber. However, the symptoms were compared to those at the baseline, and that patients themselves were their own controls. The additional age and sex matched control group was recruited to assess if there is any side effects or change in anorectal physiology in healthy subjects. The current study thus showed that dietary fiber in terms of kiwifruit is effective in Chinese patients with functional constipation, and with improvement in anorectal physiology. Further studies on the fiber intake in both constipated patients and healthy controls are warranted. In addition, studies may be needed to dissect the individual nutrient in kiwifruit, other than fiber, that may contribute to the laxative effect.

COMMENTS

Background

Dietary fiber has been suggested to improve functional constipation. However, are only a few studies that looked for dietary fiber intake by people with chronic constipation. In addition, in a trial with proprietary fiber product, less than a half of the patients with self-defined constipation responded. Also, anorectal physiology was not assessed in most of these studies.

Research frontiers

Therefore, we investigate if increased dietary fiber, in terms of kiwifruit, is effective in Chinese constipated patients. The anorectal physiology before and after the introduction of kiwifruit was assessed.

Innovations and breakthroughs

We found that responder rate to kiwi fruit was 54.5% in the constipated group. They have improvement in complete spontaneous bowel motion per week, symptom scores for constipation, as well as in colonic transit time.

Applications

Increase dietary fiber may improve functional constipation.

Peer review

This article is novel and provides an insight in the pathophysiology of constipation.

Abstract

AIM: To investigate the distribution pathway of metastatic lymph nodes in gastric carcinoma as a foundation for rational lymphadenectomy.

METHODS: We investigated 173 cases with solitary or single station metastatic lymph nodes (LN) from among 2476 gastric carcinoma patients. The location of metastatic LN, histological type and growth patterns were analyzed retrospectively.

RESULTS: Of 88 solitary node metastases cases, 65 were limited to perigastric nodes (N₁), while 23 showed skipping metastasis. Among 8 tumors in the upper third stomach, 3 involved right paracardial LN (station number: No.1), and one in the greater curvature was found in No.1. In the 28 middle third stomach tumors, 10 were found in LN of the lesser curvature (No.3) and 6 in LN of the left gastric artery (No.7); 5 of the 20 cases on the lesser curvature spread to No.7, while 2 of the 8 on the greater curvature metastasized to LN of the spleen hilum (No.10). Of 52 lower third stomach tumors, 13 involved in No.3 and 19 were detected in inferior pyloric LN (No.6); 9 of the 29 cases along the lesser curvature were involved in No.6.

CONCLUSION: Transversal and skipping metastases of sentinel lymph nodes (SLN) are notable, and rational lymphadenectomy should, therefore, be performed.

Key words: Gastric cancer; Metastatic lymph node, Lymph node dissection; Rational lymphadenectomy; Sentinel lymph node

INTRODUCTION

Lymphatic metastasis is the most important factor for prognosis of gastric carcinoma. To avoid missing positive lymph nodes, surgeons have performed an extensive radical lymphadenectomy for gastric cancer, a method which is also used when early tumors are present. As a result, patients that did not have lymph node metastasis have had to undergo operations and face potentially avoidable risks^[1,2].

As the SLN concept gains acceptance, onco-surgery researchers are optimistic that the concept may serve as a breakthrough management tool to be used in gastric cancer; however, the concept is still considered to be at an investigative stage^[3]. We studied the distribution pathway of solitary or positive lymph nodes limited to a single station to provide a foundation for undertaking rational lymphadenectomy for gastric carcinoma.

MATERIALS AND METHODS

Patients

One hundred and seventy-three patients were selected from the 2476 patients with gastric cancer for whom radical operations were performed at the first affiliated hospital of the China Medical University between 1980 and 2003. The criteria used for inclusion was: (1) D2 lymph node dissections had been performed^[4]; (2) there were greater than 15 lymph nodes, and the resected specimens had been analyzed pathologically^[5]; (3) patients with pT4 and M1 stage were excluded^[5]; (4) patients' medical records were complete. Among the 173 cases, 88 had solitary lymph metastasis and 85 involved a single station lymph node. Sixty-four of the 88 patients were male and 24 female. The average age of the patients in this group was 57.6 ± 7.2 years (range 30-80). With respect to tumor location, the tumor was found in the upper third stomach area (U) in 8 cases, in the middle third (M) in 28, and in the lower third (L) in 52. Amongst the 85 patients with

No.2, left paracardial node; No.4, greater curvature node; No.5, superior pyloric node; No.8, common hepatic node; No.9, celiac artery node; No.11, splenic artery node; No.12, hepatoduodenal node. ¹Solitary metastatic node; ²Single station metastatic node; ³Differences of the frequency distributions between the two groups were not determined; ⁴Not significant.

single station node metastasis, 60 were male and 25 female. The average age of the patients in this group was 58.2 ± 8.3 years (range 32-76). In respect of tumor location; the tumor was in the U in 23 cases, in the M in 12, and in the L stomach areas in 50.

Reference standard

The location of the tumor, the classification of the lymph node and histological type were by the Japanese Classification of Gastric Carcinoma^[6]. For classification, the symbol "No." indicates lymph node station number and "N" indicates the lymph node group. The histological types included differentiated and undifferentiated. An "adjacent metastasis" was defined as when lymph node metastasis is limited to the tumor side of N₁; "transversal metastasis" is limited to the region of N₁ opposite the tumor; and a "skipping metastasis" indicates a lymph node metastasized outside of N₁.

Histological growth patterns included massive, nest, and diffuse types^[7].

Statistical methods

All data were analyzed using SPSS13.0 statistics software. The differences of the frequency distributions between the two groups of lymph nodes were determined by a χ^2 -test or by Fisher's exact test. A χ^2 -test was adopted in the analysis of a single factor and a P value of less than 0.05 was considered statistically significant.

RESULTS

The distribution of metastatic nodes

Among the 88 patients with a solitary metastatic lymph node, in 65 (73.9%) the lymph nodes involved were within N₁, and 23 (26.1%) were over N₁. In 8 cases the tumor was in the U location, amongst which 6 (75%) were observed to be in N₁ and 2 (25%) in N₂. In 28 cases the tumor was in the M region, amongst which 19 (67.9%) were involved

¹Tumors located at the greater curvature; ²Tumors located at the lesser curvature; ³Tumors extended in a circle of the stomach.

in N₁ and 9 (32.1%) in N₂. Among the 52 patients with L region cancers, 40 were found with solitary metastatic nodes in N₁, 10 (19.2%) with nodes in N₂ and 2 (3.9%) in N₃ (Table 1).

Comparisons were also made between cases with a solitary metastasis lymph node and single station nodes. No statistically significant difference was found with respect to the distribution of metastatic lymph nodes in the U, M and L regions using a χ^2 -test or Fisher's exact test (Table 1).

Adjacent metastasis

In 7 of the 8 cases with a U region tumor, the tumor located at the side of the lesser curvature region. Amongst them, metastatic lymph nodes in 2 (28.6%) were detected within No.1. Among the 28 cases with a tumor in the M area, in 20 the tumor was observed in the lesser curvature region and in 8 in the greater curvature region. Metastatic lymph nodes in 10 of the 20 cases were found within No. 3, while 3 of the 8 were within No. 4.

Fifty-two cases had tumors in the L stomach area. Amongst these the tumors in 29 located at the lesser curvature region, 15 at the greater curvature side and 8 extended in a circle. Metastatic lymph nodes in 9 of the 29 cases were found within No.3, in 7 of the 15 within No.6, and in 3 of the 8 within No. 6 (Table 2 and Figure 1).

Transversal metastasis

There was just one case with a tumor in the U area, and solitary metastatic lymph nodes were found within No.1. Twenty-nine patients had tumors at the lesser curvature side in the L area, and 9 (31%) of them were found to have metastatic lymph nodes within No.6. Of the 15 cases with tumors at the greater curvature side, in the L stomach area, 3 (20%) were involved in No.3 (Table 2 and Figure 1).

Skipping metastasis

Among the 8 cases with tumors in the U area of the lesser curvature region, one solitary metastatic lymph node (14.3% of total) was observed within No.7, and another node (14.3%) was found within No.8. In the M area, 5 (25%) of the 20 patients who had tumors at the lesser curvature

side had metastatic lymph nodes within No.7, while a metastatic node was detected within No.10 in 2 (25%) of the 8 patients with a tumor in the greater curvature side. Among the 29 cases with a tumor in area L, the number of lymph node metastases involved in No.1, No.7 and No.8 were 2 (6.9%), 2 (6.9%) and 3 (10.3%), respectively (Table 2 and Figure 1).

Relationships among histological type, growth pattern, and distribution pattern of solitary lymph nodes

Comparing the 65 patients with metastasis within N₁ and the 23 with a skipping metastasis, no statistical significance was found between histological type and the growth patterns of the two groups (Tables 3 and 4). Also, there was no significant difference between the adjacent metastasis group (39) and the transversal metastasis group (20) (Tables 5 and 6).

DISCUSSION

The distribution pattern of solitary metastatic nodes

There is little clinical literature available on the lymphatic routes of the stomach^[8-10]. After analyzing 51 cases, Kosaka *et al*^[11] reported that 44 gastric carcinomas with solitary lymph node metastasis were involved within N₁. Ichikura

¹Transversal metastatic nodes; ²Adjacent metastatic nodes.

et al^[12] analyzed 69 cases with solitary lymph node metastasis, and found that in 6 of the 28 cases that had a lesion along the lesser curvature region, lymph node metastasis was observed along the greater curvature region. Kikuchi^[13] reported that skipping metastasis occurred in 14% of their patients with a solitary lymph node.

We investigated 173 cases with a solitary or single station metastatic lymph node from 2476 gastric cancer patients. First, 74.2% of the solitary metastasis lymph nodes were limited to within N₁. The lesion found in each region had one or more adjacent lymph node stations where a metastasis was more frequently found. These lymph node stations were relatively certain for the lesion in each region. Second, the frequency of transversal lymph node metastases, referring to the lesion in each region, was also relatively high. For example, with reference to a lesion in the L region, 31% of patients with a primary tumor on the lesser curvature area involved No.6, while 20% with a lesion on the greater curvature involved No.3. Third, the frequency of skipping metastases in our study was 25.8%. The frequencies of metastases in N₂ in regions U, M and L were 25%, 32.1% and 19.2%, respectively. We noted that the frequency of skipping metastasis in region M was 25%, that is, 25% of the lesions at the lesser curvature side were

¹Transversal metastatic nodes; ²Adjacent metastatic nodes.

detected in No.7 and No.8, and 25% of the lesions at the greater curvature were found in No.10.

From the above results, it is apparent that the distribution patterns of solitary nodes in gastric carcinoma are basically adjacent metastases; however, transversal and skipping metastasis were also found. The histological type and growth patterns did not influence the distribution of solitary metastatic nodes.

The first possible nodes of metastasis along the route of lymphatic drainage from the primary lesion should be SLN^[14]. However, because of the multidirectional and complicated lymphatic flow from the GI tract, when using methods that inject dyes or radioactive tracers, there is likely to be some bias in the description of the distribution pathway of SLN in gastric carcinoma^[15-17]. By analyzing the location of solitary metastatic lymph nodes, the distribution pathway of SLN in gastric carcinoma can be accurately assessed.

Reasons for skipping metastasis

After analyzing the clinical records of 51 patients with solitary lymph node metastasis, Kosaka *et al.*^[11] reported 7 cases of lymph node metastases in N₂-N₃ without being in N₁. Kosaka *et al.*^[11] suggested that the following could have a role in skipping metastasis: (1) occult metastases may remain unseen in a routine histopathological examination; (2) there may be a great number of lymphatic routes in the minor omentum; and (3) there may have been only a few perigastric nodes in those cases.

In this study, transversal and skipping metastasis were found to be notable. However, to date the reasons for the occurrence of skipping metastasis remain poorly understood. Chen *et al.*^[18] studied the dynamic role of stomach lymphatic flow from 138 infant corpses using 20% Prussian Blue Chloroform Solution as lymphatic dye. They reported that in 40 of 41 cases in which the drainage pointed at the greater curvature of the corpus gastricum, the lymphatic channel flowed directly to No.10. Therefore, with reference to lesions in a certain region, the so-called “skipping metastasis” of a SLN may be the first lymph

node in the lymphatic drainage system. In cases where metastasis first occurs in N₂ or N₃, the function of N₂ or N₃ is considered to be the same as N₁^[14].

Clinical implications

In the past 23 years, 2476 patients with gastric cancer were treated at our hospital. Among them, for the 728 patients without metastatic lymph nodes an extended D1 dissection was also performed, and as a result some cases had complications connected with the dissection. A great achievement of gastric surgeons in the last century, one that deserves unequivocal respect, has been to establish radical surgery with extensive lymph node dissection for gastric cancer. However, we now need to proceed to another stage by improving post-operative function and quality of life after gastric cancer surgery without impairing long-term outcomes^[19,20]. The concept of a “minimally invasive, curative, safe operation” has gradually gained acceptance^[21,22]. Here, we have attempted to discover the distribution pathway of SLN in order to provide clinical data for rational lymphadenectomy.

Based on the study we suggest that: (1) for patients with U area cancer at the lesser curvature region, No.7 and No.8 should be treated in the same way as N₁; (2) for patients with cancer in the M area in the lesser curvature region, No.7 should be treated in the same way as N₁; (3) for patients with cancer in the M area at the greater curvature region, No.10 should be inspected more carefully, although No.10 can be regarded as the same as N₃ for an M area cancer^[6]; further, if No.10 is questionable, a resection of the spleen should be undertaken^[4]; and 4) for patients with cancer in the L area at the lesser curvature region, No.1, No.7 and No.8 should be inspected more carefully.

COMMENTS

Background

The first possible nodes of metastasis along the route of lymphatic drainage from the primary lesion should be a sentinel lymph node (SLN). If a SLN is negative, patients can be considered to be without lymph node metastasis, and should not have to endure possible operations and face avoidable risks. The SLN concept is gaining greater acceptance, and thus clinicians and researchers can be optimistic that it may serve as a breakthrough management tool for use in gastric cancer.

Research frontiers

Many clinicians and researchers are presently undertaking studies of the distribution pathway of SLN in gastric carcinoma. However, because of the multidirectional and complicated lymphatic flow from the GI tract, there is likely to be some bias in the description of the distribution pathway of SLN in gastric carcinoma when using methods that inject dyes or radioactive tracers. The first possible sites of metastasis along the route of lymphatic drainage from the primary lesion are known as SLN. Therefore, a solitary metastatic lymph node could be regarded as SLN in gastric carcinoma. Some onco-surgery scholars have attempted to assess the distribution pathway of SLN in gastric carcinoma by analyzing the location of solitary metastatic lymph nodes.

Innovations and breakthroughs

Based on a large sample study, we described the distribution pathway of solitary metastatic lymph nodes and put forward concrete suggestions for lymph node dissection in gastric cancer.

Applications

We attempted to discover the distribution pathway of solitary metastatic lymph nodes in gastric cancer. Our results provide clinical data for rational lymphadenectomy and for experimental study of SLN.

Terminology

Minimally invasive surgery (MIS) is well recognized; however, rational lymphadenectomy operations are more focused on in this study. MIS is more about treatment of early gastric cancer, while rational lymphadenectomy is more about advanced gastric cancer.

Peer review

This manuscript presents a good overview of the distribution of lymph node metastasis in gastric cancer and should be of interest to GI researchers and clinicians.

Abstract

Extragenadal germ cell tumors are rare. The most common sites for EGGCTs are in midline locations such as the mediastinum, retroperitoneum and pineal gland. These tumors rarely present in the stomach. We describe here a case where a middle aged man presented with typical symptoms of gastric cancer. After extensive workup, which included blood work, CT abdomen scan, upper endoscopy, and endoscopic ultrasound, the patient was diagnosed with gastric cancer. However, due to very high blood levels of alpha-fetoprotein, the specimen was sent for special histochemical staining, which demonstrated that the tumor had features of both adenocarcinoma and endodermal sinus tumor. This is a very aggressive tumor with a very poor prognosis.

INTRODUCTION

Extragenadal germ cell tumors are rare, accounting for only 1% to 4% of all germ cell tumors. Ninety-five percent of all testicular tumors are germ cell tumors. These tumors originate in the sperm forming cells in the testicles (the male gonads) or egg producing cells in the ovary (female gonads). On rare occasions, however, germ cell tumors

develop elsewhere in the body without any evidence of cancer in the testes. When this happens, they are referred to as extragonadal germ cell tumors (EGGCTs) (from the Testicular Cancer Resource Center)^[1].

At approximately 4 to 6 wk of embryonic development, the germ cells migrate into the embryo where they populate the developing testes or ovaries. If these cells miss their destination, they are likely to come to rest in one of a number of midline sites in the body. Extragonadal tumors arise when these cells become cancerous.

EGGCTs can be either benign or malignant and the malignant tumors can be either seminoma or non-seminoma. Extragonadal tumors are much more common in females. Malignant extragonadal tumors are much more common in men.
