The patient was started on steroid therapy due to a history of vasculitis. However, antinuclear antibody titer (ANA) of < 1:16, excluded this possibility. Bleeding scan suggested a bleeding site in the small bowel bleeding most likely in the ileum. On the second day of admission an angiogram was performed with intent of embolization, and showed normal aorta and renal arteries and extensive vascular abnormalities involving all branches of the superior mesenteric artery, which included ectasia, bleading and narrowing; and marked ectasia of the inferior mesenteric artery and areas of hypervascularity. There was no evidence of contrast extravasation. Due to drop of hemoglobin and failure of medical treatment including attempted embolization, the patient was taken to surgery. Intraoperative colonoscopy showed obvious bleeding at the anastomosis site from the previous small bowel resection, in the ileum, with old blood distally. A segment of distal ileum, 6 cm away from the ileocecal valve was resected. No obvious bleeding site was identified.

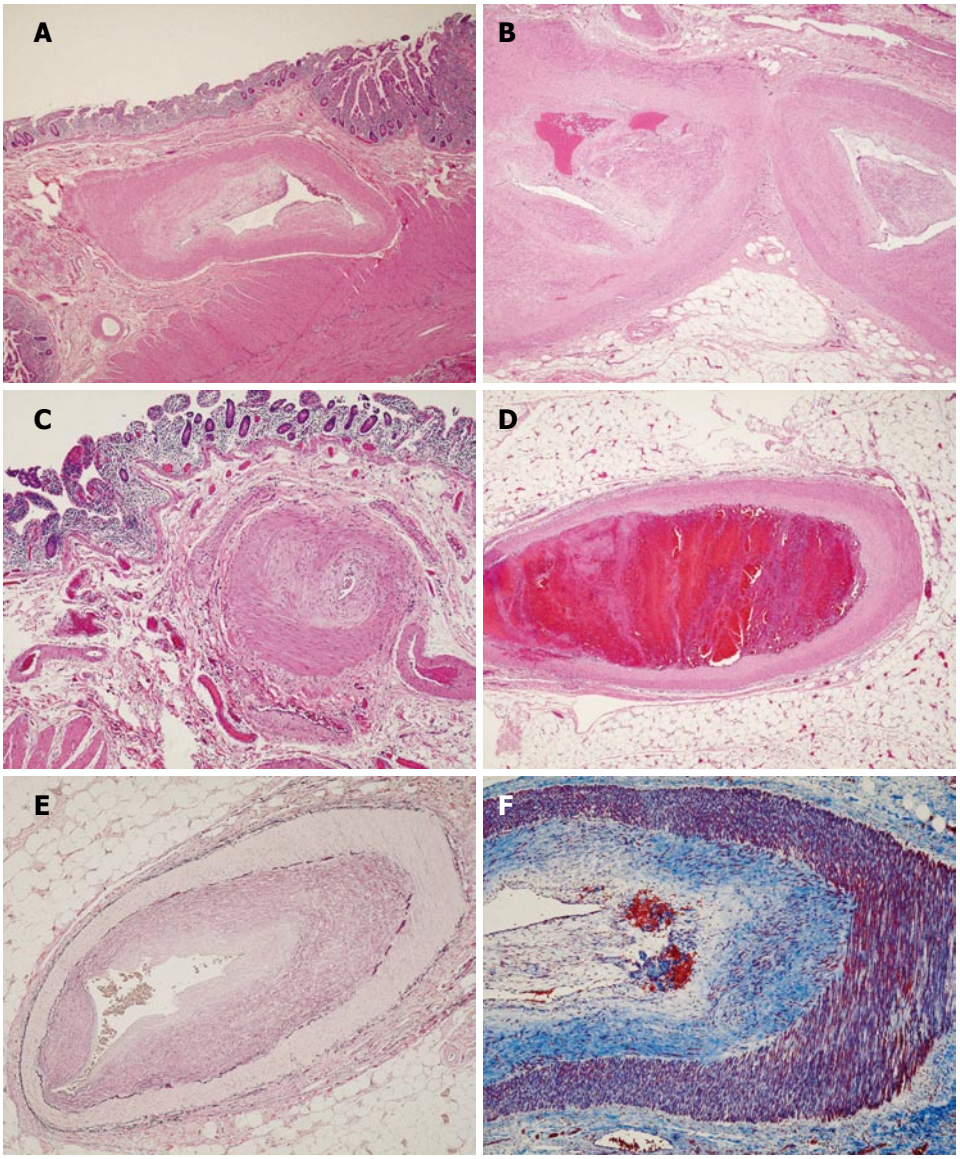

Figure 1 Microscopic sections showing marked thickening (**A**) and hyalinization (**B**) of medium sized vessel walls with prominent eccentric intimal proliferation with no arteritis, necrosis, inflammation and calcification (hematoxylin-eosin, original magnification × 200); sparing of small sized vessels (**C**) (hematoxylin-eosin, original magnification × 200); focal evidence of recent vascular thrombosis with early organization in one vessel (**D**) (hematoxylin-eosin, original magnification × 200); Verhoeff's Van Gieson elastic stain highlighting the prominent intimal hyperplasia (**E**) (original magnification × 200; Masson's trichrome stain highlighting a loose matrix of fibrous tissue replacing and expanding the intima (**F**) (original magnification × 200).

The specimen received consisted of a 37.5 cm segment of small bowel designated as "distal ileum" and a grossly unremarkable vermiform appendix. On opening the small bowel, the mucosal surface was intact without evidence of ulcers or masses. There were multiple yellow, tan slightly elevated areas of the mucosa, giving the appearance of papules, ranging from 0.3 to 0.5 cm. The previous anastomosis site was intact. Sections through the mucosa, perineal fat and mesentery showed thickened and tortuous submucosal, subserosal and mesenteric vessels, some of them contained clotted blood.

Microscopic sections (Figure 1) revealed marked thickening and hyalinization of medium sized vessel walls, with prominent eccentric intimal proliferation (Figure 1A and B) and apparent sparing of small sized vessels (Figure 1C). Focal evidence of recent vascular thrombosis with early organization was noted in one vessel (Figure 1D). Arteritis, necrosis, inflammation and calcification were absent. Verhoeff's Van Gieson elastic stain (Figure 1E) highlighted the prominent intimal hyperplasia. Masson's trichrome stain (Figure 1F) highlighted a loose matrix of fibrous tissue replacing and expanding the intima.

DISCUSSION

FMD was first described more than 68 years ago by Leadbetter, as a cause of hypertension, but was not until 1938 that it received an accurate pathological description by Mc Cormack, who reported four cases as "fibromuscular hyperplasia"[1,3]. Currently, FMD is well recognized as a nonatherosclerotic, noninflammatory vascular disease that most commonly affects young females, involving the renal and internal carotid arteries but has been described in almost all arterial beds in the body[1-9]. This entity accounts for less than 10% of cases of renal-artery stenosis[2]. Among 1200 cases of FMD studied by Meetinger[3], 60% involved renal arteries, 34% extracranial carotid and vertebral arteries, and less than 2.5% involved iliac, celiac and mesenteric arteries.

Two histopathological classifications of renal FMD have been proposed. In 1971, Harrison and McCormack[10] made the first classification, based on the arterial layer in which the lesion predominates: intimal fibroplasias, medial fibroplasias and adventitial fibroplasias. Intimal fibroplasia was found in less than 10% of patients with FMD, and can be confused with arteritis by angiography because it may appear as a focal, concentric stenosis or a long smooth

narrowing. Medial fibroplasia, characterized on imaging studies by a "string of beads appearance", represents the most common dysplastic lesion, with medial compromise and sparing of intimal and adventitial layers. Medial fibroplasias include two uncommon subtypes: perimedial fibroplasia and medial hyperplasia. Perimedial fibroplasia is characterized by a collar of elastic tissue at the junction of the media with the adventitia. Medial hyperplasia, corresponds to less than 1% of causes of renal stenosis, and consists of medial hyperplasia without loose matrix of fibrous tissue formation. The third category, also the rarest type of FMD is adventitial (periarterial) hyperplasia.

In 1975, Stanley[4], subdivided FMD into four categories, instead of three, according to histopathological findings: intimal fibroplasias, medial hyperplasia, medial fibroplasia and perimedial dysplasia. The first category, intimal fibroplasia accounts for 5% of cases of FMD appearing as irregular tubular stenosis in young patients and smooth focal stenosis in older persons, characterized histologically by an accumulation of irregularly arranged subendothelial mesenchymal cells within a loose matrix of fibrous connective tissue, often eccentric, with absence of inflammatory cells or foamy macrophages. The second, medial hyperplasia is characterized by increase in medial muscle, without demonstrable fibrotic changes, and accounts for less than 1% of cases. This category is difficult to differentiate roentographically from intimal fibroplasia. The third and most common category, medial fibroplasia, represents 85% of cases of renal FMD, and is most commonly seen in the pediatric population. It is characterized histologically by compromise of the outer media, or diffuse involvement of the entire media. Involvement of the outer media presents with compact fibrous connective tissue replacing smooth muscle peripherally, and a moderate accumulation of collagen in the inner media, separating disorganized smooth muscle. On the other hand, diffuse medial fibroplasia is characterized by severe disorganization, with disruption and replacement of smooth muscle by haphazard arrangements of fibroblasts and collagen. The last category, perimedial dysplasia, found in 10% of cases of FMD, is characterized by relatively acellular tissue in the region of the external elastic lamina that can be mistaken for dense collagen.

Both authors reported that macroaneurysms and dissections are the common complications of FMD. Aneurysms can present in any subtype, and their presence should not lead to a different diagnosis. To date, classifications are used in the literature, indistinguishably.

The etiology of FMD is unknown, but several factors, genetic, mechanical and hormonal, have been implicated[1-4,7-8]. Hormonal influence is considered due to the prevalence of the disease in hormonally active females. Although no association has been found between FMD and history of use of oral contraceptives or abnormalities of endogenous sex hormones, physiologic preconditioning of cellular elements to fibroblastic activities by estrogen has been shown. Mechanical factors, such as artery traction due to renal ptosis, could explain the increased frequency in the right kidney, compared to the left kidney. The stress involved in the stretch traction may predispose to fibroplasia directly by altering vessel wall tissues or indirectly by disrupting the vasa vasorum. Vasa vasorum of muscular arteries originates from branching of the parent vessel and arteries such as renal, extracranial carotid and external iliac arteries may have a normal paucity of vasa vasorum, making them prone to alteration. Genetic factors may be contributory, since FMD is more common among first degree relatives with renal FMD and among persons with angiotensin-converting-enzyme allele I (ACE-I).

The differential diagnosis is broad, but usually straight forward, once common etiologies are excluded[1,13]. Atherosclerosis typically occurs in older patients with cardiovascular risk factors and usually involves the origin or the proximal portion of the artery. In contrast, renal FMD occurs in younger patients, with few or no cardiovascular risks and frequently involves the middle or distal segments of artery. FMD is distinguished from active vasculitis, based on the absence of inflammation, anemia, thrombocytopenia or acute phase reactants. If histologic diagnosis is unavailable, angiography is unable to differentiate FMD and vasculitis, due to the extreme similarity in radiographic appearance, especially in the case of intimal fibroplasias, where both entities have identical manifestations, as illustrated in this case. Diseases affecting medium size vessels may induce identical histopathological changes in the vessel wall and should be considered in the differential diagnosis, including familial diseases such as neurofibromatosis and Friedreich's ataxia, endocrine diseases such as diabetes and homocystinuria, autoimmune diseases including any type of vasculitis, allograft rejection, infectious vasculitis such as Rickettsia, Rocky Mountain spotted fever, epidemic typhus, scrub typhus, Q-fever, pseudomonas, syphilis, fungi, plague, Whipple's disease, leptospirosis and schistosomiasis, toxic agents such as cocaine, coagulopathies such as thrombotic thrombocytopenic purpura, hemolytic uremic syndrome and disseminated intravascular coagulation, systemic hypertension, neoplastic entities such as intravascular lymphomatosis, endovascular papillary angioendothelioma or intravascular papillary endothelial hyperplasia, amyloidosis or emboli.

Visceral or splanchnic FMD accounts for 2.5% of cases of FMD and its clinical presentation has a wide spectrum[3,5-9,11-13]. When symptomatic, its presentation can be as occlusive disease or as aneurysmal disease. Occlusive disease ranges in spectrum from abdominal angina to intestinal gangrene. Of the seven case reports found in the literature with visceral FMD, two[8,9] had a family history of FMD or associated renal FMD. The other four[5,6,11,13] presented with only visceral involvement. The age ranged from 5 to 78 years. Three cases occurred in women and four in men. The initial presentation was acute abdomen in all the patients, with compromise of superior mesenteric artery in four patients, superior rectal artery in one, jejunal and sigmoid artery and colonic artery in one, and unspecified in the other patient. Two out of the seven patients presented with gastrointestinal bleeding. Histological analysis revealed mucosa with ischemic changes and FMD of different categories, intimal fibroplasia in three patients, medial fibroplasia in two patients, perimedial dysplasia in one patient and adventitial fibroplasia in one patient. Three patients died and four

of the seven survived. Among the successfully treated patients, three had surgery with a segmental resection, one of them combined with angioplasty. One patient was medically treated with anticoagulation and thrombolysis, without requiring any invasive procedure.

Interestingly enough, a study that originated from a case of ischemic proctitis, analyzed 50 rectums and their blood supply in patients with a median age of 61 years[11] showed that adventitial FMD was found in more than 50% of unselected, examined specimens, indicating that a relatively mild, asymptomatic form of adventitial FMD is common in later life.

Treatment for visceral FMD is more anecdotic and based on retrospective case series[1]. Revascularization through angioplasty without stent, segmental resections, anticoagulation and fibrinolysis has been used.

We present a case of extrarenal, visceral FMD, with intimal fibroplasia histopathologic type, causing intractable and recurrent gastrointestinal bleeding, without ischemia or necrosis of the bowel, who was successfully treated surgically with partial jejunectomy. The patient did well, and a year after small bowel resection he developed a ventral hernia, requiring laparoscopic and open repair. The specimen showed a large artery with fibromuscular and intimal hyperplasia. No new episodes of gastrointestinal bleeding or gastrointestinal symptoms have been documented.

Abstract

We present a rare case of well- to moderately-differentiated hepatocellular carcinoma (HCC) in a 71-year-old woman with hepatitis C virus-related cirrhosis and unusual radiologic features. A 20-mm hypoechoic nodule disclosed by ultrasound in segment two showed hyperattenuation on both computed tomography hepatic arteriography and computed tomography during arterial portography. Contrast-enhanced ultrasound revealed hypervascularity in the early vascular phase and defect in the post-vascular phase, with the same pattern detected by the two imaging techniques. SPIO-MRI revealed a hyperintense nodule. These findings were compatible with those of moderately-differentiated HCC. An ultrasound-guided biopsy showed histological features of well- to moderately-differentiated HCC characterized by more than two-fold the cellularity of the non-tumorous area, fatty change, clear cell change and mild cell atypia with a thin to mid-trabecular pattern. Further studies may provide insights into the correlation between tumor neovascularity in multistep hepatocarcinogenesis and dual hemodynamics, including the artery and the portal vein.

Key words: Hepatocarcinogenesis; CT hepatic arteriography; CT during arterial portography; Hyperattenuation; Dual hemodynamics; Well- to moderately-differentiated hepatocellular carcinoma

INTRODUCTION

Recent advances in imaging have enabled clinicians to identify not only advanced HCC but also dysplastic nodules or early hepatocellular carcinoma (HCC). Moreover, clinicians can now obtain images by CT hepatic arteriography (CTA) and CT during arterial portography (CTAP) concurrently, and can evaluate the hemodynamics of lesions preoperatively[1,2].

To determine the treatment of choice for HCC, examinations by both CTA and CTAP are indispensable because of the high sensitivity of CTAP in detecting hepatic lesions and the capability of CTA of characterizing them. Moderately-differentiated HCC is generally demonstrated as a perfusion defect on CTAP and as an enhanced area on CTA, principally because of the reciprocal blood flow of these two features. We investigated a case of well- to moderately-differentiated HCC, manifesting hyperattenuation on both CTA and CTAP.

CASE REPORT

A 71-year-old woman with hepatitis C virus (HCV)-related cirrhosis was admitted to Kobe Asahi Hospital in January 2007 for further examination of a 20-mm hypoechoic nodule in segment two (S2). She had no history of alcohol, blood transfusion, or drug abuse. Six months earlier, the patient had undergone to radiofrequency ablation of a 20-mm totally necrotic HCC in segment 7 (S7).

Figure 1 Ultrasound (US) image of a 20-mm hypoechoic nodule in segment 2 (S2).

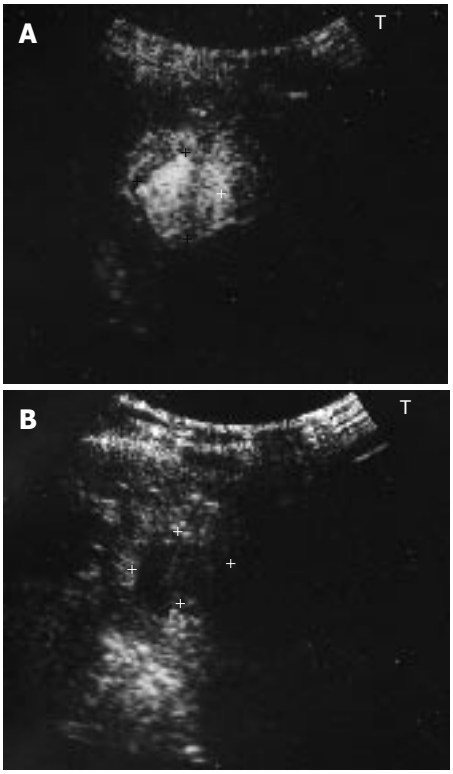

Figure 2 Contrast enhanced US of the nodule in S2. **A**: Hypervascularity in the early vascular phase; **B**: Defect in the post-vascular phase.

On admission, a physical examination showed no remarkable abnormalities. Serum HCV RNA was positive, and the HCV genotype was 1b. Serum hepatitis B virus (HBV) was negative for surface antigen, surface antibody, core antibody, and deoxyribonucleic acid (DNA). Laboratory studies disclosed the following abnormal values: platelets $6.0 \times 10^4/\mu L$ (normal 13.4-34.9), aspartate aminotransferase 50 U/L (10-40), alanine aminotransferase 46 U/L (5-40), alkaline phosphokinase 744 U/L (115-359), thymol turbidity 13.9 U (< 4.0), zinc surface turbidity 25.2 U (2.0-12.0), ICG R15 43% (0-10), γ globulin 52.8% (10.5-20.3). The levels of tumor markers were as follows: alpha-fetoprotein (AFP) 63.8 ng/mL (< 10.0), lens culinaris agglutinin A reactive fraction of alpha fetoprotein (AFP-L3) 4.6% (< 10.0), and protein-induced vitamin K absence (PIVKA II) 91 mAU/mL (<40).

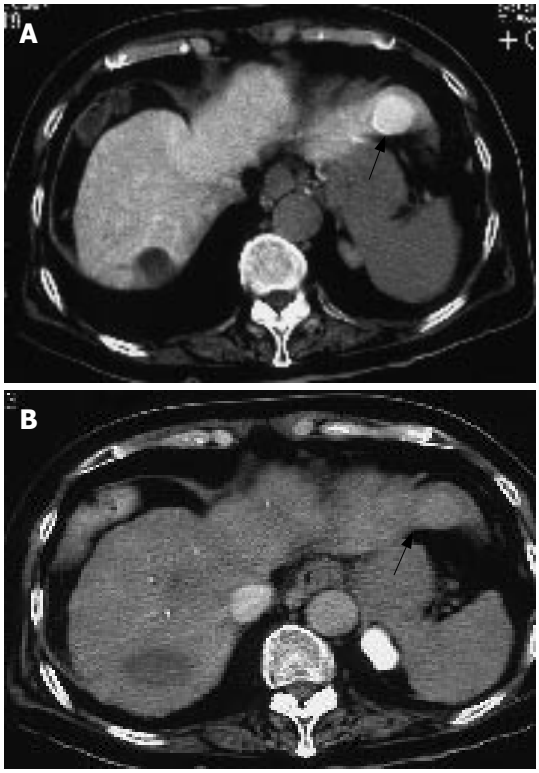

Figure 3 **A**: Hyperattenuation in S2 on computed tomography during arteriography (CTA); **B**: Hyperattenuation in S2 on computed tomography during arterial portography (CTAP).

Ultrasound (US) disclosed a 20-mm hypoechoic nodule in S2 (Figure 1). Contrast-enhanced US revealed hypervascularity in the early vascular phase (Figure 2A), and defect in the post-vascular phase (Figure 2B). Magnetic resonance imaging (MRI) revealed a high intensity nodule at both T1- and T2-weighted sequences. Contrast-enhanced MRI revealed a hypervascular nodule in the early phase and washout in the late phase. SPIO-MRI revealed a hyperintense nodule. Contrast-enhanced CT revealed an enhanced nodule in the early phase and washout in the late phase. Both CTA and CTAP revealed hyperattenuation (Figure 3A and B). Histologically, the nodule was well- to moderately-differentiated HCC characterized by more than two-fold the cellularity of the non-tumorous area, fatty change, clear cell change and mild cell atypia with a thin to mid-trabecular pattern (Figure 4A).

Immunohistochemical staining of heat shock protein (HSP) 70 (Figure 4B) was partly positive, and that of cyclase-associated protein (CAP) 2 was strongly positive (Figure 4C). Immunohistochemical staining of CD34 in HCC was positive in the sinusoidal blood space (Figure 4D). Immunohistochemically, CD68 was significantly underexpressed in the sinusoidal blood space compared with its expression in the non-HCC area (Figure 4E).

DISCUSSION

According to the classification by the International Working Party of the World Congress of Gastroenterology[3], hepatic nodules observed in patients with chronic liver disease can be subdivided into regenerative nodules

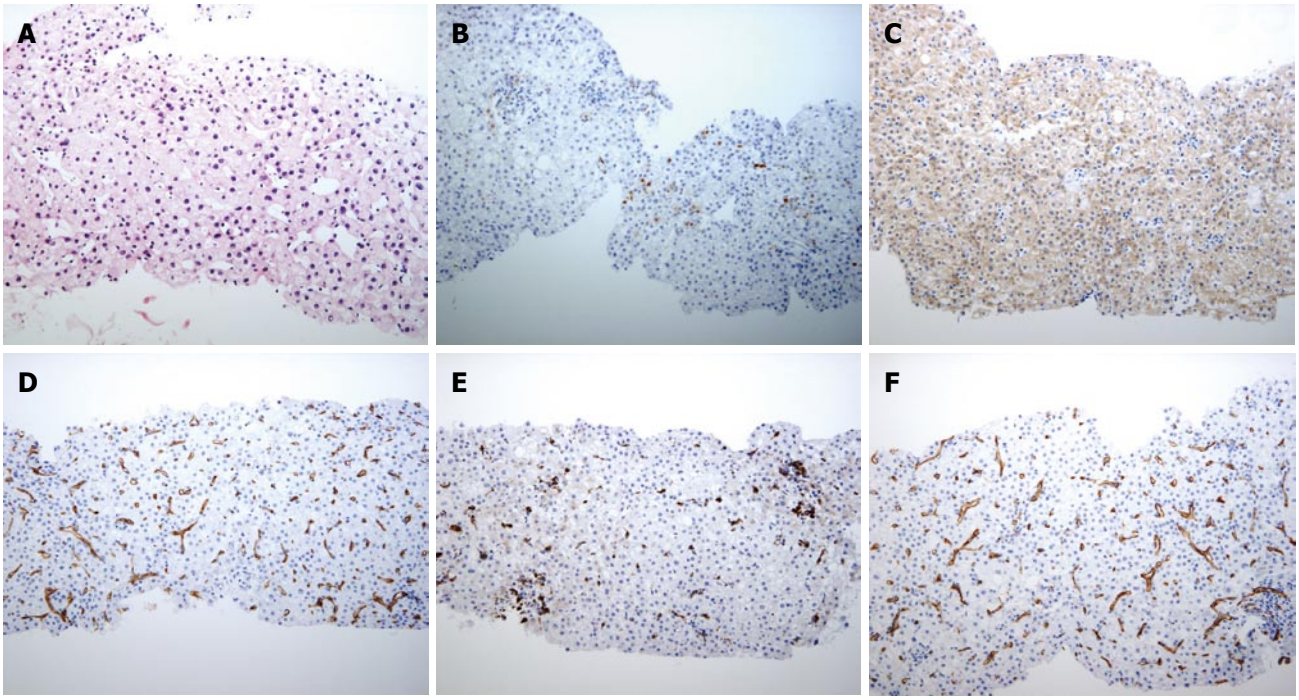

Figure 4 Histological features of a US-guided biopsy of a hyperechoic nodule in S2. **A**: Well- to moderately-differentiated HCC characterized by more than two-fold the cellularity of the non-tumorous area, fatty change, clear cell change and mild cell atypia with a thin to mid-trabecular pattern (HE×100); **B**: Immunohistochemical finding, HSP70 partly positive HCC cells; **C**: Immunohistochemical finding, CAP2 strongly positive HCC cells; **D**: Immunohistochemical staining of CD34 in the sinusoidal blood space is positive, showing capillarization; **E**: Immunohistochemical staining of CD68 Kupffer cells in the sinusoidal blood space is relatively less positive; **F**: Non-HCC area of immunohistochemical staining of CD68 Kupffer cells in the sinusoidal blood space.

(monoacinar and multiacinar), low-grade dysplastic nodules (LGDS), high-grade dysplastic nodules (HGDS), well-differentiated HCC (wHCC), moderately-differentiated HCC (mHCC), and poorly-differentiated HCC (pHCC), in the ascending order of histologic grades, representing a sequence of multistep hepatocarcinogenesis.

Several studies have shown sequential changes of hemodynamics in such hepatocellular neoplastic nodules and have reached similar conclusions: in the multistep developmental process of HCC, first, intratumoral hepatic arterial flow transiently decreases in the early stages of hepatocarcinogenesis and corresponds, histopathologically, to the obliteration of pre-existing hepatic arteries[2]; next intratumoral portal flow decreases gradually with the elevation of the histopathologic grades of hepatocellular nodules; and then hepatic arterial flow shows a gradual increase[4].

As is well documented through imaging techniques, such as CTA and CTAP, and histopathologically, the hepatocarcinogenetic process involves a gradual decrease in portal blood flow within the lesion and a reciprocal increase in hepatic arterial blood.

Although the HCC lesion is usually demonstrated as an iso- or hypoattenuated mass on CTAP, hyperattenuated lesions on CTAP are rare and limited to observations made in Japan[5-7].

Hyperattenuation on CTAP has been postulated as being reciprocal compensation for portal venous flow and hepatic arterial flow[5]; however, it is difficult to explain such hyperattenuation on CTAP by this premise because of the crucial gradual pressure between the hepatic artery and the portal vein. Although this hypothesis has not been pathophysiologically proven yet, one possible explanation[8] could be the following.

Abnormal thick-walled tumor vessels or tumor neovascularity may not necessarily carry arterial blood, considering the unique dual blood supply system of the originating organ, the liver. Tumor vessels may be communicating predominantly with the portal venous system through pre-existing intratumoral portal veins at the early stage of hepatocarcinogenesis (LGDN to wHCC), when both pre-existing arteries and portal veins decrease in number and when tumor angiogenesis may already have begun.

Net portal perfusion seen on CTAP in such tumors may reflect the sum or an additional effect of the reduced preexisting portal vein and the increased tumor vessels. These two factors may thus cancel out each other, resulting in isoperfusion on CTAP. When tumor angiogenesis exceeds the loss of a preexisting portal vein, the lesion may exhibit hyperattenuation on CTAP. Despite the communication between tumor vessels and portal veins, the tumor may become hypoxic because of the paucity of oxygen in portal venous blood compared with arterial blood. The hypoxia may thus induce gradual angiogenesis. As the histologic grades of the liver nodule advance, tumor vessels increase and may start to communicate with the arterial system as well, either through preexisting arteries or directly through outside arteries. Portal communication of the tumor vessels may gradually decrease; instead, arterial communication becomes gradually dominant. In mHCC and pHCC, therefore, the tumor may be fed exclusively by

arterial supply.

We have previously presented a rare case of well-differentiated HCC manifesting hypoattenuation on CTA and hyperattenuation on CTAP[7]. Takayasu et al[6] also have presented three such cases of HCC. These observations give rise to one possible explanation of the present case manifesting hyperattenuation on both CTA and CTAP: in the course of dedifferentiation from well- to moderately-differentiated HCC, there may be an intermediate phase between the manifestation of hypoattenuation on CTA and hyperattenuation on CTAP and the manifestation of hyperattenuation on CTA and hypoattenuation on CTAP. To the best of our knowledge, this is the first case of well- to moderately-differentiated HCC manifesting hyperattenuation on both CTA and CTAP.

Histopathologically, the tumor showed well- to moderately-differentiated HCC characterized by more than two-fold the cellularity of the non-tumorous area, fatty change, clear cell change and mild cell atypia with a thin to mid-trabecular pattern. Varying degrees of fatty changes may be one of the significant morphological markers of malignant transformation in the nodule, as observed in our US guided biopsy specimen.

Immunohistochemically, HSP70 is significantly overexpressed in early HCC, compared with its expression in dysplastic nodules, reaching 80% in most cases of well-differentiated HCC[9].

All cases of dysplastic nodules have been negative or focally positive (5%-10% of the lesions) for CAP2; in contrast, most cases of HCC (27 of 29 cases) have been partly positive for CAP2. Of the lesions, 70%-100% have been positive in the advanced components, and the positivity of well-differentiated HCC has ranged from 10% to 100%[10].

Positive immunohistochemical staining of both HSP70 and CAP2 confirmed the diagnosis of well- to moderately-differentiated HCC in the present case.

Positive immunohistochemical staining of CD34 in endothelial cells in the sinusoidal blood space has shown capillarization[11]. The immunohistochemical staining of CD34 was compatible with the hypervascularity of our tumor, as shown by imaging studies. Relatively less positive staining of CD68 of Kupffer cells in the sinusoidal blood space revealed the dedifferentiation. This finding was compatible with the imaging studies based on SPIO-MRI.

Further studies on sequential homodynamic change in hepatocarcinogenesis are indicated.

Abstract

We describe a 45-year-old woman with minute signet ring cell carcinoma occurring in a gastric hyperplastic polyp. A biopsy specimen obtained from the gastric hyperplastic polyp revealed signet ring cell carcinoma. Endoscopic mucosal resection (EMR) was performed to confirm the diagnosis. Histological examination of the EMR specimen revealed focal signet ring cell carcinoma in the hyperplastic polyp. There are few cases of gastric hyperplastic polyp associated with signet ring cell carcinoma.

Key words: Minute gastric cancer; Signet ring cell; Endoscopic mucosal resection

INTRODUCTION

Patients with gastric hyperplastic polyps may present with anemia, abdominal pain or gastric outlet obstruction[1,2]; therefore, most endoscopists agree that large gastric polyps or polyps associated with complications should be removed endoscopically or surgically. On the other hand, signet ring cell carcinoma rarely occurs in gastric hyperplastic polyps; however, no standardized therapy for such cases has been established. Herein, we report a rare case of a Japanese woman diagnosed with minute signet ring cell carcinoma in a gastric hyperplastic polyp and treated with endoscopic mucosal resection (EMR).

CASE REPORT

A 45-year-old woman visited our hospital for a follow-up study of a gastric polyp. She had been diagnosed with gastric hyperplastic polyp on the posterior wall of the middle third area 5 years previously. Her body temperature was 36.4℃, blood pressure was 126/78 mmHg, and radial pulse rate was 66 beats/min and regular. She had neither anemia nor jaundice. A neurological examination revealed no abnormal findings and there was no lymphadenopathy. No specific family history was identified. Routine hematological examination and biochemical tests were within normal limits. Serum anti-*H pylori* immunoglobulin G (IgG) antibody was positive. Endoscopic examination of the upper digestive tract revealed a small gastric hyperplastic polyp in the posterior wall of the gastric body (Fig. 1). The first biopsy specimen obtained from the polyp showed signet ring cell carcinoma. However, the biopsy specimen obtained repeatedly (three times) from the lesion revealed hyperplastic foveolar epithelium. Thus, the definite diagnosis could not be made. The patient underwent an EMR for histological confirmation. The protruding lesion, 6 × 5 mm in size, was resected completely with a safe lateral and vertical margin (Fig. 2). Histological examination showed neoplastic cells with signet ring features surrounded by the tissue of the hyperplastic polyp (Fig. 2). The protruding lesion was diagnosed as minute signet ring cell carcinoma in a hyperplastic polyp with mucosal invasion, ly0, and v0.

DISCUSSION

This case involved the unusual association of a gastric hyperplastic polyp and focal signet ring cell carcinoma. Histological features in this case fulfilled the criteria of Nakamura *et al*[3] for the malignant transformation of hyperplastic polyps: (1) coexistence of benign and malignant parts in the same polyp; (2) existence of sufficient evidence that the benign area had previously been a benign polyp; and existence of sufficient cellular and structural atypia in the malignant area to be diagnosed as cancer.

The relationship between gastric hyperplastic polyp and gastric cancer remains unknown. In a study of gastric polyps[2,4] we found that hyperplastic polyps are the most common; nearly 85%-91% of all polyps were hyperplastic polyps. In another report, the incidence of gastric hyperplastic polyps was reported to be 28.3% in one series of 5515 gastric polyps by Stolte *et al*[5]. As gastric

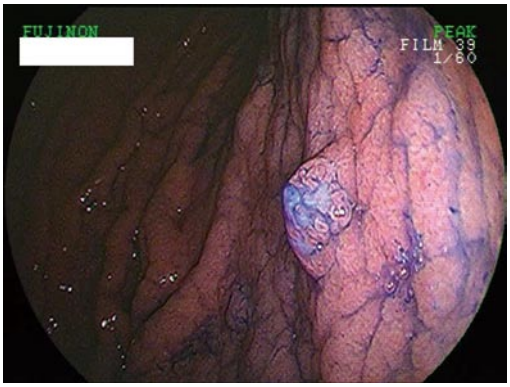

Figure 1 Endoscopic appearance of the gastric hyperplastic polyp in the posterior wall of the gastric body.

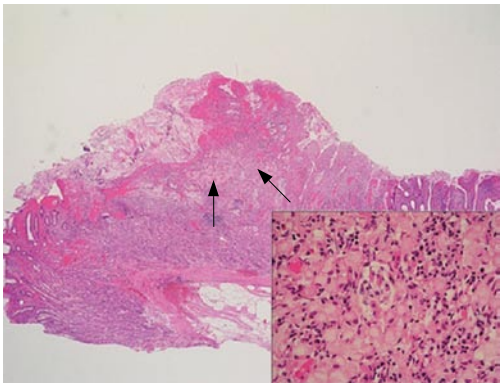

Figure 2 The resected specimen obtained by endoscopic mucosal resection showing localized neoplastic cells with signet ring features limited to the mucosal layer (arrows) (HE, × 10, × 100).

hyperplastic polyps are common, we should identify the relationship between gastric hyperplastic polyps and gastric cancer. It is generally acknowledged that the natural course of hyperplastic polyps does not include transformation to carcinoma, although hyperplastic polyps occasionally associate with gastric cancer[6-8]. In these reports, most hyperplastic polyps harboring cancer were larger than 1 cm in size[6-8]. The malignant transformation of a hyperplastic polyp is considered to relate to the size and macroscopic type; as the polyp grows larger and becomes semipedunculated or pedunculated, adenomatous or dysplastic foci appear first, followed by the cancerous lesion. Most adenocarcinomas found within hyperplastic polyps are the differentiated type. Few cases of signet ring cell carcinoma occurring in gastric hyperplastic polyps have been reported[4,9].

In the present case, the hyperplastic polyp, 6 mm in diameter, was associated with focal signet ring cell carcinoma and was diagnosed by endoscopic biopsy by chance. However, we could not locate the cancer in the polyp by careful observation with endoscopy. Thus, association of hyperplastic polyp and gastric cancer should generally be taken into consideration when endoscopists detect gastric hyperplastic polyps. Endoscopists should aggressively obtain biopsy specimens from hyperplastic polyps even if they are small.

In conclusion, we report the case of a woman diagnosed with minute signet ring cell carcinoma in a hyperplastic gastric polyp. This case emphasizes that small gastric hyperplastic polyp may be associated with gastric cancer, and periodic follow-up endoscopy and careful observation are necessary when treating patients with gastric hyperplastic polyp, even when it is less than 1 cm.

Abstract

Heterotopic pancreatic tissue within the stomach is rare and dysplasia within heterotopic pancreatic tissue is very rare. We present the first report of a patient with concurrent occurrence of heterotopic pancreas in the stomach with a gastrointestinal stromal tumour.

Key words: Dysplasia; Gastrointestinal stromal tumour; Heterotopic pancreas; Mucinous cyst; Stomach

INTRODUCTION

Heterotopic pancreas is a relatively common lesion found in approximately 1 in 500 abdominal laparotomies[1] with approximately 62% found in the stomach[2]. Pancreatic heterotopia is defined as pancreatic tissue lacking vascular or anatomical continuity with the normal pancreas[1]. Symptoms associated with heterotopic pancreas are rare, but when present are usually associated with a gastric site. Symptoms may be due to mass effect such as pyloric obstruction, ulceration or bleeding, or due to pancreatic diseases such as pancreatitis, cyst formation or pancreatic neoplasia. Dysplasia and malignancy within pancreatic heterotopia are rare events[3]. The synchronous occurrence of gastrointestinal stromal tumour (GIST) and heterotopic pancreas has not, to our knowledge, been previously reported.

CASE REPORT

A 71 year-old female was admitted to our hospital for melaena (77 g/L haemoglobin). She underwent endoscopy, and two lesions were visualised in the gastric antrum, one with overlying mucosal ulceration. The lesions were not biopsied as they were scheduled for resection. On the following day, both lesions were resected. Macroscopically the lesions measured 70 mm × 50 mm × 40 mm and 15 mm × 15 mm × 12 mm. The former was a solid tumour with a fleshy tan cut surface, while the latter was a solid and cystic lesion containing a single cyst (10 mm in diameter) filled with mucinous material. The solid lesion with surface ulceration was a gastrointestinal stromal tumour (intermediate risk, uncertain malignant potential)[4] composed of fascicles of spindle cells exhibiting mild nuclear pleomorphism and up to 4 mitotic figures per 50 high power fields (Figure 1). Large areas of tumour necrosis were present. Surface ulceration was present, which was the likely source of melaena.

The smaller lesion was composed of pancreatic ducts and acini within the gastric submucosa and focally extended into the muscularis propria. Within this area was a cyst partly lined by mucinous epithelium while in some areas the lining epithelium was denuded. The mucinous epithelium exhibited moderate to severe dysplastic cytoarchitectural features (tufted and micropapillary architecture, along with nuclear enlargement, stratification, coarsely granular chromatin and nucleolar prominence) (Figure 2). Around the cyst there were small pools of extracellular mucin, associated with a chronic inflammatory response suggestive of partial rupture. Adjacent smaller dilated ducts were lined by non-dysplastic columnar mucinous epithelium. No evidence of stromal invasion was present. The cyst lining cells were positive for CK7 and CK20 (Figure 2), the latter was localized in the dysplastic areas. The intracytoplasmic mucin was positive for alcian blue pH 0.5 and periodic acid Schiff.

The gastric mucosa adjacent to the lesions showed active chronic gastritis, *H pylori* organisms and intestinal metaplasia.

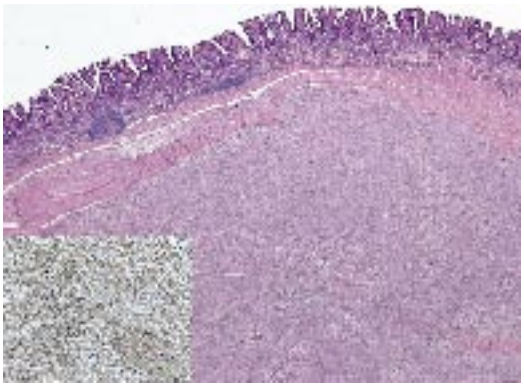

Figure 1 Gastrointestinal stromal tumour composed of fascicles of spindle cells. The tumour cells are positive for CD117 (inset).

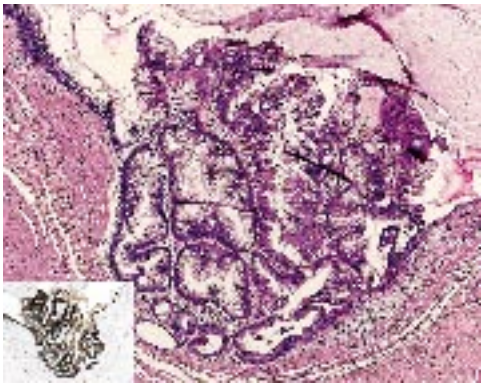

Figure 2 Severely dysplastic mucinous epithelium lining mucin-filled cyst in heterotopic pancreas. The dysplastic epithelium is positive for CK20 (inset).

DISCUSSION

Heterotopic pancreas is a relatively common lesion most often present in the gastric antrum seen macroscopically as a round or lobulated white to yellow which can be up to a few centimetres in dimension[2]. Diagnosis is difficult and often not made until surgical removal of the lesion. Heterotopic pancreas has been classified into three types by Heinrich: class I is typical pancreatic tissue with acini, ducts and islet cells, class Ⅱ shows a large number of acini and few ducts, and class Ⅲ shows numerous ducts with few acini or islet cells[5]. Neoplasms arising in heterotopic pancreatic tissue are rare[6] and include borderline mucinous cystic tumour[7], adenocarcinoma[6], mucinous cystadenocarcinoma[8], acinar cell carcinoma[2], islet cell tumour[9], or solid and papillary neoplasm[10]. Cystic degeneration without malignant change appears to be more common and may mimic mucinous carcinoma from another primary site[11]. The case report by Naqvi *et al*[7] includes a description of jejunal pancreatic heterotopia with cystically dilated ducts lined by mucinous epithelium showing low grade dysplastic cytoarchitectural features. They diagnosed a borderline mucinous cystic tumour without documenting the presence of ovarian type stroma. Of the reported cases of malignancy few have included reference to dysplastic or pre-malignant change[8,12]. These reports note the presence of dysplasia or carcinoma *in-situ* within the heterotopic pancreas adjacent to invasive ductal adenocarcinoma. Given the morphological appearances of the severe dysplasia seen in our patient, it is likely that the changes represent a pre-malignant change akin to that reported in orthotopic pancreas under the rubric "pancreatic intraepithelial neoplasia" (PanIN). Although malignant change within heterotopic pancreas is rare, we recommend that in the presence of dysplastic change within heterotopic pancreas tissue, the entire lesion should be sampled and examined histologically to exclude the presence of invasive malignancy.

Abstract

A high incidence of IgA nephropathy has been reported in patients with liver cirrhosis, though, clinically evident nephrotic syndrome is very uncommon. Impaired hepatic clearance of circulating IgA immune complexes and subsequent deposition in renal glomeruli has been considered principally in the pathogenesis of liver cirrhosis associated IgA nephropathy. Here we report on a patient with cryptogenic liver cirrhosis and splenic vein thrombosis, who presented with nephrotic syndrome. Renal biopsy showed findings consistent with IgA nephropathy. Lower endoscopy showed features of portal hypertensive colopathy. Following initiation of propranolol and anticoagulant treatment to reduce portal pressure, a gradual decrease of proteinuria and hematuria to normal range was noted. The potential pathogenetic role of portal hypertension in the development of IgA nephropathy in cirrhotic patients is discussed.

INTRODUCTION

IgA nephropathy (IgAN) is a well known concomitant of liver cirrhosis (LC) with largely unknown pathogenesis[1,2]. Most of the literature has focused on the causative role of impaired clearance of circulating IgA immune complexes (IgAIC) by the diseased liver with subsequent intraglomerular deposition[1,3-5]. Other reports suggested that some etiological factors of chronic liver disease may be associated per se with development of IgAN[6-11]. We report the case of a patient with portal hypertension (PH) due to cryptogenic LC and splenic vein thrombosis (SVT) presented as nephrotic syndrome (NS), caused by IgAN. Proteinuria resolved after the introduction of propranolol and oral anticoagulation. The association of PH with IgAN is reviewed and potential pathogenetic mechanisms through which PH can cause IgAN in cirrhotic patients are proposed.

CASE REPORT

A 34-year-old man was evaluated for nephrotic range proteinuria and LC. Seven days before, he was admitted to another hospital with a 6-mo history of ankle swelling and periorbital oedema, and a 3-wk history of increased abdominal distention. Abdominal ultrasound showed a nodular liver, moderate ascites, and splenomegaly; the kidneys had normal dimensions and structure. Diagnostic aspiration of peritoneal fluid showed no evidence of infection; the serum ascites albumin gradient was consistent with PH (1.2). A large volume paracentesis was performed and daily treatment with furosemide 40 mg and spironolactone 100 mg was initiated.

On admission, the patient had mild peripheral oedema and ascites. Past history, including blood transfusion and alcohol consumption, was unremarkable, and he denied taking regular medication. There was no history of family renal or liver disease. Abnormal laboratory results were as follows: hemoglobin 114 g/L (normal range, 130-180), platelet count 79 000/mm^3 (130 000-400 000), international normalized ratio 1.2, fibrinogen 3.2 g/L (2-4), plasma D-dimers 1310 mg/L (< 200), serum urea 9.86 mmol/L (1.7-8.3), serum creatinine 88.4 μmol/L (53-106), total bilirubin 20.5 μmol/L (5.1-17), alanine aminotransferase 59 U/L (4-36), serum total protein 56 g/L (60-78), and serum albumin 22 g/L (32-45). Urinary protein was 3.6 g/day (< 0.06), red cell content 80-100 per field, white cell content 0-2 per field. Serum IgA was 7.1 g/L (0.9-3.2), IgG 15.7 g/L (8-15), and IgM 2.3 g/L (0.5-3). Serum C3 and C4 were 0.76 g/L (0.86-1.84) and 0.1 g/L (0.2-0.58), respectively. Chest radiography and echocardiography were normal. Stool examination for occult blood was positive with a ferritin of 5 ng/mL (6-80).

Liver biopsy confirmed LC but failed to disclose the aetiology of liver disease. The results of a thorough diagnostic work-up, including PCR for HBV and HCV, antimitochondrial antibodies, antinuclear antibodies, anti-smooth muscle antibodies, anti-liver-kidney microsomal antibodies, soluble liver antigen, alpha1-antitrypsin, copper and iron studies, and cryoglobulins, were also negative. Upper gastrointestinal endoscopy showed 1st degree esophageal varices and congested gastric mucosae. Colonoscopy revealed hyperemia, mucosal oedema, and friability throughout the entire colon, indicative of PHC. Abdominal computed tomography and venography revealed SVT and extensive venous collateral circulation; there was no evidence of splenorenal shunt, and portal or renal vein thrombosis. Investigation for acquired and inherited thrombophilic factors revealed the G20210A heterozygous mutation of prothombin. Other coagulation defects, including deficiencies of natural inhibitors of coagulation (protein C, protein S, antithrombin), factor V Leiden mutation, TT677 mutation of methylene-tetrahydrofolate reductase, and anticardiolipin antibodies, were not detected.

A renal biopsy demonstrated a diffuse endocapillary glomerulonephritis with a small proportion of crescends. The immunofluorescent study revealed IgA deposits of high intensity, localized within the mesangium of all glomeruli, as well as lesser amounts of IgM and C3. The electron-microscopic study showed electron-dense deposits under the basement membrane of capillaries that extended to the paramesangial region. A few intramembranous deposits were also seen (Figure 1).

Propranolol, increasing to 60 mg daily to achieve a reduction of heart rate by 25%, the vitamin K antagonist acenocoumarol, targeting an INR in the range of 2-3, and iron sulfate were added to diuretic treatment. Renal protein excretion decreased to normal range within 20 d together with a reduction of IgA levels (3.4 g/L) and disappearance of hematuria; ascites and oedema gradually resolved. One month later, repeated tomography showed patent splenic vein and a decrease in collateral circulation and size of spleen.

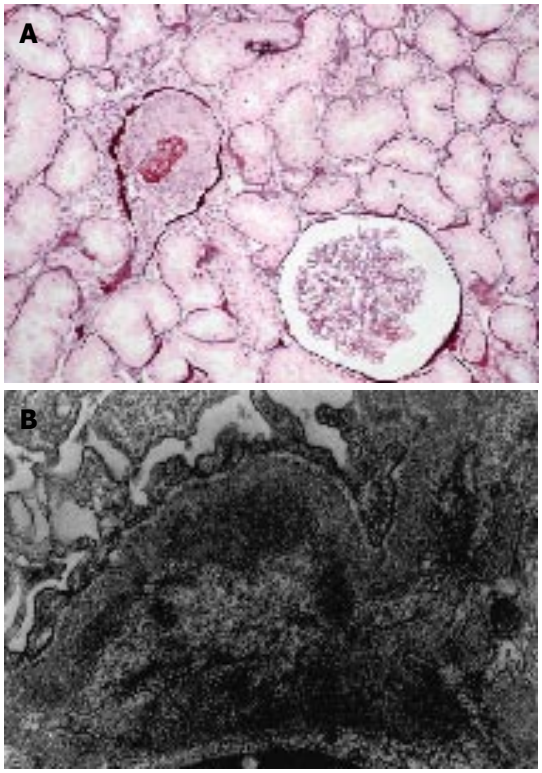

Figure 1 **A**: Light microscopy study showing endocapillary and extracapillary proliferation. A large cellular crescend is observed in the left upper glomerulus (silver methoxamine stain, × 200); **B**: Electron-microscopic study showing intramembranous and paramesangial electron-dense deposits (× 13 000).

DISCUSSION

IgAN associated with liver disease is the commonest form of secondary IgAN[12]. Glomerular deposits of IgA and fewer amounts of other immunoglobulins and C3 have been noted in 35% to 90% of cirrhotic patients[1,2]. The majority of IgA synthesis in human is mucosal, predominantly polymeric (pIgA) with two isotypes, IgA1 and IgA2, in about equal proportions. Normally, little mucosal pIgA reaches the circulation[12]. In patients with chronic liver disease, increased circulating IgA against gut flora and IgAIC have been reported[5,13]. Serum complement factor levels may be low due to activation of complement components by immune complexes, hepatic hyposynthesis, or both[14]. PIgA2 is mainly eliminated through the hepatic asialoglycoprotein receptor (ASGR) whereas only a small percentage of pIgA1 is cleared through this pathway[15], which explains the higher proportion of circulating IgA2 in chronic liver disease[16]. The majority of pIgA is then released back to the circulation in degraded forms[17]. Kupffer cells participate in the removal of IgA expressing specific Fc receptors[18]. PIgA1 is the predominant form in mesangial deposits[19], yet no antigens have been identified within the mesangial deposits.

LC-related IgAN is usually clinically silent[1]. Nakamoto *et al*[20] reported NS in 1.6% of a series of 752 cirrhotic patients. Microscopic but rarely gross hematuria may occur, but it is less common than in patients with primary IgAN[1,20].

The pathogenesis of LC-related IgAN remains uncertain. Impaired hepatic clearance of IgAIC due to reduced phagocytic[1,3-5] or ASGR[6] activity, which subsequently are deposited in the renal glomeruli, have been considered principally in the literature. However, there is no correlation between the degree of liver damage and the IgAIC levels[16]. In addition, a direct association of various causes of chronic liver disease, such as hepatitis viruses B[6] and C[7] infections, heavy alcohol consumption[8], autoimmune hepatitis[9], primary hemochromatosis[10], and alpha1-antitrypsin deficiency[11] with immunological renal injury has been suggested.

In the present case, IgAN was secondary to LC of unknown etiology complicated by PH and portosystemic shunting, as shown by the imaging results, and the presence of PHC[21] and esophageal varices. Proteinuria and hematuria resolved after introduction of propranolol to improve PHC[21] by decreasing portal pressure and tributary flow[22]. No significant renal effects of propranolol have been reported in cirrhotic patients to

justify decrease of proteinuria[23]. SVT has been associated with left-sided PH in non-cirrhotic subjects[24]. Therefore, acenocumarol may have exerted an additive portal hypotensive effect in our patient by restoring SVT, possibly related to PTHR A20210 mutation[25] or NS per se[26]. Renal vein thrombosis[26] or spontaneous splenorenal shunt[27], which might have been involved in the development and progress of IgAN in our patient, were not confirmed by computed tomography and venography.

Consistent with our observations, three previous case reports highlighted the pivotal role of PH in the development of LC-related IgAN[28-30]. Nakamura *et al*[28] reported a progressive fall in proteinuria together with clinical remission of NS after initiation of propranolol in a patient with cryptogenic LC. In another case of non-cirrhotic PH and IgAN induced NS, portacaval anastomosis decreased portal pressure causing proteinuria and hematuria to disappear[29]. Finally, Babbs *et al*[30] described a case of IgAN in a non-cirrhotic patient with a large splenic artery aneurysm causing PH and extensive collateral circulation. Splenectomy and aneurysm resection induced remission of the NS and hematuria.

The portosystemic shunting that results from PH may cause IgA to deviate from hepatic uptake and depolymerization[1]. Therefore, reduction of PH is expected to increase hepatic processing of IgAIC. PH also decreases small intestinal motility promoting bacterial overgrowth[31,32], while in the same time increases intestinal permeability[33]. In this regard, increased circulating IgA and IgAIC may represent an exaggerated response of immune system to excess gut antigen exposure[34,35], resulting from diminished mucosal integrity and spillage of IgA into the circulation. Another mechanism could involve the endotoxemia that frequently accompanies LC with PH[36], suggested to be generated by gut flora through bacterial translocation[37,38] favored by dysfunction of intestinal barrier[33,37]. Previous literature showed that endotoxemia may decrease hepatic ASGR binding[39]. Therefore, portal hypotensive treatment may decrease bacterial translocation and endotoxin levels[40], which could restore ASGR function.

In conclusion, PH seems to play a significant role in the pathogenesis of IgAN associated with LC. In this point of view, a decrease in PH is likely to reduce renal protein excretion in patients with significant proteinuria. Further studies are needed to assess if the severity of PH is related with the magnitude of renal IgA deposition.

Abstract

We first report a rare case of metastasis from gastric hepatoid adenocarcinoma (HAC) to cerebral parenchyma, in a 50-year-old Chinese patient. He complained of a one-month history of a paroxysm of headache in the left temple and pars parietalis accompanied with binocular caligation caligo, insensible feeling of limbs and transient anepia. Magnetic resonance (MR) imaging revealed a spherical occupying lesion in the left posterior-temple lobe which was clinically diagnosed as a metastatic tumor. Three years ago, the patient accepted total gastrectomy as he was pathologically diagnosed at gastroscopy having an adenocarcinoma. Eight months after gastrectomy, the occupying lesion in liver was detected by ultrasound and CT, and he accepted transcatheter arterial embolization. Before operation of the brain metastasis, no obvious abnormality was found in liver by ultrasound. Histopathological characteristics of the brain tumor were identical to those of stomach tumor. The growth pattern of both tumors showed solid cell nests. The tumor cells were polygonal, and had abundant eosinophilic cytoplasm and round nuclei with obvious nucleoli. Sinusoid-like blood spaces were located between nodular tumor cells. Immunohistochemistry-stained tumor cells were positive for AFP and negative for Hep-Par-1. According to these histopathological findings, both tumors were diagnosed as HAC and metastatic HAC. The patient remained alive 16 mo after tumorectomy of the cerebral metastasis. The differential diagnosis of brain metastasis from metastatic tumors should use a panel of antibodies to avoid confusing with the brain metastasis of hepatocellular carcinoma (HCC). This paper describes this rare case of metastasis from gastric hepatoid adenocarcinoma to cerebral parenchyma, and provides a review of the literature concerning its histopathological and immunohistochemical characteristics.

INTRODUCTION

Gastric carcinoma is one of the most frequent tumors in the world. Its histological types include well- and poorly-differentiated adenocarcinoma, hepatoid adenocarcinoma (HAC), adenosquamous carcinoma, *etc*[1]. Metastasis of gastric carcinoma occurs mainly in organs and lymph nodes in venter imus, rarely in distant sites. Since Bourreille *et al*[2,3] reported the first case of gastric carcinoma with an increased level of serum alpha fetoprotein (AFP) in 1970, other cases have been reported[4,5]. In 1985, the term of hepatoid adenocarcinoma was used as malignant epithelial tumor derived from stomach by Ishikura *et al*[6]. The incidence rate of HAC is about 1.3%-1.5%. HAC produces a large amount of AFP, and is characterized by histopathological features, such as hepatoid differentiation, metastasis and poor prognosis. The number of brain metastases from gastric carcinoma, especially from gastric hepatoid adenocarcinoma is small. Only one case of cerebellar metastasis from gastric cancer with a higher level of AFP has been reported by Goda *et al*[7]. We present the first case of gastric hepatoid adenocarcinoma metastasis to cerebral parenchyma.

CASE REPORT

History and examination

A 50-year-old patient was admitted to our hospital with complaint of a one-month history of a paroxysm of headache in the left temple and pars parietalis accompanied with binocular caligation caligo, insensible feeling of limbs and transient anepia. The patient had no history of nausea and vomiting, spasm, palsy, aconuresis and copracrasia. Physical examination revealed decreased visual acuity and papilledema.

Radiological studies

Magnetic resonance (MR) imaging revealed a spherical occupying lesion of about 6.0 cm × 4.8 cm × 4.0 cm in

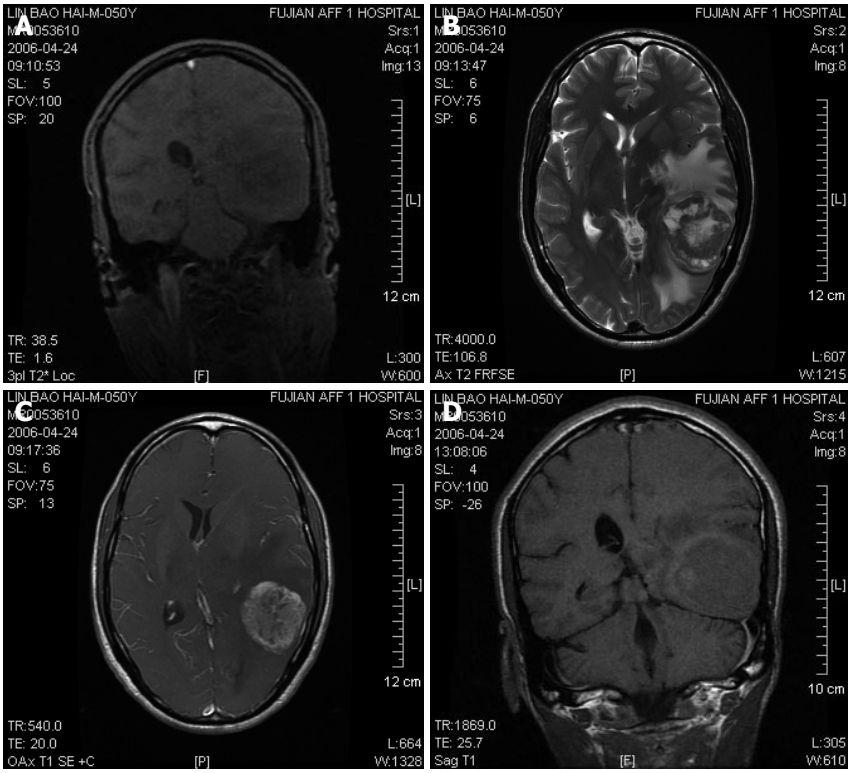

Figure 1 MR imaging revealing a spherical occupying lesion in the left posterior-temple lobe with a high intensity on T_2-weighted images and irregular contrast enhancement with a clear boundary and uneven signal in size of about 6.0 cm × 4.8 cm × 4.0 cm after administration of gadolinium-diethylene triamino pentaacetic acid (Gd-DTPA). **A**: Coronal gradient-recalled echo; **B**: Cross-sectional T2WI; **C**: Cross-sectional contrast enhancement T1WI; **D**: Coronal T1WI-delayed scan 4 h after contrast media injected *via* veins.

the left posterior-temple lobe with a high intensity on T_2-weighted images and irregular contrast enhancement with a clearly boundary and uneven signal after administration of gadolinium-diethylene triamino pentaacetic acid (Gd-DTPA). The lesion displayed an occupying effect, an out-inferior border close to the left transverse sinus, a perilesional irregular edema zone, compressed and deformed left posterior ventricle, and median line turned to dextroposition (Figure 1). The lesion was clinically diagnosed as a metastatic tumor.

Operation

On the 7th d after admission, the patient underwent tumorectomy. A tumor was found in subcortex of the left temporal lobe of about 0.3 cm and resected. A sample of about 4.0 cm × 5.0 cm × 5.0 cm was taken for pathological examination.

Pathological findings

Pathological analysis of the tumor sample revealed the growth pattern of solid cell nests. The polygonal tumor cells had abundant eosinophilic cytoplasm and round nuclei with obvious nucleoli. A pseudoglandular configuration containing proteic fluid was found in some parts of the tumor. Sinusoid-like blood spaces were located between nodular tumor cells (Figure 2). Metastasis of hepatocellular carcinoma was suspected.

Immunohistochemistry

Immunohistochemistry-stained hepatoid cells were positive for alpha-fetoprotein (AFP) and negative for Hep-Par-1 (Table 1, Figure 3), which did not match the immunohistochemical features of hepatocellular carcinoma metastasis.

Clinical history

Three years ago the patient was admitted to hospital due to recurrent pain in the epigastrium and accepted total gastrectomy because he was diagnosed having adenocarcinoma in cardia and corpora of the stomach with lymph node metastasis (Figure 4). No abnormal acoustic image in liver, pancreas, spleen and other organs was found on ultrasonograph. After surgery the patient received 6 mo of chemotherapy [calcium folinate (CF), 5-fluorouracil (5-FU) and cis-diamminedichloroplatinum (DDDP)]. The histopathological characteristics of brain tumor were identical to those of the sample sections. Immunohistochemistry-stained specimen of gastric carcinoma was positive for AFP and negative for Hep-Par-1 (Figure 5). Eight months after gastrectomy, an occupying lesion was detected in liver by ultrasound. CT scan also revealed a nodular or lump-like, high-density contrast mass in liver lobes during arterial phase, but the size of liver did not change, liver boundary was smooth and hepatic lobes were normal. The density of a larger mass of about 6.7 cm × 5.5 cm was uneven and the interior density was low at portal venous phase. The architecture of porta hepatis was clear (Figure 6). The diagnosis was liver metastasis from gastric carcinoma. Transcatheter arterial embolization for hepatic metastatic tumors with CF, 5-FU and DDDP was performed. The liver was rechecked by ultrasound every 6 mo after embolization. Before operation of the brain metastasis, ultrasound displayed no obvious abnormalities in liver and kidney and color Doppler flow imaging revealed no obvious bloodstream signals (Figure 7). Based on the results of histopathology and immunohistochemistry, the lesions were finally diagnosed as hepatoid adenocarcinoma (HAC) of cardia and corpora of the stomach and

metastatic hepatoid adenocarcinoma in the left posterior temple lobe, respectively. The patient was alive in the 16-mo follow-up period after operation of brain tumor.

DISCUSSION

Most patients with advanced gastric carcinoma die of metastasis and progressive cachexia. Metastasis of gastric carcinoma mainly occurs in peritoneal organs such as liver and lymph nodes; distant metastasis is rare. The incidence of intracranial metastasis from gastric carcinoma carcinoma ranges 1.3%-9.8%[8-10]. However, autopsy showed that the incidence of intracranial metastasis from gastric carcinoma is over 10.87%[11].

HAC is a special type of extrahepatic adenocarcinoma and its morphology is strikingly similar to that of hepatocellular carcinoma (HCC). Tumor cells consist of polygonal tumor cells with large central nuclei, prominent nucleoli, and abundant eosinophilic cytoplasm, showing solid growth pattern and less trabecular and glandular as well as frequent lymphatic and vascular invasiveness, regional prominent mitoses, but no bile secretion and periodic acid-Schiff-positive diastase-resistant hyaline globules. HAC has been found in different organs, such as the stomach, lung, pancreas, esophagus, papilla of Vater, colon, bladder, kidney, ovary, uterus, cervix and peritoneal organs[4,5,12-21]. Most patients are males, ranging in age from 40 to 77 years. The antrum and pylorus are the frequent locations of gastric HAC. Most patients with HAC show an elevated AFP serum level. The clinical course of HAC patients is aggressive and poor in survival. The biological behavior of HAC is associated mainly with extensive hematogenous metastasis to the liver and early involvement of lymph nodes. Up to date, only one case of cerebellum metastasis from gastric carcinoma with an elevated AFP level has been reported[7]. However, no report on supratentorial cerebral parenchymal metastasis of gastric HAC is available.

Kodama *et al*[22] have reported two histological types of AFP-producing gastric carcinoma: medullary type and well-differentiated papillary or tubular type[22]. HAC of the medullary type is positive for AFP and well-differentiated adenocarcinomatous type is negative for AFP[6]. HAC of the medullary type has a striking morphologic similarity to HCC, and both of them produce high levels of AFP. Our patient had the morphology of the medullary type and was positive for AFP. Ishikura *et al*[6] suggested that this may be

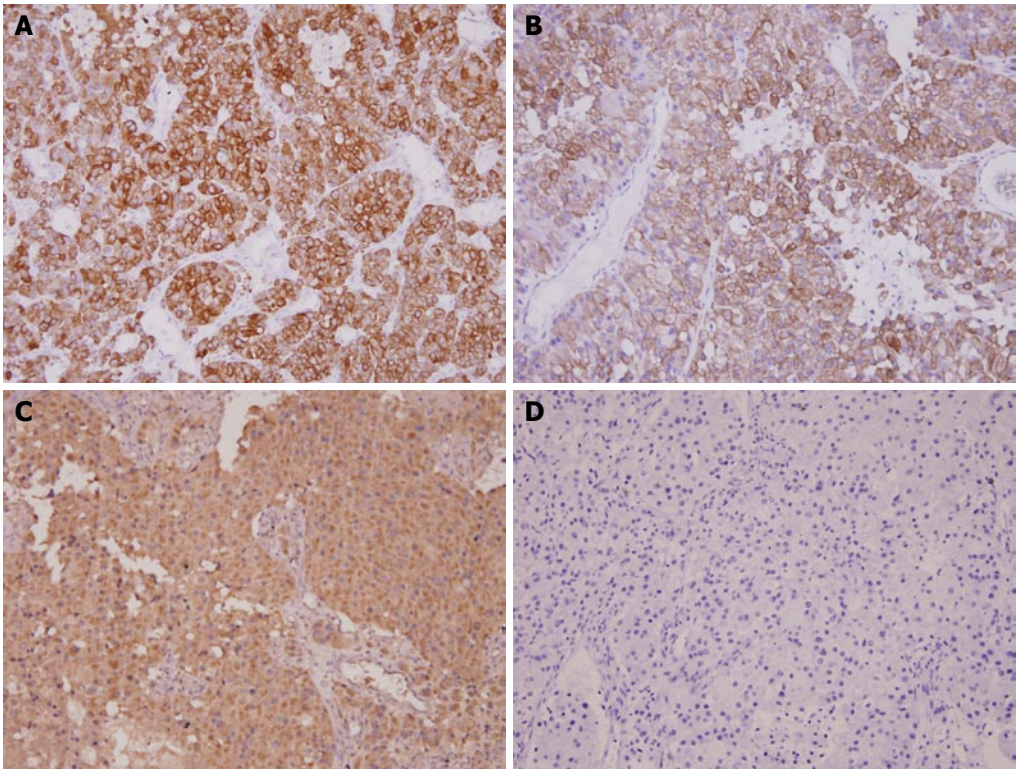

Figure 3 Immunoreactive characteristics of brain metastatic tumor (EnVision). **A**: Positively- stained cytokeratin AE1/AE3 (× 200); **B**: Positively-stained cytokeratin 8 (× 200); **C**: Positively-stained AFP (× 200); **D**: Negatively-stained Hep-Par-1 (× 200).

due to the fact that the stomach and liver are both derived from primitive foregut of the embryo, and disturbances of differentiation may ultimately result in the development of foci of hepatocellular differentiation.

HAC and HCC share numerous clinicopathological features, such as elevated AFP serum level, hepatoid morphology and immunoreactivity with AFP, polyclonal carcinoembryonic antigen (CEA), and alpha-1 antitrypsin[23]. The histopathology of HAC and HCC is extremely similar, thus making the differential diagnosis difficulty, especially when the primary tumor is unknown. Immunohistochemistry of extrahepatic HAC and HCC is positive for AFP, CEA and cytokeratins 8 and 19, but not for cytokeratin 7[23,24]. The immunoreactivity of CK7 was positive in brain metastasis of our patient but negative in primary gastric carcinoma. The inconsistent phenomenon

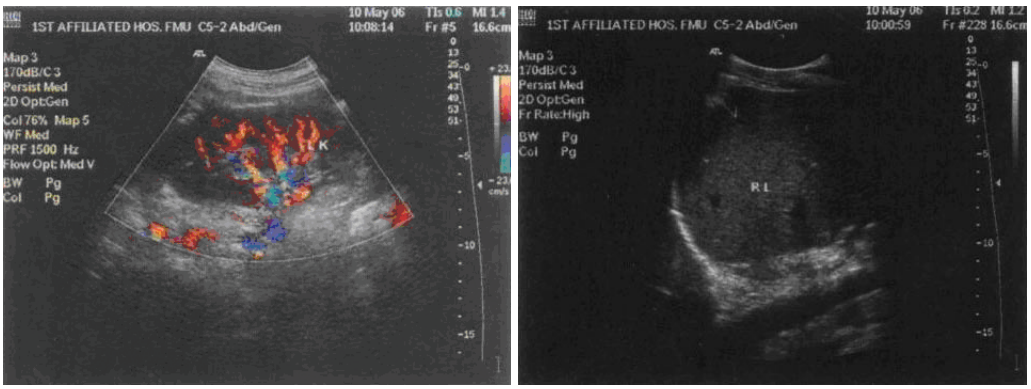

Figure 7 Features of ultrasound examination before operation of the brain metastasis.

of CK7 immunostaining is unable to explain. Therefore, it is uncertain that the brain metastasis is derived from liver metastasis from gastric HAC or from the primary gastric carcinoma.

Hep-Par-1 is a recently developed new monoclonal antibody that reacts with a hepatocyte-specific epitope. It was reported that the sensitivity and specificity of Hep-Par-1 in HCC are 82% and 90%, respectively[25], suggesting that this antibody is the most sensitive and specific immunohistochemical marker for hepatocyte differentiation[26-28]. In our patient, immunostaining showed that HCC was positive for Hep-Par-1 and extrahepatic

HAC was negative for Hep-Par-1.

Brain is one of the frequent hematogenous metastatic sites. It was reported that metastasis accounts for 13% of all brain tumors[9]. Usually, intracranial metastases and primary gliomas can be differentiated based on conventional MRI findings and clinical history. However, in some circumstances, especially when the lesion is solitary and its clinical features are nonspecific, conventional MRI alone is difficult to differentiate them. Although the management of metastases and primary gliomas is different, their morbidity and mortality are similar.

It was reported that the frequent symptoms of brain metastasis in recipients are headache, psychiatric symptom, hemicrania, vision disorder, cortical epilepsy[9]. The present patient had a similar clinical situation and intracranial metastases confirmed by MRI. Of the intracranial metastases, malignant melanomas account for 90%, chorioepithelioma malignum 60%, lung cancers 20%, breast cancers 16%, renal carcinomas 13% and thyroid carcinomas 9%. Brain metastasis of gastric cancer has been found only in about 0.5%-5% of cases reported, in which poorly-differentiated adenocarcinomas account for 27.3%-50%[9,29,30]. Most intracranial metastases from gastric cancer are lymphogenous and occur at meninges. Metastasis to the cerebral parenchyma *via* the arterial blood flow is rare. In general, patients with brain metastasis from gastric carcinoma have a higher stage of cancer and lymphovascular invasion or lymph node metastasis[9]. It is difficult to predict brain metastasis. If the patients have lymph node metastasis, lymphovascular invasion, or metastasis of other organs, they should be monitored carefully in order to detect brain metastases.

Treatment of brain metastasis depends mainly on whether it is solitary or multiple. Solitary metastasis is treated through resection, and multiple metastases are treated mainly with radiotherapy and chemotherapy. It was reported that multiple brain metastases account for 60%-70%, the prognosis of patients with brain metastasis is generally poor, and the mean postoperative survival time is about 6 mo[9]. The present patient remained alive 16 mo after the operation of brain metastasis. A longer survival time may be associated with the complete resection of brain metastasis and sensitivity to chemotherapy and radiotherapy.

In conclusion, metastasis of gastric hepatoid adenocarcinoma to the brain is rare. The differential diagnosis of metastatic tumors needs to use a panel of antibodies to avoid confusing with the brain metastasis of HCC. Long-term follow-up and close observation are required to find the symptoms of nervous system after gastrectomy, and early CT or MRI should be performed for the diagnosis of brain metastases. Solitary brain metastases are usually treated with surgery, radiotherapy and chemotherapy.

ACKNOWLEDGMENTS

Acknowledgments to Reviewers of *World Journal of Gastroenterology*

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.
EDITORIAL and LETTERS TO THE EDITOR are free of charge.

Abstract

Natural killer T lymphocytes (NKT) have been implicated in the regulation of autoimmune processes in both mice and humans. In response to stimuli, this subset of cells rapidly produces large amounts of cytokines thereby provoking immune responses, including protection against autoimmune diseases. NKT cells are present in all lymphoid compartments, but are most abundant in the liver and bone marrow. They are activated by interaction of their T-cell receptor with glycolipids presented by CD1d, a nonpolymorphic, major histocompatibility complex class I-like molecule expressed by antigen presenting cells. Several possible ligands for NKT cells have recently been suggested. β-glucosylceramide, a naturally occurring glycolipid, is a metabolic intermediate in the anabolic and catabolic pathways of complex glycosphingolipids. Like other β-glycolipids, β-glucosylceramide has an immunomodulatory effect in several immune mediated disorders, including immune mediated colitis. Due to the broad impact that NKT cells have on the immune system, there is intense interest in understanding how NKT cells are stimulated and the extent to which NKT cell responses can be controlled. These novel ligands are currently being evaluated in animal models of colitis. Here, we discuss strategies to alter NKT lymphocyte function in various settings and the potential clinical applications of natural glycolipids.

Key words: Natural killer T lymphocyte; Immunomodulatory; Colitis; Inflammatory bowel disease; Ligand

NKT REGULATORY LYMPHOCYTES

The term 'NKT cells' was first described in 1995[1] and defines a broad subset of mouse T-cells that share some characteristics with natural killer (NK cells), expression of the NK1.1 marker in particular. This is a heterogeneous subset of lymphocytes some of which do not express the NK1.1 marker[2]. NKT cells develop from thymocyte progenitor cells similarly to conventional T-cells. However, unlike conventional T-cells, NKT cells express a T-cell receptor (TCR) that recognizes glycolipids rather than protein antigens[3]. The largest subset of NKT cells expresses a highly restricted TCR comprised of an invariant TCR α chain with a single rearrangement (in mice Vα14-Jα18, and in humans Vα24-Jα18)[4] coupled with TCR β chains with limited heterogeneity due to marked skewing of Vβ gene usage (mostly Vβ8.2 in mice and Vβ11 in humans)[5]. This population, also referred to as invariant NKT cells (iNKT), is highly conserved in most mammals studied to date. iNKT cells are restricted by the major histocompatibility complex (MHC) class I-like molecule CD1d, which is expressed by conventional antigen presenting cells (APCs) including macrophages, dendritic cells, and marginal zone B cells[2].

CD1d-mediated glycolipid presentation to NKT cells is an important aspect of immune regulation. However, as an illustration of NKT complexity, there is a type of NKT-cell that expresses the NK1.1 marker, but is CD1d independent. There are two broad classes of cells that satisfy the criteria of being CD1d dependent NKT cells. For the purposes of this review, we classify these as type I NKT cells, being the Vα14-Jα18 (mouse) or Vα24-Jα18 (human) population, and type II NKT cells, which includes all other CD1d-dependent T cells[6].

The inherent, low-level auto-reactivity of certain specialized immune cell types that have both innate and adaptive characteristics, such as CD1d restricted NKT cells, γδ T cells, and B1 cells, suggests that these cell types may also have the potential to stimulate autoimmunity[2]. Activation of iNKT cells occurs early in a number of microbial infection models in mice, and such activation can lead to reinforcement of the innate immunity and promote subsequent adaptive immunity. Thus, immune responses to certain bacterial, viral, and parasitic infections and tumors can be enhanced whereas autoimmune disease and allograft rejection can be suppressed[5].

THE ROLE OF NKT CELLS IN IMMUNE RESPONSES

NKT cell Th1 and Th2 responses can offset one another;

therefore, polarizing cytokine release toward either one may serve as an important therapeutic tool[7]. These lymphocytes constitutively express cytokine mRNA, and within hours of activation produce large amounts of cytokines such as IFN-γ, TNF, IL-4, and IL-10[5]. NKT cell-mediated regulation of immune responses has been demonstrated to influence a large number of disease states[5]. These cells have received considerable attention in recent years as innate lymphocytes that can modulate T-cell and APC functions in autoimmunity. A potential link between NKT cells and autoimmunity was suggested by the finding that various mouse strains, including non-obese diabetic (NOD) mice that are genetically susceptible to autoimmunity[8,9], have a reduced number and defective function of iNKT cells as compared with non-autoimmune mouse strains[10]. Diminished numbers of NKT cells have been correlated with an increased incidence of autoimmune diseases including systemic lupus erythematosus, scleroderma, type I diabetes, multiple sclerosis, and rheumatoid arthritis[11-16].

The adoptive transfer of NKT cells has ameliorated disease in several immune-mediated animal models, including experimental autoimmune encephalomyelitis[17], immune mediated colitis[18], and graft versus host disease (GVHD)[19]. In addition, NKT lymphocytes play an important role in diverse neoplastic and infectious processes, and as such may serve as a target for potential new immune-therapeutic strategies[20,21]. NKT cells are now known to be a major source of IFN-γ, which is required for early activation of macrophage bactericidal activity[22]. Several studies have demonstrated a role for NKT lymphocytes in anti-tumor immunity[23]. Mouse and human NKT cells were shown to exert cytotoxic activity towards several tumor cell lines[24]. NKT lymphocytes were found to promote tumor rejection in experimental models of tumor immunotherapy by administration of IL-12 or α-GalCer[25]. In a murine hepatocellular carcinoma (HCC) model, NKT cells were shown to have a role in oral immune regulation with HCC lysate and HBV envelope proteins, and in adoptive transfer of dendritic cells pulsed *ex vivo* with the same antigens[20].

LIGANDS FOR NKT REGULATORY CELLS

Through their semi-invariant TCR, NKT cells recognize glycolipids presented in the context of the CD1d molecule[26]. CD1 proteins are a family of molecules that have structural homology to MHC class I molecules, but are unusual in their ability to present glycolipid antigens to T-cells[27]. Because NKT cells can produce cytokines that result in conflicting responses, the possibility exists that the ligand structure can polarize NKT cell responses toward either a Th1 or a Th2 response[28].

Glycosphingolipids, or glycolipids, are a family of both naturally occurring and synthetic molecules composed of a hydrophobic ceramide backbone, N-acylsphingosine, and a hydrophilic head group made of carbohydrates, mono- or oligosaccharides[29]. Enzymatic defects and subsequent accumulation of certain glycolipids can lead to "storage" diseases such as metachromatic leukodystrophy, Gaucher's or Fabry's disease[30]. Patients with Gaucher's disease have altered humoral and cellular immune profiles[31] and increased peripheral blood NKT lymphocytes[32]. In the context of stimulatory glycolipids, an understanding of how glycolipid structure affects cytokine release profiles is essential.

α-galactosylceramide (α-GalCer) was originally discovered during a screen for reagents derived from the marine sponge *Agelas mauritianus* that prevented tumor metastasis in mice[33]. KRN7000, the synthetic α-GalCer analogue, is a high-affinity ligand for the CD1d molecule[34]. *In vivo* administration of α-GalCer to mice or humans results in rapid and robust cytokine secretion by iNKT cells, followed by the activation of a variety of cell types of the innate and adaptive immune systems[35].

OCH is a truncated analogue of α-GalCer in which the sphingosine chain has been shortened from 18 to 9 carbons. Following its administration to mice, the early production of IL-4 by NKT cells remained intact while the bulk of IFN-γ, mostly derived from NK cells, was lost, leading to a Th-2 biased response[36]. The ratio of IL-4 to IFN-γ released by NKT cells is influenced by the length of the lipid chain; shorter chain lengths increase this ratio[3]. Administration of α-C-GalCer leads to a strong Th-1 biased response with sustained IFN-γ levels for several days compared to the 24-h response induced by α-GalCer[37]. Treatment with α-C-GalCer was more potent than α-GalCer in mouse models of malaria and malignant tumors, while treatment with OCH was more efficacious than α-GalCer in the Th-1 mediated autoimmune disease models of encephalomyelitis and colitis[38].

Activation of NKT cells *via* α-GalCer has been shown to affect numerous models of malignancy, infection, and autoimmune disease[3]. In models with strong NKT cell involvement, such as in type I diabetes-prone NOD mice, activation of NKT cells with α-GalCer delayed disease induction and prevented its recurrence[39,40]. On the other hand, treatment with α-GalCer can cause disease exacerbation, an effect noted mainly in models where these molecules play a "pathogenic" role such as in the F1 mouse model of lupus nephritis (NZB × NZW)[41], or the apolipoprotein E knockout mouse model of atherosclerosis[42,43]. Despite their promising effects in diverse disease situations, the clinical use of α-glycolipids has been limited by their side effects, mainly hepatotoxicity[44,45].

NATURAL LIGANDS FOR NKT CELLS

The discovery of the marine sponge-derived glycolipids as ligands for NKT cells led to studies looking for possible natural ligands. These natural antigens can be separated into two groups: (1) antigens that are produced by the host (endogenous antigens), and (2) antigens from foreign pathogens (exogenous antigens). The strongest evidence for the presence of an endogenous antigen is that positive selection of NKT cells in the thymus requires presentation of an antigen recognized by the TCR[3]. The best evidence for the presence of exogenous antigens is that antigen presentation proteins related to CD1d have been characterized as presenters of microbial glycolipids, and it was speculated that NKT cells might survey for the

presence of infectious agents[46-48].

Given the auto-reactivity of the NKT TCR to CD1d and the limited diversity of TCRs that NKT cells express, it is generally accepted that a single, or set of closely related, autologous glycolipid ligands are responsible for the activation of these cells. These endogenous ligands have yet to be identified. Recently, the lysosomal glycolipid, isoglobotrihexosylceramide (iGb3) has been proposed as a natural ligand for NKT cells[49]. This beta structured-glycolipid, in its natural or synthetic forms, has the ability to activate most human or mouse NKT cells *in vitro*. Impaired generation of lysosomal iGb3 in mice lacking β-hexosaminidase *b* resulted in severe NKT cell deficiency, suggesting a role for iGb3 in murine NKT cell development[49]. Recently, some NKT cell activating antigens of microbial origin have been found[50]. NKT cells have been found to play a role in controlling infection by organisms such as *Mycobacterium tuberculosis* where NKT cells predominate in the anti-mycobacterial granulomatous reaction[51,52], *Plasmodium bergehi*, *Listeria monocytogenes*[53], *Ehrlichia muris*, and *Sphingomonas capsulata*[54].

At least two mechanisms have been proposed for NKT cell activation. The first is "enhanced auto reactivity", where APC recognition of microbial antigen results in IL-12 mediated APC-NKT cell activation. The second is a CD1d presented microbial glycolipid that triggers iNKT cells through TCR recognition[2,3]. There has been some success in identifying specific microbial glycolipid ligands of CD1d that can activate NKT cells, most notably, α-glycuronosylceramides (α-galacturonosyl and α-glucuronosylceramide) derived from the lipopolysaccharide-negative *Sphingomonas* bacteria cell wall[55]. These α-glycuronosylceramides are of specific significance because they share structural homology with α-GalCer. Other examples include the CD1-restricted presentation of *Plasmodium berghei* sporozoite-derived GPI anchor that stimulates NKT-cell-mediated B-cell activation and antibody production[56], and the phosphatidylinositol tetramannoside (PIM4) produced by *Mycobacterium bovis*[57]. These activities suggest a role for NKT cells in the innate response against pathogens that do not activate classical pattern-recognition receptors, such as Toll-like receptor 4.

β-GLYCOLIPIDS AS NKT LIGANDS

Recent studies have shown that different glycolipids preferentially target different organelles. Because different isoforms of CD1 localize to different subcellular compartments, they allow APCs to present a variety of glycolipid antigens that enter the cell by different pathways and are targeted to different locations[58]. β-glycolipids are naturally occurring intermediates in the anabolic and catabolic pathways of complex glycosphingolipids and are found in cell membranes[59]. Past studies have suggested that β-glycolipids do not possess stimulatory properties on NKT cells[59]. However, recent data have suggested that these compounds may have an important NKT cell mediated immune modulatory effect. β-glucosylceramide (GC) is a beta glycolipid that is degraded into ceramide by glucocerebrosidase. CD1d-bound GC does not stimulate NKT cells directly[60]. β-glycolipids may inhibit NKT activation and even block the stimulatory effect of α-GalCer on these cells. Glucosylceramide-synthase deficiency leads to defective ligand presentation by CD1d, with secondary inhibition of NKT cell activation[60]. *In vitro*, administration of GC led to a 42% decrease in NKT cell proliferation in the presence of DCs, but not in their absence[61]. Additional naturally occurring β-glycolipids such as β-lactosylceramide (LC) and β-galactosylceramide (GLC) are being tested for their immunomodulatory effects (unpublished data).

Administration of β-glycolipids in several Th1 mediated disease models such as auto-immune hepatitis, metabolic syndrome, and acute GVHD, alleviated the disease while inducing a Th2 cytokine profile[61-63]. In a murine model of concanavalin A-induced hepatitis, administration of GC led to significant amelioration of liver damage[61]. This beneficial effect was associated with a 20% decrease in intrahepatic NKT lymphocytes, a significant lowering of serum IFN-γ levels, and decreased STAT-1 and STAT-6 expression. The administration of GC to leptin-deficient ob/ob mice, an NKT dependent model, significantly improved the metabolic alterations[62]. Liver fat content was reduced significantly in both MRI and histological examinations. In addition, treated mice achieved near-normalization of glucose tolerance and decreased serum triglyceride levels. These effects have been associated with a marked increase of the peripheral/intrahepatic NKT cell ratio. In a semi-allogeneic model of acute GVHD, GC-treated mice manifested a significant decrease in skin, bowel, and liver GVHD manifestations[64]. The beneficial effect of GC was associated with decreased IFN-γ and increased serum IL-4 levels, as well as a significant increase in the intrahepatic to peripheral NKT lymphocyte ratio and in intrahepatic $CD8^+$ lymphocyte trapping[64]. In contrast, in Th2 mediated models of disease, administration of β-glycolipids also led to NKT mediated disease alleviation associated with an opposite Th1 immune shift. In a murine model of hepatocellular carcinoma, GC led to improved survival rates and a decreased tumor volume[63]. These effects have been associated with an 11-fold increase in intrahepatic NKT lymphocyte number. Taken together, these results suggest that certain β-glycolipids may serve as a "fine tuners" for NKT lymphocyte-mediated immune responses and may have a beneficial effect in seemingly opposing disease models.

NKT CELLS IN INFLAMMATORY BOWEL DISEASE

Inflammatory bowel diseases (IBD) are chronic inflammatory disorders of the gastrointestinal tract that are associated with an imbalance between Th1 pro-inflammatory and Th2 anti-inflammatory subtypes of immune responses. The abundance of CD1d-positive cells in the human intestine suggests a role for these cells in chronic inflammatory disorders of the bowel. NKT cells have been proposed to make both protective and pathogenic contributions to IBD[65]. Ulcerative colitis (UC) is a subtype of IBD that is limited to the superficial

layers of the colon and is dominated by the production of Th2 cytokines. Studies have shown that classical (type I) CD1d-restricted NKT cells contribute to a murine model for UC[66,67]. NKT cells exerted protective effects against DSS colitis, a model for intestinal inflammation that primarily targets mucosal macrophages. In this model, administration of α-GalCer and adoptive transfer of NKT cells resulted in reduction of inflammation.

The role of NKT cells in chronic bowel inflammation is complex. They can play either a protective or a pathogenic role in intestinal inflammation, depending on the type of inflammatory process and the antigen presented in the gut. NKT cells support a pro-inflammatory immune response in TNBS-colitis, a Th1 model. Thus, depletion of NKT cells results in alleviation of the disease[68], effects which were mediated by altered intrahepatic $CD8^+$ trapping and that increased INF-γ producing lymphocytes[69]. Feeding colitis-extracted proteins (CEP) to mice with TNBS-induced colitis induces oral tolerance and alleviates TNBS-induced colitis[70]; NKT depletion prevents oral tolerance induction18. Adoptive transfer of *ex vivo* CEP-pulsed NKT cells also alleviated colitis[69]. NKT cells exerted protective effects against DSS colitis, a model for intestinal inflammation (Th2 model) that primarily targets mucosal macrophages. In this model, administration of α-GalCer and adoptive transfer of NKT cells reduced inflammation. In contrast, oxazlone-colitis could not be induced in animals lacking NKT[71]. Several studies proposed a role for NKT cell activation in IBD patients. Expression of CD1d is higher in the epithelia of the affected terminal ilea of CD patients and in the affected cecum of UC patients, which may lead to recruitment of proinflammatory CD1d-reactive cells from the periphery, resulting in mucosal destruction[72]. However, a more recent report suggested that, in contrast to normal colon surface epithelium, epithelial cells derived from UC or CD patients do not express CD1d[73]. The diminished expression of CD1d was suggested as a possible mechanism for impaired regulatory NKT cell function in IBD. Taken together, these data suggest a complex role for NKT cells in chronic inflammatory disorders of the bowel, which may involve various factors in the immune microenvironment.

EFFECT OF NKT LIGANDS IN ANIMAL MODELS OF IMMUNE MEDIATED COLITIS

Experimental colitis induced by intracolonic installation of TNBS, is associated with a Th-1 immune response as evidenced by increased IFN-γ secretion, decreased IL-10 and IL-4 secretion, and reduction in the intrahepatic $CD8^+$ trapping. These effects were hypothesized to be mediated by regulatory NKT cells[69]. Several glycolipid derivatives have been shown to alleviate hapten mediated colitis. OCH, and α-Gal-Cer analogue with truncated sphingosine chain, attenuates colonic inflammation as defined by body weights and histological injury[38]. The protective effects could not be observed in Vα14 NKT cell-deficient mice, further evidence of an NKT role in the pathogenesis of colitis. The immunomodulatory effect of several β-glycolipids, including GC (glucosylceramide), LC (lactosylceramide), GLC (galactosylceramide), and IGL (GC + LC), was shown to be associated with increased survival and significant alleviation of colitis with improvement in the macroscopic and microscopic scores[63]. Administration of GC alleviated immune mediated experimental colitis, improving both the macroscopic and microscopic scores. The beneficial effects of GC were associated with an increased peripheral/intrahepatic CD4/CD8 lymphocyte ratio and a Th2 immune shift.

In summary, NKT cells may make both protective and pathogenic contributions to IBD[65]. Studies show that these cells are involved in the maintenance of mucosal homeostasis. On the other hand, this subset of cells plays a pathogenic role in human ulcerative colitis. Similar contrasting data have been generated in murine models of IBD[65]. Whether the apparent differences in NKT response patterns depends on variations in NKT ligands and/or on the presence of specific subsets of mucosal NKT cells remains to be elucidated. Further studies that determine the subset of NKT cells and the specific ligands involved in these disorders may facilitate the development of novel therapies for IBD.

Abstract

Multidisciplinary approach for rectal cancer treatment is currently well defined. Nevertheless, new and promising advances are enriching the portrait. Since the US NIH Consensus in the early 90's some new characters have been added. A bird's-eye view along the last decade shows the main milestones in the development of rectal cancer treatment protocols. New drugs, in combination with radiotherapy are being tested to increase response and tumor control outcomes. However, therapeutic intensity is often associated with toxicity. Thus, innovative strategies are needed to create a better-balanced therapeutic ratio. Molecular targeted therapies and improved technology for delivering radiotherapy respond to the need for accuracy and precision in rectal cancer treatment.

Key words: Rectal cancer; Chemoradiotherapy; Intensity-modulated radiation therapy; Molecular targeted therapy

WHERE WE ARE: INTRODUCING THE CHARACTERS

Since the early 90's, radical surgery and fluoropirimidine-based chemoradiotherapy (CHRT) are the gold standards of treatment for locally advanced rectal cancer. Studies conducted by the Gastrointestinal Tumor Study Group[1,2] and the North Central Cancer Treatment Group[3] concluded that the combination of postoperative chemotherapy with radiotherapy improved local tumor control and survival in stage Ⅱ and Ⅲ rectal cancer relative to surgery alone.

Although currently the big picture mostly remains, some of the characters of the puzzle have changed. The main milestones in this development began with the improvement of the surgical technique, total mesorectal excision (TME). TME became the choice surgical procedure, with a relevant increase in local control. Actually, at some point it was thought that TME could make radiotherapy (RT) unnecessary. Nevertheless, a randomized study soon followed showing the maintained benefit of RT despite an excellent surgery, at least in terms of local control[4], outcomes that even are improving with longer follow-up.

The second landmark was to move the CHRT segment before the surgery. Initially, preoperative radiotherapy was found to improve overall survival as compared with surgery alone[5,6]. In the last decade, the dominant tendency in the therapeutic development of rectal cancer, both in Europe and North America, has been the use of preoperative radiotherapy with conventional protracted fractionation (45-50 Gy in daily fractions of 1.8-2 Gy during 5-6 wk) with concurrent chemotherapy followed by surgery at 4-8 wk. Extensive experience with preoperative CHRT showed feasibility and promising results in terms of down staging, sphincter preservation and disease control and survival parameters as interesting elements of analysis, with an acceptable toxicity profile. The most frequently used chemotherapy agent in this clinical context is 5-fluorouracil (5-FU, i.v.)[7-13]. More recently, the only phase Ⅲ trial concluded comparing pre- *vs* post-operative CHRT, demonstrated better tolerance, sphincter-saving surgical procedures and local control with preoperative CHRT[14].

Preoperative radiotherapy alone (no chemotherapy) and delayed surgery reported down staging rates of 18%[15,16]. However, the prolonged administration of CH-RT achieves down staging figures of around 65%[7-11,17]. Additionally, induction of tumor down staging improves the probability of a complete resection and sphincter-preserving surgery[11,13,18-20].

Complete pathologic response (pCR) rates range from 8% to 27% using i.v. 5-FU with preoperative irradiation[7,10,11,14,21]. In studies of postoperative 5-FU-based CHRT, severe acute toxicity ranges from 24%-40%[1,14,22,23]. However, in Phase Ⅱ studies of preoperative CH-RT, Grade 3-4 acute toxicity occurs in 15%-28% of patients[7,11,13,14,20].

Regarding tumor control and survival, published series

Table 1 Novel chemoradiation combinations

	Chemotherapy		RT (Gy)	GI grade 3-4 toxicity (%)	DS (%)	pCR (%)
	Capecitabine (mg/m^2 bid)

Rodel *et al*	825 d 1-14 and 22 - 35	50 d 1, 8, 22	50.4	6	55	19
Machiels *et al*	825 bid continuous	50 weekly	45	30	-	14

RT: Radiotherapy; DS: Downstaging; bid:Twice daily; CI: Continuous infusion; HART: Hyperfractionated accelerated radiotherapy; MTD: Maximun-tolerated-dose; GI: Gastrointestinal.

vary in follow-up. Preoperative CHRT in rectal cancer assumes ranges for 5-year local recurrence from 2% to 15%, disease-free survival from 70% to 86%, and overall survival from 60% to 85%[7,9,10,14,18,21,24-26].

In summary, incorporation of TME surgical procedure and 5-FU-based preoperative CHRT have been translated to an improvement in local control, with the additional advantage of more tolerable treatments in terms of acute toxicity and saving-sphincter surgical procedures.

MOVING FORWARD: IMPROVING THE PORTRAIT

The picture is drawn. What is next, more characters or better colors?

Therapeutic intensity is often linked to better response and outcomes. But in oncology more is not always better. Increases in doses or number of therapeutic agents combined together lead to higher rates of toxicity. This situation is especially true in rectal cancer. Moreover, the risk of over-treatment in some patients with rectal cancer is present. One treatment approach for all rectal adjuvant patients may not be warranted. We already know that not every stage Ⅱ-Ⅲ rectal cancer is the same[27]. Prognostic factors have been studyed, both at clinical and at molecular and genetic level. In the near future these signatures should be taken into account. An adequate therapeutic index should be found, with a well-balanced ratio of benefit/toxicity.

Where can we find additional benefit in rectal cancer treatment? On the one hand, despite the improvement in local control with multimodality approaches, the rate of distant metastasis is still high, around 19%-36%[10,14]. On the other hand, growing data demonstrates a relationship between response to preoperative CHRT and survival. A higher grade of tumor regression in the surgical specimen has been associated with increased disease-free survival and overall survival after preoperative CHRT in rectal cancer[10,24,17,28-31]. Thus, achieving higher rates of complete pathologic response, but also major tumor regression, is one of the current goals in the protocols of preoperative CHRT in rectal cancer. Both effects, reduction of distant metastasis and higher tumor regression grade, require the use of more active and effective chemotherapeutics agents, with adequate toxicity profiles when administered with radiotherapy.

Exploring novel CHRT combinations

Oral fluoropyrimidines: Oral fluoropyrimidines have been developed as a therapeutic alternative to i.v., continuous infusion of 5-FU, and have been shown to deliver similar efficacy and tolerability with the additional advantage of offering the convenience of oral chemotherapy (Table 1).

Few studies have investigated the safety and efficacy of tegafur with or without uracile (5-FU pro-drugs) and radiotherapy[32-35]. Down staging rates (54%-68%), pCR (8%-15%), and grade 3-4 toxicity (12%-43%) match quite well with those with i.v. 5-FU. Although follow-up is not as long as in the 5-FU series, outcomes in terms of local control, distant metastasis rate, disease-free survival and overall survival seem to be similar.

Capecitabine is a fluoropyrimidine carbamate active

in several solid tumors. A recent phase Ⅲ trial (X-ACT trial) has demonstrated the equivalence of capecitabine to bolus 5-FU/leucovorin in the adjuvant treatment of colon cancer[36]. Thymidine phosphorylase (TP) is a key enzyme for the metabolism of capecitabine to 5-FU. Some data suggest that tumor tissue shows higher concentrations of TP than normal tissue[37]. This phenomenon would lead to a preferential activation of capecitabine in the tumor tissue, providing a favorable ratio for toxicity and radiosensitization. Preclinical studies have shown that RT might up-regulate the TP expression in tumor cells, resulting in a selective and synergistic effect between RT and capecitabine[38]. Phase I studies have been conducted to determine the maximun-tolerated-dose (MTD) of capecitabine in combination with radiotherapy. The recommended dose for this combination was 825 mg/m^2 bid without break during radiotherapy period (5-6 wk)[39,40]. Two published phase Ⅱ studies have shown that preoperative CHRT with capecitabine appears to be effective in locally advanced, resectable rectal cancer. Encouraging rates of down staging (up to 84%) and pCR (24%-31%) with a favorable safety profile of the combination might warrant the use of capecitabine and RT with other effective new drugs[40-42].

Irinotecan (CPT-11): Irinotecan is an active chemotherapeutic agent in colorectal cancer. The combination of Irinotecan and 5-FU has been approved as first line chemotherapy for patients with metastatic colorectal cancer[41,43,44]. Phase I studies have demonstrated that CPT-11 can be safely administered concomitantly with radiotherapy (MTD: 10 mg/m^2 daily or 50 mg/m^2 weekly)[45]. Several phase Ⅱ studies have determined the efficacy and feasibility of the irinotecan and 5-FU combined-therapy plus radiotherapy in the neo-adjuvant management of rectal cancer. The rates of tumor down staging (49%-78%) and pCR are high (14%-37%) with an acceptable rate of acute severe toxicity (14%-37%)[46-49].

The combination of CPT-11 and Capecitabine with radiotherapy has been studied in recent phase Ⅰ-Ⅱ trials[50,51]. The MTD dose of Capecitabine was 500 mg/m^2 while combining with CPT-11 50 mg/m^2 weekly and 750 mg/m^2 while combining whit CPT-11 40 mg/m^2 weekly. The rate of tumor down staging and pCR were similar with the two schedules (72%-75% and 14%-21%, respectively) and similar with the combination of 5-FU, CPT-11 and radiotherapy.

Oxaliplatin: Oxaliplatin is a novel anti-neoplastic platinum. When combined with 5-FU, oxaliplatin improves overall survival for patients with metastatic colorectal cancer and the rate of progression-free survival for patients with completely resected stage Ⅱ and Ⅲ colon cancer[52,53]. These data encourage combining oxaliplatin and 5-FU in the preoperative setting of rectal cancer management for an improved response. Moreover, oxaliplatin has radiation sensitization properties[54].

Several phase Ⅱ studies have evaluated weekly administration schedules of oxaliplatin and 5-FU and radiotherapy. They have demonstrated that this regimen is feasible with moderate toxicity. The addition of oxaliplatin to standard 5-FU-RT seems to be associated with a promising down staging (65%-84%) and pCR rates (15%-28%)[55-57].

Oxaliplatin has been combined with Capecitabine in metastatic colorectal disease[58-60]. The combination has been adapted to preoperative CHRT and phase Ⅰ-Ⅱ trials have been published. The studies show that this regimen is active and feasible, with attractive down staging (55%-72%) and pCR rates (14%-28%)[61-63].

RAISING THE BAR: THERAPEUTIC MODULATION

One of the paradigms for loco regional treatment of cancer is anatomic precision. Technical advances in radiation oncology including functional and molecular imaging and intensity-modulated radiation therapy (IMRT) delivery techniques are allowing greater treatment precision and dose escalation. Moreover, cancer is a biologic entity. Treating cancer requires understanding cancer biology which is changing the approach in cancer therapeutics. A number of genetic signatures and molecular pathways involved in cancer have been discovered. Parallel molecular therapeutic development is emerging. Molecular targeted treatments have being combined with conventional anticancer drugs, accordingly with specific tumor biology.

Coming back to loco regional treatment of rectal cancer, IMRT might provide anatomical specificity. Molecular therapies will complement anatomical specificity by targeting biological pathways that are deregulated in individual tumors. Precision is technologically based while accuracy is biologically based[64].

New biological agents: biological modulation

Epidermal growth factor receptor (EGFR) and angiogenesis-related pathways are perhaps the molecular mechanisms best explored in colorectal cancer. Both mechanisms are involved either in colorectal carcinogenesis and tumor growth[65,66], and in radioresistence[67-69]. Thus, novel targeted biologic agents including angiogenesis and EGFR inhibitors hold tremendous promise as RT sensitizers and as systemic therapy in rectal cancer[69-71].

Preliminary reports show feasibility and promising activity combining Bevacizumab with 5-FU and RT. The MTD was determined for Bevacizumad at 5 mg/kg[72]. Additionally, surrogate markers are being investigated suggesting the ability of Bevacizumab to specifically target tumor angiogenesis[72,73].

A recent phase I study combining capecitabine, oxaliplatin and bevacizumab with preoperative RT establishes the MTD to be capecitabine 625 mg/m^2 BID, Oxaliplatin 50 mg/m^2 per week and Bevacizumab 15 mg/kg d 1 and 10 mg/kg d 8 and 22. Down staging was observed in 9/11 patients (82%) and 2/11 (18%) patients achieved pCR and in 2 of 11 only microscopic disease was found in the surgical specimen[74].

C225 (Cetuximab) is a chimeric monoclonal antibody that targets the extracellular domain of epidermal growth

factor receptor (EGFR) with high specificity and affinity[75]. Cetuximab has demonstrated increased responses combined with chemotherapy in metastasic colorectal cancer[76]. The radiosensitization activity of Cetuximab has been broadly explored[77]. Thus, the combination of chemotherapy and RT with C225 is an attractive strategy to be explored.

A pilot study has explored the addition of Cetuximab (250 mg/m^2 per week) to conventional i.v., continuous infusion of 5-FU and RT. Grade 3-4 diarrhea was detected in 10% and acneiform rash in 15%. Pathological complete response was achieved in 12% of patients[78].

Cetuximab has been combined with Capecitabine and RT in rectal cancer. The dose suggested is Capecitabine 825 mg/m^2 bid without interruption during the duration of RT and Cetuximab 250 mg/m^2 weekly. Grade 3 diarrhea was 10%, rectal pain 20%. Ten percent of the evaluated patients achieved pCR[79].

A phase I trail has recently evaluated the combination of Capecitabine, Oxaliplatin and C225 with RT. Doses suggested were for Cetuximab 400 mg/m^2 on d-7, then 6 weekly doses of 250 mg/m^2, for oxaliplatin 50 mg/m^2 d 1, 8, 22 and 29 in combination with capecitabine 1650 mg/m^2 bid d 1-14 and 22-35. Grade 3-4 diarrhea was 15% and grade 3-4 toxicity as skin reaction 7%[80]. The results of the phase Ⅱ study with 31 patients enrolled are coming soon.

Intensity Modulated Radiotherapy in rectal cancer: Rational and preliminary experience

New drugs and biological treatments may enhance global radiotherapy effects improving therapeutic outcomes but acute effects may also be increased. Moreover, a dose-volume relationship has been established between the severity of diarrhea toxicity and the volume of irradiated small bowel at all dose levels in patients treated with preoperative chemoradiation for rectal cancer[81]. The volume of irradiated small bowel thresholds to predict acute gastrointestinal toxicity is unknown although a strong correlation exists between the volume of small bowel receiving 15 Gy (V15) and the degree of acute small bowel toxicity[82].

The development of novel and sophisticated irradiation techniques as intensity modulated radiation therapy (IMRT) represents a spectacular progress in planning and delivering external beam radiation therapy. IMRT generates highly conformal and irregularly shaped dose distribution while reducing dose to adjacent normal tissue structures. IMRT has demonstrated dosimetric superiority over 3D-conformal radiation therapy (3D-CRT) in the majority of tumor sites, including pelvic tumors where the irradiated bowel can be significantly reduced[83].

Researchers at the Royal Marsden Hospital have reported a dosimetric study comparing IMRT *vs* 3D-CRT in five rectal cancer patients. The irradiated bowel volume at 45 Gy and 50 Gy can be reduced with IMRT techniques, which could potentially resulted in marked reductions in acute and chronic bowel toxicity[84]. Tho and colleagues[81] evaluated the role of IMRT in 41 patients with locally advanced rectal cancer treated with preoperative 5FU CHRT. The results showed that IMRT provided dosimetric and radiobiological modeling benefits by reducing the dose to the small bowel, and the likelihood of late normal tissue complications. A dosimetric comparison of 3D-CRT using pelvic anatomical references, 3D-CRT with more restrictive volumes, and IMRT was explored by our institution in nine patients diagnosed with locally advanced rectal cancer. A number of parameters, such as conformity index in the planning target volume, different dose levels at the planning target volume and organs at risk were calculated and compared between the three plans. Target coverage was similar, but the conformity index was better using IMRT. Irradiation doses at small bowel and bladder were significantly reduced with IMRT planning.

Dosimetric parameters in rectal cancer with IMRT are encouraging. Clinical research looking for acute and late toxicity, tumor response, tumor control and survival is warranted. The rationale for the use of chemo-IMRT in locally advanced rectal cancer is based on the potential decrease of gastrointestinal toxicity while maintaining conventional dose to the primary tumor, draining lymph node regions and presacral region. This capacity to change the gastrointestinal toxicity profile may also allow reducing the number of fractions by increasing fraction size, which ultimately may improve the rate of pCR and cost-effectiveness.

Our institution has carried out a prospective study of preoperative chemo-IMRT in rectal cancer. The treatment protocol includes simultaneous combination of capecitabine and oxaliplatin with three escalating dose levels of IMRT, 37.5 Gy 42.5 Gy and 47.5 Gy in 15, 17 and 19 fractions, respectively[85] Chemotherapy consisted on capecitabine 825 mg/m^2 bid during radiation therapy (resting over the weekend) and oxaliplatin 60 mg/m^2 d 1, 8 and 15. Resection was scheduled 6 wk after termination of chemo-IMRT. Simulation was made with the patient positioned prone and immobilized using a combination of prone head cushion and shell with a mixed foam bag. The patient was CT scanned from the L2 vertebral body to the entire perineum with a slice thickness of 5 mm. The slices were transferred through local network to the treatment planning system. The target volumes and organs at risk (OARs) were delineated on axial CT slices in the Helax-TMS treatment planning system (Nucletron Scandinavia, Uppsala, Sweden) as seen in Figure 1. The gross tumor volume (GTV) was defined as the primary tumor and the suspicious metastasic lymph nodes visualized on the CT scan. The clinical target volume (CTV) included the GTV, the presacral region and the common and internal iliac lymph nodes. Adding a margin of 0.5-1 cm around the CTV generated the planning target volume (PTV). The OARs outlined were the bladder and the small bowel. After the GTV, CTV, PTV and OARs were contoured the edited CT slices were transferred from the Helax-TMS treatment planning system to the inverse planning system (KonRad version 2, Siemens Oncology Care Systems, Heidelberg, Germany). Inverse planning for step-and-shoot treatment was performed using 15 MV photons generated on a Mevatron Primus linear accelerator (Siemens Oncology Care Systems, Concord, USA). Seven coplanar equally spaced fields (gantry angles 0°, 51°, 103°,

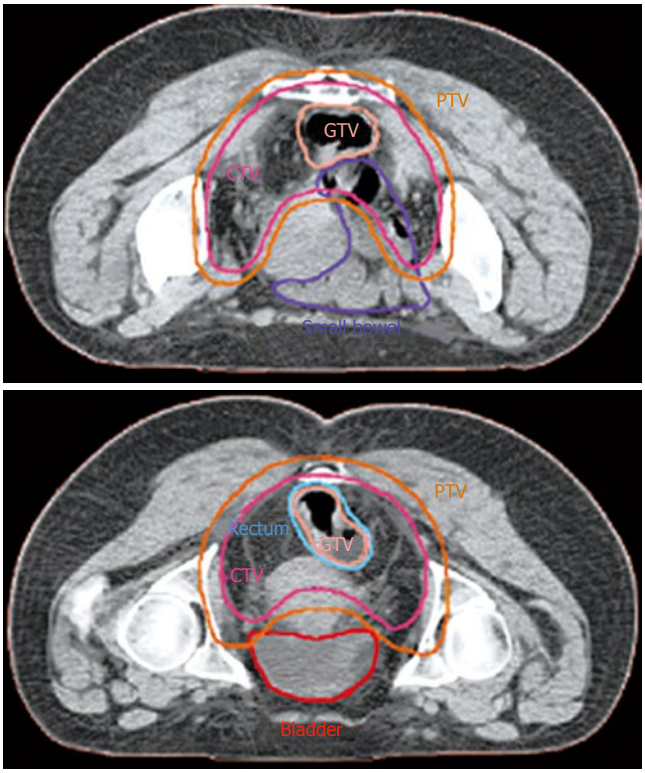

Figure 1 The GTV, PTV and organ at risk (small bowel and bladder) countered on the axial CT slices.

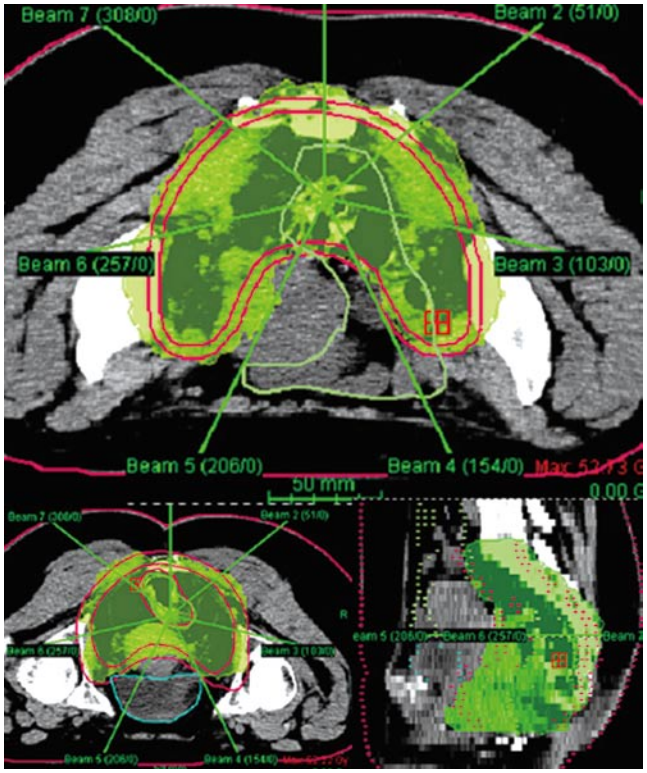

Figure 2 Axial and sagital CT scan images with dose distributions. The 45 Gy isodose surface (green) encompass the GTV and PTV.

154°, 206°, 257° and 308°) were used and the isocenter was placed in the geometric center of the PTV. Figure 2 displays the clinical dosimetry over the patient CT scans.

The first three patients received 37.5 Gy and there were no dose-limiting toxicity (DLT) defined as any grade 3 or 4 gastrointestinal toxicities or grade 4 hematological toxicity. The next three patients received 42.5 Gy without observed DLT and the remaining patients received 47.5 Gy in 19 fractions. Preliminary data show that treatment compliance was 80%, grade 3 adverse events were seen in 21% of the cases, down staging was observed in 52% of patients and pathological response grade 3+ or 4 according to the scale established by Ruo *et al*[86] occurred in 45% of patients.

The use of preoperative IMRT combined with more active systemic chemotherapy provides a major challenge to improve treatment-related toxicity observed with more conventional radiation techniques. Furthermore, the promising favorable pathological response observed with these strategies has the potential to be associated with better loco regional control of disease and may predict better survival.

CONCLUSIONS

Preoperative CHRT followed by TME surgery is the current framework for rectal cancer treatment picture. Further advances with better agents (chemotherapy and molecular targeted therapies) and technology (IMRT) will be translated to improved shapes and colors, enhanced contrast and brightness: response intensity with balanced toxicity.

Abstract

Colorectal cancer is the third most common cancer and is highly fatal. During the last several years, research has been primarily based on the study of expression profiles using microarray technology. But now, investigators are putting into practice proteomic analyses of cancer tissues and cells to identify new diagnostic or therapeutic biomarkers for this cancer. Because the proteome reflects the state of a cell, tissue or organism more accurately, much is expected from proteomics to yield better tumor markers for disease diagnosis and therapy monitoring. This review summarizes the most relevant applications of proteomics the biomarker discovery for colorectal cancer.

Key words: Proteomics; Colorectal cancer; Biomarker

INTRODUCTION

Cancer is not a single disease, but an accumulation of genetic and epigenetic events. It is characterized by uncontrolled growth of cells that can invade and destroy normal tissues. These abnormal cells can also spread through the bloodstream or lymph system to start new tumors in other parts of the body. The disease is a great challenge to clinicians and scientists.

Recent progress in molecular biology has allowed the identification of markers useful for patient management through the identification of genetic alterations and an understanding of chemotherapy molecular targets. Several examples in digestive oncology underline the relevance of molecular biology in clinical research[1].

Colorectal cancer is a common malignancy with an annual incidence of over 945 000 cases worldwide and an annual mortality of 492 000[2]. Surgery is the treatment of choice offering a potential cure. However, 30%-40% of patients have local regionally advanced or metastatic disease on presentation, which cannot be cured by surgery alone[3]. In addition, more than half of patients initially believed to be cured develop recurrence and die of the disease[4].

Advances in genomics and proteomics contribute to our understanding of pathways that control growth, differentiation, and death of cells. In these processes, the identification of candidate disease genes and modifier genes by integrated study of gene expression and metabolite levels is instrumental for future health care. This approach, called systems biology, can recognize early onset of disease and identify new molecular targets for novel drugs in cancer[5].

Proteomics analyzes proteins within a cell or in the corresponding tissue; the proteins of interest are identified, but their function and interactions are not determined. The research provides complete and detailed data about structure, expression, and function of genes, but fails to demonstrate how all the information implicated in the genome is used. In the "post-genomic era," proteomics might be the key to understand systems biology. During the past few years, proteomics has been utilized in many fields of science, medicine, pharmacy, industry and agriculture[6]. In most of the applications proteomics is used to determine expression profiles of proteins in cells and tissues in normal or disease states[7] that are responsible for abnormal cell proliferation. The identification of proteins that are characteristic for cancer development can potentially uncover diagnostic, or prognostic markers, or novel drug targets, and could help understand the mechanisms underlying tumor formation (Figure 1).

Currently, proteomic technology has been used in two areas of cancer research, in early diagnosis and in the treatment of patients, that also includes prediction of response. This technology, when combined with

genomic analysis, may provide more information about the molecular basis of carcinogenesis and the development of more effective anti-cancer therapies. This review focuses on the proteomic studies applied in colorectal cancer.

PROTEOMIC TECHNIQUES IN CANCER RESEARCH

Sample preparation in proteomic

Sample preparation is the most critical step in any proteomics study. This is important because it affects reproducibility as a result of the heterogeneity of proteins derived from cell populations[8]. From the time of sample collection to when proteins are processed for analysis, multiple factors come into play. Mechanical methods, such as surface scrapping and fine needle aspiration, have been used for capturing cancer cells[9]. Calcium depletion and other nonenzymatic methods, such as immunomagnetic separation, have been used to obtain pure populations of cancer cells[10]. An important advancement in sample preparation has been the development of laser capture microdissection (LCM). The LCM system permits obtaining pure populations of cancer cells from frozen, paraffin-embedded, stained, and unstained tissues for molecular analysis. The system is based on visualizing a tissue section via light microscopy and procurement of cells by activating a 7.5-30 micron diameter infrared laser beam which adheres the tissue to a plastic cap. Intact deoxyribonucleic acid, RNA, and protein are then extracted from the adhered tissue which then can be analyzed using conventional methods[11,12]. Protein expression has been compared using 2-D PAGE and differentially expressed proteins identified by mass spectrometry, permitting the discovery of a novel colorectal cancer biomarker[13,14].

Two-dimensional gel electrophoresis and tumor protein detection (2D)

Traditional proteomic studies are based on 2-dimensional polyacrylamide gel electrophoresis (2-D PAGE) to compare protein expression patterns from different tissues or cell lines. The first dimension separates proteins by pH, isoelectric focusing, and the second dimension by molecular mass, sodium dodecyl sulfate PAGE. Although, 2-D PAGE has been available for several decades, improvements in this technology have dramatically improved sensitivity, resolution and reproducibility.

The more important application of this technique in disease proteomics is the discovery of proteins which might serve as prognostic biomarkers for survival of cancer patients. A novel application of 2-D PAGE has been in the discovery of circulating autoantibodies in cancer patients. In some cancer patients, there is evidence that a humoral immune response against tumor antigens might be elicited, and this might be used in serum assays of disease progression or in the development of anticancer vaccines.

An advantage of 2-D PAGE is that it has the capacity to resolve and investigate protein, abundance in a single sample and the possibility to directly detect changes in diseased and healthy tissue.

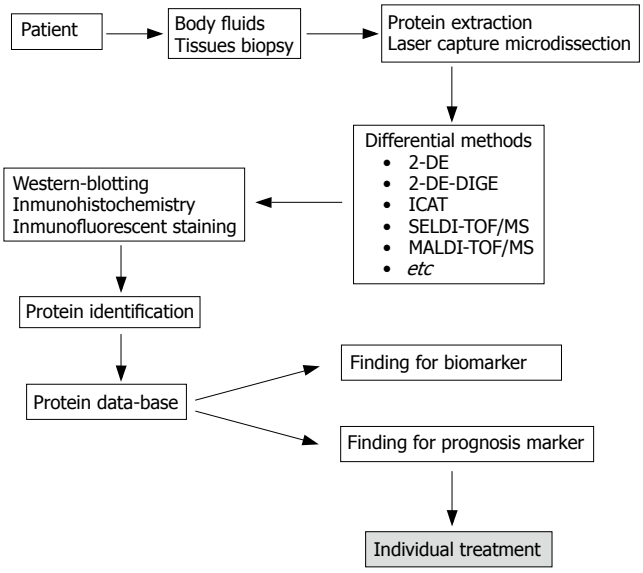

Figure 1 Proteomic differential display methods.

The major disadvantage of 2-D PAGE is that it is laborious and does not resolve highly basic or proteins, smaller than 10 kDa. Because most clinical biomarkers are high large proteins 2-D PAGE is an ideal technology for the study of cancer biomarkers. Therefore, 2-D PAGE, complemented with mass spectrometry, has been used to identify protein changes associated with a variety of human cancers[12].

Two-dimensional difference gel electrophoresis (2D-DIGE)

One of the most recent technical advances in 2-DGE has been multiplexing fluorescent 2D-DIGE[15]. This method directly labels lysine groups in proteins with cyanine (Cy) dyes prior to IEF and can allow for quantitative comparisons between patients and control samples when different fluorescent labels are used for each sample.

The critical aspect of 2D-DIGE technology is the ability to label 2-3 samples with different dyes and then electrophorese all samples on the same 2-D gel. This ability reduces spot pattern variability and the number of gels in an experiment making spot matching much more simple and accurate[16]. The single positive charge of the CyDye replaces the single positive charge present in the lysine at neutral and acidic pH keeping the pI of the protein relatively unchanged. A mass of approximately 500 Da is also added by the CyDye to the labeled protein. The individual protein data from the control and diseased/treatment (Cy5 or Cy3) samples are normalized against the Cy2 dye-labeled sample, Cy5:Cy2 and Cy3:Cy2. These logarithm abundance ratios are then compared between the control and diseased/treatment samples from all the gels using statistical analysis (*t*-test and ANOVA)[17,18]. The principal disadvantage of this technique is that it has a low throughput (three samples per gel) (Figure 2).

Antibody, protein and peptide arrays

Antibody array based measurement technologies have long provided an important tool to detect and manipulate specific biological molecules. While previous uses of

antibodies and related affinity reagents have focused on single targets, recent developments have included multiplexed use of antibodies in arrays, so that many targets can be measured in parallel, sometimes in very small sample volumes. The uses of such arrays are varied and new applications and formats continue to evolve[19].

The experimental features of microarrays have advantages for cancer research. The low sample volumes result in the consumption of small amounts of both precious clinical samples and expensive antibodies. The assays can be run efficiently in parallel, making possible studies on the large populations of samples that are necessary for marker detection and validation. In addition, these assays have good reproducibility, high sensitivity, and quantitative accuracy over large concentration ranges[20]. Antibody and protein arrays are complementary and in some aspects preferable to separation based and mass spectrometry based technologies. Reproducibility and throughput can be higher, and the identities of the considered proteins are known or can be readily characterized. Therefore, specific hypotheses regarding the nature of molecular alterations can be tested, and biologically interpreted[21]. Applications of antibody array methods to cancer research are increasing in scale and effectiveness.

Protein and peptide arrays are effective for probing the interactions of protein and peptides with other antibodies, protein or other molecules. Protein microarrays are an emerging class of nanotechnology for analysing many different proteins simultaneously. Much progress has been made for applications in basic science[22]. These approaches are likely to recapitulate at the protein level the mRNA expression profiling studies by arraying various protein probes on top of specific surfaces, and then determining interactions with specific proteins in complex samples. The most advanced format in this setting is the antibody microarray, where the proteins are specific antibodies printed on solid surfaces.

Protein arrays recently have confirmed the use for probing the abundance of specific proteins in biological samples, this phase call "reverse phase". Protein lysates from cell culture or tissue samples are spotted in microarrays on nitrocellulose membranes. A labeled antibody specific for a particular protein is incubated on a microarray, and quantification of the bound antibody reveals the amount of that protein in each sample[23,24]. Therefore, reverse phase array experiments quantify a single protein in many samples, in contrast to antibody arrays that quantify many proteins in one sample. Numerous demonstrations that this technology uses for profiling proteins in cancer have appeared.

The various methods presented here are complementary with each other and with other proteomic methods, and they may be used together for added benefit as demonstrated in a study of proteins in breast cancer cells using cytokine arrays, reverse phase arrays, and bead-based arrays in conjunction with two-dimensional gels (Figure 3).

TOF-Mass Spectrometry applications in clinical oncology

SELDI-TOF MS is a commonly used non-gel based method. The technique combines protein separation directly with presentation to the mass spectrometer. Various types

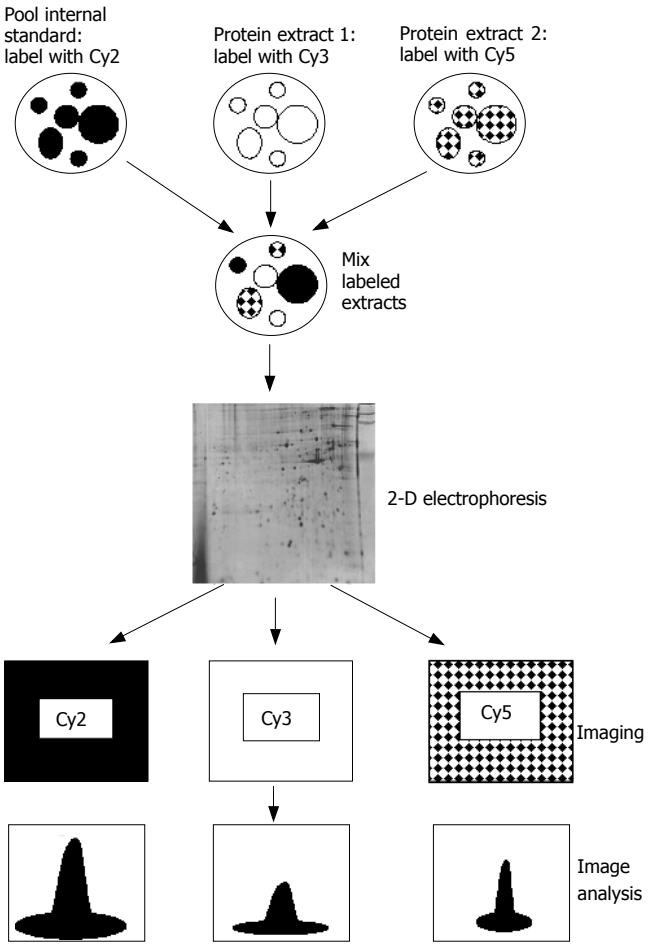

Figure 2 2D-DIGE techniques. Cy2, Cy3 and Cy5 are different fluorescent dyes.

of substrates have different affinities for different proteins, thus it is possible to increase protein representation when combining various arrays. The combination of these arrays with up-front prefractionation chromatography (e.g., anion exchange) permits the detection of up to 2000 protein species from serum[25,26]. The resulting spectral masses are analyzed using univariate and multivariate statistical instruments to provide a single marker or multimarker pattern that can classify clinical samples. Discriminator protein pinnacles are then purified and submitted to the MSbased identification process (Figure 4).

The SELDI technique was developed to profile clinical biological fluids, notably serum and/or plasma, and became important when numerous studies showed its potential in identifying unique biomarkers or complex patterns with diagnostic value, allowing its use for screening and early diagnosis in various cancers[27,28]. One major criticism of the technique relies on the overall lack of sensitivity and capability to detect tumor-specific protein traces within a large amount of nonspecific protein species[29]. However, even though still controversial in its reproducibility and ability to detect actual specific tumor signatures, SELDI has several advantages, such as easy of use, high throughput, and relatively reasonable cost, all making it a very attractive technique for working with large clinical sample.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS), is a

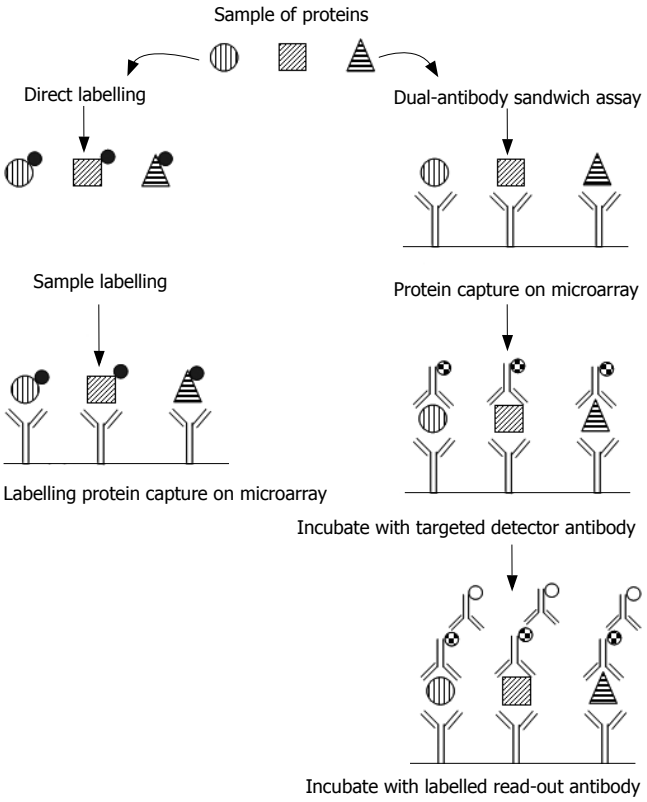

Figure 3 Representation of the two antibody microarray experimental formats. Direct labelling: single-capture antibody experiments; all proteins in a sample are labelled (black circles) thereby providing a means for detecting bound proteins following incubation on an antibody microarray. Dual-antibody (capture and read-out antibody) sandwich immunoassays: proteins captured on an antibody microarray are detected by a cocktail of tagged detection antibodies, which are matched to the spotted antibodies. The detector antibody tag is then measured by binding of a labelled (empty circles) read-out antibody.

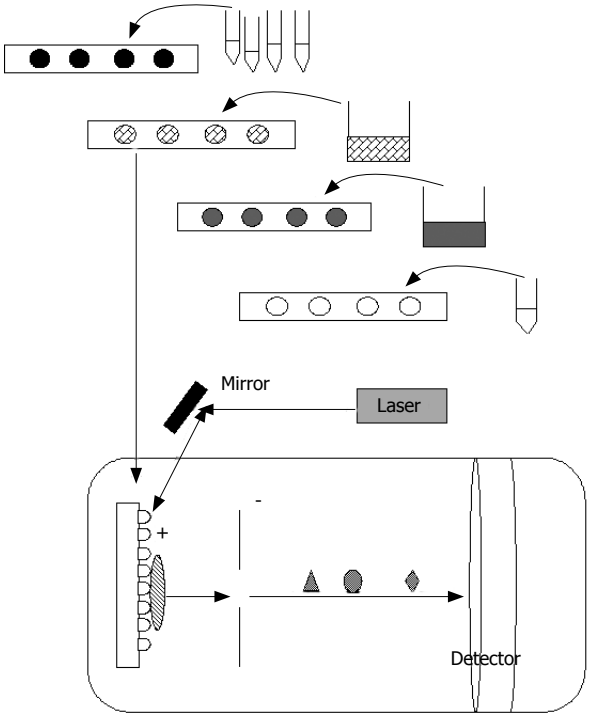

Figure 4 Principles of SELDI-TOF MS. The application of sample from to an eight-spot array with hydrophilic, hydrophobic, cationic, anionic or immobilized-metal affinity capture chromatography surface (black colour). The addition of an appropriate binding buffer (purple colour). On-chip sample purification using one or more wash buffers (grey colour). The application of energy-absorbing matrix for the absorption of laser energy (empty colour). Laser irradiation desorbs bound proteins and positively ionizes them. Owing to the electric field, they migrate in the mass analyser: (small diamond) and multiply charged proteins (oval) faster than large and single-charged ones (triangle). Thus, the proteins are separated. Time of flight (t) is proportional to protein mass per charge.

technique to analyze peptides and proteins in relatively complex samples. It has even been used for the direct analysis of tissue specimens[30]. In MALDI-TOF MS, a small quantity of specimen containing peptides and protein is dried on a target plate together with a light-absorbing matrix molecule.

Two technical advancements have improved resolution of MALDI-TOF MS to its current state. First, use of an electronic mirror (reflectron) to reflect ions substantially increases resolution, and second, delayed extraction introduced after sample vaporization and earlier than the electric potential is applied. Shorter times are optimal for small molecules, and longer times for large molecules. The standard detector for MALDI-TOF MS is a microchannel plate, which acts as an electron multiplier for ions reaching the detector. Detector replys relate to the number of ions reaching the detector and ion velocities.

MALDI-TOF MS permits a rapid determination of molecular masses and the heterogeneity of small amounts of peptides and proteins. Usually, intact molecular ions are formed and determination of polypeptide mass.

LC-MS and LC-MS-MS in comparative proteomic

Capillary-scale HPLC-MS/MS (LC-MS) is rapidly emerging as a method of choice for large scale proteomic analysis[31]. LC-MS systems can be used to identify and track the relative abundance of thousands of molecules[32]. For standard bottom-up profiling experiments, the molecules in question are peptides derived by proteolysis of intact proteins. For very complex protein samples, such as blood, the peptide mixtures are resolved by chromatographic separation prior to injection into the mass spectrometer. This generates a more informative map, that consists of both the unique elution of individual peptides. Distinct peptides of interest are induced by collision fragmentation followed by database matching for the purpose of sequence identification, while the recorded pattern of precursor ion intensities can be used to infer the relative quantities of the various proteins between samples[33].

LC-MS systems consists of different instruments to separate peptide mixtures based on physicochemical properties, separate ions on the basis of m/z ratios and registers the relative abundance of ions at discrete m/z.

In LC-MS-MS technique, precursor ions are recorded in full-scan mode, followed by selective ion isolation and fragmentation for sequence identification[33] (Figure 5).

Isotope-coded affinity tags (ICAT and iTRAQ)

This is the prototypical and the most popular method for quantitative proteome analysis based on stable isotope affinity tagging and MS[34].

The ICAT reagent is a sulphydryl-directed alkylating agent composed of iodoacetate attached to biotin through

a short oligomeric coupling arm (d0). The exchange of 8 deuterium atoms for hydrogen atoms in the coupling arm produces a heavy isotope version of the reagent (d8). Thus the reagent comprises of a cysteine reactive group, a linker containing the heavy or light isotopes (d8/d0) and a biotin affinity tag. This method involves *in vitro* derivatization of cysteine residues in protein with d0 or d8 followed by enzymatic digestion of the combined sample. All the cysteine residues thus tagged with biotin are selectively separated by avidin column and the cysteine-containing peptides are further separated followed by MS analysis[35].

The iTRAQ technique capable of multiplexing samples is primarily based on the ICAT technique and compared in detail. The iTRAQ technique uses four isobaric reagents allowing the multiplexing of four different simples in a single LC-MS-MS experiment. The multiplexing capability of iTRAQ allows a control sample to be compared with different points in time of a disease state, as well as with respect to different drug treatments. One of the major advantages of this technique is its ability to label multiple peptides per protein, which increases the confidence of identification and quantitation[16].

There are numerous differences (advantages and disadvantages) between the select proteomic technologies for protein profiling (Table 1).

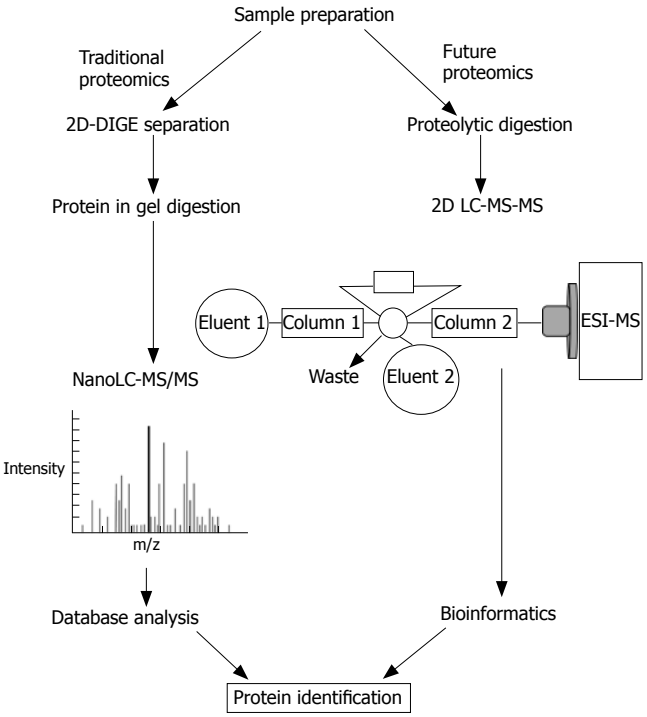

Figure 5 Different strategies for proteomic studies.

High-resolution hybrid quadrupole TOF

One of the first major advances used in any developing area of research was a high-resolution hybrid quadrupole TOF (QqTOF) MS fitted with a SELDI ion source to acquire proteomic patterns from serum. A recent study was designed to determine whether there is any diagnostic advantage provided by acquiring the proteomic patterns of serum samples using a high-resolution, high mass accuracy MS instrument. Results were analyzed on the exact same ProteinChip surface, thus eliminating all experimental variability apart from the use of two different instruments. Different combinations of bioinformatic heuristic parameters were used to generate different diagnostic models using the data acquired from the two distinct mass spectrometers[35]. These parameters included the similarity space for cluster classification, and the learning rate in training of the genetic algorithm. The diagnostic models generated from mass spectra acquired using the higher-resolution Qq-TOF MS were statistically superior[36].

Proteomic analysis software

The result of the analysis of a complex proteomic mixture by SELDI-TOF-MS is a low resolution profile of the protein or peptide species that were subsequently ionized from ProteinChip surface. It has been the development and combination of sophisticated bioinformatic algorithms for the analysis of SELDI-TOF-MS data. The intention of this bioinformatic analysis has led to the potential application of this technology as a major advancement in the diagnosis of cancer and other diseases. There are several different types of bioinformatic algorithms, such as single classification trees, neural nets, genetic algorithms, and random forest algorithms, which have been applied to enable SELDI-TOF-MS data to be investigated as a diagnostic technology. Although they function in different protocols, these algorithms share a common goal: to construct a classifier and discover peak intensities most likely to be responsible for segregating classes of samples[37]. Since its inception, SELDI-TOF-MS has been used to develop diagnostic platforms for several different cancers.

PROTEOMIC ANALYSIS IN COLORECTAL CANCER

During the past decade, genomic analyses have been introduced into cancer studies with variable success. It has become recognized that genomic techniques are insufficient to study the complex pathways of carcinogenesis; this has led to the application of proteomic techniques, which allow for the reliable analysis of complex mixtures of proteins[38].

Colorectal cancer is the third most common cancer in the world. It is well known that the adenomatous polyposis coli (APC) gene is mutated in patients with familial adenomatous polyposis (FAP) and sporadic colorectal cancer, and that mutations initiate colorectal carcinogenesis. It is now suggested that many colorectal cancers arise from preexisting adenomas. Following several steps of mutation of oncogenes and tumor suppressor genes, adenomas develop to colorectal cancers[7].

Many groups have reported the proteomic analyses of colorectal cancers. Dundas *et al*[39] found that mortalin, also known as mitochondrial HSP70, is involved in cell cycle regulation with important roles in cellular senescence and immortalization pathways and was over-expressed in colorectal adenocarcinomas and correlated with poor survival. Lane *et al*[40] identified over-expressed multiple cytochrome P450 enzymes in human colorectal cancer tissues and metastases. Cytochrome P450 proteins (CYPs)

Table 1 Advantages and disadvantages of proteomic technologies for protein profiling

Technique	Methods	Advantages	Disadvantages
2D	Separation on a gel of the protein content of a sample in two dimensions according to mass and charge; gels are stained and spot intensities in samples are compared among different gels	High separation (thousands of proteins per gel)	Low throughput laborious (one samples per gel); poor resolution for extreme masses and extremely acidic or basic proteins; no direct protein identification; large amount of starting material compared with other techniques
2D-DIGE	Measuring three samples per gel; each of them is labelled with a different fluorescent dye, and the intensities of each gel spot for each sample are measured at a wavelength specific for the label	Direct comparison of samples on one gel: better reproductibility	Low throughput (three samples per gel)
Protein microarrays	Binding of a targeted protein in one sample to spotted probes on a 'forward' microarray; conversely, binding of specific probes to a targeted protein in spotted samples on a 'reverse' microarray; detection of bound proteins by direct labelling or by labelled secondary antibodies	High throughput in terms of number of probes per (forward) array or number of samples per (reverse) array; biomarker identity or class readily known	Synthesis of many different probes necessary; identity or class of targeted proteins must be known; limited to detection of proteins targeted by the probes
SELDI-TOF MS	Selected part of a protein mixture is bound to a specific chromatographic surface and the rest washed away	High throughput; direct application of whole sample (fast on-chip sample cleanup); small amount of starting material	Unsuitable for high molecular weight proteins; limited to detection of bound proteins; lower resolution and mass accuracy than MALDI-TOF
MALDI-TOF MS	Application of a protein mixture onto a gold plate; desorption of proteins from the plate by laser energy and measurement of the protein masses; comparison of peak intensities between multiple samples	High throughput	Need for sample fractionation of complex samples; more starting material needed for sample fractionation; unsuitable for high molecular weight proteins
LC-MS-MS	Separation of a mixture of peptides (resulting from protein digestion with trypsin) by one-, two-or three-dimensional LC and measurement of peptide masses by MS-MS	Direct identification of several hundred proteins per sample by MS-MS of peptides	Low throughput; time consuming; detection by MS–MS often not comprehensive, tus complicating comparison of different samples
ICAT	Chemical tagging of proteins on cysteine residues with a heavy or light stable isotopic; after labelling samples are mixed, proteins are digested with trypsin, and labelled peptides isolated by affinity chromatography; both samples are analysed concomitantly by LC-MS-MS	Direct identification of biomarkers by MS-MS of peptides; relative quantitation; less sample complexity than with iTRAQe; MS-MS of only differentially expressed proteins	Low throughput; tagging of only cysteine-containing peptides
iTRAQ	Chemical tagging of proteins on their amine groups with stable isotopic labels of identical mass ('isobaric'); four different labels are available for four different samples; after labelling, samples are mixed, proteins digested with trypsin and analysed concomitantly by LC-MS-MS	Direct identification of biomarkers by MS-MS of peptides; owing to isobaric labels, selection for MS-MS of the same peptide in all four samples in the same single MS run	Low throughput (four samples per run); for generating signature ion, MS-MS of all peptides in a sample is necessary; high sample complexity and limited resolution of LC (even three dimensional), confounding by co-eluting isobaric peptides

in the liver are known to be of major importance to the fate of anticancer agents; however, their expression and role in tumours has received little attention. CYP-mediated metabolism is generally viewed as a route to drug detoxification and increased elimination, although CYP activation of certain anticancer drugs. The presence of metabolically active CYPs in a colon metastastic deposit is likely to be important in determining the metabolic fate of chemotherapeutic agents and hence the outcome of treatment. Stulik *et al* performed proteomic differential display between the matched sets of macroscopically normal colon mucosa and colorectal cancer tissues. They report that the expression of HSP70, S100A9, S100A8, S100A11 and S100A6 was up-regulated in colorectal cancer tissues compared to normal colon mucosa, and the levels of liver fatty acid-binding protein, actin-binding protein/smooth muscle protein 22-a and cyclooxygenase 2 were down-regulated in transformed colon mucosa[41]. The S100A6 protein was the first S-100 protein specifically identified as being related to the state of cellular proliferation. The possible correlation between increased expression of some members of the S100 protein

Table 2 Proteomic analysis in human colorectal cancer tissues

Up-regulated		Down-regulated
Annexin Ⅳ		NCF2
MTA-1		PMM2
SSX5 protein		Serpin 1
Dynein heavy chain		CNRC
Cytochrome P450		Annexin Ⅴ
CPT1		APC
Keratin 10		VAV3 protein
Keratin 8		RSP 4
Keratin 19		SPARC like protein 1
Vimentin		PDI
β-actin		GN6ST
REL1		Cathepsin D
HSP60		Calreticulin
Mortalin	Cathepsin fragment	SM31
		PDA6
	Proteasome subunit a type 6	ApoA1 precursor
Cytochrome P450 enzymes		ATP synthase b chain
(in cancer tissues and metastatic tissues)	Triosephosphate isomerase 14-3-3 proteins	Albumin
		Liver fatty acid-binding protein
HSP70	GST-P	Actin-binding protein/smooth muscle protein 22-a
S100A9		
S100A8	P13693 translationally controlled tumor protein	Cyclooxygenase 2
S100A11		
S100A6		Puromycin-sensitive aminopeptidase
	Nucleoside diphosphate kinase A	
		NADH-ubiquinone oxidoreductase
Adenosyl homocysteinase	Calgranulin B; S100 A9	
Leukocyte elastase inhibitor, claude B		Succinate dehydrogenase subunit A
Macrophage capping protein		
Biliverdin reductase A		Aldehyde dehydrogenase, cytosolic, class Ⅰ
Annexin 1 fragment		
α-tubulin		
Elongation factor 1-d		Selenium-binding protein
Tropomyosin a1		Creatin kinase B chain
Tropomyosin a4 chain		Placental thrombin inhibitor
Actin fragment		Vimentin
Annexin 5		Desmin
Microtuble-associated protein RP/EB		Tubulin b 5 chain
Pyridoxal kinase		Carbonic anhydrase Ⅰ
Annexin 3		Myosin regulatory light chain 2
Annexin 4		

family and colon carcinogenesis is also supported by the finding that documents the participation of the S100A4 protein in the progression and metastasis of colorectal carcinogenesis. Alfonso *et al*[42] reported the up-regulation of annexin Ⅳ, MTA-1 and others in colorectal cancer tissues, and the down-regulation of NCF2, PMM2 and others. Several functional groups of proteins were affected, including regulators of transcription, structural proteins, and those involved in protein synthesis and folding. The MTA-1 gene encodes a protein that was identified in metastatic cells, specifically, mammary adenocarcinoma cell lines. Expression of the MTA-1 gene has been associated with the progression of several carcinomas in colon, lung, prostate, and liver. A annexin Ⅳ is a calcium-binding protein and I involved in cellular communication and signal transduction, for this reason it was up-regulated in colorectal cancer. Friedman *et al*[43] identified adenosyl homocysteinase, leukocyte elastase inhibitor and others as up-regulated proteins, and puromycin-sensitive aminopeptidase, NADH-ubiquinone oxidoreductase and others as down-regulated proteins in colorectal cancer tissues.

Minowa *et al*[44] identified truncated β-tubulins as a protein specific to polyp samples from APC gene-mutant mice by proteomic analysis of the small intestine and colon epithelia. The adenomatous polyposis coli gene (APC) is mutated in patients with familial adenomatous popyposis (FAC) and sporadic colon cancer, and these mutations initiate colon carcinogenesis. Simpson *et al*[45] performed membrane proteomic analysis of the human colon carcinoma cell line LIM 1215 to search for novel tumor marker proteins expressed during various stages of cancer progression, although the data are not shown.

Given the continual rise in the number of potential biomarkers of CRC, future studies will increasingly employ genomic and proteomic technologies, which enable the measurement and analysis of numerous potential biomarkers simultaneously. These techniques are able to produce gene or protein 'profiles' associated with clinical outcome, the analysis of which may then yield novel biomarkers with prognostic and/or therapeutic potential[46] (Table 2).

At this moment, biomarkers whose sensitivity and

specificity are better than bloody stool examination have not yet been found. Since the bloody stool test is easier than examination using cancer specimens and easier to handle than sera, from a clinical aspect, the bloody stool examination is better than biomarkers[34].

In another recent study, the detection of upregulated α-defensins 1, 2 and 3 in colorectal cancer tissue were reported in two independent, but similar analyzes. In both studies, SELDI-TOF MS results in tissue correlated with serum levels that were determined using ELISA or SELDI-TOF MS. This provides an interesting approach for finding new serum markers because biomarkers identified first in tissue could prove to be more specific. Unfortunately, α-defensin levels are also increased in serum during, for example, infection[47]. α-defensin and β-defensin are major components of the epithelial mammalian innate immune system. Defensins are small cationic peptides with high activity against a variety of microbials, encoded by genes and some are regulated in response to challenge with bacterial antigens. Gastrointestinal α-defensins (HD5 and HD6) are almost exclusively expressed in and secreted from Paneth cells of the small intestine, while β-defensins (hBD-1, hBD-2, hBD-3) are secreted by virtually all gastrointestinal epithelial cells to a varying extent.

CONCLUSIONS AND FUTURE PERSPECTIVES

Rapidly developing techniques that considerably enhanced information gained from proteomes integrate proteomics with other disciplines such as cell biology, biochemistry, molecular genetics, and chemistry. This consolidation certainly demonstrates incredible power and possibilities of proteomics for further applications. It is necessary to cross the barriers of limited resolution, mass range, detection level, and other reasons for protein underrepresentation in analyzed proteomes. Once achieved, the door that allows complete identification of specific protein markers will open and the comprehension of complex networks of protein/peptide interactions involved in cancer will begin to be elucidated[6]. While the application of computational and statistical methods to proteomic profiling is relatively new, it is rapidly gaining interest. Hence, it is worthwhile suggesting fruitful avenues for moving forward. It was suggested above that simultaneous LC-MS data alignment and normalization may be beneficial for comparative profiling.

Proteomic technologies are now in place to examine simultaneously and comprehensively many protein expression differences that result from disease and treatment, with the ultimate payoff being the use of specific protein profiles for the early diagnosis of patients and for patient-tailored therapies[47].

Abstract

Immunotherapy encompasses a variety of interventions and techniques with the common goal of eliciting tumor cell destructive immune responses. Colorectal carcinoma often presents as metastatic disease that impedes curative surgery. Novel strategies such as active immunization with dendritic cells (DCs), gene transfer of cytokines into tumor cells or administration of immunostimulatory monoclonal antibodies (such as anti-CD137 or anti-CTLA-4) have been assessed in preclinical studies and are at an early clinical development stage. Importantly, there is accumulating evidence that chemotherapy and immunotherapy can be combined in the treatment of some cases with colorectal cancer, with synergistic potentiation as a result of antigens cross-presented by dendritic cells and/or elimination of competitor or suppressive T lymphocyte populations (regulatory T-cells). However, genetic and epigenetic unstable carcinoma cells frequently evolve mechanisms of immunoevasion that are the result of either loss of antigen presentation, or an active expression of immunosuppressive substances. Some of these actively immunosuppressive mechanisms are inducible by cytokines that signify the arrival of an effector immune response. For example, induction of 2, 3 indoleamine dioxygenase (IDO) by IFNγ in colorectal carcinoma cells. Combinational and balanced strategies fostering antigen presentation, T-cell costimulation and interference with immune regulatory mechanisms will probably take the stage in translational research in the treatment of colorectal carcinoma.

INTRODUCTION

Conventional therapy for cancer is based on surgical resection, chemotherapy with drugs with selective toxic effects against dividing cancer cells, and localized gamma irradiation. Biological therapy has only recently been introduced[1]. This includes the use of agents that interfere with growth factors for malignant cells, and block tumor neovascularization[2]. Among the monoclonal antibodies (mAbs) that have been approved for cancer treatment, most operate *via* indirect mechanisms, and only a minority target natural or artificial mechanisms of cell destruction.

Colorectal carcinoma (CRC) is one of the leading causes of cancer-related deaths worldwide[3]. Unfortunately, more than 20% of patients with CRC have metastatic disease at the time of diagnosis (http://www.seer.cancer.gov). Although the most common indication for liver resection in developed countries is metastatic CRC, surgery can only be performed in 20% patients, with the 5-year survival rate of 25%-40% despite adjuvant chemotherapy[4]. Regardless of this depressing scenario, a better understanding of tumor biology, combined with advances in molecular and cell biology, have opened up novel avenues of treating advanced CRC using immunotherapeutic strategies.

Tumor escape: Perverted local and systemic immune regulation by tumors

The cellular immune system has been endowed with powerful and at the same time toxic mechanisms designed to induce inflammation and cell destruction, which should be kept under tight control and guided precisely to the target tissues. Cytotoxic mechanisms are designed to recognize and destroy cells that are infected with viruses or other intracellular pathogens, whereas inflammation

is a vascular and leukocyte mediated local response that selectively directs the cellular and macromolecular elements of the innate and adaptive immune systems to the infected site. If properly aimed and enhanced, both immune functions can be therapeutically exploited to control and even eradicate malignant lesions[5]. Genetic and epigenetic changes involved in carcinogenesis generate antigens that are recognized by T lymphocytes in analogous fashion to microbial antigens[6]. Unfortunately, tumor cells in spite of being antigenic are very poorly immunogenic by themselves. Therefore, advanced cancer disease can impede any effort to induce antitumor immunity.

Genetically unstable cells can undergo genetic or epigenetic changes in order to escape a tumoricidal immune response in a "survival of the fittest" type of selection. The escape mechanisms may result from loss of antigen or antigen presentation as well as from active biosynthesis of immunosuppressive molecules[7,8]. These factors include TGF-β, VEGF, IL-8 and IL-10 which are known to cause significant inhibition of both innate and adaptive mechanisms of tumor immunity. Recent evidence points to activation of the transcription factor *Stat3* as a master switch in the control of various immunoevasive substances in tumor cells[9]. Moreover, intrinsic *Stat3* signaling in hemopoietic cells hindered their performance in tumor immunity including dysfunction of NK cells, granulocytes, and conventional DCs which become tolerogenic. Infiltration of tumors by effector T cells seems largely an inefficient process that may be related to poor expression of chemokines and vascular adhesion molecules in the malignant lesions[10]. Besides, the myeloid and lymphoid cells present in tumor stroma appear to be related more to the mechanisms of inhibition than to the activation of tumor immunity.

Indoleamine 2, 3 dioxygenase (IDO) catalyses the degradation of the essential amino acid tryptophan and synthesizes immunosuppressive metabolites[11]. Local up-regulation of the expression and activity of IDO in tumors and the draining lymph nodes can suppress T cell activation and is thought to facilitate the escape of tumor cells from the immune system[12]. Indeed, this enzyme depletes tryptophan and produces kynurenines locally in such a way that both mechanisms impair the function of T cells[13]. IFNs are the key factors upregulating IDO, thus generating a clever mechanism that becomes operational when tumors sense an active immune response in their neighborhood. There is recent evidence indicating that upregulation of IDO by colorectal cancer cells provides an immunosuppressive microenvironment created by tumors to promote cancer growth and spread[14]. We have observed in *in vitro* studies that the addition of IFN-γ to CT26 murine colorectal carcinoma cells induces IDO mRNA expression as well as IDO enzymatic activity, detected as kynurenine production (Figure 1).

Co-signaling molecules are cell-surface glycoproteins that can direct, modulate and fine tune T-cell receptor (TCR) signals[15]. The functional outcome of T cell activity upon its binding to a ligand on an adjacent cell membrane classifies co-signaling molecules as co-stimulators and co-inhibitors. Tumors can express co-inhibitory B7 family

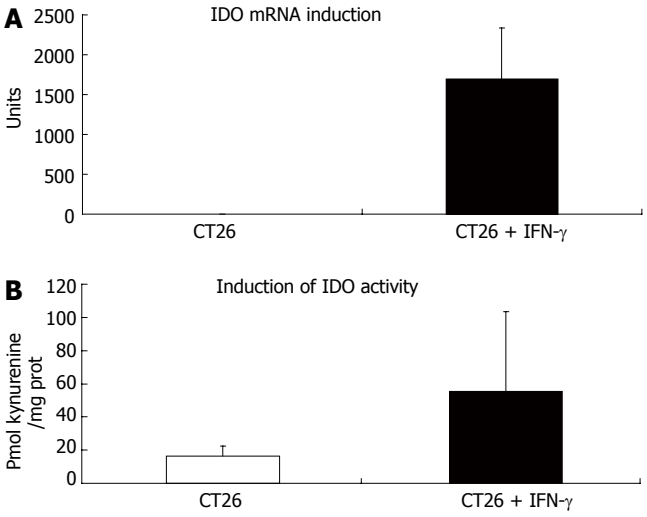

Figure 1 IFN-γ induces IDO mRNA and enzymatic activity in colon cancer cells. **A**: IDO mRNA was induced after 48 h stimulation with 1000 IU/mL of IFN-γ, as assessed by real time-PCR; **B**: In the same culture conditions, IDO activity was measured in CT26 cellular extracts as previously described by Takikawa *et al*[83].

members, such as B7-H1, B7-H4, and B7-1 (CD80) at a low density, which downregulates T cell activation and/or cytolytic activity[16,17]. Tumors can also induce B7-H1 and B7-H4 expression on tumor-associated macrophages (TAM)[18]. Myeloid suppressor cells can further inhibit anti tumor T cells *via* the production of nitric oxide by the enzyme arginase[19].

Regulatory T cells (T-reg) are important inhibitors of anti tumor immunity[20]. T-reg, characterized by the FoxP3 transcription factor, up-regulate a number of cell membrane molecules, including LAG-3, CTLA-4, GITR, and neuropilin. T-reg can inhibit effector T cell activation and function *via* T-T inhibition or inhibition of antigen presenting cells. There is experimental evidence to support a grim scenario in which T cells in tumor tissue or draining lymph nodes can be perverted into regulatory T cells[21]. Local production of TGF-β may be a key factor in transforming effector T cells locally into suppressive T-reg. Convincing data concerning the role of $CD4^+$ $CD25^+$ regulatory T cells in human cancer comes from the work of Curiel *et al*[22], who showed that the presence of such T-reg in advanced ovarian cancer correlated with reduced survival. Considering the role of T-regs as inhibitors of anti tumor immunity, it has been observed in murine models and in patients that prior host immunosuppression with chemotherapeutic agents (such as cyclophosphamide) can increase the efficacy of adoptive cell therapy as well as other kinds of immunotherapy[23]. The reason for this immunomodulatory effects is based, at least partially, on the elimination of $CD4^+$ $CD25^+$ T cells and the engraftment of specific cytotoxic T lymphocytes[24].

Experimental evidence with TCR transgenic mice clearly shows that tumor-reactive T cells can be tolerized to the point where there is no response to the surrogate tumor antigen. Tolerance results from presentation in the context of a DC that is not expressing high levels of costimulatory molecules and does not secrete cytokines such as IL-12, IL-15 and IFNs.

Chronic exposure to high levels of antigen drives T lymphocytes to a state of non-responsiveness termed "exhaustion". This phenomenon may play a role in impaired CD8 T-cell activity in response to persistent tumor antigens. In a way, the phenomenon of CD8 T-cell exhaustion is actually encouraging from the perspective of immunotherapy, since tumor-specific CD8 T-cells may be present and partially primed in a tumor-bearing host. The B7H1 and PD1 ligand receptor pair is a clear candidate to mediate and sustain exhaustion and offers an opportunity for therapeutic intervention.

In many cases however, a responsive TCR repertoire and tumor antigens coexist without signs of immunization or tolerization. Such a situation is termed immunological ignorance or indifference[25]. Ignorance can conceivably take place in two different ways. First, the quantity of antigen presented to the lymphoid tissue may be too small to induce immunity or tolerance. That would be ignorance/indifference at the priming phase of the immune response[26]. Second, studies in mice show that an expanded effector cell population respects tissues that are not inflamed[27,28]. This can be termed ignorance at the peripheral level that can occur in peripheral solid tumors[28,29].

The possibility of overcoming immunoescape

Immunotherapy, which is an intervention designed to increase anti-cancer immunity, remains an experimental discipline[30]. However several approaches including inducing and redirecting immunity to either the malignant cells or to critical components of the tumor stroma, such as the vasculature or the connective tissue, have been shown to profoundly impact disease progression in mouse models of cancer[31,32].

Therapeutic vaccination has been attempted in several ways. The immunogenic source can be autologous or allogenic malignant cells that are modified to increase their immunogenicity[33]. *Ex-vivo* or *in vivo* gene transfer of cytokines and other immune-potentiating molecules is a promising strategy. Alternatively, many experimental protocols rely on *in vitro* culture/differentiation of DCs manipulated in such a way that they artificially present tumor antigens[34]. However, the promising results in mouse models have not been replicated in clinical trials. In spite of this drawback there is ample biological evidence in humans that there is an increase in the numbers and activity of lymphocytes against the vaccinating antigen, although such increases fail to reach by 1-2 logs the levels of T cell immunity observed in viral infections.

Adoptive T cell therapy with activated T lymphocytes reaches higher levels of circulating antitumor T cells[35]. These techniques are based on *ex-vivo* reactivation and expansion of cloned or polyclonal cultures of tumor reactive T cells. After culture, T cells are reinfused into the patient along with IL-2. Three important concepts have gained experimental support: (1) polyclonal cultures that recognize several antigen specificities improves the outcome, and the development of tumor-escape antigen loss variants are less likely to occur, (2) co-infusion of both CD4 and CD8 tumor reactive T cells improves antitumor activity, and (3) treatment with lymphodepleting chemotherapy before reinfusion increases the duration and *in vivo* re-expansion of the infused T cells. This is due to both depletion of regulatory T cells and decrease in the competition for T cell homeostatic survival factors such as IL-15 and IL-7. Adoptive T cell therapy probably will benefit much more from the availability of clinical grade IL-15, which can condition the infused cells and sustain their function on administration to the patient.

The sense that chemotherapy and immunotherapy are incompatible is a fading paradigm in tumor immunotherapy. It used to be reasoned that if T cell responses require cell expansion, active or adoptive immunotherapy could not be used in combination with chemotherapy drugs that are selectively toxic for dividing cells. Several lines of experimental evidence suggest otherwise. In fact, there are a number of mechanisms that define additive and synergistic effects: (1) tumor cell destruction makes tumor antigens available for cross presentation by DCs, (2) there is decrease in regulatory T cells, and (3) there is reduced competition for T-cell homeostatic growth factors during/after active immunization. Local destruction of tumors followed by injection of proinflammatory substances holds much promise according to preclinical data and probably represents the simplest method of converting tumors into tumor vaccine.

Immunostimulatory monoclonal antibodies for the treatment of colorectal carcinoma

Immunostimulatory mAbs directed to immune receptors have emerged as a new and promising strategy to fight cancer[36]. In general, mAbs can be designed to bind molecules on the surface of lymphocytes or antigen presenting cells to provide activating signals (e.g., CD28, CD137, CD40 and OX40)[36]. On the other hand, mAbs can also be used to block the action of surface receptors that normally downregulate immune responses (CTLA-4 and PD-1/B7-H1). In combined regimes of immunotherapy, these mAbs are expected to improve therapeutic immunizations against tumors as observed in preclinical studies.

Anti-4-1BB (agonistic anti-CD137) is one of the most interesting mAbs tested as anti-cancer molecules in preclinical studies[36]. 4-1BB is a member of the tumor necrosis factor/nerve growth factor family of receptors and has a natural ligand (4-1BBL) that is expressed on activated T lymphocytes as well as on NK cells and dendritic cells[37]. This mAb, which acts against CD137, has the ability to stimulate potent antitumor responses[38] and, paradoxically, ameliorates autoimmune manifestations in mice[36]. On the other hand, therapy with mAbs against CTLA-4, which block the inhibitory action of CTLA-4 on T-cells, is capable of inducing antitumor responses in mice as well as in humans but is accompanied with adverse events in the form of autoimmune reactions[39].

Kocak *et al*[40] took advantage of both the mAbs and showed that the combination of CTLA-4 and 4-1BB acts synergistically in the eradication of MC38 colorectal carcinoma after stimulation of a potent antitumor immune response. It was observed that this antitumoral effect

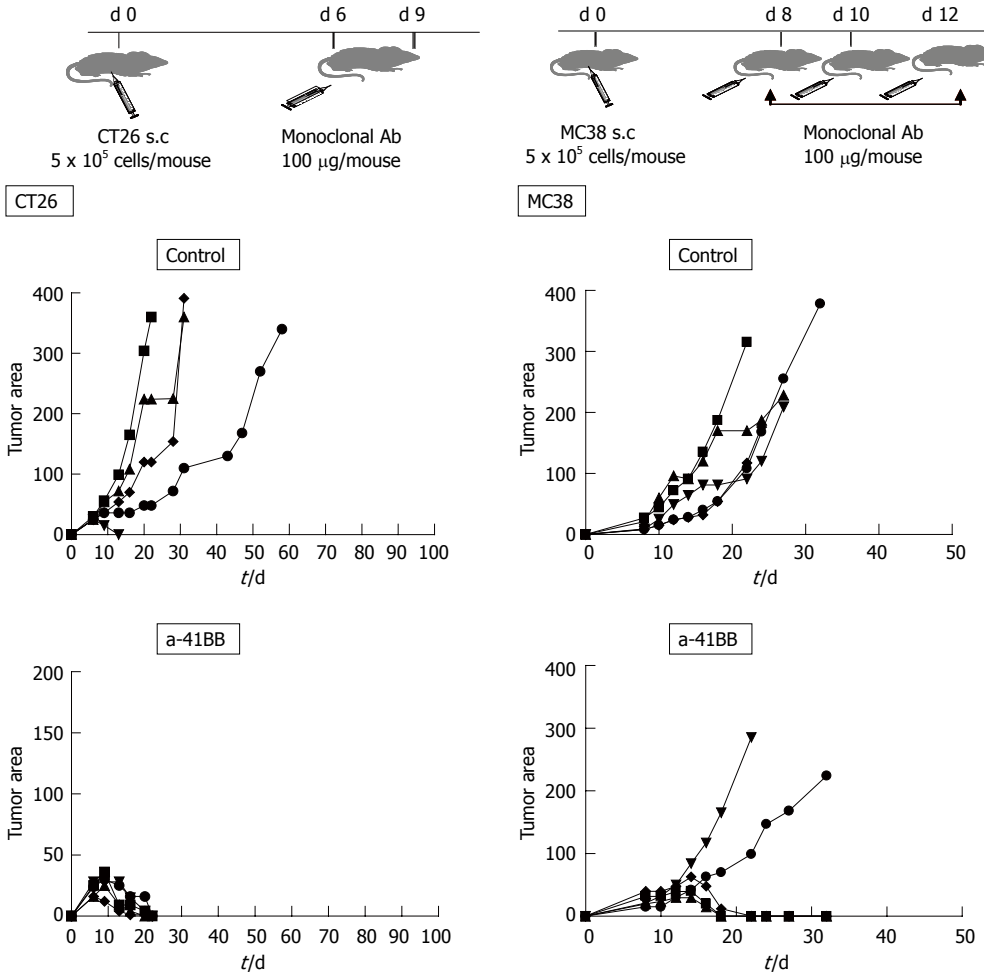

Figure 2 Systemic treatment with agonist anti-CD137 monoclonal antibodies eradicates transplanted murine colon cancers. Mice subcutaneously grafted with 5 x 10^5 CT26 or MC38 cells were treated with anti-CD137 (2A) mAb or polyclonal rat IgG as a control. Sequential follow up of tumor size (mean diameter) is depicted for individual mice.

is critically dependant on the presence of $CD8^+$ T-cells induced after treatment[40]. However, we did not observe such a synergy in the same experimental model (A Arina *et al*, unpublished observations).

In our studies in mice, we used the MC38- and CT26-derived tumor model (colorectal carcinoma cell lines) to explore the antitumor effect of repeated systemic injections of agonistic anti-CD137 (anti-4-1BB) mAbs. As a result of the amplification properties of anti-CD137 antibodies on CTL immune response, this treatment was able to induce tumor eradication in 3 out of 5 mice bearing CT-26 tumors and in 3 out of 5 animals with MC38 nodules (Figure 2).

CD137 stimulation can be achieved not only by direct administration of mAbs in monotherapy, but also in the context of different combinations usually including immunostimulatory cytokines. For example, simultaneous gene transfer of local-membrane bound 4-1BB ligand and IL-12 results in successful eradication of advanced colorectal liver metastasis induced in mice[41]. In a similar line of work, Martinet *et al*[41] demonstrated that the combination of 4-1BB costimulation using an adenovirus expressing membrane-bound 4-1BB-L with another adenovirus expressing IL-12 genes induced a potent antitumor response in mice with colorectal carcinoma. Systemic administration of soluble Ig-4-1BB ligand gave rise to a stronger T-cell immune response compared to local gene transfer[42]. It appears that anti-4-1BB can upregulate a formerly weak immune response, but it fails to initiate an immune response if it was nonexistent initially[43].

Systemic treatment with anti CTLA-4 mAb increased the number of CTLs and caused complete tumor regression in established colorectal carcinoma in mice[44]. Another attractive immunostimulatory combination was recently examined by Tirapu *et al*. These workers searched for strategies to enhance the efficacy previously achieved by intratumoral injection of DCs engineered to secrete IL-12 in a mouse model of colorectal carcinoma (using MC38 cell line). They were able to induce a systemic immune response (measured by IFN-γ ELISPOT assay) that eradicated large and metastatic tumor lesions using a combination of systemic anti-CD137 mAb and IL-12 producing semiallogeneic DCs injected intratumorally[45]. This study offers a promising technique of enhancing the efficacy of DC-based strategies currently been tested in clinical studies[46].

GENE TRANSFER OF IMMUNOSTIMULATORY MOLECULES AND GENETIC VACCINATION

Several cytokines (e.g., IL-2, IL-4, IL-6, IL-7, IL-10, IL-12, IFN-γ, TNF-α and GM-CSF) demonstrate an ability to increase anti-tumor immunity when expressed by cancer

Table 1 Gene transfer of immunostimulatory molecules and genetic vaccination

Cytokine	Vector	Clinical application	Mechanism	Ref.
IL-2 + IL-12	Ad	No	CTLs	10
IL-10	Retrovirus	No	$CD8^+$	54
TNF-alpha	Ad	Yes	Antiangiogenic, bystander effect	75
HLA-B7/b2 microglobulin	DNA	Yes	CTLs	76
IL-12	Ad	Yes	NK, $CD4^+$, $CD8^+$	46
IL-12 + IL-10	Retrovirus	No	$CD8^+$, $CD4^+$, NK, Macrophages, Neutrophils	55
IL-2	Ad, retrovirus	Yes	CTLs	59
CCL21/LIGTH	Ad	No	DC, $CD8^+$, Macrophages	61

Ad: Adenovirus; DNA: Plasmid DNA; CTLs: Cytotoxic T lymphocytes; NK: Natural killers.

cells[47]. However, systemic administration of recombinant cytokines has limitations because of their short half-life, production difficulty and toxicity. Gene therapy appears to be a novel strategy that may help in delivering therapeutic genes locally, as well as the possibility of controlling transgene expression using specific and regulatable promoters[48] (Table 1).

Currently, we consider two principal approaches to the transfer of immunostimulating molecules inside tumors in order to facilitate immunity against colorectal cancer[47]: (1) *in vivo* injection of vectors expressing cytokines/costimulatory molecule genes into the tumor milieu (may be the most straightforward technique), and (2) tumor cells, DC and lymphocytes can be transduced *ex vivo* with vectors encoding cytokines/costimulatory molecules and re-administered into the host. One of the aims of these strategies is to induce high tumoral or peritumoral production of transferred cytokines, to promote localized regional inflammation (to stimulate innate anti-tumor response), and to induce systemic immunity capable of eliminating disseminated disease.

One of the most extensively studied cytokines in cancer treatment is interleukin-12 (IL-12), which has been shown to have significant antitumor activity against a wide panel of experimental malignancies. IL-12 promotes antitumor immunity because of its ability to activate cytotoxic T lymphocytes (CTLs), natural killer (NK cells) and Th1 response[49,50]. Moreover, IL-12 has antiangiogenic effect, dependent on Interferon gamma (IFN-γ) Inducible Protein 10 (IP10) that facilitates its anticancer effect through different mechanisms[51,52]. It is well known that systemic therapy with rIL-12 protein carries the risk of severe toxicity because of the stimulation of large quantities of IFN-γ, with the potential for individually heterogeneous susceptibility[53].

It has been observed that a combination of immunostimulatory genes may achieve superior therapeutic effects. Narvaiza *et al*[51] demonstrated that intratumoral administration of an adenovirus encoding IL-12 (AdIL-12) together with another adenovirus encoding the chemokine IP-10 (AdIP-10) results in marked antitumoral synergy leading to eradication of metastatic colorectal carcinomas. In this study, the authors used vectors in doses that were not effective when given separately. Moreover, this strategy allowed reduction in the dose of AdIL-12 without losing its anti-tumor efficacy and with less risk of IL-12-related toxicity[51]. The underlying principle of combining AdIL-12 and AdIP-10 is based on the prospect of attracting lymphocytes to tumors expressing IP-10 and to activate them by simultaneous infection of the tumor with AdIL-12.

It is well known that IL-12 has the ability to induce a Th1 type of immune response. By contrast, IL-10 is mainly expressed by Th2 cells and downregulates the production of IL-12 by antigen presenting cells, thus decreasing Th1 activity[51]. However, it has been observed that IL-10 enhances IL-2-induced proliferation and differentiation of $CD8^+$ T-cells[29]. Adris *et al*[54] showed that inoculation of mice with tumor cells expressing IL-10 inhibits the establishment of colorectal carcinoma cells and induces a T cell-mediated tumor suppression in the context of a systemic Th2 response. In an effort to treat colorectal carcinomas using both cytokines, Lopez *et al*[55] have shown that tumor cell vaccines producing both IL-10 and IL-12 act synergistically to eradicate established colorectal cancer (CT26 cell line) and, surprisingly, mammary carcinomas as well. The authors also observed that the antitumor effect of the combined immunotherapy was mainly dependent on $CD8^+$ cells.

In addition to IL-12, heat shock proteins (HSPs) also have the ability to stimulate antigen-presenting cells and induce a Th1-type response. HSP have been employed as an adjuvant to facilitate the induction of specific immunity. Moreover, HSPs have been evaluated in clinical studies as an adjuvant in combination with BCG (Bacille Calmette-Guerin) and HPV16E7 in patients with papillomavirus-related carcinoma[56]. Wu *et al*[57] demonstrated that vaccination of transgenic mice with HSP70-like protein (Hsp70L1) fused with a fragment of carcinoembryonic antigen (CEA576-669) induced the maturation of DCs, with a strong specific CD8 T cell response and *in vivo* antitumor activity in mice.

Systemic administration of recombinant IL-2 has been used in clinical practice in patients with metastatic renal carcinoma and malignant melanoma, although with low efficacy and high toxicity[58]. Among other functions, IL-2 is necessary for the survival of activated T cells and is employed in large doses in protocols were immune cells are adoptively transferred to cancer patients. Adenovirus containing mouse IL-2 cDNA can be injected into tumors, and in combination with a suicide gene (herpes simplex virus thymidine kinase vector) can be a powerful tool in the treatment of metastatic colon carcinoma of the liver[59].

One of the synergistic combinations include a chemokine plus a T-cell-activating cytokine designed to promote the attraction and activation of infiltrating immune cells (attraction theory). Macrophage inflammatory protein 3 (MIP-3) is a chemokine mainly secreted by activated macrophages, which attracts leukocytes to inflammatory foci with selectivity for tisular

DCs. The combination of two adenoviruses, one encoding MIP-3 (Ad MIP-3) and the other IL-12 genes (AdIL-12) given intratumorally in mice with colorectal carcinoma eradicates nearly 90% of subcutaneously implanted tumors[60]. Similarly, co-expression of the chemokine CCL21/secondary lymphoid tissue chemokine and a costimulatory molecule LIGHT in colon carcinoma cells (CT26) resulted in significantly reduced tumor growth in mice. A markedly increased infiltration of mature DCs and $CD8^+$ T cells was observed in the tumor mass, and the splenocytes showed a potent CTL activity against CT26 tumor and IFN-γ production. These results suggest that combined treatment with CCL21 and LIGHT is capable of inducing a synergistic antitumor effect[61].

Dendritic cell-based immunotherapy

Dendritic cells (DCs) are leukocyte populations that present antigens captured in peripheral tissues to T cells *via* both MHC class Ⅱ and I antigen presentation pathways[62]. DC maturation is referred to as the status of DC activation at which such antigen-presenting DCs leads to T-cell priming, while its presentation by immature DCs results in tolerance[63]. DC maturation is chiefly caused by biomolecules with microbial features detected by innate receptors (bacterial DNA, viral RNA, endotoxin, *etc*), pro-inflammatory cytokines (TNF, IL-1, IFNs), ligation of CD40 on the DC surface by CD40L, and substances released from cells undergoing stressful cell death.

It is well known that DCs are potent inducers of immune responses and the activation of these cells is a critical step for the induction of antitumoral immunity. We successfully tested a technique designed to take advantage of the therapeutic effect of IL-12 infecting DCs *ex vivo* with an adenovirus that expresses IL-12 genes (AdIL-12), and injecting the engineered cells into colorectal carcinomas in mice[64]. This strategy has proved to be exceptionally effective in eliminating neoplastic nodules and in eliciting anti-tumor immunity. This strategy is also effective in mouse models when DCs are transfected to express IL-7[65] and IL-15[66].

Transfection of DCs with mRNA is a promising antigen-loading technique of stimulating strong antitumor immunity. Chu *et al*[67] transfected RNA from CT26 colorectal adenocarcinoma to the bone marrow-derived monocytes and obtained strong specific CTL activity *in vivo*. Saha *et al* [68] showed that immunization of CEA transgenic mice with bone marrow-derived mature dendritic cells loaded with the antidote antibody 3H1 (which mimics CEA) resulted in a CEA-specific immune response and suppression of colon carcinoma cells (expressing CEA) in nearly 100% of mice, whereas only 40% of experimental mice immunized with dendritic cells loaded with CEA were protected from tumor growth.

Furumoto *et al*[69] injected MIP-3 chemokine together with CpGs into colorectal carcinomas in order to activate *in vivo* dendritic cells without *ex vivo* manipulation. These workers observed an increase in the number of activated DCs in tumors that were eradicated through specific T cell-mediated antitumor response.

CD40L, a costimulatory molecule expressed on activated $CD4^+$ T cells, acts on B cells and DCs, and plays a key role both for maturation of antibody responses and for CTL induction. Investigators from Crystal's group demonstrated in studies on mice, synergy in the eradication of subcutaneously implanted CT26 when treated with a combination of intratumor injection of an adenovirus expressing CD40-L with DCs or when each treatment was applied sequentially[70,71].

Morse *et al* reported a phase I clinical trial in which autologous dendritic cells loaded with carcinoembrionic antigen RNA (peptide CAP-1) were administered to patients with resected liver metastases from colorectal carcinoma. The procedure was well tolerated, and one patient had a minor response, and one showed stable disease[72]. With the aim to expand the presence of circulating DCs (DC mobilization), Fong *et al*[73] in a phase I study used the hematopoietic growth factor Flt3 ligand prior to the injection of CEA-derived peptide loaded DCs in 12 patients with colon or non-small cell lung cancer. One patient had a mixed response while two showed stable disease.

DCs engineered to produce IL-12 have been shown to induce potent anti-tumor responses. We have recently completed a phase I clinical trial which involved intratumor injection of monocyte-derived autologous dendritic cells transfected *in vitro* with an adenovirus encoding human IL-12 in patients with metastatic gastrointestinal carcinomas[46]. The main objectives of the trial were to assess feasibility and safety, and secondarily to determine biologic and clinical responses. We observed that this strategy was safe and well tolerated, with injection of up to 50×10^6 dendritic cells. Five patients showed increased NK activity and 4 showed augmented intratumor $CD8^+$ T-cell infiltrate. One partial response and two stabilizations were observed. The reasons for the weak antitumor response were explored. It appears that DCs can be retained inside malignant tissue by means of high intratumor concentrations of IL-8. Besides, scintigraphic tracking of intratumorally injected DCs labelled with ^{111}In indicated the retention of DCs inside malignant lesions in patients with digestive carcinomas[74].

CYTOKINE GENE TRANSFER FOR COLORECTAL CARCINOMA IN CLINICAL SETTING

Over 1100 gene therapy clinical trials have been carried out around the world and almost 70% of them were directed at the treatment of advanced or metastatic cancer. In clinical trials, cytokine and tumor antigen genes represent 42% of the genetic material that is transferred (for details see: www.wiley.co.uk/genmed/clinical). In the following section, we focus on some of the most important cytokines currently under clinical investigation in immunogene therapy of colorectal carcinoma.

The encouraging results obtained with the administration of non-replicative adenovirus encoding for IL-12 genes in several experimental models of gastrointestinal cancers (for review see reference[1])

prompted us to initiate a clinical trial at the University of Navarra in patients with advanced gastrointestinal carcinomas[46]. Patients with hepatic tumors (either primary or secondary colorectal carcinomas) were treated intratumorally in a dose-scale fashion with an adenovirus encoding human IL-12 genes. This strategy was safe and well tolerated with only minor side effects. Biological activity was observed in some patients (e.g., rise in serum levels of IFN-γ, infiltration of tumors by $CD8^+$ T cells and induction of neutralizing anti-adenovirus antibodies). Partial tumor regression was observed in one patient and stable disease in 30% patients. Reduction in the gap between doses in the same patient, or application of the vector as neoadjuvant therapy before tumor resection are some of the potential approaches to increase the efficacy of this treatment strategy.

The dose-limiting toxicity of large systemic concentrations of TNF- has led to a decline in its use in cancer patients. By contrast, local gene transfer of this cytokine using an adenovirus (TNFerade®) may reduce the systemic effects. TNF- gene under the control of an early growth response 1 (EGR-1) promoter followed by external beam radiation allows the control of TNF- release. Promising antitumor activity without any significant toxicity was observed in patients with solid tumors[75]. TNFerade® in combination with capecitabine and radiation therapy is now being tested in a phase Ⅱ clinical trial on patients with rectal cancer, before surgical resection.

Rubin *et al*[76] showed that direct gene transfer of HLA-B7 and 2-microglobulin, which together form a MHC-I complex, into the liver of patients with metastatic colorectal carcinoma is a feasible and safe procedure. These workers used a single plasmid construct that encodes for both genes in a formulation containing the lipid complex DMRIE-DOPE (Allovectin-7®). Genes transfected into tumors were detected by PCR in 14 out of 15 patients, however. the clinical results have not published. It should be noted that better results have been obtained in patient with melanoma.

With the advent of agents such as irinotecan and oxaliplatin, chemotherapy has made some progress in the treatment of colorectal carcinoma. The use of biological therapy with monoclonal antibodies against VEGF and EGFR has been shown to benefit a small proportion of patients[77]. Immunotherapy in different forms should be tested in addition to the conventional treatment regimens which improve patient survival.

Concluding remarks and future directions

There is a striking correlation between lymphocyte infiltration in colorectal cancer and the overall outcome of the disease[78,79]. Indeed, the density of T cells close to the tumor cells in the primary tumor is a better predictor of survival in these patients than traditional staging based on tumor size and spread[80]. According to this study, patients whose tumors contained large numbers of CD3-positive T cells, had a 5-year survival rate of 73%, compared with 30% in patients with low density of these cells.

There are important conclusions to be drawn from this study: (1) There is much natural immune pressure on colon cancer that may control the disease successfully in many patients, (2) The immune pressure possibly selects tumor variants that eventually escape immune control, (3) Artificial augmentation of the immune response may tilt the balance towards a curative response at least in some cases.

Immunotherapy intervention requires tumor-debulking and therefore should be combined with surgery and chemotherapy. To make the most of immunotherapy, this technique should be tested on patients whose tumors have been completely resected but are at high risk of relapse. For instance, our current efforts are focused on patients whose liver metastases have been resected surgically and are receiving adjuvant chemotherapy. In these patients, measures to induce/enhance cellular antitumor immune responses may confer a clinically significant delay in tumor relapse. Moreover, the complete removal of any detectable disease greatly diminishes the immunosuppressive mechanisms that may otherwise be induced by the cancer, while the surgical samples provide a rich antigenic source for immunization. Interference with the immunosuppressive mechanisms is clinically feasible with the use of low doses of cyclophosphamide[81] and other such mechanisms may become clinically available in the near future.

In our opinion, it is at the stage of minimal residual disease when immunotherapy should be fully deployed with a combination of strategies comprising of immunization with different tumor antigens and amplification techniques using cytokines or/and immunostimulatory monoclonal antibodies[82].

Abstract

Even though liver metastasis accounts for the vast majority of cancer deaths in patients with colorectal cancer (CRC), fundamental questions about the molecular and cellular mechanisms of liver metastasis still remain unanswered. Determination of gene expression profiles by microarray technology has improved our knowledge of CRC molecular pathways. However, defined gene signatures are highly variable among studies. Expression profiles and molecular markers have been specifically linked to liver metastases mechanistic paths in CRC. However, to date, none of the identified signatures or molecular markers has been successfully validated as a diagnostic or prognostic tool applicable to routine clinical practice. To obtain a genetic signature for liver metastasis in CRC, measures to improve reproducibility, to increase consistency, and to validate results need to be implemented. Alternatives to expression profiling with microarray technology are continuing to be used. In the recent past, many genes codifying for proteins that are directly or indirectly involved in adhesion, invasion, angiogenesis, survival and cell growth have been linked to mechanisms of liver metastases in CRC.

Key words: Colorectal cancer; Liver metastasis; Genetic signature; Expression profile; Arrays

INTRODUCTION

Colorectal cancer (CRC) is the third most commonly diagnosed cancer, with a worldwide incidence of almost a million cases annually in both males and females[1]. Despite advances in screening, approximately 25% of patients have initially detectable liver metastases (synchronous metastases), and an additional 25% of patients will develop liver metastasis during the course of their disease (metachronous disease)[2]. Of all patients who die of advanced colorectal cancer (ACRC), 60% to 70% show liver metastasis[3]. Metastatic spread to the liver is the major contributor to mortality in patients with CRC.

CRC is a genetically heterogeneous and complex disease. Initially, two major pathways were described as being responsible for the CRC tumorigenic process: the chromosomal instability pathway and the microsatellite instability pathway. The chromosomal instability or classical pathway accounted for 85% of the tumorigenic processes and was mainly characterized by the sequential allelic losses on chromosomes 5q (APC gene), 17p (TP53) and 18q (DCC/Smad4). The microsatellite instability pathway (MNI), which is associated with the mutator phenotype, only accounted for 15% of the carcinogenic processes. Recently, it has been shown that colorectal carcinogenesis is much more complex, involving new pathways, such as the serrated, the TGFβ/Smad and epigenetic pathways, and also non-pure or mixed pathways[4-6].

The general mechanisms of tumorogenesis also include metastasis generation mechanisms. But, is the knowledge of CRC tumorigenic pathways extensible to metastasis generation? What do we really know about the molecular determinants of liver metastases formation in CRC?

MECHANISMS OF LIVER METASTASIS

Colorectal liver metastasis, or dissemination and colonization by colorectal tumor cells coming from the primary CRC to the liver, is a complex process and has many different steps. In order to metastasize, tumor cells detach from the primary tumor, invade and migrate through the stroma and intravasate into the lymphatic and/or venous vessels. With either as the vasculature entrance, cells will mainly end up travelling through the portal vein system. During transportation they manage to survive mechani-

Table 1 Summary of gene expression profile studies related to CRC liver metastasis

Source for transcription profile comparisons	Authors	Signature	Prediction
Primary tumors (Stage Ⅱ and Ⅲ)	Bertucci *et al*[11]	46 gene set	Lymph Node (+)
Primary tumors (Dukes C)	Arango *et al*[12]	Two different gene sets	Survival

[1]Mannosyl (alpha-1, 3-)-glycoprotein beta-1, 4-N-acetyl-glucosaminyl-transferase, which was found up-regulated in CRC liver metastases compared to primary CRC tumors; [2]Comparing SW480 to SW620; [3]Down-regulation of Cadherin 17 (CDH17)[11,22], Insulin-like growth factor 2 (IGF2)[14,17], Tyrosine 3-monooxygenase/tryptophan-5-monooxygenase activation protein (YWHAH)[12,16], DEK oncogene (DEK)[11,12] and GATA binding protein (GATA6)[11,14], up-regulation of Linker for activation of T cells (LAT)[14,16] and Protein Kinase, cAMP dependent, catalytic alpha (PRKACA)[12,14], and altered expression of IQ motif containing GTPase activating protein 1 (IQGAP1)[11,12], Tumor protein 53 (TP53)[11,12], Oligoadenylate synthetase 1 (OAS1)[11,12], Interferon regulatory factor (IRF2)[11,14], Retinoic acid receptor beta (RARB)[11,12] and Programmed cell death 10 (PDCD10)[12,13].

cal stresses and escape from the immune system. Some stresses keep acting once cells arrest in the liver capillaries. Some of the arrested cells manage to adhere to endothelial cells, contact the extracellular matrix and extravasate to the surrounding tissues. Kupffer cells, belonging to the monocyte-macrophage system, are a perfect barrier to unwanted hosts. Being in the liver parenchyma, tumor cells establish crosstalk with the stroma and create a microenvironment. Only if this microenvironment is favourable to tumor cells, signals of proliferation and neoangiogenesis will lead to macroscopic liver metastasis formation[7-9]. Even though liver metastasis accounts for the vast majority of all cancer deaths in patients with colorectal cancer, fundamental questions about the molecular and cellular mechanisms of liver metastasis still remain unanswered.

Genetic signatures: The breakthrough

The availability of DNA array technology, allowing genome-wide analyses of gene expression, has been providing new insights on the determination of gene expression or transcriptional profiles. Expression profiling studies in CRC have mainly focused on comparisons of normal mucosa, adenoma and primary carcinomas. Few studies have thrown light on differences between primary tumors and metastases. For this reason, in contrast to the many molecular alterations involved in the CRC adenoma to carcinoma step characterized to date, comparatively little information is available on the possible mechanisms of metastases, with even less for liver specific metastases[10].

There are two different aspects of metastasis to consider: metastatic ability and tropism or organ-specificity. Metastatic ability accounts for the potential to establish a distant secondary tumor. Organ-specificity or tropism means the capacity of this happening in a specific type of tissue. The ability to metastasize together with the specificity for it to happen in one organ and not in another can be genetically marked by what is called a metastatic signature. Studies looking at mRNA or protein levels take into account expression regulation, splicing mechanisms, epigenetic phenomena, and the complexity of post-translational changes or modifications. A metastatic signature, therefore, is not a gene list but is a translation of the functional status of gene expression. Metastatic signatures are gene expression patterns conditioned by both an intrinsic gene composition and phenomena regulating expression.

In order to determine metastatic signatures by microarray technology in CRC, three different strategies have been followed (Table 1). The first approach consists of comparing transcriptional profiles of primary CRC from metastasis-free patients to those affected by metastatic spread during a 5-year follow-up period. The main goal is finding gene expression profiles as prognostic markers of metastatic spread. Identification of a gene set capable of classifying CRC patients according to prognosis or 5-year survival rate was carried out by Bertucci *et al*[11]. A total of 219 genes and 25 genes were found to be respectively down- and up-regulated in metastatic samples when compared to non-metastatic patients. Moreover, a 46 gene set signature was isolated, discriminating between CRC with and without lymph node metastases. Arango *et al*[12] checked the expression profile of Dukes C CRC and reported two different signatures according to survival. Barrier *et al*[13] built an accurate 30-gene tumor-based prognosis predictor for stage Ⅱ and Ⅲ colon cancer patients, based on gene expression measures. The group of Komuro *et al*[14] analyzed gene expression profiles in a total of 89 CRC. After stratifying according to right and left locations, they were able to extract gene expression profiles characteristic of the presence versus absence of lymph node metastasis with an accuracy of more than 90%. Kwon *et al*[15] analyzed the gene-expression profiles of colorectal cancer cells from 12 tumors. Sixty genes possibly associated with lymph node metastasis in CRC were selected on the basis of clinicopathological data. Wang *et al*[16] analyzed RNA samples from 74 patients with Dukes' B CRC. Gene expression profiling identified a 23-gene signature that predicted recurrence. This signature was validated in 36 independent patients. The overall

performance accuracy was 78%. D´Arrico *et al*[17] compared the transcriptional profiles of 10 radically resected primary CRCs from patients who did not develop distant metastases within a 5-year follow-up period with those of 10 primary/metastatic tumor pairs from patients with synchronous liver metastases. The study was conducted on laser-microdissected bioptic tissues. Arrays of 7864 human cDNAs were utilized. Non-metastasizing primary tumors were clearly distinct from the primary/metastatic tumor pairs. Of 37 gene expression differences found between the 2 groups of primary tumors, 29 also distinguished nonmetastasizing tumors from metastases. The gene encoding for mannosyl (alpha-1, 3-)-glycoprotein beta-1, 4-N-acetyl-glucosaminyl-transferase (GnT-IV) became significantly upregulated in primary/metastatic tumor pairs ($P < 0.001$), supporting the existence of a specific transcriptional signature distinguishing primary CRCs with different metastatic potential[17].

The second approach consists of comparing gene expression in primary tumors with their matched metastases. Studies comparing gene expression between primary and corresponding metastases indicate that there is a high transcriptional resemblance. The above mentioned study found a striking transcriptional similarity between primary tumors and their distant metastases[17]. Another study by Koehler *et al*[18] determined expression profiles from 25 CRCs and 14 corresponding liver metastases using cDNA arrays containing 1176 cancer-related genes. Most primary tumors and matched liver metastases clustered together. A specific expression signature in matching metastases was not found, but a set of 23 classifier genes with statistically significant expression patterns in high- and low-stage tumors was identified. Gene expression studies in breast cancer also support the notion that primary tumors genetically resemble their matched metastases more than their primary counterparts[19]. Agrawal *et al*[20] found a signature of 11 markers for tumor progression when comparing gene expression among different stages, including liver metastases in a total of 60 samples.

Expression profiling using CRC cell lines with different metastatic potential is another approach[21,22]. Studies using cDNA microarrays have identified genes that are differentially expressed in primary *versus* metastatic CRC cell lines. Differential expression of 11 genes has been found in SW480 and SW620 CRC cell lines[21]. Unfortunately, metastatic signatures described in the above mentioned studies do not show much in common. Gene expression patterns do not overlap enough to show consistency. Only a few genes reported in at least two independent studies have been linked to metastatic ability (Table 1).

It is interesting that no expression profile has been specifically linked to liver metastases in CRC. Apart from gene expression profiling, other techniques, such as genomic profiling, have also been used to determine metastatic ability in CRC. Genomic analyses of primaries and their matched metastases[23] showed that CRC primary tumors resemble their corresponding metastases. Array-based comparative genomic hybridization (CGH) was used to detect genetic alterations in CRC that predicted survival after liver resection[24]. Genome wide copy number analysis revealed the involvement of Cycline D3 in liver metastases formation in CRC[25].

Genetic signatures: Handicaps and pitfalls

When determining metastatic expression profiles or signatures with array technology, several confounders have to be taken into account. Studies have employed important methodological differences, which are mainly due to the use of different array platforms (Affymetrix, cDNA nylon membranes) or experimental conditions. Tissue sampling is almost always an issue in this regard. Availability of frozen tissues is not the norm in many institutions. Formalin-fixed or paraffin-embedded tissues usually yield low quality RNA and/or DNA. The creation of frozen-tissue tumor banks is rapidly increasing. Also methodologies for RNA isolation can lead to different results. The number of samples used varies enormously in different studies. Relatively small cohorts of tumors have been analyzed in some studies, especially if they include the analysis of matched metastases. Selection of homogeneous samples among heterogeneous tumors can often be a problem. Anatomical localization (right *vs* left sided, colon *vs* rectum) and genetic instability status (MSI/classical) may justify the variability of CRC gene expression profiles characterized to date. Macrodissection techniques include tumor tissue with both tumor cells and tumor stroma and valid tissue samples should be at least 50% tumor cells. One of the major criticisms of "metastatic signature" -seeking studies is the fact that tumors are analyzed as a whole, mixing tumor cells with microenvironment and stroma components. Certainly, data coming from these experiments is a mixture representing gene expression of tumor cells, stroma cells as well as their interactions. Moreover, expression data can be highly conditioned by the host genetic background. Resulting data can be highly interesting in terms of defining prognosis, but not in understanding the mechanisms of metastasis generation. Microdissection techniques help to avoid this problem. Laser capture microdissection (LCM) allows isolation of only tumor cells and is considered the gold standard in microdissection procedures[26]. It is a time-consuming technique and it is not available at all institutions. Other strategies include subtracting non-tumor cell signatures from gene expression data[27]. It is still unclear whether the analysis of pure tumor cell populations will lead to an appropriate result in terms of prognostic value.

Description of metastatic signatures has been done on the basis of transcription analysis of tumors. Data from DNA microarray analysis is often overwhelming and mixed. Analysis of differentially expressed genes can be altered by the use of different criteria to define low-quality spots, different normalization procedures, different baseline references for ratio calculations, and arbitrary criteria for cut-off values applied to fold-change and significance level. Commonly, quantitative levels of expression are the basis for filtering the raw data. During filtering, information coming from qualitative data can be lost[10]. Moreover, the final data set has to be interpreted and integrated to make sense in biological terms. This step is highly subjective and probably often leads to false conclusions. Nearly

Table 2 Proteins related to liver metastasis formation and their function, and their differential expression when comparing primary tumors and liver metastasis by immunohistochemical technique

Proteins related to liver metastasis formation	Function	Liver expression compared to primary tumor (IHC)
E-Cadherin	Adhesion	Down-regulated[34]
Epithelial Cell Adhesion Molecule (EpCAM)	Adhesion	NA
P-Selectin and L-Selectin	Adhesion	NA
Carcinoembryonic Antigen (CEA)	Adhesion	NA
Integrin αvβ5	Adhesion, Survival	NA
sLex and sLea	Adhesion	Up-regulated[48,51]
Osteopontin (OPN)	Adhesion, Survival, Motility	Up-regulated[63]
Intracellular Adhesion Molecule (ICAM-1)	Adhesion	NA
Vascular Cell Adhesion Molecule (VCAM-1)	Adhesion	NA
CD44v6	Adhesion	NA
Cathepsine B	Invasion	NA
MMP-7	Invasion	Up-regulated[81]
MMP-2 and MMP-9	Invasion	Up-regulated[86]
Angiopoietin	Angiogenesis	Up-regulated[110]
Epidermal Growth Factor Receptor	Growth	Equal[125]
Urokinase Plasminogen Activator Receptor (uPAR)	Invasion, Motility, Dormancy	NA
Vascular endotelial Growth Factor (VEGF)	Angiogenesis	Equal[109]
Thrombospondin-1 (TSP-1)	Angiogenesis	NA
Angiostatin	Angiogenesis	NA
Endostatin	Angiogenesis	NA
Thimidine Phosphorylase (dThdPase or PDECGF)	Angiogenesis	NA
c-erb-2	Growth	NA
c-Src/β-Arrestin 1	Growth	NA
FAS Receptor (CD95)	Apoptosis	Down-regulated[134]
TRAIL Receptors (-R1, -R2, -R3 and -R4)	Apoptosis	NA
Nm23-H1 and Nm23-H2	Metastasis Suppresor Genes	NA
PRL-3	Motility, Extravasation	Up-regulated[157]

NA: Not available.

all studies lack internal and external validation tests for the generated lists of implicated genes. Different selection algorithms should be tested in order to improve the accuracy of the classifier sets[10].

In conclusion, to obtain a genetic signature for liver metastases in CRC, measures to improve reproducibility, increase consistency, and validate results need to be implemented.

Genes involved in liver metastasis formation in CRC

Alternatives to expression profiling by microarray technology have also been used in recent past years. Many genes codifying for proteins directly or indirectly involved in adhesion, invasion, angiogenesis, survival and cell growth have been linked to mechanisms of liver metastasis in CRC[28] (Table 2).

Adhesion: Different proteins involved in adhesion/deadhesion processes have been linked to liver metastasis development in CRC. Deadhesion is a necessary step for tumor cells to detach from a tumor and disseminate. Adhesion is needed for circulating cells to contact helping counterparts in the dissemination process. It is also needed to attach to the vascular endothelium, induce endothelial retraction, and subsequently bind to glycoproteins of the basement membrane to extravasate.

E-cadherin/α-catenin is a cell to cell adhesion complex that keeps tumor cells together. Cells detaching from the primary CRC undergo an epithelial to mesenchymal transition, during which E-cadherin downregulatates in favour of other cadherins, such as N-cadherin. This process is known as the "cadherin switch" and leads to acquisition of a mesenchymal phenotype that favours invasion and migration through the stroma and thus dissemination of tumor cells[29]. Downregulation of E-cadherin/α-catenin expression has been related to tumor aggressiveness[30,31] and metastatic potential[32,33] in gastrointestinal cancers. Low expression of α-catenin and E-cadherin in CRC patients has been associated with an increment of β-catenin[34-36], advanced stages[33,37,38] and acquisition of metastatic potential[39,40]. Immunohistochemical studies show that CRCs metastasizing to liver have a significant ($P = 0.014$) reduction or complete absence of E-cadherin expression when compared to non-liver metastases[34].

Epithelial cell adhesion marker (EpCAM) is a widely expressed adhesion molecule. It has been found to present a more diffuse pattern and higher expression in CRC compared to non-malignant tissues[41]. EpCAM plays a role in modulating cadherin mediated cell-cell interactions[42] and its expression has been linked to downregulation of cadherin levels[43], suggesting that this protein possibly plays a role in ETM processes, facilitating migration and dissemination of tumor cells. Supporting this notion, isolation of EpCAM positive cells in blood samples of advanced CRC patients[44] has recently been achieved. All these preliminary data suggest that possibly EpCAM plays a role in CRC cell dissemination. Whether there is liver specificity remains unknown.

Sialyl Lewis X (sLex or CD15s) and A (sLea) are oligosaccharides commonly found in surface glycoproteins

of metastatic tumor cells[45]. sLex and sLea are natural ligands for E-selectin, which is a receptor that has been found to be expressed by activated endothelial cells. Interaction between sLex and sLea induces endothelial adhesion of tumor cells and thus favours stasis, extravasation and metastases formation. sLex and sLea expression in primary CRC have been related to poor prognosis[46] and metastatic potential[46-48] in CRC patients. sLex and sLea stain significantly positive in vessel invasion CRC cells that develop metastases compared to those that do not (71.4% *vs* 31%)[49]. sLex and sLea have been found to be present on the surface of tumor cells[50] in CRC patients who develop liver metastases. Similarly, CRC liver metastases express sLex and sLea in a larger proportion of tumor cells than in primary tumors[48,51]. E-selectin is overexpressed by endothelial cells from tumor and non-tumor vessels in CRC patients who develop liver metastasis[52,53]. In general, as has been demonstrated in *in vivo* models, glycosylated and sialylated mucins are associated with liver metastasis formation[54]. Some proteins allow the adhesion of CRC cells with blood components, such as platelets and leukocytes. Among those proteins are P-Selectin and L-Selectin. This interaction facilitates tumor emboli formation, favouring protection of tumor cells from immune attack and also enhancing their ability to contact blood vessels by mechanical means. This interaction between tumor cells and blood cells also increases contact with the endothelial surface, facilitating stasis and thus enhancing the chances of extravasation[55].

Carcinoembryonic antigen (CEA) is a cell surface glycoprotein containing significant amounts of sLex and sLea. Expression of (CEA) has been clearly correlated to generation of liver metastases in experiments transfecting CEA to CRC cell lines or administering CEA in animal models previous to CRC cell injection[56]. Initially it was speculated that CEA would act as an adhesion molecule, facilitating tumor cell aggregation and interaction with the endothelial surface. However, studies with immunosuppressed mice show that administration of intravenous CEA results in an increase of hepatic colonization and retention of CRC cells, but not an increase of adhesion[57]. Kupffer cells that express a CEA receptor bind to and degrade it, activating a signaling cascade that ends up releasing IL-1, 6 and TNF-α which, in turn, facilitates CRC cell stasis and growth[58,59]. The ability to secrete CEA offers CRC cells a selective advantage in forming metastases in the liver.

Integrins are molecules that can bind to many ECM components, such as laminin, collagen, fibronectin and vitronectin. Cancer cells expressing integrins are more likely to adhere to ECM components surrounding microvasculature. High expression of $\alpha 6\beta 4$ and $\alpha 5\beta 3$ integrins has been related to a more aggressive CRC phenotype[60,61]. Intravital fluorescence-video microscopy has been used to investigate liver metastas formation by CRC cells in animal models[62] and results have shown that $\alpha v\beta 5$ integrin is useful as an adhesion molecule and its inhibition diminished liver metastas formation.

Osteopontin (OPN) is a secreted phosphoglycoprotein capable of binding and inducing integrin-mediated cell survival, motility and anti-apoptotic intracellular pathways. OPN has been isolated in gene expression profiling studies as a candidate marker for CRC progression[20]. CRC liver metastases express OPN at higher ratios than primary CRC or normal mucosa[63]. OPN up-regulation can occur due to TCF4/LEF transcription factor activation[64]. Mechanisms by which OPN promotes liver metastases formation in CRC are unknown, but could be related to up-regulation of Upa[65], c-Met receptor and integrins[66].

Other adhesion molecules, such as the intracellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1), have been measured in ACRC patients showing higher serum levels when compared to non-advanced CRC or healthy controls[67,68]. Nevertheless, neither clinical nor physiological relation has been established with specific development of liver metastases.

CD44 glycoprotein, more specifically v6 and v8-10 splicing variants, have been related to metastases and disease recurrence in CRC[69,70]. There is quite a bit of controversy regarding the real value of CD44 in liver metastases formation because plasma levels have not been linked to advanced stages of the disease[71] and immunohistochemical studies measuring CD44v6 staining have not found significant differences when comparing CRCs metastasizing to liver or not[34].

Invasion: Invasion processes are crucial for liver metastasis formation in CRC. Invasion occurs mainly due to basal membrane and extracellular matrix (ECM) degradation in both intravasation and extravasation steps. Some of the enzymes responsible for degradation are proteases. Among proteases, matrix metalloproteases (MMPs), cathepsins and plasminogen activators are the most relevant.

Matrylysin (MMP-7) is a proteolytic enzyme belonging to the MMPs family[72,73]. It is synthesized and secreted by tumor epithelial cells as a 28-kDa proenzyme, which can be activated through proteolytic removal of a 9-kDa prodomain from the N-terminus. The soluble activated form binds to the tumor epithelial cell surface. Both active forms, the soluble and the membrane-bound, have proteolytic activity. Its expression can be regulated by epidermal growth factor through transcription factors such as PEA3[74] or AP-1 and the β-catenin/ tcf4 complex. By degrading elastin, laminin, proteoglycans, osteopontin, fibronectin and type Ⅳ collagen, MMP-7 gains the capacity to invade. Matrilysin can also promote tumor invasion by activating other MMPs (MMP-2, MMP-9), through ectodomain shedding of E-cadherin[75] and receptor activator of nuclear factor-kappa B ligand (RANKL)[76] or through cleavage of adhesion molecules, such as integrin $\beta 4$[77].

Matrilysin has been found overexpressed in CRC[78]. MMP-7 overexpression in localized CRC disease has been correlated with invasion and liver metastasis formation[79,80]. Colorectal liver metastases show intense expression of MMP-7 compared to normal liver, and differences are more evident when comparing the MMP-7 activated form, measured by zymography, emphasizing the role of MMP-7 in CRC liver metastases formation[81]. While testing liver metastasis formation *in vivo*, it has been shown that treating colorectal cancer cells with MMP-7 specific antisense

oligonucleotides leads to a decrease in liver metastasis generation[82], while adding active MMP-7 results in an increase of liver metastasis generation[83].

MMP-9 and MMP-2 also seem to play a role in liver metastasis formation in CRC. High MMP-9 and MMP-2 levels have been detected by immunohistochemistry in the tumor-stroma interface in both primary CRC and liver metastases[84,85]. Moreover, MMP-2 and -9 activities seem to be higher in metastases than in the originating primary tumor[86]. A close correlation between high MMP-9 RNA levels and worse survival and higher risk of liver relapse after surgery has also been established[81].

Cathepsins have also been implicated in liver metastasis formation in CRC. They are a family of proteolytic enzymes with a wide variety of physiological functions. They act as serin-proteases, cystein-proteases or aspartate-proteases. They are stored as proforms in cell lysosomes and secreted to the ECM secondarily to inflammatory and oncogenic stimuli[87].

Cathepsins B, L and D are especially involved in ECM degradation in CRC. Their levels and activity[87-88] have been found to be elevated in the invasion edge of CRC. Still, Cathepsin B is the most valuable in determining invasion in CRC[89]. Cathepsin B degrades ECM directly or indirectly, by stimulating other proteases or blocking their inhibitors[87]. It can be detected in early stages of CRC but it is a good marker to determine metastatic disease[90,91]. High plasma and urine levels of Cathepsin B have been found in CRC patients[92]. *In vivo* experiments show that inhibition of Cathepsin B by selective compounds results in reduction of liver metastases formation up to 60% and reduction of liver metastases burden up to 80%[93]. A proteolytic profile, taking into account MMP and cathepsin expression, has been defined for CRC by some authors[94].

Urokinase plasminogen activator receptor (uPAR) is a factor involved in metastasis development in several cancers[95,96]. uPAR binding to urokinase plasminogen activator (uPA) enhances plasmin production which, in turn, degrades ECM and activates pro-MMPs. Inhibition of uPAR expression is associated with decreased motility and invasiveness in the human CRC cell line HCT116[97]. High uPAR expression in CRC has been related to low 5-year survival[98]. Use of antisense uPAR mRNA in a nude mice model inhibited CRC liver metastasis development[99].

During invasion, apart from basal membrane and ECM degradation processes, cancer cells have to migrate through the stroma. Clues for success are acquisition of a mesenchymal phenotype during ETM and ability to survive independently of the tumor cell population. To gain the ability to disseminate, tumor cells have to detach from the tumor population, overcome anoikis and transit from an epithelial to a mesenchymal phenotype. As a principle, cells need to be in contact with other cells in order to survive. If they lose contact or penetrate to the ECM they undergo anoikis. Overcoming anoikis, an apoptotic program related to tumor cell population detachment, is a necessary requirement to disseminate. Integrins are responsible for epithelial cancer cell cross-talk with the ECM in order to overcome anoikis, survive and migrate.

In vitro experiments have shown that activation of Src and Akt pathways are linked to decreased sensitivity of detached CRC cells to anoikis[100]. Down-regulation of $\alpha v\beta 3$ integrin has also been linked to resistance to anoikis in CRC cells[101,102]. Integrins can bind to many ECM components such as laminin, collagen, fibronectin and vitronectin. Cancer cells expressing these integrins are more likely to invade and migrate through the ECM[103,104]. High expression of $\alpha 6\beta 4$ and $\alpha 5\beta 3$ integrins has been related to more aggressive CRC phenotypes[60,61]. Intravital fluorescence-video microscopy has been used to investigate liver metastasis formation by CRC cells in animal models[62] showing that $\alpha v\beta$-integrin inhibition did not affect migration within the liver parenchyma. The role of integrins in the migration and invasion through the ECM in order to generate liver metastasis has not been extensively explored.

Angiogenesis: Different angiogenic factors have been related to metastasis formation because they can promote primary tumor growth and increase tumor cell chances to contact blood and thus disseminate. However, it is likely that angiogenesis plays a major role in metastasis generation regulating micrometastases outgrowth. Balance between angiogenic/antiangiogenic factors in the microenvironment of the metastatic tissue can promote metastasis formation by directly stimulating tumor cell growth or by increasing blood vessel formation and supply. Even in quiescent tumor cells, alteration of angiogenic balance can induce metastasis formation. This phenomenon is known as "angiogenic switch"[105] and causal factors are still under investigation.

Expression levels of vascular endothelial growth factor (VEGF) in primary CRC have been related to a poor prognosis[106]. VEGF isoform patterns have been defined using reverse transcription polymerase chain reaction (RT-PCR) analysis in 61 primary CRC. Patients developing liver metastases showed expression of VEGF121 + VEGF165 + VEGF189 at a significantly higher incidence (12 of 16, 75%) than those without liver metastasis (20 of 45, 44%) ($P = 0.036$)[107]. VEGF expression in primary CRC seems clearly associated with increased chances of dissemination. However, other studies support the contrary[108]. When VEGF mRNA levels were measured in 31 pairs of primary CRC and corresponding liver metastases, no significant differences were detected (median value 3.79 *vs* 3.97: $P = 0.989$). On an individual basis, there was a significant correlation in VEGF mRNA expression between primary CRCs and matched liver metastases ($r = 0.6627$, $P < 0.0001$). VEGF mRNA levels of patients having two or more liver metastatic tumors were significantly higher than those of patients who had solitary liver metastatic tumors in both primary cancer (5.02 *vs* 3.34: $P = 0.0483$) and liver metastases (4.38 *vs* 3.25: $P = 0.0358$)[109]. Together these results indicate that VEGF is probably not more active in metastases than in primary tumors. Despite that, increased blood supply and tumor vessel formation, as estimators of angiogenic activity, have been found to be higher in liver metastases that in primary CRC. Some molecular mediators have been thought to fulfill this role, such as angiopoietin-2 (Ang-2)[110].

Other distinctive molecules related to angiogenesis and

liver metastatic progression are platelet-derived endothelial cell growth factor or thymidine phosphorylase (PD ECGF or dThdPase). Inhibitors of angiogenesis, such as angiostatin, endostatin and thrombospondin-1 (TSP-1), either secreted by the primary or the metastatic CRC cells, can also regulate liver metastasis growth. Frequency of hepatic recurrence was significantly higher in patients with TSP-1-negative primary CRC[111]. Angiostatin transfected cells developed liver metastases in lower proportion than controls in animal models[112]. Removal of primary CRC resulted in an increase in metabolic activity in liver metastasis, while decreases in plasma levels of angiostatin and endostatin were observed. This finding indicates that primary tumors suppressed angiogenesis in distant metastases, and that removal of the primary lesion caused a flare-up in vessel neoformation and, thus, enhanced metabolic activity in liver metastases[113].

Other molecules mentioned above also contribute to liver metastasis formation through angiogenesis regulation. MMP-7 induces a direct proliferative effect on vascular endothelial cells[114] and produces angiogenesis inhibitors (angiostatin, endostatin, neostatin-7)[115] and activators (sVEGF)[116]. MMP-2 and MMP-9 stimulate degradation of ECM, increasing the availability of angiogenic activators. E-selectin acts by facilitating endothelial cell migration. α and β integrins play an important role by sending survival signals for endothelial cell maintenance[117].

Cell growth: Once established in the liver tissue microenvironment, micrometastases need growth factor stimuli in order to grow. Degradation of ECM results in an increased availability of growth and inhibitory factors. The resulting balance will then determine micrometastasic growth. Extrapolation to a non-physiological situation can be highly illustrative. Liver tissue thermal ablation was performed in mice models bearing CRC liver metastases. After ablation, increased expression of FGF-2 and VEGF was detected in the surrounding tissue. Subsequently, a greater amount of metastases occupied the regenerated thermal-ablated lobe compared with controls (55% ± 4% *vs* 29% ± 3%, $P < 0.04$)[118].

Tumor cells growth factor receptors also seem to determine success in metastatic liver growth. Her-2/neu has been detected by immunohistochemistry in 5% to 50% of primary CRC[119]. The mechanism of overexpression seems to be not linked to gene amplification. Her-2/neu positive CRCs were associated with higher postoperative non-liver specific recurrence rates (39.3% *vs* 14.6%, $P = 0.013$) and worse prognosis at 5 years (55.1% *vs* 78.3%)[120]. Other studies showed that primary CRC with high c-erbB-2 expression (27%), determined by immunohistochemical techniques, develop liver metastases more often than CRC with low c-erb-2 expression (3%)[49].

Epidermal growth factor receptors (EGFR) have been reported to be highly expressed and/or gene amplificated in 72% to 82% of metastatic CRC tissue samples[121-123]. Some studies have reported that expression of EGF receptors in CRC is associated with aggressiveness and metastatic ability. EGFR status has been shown to express similarly when measured in primary CRC and corresponding liver metastases[124]. However, some authors have seen that its status in the corresponding metastatic site is not always the same[125,126]. Conventional immunohistochemistry techniques have not been able to reveal any association between EGFR expression and outcome predicted by the biological role of EGFR in tumor behavior[127].

The C-Src gene, codifying for pp60 tyrosine kinase, has been reported to be mutated and thus is highly activated in CRC, implying an increase in proliferative potential. High activation is present especially in those CRC that metastasize to liver[128,129]. Prostaglandin E_2 (PGE_2)-induced transactivation of the EGF receptor (EGFR) in colorectal carcinoma cells has been recently found to be mediated by β-arrestin 1, which acts as an important mediator in G protein-coupled receptor-induced activation of c-Src. Interaction of beta-arrestin 1 and c-Src seems to be critical for the regulation of CRC metastatic spread of disease to the liver *in vivo*[130].

Cell survival: CRC cells need molecular factors, specifically growth factors, in order to survive in the liver parenchyma. However, there is also the need to survive immune system action (immunoescape) and to overcome anoikis.

Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), a member of the TNF family, is known to be expressed in human hepatic NK cells[131]. CRC cells expressing TRAIL-receptor would undergo apoptosis upon triggering the ligand. The same would happen in CRC cells expressing tumor necrosis factor receptor FAS (Apo-1; CD95) when contacting its corresponding ligand FASL (Apo-1L; CD95L) expressing cells, as activated lymphocytes.

During the CRC tumorigenic process, cells tend to down-regulate FAS receptor expression and up-regulate FASL[132]. Fas expression is significantly down-regulated in liver metastasis compared to corresponding primary colorectal carcinoma[133]. The link between functional Fas status and malignant phenotype was investigated using matched pairs of naturally occurring primary (Fas-sensitive) and metastatic (Fas-resistant) human colon carcinoma cell lines in both *in vitro* and *in vivo* (xenograft) settings. Results showed that loss of Fas function was linked to the acquisition of a detectable metastatic phenotype, however, only loss of Fas function was insufficient. Also, results showed that metastatic subpopulations pre-existed within the heterogeneous primary tumor and that anti-Fas interactions served as selective pressure for their outgrowth. Thus, Fas-based interactions may represent novel mechanisms for the biological or immunological selection of certain types of Fas-resistant neoplastic clones with enhanced metastatic ability[134]. Moreover, univariate and multivariate analyses revealed that Fas/CD95 expression in CRC resected liver metastases is a significant prognostic indicator of survival[135]. Increases in TRAIL sensitivity, due to changes in the balance between TRAIL receptors TRAIL-R1 and -R2 and "decoy" receptors TRAIL-R3 and -R4, have also been described during malignant progression in CRC. Still, studies measuring receptors by flow cytometry have not

been conclusive[136].

Experimental metastases studies with a CRC cell line allowed the characterization of metastatic derivatives, showing that they were less susceptible for killing by syngeneic NK cells, due to a decreased sensitivity towards TRAIL- and CD95L[137]. Data suggest that CRC cells forming metastases acquire the ability to surpass immune surveillance through desensitization to FAS/TRAIL killing. As discussed previously, integrins and Src activation may contribute to CRC progression and liver metastasis, in part, by activating survival pathways that decrease sensitivity of detached cells to anoikis[100].

Other molecules related to liver metastatic spreading: k-ras (12p) activation, present in 40% to 50% of sporadic CRC[4], has been related to a decrease in overall survival and disease free survival in CRC[6,138,139]. p53 (17p) abolition, occurring in 70% to 80% of CRC[4] and resulting in accumulation of abnormal protein detectable by immunohistochemistry, has been linked to a poor prognosis[6,140-142]. The deletion or mutation of the DCC (deleted in colorectal cancer) gene has also been related to poor prognosis tumors[143-146]. Even p53, Ras and/or DCC alterations have been linked to metastatic spreading in CRC, however, there is still no evidence specifically relating them to liver metastasis formation. The human nm23 genes, nm23-H1 and nm23-H2, are candidate metastasis suppressor genes. Their role in CRC is still confusing. Some authors claim that a reduced protein expression, secondary to gene alterations, is associated with metastasis development[147,148]. Genetic alterations were detected in four of eight CRCs associated with metastasis in lymph nodes, lung, or liver, while no alteration was observed in 12 additional CRC specimens without metastasis[149]. Others have found that gene overexpression is linked to higher recurrences, liver metastasis and decreased overall survival[150,151]. This contradiction could be explained if overexpression of nm23 was a reflection of a deletion in the nm23 gene, leading to accumulation of an altered protein product. However, more recent works have not been able to relate nm23 expression to prognosis[152-154]. The PRL-3 protein tyrosine phosphatase gene gained importance in 2001 when an article was published in Science showing that it was expressed at high levels in each of 18 cancer metastases studied but was expressed at lower levels in nonmetastatic tumors and in normal colorectal epithelium[155]. Subsequently, new data established an unexpected and unprecedented specificity in metastatic gene expression profiles: PRL-3 was apparently expressed in CRC metastasis to any organ but was not expressed in metastases of other cancers to the same organs or in nonmetastatic CRC[156]. At that time PRL-3 was determined to be a potential marker for liver metastasis of CRC with a negative impact in prognosis[157]. CRC specificity was objected to in further studies. Some authors claimed that PRL-3 acted by enhancing cell motility and thus facilitating extravasation into liver tissue[158]. The mechanism of action is still under investigation but it has already been related to integrin $\alpha 1$[159] and the Rho family of small GTPases[160].

CONCLUSION

A significant amount of experimental data points to tumor cells having a metastatic signature. This signature codifies not only for the ability to form metasteses but also for organ-specificity. DNA microarray technology has significantly improved efficiency in wide-range analysis of gene expression. Many authors have provided gene expression profiles that have been related to CRC liver metastases, however, in order to obtain a real genetic signature for liver metastases in CRC by transcription profiling, measures to improve reproducibility, increase consistency, and validate results need to be implemented. Seeking metastatic signatures through expression profiling is a tool to fight cancer, but its indiscriminate use can be misleading. Advances in molecular assays on isolated cells and in the study of cell-cell and cell-stroma interactions will likely enable the dissection of the metastatic cascade. Genes codifying for proteins directly or indirectly involved in adhesion, invasion, angiogenesis, survival and cell growth have already been linked to mechanisms of liver metastases in CRC. Improvement in knowledge of the molecular pathways involved in the development of colorectal liver metastasis will lead to a better approach to prevent and treat this disease.

Abstract

Novel molecular targets are being discovered as we learn more about the aberrant processes underlying various cancers. Efforts to translate this knowledge are starting to impact on the care of patients with gastrointestinal cancers. The epidermal growth factor receptor (EGFR) pathway and angiogenesis have been targeted successfully in colorectal cancer with cetuximab, panitunumab and bevacizumab. Similarly, EGFR-targeting with erlotinib yielded significant survival benefit in pancreatic cancer when combined with gemcitabine. The multi-targeting approach with sorafenib has made it the first agent to achieve significant survival benefit in hepatocellular carcinoma. Efforts to exploit the dysregulated Akt/mTOR pathway in GI cancer therapy are ongoing. These molecular targets can be disrupted by various approaches, including the use of monoclonal antibody to intercept extracellular ligands and disrupt receptor-ligand binding, and small molecule inhibitors that interrupt the activation of intracellular kinases.

Key words: Colorectal; Pancreatic; Liver cancers; Targeted therapy; Epidermal growth factor receptor; mTOR; Angiogenesis

INTRODUCTION

Cellular proliferation, differentiation and death are regulated by a number of extracellular factors, such as hormones, cytokines and growth hormones. Interactions between extracellular stimuli and the nucleus is mediated by a complex and interconnecting network of signaling pathways[1]. This process is often abnormal in cancer cells and our understanding of these molecular events led to the identification of novel targets for therapy development. Various approaches are been used to target these dysfunctional elements, including ligand neutralization, disruption of receptor binding, and inhibition of receptor kinases and intracellular signal messengers.

A plethora of compounds are now under development that targets these aberrant processes. Almost all of these biological agents have limited single agent activity but are synergistic when combined with conventional cytotoxic agents[2]. Therefore, they are usually tested in combination with standard therapy in specific cancer types. In colorectal cancers, fluorouracil-based regimens form the backbone of therapy in both adjuvant and metastatic settings[3-5]. Likewise, gemcitabine based therapy remains the cornerstone for untreated advanced pancreatic cancer and sorafenib is likely to become the standard therapy for hepatocellular carcinoma (HCC)[6-8].

Successful targeting of angiogenesis and the epidermal growth factor pathway has made colorectal cancer a prototypical model for the development of signaling pathway-specific agents in gastrointestinal (GI) cancers[9-11]. Akt/mTOR pathway is another candidate target in anti-cancer therapies[12]. This paper will review the approaches currently used to exploit these novel targets in the development of GI cancer therapy. The review will focus specifically on colorectal, pancreatic and primary liver cancers (hepatocellular carcinoma, or HCC).

EPIDERMAL GROWTH FACTOR RECEPTOR PATHWAY

Epidermal growth factor receptor (EGFR) is a member of the HER-family kinases, which includes EGFR, HER2, Erbb3 and Erbb4[13,14]. Upon ligand binding, EGFR homodimerizes with another EGFR or other members of the HER-family (heterodimerization), and lead to the activation of proliferative and survival signaling pathways, such as the Ras/Raf/MEK (mitogen-activated protein kinase, or MAPK) and Akt/mTOR cascades[15].

Abnormal expression or regulation of epidermal growth factors (EGF) and the receptors are implicated in the pathogenesis of many malignancies[16]. EGFR is overexpressed or up-regulated in colorectal cancers and pancreatic cancers, and is associated with early progression

and poor survival[17-22]. Similarly, EGFR is overexpressed in HCC and is associated with aggressive features with increased cellular proliferation and reduced apoptosis. *In vitro* inhibition of EGFR in HCC cell lines results in cell cycle arrest and apoptosis[23-25]. These led to the clinical development of anti-EGFR agents as single agent, or in combination therapy in view of their *in vitro* and *in vivo* synergistic activity with cytotoxic agents[26].

Cetuximab

Cetuximab is a chimeric murine/human IgG1 monoclonal antibody that blocks ligand-dependant EGFR receptor activation. The antibody has a higher affinity for the receptor than the ligands, such as EGF and transformaing growth factor (TGF-α)[27-29]. The drug is cytostatic when administered alone but highly synergistic with irinotecan in refractory colorectal cancer xenografts, leading to clinical development in irinotecan-refractory colorectal cancer patients[30,31]. In the pivotal multi-center randomized phase Ⅲ trial, 329 patients with metastatic colorectal cancer who progressed on irinotecan-based therapy were randomized to receive cetuximab alone or a combination of cetuximab and irinotecan[9]. The patients in the combination arm achieved a superior response rate of 22.9% and median time to progression of 4.1 mo compared to 10.8% and 1.5 mo in the monotherapy arm respectively. The median survival was not statistically different between the two groups.

Compared to best supportive care, metastatic colorectal cancer patients who failed multiple previous regimens achieved better overall survival, time to progression and quality of life with cetuximab monotherapy in the recent study by National Cancer Institute of Canada Clinical Trials Group (NCIC-CTG) and Australasian Gastro-Intestinal Trials Group (AGITG)[32]. In the first line setting, Cetuximab improved response rate and time to progression when administered in combination with irinotecan-based regimen (FOLFIRI) in the CRYSTAL trial[33].

The efficacy of cetuximab with oxaliplatin-based regimen (such as FOLFOX) in second- and first-line settings is being evaluated in randomized trials (the EXPLORE and OPUS trials, respectively)[34-36]. However, the addition of cetuximab to oxaliplatin based fluoropyrimidine regimens (FOLFOX or CapOx) seemed to increase the frequency of grade 3/4 adverse events, specifically gastrointestinal toxicities, rash and lethargy[37]. The role of cetuximab in adjuvant, or postoperative, setting is being studied in 2 ongoing randomized trials (PETACC-8, Intergroup 0147) in combination with oxaliplatin-containing regimens[38-40].

Cetuximab is approved by FDA in U.S. for use in patients with EGFR-expressing colorectal cancer who failed previous irinotecan-based therapy. This was due to the fact that the trials mentioned enrolled only patients with EGFR-expressing tumors, based on preclinical data suggesting the predictive value of EGFR expression for cetuximab efficacy. However, patients with EGFR-negative colorectal cancer were later found to benefit from cetuximab therapy as well, suggesting that EGFR expression level does not correlate with cetuximab response[41,42]. This is an important lesson for the development of biological agents: patient selection based on expression, or non-expression, of specific molecular markers can be faulty. Such hypothesis should be validated vigorously in well-designed clinical trials.

The side effects of cetuximab are fairly tolerable with appropriate management. Hypersensitive infusion reaction was reported in about 3% of the patients. About 75% of patients receiving cetuximab developed a mild acneiform-like rash. The development of cetuximab-related rash seemed to correlate with response but this needs to be studied further[43].

Cetuximab was evaluated in combination with gemcitabine in advanced pancreratic cancer. Despite encouraging phase Ⅱ results, the recent randomized phase Ⅲ trial (SWOG S0205) failed to confirm the superiority of cetuximab plus gemcitabine combination over gemcitabine monotherapy in this patient population[44].

Cetuximab monotherapy proved to be tolerable in patients with advanced HCC though activity was lacking in phase Ⅱ trials[27,45]. Gruenwald *et al* enrolled 32 unresectable HCC patients and 27 were evaluable. Seventy-two percent (23 of 32) had Child-Pugh Stage A cirrhosis, 25% Stage B and 3% Stage C. Previously treated patients were eligible for this trial and 44% achieved stable disease for at least 8 wk and median time to progression was 22.5 wk. The agent is been evaluated in combination with cytotoxic chemotherapy in HCC[46].

Panitumumab

Panitumumab is a fully humanized anti-EGFR monoclonal antibody that is being evaluated in metastatic colorectal cancer. The agent has the advantage of avoiding the hypersensitive reaction typical of chimeric murine proteins, such as cetuximab. In a multi-institutional phase Ⅲ trial, patients with refractory metastatic colorectal cancer were randomized to receive panitumumab plus best supportive care or best supportive care alone[47]. Eight percent (8%) of patients receiving panitumumab achieved partial response. About 90% developed the characteristic acneiform rash comparable to cetuximab monotherapy. As expected and importantly, hypersensitivity infusion reaction for the humanized monoclonal antibody was lower than that reported for cetuximab. Combination regimens containing panitunumab are been evaluated clinically.

Erlotinib

Erlotinib is an oral quinazoline that reversibly inhibits EGF receptor tyrosine kinase. The small molecule induces in vitro cell cycle arrest and apoptosis, and has *in vivo* anti-tumor effects[48,49]. Major side effects are rash and diarrhea, characteristic of this class of drug. Erlotinib was approved in 2004 by FDA in U.S. for use as single agent in previously treated non-small cell lung cancer (NSCLC) following the demonstration of survival benefit in a randomized phase Ⅲ trial (NCIC-CTG BR.21)[50]. EGFR mutations seems to correlate with the efficacy of anti-EGFR therapy in NSCLC though effort to uncover additional molecular predictors continues[51].

Among GI cancers, erlotinib is furthest along clinical development in pancreatic cancer. Gemcitabine has been

Table 1 Agents targeting EGFR pathway in GI cancers

Agents	Tumor types	Regimen	Study design	References

RT: Radiation therapy.

the standard first-line therapy for advanced pancreatic cancer in improving symptoms and survival, but not curative[6]. In the NCIC-CTG sponsored multi-institutional trial, 569 patients with untreated advanced pancreatic adenocarcinoma were randomized to receive gemcitabine plus erlotinib or gemcitabine plus placebo[52]. Intension-to-treat analysis showed longer survival in patients receiving erlotinib plus gemcitabine (6.24 mo *vs* 5.91 mo; HR 0.82, $P = 0.038$) compared to gemcitabine only. One year survival was also higher in the erlotinib-containing arm (23% *vs* 17%, $P = 0.023$). Unlike colorectal cancer, tumor EGFR expression was not a pre-requisite in this trial. There was more frequent mild grade rash, diarrhea and hematological toxicity in the combination arm but the frequency of moderate and severe toxicities were comparable in both arms. However, routine use of erlotinib and gemcitabine combination cannot be recommended in patients with advanced pancreatic cancer in view of the high cost of erlotinib[53].

Erlotinib use in colorectal cancer remains investigational. The drug showed encouraging result when used in combination with capecitabine and oxaliplatin in previously treated disease in phase Ⅱ trial[54]. The result needs to be validated in a larger randomized trial. The drug had unacceptably high rate of toxicity when combined with dose-reduced FOLFIRI in patients with metastatic colorectal cancer[55].

Erlotinib is being tested in untreated advanced HCC patients in an ongoing open-labeled phase Ⅱ trial[56]. Tumor EGFR expression is not an exclusion criteria in this trial. Interim analysis of 25 patients suggested a longer median survival among erlotinib-responding patients of 44 wk compared to 25 wk in erlotinib-non-responders. All responders developed rashes. The trial aims to accrue a total of 40 patients.

Lapatinib

Lapatinib is an interesting oral inhibitor of two tyrosine kinases: ErbB1 (EGFR) and ErbB2 (HER-2/*neu*). The agent has significant efficacy in advanced breast cancer when combined with capecitabine[57]. Both EGFR and HER-2/*neu* are co-expressed in colorectal cancer cells and simultaneous targeting of these receptors in preclinical studies enhanced apoptosis. Lapatinib is currently being tested in previously treated colorectal cancer patients[58,59].

EGFR pathway proves to be a valid target in GI cancers, especially in colorectal cancer with cetuximab and panitumumab. The small but statistically significant survival improvement by erlotinib in pancreatic cancer has been more a demonstration of "proof-in-principle" and the optimal approach to using anti-EGFR agents in pancreatic cancer still needs to be defined. Lapatinib development will hopefully shed light on whether dual-targeting of the ErbB receptor family is a successful approach in colorectal cancer (Table 1).

ANGIOGENESIS

Angiogenesis is vital to cellular growth, reproduction and development[69]. The process is often pathological in cancers, driven by an imbalance of pro- and anti-angiogenic factors in tumors[70]. The resulting tumor-induced vasculature is often leaky and dysfunctional, leading to increase interstitial pressure that impedes the delivery of both oxygen and chemotherapeutic agents[71].

VEGF-A (commonly known as VEGF) is among the first angiogenic factor discovered and shares sequence homology to the platelet-derived growth factor (PDGF) superfamily[72,73]. VEGF-A interacts with two transmembrane receptor tyrosine kinases: VEGFR-1 (Flt-1) and VEGFR-2 (KDE, Flk-1). VEGFR-2 is the primary mediator of VEGF-A and is often overexpressed in tumor vasculatures. Activation of VEGFR-2 promotes endothelial cell proliferation, survival and migration. As such, VEGFR-2 has been a major anti-angiogenic target.

VEGF over-expression and increased microvessel

density correlated with disease recurrence, metastases and survival in colorectal cancers[74-84]. Similarly, increased VEGF expression in pancreatic adenocarcinoma was also associated with poor prognosis though some studies suggest that PDGF and bFGF, instead of VEGF-A, are more important in the modulation of angiogenesis in pancreatic cancer[85-88]. HCC is highly vascular and patients with the liver neoplasm have higher serum VEGF levels than those with benign liver tumors[89-91]. In addition, increased VEGF expression following surgical resection or prior to transarterial chemoembolization correlated with poor prognosis[92-95].

As such, angiogenesis has been a focus of GI cancer therapy and can be accomplished by monoclonal antibody and small molecule tyrosine kinase inhibitor. These anti-angiogenic agents are believed to exert their anti-tumor effects by either affecting the tumor directly, inhibiting neovascularization, or enhancing chemotherapy delivery by normalizing the tumor vasculature[71,96].

Bevacizumab

Bevacizumab is a humanized monoclonal VEGF-binding antibody with anti-angiogenic properties that is the furthest along clinical development in its class. The drug was approved by FDA in U.S. for use with intravenous fluorouracil-containing regimens in patients with metastatic colorectal cancer[97].

The hint for bevacizumab efficacy in colorectal cancer in first-line setting was observed in a phase Ⅱ trial. 104 patients with metastatic colorectal cancer were randomized to receive fluorouracil and leucovorin (5FU/LV) (control arm), 5FU/LV plus "low dose" bevacizumab (5 mg/kg) and 5FU/LV plus "high dose" bevacizumab (10 mg/kg)[98]. Patients in both bevacizumab-containing arms achieved higher response rate (control: 17%; "low dose" bevacizumab: 40%; "high dose": 24%), longer time to progression and median survival (13.8 mo; 21.5 mo; 16.1 mo, respectively). Interestingly, outcome was better in the "low dose" bevacizumab arm than the "high dose" arm and was attributed partly to a higher proportion of poor risk patients in the "high dose" arm. Bevacizumab-related toxicities in this trial included thrombosis, hypertension, proteinuria and epistaxis. Bevacizumab at 5 mg/kg was thus chosen as the recommended dose for further development.

Bevacizumab was subsequently tested in metastatic colorectal cancer patients in combination with 5FU, leucovorin, leucovorin and irinotecan (IFL) in the pivotal phase Ⅲ trial. 813 patients with untreated metastatic colorectal cancer were randomized to receive IFL plus placebo (control arm), IFL plus bevacizumab 5 mg/kg or 5FU/LV plus bevacizumab 5 mg/kg[10]. IFL superseded 5FU/LV as the standard first-line regimen in U.S. by the time this trial was planned and was chosen as the control arm. The 5FU/LV plus bevacizumab arm was added as a backup since the safety of IFL plus bevacizumab was unknown. The 5FU/LV/bevacizumab arm was discontinued later during the planned interim analysis when IFL plus bevacizumab proved to be safe. The superior survival of 20.3 mo in the IFL plus bevacizumab over the IFL plus placebo arm of 15.6 mo supported the use of bevacizumab in the first-line treatment of metastatic colorectal cancer. Consistent with the earlier phase Ⅱ trial, reversible hypertension and proteinuria were more frequent with bevacizumab use. Other rare but serious side effects include gastrointestinal perforation, thrombosis and wound dehiscence.

Bevacizumab was also tested in metastatic colorectal cancer combined with oxaliplatin-based regimen in second-line setting. In the randomized phase Ⅲ trial (E3200), patients with previously treated colorectal cancer were randomized to 3 arms: FOLFOX4 plus bevacizumab, FOLFOX4 and bevacizumab only. The dose of bevacizumab chosen was 10 mg/kg[99]. The patients were not exposed to bevacizumab previously. Preliminary result showed superior survival and progression free survival in the FOLFOX4 plus bevacizumab arm. In a separate analysis, 56% of patients receiving FOLFOX4 plus bevacizumab had bevacizumab dose reduction but the survival was not significantly different from those without dose reduction[100]. Preliminary results indicate that bevacizumab is equally effective with oxaliplatin-based regimen and should be considered in second-line setting for metastatic colorectal cancer patients without previous bevacizumab exposure.

Despite the progress with bevacizumab in metastatic colorectal cancer therapy, many clinical questions remained unanswered, such as the role of continuing bevacizumab from first- into second-line setting and the synergism of bevacizumab with oral fluoropyrimidines. The combination of bevacizumab, erlotinib plus FOLFOX was examined in a phase Ⅱ trial but 40% of patients developed unacceptable toxicity and the treatment was stopped[101]. Bevacizumab is been tested with FOLFIRI in an ongoing phase Ⅱ trial involving patients with metastatic colorectal cancer[102].

The combination of bevacizumab and gemcitabine was been evaluated in pancreatic cancer. The multi-center phase Ⅱ trial demonstrated a modest partial response rate of 21% in untreated advanced pancreatic cancer patients treated with the combination[103]. Unfortunately, the combination failed to achieve survival improvement compared to gemcitabine only therapy in the subsequent phase Ⅲ randomized trial (CALGB 80303)[104]. The combination of bevacizumab with gemcitabine plus oxaliplatin (GemOx) is being evaluated in an ongoing North Central Cancer Treatment Group phase Ⅱ trial[105].

VEGF-Trap

VEGF-Trap (Regeneron) is a novel chimeric decoy receptor with higher affinity for VEGF-A than monoclonal antibodies[106]. The molecule consists of the extracellular domains of VEGFR-1 and -2 fused to the constant region (Fc) of IgG1[107]. Preclinical studies demonstrated potent anti-tumor and anti-angiogenic activities in various cancer models, prompting further clinical testing of the agent[108,109]. Phase I study of the agent in patients with advanced solid tumors showed that the agent is well-tolerated and the toxicities, including fatigue, pain, constipation and arthralgia, can be managed safely[110]. VEGF-Trap is being tested with fluorouracil-based regimens in phase I trials[111,112].

Table 2 Agents targeting angiogenesis in GI cancers

Agents	Tumor types	Regimen	Study Design	References
Monoclonal antibodies				
Bevacizumab	Colorectal cancer	Bevacizumab/IFL	Phase Ⅲ	[10]
		Bevacizumab/FOLFOX (E3200)	Phase Ⅲ	[99]
		Bevacizumab/FOLFIRI	Phase Ⅱ	[102]
	Pancreatic cancer	Bevacizumab/gemcitabine	Phase Ⅱ/Ⅲ	[103]
		Bevacizumab/gemcitabine/oxaliplatin	Phase Ⅱ	[105]
		Bevacizumab/capecitabine/RT	Phase Ⅰ	[124]
VEGF decoy				
VEGF-Trap	Solid tumors	I-LV5FU2/ VEGF-Trap	Phase Ⅰ	[111]
	Solid tumors	FOLFOX4/ VEGF-Trap	Phase Ⅰ	[112]
Tyrosine kinase inhibitors				
Sorafenib	Hepatocellular carcinoma	Sorafenib	Phase Ⅲ	[8]
	Pancreatic cancer	Gencitabine/sorafenib	Phase Ⅰ	[116]
	Colorectal cancer	Oxaliplatin/sorafenib	Phase Ⅰ	[115]
Sunitinib	Colorectal cancer	Irinotecan/cetuximab/sunitinib	Phase Ⅰ/Ⅱ	[122]
	Hepatocellular carcinoma	Sunitinib	Phase Ⅰ/Ⅱ	[121,123]

IFL: Irinotecan/leucovorin/bolus fluorouracil; FOLFOX: Oxaliplatin/leucovorin/infusional fluorouracil; FOLFIRI: Irinotecan/leucovorin/infusional fluorouracil; RT: Radiation therapy.

Sorafenib

Sorafenib (BAY43-9006) is an oral bi-aryl urea initially developed as a potent inhibitor of Raf protein[113]. The agent is also a multi-target kinase inhibitor and has significant activity against VEGFR-1, VEGFR-2, VEGFR-3 and PDGFR. As such, sorafenib is also been evaluated for its anti-angiogenic properties. The drug significantly inhibits neovascularization in colon, breast and non-small cell lung cancer xenografts in preclinical studies, marked by decreased tumor microvessel density.

Phase I trial involving patients with refractory solid tumors showed that sorafenib is fairly well tolerated. The main toxicities were diarrhea, skin rash and fatigue[114]. Downstream ERK protein was significantly inhibited at sorafenib $\geqslant$ 200 mg bid dose, indicating Raf inhibition. Partial response was observed in one (of 6) patients with HCC (400 mg bid dose) and stable disease for more than 6 mo in 6 (of 26) of colorectal cancer patients[115,116].

Sorafenib became the first agent to achieve significant survival benefit in advanced HCC in a multi-center randomized trial (SHAPR trial)[8]. 602 patients with previously untreated advanced disease with Child-Pugh Stage A cirrhosis and good performance status (ECOG PS 0-2) were randomized to receive sorafenib or placebo. Compared to the placebo arm, patients receiving sorafenib had a longer median survival (10.7 mo *vs* 7.9 mo; HR 0.69, $P < 0.01$) and time to progression (HR 0.58, $P < 0.01$). Serious side effects were similar in both groups though diarrhea and hand-foot syndrome were more frequent in those receiving sorafenib. Criticisms of the study include the generalisability of the result since majority of the patients enrolled were European and had minimal liver dysfunction. The benefit in Child's B and C patients remains unclear. Moreover, the therapy is quite costly and is a significant financial burden for most HCC patients who live in poorer developing countries. Sorafenib continues to be evaluated in HCC in combination therapy.

Sunitinib

Sunitinib (SU11248) is an oral inhibitor of VEGFR-2, PDGFR, c-kit and FLT-3. Preclinical studies showed anti-tumor activity in various malignancies, including leukemia, breast and lung cancer models[117-119]. In a phase I study, the recommended dose for sunitinib was determined to be 50 mg/d on a "4-wk-on/2-wk-off" schedule[120]. The toxicities include hypertension, thrombocytopenia, neutropenia, diarrhea, hair and skin changes. Sunitinib is being tested in HCC and in combination with irinotecan and cetuximab in previously treated metastatic colorectal cancer[121-123].

Of the anti-angiogenic agents discussed, bevacizumab proved to be an exceptionally efficacious agent in colorectal cancer when combined with conventional cytotoxic agents. However, this monoclonal antibody failed to achieve the clinical benefit expected in pancreatic cancer in combination therapy. More excitingly, sorafenib becomes the first chemotherapeutic agent to achieve significant clinical benefit in HCC (Table 2).

AKT/mTOR PATHWAY

The mammalian target of rapamycin (mTOR) is a cytosolic serine/threonine kinase that plays a central role in cell proliferation and survival[125]. The kinase is downstream to the phosphatidylinositol 3'-kinase (PI3K)/Akt signaling pathway. Activated mTOR interacts with downstream effectors, such as 4E-BP1 and p70s6K, to modulate various growth and survival-related cellular functions. The pathway is sensitive to extracellular growth factors (EGF, VEGF and IGF) and nutrients (amino-acids, glucose and oxygen).

In a series of 101 resected primary hepatoma (with 73 HCC), 15% had overexpression of phospho-mTOR and 5% had increased total mTOR protein expression[126]. In pancreatic cancers, more than 90% of the tumors contain an activating upstream ras mutation and about half of the surgically resected pancreatic cancer specimens had mTOR activation[127-131].

Loss of the suppressive PTEN gene expression, PI3K gene mutations and amplification of Akt result in constitutive activation of the upstream PI3K/Akt pathway

observed in some tumors[126-129,132-135]. Such activation increases the tumors' susceptibility to mTOR inhibitors and provided the rationale in developing rapamycin (mTOR inhibitor) analogs in various cancer types[136-140]. In addition, inhibition of mTOR reversed gemcitabine resistance in gemcitabine-resistant pancreatic cancer cell lines in preclinical xenograft model[131]. These preclinical data support the clinical testing of mTOR inhibitors in HCC and pancreatic cancer.

Rapamycin

Rapamycin (sirolimus) is an oral macrolide derived from *Streptomyces hygroscopicus* that is widely used as immunosuppressant in organ transplantation[141-145]. Rapamycin and its analogs also inhibit cellular proliferation in a wide range of human tumors. The drug complexes with FKBP12, a member of the immunophilin family of FK506-binding proteins, intracellularly which in turn inhibits the mTOR kinase activity, leading to G1 phase cell cycle arrest and apoptosis[146,147]. However, the drugs poor aqueous solubility, chemical stability and lack of investor interest impeded its clinical development as an anti-neoplastic agent[12]. Currently, rapamycin is being tested in a pharmacodynamic-guided dose-finding study involving patients with advanced solid tumor and also in a phase Ⅱ trial involving patients with advanced pancreatic cancer[148].

Temsirolimus

Temsirolimus (CCI-779) is a water-soluble synthetic rapamycin ester with significant anti-proliferative properties that can be administered *via* both oral and intravenous routes[149-154]. The drug demonstrated comparable *in vitro* anti-tumor effect to rapamycin against a wide range of human cancer cell lines, including prostate, breast, small-cell lung carcinoma, melanoma, glioblastoma and T-cell leukemia. The agent inhibits tumor growth, or is cytostatic, in a variety of cancer xenograft models but did not achieve tumor shrinkage.

Two dosing schedules of temsirolimus were tested in separate phase I trials: weekly intravenous dose versus the 30 minute intravenous infusion administered daily for 5 d on a bi-weekly schedule[155,156]. Toxicities observed include skin changes, muscostomatitis, asthenia, myelosuppression (thrombocytopenia, neutropenia), dyslipidemia and elevated liver enzymes. Dose escalation for the weekly regimen was stopped at 220 mg/m^2, which was the highest planned dose. Toxicities were fairly manageable and reversible at this dose. Interestingly, tumor shrinkages (partial and minor responses) were observed clinically, contrary to the cytostatic phenomenon seen in preclinical studies. Two patients achieved partial response: one with renal cell carcinoma and another with breast cancer. This led to further testing of temsirolimus in various cancer types[157-160]. Temsirolimus was recently approved by FDA in U.S. for the treatment of poor risk renal cell carcinoma patients based on the positive result from a randomized phase Ⅲ trial[161].

Everolimus

Everolimus (RAD001) is an oral rapamycin analog that inhibits tumor growth and angiogenesis in a dose-dependant manner and has anti-proliferative activity against a wide range of human cancers[162,163]. The optimal biologically active dose of everolimus was studied in two phase I trials. Everolimus 20 mg weekly was determined to be biologically active and toxicities associated with weekly everolimus administration were well tolerated and included anorexia, fatigue, rash, mucositis, headache, hyperlipidemia and gastrointestinal disturbance. The dose-limiting toxicities of daily everolimus were stomatitis, neutropenia and hyperglycemia. Pre-treatment and during-treatment tumor biopsies were done to evaluate pharmodynamic effects of everolimus and a 10 mg daily dose was recommended as the optimal dose. Partial response was seen in one colorectal cancer patient and everolimus is in phase Ⅱ development as single agent in refractory colorectal cancer[164]. The agent is being developed in other cancer types as well, such as gastrointestinal stromal tumor, neuroendocrine tumors, renal cell carcinoma, non-small cell lung cancer and melanoma[165-169].

The Akt/mTOR pathway seems to be an important survival and pro-growth pathway in GI cancers. Temsirolimus is the first of its class to achieve significant anti-tumor efficacy and clinical development of the class of mTOR inhibitors in pancreatic cancer and HCC continues.

CONCLUSION

Angiogenesis and EGFR pathways were hypothesized as targets for anticancer therapy more than three decades ago. Efforts to translate this knowledge to bedside are just starting to benefit patients with GI cancers. Successful development of cetuximab and bevacizumab in colorectal cancer ushered in the era of biologically targeted agents in the fight against GI cancers. More milestones were later achieved when the survival of previously difficult-to-treat GI cancers were improved by these novel biological agents, as in the case of erlotinib in pancreatic cancer and sorafenib in HCC. More molecular targets will become apparent as our knowledge of the complex neoplastic processes increases, and will provide exciting translational opportunities in the development of GI cancer therapy.

Abstract

Colorectal carcinoma (CRC) is one of the leading causes of cancer death worldwide. In the last decade, the addition of irinotecan and oxaliplatin to standard fluorouracil-based chemotherapy regimens have set the new benchmark of survival for patients with metastatic CRC at approximately 20 mo. Despite these advances in the management of CRC, there is a strong medical need for more effective and well-tolerated therapies. The dependence of tumor growth and metastasis on blood vessels makes angiogenesis a rational target for therapy. One of the major pathways involved in this process is the vascular endothelial growth factor (VEGF) and its receptors (VEGFR). In 2004, the first agent targeting angiogenesis, bevacizumab (BV), was approved as an adjunct to first-line cytotoxic treatment of metastatic CRC. The role of BV as part of adjuvant treatment and in combination with other targeted therapies is the subject of ongoing trials. However, BV is associated with an increase in the risk of arterial thromboembolic events, hypertension and gastrointestinal perforations and its use must be cautious. Novel VEGFR TK inhibitors with different ranges of nanomolar potencies, selectivities, and pharmacokinetic properties are entering phase Ⅲ trials for the treatment of cancer. Conversely, one of these novel agents, vatalanib, has been shown not to confer survival benefit in first and second-line treatment of advanced CRC. The basis of these findings is being extensively evaluated. Ongoing and new well-designed trials will define the optimal clinical application of the actual antiangiogenic agents, and, on the other hand, intensive efforts in basic research will identify new agents with different antiangiogenic approaches for the treatment of CRC. In this review we discuss and highlight current and future approaches in angiogenic targeting for CRC.

INTRODUCTION

Colorectal carcinoma (CRC) is one of the leading causes of cancer death worldwide despite progressive improvements in preventive, diagnostic, and therapeutic approaches[1]. Approximately 50 percent of patients who undergo potentially curative surgery alone ultimately relapse and die of metastatic disease[2]. From the late 50 s, 5-fluorouracil (5-FU) was the only drug approved for the treatment of advanced CRC with an overall response rate (RR) and median survival of 10% and 10 mo, respectively[3,4]. This RR was improved to nearly 25% when leucovorin (LV) was used to modulate 5-FU[5]. Recently, irinotecan and oxaliplatin have been added to the armamentarium of agents with activity in CRC. The addition of these two cytotoxic agents to the standard 5-FU/LV-based regimens improves not only RR, but also overall survival (OS) over 5-FU/LV alone, setting the new benchmark of survival for patients with unresectable advanced CRC at around 20 mo[6-10]. Despite these advances in the management of CRC, there is a strong medical need for more effective and well-tolerated therapies and further improvements in survival are anticipated with the introduction of novel targeted therapies both as single agents and in combination. Among them, anti-angiogenesis agents have become a new therapeutic approach in the metastatic setting. In this review we will discuss and highlight current and future approaches in angiogenic targeting for CRC.

ANGIOGENIC TARGETING

The dependence of tumor growth and metastasis on blood vessels makes angiogenesis one of the fundamental hallmarks of cancer[11] and a rational target for[12]. Several growth factor receptor pathways have been implicated in the promotion of tumor angiogenesis. One of the major pathways involved in this process is the vascular endothelial

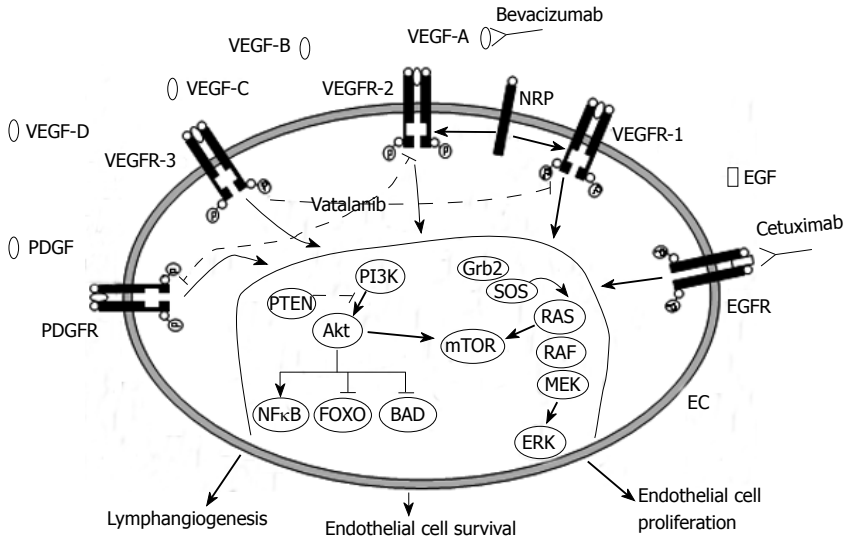

Figure 1 Vascular endothelial growth factor (VEGF) signaling network and novel targeted therapies. growth factor (VEGF) family of proteins, also known as vascular permeability factors, and its receptors (Figure 1). The VEGF pathway plays a crucial role in normal and pathologic angiogenesis, triggering multiple signaling networks that result in endothelial cell survival, migration, mitogenesis, differentiation, and vascular permeability[13]. The VEGF-related gene family of angiogenic and lymphangiogenic growth factors comprises six secreted glycoproteins referred to as VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placenta growth factor (PlGF) 1 and 2. The primary effects of VEGF ligands are mediated through binding to the VEGF tyrosine kinase receptors (VEGFR): VEGFR-1, which binds VEGF-A, VEGF-B, and PlGF-1; VEGFR-2, which binds VEGF-A, VEGF-C, VEGF-D, and VEGF-E; and VEGFR-3, which binds VEGF-C and VEGF-D, and its expression is limited to the lymphatic endothelial cells. In addition to these receptors, VEGF interacts with neuropilins, a family of activating coreceptors without an intracellular signaling domain[14,15]. VEGFR-1 and VEGFR-2 have seven extracellular immunoglobulin-like domains, a single transmembrane region and a consensus kinase sequence that is interrupted by a kinase-insert domain[16]. Once bound by VEGF, two receptors dimerize, and the tyrosine kinase domain of each receptor "autophosphorylates" the other, leading to an active receptor that initiates a signaling cascade. The VEGF pathway is upregulated by hypoxia[17] and by several growth factors, such as epidermal growth factor (EGF)[18], platelet-derived growth factors (PDGFs)[19,20], hepatocyte growth factor[21] and other cytokines.

Overexpression of VEGF has been associated with tumor progression and poor prognosis in several tumor systems, including CRC[22,23]. Preoperative serum VEGF have also been shown to correlate with advanced tumor stage or nodal status at the time of surgery[24]. Furthermore, intense expression of VEGF mRNA is detected in human liver metastases from primary colon or rectal carcinomas[25]. In 1993, Kim *et al*[26] reported that antibodies to VEGF exert a potent inhibitory effect on the growth of several tumor cell lines in nude mice. In addition, the combination of anti-VEGF antibody and chemotherapy in nude mice injected with human cancer xenografts has an increased antitumor effect compared with antibody or chemotherapy treatment alone[27]. It is, therefore, not surprising that most of the antiangiogenesis treatment strategies focus on inhibition of the VEGF pathway and its regulators. However, the mechanisms of action of anti-VEGF therapy in cancer patients are still far from being fully understood.

In December 2004 the first agent targeting angiogenesis, bevacizumab (Avastin®; Genentech, Inc., South San Francisco, CA), was approved to be given intravenously as a combination treatment along with standard chemotherapy drugs for metastatic CRC, increasing RR, progression-free survival (PFS) and overall survival (OS) with limited toxicity[28]. Gradually, many other antiangiogenic agents that target the VEGF pathway are entering the clinic. These novel targeted agents inhibit the VEGF pathway by targeting the VEGF ligand, its receptors or by blocking downstream signaling pathway components. Antiangiogenic agents include antibodies, low-molecular-weight tyrosine kinase (TK) inhibitors, antisense oligonucleotides and aptamers (Table 1).

BEVACIZUMAB IN CRC

Bevacizumab (BV) is a recombinant humanized monoclonal antibody that binds to all isoforms of VEGF-A with a reported half-life of 17-21 d[29]. In phase I trials, BV was generally well tolerated and did not demonstrate dose-limiting toxicity or interactions with commonly used chemotherapy regimens[30,31]. Based on the data obtained in these phase I trials, Kabbinavar *et al*[32] conducted a randomized, phase II trial comparing the safety and efficacy of BV (at two dose levels, 5 and 10 mg/kg every 2 wk) plus 5-FU (500 mg/m^2)/LV (500 mg/m^2) versus 5-FU/LV alone as first-line therapy for metastatic CRC(Table 2). One hundred and two patients were included. Administration of BV at low-dose and high-dose every 2 wk resulted in a significant increase of 3.8 mo and 2.0 mo, respectively, in the estimated progression-free survival (PFS) compared with 5-FU/LV alone. Treatment with 5-FU/LV/BV at both dose levels compared with 5-FU/LV resulted in

Table 1 Anti-VEGF agents currently in clinical development

Agent	Targets	Phase of development
Specific anti-VEGF antibodies		
Bevacizumab (Avastin)	VEGF-A	Phase Ⅲ

CRC: Colorectal carcinoma; 5-FU/LV: 5-fluorouracil/leucovorin; IFL: Irinotecan/5-FU/leucovorin; FOLFOX-4: Oxaliplatin/5-FU/leucovorin; BV: Bevacizumab; Pts: Patients enrolled; REF: reference; RR: Response rate; PFS: Progression-free survival; TTP: Time to tumor progression; OS: Overall survival; NR: Not reported.

higher RR [control arm, 17%, (95% CI, 7% to 34%); low-dose arm, 40%, (95% CI, 24% to 58%); high-dose arm, 24%, (95% CI, 12% to 43%)]. Although median survival was 7.7 and 2.3 mo higher in the 5-mg/kg arm and 10-mg/kg arm, respectively, it was not statistically significant. These findings contrast with the effective higher dose administered in other tumors like non-small cell lung cancer (15 mg/kg every three weeks)[33], breast cancer (10 mg/kg every two weeks)[34] and renal cancer (10 mg/kg every two weeks)[35]. Nevertheless, the majority of subsequent CRC studies administered a BV dose of 5 mg/kg. Potential safety concerns observed in this phase Ⅱ study were thrombosis, hypertension, proteinuria, and epistaxis.

In 2004, a large (813 patients) phase Ⅲ, double-blind, randomized trial in patients with untreated metastatic CRC demonstrated that the addition of BV to IFL (irinotecan/5-FU/LV) chemotherapy prolonged OS by 4.7 mo compared with IFL alone (20.3 *vs* 15.6 mo; HR = 0.66, $P < 0.001$)[28]. The one-year survival rate was 74.3% in the group given IFL plus BV and 63.4% in the group given IFL plus placebo ($P < 0.001$). All secondary efficacy end points were also improved with the addition of BV to the chemotherapeutic regimen: PFS increased from 6.2 to

Table 3 Trials for Vatalanib with chemotherapy in metastatic CRC

	FOLFOX-4 + Vatalanib	585	42	NS	7.7	0.118	NR	-
59-60	FOLFOX-4	429	18	NR	4.1	0.026	11.8	0.511
	FOLFOX-4 + Vatalanib	426	19		5.5		12.1	

CRC: Colorectal carcinoma; REF: Reference; Pts: Patients enrolled; FOLFOX-4: Oxaliplatin/5-FU/leucovorin; RR: Response rate; PFS: Progression-free survival; TTP: Time to tumor progression; OS: Overall survival; NS: Statistically nonsignificant; NR: Not reported.

10.6 mo (hazard ratio HR = 0.54; $P < 0.001$), RR increased from 34.8% to 44.8% ($P = 0.004$), and median duration of the response increased from 7.1 to 10.4 mo (HR = 0.62; $P = 0.001$). Grade 3 hypertension was more common during treatment with IFL plus BV than with IFL plus placebo (11.0 percent *vs* 2.3 percent, $P < 0.01$) but it was easily managed with medical treatment. Although the overall incidence of grade 3 or 4 adverse events was higher among patients receiving the combined treatment, the study did not identify hemorrhage, thromboembolism, and proteinuria as possible BV-associated adverse events. Uncommon but serious side-effects of BV included the appearance of gastrointestinal perforations (1.5%), in some instances with fatal outcome[28].

Toxicity derived from antiangiogenic therapy is a main concern in the management of CRC. BV is associated with a two-fold increase in the risk of arterial thromboembolic events, from 2.5% to 5% ($P < 0.01$)[36]. These events consist primarily of acute coronary syndrome, transient ischemic attack and stroke. Patients at risk for these events are those with a prior history of arterial thromboembolism and age older than 65 years. Moreover, BV administration can result in the development of wound dehiscence. However, the risk of wound healing is not increased if the administration of BV with or without chemotherapy is delayed until 28-60 d after primary care surgery[37].

Although the addition of BV to 5-FU-based combination chemotherapy resulted in statistically significant and clinically meaningful improvement in RR, PFS and OS among patients with metastatic CRC, previous studies have suggested that the benefit observed with irinotecan-based schedules might be limited to patients with a performance status (PS) of 0[38]; and certain subgroups, including those with advanced age, impaired PS, low serum albumin, and prior pelvic radiotherapy, may experience significant toxicities when adding irinotecan to 5-5-FU/LV regimens[39]. In this particular population, the combination of BV and 5-FU/LV would remain a potentially useful therapeutic alternative. Two studies led by Kabbinavar *et al*[40,41] addressed this question enrolling patients who were not candidates for irinotecan because of advanced age or poor PS. The results suggested that 5-FU/LV (Roswell Park Schedule[42]) plus BV seems as effective as IFL and might have a better safety profile. Based on all of the previous data, BV became the first anti-VEGF agent to be approved by the FDA for cancer patients.

On June 2006, the FDA granted approval for a labelling extension for BV in combination with intravenous 5-FU-based chemotherapy for the second-line treatment of metastatic CRC. This decision was based on the preliminary results of the E3200 phase Ⅲ trial of the Eastern Cooperative Oncology Group (ECOG). The aim of this randomized, three-arm, multicenter study was to determine the efficacy of infusional 5-FU/LV/oxaliplatin (FOLFOX) with or without BV (10 mg/kg every two weeks) in 829 patients with irinotecan-refractory advanced CRC not previously treated with BV[43]. The median age was 61 years, 49% had an ECOG performance status of 0, and 80% received prior adjuvant chemotherapy. The combination therapy showed an improvement in the OS by 2.1 mo (12.5 *vs* 10.7 mo; $P = 0.0024$) without a significant difference in the toxicity profile. The BV-alone arm was closed at the interim analysis due to a low RR and an apparent lack of activity in this setting. Final analyses of this trial are forthcoming.

Whether the combination of BV with oxaliplatin/5-FU/LV-based chemotherapy regimens will be the best option for first-line therapy for CRC is under investigation in the TREE study[44] and NO16966[45]. The TREE study was previously designed to assess the safety, tolerability and efficacy of each of three oxaliplatin plus fluoropyrimidine regimens without (TREE1 cohort) or with (TREE2 cohort) BV. In the TREE-2 cohort, BV was added to each regimen. With a follow-up of 27 mo, median OS with infusional 5-FU/LV and oxaliplatin (mFOLFOX-6) plus BV was 26.0 mo, 20.7 mo with bolus 5-FU/LV and oxaliplatin (bFOL) plus BV, and 27.0 mo with capecitabine and oxaliplatin (CapeOX) plus BV. Median OS with oxaliplatin-containing regimens without BV in sequential historical cohorts (TREE-1 study), reached 18.2 mo[44]. However, the first large, randomized, multicenter phase Ⅲ trial to evaluate the efficacy of BV in combination with the standard chemotherapy regimen FOLFOX and the XELOX regimen in the first-line treatment of metastatic CRC is the NO16966[45]. Interestingly, in the general treated population, the addition of BV to FOLFOX did not significantly improve PFS (HR = 0.89, $P = 0.1871$). However, 50% of patients discontinued treatment for reasons unrelated to progression of disease. Further analyses focusing on the on-treatment subgroup population revealed that median PFS for XELOX-BV and FOLFOX-BV was 10.4 mo compared to 8.1 mo for XELOX-Placebo and FOLFOX-Placebo (HR = 0.63, $P < 0.0001$). These results demonstrated that the addition of BV to oxaliplatin-based chemotherapy regimens significantly improves PFS. In addition, continuation of BV until disease progression could be necessary to

optimize the contribution of BV to PFS[45].

The activity shown by BV in the metastatic setting justified the evaluation of this antibody in the adjuvant scenario. In the first trial, the National Surgical Adjuvant Breast and Bowel Project C-08 phase Ⅲ trial[46], 2632 patients with stage Ⅱ or Ⅲ colorectal cancer have been randomized to receive mFOLFOX-6 for 12 cycles with or without BV. Patients assigned to BV plus chemotherapy also received an additional 6 mo of BV alone. This trial has already completed accrual. In a second trial recently finished, the AVANT phase Ⅲ study[47], patients with stage Ⅱ or Ⅲ colorectal cancer were randomized to three combination chemotherapy regimens (FOLFOX-4 *vs* FOLFOX-4 plus BV *vs* capecitabine/oxaliplatin plus BV). In addition, a phase Ⅱ clinical trial, the Eastern Cooperative Oncology Group (ECOG) E5202[48], is evaluating the addition of BV in combination with FOLFOX on patients with stage Ⅱ colon cancer at high-risk for recurrence. In conclusion, at this point in time, no evidence supports the actual use of BV in the adjuvant setting in order to prolong survival. The results of these important clinical trials are eagerly awaited.

VATALINIB IN CRC

A second antiangiogenic approach is to target both cancer cells and endothelial cells with small molecules. Similar to BV, VEGFR multitargeted TK inhibitors have been evaluated in combination with chemotherapy in phase Ⅲ trials. The first agent, semaxinib (SU5416, Pharmacia, San Francisco, California) which targets VEGFR-1, VEGFR-2 VEGFR-3, and PDGFR-β did not show any survival benefit when added intravenously to standard chemotherapy in metastatic CRC. In addition worse toxicity in the semaxinib arm was observed[49]. Finally, in a phase I trial that evaluated the combination of semaxinib with cisplatin/gemcitabine in solid tumors, an unexpected high incidence of thromboembolic events was observed which discouraged overall further investigation of this agent[50].

Another novel synthetic agent, with orally bioavailability, vatalanib (PTK787/ZK222584, Novartis, Basel, Switzerland) belongs to the chemical class of aminophthalazines[51]. It is a potent inhibitor of all known VEGFR tyrosine kinases (TK) with greater potency against VEGFR-1 and VEGFR-2[52,53] (Figure 1). It also inhibits other kinases, such as platelet-derived growth factor receptor beta (PDGFR-β) and c-Kit tyrosine kinase. In preclinical studies, vatalanib has shown antitumor activity in subcutaneously implanted human tumor xenografts in nude mice[53]. Dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) and pharmacokinetic (PK) data indicated that vatalanib ⩾ 1000 mg total daily dose is the biologically active dose[54] with a terminal half-life of about 6 h. In view of the short half-life of the drug, a phase I study with vatalanib given twice daily was conducted to exploit the theoretical advantage of maintaining constant drug levels[55]. PK data from this study showed that at equivalent daily doses, drug exposure is comparable with the previous once-daily-dosing schedule[54]; however, the trough levels are significantly higher with the bid dosing. Whether this will translate into improved efficacy is unknown at this time.

Vatalanib has been evaluated in two phase Ⅰ / Ⅱ studies as a single daily-dose in combination with FOLFOX or FOLFIRI, as first-line treatment for patients with metastatic CRC[56,57]. In both studies, vatalanib was safe and well tolerated at doses of 1250 mg/d. Ataxia, expressive dysphasia and dizziness were seen at higher doses when administered in combination with FOLFOX and these were considered dose-limiting toxicities. The combination of vatalanib with chemotherapy significantly affected the PK parameters of SN38, the active metabolite of irinotecan. Indeed, the concentration-time curve (AUC) of SN38 was decreased when vatalanib was added to the FOLFIRI regimen. The relevance of this finding needs further investigation.

Two phase Ⅲ studies have evaluated the administration of vatalanib (single daily-dose of 1250 mg/d) in combination with chemotherapy in CRC (Table 3). A first randomized phase Ⅲ trial (CONFIRM-1) compared the efficacy of vatalanib in combination with FOLFOX versus FOLFOX alone in 1168 patients for first-line treatment of metastatic CRC[58]. The results of the primary endpoint of this trial, PFS, showed a modest benefit of adding vatalanib to FOLFOX without achieving statistical significance (HR = 0.88; P = 0.118). OS has not been reported. The adverse events attributable to vatalanib (hypertension, deep-vein thrombosis, diarrhea and dizziness) were generally reversible and similar to other VEGF pathway inhibitors. No increase in bleeding or bowel perforation compared to placebo was observed. The second phase Ⅲ trial (CONFIRM-2) evaluated the efficacy of vatalanib in combination with FOLFOX *versus* FOLFOX alone in 855 patients with irinotecan-refractory advanced CRC[59,60]. PFS was 1.4 mo significantly longer in the vatalanib arm (5.5 mo *vs* 4.1 mo, HR = 0.83; P = 0.026). No improvement in OS was demonstrated. In the CONFIRM-2 trial, the most frequent grade 3/4 events associated with vatalanib were again hypertension (21% *vs* 5%), diarrhea (16% *vs* 8%), fatigue (14.5% *vs* 6.9%), nausea (11% *vs* 5%), vomiting (9% *vs* 5%) and dizziness (9% *vs* 1%). Two hypotheses have been tried to explain why survival was not affected when adding vatalanib in first and second-line therapy. The first one deals with the short half-life of vatalanib. The once-daily administration of the drug might not be the optimal schedule to maintain constant blood levels of vatalanib, although another study refutes this hypothesis[54]. A second one would be the "off-target" effects, such as targeting PDGFR-β. The inhibition of PDGFR-β could interfere with vascular normalization by blocking perivascular cell recruitment and thus impeding the delivery of chemotherapeutics to chemoresponsive tumors[61].

Major *et al*[62] reported a metanalysis by pooling preplanned strata in CONFIRM-1 (C1) and CONFIRM-2 (C2) trials and showed that patients with high LDH (> 1.5 X ULN) experienced the greatest improvement in PFS for C1 (HR = 0.67; P = 0.01) and for C2 (HR = 0.63; P < 0.001). This finding brings forward an eventual role of LDH in angiogenesis-dependent tumor growth and progression in CRC. Previously, the expression of LDH-5, a LDH isoform, has been linked with distant metastases in

CRC and with the expression of hypoxia inducible factor (HIF)[63]. Furthermore, evidence of a biologic link between tumor LDH, hypoxia and activated VEGF pathway has been described in CRC[64]. LDH, being regulated by the same pathway as VEGF, is expected to reflect a subset of tumors with a high likelihood to bear an activated VEGF signalling pathway. Nevertheless, whether LDH can be used as a surrogate marker for screening patients for TK inhibitor therapy remains an open question. Thus, validation of biomarkers of efficacy of anti-VEGF therapy with the aim of identifying responsive patients and predict the optimal biological dose are imperative.

TARGETED THERAPY COMBINATIONS

Growth factors and their receptors play a pivotal role in the regulation of cancer progression and neovascularization[65], stimulating downstream signaling cascades involved in cell proliferation, survival and antiapoptosis. The expression or activation of epidermal growth factor receptor (EGFR) and ErbB2 are altered in many epithelial tumors, and clinical studies indicate that they have an important role in tumor progression[66]. Inhibiting signaling pathways through EGFR and ErbB2 has become a cornerstone in the treatment of a subgroup of patients with non-small cell lung cancer and breast cancer, respectively. In CRC, cetuximab (IMC C225, Erbitux, ImClone, New York, NY), a monoclonal antibody targeting EGFR[67], has been shown to induce apoptosis of CRC cells[68], and cetuximab in combination with irinotecan (in irinotecan-refractory and EGFR expressing metastatic CRC) was found to reverse resistance to irinotecan, producing a 22.9% RR (BOND-1 Trial)[69,70]. These findings have led to the approval of cetuximab for irinotecan-refractory advanced CRC in the Unites States and, more recently, in Europe.

As it is known, the expression of proangiogenic molecules by tumor cells can be stimulated by EGFR receptor signaling[71]. Furthermore, several studies have shown that EGFR inhibitors reduce VEGF and microvessel density in tumors that regress upon EGFR blockade[72,73]. These results provide a strong rationale for combinations of anti-EGFR agents with angiogenesis inhibitors in CRC.

The safety and efficacy of concurrent administration of BV and cetuximab has been evaluated in a randomized phase Ⅱ trial in patients with irinotecan-refractory metastatic CRC (BOND-2 trial)[74]. Seventy-five patients were assigned to receive either irinotecan/cetuximab/BV (5 mg/kg every other week) or cetuximab/BV. This study presents a similar design to BOND-1 trial with BV included in both arms. The combination of cetuximab/BV, alone or with irinotecan, is tolerable, and RR and median TTP seen with the addition of BV to either arm appear favorable compared to historical controls of the BOND-1 trial. The results of the BOND-2 trial validate the design of the planned intergroup trial CALGB/SWOG 80405[75], which plans to randomize 2289 patients to receive standard chemotherapy with the addition of cetuximab, BV, or both monoclonal antibodies in first-line metastatic CRC. The primary end-point of this trial will be to detect differences in overall median survival.

SMALL-MOLECULE TK INHIBITORS IN CRC

Finally, novel VEGFR and/or PDGFR TK inhibitors with different ranges of nanomolar potencies, selectivities, and pharmacokinetic properties are entering phase Ⅰ/Ⅱ trials for the treatment of cancer[76-78]. In addition, there are now available a series of TK inhibitors that block both the EGFR and the downstream signalling molecules on the one hand and the VEGF receptor TK on the other (Table 1). Zactima (ZD6474, AstraZeneca Pharmaceuticals, Cheshire, UK) is an orally bioavailable, anilinoquinazoline derivative, multitargeted tyrosine kinase inhibitor that targets VEGFR-2, EGFR, and RET tyrosine kinases, and is currently in phase Ⅰ/Ⅱ evaluation for the treatment of cancer[79,80]. Another broad spectrum multitargeted agent, AEE788 (Novartis, Basel, Switzerland), is an oral small-molecule inhibitor of both EGFR and VEGFR tyrosine kinases[81,82]. In preclinical studies, this agent has shown growth and metastases inhibition of human colon carcinoma in an orthotopic nude mouse model[83]. Sorafenib (BAY 43-9006; Nexavar®, Bayer Aktiengesellschaft, Leverkusen-Bayerwerk, Germany, and Onyx Pharmaceuticals Inc., Emeryville, CA) targets VEGFR2 and VEGFR3, PDGFR-β, c-Kit and FLT3 (fms-related tyrosine kinase 3) and the downstream signalling molecule of EGFR known as Raf[84]. This agent efficiently inhibits both tumor-cell proliferation and angiogenesis in preclinical models, and monotherapy treatment has shown efficacy in a phase Ⅲ trial in patients with cytokine-refractory advanced renal carcinoma, which led in 2005 to the approval by the FDA for this indication[85]. In contrast with BV, the monotherapy efficacy demonstrated by Sorafenib could mimic the synergistic effect of the combination of an anti-VEGF antibody and chemotherapy[86]. The activity of Sorafenib and similar agents in the treatment of CRC needs further development. In addition, whether it will be better to target the EGFR and VEGF receptor with two compounds, each targeting one system, or to use these new class of oral duals or broad-spectrum inhibitors, is not known at this time[87].

SUMMARY AND CONCLUDING REMARKS

The increased knowledge of the VEGF signaling network and its implication in the development and progression of CRC, together with the initial positive clinical results observed with anti-VEGF therapies, makes angiogenic targeting an appropriate cancer treatment strategy. Based on the results of the completed phase Ⅲ trials, BV can increase survival when combined with standard chemotherapy in first and second-line therapy of advanced CRC. These findings have led to the approval of BV for the treatment of metastatic CRC. Simultaneously, the activity of BV in combination with 5-FU/LV-based chemotherapy regimens is being evaluated in early disease, a period when angiogenesis might be particularly critical. Results of these trials are eagerly awaited. The initial positive results of anti-VEGF therapy are not accomplished without added toxicity. Side effects of anti-VEGF agents are usually moderate compared with other

therapies, but the etiology is poorly understood. Major safety concerns have been raised by increased morbidity, and a number of treatment-related deaths from bowel perforations and cardiovascular events. Modest elevations in blood pressure occur occasionally and are easily managed with standard antihypertensive medications.

Since multiple growth-controlling pathways may be altered in cancer cells, combination antibody strategies are being explored in advanced CRC. BV is being assessed in combination with cetuximab in irinotecan-refractory metastatic CRC, based on the positive results of anti-EGFR therapies in this context. Preliminary data for this combination shows remarkable results without substantial differences about toxicity. New clinical trials with both targeted strategies in first-line metastatic CRC are recruiting patients. Combination of BV with novel VEGFR and broad-spectrum TK inhibitors also needs to be assessed in the treatment of CRC. One of these VEGFR TK inhibitors, vatalanib, combined with standard chemotherapy has been shown not to improve survival in first and second-line treatment of advanced CRC in both phase Ⅲ trials. New broad-spectrum TK inhibitors, such as Sorafenib, oppositely to the VEGF antibody, have shown promising monotherapy activity in other tumors. The basis of these findings is being extensively evaluated, and the identification of biomarkers to predict therapeutic response and optimal doses of anti-VEGF therapy is urgently needed in order to identify patients who will benefit from antiangiogenic therapy.

Angiogenesis research moves in two directions. In one hand, ongoing and new, well-designed trials will define the optimal clinical application of the actual antiangiogenic agents, and, on the other, intensive efforts in basic research will identify new agents with different antiangiogenic approaches for the treatment of CRC.

Abstract

Colorectal cancer remains one of the major causes of cancer death worldwide. During the past years, the development of new effective treatment options has led to a considerable improvement in the outcome of this disease. The advent of agents such as capecitabine, irinotecan, oxaliplatin, cetuximab and bevacizumab has translated into median survival times in the range of 2 years. Intense efforts have focused on identifying novel agents targeting specific growth factor receptors, critical signal transduction pathways or mediators of angiogenesis. In addition, several clinical trials have suggested that some of these molecularly targeted drugs can be safely and effectively used in combination with conventional chemotherapy. In this article we review various treatment options combining cytotoxic and targeted therapies currently available for patients with metastatic colorectal cancer.

Key words: Targeted therapy; Chemotherapy; Combinations; Clinical trials; Colorectal cancer

INTRODUCTION

Chemotherapy remains the cornerstone of treatment of metastatic colorectal cancer (mCRC) and, with the exception of a minority of patients (pts) who are candidates for salvage surgery, the goal of chemotherapy is palliation. Remarkable and clinically relevant advances have been made in the last 5 years in the treatment of this disease, essentially owing to the introduction of combination chemotherapy regimens containing oxaliplatin and irinotecan (CPT-11)[1]. The addition of either drug to 5-fluorouracil/leucovorin (5-FU/LV) proved to significantly increase overall response rates and survival times. Indeed, median overall survival is highly correlated with the percentage of patients who receive the three cytotoxic agents in the course of their disease. Results from a Phase Ⅲ study by Falcone *et al*[2] suggested that the up-front use of a triplet combination of irinotecan, oxaliplatin and 5-FU/LV significantly improved the outcome in terms of response rate (RR) and survival times compared to a standard doublet of irinotecan and 5-FU/LV.

Interestingly, with the more recent incorporation of bevacizumab and cetuximab into the treatment armamentarium, the median overall survival (OS) has doubled from 12 mo to approximately 2 years in Phase Ⅲ trials. In fact, most recent trials that attempt to expose patients to all five drug classes (fluoropyrimidines, irinotecan, oxaliplatin, bevacizumab and anti-EGFR antibody) target an OS well over 2 years. In this review we will summarize some of the available therapeutic repertoire based on targeted therapies in combination with chemotherapy for patients with mCRC.

COMBINING CHEMOTHERAPY AND EGFR-TARGETED THERAPIES

The epidermal growth factor receptor (EGFR), a transmembrane tyrosine kinase, is one of four members of the HER receptor family. This receptor is overexpressed in a number of solid tumors of ectodermal origin, including colon adenocarcinoma[3]. EGFR over expression has been correlated with disease progression, poor prognosis and reduced sensitivity to chemotherapy[4]. Therefore, several strategies have been developed to target EGFR, including small molecule tyrosine kinase inhibitors and monoclonal antibodies[5].

Cetuximab-based combination therapy

Cetuximab is the most advanced monoclonal antibody against EGFR in clinical development. Since preclinical

and early clinical studies suggested that Cetuximab might revert irinotecan resistance in CRC both *in vitro* and *in vivo*, a phase Ⅱ trial of cetuximab with irinotecan was performed in patients with EGFR positive colorectal cancer that was refractory to both 5-fluorouracil (5-FU) and Irinotecan. Among the 120 patients treated with this regimen, overall response rate was 22.5%[6].

To confirm these clinical findings, 329 EGFR-positive, irinotecan-refractory mCRC patients were randomized in a 2:1 ratio to receive cetuximab plus irinotecan (arm A; $n = 218$) or cetuximab alone (arm B; $n = 111$) with the option to switch to the combination of cetuximab with irinotecan after failure of cetuximab as a single agent. Both the response rate (22.9% *vs* 10.8%, $P = 0.007$) and the median time to progression (4.1 *vs* 1.5, $P < 0.001$) favored the combination arm. Although no survival benefit was observed for arm A, cetuxibab was demonstrated to have clinically significant activity when given alone or in combination with irinotecan and consequently received FDA approval[7].

More recently, MABEL trial[8] investigated the combination of cetuximab and CPT-11 at a dose and schedule as pre-study in an uncontrolled, multicenter study including 1123 mCRC pts with detectable EGFR. 64% of the patients had received ⩾ 2 lines of chemotherapy. 76% had also been pretreated with cetuximab. The estimated median survival was 9.2 mo at as expense of an acceptable toxicity profile, including grade 3-4 diarrhea (20%) acne-like rash (19%), neutropenia (9%) and asthenia (8%). MABEL clearly confirmed in a wider setting the efficacy and safety or C225 plus CPT-11 seen in previous studies. Similarly, EPIC trial is a randomized phase Ⅲ trial comparing cetuximab plus irinotecan to irinotecan as second line therapy in patients with EGFR-expressing mCRC who have failed first line oxaliplatin in combination with a fluorpyrimidine. Accrual is currently ongoing[9].

Cetuximab-based combinations as salvage therapy: Several trials have addressed the potential of cetuximab-based combinations in heavily pretreated patients. Vincenzi *et al*[10] evaluated the efficacy of cetuximab plus oxaliplatin in patients previously failed on an oxaliplatin-based regimen in first line, irinotecan-based regimen in second line, and cetuximab plus irinotecan in third line. No objective clinical response was identified after the interim analysis planned according to the two-staged Simon accrual design. The same group[11] evaluated the activity of cetuximab and weekly irinotecan (90 mg/m^2) in patients refractory to one oxaliplatin-based chemotherapy regimen (Capecitabine + Oxaliplatin or FOLFOX Ⅳ regimen, as first line) and one Irinotecan-based based-chemotherapy (FOLFIRI regimen, as second-line chemotherapy) for at least 2 mo. Overall response rate was 25.4% (95% CI: 21.7%-39.6%); 38.2% (95 CI: 18.6%-39.8%) of patients showed a disease stability as the best response. The median time to progression was 4.7 mo (95% CI: 2.5-7.1 mo) and the median survival time was 9.8 mo (95% CI: 3.9-10.1 mo). The most common G3-4 noncutaneous side toxicities were diarrhoea (16.4%), fatigue (12.7%), stomatitis (7.3%) and skin toxicity (32.6%). A statistically significant ($P = 0.006$) association between the cutaneous toxicity and both tumour response and time to progression was observed. The authors also identified a borderline significant difference in terms of overall survival.

The combination of Cetuximab plus FOLFIRI has been prospectively evaluated in 41 EGFR expressing mCRC pts refractory to prior FOLFIRI for metastatic disease[12]. Most of the patients were treated in third line. A 20% overall response rate was recorded, with a median PFS of 4.3 mo and a median overall survival of 5 mo.

Cetuximab-based combinations in front-line therapy: Cetuximab established activity in the salvage setting prompted its incorporation to first-line combination therapy. Available preliminary data from Phase Ⅱ trials combining cetuximab with either irinotecan or oxaliplatin-based chemotherapy have shown very encouraging activity. CALGB 80203[13] randomized untreated mCRC patients to FOLFOX or FOLFIRI with or without C225 independent of EGFR status. ORR was similar in the FOLFIRI or FOLFOX arms, while C225 containing arms had a higher ORR (49% *vs* 33%, $P = 0.014$) when compared to non cetuximab containing arms. No significant differences in grade 3 diarrhea or any grade 4 toxicity were seen with the addition of C225. Preliminary results of the combination of C225, capecitabine (800 g/m^2 bid po on d 1 to 14) and Irinotecan (200 g/m^2 i.v on d 1) *vs* C225 combined with capecitabine (1000 mg/m^2 bid in d 1-14) and oxaliplatin (130 g/m^2 on d 1) reported an overall response rate of 41% (95%; 22% to 61%) and 71% (95%; 48% to 89%) respectively, with both arms showing a manageable toxicity profile[14].

Promising results have also been reported[15] combining cetuximab with (AIO) infusional 5-FU/FA plus irinotecan regimen in EGFR-expressing mCRC.Grade 3 or 4 toxicities were acne-like rash (38%), diarrhea (29%), cardiovascular events (20%) and nausea/vomiting (5%). Objective responses were observed in 67% of the patients. The median time to progression was 9.9 mo and the median survival time was 33 mo.

The combination of cetuximab with modified FOLFOX 6 in 83 chemo-naive mCRC pts with positive or undetectable EGFR expression show a preliminary ORR of 53%[16]. Main grade 3-4 toxicities included neutropenia (38%), diarrhea (10%), rash (10%) and neurotoxicity (7%). The combination of FOLFOX-4 plus C225[17] has also been evaluated in 47 EGFR-expressing mCRC, with a reported ORR of 68%. Grade 3-4 adverse events included acne-like rash (18%) diarrhea (7%), nausea and vomiting (4%) and anemia (4%).

Preliminary results of the OPUS trial[18], a randomized phase Ⅱ study in the first line treatment of mCRC, confirmed the superiority of FOLFOX plus cetuximab *vs* FOLFOX in terms of overall response rate (45.6% *vs* 36.8%).

These small trials supported the conduct of a multicenter Phase Ⅲ clinical trial that compared FOLFIRI plus Cetuximab with FOLFIRI alone in 1217 EGFR-expressing chemotherapy-naive patients. Cetuximab plus FOLFIRI significantly increased response rate and progression-free survival, reducing the relative risk of progression by approximately 15%[19].

Panitumumab-based combination therapy

Panitumumab is a fully human IgG2 monoclonal antibody directed against the epidermal growth factor receptor. Its use in combination with IFL and FOLFIRI in first line treatment of metastatic CRC has been evaluated in a multicenter, single arm, phase 2 trial[20]. Panitumumab was given at a weekly dose of 2.5 mg/kg i.v. over 60-90 min followed by chemotherapy. The combination with IFL was considered too toxic, with grade 3-4 diarrhea in 47% of the patients. The FOLFIRI plus panitumumab combination was associated with a more manageable side effect profile with grade 3-4 diarrhea in 25% of the pts and grade 3-4 hypomagnesemia in 8%. Skin and nail toxicities occurred in at least 20% of patients but were rarely severe (grade 3 in 2 out of 24 pts). The objective response rate with FOLFIRI plus panitumumab was 66%, with a disease control rate of 79%. Median progression free survival was 10.9 mo. Further investigation of FOLFIRI with an every two weeks schedule of panitumumab is ongoing in randomized phase 3 trials.

Cetuximab-induced papulopustular skin rash is thought to be mechanism- and dose-related, and may be a surrogate indicator of an adequate degree of receptor saturation by cetuximab. The possibility of increasing Cetuximab efficacy by inducing skin rash has been recently confirmed. Cetuximab dose escalation up to 500 mg/m^2 improves response rate in patients with absent or slight skin reaction on standard dose treatment[21].

Future directions

Large studies validating molecular predictive markers are needed in order to identify the subset of patients more likely to respond to EGFR-targeted therapies. Candidate markers include total and phosphorylated EGFR, total and phosphorylated forms of AKT, mitogen-activated protein kinase (MAPK), mitogen-activated protein/ERK (MEK), ERK, signal transducers and activators of transcription (STAT), PTEN and mTOR[22] Although EGFR gene copy number has also been proposed[23], EGFR amplification, measured by FISH is a rare event (4%) in colorectal cancer[24]. Other potential predictive markers are k-ras[25] cyclin D1 A870G polymorphisms[26], HER-2 expression[27] or higher gene expression levels of VEGF[28]. More recently, a combination of various predictive biomarkers has retrospectively been able to identify subsets of patients more likely to benefit from cetuximab therapy[29]. In addition, several polymorphisms in genes involved in the EGFR and angiogenesis pathway have been associated with clinical outcome[30]. Prospective studies are clearly needed to confirm these preliminary findings.

EGFR tyrosine kinase inhibitor (TKI)-based combination therapy

Gefitinib: Gefitinib (ZD1839) selectively inhibits the EGFR tyrosine kinase and has approximately 100-fold greater potency against EGFR compared with other tyrosine or serine/threonine kinases. Unlike cetuximab, gefitinib does not induce EGFR internalization or degradation in CRC cells, nor does it reduce EGF binding sites or EGFR protein content. Both *in vitro* and *in vivo* studies indicated that gefitinib monotherapy had antitumor activity in some CRC cell lines[31]. However, phase I / Ⅱ clinical studies in patients with mCRC indicated that gefitinib had negligible activity[32,33]. Preclinical suggestions of a supra-additive, growth-inhibitory effect of gefitinib and a wide variety of cytotoxic drugs with different mechanism(s) of action[34] prompted several trials of gefitinib in combination with chemotherapy in mCRC patients.

Gefitinib plus fluoropyrimidines: In preclinical models a strong synergistic interaction between gefitinib and 5'-deoxy-fluorouridine (5'-DFUR) was demonstrated when ZD1839 was applied before or concurrently with 5'-DFUR[35]. Subsequently, the combination of intermittent gefitinib (250-500 mg/d on d 1-14) plus 5-FU/LV administered as a bolus in a dose-reduced Mayo Clinic regimen (370/20 mg/m^2) on d 8-12 with 5-FU and leucovorin as first-line therapy in mCRC was tested, with no evidence of cumulative toxicity or major drug-drug pharmacokinetic interactions[36]. In the second part of the study, gefitinib was administered continuously at 500 mg/d, and 5-FU/LV was added to the schedule on d 8-12 and 36-40. Overall response rate was 23%, with the most common toxicities being rash and diarrhea.

Preliminary results from a small phase I / Ⅱ trial combining gefitinib 250-mg daily with capecitabine 1000-1250 mg twice daily after failure of first-line therapy[37] also suggest some evidence of activity .

Gefitinib plus irinotecan-based therapy: A dose-finding trial of irinotecan plus gefitinib in mCRC patients pretreated with fluoropyrimidine-based chemotherapy defined irinotecan given at a dose of 225 mg/m^2 every 3 wk plus gefitinib at a dose of 250 mg/d as the maximun tolerated dose (MTD) of this regimen[38]. Dose-limiting toxicities (DLTs), such as neutropenia and diarrhea, occurred at unexpectedly low doses of irinotecan. Disease stabilization was achieved in 21% of the patients.

The combination of gefitinib plus FOLFIRI in both chemotherapy-naive mCRC patients[39] and as salvage therapy[40] was considered too toxic despite reduced weekly doses of 5-FU, LV, and irinotecan.

Gefitinib plus oxaliplatin-based therapy: Gefitinib plus FOLFOX has been tested in both the first line and the salvage setting. Kuo *et al*[41] reported data on a phase Ⅱ study of one cycle of FOLFOX-4, and then additional cycles of FOLFOX-4 with 500 mg/d of gefitinib in 27 patients with documented progressive colorectal cancer after at least one chemotherapeutic regimen (usually irinotecan based). 33% of the patients achieved objective responses, whereas 48% had stable disease for a prolonged period. Response rates did not differ depending on number of prior regimens. Median event-free survival was 5.4 mo, and overall survival was 12 mo. Another feasibility study assessed the combination of gefitinib (250 mg/d) plus capecitabine (2000 mg/m^2 per day, d 1-15) plus oxaliplatin (120 mg/m^2 every 3 wk for six courses) as first-line treatment in patients with mCRC[42]. The most common grade 3 adverse events were diarrhea and neutropenia. A clinical benefit rate of 58% has been noted.

Overall, toxicity rates with the addition of gefitinib to an oxaliplatin-fluoropyrimidine combination are markedly more favorable than with the irinotecan-based regimens, although higher incidences of grade Ⅲ or Ⅳ diarrhea, nausea, and vomiting than with FOLFOX alone are noted. Further studies of TKI-based therapy for CRC are planned or recruiting.

Erlotinib: Erlotinib, an orally reversible TKI reduces intratumoral EGFR autophosphorylation[43] with no effect on EGFR expression or surface receptor density. Evidence of single agent erlotinib activity in mCRC patients derived from disease-specific phase Ⅱ studies[44] led to the design of several trials in combination with chemotherapy.

Tarceva plus fluoropyrimidines: Additive activity of capecitabine and erlotinib in tumor models[45] supported a phase 2 trial evaluating the combination of erlotinib 150 mg daily with capecitabine 1000 mg/m^2 bid. for 14 d every 3 wk in chemotherapy-naive mCRC patients. Grade 3 diarrhea (30%) grade 3 renal insufficiency (10%) and grade 3 hiperbilirrubinemia (10%) were the most troublesome toxicities. Regarding efficacy, no complete responses were achieved whereas disease control rate was 34%[46].

Tarceva plus oxaliplatin: Meyerhardt *et al*[47] reported on the results of a triplet regimen of erlotinib, 100 mg/d, capecitabine, 1650 mg/m^2 per day (d 1-14), and oxaliplatin, 130 mg/m^2 every 3 wk in 32 patients mostly pretreated with an irinotecan-containing regimen. By intent-to-treat analysis, 25% of the patients experienced a partial response and 44% had stable disease for at least 12 wk. 29% of the patients discontinued study therapy due to toxicity.

Other TKIs-based combinations

EKB-569, an irreversible dual inhibitor of the EGFR and HER-2 tyrosine kinases, inhibits the growth of tumor cells that overexpress EGFR or HER-2 *in vitro* and *in vivo*[48]. Dose-limiting toxicities with EKB-569 plus FOLFIRI in 47 chemotherapy-naive mCRC patients[49] were grade 3 diarrhea and grade 3 fatigue. The MTD was selected as 25 mg EKB-569. The response rate was 38% and the clinical benefit rate was 85%. EKB-569 treatment resulted in complete inhibition of pEGFR and significant inhibition of pMAPK in both skin samples (11 patients) and tumor samples (three patients) with no change in pAkt activity.

In a dose-escalation study[50] with FOLFOX-4 plus EKB-569, 25-75 mg/d, starting from d 3, DLTs were observed with EKB-569 at a dose of 35 mg/d (grade Ⅲ diarrhea and febrile neutropenia), leaving an MTD of 25 mg/d. The most common grade Ⅲ or Ⅳ adverse events were neutropenia (32%; 9 of 29 patients) and diarrhea (8%; 2 of 29 patients).

COMBINING CHEMOTHERAPY AND VEGF-TARGETED THERAPIES

Bevacizumab

Clinical development of Bevacizumab (BV) has rapidly progressed to Phase Ⅲ trials after a preliminary randomized Phase Ⅱ trial in which 104 previously untreated mCRC patients were randomized to two doses of BV (5 and 10 mg/kg) in addition to bolus 5-FU/LV (high dose, Rosewell-Park regimen) or to 5-FU/LV alone[51]. The combination of 5-FU/LV with low-dose BV (5 mg/kg every 2 wk) demonstrated superiority compared with the control monotherapy arm and to the BV-containing arm at a higher dose. These results provided the rationale for the key front-line Phase Ⅲ study by Hurwitz *et al*[52] which demonstrated superiority of IFL plus BV over IFL plus placebo in terms of RR (45% *vs* 35%), PFS(10.6 mo *vs* 6.2 mo) and OS(20.3 mo *vs* 15.6 mo). A subanalysis of this trial has recently stablished the benefit of Bevacizumab in mCCR patients with poor conditions[53].

The second trial (E3200) was a second-line Phase Ⅲ study, designed for patients who already failed an irinotecan-containing therapy and did not receive BV in first-line treatment[54]. Initially, the study included three randomization arms: FOLFOX4 plus BV 10 mg/kg, FOLFOX4 alone or BV 10 mg/kg alone. The BV single-agent arm was closed ahead of time since it was clearly inferior to both other arms (RR 3% and PFS 2.7 mo). The results again largely favored the BV-containing arm, especially in terms of RR (21.8% *vs* 9.2%, $P < 0.0001$) and PFS (7.2 mo *vs* 4.8 mo, $P < 0.0001$). The primary end point of the study was reached, since a statistically significant increase in median survival was obtained in the experimental arm (12.5 mo *vs* 10.7 mo, $P < 0.0024$).

Finally, updated results of N016966, a randomized phase Ⅲ trial evaluating the addition of bevacizumab to oxaliplatin-based first line chemotherapy have been reported. Bevacizumab-containing arms demonstrated a significant benefit in terms of progression-free survival, although overall response rate did not significantly differ[55].

More recently, several phase Ⅱ trials have addressed the feasibility and activity of bevacizumab when combined with various cytotoxic regimens. The First BEATrial[56] enrolled 1927 chemotherapy-naïve patients treated with a combination of bevacizumab and several first-line chemotherapies, including FOLFOX, FOLFIRI and XELOX. Median PFS was 10.4 mo. Combinations of XELOX or XELIRI plus bevacizumab have yielded tumor control rates in the range of 80% as front-line therapy for mCRC[57].

In contrast to its efficacy when used in combination with first- and second-line chemotherapy, activity of bevacizumab in chemoresistant disease has been disappointing. Chen *et al*[58] developed a treatment referral center (TRC) protocol (TRC-0301) for patients with mCRC in the third-line setting with the aim of evaluating the safety and activity of BV plus FU/LV in patients progressed after treatment with both irinotecan-based and oxaliplatin-based chemotherapy regimens. Independent review confirmed one PR (1%; 95% CI, 0% to 5.5%). Median PFS in this cohort was 3.5 mo (95% CI, 2.1 mo to 4.7 mo) and median OS was 9.0 mo (95% CI, 7.2 mo to 10.2 mo). The authors conclude that BV, alone or in combination with an ineffective chemotherapy in the third-line setting, is likely to be of minimal, if any, clinical benefit.

An important question that remains unresolved is

whether to continue bevacizumab with second-line therapy following failure of a bevacizumab-containing first-line regimen. Although retrospective data from the BRiTE trial suggest that the use of bevacizumab beyond first progression correlate with an improved survival, more mature data are required to draw any firm conclusion[59].

VEGF Tyrosine kinase inhibitors (TKI)-based combination therapy

Tyrosine kinase inhibitors of vascular endothelial growth factor receptors (VEGFRs) are low molecular weight, ATP-mimetic proteins that bind to the ATP-binding catalytic site of the tyrosine kinase domain of VEGFRs, resulting in a blockade of intracellular signaling. Several of these molecules have entered clinical evaluation.

Semaxanib: Semaxanib is a small, lipophilic, synthetic molecule that inhibits VEGFR-1, and -2 tyrosine kinases[60]. A promising response of 31.6% was observed with semaxanib at two different dose levels, 85 and 145 mg/m^2 twice weekly in combination with fluorouracil plus leucovorin as first-line therapy for 28 patients with mCRC[61]. However, a randomized, multicenter, phase Ⅲ trial failed to show any improvement in clinical outcome with semaxanib in combination with fluorouracil and leucovorin (Roswell Park regimen) *versus* fluorouracil and leucovorin alone as first-line therapy for 737 mCRC patients; moreover, worse toxicity in the semaxanib arm (in terms of diarrhea, cardiovascular events, vomiting, dehydration, and sepsis) was observed[62].

Vatalanib: Valatanib is a synthetic, low molecular weight, orally bio-available agent that inhibits all known VEGFR tyrosine kinases, platelet-derived growth factor receptor beta (PDGFR-β) and c-Kit tyrosine kinase[63].

Vatalanib was evaluated in two phase Ⅰ/Ⅱ studies as a single daily dose in combination with FOLFOX-4 or FOLFIRI. In the first study, the pharmacokinetics and toxicity profiles of both vatalanib and FOLFOX-4 were unaffected by co-administration[64]. The reported response rate was 54%, with a median PFS of 11 mo and an estimated median OS time of 16.6 mo . In the second study[65], co-administration of vatalanib at 1250 mg/d with FOLFIRI had minor effects on irinotecan exposure but lowered by 40% the AUC of SN-38 in patients' serum. The response rate was 41%, with a median PFS duration of 7.1 mo and a median OS time of 24.3 mo. Two large, randomized, double-blinded, placebo-controlled, phase Ⅲ trials compared the efficacy of oral vatalanib in combination with FOLFOX-4 with FOLFOX-4 alone in patients with mCRC, and none of them met the primary end points. In the CONFIRM-2 trial, the addition of PTK/ZK to FOLFOX-4 in previously treated mCRC did not meet the primary end points of the study. OS was 12.1 mo in the PTK/ZK arm and 11.8 mo in the placebo arm. The overall response rate was, respectively, 18.5 and 17.5%. PFS was significantly longer in the PSK/ZK arm (5.5 mo *vs* 3.8, $P = 0.026$) As in confirm 1 trial, patients with pretreatment high LDH showed a strong improvement in PFS[66]. Adverse events were similar to those of the CONFIRM-1 trial. Thrombotic and embolic events of all grades occurred in 6% of the patients treated with PTK/ZK *vs* 1% in the placebo arm. Trying to further analyze the relation between LDH levels and clinical outcome with PTK/ZK, Fixed paraffin embedded tumor samples from 36 mCRC not included in the CONFIRM trials were analyzed and tumor gene expression correlated with serum levels of LDH in the same group of patients. Intratumoral levels of LAMA, hipoxia inducible factor 1 (HIF-1), Glut-1 and VEGFA were significantly correlated. Moreover, patients with high serum LDH showed increased intratumoral gene expression of VEGFA, supporting the hypothesis of serum LDH levels as a surrogate maker for activation of the hypoxia inducible factor related genes in the tumor[66].

AZD2171: Preliminary data of a phase I evaluation of AZD2171, a highly potent and selective inhibitor of VEGFR signaling, in combination with several chemotherapy regimens including FOLFOX-6 and CPT-11, has shown some evidence of activity[67].

Vandetalib: Vandetalib, a once-daily oral inhibitor of VEGFR-dependent tumor angiogenesis, EGFR- and RET-dependent tumor proliferation, in combination with FOLFOX6[68] or FOLFIRI[69] has also shown some evidence of activity in mCRC, with diarrhea and neutropenia being the most frequent grade 3 toxicities.

Future directions

So far, clinical, biochemical, and molecular markers have failed to discriminate which patients are more likely to benefit from bevacizumab-containing regimens. An analysis of predictive markers showed indeed that bevacizumab increased the activity of irinotecan plus FU/LV regardless of the level of VEGF expression, thrombospondin expression, and microvessel density[70]. Mutations of *k-ras*, *b-raf*, and *p53* could not predict for a prolonged survival on bevacizumab plus irinotecan plus bolus FU/LV[71]. Recently, Shaye *et al* evaluated functionally significant polymorphisms of genes involved in the angiogenesis pathway in mCRC patients who receive bevacizumab as part of their front-line therapy. There were statistically significant associations between genomic polymorphisms of KDR, CXCR2, MMP7, leptin and both progression-free survival and response rate. Hopefully, prospectively collected samples from patients enrolled onto cooperative group studies and the development of selective micro arrays to define the angiogenesis-related genes in individual tumors, and at different stages of therapy and tumor progression may allow improved therapeutic efficacy.

COMBINATION OF TARGETED THERAPIES

The assumption that most advanced solid tumors derive their growth advantage from more than a signaling pathway and the significant level of compensatory cross talk among receptors within a signaling network as well as with heterologous receptor systems has provided the basis of a combined molecular targeting approach, in which more than one class of inhibitor is applied simultaneously.

A phase Ⅱ study with the combination of FOLFOX,

bevacizumab (5 mg/kg) and erlotinib (150 mg/d) every two weeks in 31 chemotherapy naive mCRC patients has been recently conducted. Grade 3-4 adverse events included diarrhea (29%) neutropenia (29%) rash (18%), fatigue (14%) and neuropathy (11%) 78% of the patients had at least one grade 3-4 toxicity. Remarkably, as much as 42% of the patients came off for toxicity. Similar results have been reported in the DREAM-OPTIMOX3 study, with a 70% incidence of grade 3-4 toxicity when adding erlotinib to a combination of bevacizumab and XELOX[73].

A phase Ⅱ trial of FOLFOX plus bevacizumab and cetuximab in 67 chemotherapy-naïve mCRC patients yielded a 55% response rate, with a median PFS of 9.6 mo and 71% of the patients progression-free for at least 8 mo[74].

The combination of FOLFOX or FOLFIRI with panitumumab and AMG706, an oral multikinase inhibitor targeting VEGF, PDGF and Kit receptors has been tested in 45 mCRC patients, with no apparent PK/PD interactions and an overall response rate in the range of 50%[75].

Based on these results, combinations of monoclonal antibodies are currently being actively tested in first-line therapy of mCRC. The Cancer and Leukemia Group B (CALGB)/South West Oncology Group (SWOG) Intergroup 80405 Phase Ⅲ trial randomizes patients to either cetuximab or bevacizumab, or both antibodies in combination, with the oncologist's choice of FOLFOX or FOLFIRI. In addition, the Panitumumab Advanced Colorectal Cancer Evaluation (PACCE) trial is currently evaluating the efficacy of FOLFOX or FOLFIRI (depending on the investigator choice) plus BV, versus the same combination plus panitumumab.

OTHER TARGETED THERAPIES-BASED COMBINATIONS

Cell cycle inhibitors

Kortmansky *et al*[76] reported the results of the combination of 5-FU and UCN-01, a selective inhibitor of a number of serine-threonine kinases, including calcium and phospholipid-dependent protein kinase C and cell cycle specific kinases, among 35 patients with advanced solid tumors, the majority of them with a diagnosis of mCRC. No objective responses were observed, although eight patients had stable disease. Most of the patients with stable disease had previously received and progressed on 5-fluorouracil. There was minimal toxicity attributed to the combination, although expected toxicities associated with UCN-01 were observed.

Apoptosis modifiers

Bcl-2 plays a pivotal role in the regulation of caspase activation and apoptosis. Its overexpression is found in 30%-94% of clinocopathological colorectal carcinoma specimens and confers a multidrug resistant phenotype in several cell lines. In support of this data, antisense oligonucleotide therapy directed against bcl-2 was shown to significantly enhance the chemosensitivity in several cancer cell lines compared with controls *in vitro*. A recently published phase I trial assessed the feasibility and pharmacokinetic behaviour of the combination of oblimersen sodium, a phosphorothioate antisense oligonucleotide that hybridizes to the first six codons of the bcl-2 open reading frame mRNA, with CPT-11 in 20 pts with mCRC. Among them, 1 pt experienced a PR while 10 additional patients had stable disease lasting 2.5-10 mo. The authors recommend oblimersen at 7 g/kg/d, d 1-8 with CPT-11 280 mg/m^2 on d 6 once every 3 wk was the RD for further development in phase Ⅱ trials[77].

Proteasome inhibitors

The proteasome inhibitor Bortezomib (PS-341), at a dose of 1.3 mg/m^2 administered twice weekly every 21 d in pretreated patients with mCRC did not prove to have clinical activity[78].

The main nonhematologic toxicities were elevation of alkaline phosphatase, constipation, fatigue, nausea, and sensory neuropathy. A phamacokinetic and phamacodynamic analysis of topotecan plus PS-341 in 22 patients with advanced solid malignancies found that, with the addition of PS-341, peripheral blood mononuclear cells (PBMC) topoisomerase I levels got stabilised or increased. These findings suggest that PS-341 may overcome resistance to topoisomerase I inhibitors, since in vitro exposure to campothecin results in down-regulation of the target enzyme. Preliminary data of the combination of FOLFOX4 plus bortezomib in mCRC patients[79] show evidence of clinical activity, with bortezomib at a dose of 1 mg/m^2 being the RD for phase Ⅱ trials.

COX inhibitors

Numerous clinical trials are ongoing to test the efficacy of nonsteroidal anti-inflammatory COX-2 inhibitors in combination regimens for therapy of advanced solid tumors[80]. Preliminary data on the combination of rofecoxib (50 mg/d) with weekly irinotecan and infusional fluorouracil demonstrated a good tolerability up to the irinotecan dose of 125 mg/m^2/wk. The phase Ⅱ study showed a 36.7% objective response rate, a clinical benefit of 76.7% and a median TTP and overall survival of 4 and 9 mo, respectively. The combination was feasible and safe, with a reduced rate of mucositis and diarrhea[81].

However, in the BICC-C trial[82], addition of celecoxib to several Irinotecan/fluorpyrimidine combinations did not impact safety or efficacy. Results of larger studies seem warranted.

Histone deacetylase inhibitors

Histone acetylation by histone acetyltransferases is important for promoting the action of several transcription factors. Acetylation facilitates binding of transcription factors to specific target DNA sequences by destabilizing nucleosomes bound to the promoter region of the target genes[83].

Vorinostat, a novel histone deacetylase inhibitor that potentiates 5-FU through a decrease in thymidylate synthase (TS) expression has been tested in combination with FOLFOX, in a phase I study that enrolled mCRC patients who had failed prior FOLFOX, irinotecan and

cetuximab therapy. Tolerance was acceptable, and some evidence of both, clinical activity (SD in some patients) and biological activity (down regulation of TS) are suggested[84].

mTOR inhibitors

Rapamycin displays potent antimicrobial and immunosuppressant effects as well as antitumor properties. Rapamycin's antiproliferative actions are due to it's ability to modulate key signal transduction pathways that link mitogenic stimuli to the synthesis of proteins necessary for the cell cycle to progress from the G1 to S phase[85].

Rapamycin clinical development has been hampered due to the poor aqueous solubility and chemical stability of the macrolide. CCI-779, a rapamycin ester derived from 2, 2-bis (hydroxymethyl) propionic acid, is one analog that was selected for further development due to its promising pharmacological, toxicological and antitumor profiles[86].

A phase I study of escalating doses of CCI-779 in combination with 5-FU/leucovorin in patients with advanced solid tumors, including mCRC reported preliminary evidence of activity including 1 complete response in a patient with mCRC receiving the 15 mg/m^2 dose and several patients with stable disease of a maximum duration of 12 mo. Further studies are required to determine appropriate regimens with this combination treatment[87].

CONCLUSION

In conclusion, the biological agents have clearly increased the therapeutic armamentarium of patients with metastatic CRC and offer also prospects for an increased chance of a longer survival. Eventually, the availability of more predictive biological factors may allow oncologists to tailor individualized targeted combination therapy to a specific patient with a specific tumor. However, the cost of novel therapies for mCRC is particularly high. Such a heavy economical burden may be counterbalanced either by a very significant breakthrough in treatment efficacy or by selection of patients with a higher chance of responding to a specific treatment.

Abstract

Colorectal cancer constitutes one of the most common malignancies and the second leading cause of death from cancer in the western world representing one million new cases and half a million deaths annually worldwide. The treatment of patients with metastatic colon cancer comprises different regimens of chemotherapeutic compounds (fluoropyrimidines, irinotecan and oxaliplatin) and new targeted therapies. Interestingly, most recent trials that attempt to expose patients to all five-drug classes (fluoropyrimidines, irinotecan, oxaliplatin, bevacizumab and cetuximab) achieve an overall survival well over 2 years. In this review we will focus on the main epidermal growth factor receptor inhibitors demonstrating clinical benefit for colorectal cancer mainly cetuximab, panitumumab, erlotinib and gefitinib. We will also describe briefly the molecular steps that lie beneath them and the different clinical or molecular mechanisms that are reported for resistance and response.

Key words: Epidermal growth factor receptor inhibitors; Cetuximab; Panitumumab; Erlotinib; Gefitinib; Metastatic colorectal cancer; Tyrosine kinase inhibitors; Monoclonal antibodies

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies and the second leading cause of death from cancer in Europe and North America. It is responsible for approximately one million new cases and half a million deaths per year worldwide[1].

Several options are currently available for the treatment of patients with metastatic colorectal cancer (mCRC), including different regimens of chemotherapeutic compounds (fluoropyrimidines, irinotecan and oxaliplatin) and targeted therapies such as bevacizumab and cetuximab. Interestingly, most recent trials that attempt to expose patients to all five drug classes (fluoropyrimidines, irinotecan, oxaliplatin, bevacizumab and cetuximab) target an overall survival (OS) well over 2 years.

In this review we will summarise state-of-the-art targeting of the epidermal growth factor receptor (EGFR) in the management of metastatic colorectal cancer.

BIOLOGY OF EGFR

EGFR belongs to the ErbB family[2]. This family is comprised by transmembrane proteins that form part of the tyrosine kinases receptor proteins which are activated by different kinds of ligands[3] (Figure 1). All the receptor tyrosine kinases share the same protein structure with an extracellular binding domain, a transmembrane domain and an intracellular domain where the catalytic domain is located. The autophosphorylation of tyrosine residues outside the catalytic domain stabilises the receptor in the active conformation and recruit different proteins required for signalling.

There are several ligands binding ErbB including EGF, TGF alpha, Neuregulin family and some others[4]. Not all the ligands 'fit' all the receptors and this feature also has its implications at a molecular level[2]. Once the ligand binds the receptor and the molecule is phosphorylated it can switch on several pathways including the RAS-RAF-MAPK, JAK-STAT and the PIK3-AKT pathways. The signalling pathways activated by different EGF ligands drive various transcription factors to the nucleus that result in different cellular responses such as proliferation, migration, differentiation or apoptosis.

There are four different receptors in the ErbB family named ErbB1 (EGFR; HER or c-erbB the first to be described), ErbB2 (HER2/neu), ErbB3 (HER3) and ErbB4 (HER4). In the active conformation, the protein forms homodimers or heterodimers that are stabilised by the ligand binding. HER2/neu cannot (due to a genetic mutation) bind to EGF-like ligands and ErbB3 does not have a functional tyrosine kinase.

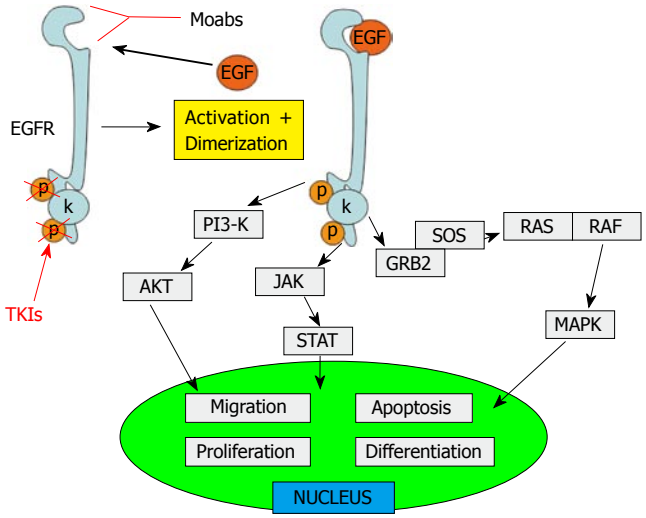

Figure 1 EGFR and its pathways.

Targeting the ErbB network may be achieved by inhibiting the tyrosine kinase (catalytic domain) with small molecules (TKIs) or by inhibiting the extracellular domain with monoclonal antibodies (Moabs) as shown in Figure 1. The moabs block the interaction between natural ligands and the EGF receptor in the extracellular space. The receptor is internalized and that can affect the network, as the timing of this process in the physiological state of the receptor also has its molecular implications[4,5]. Certain antibody isotypes such as IgG1 (cetuximab) have the potential for mediating antibody-dependent cell-mediated cytotoxicity (ADCC) and complement fixation[6], improving thus their antitumor activity. The TKIs compete with the ATP in their binding sites on the catalytic domain of the receptor and so act inside the cell.

CLINICAL APPLICATION

Monoclonal antibodies

Cetuximab: Cetuximab is an IgG1 monoclonal antibody targeting EGFR. Since preclinical data suggested that cetuximab might revert irinotecan resistance *in vitro*[7,8] and *in vivo*[9], a phase Ⅱ study[10] with 121 EGFR expressing mCRC patients refractory to irinotecan was started. A 17% overall response rate (ORR) was documented at an expense of acceptable toxicity grade 3-4. Cetuximab monotherapy has also proved activity in irinotecan refractory patients[11]. A phase Ⅱ open-label clinical trial with 57 EGFR positive mCRC patients was treated and an ORR of 9% was observed. The acne-like skin rash was the main described toxicity related to the drug. Two patients experienced grade 3 allergic reaction and discontinued the study. The study CO.17 that compared cetuximab and best supportive care (BSC) against BSC alone showed that cetuximab provides palliation in pretreated patients with advanced CRC, delaying deterioration in quality of life as well as improving survival[12] (Table 1).

These data led to the design of a study with 329 patients (pts) refractory to irinotecan who were randomized to cetuximab (111 pts) or irinotecan plus cetuximab (CI)

Table 1 Cetuximab in Irinotecan refractory mCRC

	Pts (*n*)	RR (%)	PFS (mo)	OS (mo)
C225 + Innotecan[10]	121	17	-	-
C225[11]	57	9	-	6.4
C225 + Innotecan[13]	329	23	-	8.6

Pts: Patients; mCRC: Metastatic colorectal cancer; RR: Response rate; PFS: Progression free survival; OS: Overall survival; mo: Months; C225: Cetuximab.

(218 pts). The ORR was 22.9% (95% CI: 17.5% to 29.1%) in the CI arm as opposed to 10.8% (95% CI: 5.7% to 18.1%) in the cetuximab arm. OS (8.6 mo *vs* 6.9 mo) and time to progression (TTP) (4.1 mo *vs* 1.5 mo) also favoured the CI arm. The toxicity presented in the CI group was very similar to that of patients treated with irinotecan alone[13] (Table 1).

More mature data regarding the role of CPT-11 and cetuximab in irinotecan refractory patients have been recently reported in the MABEL trial[14]. A multicenter study with 1461 CPT-11 refractory mCRC EGFR positive patients, 64% of whom had received two or more chemotherapy lines; 1123 patients are currently evaluable and a 12-week overall progression free survival (PFS) rate is 61% (58%-64%), and 34% (31%-37%) at 24 wk. The current estimate of median survival is 9.2 mo (8.7-9.9) with grade 3/4 adverse events being diarrhea (20%), skin toxicity (including acne-like rash) (19%), neutropenia (9%) and asthenia (8%). Hypersensitivity reactions occurred in 1.5% of the patients.

The above mentioned results provided the rationale for the BOND2 study that compared the combination of irinotecan, bevacizumab and cetuximab against bevacizumab plus cetuximab in CPT-11 refractory mCRC patients. A 43% ORR as opposed to 27% in favour of the irinotecan arm was presented. The median time to progression was 7.1 mo *vs* 4.6 mo and the median survival was 18.0 mo *vs* 10.3 mo for the irinotecan group[15,16]. The toxicity observed was the expected for each agent alone.

A variety of preclinical data have suggested activity of cetuximab in oxaliplatin resistant tumors[17]. Thus, a phase Ⅱ trial that combined CAPOX (oxaliplatin 85 mg/m^2, d 1, and capecitabine 2000 mg/m^2, d 1-7, every 2 wk) plus Cetuximab in patients who had progressed to oxaliplatin-based regimens has recently been presented[18]. Eighty percent of the 40 patients had also progressed on prior irinotecan-based chemotherapy. The study achieved 1 complete response (CR) (2.5%) and 7 partial responses (PR) (17.5%) with a 20% ORR and a 47.5% disease control rate (DC). The median TTP was 3 mo and the median survival 10.7 mo. Toxicity included grade 3-4 neutropenia (12.5%) and diarrhea (7.5%) and grade 2-3 neurotoxicity (22.5%). The second trial named EPIC is a phase Ⅲ study comparing cetuximab plus irinotecan and irinotecan as a second line in EGFR positive patients who received oxaliplatin plus fluoropyrimidines as a first line therapy. The primary endpoint was overall survival and quality of life being one of the secondary endpoints. Cetuximab plus irinotecan (n = 648) was superior to irinotecan alone (n = 650)

regarding progression-free survival and response rate (16.4% *vs* 4.2%, $P < 0.0001$). OS was comparable between both arms, but it may have been influenced by crossover. Health related quality of life was better preserved on the combination arm with less deterioration in symptom scores (pain, nausea, insomnia) and better health status scores[19]. Main toxicity (> 10%) grade 3-4 were neutropenia (30%) and diarrhea (21%). There is also a study by Lenz *et al*[20] analyzing with 346 refractory to irinotecan, fluoropyrimidines or oxaliplatin EGFR positive patients that achieved a RR of 12% with cetuximab monotherapy in patients.

The preliminary promising efficacy seen with C225 in refractory mCRC has prompted its use as front line therapy. In the ACROBAT study 43 EGFR positive mCRC patients were treated with cetuximab plus FOLFOX with a 77% RR, a median survival of 30 mo and a median PFS of 12.3 mo[21]. The study presented by Rosemberg *et al*[22] in 2002 was designed as a phase Ⅱ study with 27 EGFR positive patients that were treated with irinotecan, 5-fluorouracil/leucovorin (IFL) and cetuximab as frontline. They showed a 44% PR rate with another 20% of patients showing minor responses. Twenty-six out of 27 patients presented with rash, but only 19% were grade 3. Another study with a similar chemotherapeutic scheme was presented by Folprecht *et al*[23] in 2005 with a 67% RR and 29% stable disease rate in 20% of whom their liver metastases were resected after treatment. They used high and normal doses of 5-fluorouracil/leucovorin, three out of fifteen patients presented dose limiting toxicity (DLT) in the group of high dose (2000 mg/m^2). A phase Ⅱ study with 23 EGFR positive mCRC patients of whom 22 were assessable for response were treated with FOLFIRI and cetuximab in first line therapy. It showed a 46% PR rate and a 41% SD rate with a median TTP of 10.9 mo. Most common grade 3/4 toxicities were diarrhea, neutropenia and rash[24]. Seven patients underwent secondary surgery of metastases. Another study with FOLFOX-6 plus cetuximab in chemo-naive patients showed a preliminary 53% ORR with 3 CR[25]. It was a phase Ⅱ study with 82 mCRC patients showing positive or undetectable EGFR expression. 14 patients discontinued the study due to toxicity and 10% of the patients had grade 4 neutropenia and 2% grade 4 sepsis (Table 2).

More recently, results of the CRYSTAL study, a phase Ⅲ clinical trial that compares FOLFIRI plus cetuximab (arm A) *versus* FOLFIRI alone (arm B) in 1217 mCRC have been presented. The median PFS was significantly longer for arm A compared to arm B [8.9 mo (CI: 8-9.5) for group A *versus* 8 mo (CI: 7.6-9) for group B, $P = 0.036$]. RR was also significantly increased by cetuximab (46.9% *vs* 38.7%, $P = 0.005$). The most common toxicities were neutropenia (26.7% in group A, 23.3% in group B), diarrhea (15.2% and 10.5% respectively) and skin reactions (18.7% and 0.2% respectively)[26]. The OPUS study is a phase Ⅲ clinical trial[27] that randomized patients to FOLFOX or FOLFOX plus cetuximab in chemo-naive patients. Their primary objective was response rate and secondary objectives were PFS, OS, and the R0 resection rate after metastatic surgery of curative intent. The preliminary results showed an RR of 35.7% and 45.6% respectively with 337 patients enrolled at that time. The most common grade 3/4 adverse events were neutropenia (27.6% in A; 31.5% in B), diarrhea (7.1% and 6.0%), leucopenia (7.1% and 5.4%) and rash (9.4% in the cetuximab arm only). The COIN study is a phase Ⅲ trial[28] (804 pts) comparing either continuous chemotherapy plus cetuximab or intermittent chemotherapy with the standard palliative combination. The addition of cetuximab to oxaliplatin-fluoropyrimidine combinations results in increased grade 3/4 toxicities overall and specifically to the gastrointestinal (GI), skin rash and lethargy. Capecitabine combination is associated with more GI toxicity but less neutropenia. Unexpectedly, no hypersensitivity reactions have been seen yet on FOLFOX (with or without cetuximab) (Table 3).

Table 2 Cetuximab as frontline, Phase Ⅱ studies

C225 plus:	Pts (*n*)	RR (%)	PFS (mo)	OS (mo)
FOLFIRI[25]	22	80	10.9	-
FOLFOX-4[22]	43	77	12.3	30
FOLFOX-6[26]	82	53	-	-

Pts: Patients; RR: Response rate; PFS: Progression free survival; OS: Overall survival; C225: Cetuximab.

Table 3 Cetuximab as frontline, Phase Ⅲ studies

C225 plus:	Pts (*n*)	RR (%)	PFS (mo)	OS (mo)
FOLFOX Cetuximab *vs* FOLFOX[28]	337	46.6% *vs* 35.5%	-	-
FOLFIRI Cetuximab *vs* FOLFIRI[27]	1217	46.9% *vs* 38.7%	8.9 *vs* 8.0	-

Pts: Patients; RR: Response rate; PFS: Progression free survival; OS: Overall survival.

Panitumumab: Panitumumab is a fully human IgG2 monoclonal antibody directed against the epidermal growth factor receptor. Several trials have tested its role in pretreated mCRC. The study with 148 mCRC refractory to FOLFOX/FOLFIRI EGFR positive patients treated with panitumumab alone showed a 10% RR with 36% of SD. 90% of the patients appeared with skin rash but only 4% G3[29]. Another study with panitumumab in refractory patients to FOLFOX/FOLFIRI[30] showed benefit for treating those patients with Panitumumab *vs* BSC. They were 463 EGFR positive patients who were assigned to panitumumab or BSC alone. The median progression free survival was 8 wk in the Panitumumab group *vs* 7.3 wk in the BSC group and the mean PFS 13.8 wk *vs* 8.5 wk. The RR was 10% in the Panitumumab group and 0% in the BSC group. The main toxicities were rash, diarrhea and hypomagnesemia. They did not find any advantage in overall survival due to the crossover but it resulted in a 46% reduction in the risk of tumor progression. Another study with 91 mCRC pretreated patients with negative or low EGFR by immunohistochemistry (IHC) showed a 7%-9% PR rate with 36%-42% of DC presenting skin and hypomagnesemia as main toxicities[31] (Table 4).

Table 4 Panitumumab, Phase Ⅱ and Ⅲ studies

	Pts (*n*)	RR (%)	PFS	Naive	Phase
Alone[30]	148	10	-	No	Ⅱ
Alone *vs* BSC[31]	463	10	8 wk	No	Ⅲ
Alone[32]	91	8	8 wk	No	Ⅱ
IFL + Panitumumab *vs* FOLFIRI + Panitumumab[33]	19	46	5.6 mo	Yes	Ⅱ
	24	42	10.9 mo		

Pts: Patients; RR: Response rate; PFS: Progression free survival; OS: Overall survival; mo: months; BSC: Best supportive care.

Panitumumab showed better tolerability combined with FOLFIRI than with IFL[32]. In a pooled analysis of several trials[33] the skin toxicity in panitumumab patients was 90%-95% but only in 3%-5% was grade 3 and treatment limiting. The other relevant toxicities were gastrointestinal (nausea, diarrhea and anorexia) which accounts for 25%-30% of all grades (2% grade 3) and hypomagnesemia (41%; 7% grade 3). The severity of skin rash was correlated with increased efficacy in terms of ORR, PFS, and OS[34,35]. A recent study with panitumumab has correlated skin toxicity with increased efficacy and better health-related quality of life[34]. In this phase Ⅲ study patients were randomized to panitumumab plus BSC (231 patients) or BSC alone (232 patients) and the skin toxicity was analyzed in relation to PFS and OS. The incidence of grade 2-4 skin toxicity was higher in the panitumumab arm. OS was significantly prolonged in patients with more severe skin toxicity (gr 2-4 *vs* gr 1; HR = 0.67; $P = 0.0235$) (Table 4).

Tyrosine kinase inhibitors

Gefitinib: Gefitinib is a potent, specific EGFR tyrosine kinase activity inhibitor. Phase Ⅰ/Ⅱ trials in patients with mCRC showed little activity[36,37] but preclinical studies *in vitro* and *in vivo* suggested a supra-additive growth inhibitory effect of gefitinib when combined with different cytotoxic drugs[38] which gave support to several clinical trials of gefitinib combined with chemotherapy in mCRC patients.

The study by Magné *et al*[39] support studies that combined gefitinib with fluoropirimidines[40]. The study was designed in two parts with 23 patients overall. One part with intermittent dose-escalated gefitinib plus 5-fluorouracil (370 mg/m^2 Ⅳ)/LV (20 mg/m^2 Ⅳ) and the other with continuous gefitinib at the safest dose assigned by part one. The safest dose assessed was 500 mg/d achieving a 23% OS with skin rash and diarrhea as main toxicities. Preliminary results from a small phase Ⅰ/Ⅱ trial combining gefitinib 250 mg/d plus capecitabine 1000-1250 mg bid. after failure to first line therapy also suggests some evidence of activity[41].

A dose-finding trial was performed with irinotecan plus gefitinib in 18 patients with advanced CRC refractory to fluoropyrimidine-based chemotherapy. It defined irinotecan given at a dose of 225 mg/m^2 as a single agent every 3 wk plus gefitinib at a dose of 250 mg/d as the maximum tolerated dose (MTD) of this regimen[42]. Dose-limiting toxicities, such as neutropenia and diarrhea, occurred at unexpectedly low doses of irinotecan. Disease stabilization was achieved in 21% (4 out of 18 patients). Once they achieved the recommended dose level (RDL) they expanded the study to a multicenter one with a total of 27 patients at the RDL with an objective tumor response rate of 11% and median survival 9.3 mo[43]. The toxicity grades 3-4 included diarrhea (35.9%), lethargy (15.4%), neutropenia (15.4% with 10.3% febrile neutropenia) and skin rash (7.7%).

The combination of gefitinib plus FOLFIRI in both chemo-naive mCRC patients[44] and as salvage therapy[45] was considered too toxic despite dose reduction in 5-fluorouracil, leucovorin and irinotecan. Toxicity was also the main issue when combining gefitinib with capecitabine in patients who had previously received one or two chemotherapy lines being diarrhea and neutropenia, the principal related DLTs[46].

In a study by Kuo *et al*[47] with 27 patients who had previously received at least one regimen (oxaliplatin based mainly) they employed FOLFOX-4 and gefitinib at a dose of 500 mg/d. 33% of the patients achieved objective responses and 48% showed stable disease. Median OS was 12.0 mo, while median event-free survival was 5.4 mo. For first-line treatment, a 74% RR with a clinical benefit rate of 98% and a median TTP of 9.5 mo. was reported by Zampino *et al*[48] with the FOLFOX-6 regimen plus gefitinib at a dose of 250 mg/daily.

The study by Zeuli *et al*[49] assessed the doses of gefitinib (250 mg/d) plus capecitabine (2000 mg/m^2 per day, d 1-15) and oxaliplatin (120 mg/m^2 d 1) every 3 wk for six courses as first-line treatment in patients with metastatic disease. The most common grade 3 adverse events were diarrhea and neutropenia. A 50% response rate (6 out of 12 patients; 5 PRs, 1 CR) and a clinical benefit rate of 58% (7 out of 12 patients) were communicated.

In an *in vitro* study working with cetuximab-resistant cell lines, authors observed that gefitinib or erlotinib retained the capacity to inhibit growth of tumor cells that were highly resistant to cetuximab[50]. These data suggest that tyrosine kinase inhibitors may further modulate intracellular signalling that is not fully blocked by extracellular anti-EGFR antibody treatment. A phase Ⅰ/Ⅱ study that combined cetuximab and gefitinib[51] presented 56% of PR in mCRC patients. This observation deserves further evaluation.

Erlotinib: Erlotinib is a small molecule that competes with ATP for the intracellular tyrosine kinase domain of EGFR, thereby inhibiting receptor autophosphorylation and blocking downstream signal transduction (Figure 1). Evidence of single agent erlotinib activity *in vitro* and in mCRC patients, derived from disease specific phase Ⅱ studies[52,53], led to the design of several trials in combination with chemotherapy. One phase Ⅱ study presented a PR rate of 4% in 51 mCRC patients. 46 of them were assessed for response. Skin rash was observed in 62% of the patients (13% G3) and grade 3 diarrhea and nausea were also observed after erlotinib monotherapy. Another phase Ⅱ study on 38 mCRC patients treated with 150 mg of erlotinib in a continuous daily schedule presented a 39% SD rate, as the best response, with rash and diarrhea as the main toxicity events[53]. Additive activity of erlotinib when combined with

capecitabine in preclinical studies with human xenografts[54] supported a phase Ⅱ study with 10 pts evaluating the combination of erlotinib 150 g daily with capecitabine 1000 mg/m^2 bid. for 14 d in chemotherapy-naive metastatic CRC patients. Grade 3 diarrhea (30%), grade 3 renal insufficiency (10%) and grade 3 hyperbilirubinemia (10%) were the most troublesome toxicities. Regarding efficacy, no complete responses were achieved whereas disease control rate (PR + SD) was 34%[55].

In the study by Meyenhart *et al*[56] when combining oxaliplatin, capecitabine and erlotinib patients started receiving 1000 mg/m^2 bid. of capecitabine that was reduced to 750 mg/m^2 bid for 14 d after the first 13 patients experienced excess of grade 3/4 toxicities. Thus, the final doses were capecitabine 750 mg/m^2 bid. for 14 d, oxaliplatin at 130 mg/m^2 on d 1, and erlotinib 150 mg daily. The ORR was 20%. In addition, the group of Delord *et al*[57]presented a dose-finding study establishing erlotinib 100 mg/d, capecitabine 1650 mg/m^2 qd (d 1-14), and oxaliplatin130 mg/m^2 every 3 wk as the MTD for this regimen.

Erlotinib (50-150 mg/d) is also being investigated in combination with FOLFOX-4 for untreated or minimally pretreated patients with CRC, with a preliminary reported 43% response rate. The most commonly communicated grade 3 or 4 toxicities were diarrhea and neutropenia[58].

CLINICAL AND MOLECULAR MARKERS OF RESISTANCE AND RESPONSE TO EGFR INHIBITORS

A peculiar toxic effect of cetuximab is a papulopustular skin rash, generally on the face and upper torso, which is thought to be mechanism- and dose-related[59]. Findings suggest that there is a correlation between intensity of skin rash and response and survival[13]. This correlation is particularly striking in a subgroup analysis from the IMC 0144 trial reported by Pippas *et al*. In that trial, patients with no skin toxicity presented no objective responses and had a median survival of 1.7 mo, whereas those who experienced grade 3 skin rash had a 20% RR and a median survival of almost 1 year[60]. This is the first reported observation of a clinical feature that may predict the clinical outcome of an antitumor agent. Dose-escalation schedules are currently under investigation in order to explore the possibility of increasing cetuximab efficacy by inducing skin rash.

The EVEREST study was designed as a phase Ⅲ trial with cetuximab escalated-doses. They started with standard dose and increased dose every 2 wk until skin toxicity grade 2 or 500 mg/m^2 of cetuximab were achieved. The dose-escalation of up to 500 mg/w indicated improvement of RR in pts with no or slight skin reactions on standard dose treatment[61] with 166 patients included in the study. The mechanism underlying the correlation between skin toxicity and tumour response is currently unclear, however, some research groups hypothesized that the rash is a surrogate indicator of an adequate degree of receptor saturation by cetuximab. If this is the case, targeting doses to achieve a desired level of cutaneous toxicity may further increase the efficacy of this agent. While this is an appealing prospect from a potential efficacy point of view, it would suggest, if true, that there might be a narrow therapeutic window when working with this drug[59].

In early clinical trials, EGFR positivity on tumor specimen by IHC was mandatory for the use of cetuximab. However today, EGFR expression status is known not to be a predictive factor of response to cetuximab since major responses in patients with EGFR negative tumors are expected after cetuximab treatment. In fact, responses have been reported by some authors[62] and nowadays EGFR status is not mandatory for the management of CRC patients[63]. Several factors might explain this apparent discrepancy, such as low sensitivity of IHC, cytological heterogeneity of CRC and differential EGRF expression in primary and metastatic tumor niches[64,65]. There are other reasons that might explain these striking data. Two distinct EGFRs have been identified in A431 cells by epidermal growth factor-binding studies. These are a major class of low-affinity EGFR (representing approximately 95% of the receptors) and a minor class of high-affinity EGFR (representing approximately 5% of the receptors), with binding affinities differing by an order of magnitude[66-68]. The current EGFR IHC detection systems used today derived from A431 cells do not distinguish between these two distinct EGFRs. It is known that high-affinity EGFRs are the biologically active receptors that switch the ErbB pathway whereas low-affinity receptors do not contribute significantly[66,69]. Another possible explanation is related to the ADCC capacity of cetuximab antibodies and two polymorphisms related to fragment C of the immunoglobulin G that are related to progression and survival[70].

In order to assess response to EGFR inhibitors in the clinical practice different molecular approaches are being evaluated. There are some studies where they try to find a correlation between some germinal polymorphisms involved in angiogenesis, the EGFR pathway, DNA repair and drug metabolism[15,71]. In a recent study they found a correlation, in patients treated only with cetuximab, between a Cyclin D1 polymorphism (A870G) and overall survival[72]. The Cyclin D1 is a protein related to p27^{KIP1} which is involved in the G1 phase arrest produced by EGFR inhibitors and that is correlated to apoptosis in tumor biopsies of patients treated with gefitinib[73]. The heterozygous AG genotype was significantly related to higher overall survival. Patients with AA homozygous genotype survived a median time of 2.3 mo (95% CI 2.1, 5.7) compared to those having homozygous GG genotype that survived a median of 4.4 mo (95% CI 1.8, 9.8). Even patients with a heterozygous AG genotype presented in comparison, a median survival of 8.5 mo (95% CI 5.5, 11.7), ($P < 0.05$)[72]. Another study showed similar results finding a correlation between EGFR (G497C GA), Cox-2 (G-765C CC) and EGF (A61G GG) polymorphisms and PFS[74].

Furthermore, a different investigation treated mCRC patients with cetuximab or panitumumab assessing the

EGFR copy number and the mutation profile of the EGFR catalytic domain and of selected exons in KRAS, BRAF, and PIK3CA[75] in the tumor sample. They found that in 8 out of 9 patients with an objective response the EGFR copy number was increased whereas only 1 out of 21 non-responders had an increased EGFR copy number. A retrospective study showed a linkage between EGFR mRNA levels by RT-PCR and TTP but not with survival[76] and found no correlation between any other ErbB receptors or EGFR by IHC and clinical outcome. There are other studies that suggested a correlation of KRAS mutation and poor outcome in terms of response and survival[77-79]. In the study by Finocchiaro *el al*[77] they analyzed tumor blocks from 85 colorectal cancer patients for EGFR expression (IHC and FISH), HER2 (FISH) and KRAS (mutation). EGFR FISH positive patients (41 patients) had a significantly higher RR and TTP than EGFR FISH negative individuals (44 patients). EGFR expression assessed by IHC was not associated with any clinical endpoint. Increased HER2 gene copy number predicts early escape from cetuximab therapy. Compared to patients with wild type KRAS, KRAS mutation carriers (32 patients) had a significantly lower RR (6.3% *vs* 26.5%, $P = 0.02$), shorter TTP (3.7 mo *vs* 6.3 mo, $P = 0.07$) and shorter survival (8.3 mo *vs* 10.8 mo, $P = 0.2$). In 22 patients with available primary and metastatic tumor samples, there was no difference between these sites for EGFR FISH, HER2 FISH and KRAS results. A study of 59 mCRC patients treated with cetuximab plus chemotherapy looked for KRAS mutations using first direct sequencing and two sensitive methods based on SNaPshot and PCR-ligase chain reaction (LCR) assays. They compared clinical response with gene mutations. No KRAS mutation was found in the 12 patients presenting clinical response. On the contrary KRAS mutation was associated with disease progression ($P = 0.0005$) and TTP was significantly decreased in patients with mutated KRAS tumors (3 mo *vs* 5.5 mo, $P = 0.015$)[78].

The other important mutations associated with the activity of EGFR inhibitors that are related to response to TKIs in lung cancer are mutations in exons 18, 19 and 21[80,81]. In mCRC it seems not to be the case. That may be due to the fact that those mutations are not commonly found in mCRC patients[20,82,83]. Because of this issue other predictive factors of response to Gefitinib such as the insulin receptor isoform A are currently under research[84].

FUTURE DIRECTIONS IN EGFR TARGETING

Monoclonal antibodies

EMD 72000: EMD 72000 (Matuzumab) is a humanized IgG1 anti-EGFR MoAb. It has completed phase I clinical testing in EGFR-positive solid tumors. 22 patients of different origin (including colorectal) received EMD 72000 weekly[85] and a 23% RR was demonstrated. EMD 72000 administered to 22 patients with colon (15 patients), gastric, or renal tumors demonstrated PR in 2 patients and a minor response in 1 patient[86] all of them with colon cancer. Another phase I study showed near-complete EGFR signalling suppression at the 1200 mg dose level[87]. A phase I study of matuzumab administered weekly to 26 patients (18 of which had CRC) showed 2 PR, and 10 SD in patients with colon cancer. In addition a preliminary analysis of skin biopsies showed that matuzumab produced inhibition of pEGFR and pMAPK with a decrease in Ki67 expression and an increase in p27[88].

AEE788: AEE788 is an oral inhibitor against EGFR, ErbB2, VEGFR-2 and KDR. A phase I study in these patients with advanced CRC and liver metastases showed the lack of clinical activity of AEE up to 400 mg with an inhibitory effect of 100%, 90% and 39% over pEGFR, pMAPK and Ki67 respectively by IHC in tumor biopsies[89]. Another study that investigated the effects of AEE *in vitro* and in biopsies from 22 advanced colorectal cancer patients did not find any major clinical responses even at the higher dose schedule (400 mg). Laser scanning cytometry quantitative analysis confirmed the target inhibition of AEE *in vitro* and in wound-induced skin pairs[90]. The lack of significant target inhibition in tumors has to do with the lack of clinical activity of AEE in this cohort of patients and is consistent with other studies.

HKI-272: HKI-272 is an irreversible pan-erbB receptor tyrosine kinase inhibitor. It inhibits the growth of tumor cells that express erbB-1 and erbB-2 (HER-2) in culture and in xenografts. HKI-272 also inhibits the growth of cultured cells that contain sensitizing and resistance-associated EGFR mutations[91]. A phase I study with 73 patients is ongoing and the preliminary results for 51 patients (3 of which are mCRC) showed a MTD of 320 mg/d with diarrhea as the DLT. Two breast cancer patients had confirmed partial responses and 2 had unconfirmed PRs[92].

Other MoAbs directed against EGFR have recently undergone clinical testing e.g., hR3[93] and ICR62[94].

NEW GENERATION OF TYROSINE KINASE INHIBITORS

Additional oral TKIs currently under clinical evaluation, include the reversible dual EGFR/Her-2 TKI lapatinib and the irreversible EGFR TKI EKB-569.

Lapatinib: Lapatinib is a reversible inhibitor of ErbB1/ErbB2 tyrosine kinases. 64 patients (22 with colon cancer) were included in a phase I study. One CR and 22 SD were achieved. Most of the patients with SD overexpressed either ErbB1 or ErbB2. The most frequent toxicities presented were rash, diarrhea, nausea/vomiting, fatigue, and anorexia. Serum VEGF may be a potential biomarker for lapatinib activity[95]. A study in combination with FOLFOX-4 to assess the safety included 13 patients (2 colon). The dose of lapatinib 1500 mg/d with FOLFOX-4 was well tolerated although 2 patients had grade $\geqslant$ 3 hematological toxicities, which resolved after delay of the next cycle. Seven patients were evaluable for response and 2 PR, 2 SD and 3 PD were confirmed[96]. A phase Ⅱ study with lapatinib as the single-agent in 86 mCRC patients who progressed to prior therapy showed 5 patients who experienced clinical benefit with stable disease

for ⩾ 20 wk[97]. The median TTP and overall survival were 8 and 42.9 wk respectively. The most commonly encountered adverse events were diarrhea (45% grade 1-2, 5% grade 3), rash (33% grade 1-2, 2% grade 3), fatigue (27% grade 1-2, 2% grade 3), nausea (20% grade 1-2, 1% grade 3), anorexia (16% grade 1-2, 2% grade 3), and vomiting (14% grade 1-2).

EKB-569: EKB-569 is a selective, irreversible inhibitor of the EGFR, was well tolerated in patients with advanced solid tumors of the colon, lung, breast, head and neck. A phase I study with 30 patients with advanced tumors of different origins established the MTD at 75 mg EKB-569 per day for both cohorts, intermittent-dose schedule (14 d of a 28-d cycle) and continuous-dose schedule (each day of a 28-d cycle) being the DLT grade 3 diarrhea[98]. In a phase Ⅰ/Ⅱa study of EKB-569 in combination with FOLFOX-4 (29 patients), 4 out of 11 patients who completed 4 cycles achieved a PR, 6 patients had stable disease, and 1 patient had progressive disease[99]. Grade 3/4 Toxicity included neutropenia and diarrhea. Moreover, a phase Ⅰ/Ⅱa study of EKB-569 in combination with FOLFIRI (39 evaluable patients out of 47) showed a 38% of RR[100].

CONCLUSIONS

When administered alone new targeted therapies have demonstrated activity in different *in vitro* and *in vivo* studies. However, the clinical use in patients when administered as a single agent is not so brilliant. On the other hand the combination of these drugs with classical chemotherapies has shown better clinical profiles reflected in an improvement in OS and PFS. The FDA approved Cetuximab as a second line therapy in combination and Panitumumab has also been approved as a second and third line therapy for advanced CRC patients. An important number of clinical trials with second or first generation of TKIs is ongoing. Perhaps the role of TKIs in mCRC patients is maintenance treatment in individuals with objective response or stabilisation of their tumor.

There is also the challenging possibility of combining different targeted therapies in order to overpass tumor resistance. Combining targeted therapies against different pathways is also a possibility. The cross-talk at a molecular level of the different networks implicated in cell biology is almost unknown. However there are more data that implicate different molecular networks when studying resistance to targeted therapies against one pathway.

All these data must encourage clinicians and basic researches to hold on in their efforts of untangling the network behind EGFR trying to transform all that effort in improving patients quality of life as well as improving survival There are different clinical scenarios in our patients and each of them should have its own solution. In some cases the approach will be combining chemotherapy with targeted therapy, targeted therapy with radiotherapy or even targeted therapy alone. In anyway we have still a lot of clinical trials to start and new drugs to be tested in order to find the adequate solution for each of our patients.

Abstract

Interindividual differences in the toxicity and response to anticancer therapies are currently observed in practically all available treatment regimens. A goal of cancer therapy is to predict patient response and toxicity to drugs in order to facilitate the individualization of patient treatment. Identification of subgroups of patients that differ in their prognosis and response to treatment could help to identify the best available drug therapy according the genetic profile. Several mechanisms have been suggested to contribute to chemo-therapeutic drug resistance: amplification or overexpression of membrane transporters, changes in cellular proteins involved in detoxification or in DNA repair, apoptosis and activation of oncogenes or tumor suppressor genes. Colorectal cancer (CRC) is regarded as intrinsically resistant to chemotherapy. Several molecular markers predictive of CRC therapy have been included during the last decade but their results in different studies complicate their application in practical clinical. The simultaneous testing of multiple markers predictive of response could help to identify more accurately the true role of these polymorphisms in CRC therapy. This review analyzes the role of genetic variants in genes involved in the action mechanisms of the drugs used at present in colorectal cancer.

INTRODUCTION

Colorectal cancer (CRC) is the second most prevalent cancer and the third leading cause of cancer death worldwide with almost 500 000 related deaths every year[1]. Approximately half of all persons develop local recurrence or distant metastasis during the course of their illness, and the median survival time for these patients can vary from approximately 4 to 22 mo. The basis of treatment for metastasis or recurrent colorectal cancer is chemotherapy, although small number of patients can undergo surgery or others forms of loco regional treatment. While the Dukes and Tumor Node Metastasis (TNM) staging system identifies broad patients groups that vary in their long-term prognosis, considerable heterogeneity exists within each of different chemotherapy agents with regard to response to treatment.

The most studied drug in CRC, the antimetabolite 5-fluorouracil (5-FU), was developed over 40 years ago. In the metastasis disease setting, single-agent 5-FU produced response rates of only 10%-20%[2]. Over the last 5 years, the median survival for patients with metastasis colorectal cancer has nearly doubled from 12-22 mo and the combination of 5-FU with new classes of drugs, such as oxaliplatin and CPT-11 (Irinotecan), has significantly improved response rates up into the 40%-50% range in patients with metastasis colorectal cancer[3]. Figure 1 shown chemical structure of these compounds. Furthermore, the use of novel biological agents, such as the monoclonal antibodies Cetuximab (an epidermal growth factor receptor (EGFR inhibitor) and Bevacizumab (a vascular endothelial growth factor (VEGF) inhibitor), have recently been shown to provide additional clinical benefit for patients with metastatic colorectal cancer[4,5].

The objective of pharmacogenomics is to elucidate the complex genetic network responsible of drug efficacy and adverse drug reactions. The ultimate goal is to provide new strategies for optimizing the individual's response to drug therapy based on patient's genetic information[6]. Current methods of basing dosages on weight and age will be replaced with dosages based on an individual's genetics. This will maximize the therapy's value and decrease the likelihood of overdose.

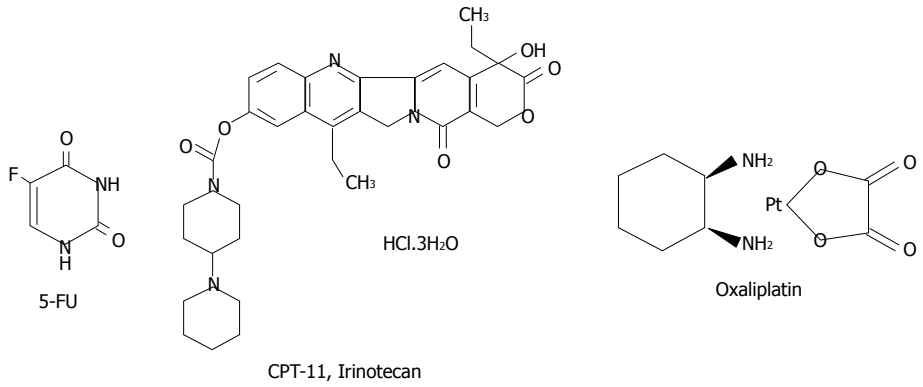

Figure 1 Chemical structure of the three most important drugs used in colorectal chemotherapy: 5-FU, CPT11 and Oxaliplatin.

In CRC, a limited number of predictive markers have been identified to date. The use of these as individual predictive markers has led to somewhat conflicting results. However, if these markers are used in combination they could provide a greater ability to reliably predict response to treatment[7]. Recent advances in our understanding of the molecular biology of CRC should lead to the identification of other panels of potential prognostic and predictive markers.

POLYMORPHISMS AND FLUOROPYRIMIDINES

To this day, the fluoropyrimidines (FPs) including 5-fluorouracil (5-FU), 5'-fluoro-2'-deoxyuridine, capecitabine, tegafur and S1, remain a major component of many standard regimens for numerous cancer types and a baseline component in many experimental regimens with novel agents[8]. Initially, 5-FU was the only effective systemic treatment for CRC, and since leucovorine enhances this effect, 5-FU and LV are given together[9]. FL reduces tumor size by 50% or more in approximately 20% of patients with advanced CRC, and prolongs median survival from approximately 6 mo to approximately 11 mo. When given as adjuvant therapy after the complete resection of tumor that has spread to regional lymph nodes (Stage Ⅲ), FL increases the probability of remaining free of tumor at 5 years from approximately 42% to 58% and the likelihood of surviving for 5 years from 51% to 64%[10].

5-FU, an analog of uracil, is an anticancer prodrug that, after administration, is converted intracellular into three main active metabolites: 5-fluoro-2-deoxyuridine monophosphate (FdUMP), fluorodeoxyuridine triphosphate (FdUTP), and fluorouridine triphosphate (FUTP). The main toxic effects are mediated by the inhibition of thymidylate synthase (TS) through the formation of an extremely stable ternary complex among FdUMP, TS, and the cofactor 5, 10-methylene-tetrahydrofolate (CH_2FH_4)[11]. The formation of this complex prevents the methylation of the deoxyuridine -5'-monophosphate (dUMP) into deoxythymidine-5'-monophosphate (dTMP) catalyzed by TS. However, the incorporation of the FP metabolites, FdUTP and FUTP, into DNA and RNA respectively, contribute also to 5-FU cytotoxicity[12] (Figure 2).

The common role played by FPs makes stratification according to likely response to this agent a relevant starting point in efforts to individualize treatment. For this purpose, reliable indicators for the prediction of the expected response are required. In the last few decades, intensive research aimed at understanding FP activity and extensive testing of patient's outcomes have highlighted a number of characteristics as potential indicators of response.

Overexpression of TS has been reported in many types of tumors including breast, colon, gastric, and melanoma. In particular, TS overexpression has been found to be significantly associated with a low response to treatment based on 5-FU, both as adjuvant[13] and metastatic therapy[14] Several studies have proposed that genetic polymorphisms of TS gene can affect the response to 5-FU[15-17]. TS expression seems to depend on the number of the so-called TSER, tandem repeat polymorphic copies of 28 bp present in the 5'-promoter enhancer region of the gene[18]. TSER polymorphisms, therefore, are involved in the modulation of TS protein levels and can affect the drug response after administration of fluoropyrimidine. Most Caucasian subjects may be carriers of double (TSER*2) or triple (TSER*3) repetitions for this type of polymorphism, although there have also been reports of sequences with even more copies. An increase in the number of repeats gives rise to an increase in both mRNA and protein TS levels. Three copies of such repeats (TSER*3) lead to a TS expression which is 2.6 times higher than that produced by the presence of only two copies (TSER*2). Patients with CRCs, which show homozygote triple-tandem repeats (3R/3R), present high levels of intratumoral TS mRNA, elevated levels of TS protein, and a lower rate of response to chemotherapy than subjects with CRCs showing homozygote double-repeats (2R/2R)[19]. Similar results have been obtained in patients with metastatic CRCs[20]. Moreover, a study involving 221 Duke's C stage CRC patients has shown that, with regard to survival rate, tumors with 3R/3R genotypes benefit less from chemotherapy than those with 2R/2R and 2R/3R genotypes[16]. A meta-analysis of 20 studies has made it possible to investigate the association between levels of TS expression and the survival of CRC patients[21]. The results have shown that high levels of TS in patients at any stage of the disease are predictive of outcome[22]. However, the predictive role of TS levels in early-stage CRC patients

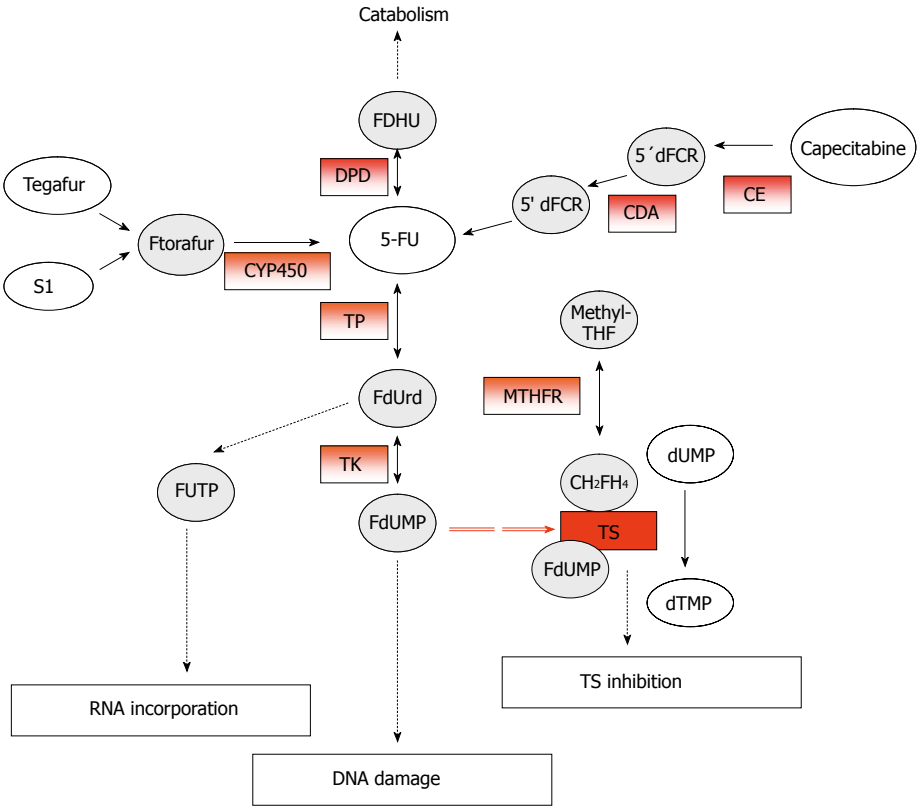

Figure 2 Metabolism and mechanism of action of 5-fluoruracil (5-FU). The potential predictive markers for 5-FU response are in red-boxes.

undergoing chemotherapy is still not fully understood; in fact, whereas in subjects undergoing surgery only, high TS levels are an independent prognostic factor for outcome, in those undergoing surgery and adjuvant FU, TS expression does not seem to predict outcome. Another study reports that in patients with advanced CRC treated with 5-FU/oxaliplatin, intratumoral TS levels appear to have an independent predictive value for survival[23]. Nevertheless, the data so far reported in literature are discordant; although, in fact, TS levels have prognostic value for CRC, this is lower in surgically-treated patients who undergo adjuvant therapy with 5-FU when the TS expression is low, but may be effective for tumors with high TS expression.

TP, also known as platelet-derived endothelial cell growth factor, catalyzes the conversion of 5-FU to the more active nucleoside form and has been shown to be an *in vitro* determinant of 5-FU activity. High expression of either TS or TP in colorectal tumors was shown to be an independent variable so that low expression of both enzymes in tumors predicted a very high expression rate to 5-FU as well as a significantly longer survival, whereas none of the patients with high expression of either TP or TS were responders. These data are in contrast to those demonstrating that cells with higher levels of TP should be more sensitive to 5-FU. These discrepancies may be due to the fact that high TP gene expression was not directly reflected in its protein products, and 5-FU metabolism may be limited by the availability of co substrates, or due to the role of TP as an angiogenic factor.

5-FU is inactivated in the liver by dihydropyrimidine dehydrogenase (DPD), which is the first key enzyme involved in the catabolism of the uracil and thymine into β-alanine. DPD activity is extremely variable in tumoral tissue and this variation might make a difference to the efficiency of 5-FU treatment, since intratumoral drug concentration is one of the most important factors for the determination of the antitumoral effect[24]. Deficiency in DPD activity, however, leads to severe toxicity correlated to 5-FU which may even be fatal. The partial or total lack of this enzyme has, in fact, been associated with severe toxicity (mucositis, granulocytopenia, and neuropathy), and in several cases even death, after 5-FU administration[25]. Analysis of the prevalence of various genetic variants of DPD among patients with DPD deficiency has shown that the most common mutation in DPYD is a G-A transition at the invariant GT splice donor site flanking exon 14 (IVS14 + 1G > A) in Caucasian populations; this mutation is responsible for the lack of exon 14 in mRNA transcript resulting in production of a truncated mRNA with virtually not present enzyme activity[26]. This allele is known as DPYD*2A and is one of the variants associated with severe toxicity after 5-FU treatment[27]. Recently two new missense mutations have been identified on codon 496 (A→G) in exon 6 and on codon 2846 (A→T) in exon 22, the latter in a patient with a total lack of DPD[28].

In the last few years, with the recognition that CH_2FH_4 was essential for the formation of the FdUMP-TS ternary complex, folate metabolism has also begin to emerge as a focus for FP response prediction. MTHFR converts CH_2FH_4 to 5-methyltetrahydrofolate. Consequently, it could be expected that the functionally comprised C677T variant would lead to increase CH_2FH_4 concentrations and thereby enhanced FP activity. Further support of a role for folate metabolism in determining FP response has been provided by the observation of a survival benefit from 5-FU treatment for colorectal cancer patients with DNA

hypermethylation. Higher levels of folate intermediates, including CH_2FH_4, have been demonstrated in tumors with DNA hypermethylation[29]. Cohen and colleagues[30] found a statistically significant trend towards increased response to fluoropyrimidine-based chemotherapy with increasing copy number of the MTHFR 677 T allele in a study of 43 patients with metastatic colorectal cancer. In contrast, Wisotzkey and co-workers[31] did not observe a difference in survival by MTHFR C677T genotype among 51 Stage Ⅲ colon cancer patients treated with 5-FU. However, both studies had a small number of subjects with the MTHFR 677TT genotype (n = 5), and lacked adjustment for potential confounding factors such as primary tumor site or type of chemotherapy received. Only one study has evaluated the effects of the MTHFR C677T, A1298C and TSER genotypes on time to progression and response to 5-FU-based treatment. Jakobsen and co-workers[32] studied 139 patients with metastatic colorectal cancer being treated in a randomized trial comparing three different 5-FU dosage levels. A greater percentage of individuals with the TSER 3R/3R or MTHFR 677T genotypes responded to treatment, and these same individuals had a statistically significant increase in time to disease progression for the first 8 mo post-treatment. However, later in the course there was no statistically significant difference in time to relapse by MTHFR or TS genotype.

Treatment of metastatic CRCs now includes the use of another chemotherapeutic agent, Capecitabine, which is an oral precursor of 5-FU. Due to its poor bioavailability and rapid catabolic clearance by DPD, 5-FU is unsuitable for oral delivery. Capecitabine or Xeloda® is a rationally designed oral fluoropyrimidine carbamate that, after selective conversion to 5-fluorouracil within solid tumors, acts by inhibiting thymidylate synthase activity. This would theoretically yield two advantages, enhanced drug concentrations at the tumor site and thus greater antitumor activity, and reduced drug levels in normal tissues with a consequent reduction in systemic toxicity.

Capecitabine is well absorbed by the gastrointestinal tract and undergoes a three-step enzymatic conversion to 5-FU. First metabolized in the liver by carboxylesterase to 5'-deoxy-5-fluorocytidine, capecitabine is converted in the liver and tumours tissues by citidine deaminase to 5'-deoxy-5-fluorouridine. A tumor-selective phenomenon is facilitated by higher intra-tumoral levels of thymidine-phosphorilase, the enzyme responsible for the final conversion step to 5-FU. With regard to 5-FU, low levels of TS and DPD lead to a better response to capecitabine. In particular, it has been observed that 75% of metastatic colorectal cancer patients, with homozygote double-repeat variants in TS (2R/2R), respond better to capecitabine administration compared with 8% of those with hetero-zygote variants (2R/3R) and 25% of those with triple-repeat homozygote variants (3R/3R)[33].

Recent advances in our understanding of the molecular biology of CRC should lead to the identification of other panels of potential prognostic and predictive markers associate with colorectal carcinogenesis.

In CRC, genetic instability has been recognized as a factor in the origin of malignant lesions, resulting in clonal evolution of genetic events acquired in the course of tumor progression. Microsatellite instability (MSI) is common to many forms of cancer and is found in 10%-14% of sporadic colon cancers[34]. MSI is caused by mutations in the mismatch repair (MMR) genes, such as hMSH2, hMLH1 and hMSH6, resulting in failure of the DNA MMR system to correct errors that occur during replication. An *in vitro* study[35] demonstrated that restoration of hMLH1 activity in the MMR-deficient HCT116 cells increased their sensitivity to 5-FU. Various studies have investigated the prognostic role of MSI in Stage Ⅱ CRC. The studies have confirmed a consistent and independent association between MSI-high (MSI-H) phenotype and superior survival in Stage Ⅱ and Stage Ⅲ CRC patients[36]. Furthermore, Lim *et al*[37] demonstrated that patients with MSI tumors exhibited better recurrence-free survival compared with those with microsatellite stable (MSS) tumors. Moreover, the use of adjuvant chemotherapy did not benefit these patients. The use of MSI as a predictive marker of response to adjuvant chemotherapy still remains controversial. On the other hand, it has been reported that 70% of colorectal cancers have lost a portion of chromosome 17p, or 18q or both. The 17p chromosome contains the p53 gene, which is an important tumor suppressor, and is reported to be mutated in 40%-60% of colorectal cancers[38]. p53 status has been studied as a prognostic factor, and more recently as a predictor of response to cancer chemotherapy[39]. The study published by Tang and colleagues describe that p53 mutation was associated with a poorer prognosis in Stage Ⅱ and Ⅲ CRC patients who received surgery alone, whereas p53 was not a prognostic factor among those patients who had received 5-FU-based adjuvant chemotherapy[40]. However, Ahnen and co-workers found that patients with Stage Ⅲ CRC, whose tumors overexpressed p53, did not derive significant survival benefit from adjuvant 5-FU-based treatment[41].

POLYMORPHISMS AND IRINOTECAN

The combination of 5-FU together with other drugs such as Irinotecan (CPT-11) has led to promising results in the treatment of CRCs, particularly in first line therapy of patients with metastatic disease. Partly as a result of the development of this agent, survival of patients suffering from incurable colorectal cancer has doubled during the last decade[42]. Like other camptothecins, the anti-neoplastic agent irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyloxycamptothecin) and in particular its active metabolite SN-38 (7-ethyl-10-hydroxycamptothecin) stabilize the DNA-topoisomerase I complex by binding to it, preventing the resealing of single strand breaks[43]. Irinotecan prevents the replication division to proceed which results in double strand breaks and ultimately in its anti-tumor effect and its characteristic adverse effects on rapidly dividing tissues, such as bone marrow and intestinal mucosa. The main dose-limiting toxicities of irinotecan therapy are therefore myelosuppression and delayed-type diarrhea[44,45].

In humans, irinotecan is hydrolyzed into its active metabolite SN-38 by carboxylesterases, present in serum, intestines, tumor tissue, and in high content in

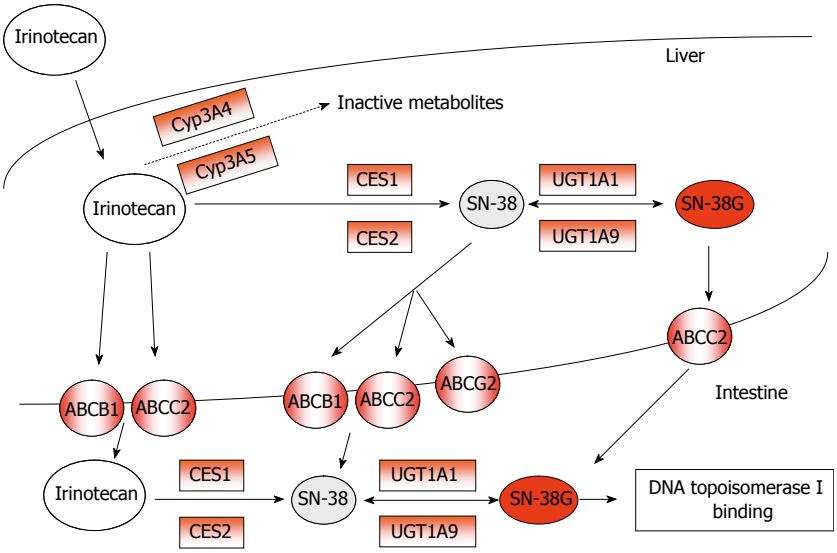

Figure 3 Metabolism and mechanism of action of Irinotecan (CPT-11). The potential predictive markers for CPT-11 response are in red-boxes.

the liver[46]. Recently, the opinion is emerging that intratumoral activation of irinotecan into SN-38 by CES might be even more important than systemic circulating SN-38 levels, formed by hepatic CES[47]. Although plasma levels of SN-38 are relatively low, relations between SN-38 and myelosuppression and/or diarrhea have been demonstrated[48]. Uridine diphosphate-glucuronosyltransferase 1A (UGT1A) mediated glucuronidation of SN-38, forming a β-glucuronic acid conjugate (SN-38G; 10-O-glucuronyl-SN-38), is the main pathway of detoxification for SN-38. Irinotecan is also sensitive to cytochrome P450 3A (CYP3A) that mediated oxidative pathways, resulting in the formation of inactive metabolites. Moreover, irinotecan, SN-38, and their metabolites are excreted by drug-transporting proteins from the adenosine-triphosphate binding cassette (ABC) transporter superfamily[49] (Figure 3).

The CES genes, located on chromosome 16q13-q22, are supposed to be highly conserved during evolution. However, recently, several polymorphisms in the CES-genes have been described, some of which with major racial differences in distribution[50]. Although the interpatient variation in CES activity is high and some SNPs appear to be very common[51], the functional consequences of reported SNPs on the *in vivo* activation of irinotecan into SN-38 are thought to be limited. Marsh *et al*[50] did not demonstrate any functional relationship between the presence of SNPs in the CES genes and CES mRNA levels, except for an intronic SNP (IVS10-88) in CES2 which was associated with reduced CES2 mRNA expression in colorectal tumors, but not in normal colonic mucosa. Neither did Charasson *et al*[52] find any influence of 11 silent SNPs in CES2 on gene expression or functional activity. Lack of association may be explained by the ineffective activation of irinotecan by CES, the role of other esterases, and the complex metabolic pathway of irinotecan. It may also be possible those other proteins regulate CES transcription and translation, or that other factors are rate limiting in the formation of active CES. However, as SNPs in CES may lead to less transcription and thus might lead to diminished local activation of irinotecan and less favorable therapeutic responses, both *in vitro* and *in vivo* functional investigation of SNPs in the CES genes is needed, especially of recently discovered SNPs in CES2.

Members of the cytochrome P450 superfamily are capable to oxidize more than half of all anti-cancer drugs. Especially the CYP3A subfamily, and in particular, the genes CYP3A4, CYP3A5, CYP3A7, and CYP3A43 are the most important. CYP3A4*1B, a SNP in the promoter area of the gene, was thought to be a promising polymorphism for irinotecan pharmacokinetics, partly as a result of its relatively high allele frequency compared to most other CYP3A4 SNPs[53]. However, Garcia-Martin *et al*[54] reported that the presence of CYP3A4*1B did not correlate with low enzyme activity in Caucasians. In a polygenetic approach to assess genotypes from multiple irinotecan pathway genes with irinotecan pharmacokinetics no effect on irinotecan pharmacokinetics was seen, neither for this SNP nor for the other studied CYP3A SNPs (CYP3A4*2, CYP3A4*3, CYP3A5*3 and CYP3A5*6)[55].

The human UGT superfamily has been classified into the UGT1 and UGT2 families, further classified into three subfamilies (UGT1A, UGT2A, and UGT2B)[56]. All nine functional members of the UGT1A subfamily are encoded by a single gene locus, the UGT1A locus on chromosome 2q37. Especially the UGT isoforms 1A1, 1A7 and 1A9 are involved in the phase Ⅱ conjugation of SN-38 to the inactive metabolite SN-38G[57]. UGT1A1 and UGT1A9 are highly expressed in the gastrointestinal tract and the liver; the primary organ involved in the detoxification of irinotecan. Polymorphisms, resulting in absent or very low UGT1A1 activity, have been associated with three heritable unconjugated hyperbilirubinemia syndromes: Crigler-Najjar syndrome type 1 and 2[58], and Gilbert's syndrome[59]. Gilbert's syndrome is common among Caucasians and is associated with the presence of an extra, seventh, dinucleotide (TA) insertion (UGT1A1*28) in the $(TA)_6$TAA-box of the UGT1A1 promoter region, leading to a considerable reduced enzyme expression of about 30%-80%. The UGT1A1 activity appears to be inversely related to the number of TA-repeats, varying from 5 to 8.

Studies have shown that the homozygous UGT1A1*28 genotype was associated with an increased risk of developing leucopenia and severe delayed-type diarrhea after treatment with irinotecan. Ando *et al*[60] analyze the association between UGT1A1 variants and irinotecan toxicity, revealing in a multivariate analysis that presence of UGT1A1*28 allele was a risk factor for severe toxicity. These data have been confirmed by other groups[9,61]. Based on this knowledge and the finding that demonstrated a good concordance between the UGT1A1*28 genotype and less effective SN-38 glucuronidation prospective studies were initiated. A significant relation was observed between the AUC of SN-38 and the number of TA-alleles[62]. In addition, two other promoter variants (UGT1A1-3279G>T and UGT1A1-3156G>A) have been identified. These variants are in strong linkage disequilibrium with the UGT1A1*28 polymorphism in Caucasians, while this link is less apparent in African-Americans and Asians, suggesting a different haplotype structure among various races[63]. Ando *et al*[64] found a strong a relation for presence of the UGT1A1-3263T>G SNP and the severity of irinotecan induced toxicity, although in a multivariate analysis including UGT1A1*28 as well, this effect was mainly attributed to this latter polymorphism[65]. Presented observations clearly illustrate that UGT1A1 mutations can influence a patient's exposure to SN-38, and, hence, the susceptibility to toxicity. Recently, a study in colorectal cancer cell lines shown that DNA methylation represses UGT1A1 expression and that this process may contribute to the level of tumoral inactivation of the anticancer agent SN38 and potentially influence in clinical response[66].

The adenosine-triphosphate (ATP) binding cassette (ABC) transporters are the largest family of transmembrane proteins that use ATP-derived energy to transport various substances over cell membranes[67]. Their localization pattern suggests that they have an important role in the prevention of absorption and the excretion of potentially toxic metabolites and xenobiotics, including irinotecan and its metabolites.

P-glycoprotein, located on chromosome 7q21, and, among others, expressed in kidney, liver, and intestine, is known for more than 50 SNPs and other polymorphisms in the gene encoding this transporter[68]. Three SNPs which show linkage disequilibrium (ABCB1 1236C>T, ABCB1 2677G>A/T, and ABCB1 3435C>T), have been studied extensively [69]. However, a relation with irinotecan or its metabolites has been not demonstrated in Caucasians. Recently, Balram *et al*[70] showed a relation for ABCB1 3435C>T with irinotecan AUC (area under concentration versus time curves) in a small Chinese population which may be the result of lowered pump activity. In a group of 46 Caucasian patients, a significant effect of the ABCB1 1236C>T polymorphism on the AUCs of irinotecan and SN-38 was seen, resulting in an increase in both AUCs[71]. Although an effect of these three related SNPs on irinotecan pharmacokinetics seems likely, the true clinical relevance of their effects still remains to be clarified.

For the canalicular multispecific organic anion transporter (ABCC2), recently a functional SNP in irinotecan pharmacokinetics has been found (ABCC2 3972C>T). This SNP, studied in 64 Caucasian patients, resulted in highly significant effects on the AUC of irinotecan, and SN-38G, all being higher in patients carrying two 3972T alleles.

In vitro studies have indicated that the irinotecan metabolites SN-38 and its glucuronide conjugate SN-38G are very good substrates for the breast cancer resistance protein[72]. ABCG2, located on chromosome 4q22, was first found to be overexpressed in cancer cells with acquired resistance to anticancer drugs[73]. The ABCG2 gene is supposed to be well conserved and most SNPs found up to now seem unlikely to alter transporter stability or function[74]. Few SNPs with presumed clinical consequence have been studied in relation to irinotecan pharmacokinetics; in particular, a single-nucleotide polymorphism in exon 5 has been described. This ABCG2 421C>A transversion results in an amino acid change of glutamine to lysine at codon 141[75]. Functional consequences of this SNP were demonstrated in Caucasian cancer patients treated with the structurally related camptothecins diflomotecan and topotecan[76]. Patients carrying at least one defective ABCG2 421A allele were found to have higher drug levels. However, in a large group of Caucasian patients pharmacokinetic parameters of irinotecan and SN-38 were not significantly different[77].

POLYMORPHISMS AND OXALIPLATIN

Oxaliplatin (OXA), a third-generation platinum analog that distorts DNA adducts, administered alone or in combination with 5-FU/LV has broaden the therapeutic choices for patients with advanced CRC who may experience hepatic and pulmonary metastasis. The cytotoxic activity of oxaliplatin is initiated by formation of a DNA adduct between the adequated oxaliplatin derivative and a DNA base[78]. Initially, only monoadducts are formed but eventually oxaliplatin attaches simultaneously to two different nucleotide bases resulting in DNA cross-links. The adducts are formed with the N-7 positions of guanine and adenine preferentially and in most cases these reactions result in intrastrand cross-links. In the cell approximately one of every 100 000 bases can be cross-linked by a platinum atom, resulting in 10 000 platinum atoms per cell[79].

In general, the cytotoxic efficacy of platinum compounds in cancer cells can be related to inhibition of DNA synthesis or to saturation of the cellular capacity to repair Pt-DNA adducts. Platinum atoms modify the three-dimensional DNA structure, which inhibits the normal DNA synthesis and repair processes[80].

Interestingly, cellular DNA repair mechanisms seem to differ in their response to Pt or Pt-DACH complexes. After DNA-adduct formation by oxaliplatin, cells will activate cellular repair mechanisms. In general, DNA repair is carried out by specific enzymes that consist of several amino- and sulphur groups. Therefore, oxaliplatin can be covalently bound to these repair enzymes as well, impairing their function[81]. If substantial DNA damage persists this may ultimately lead to the activation of apoptotic pathways and cell death[82].

Several mechanisms are described that confer resistance to oxaliplatin, including diminished cellular drug

accumulation, increased intracellular drug detoxification and increased Pt-DNA adduct repair. However, the overall sensitivity of a cell is multifactorial and the relative importance of each process on ultimate drug sensitivity is difficult to predict[83]. There is growing evidence that common gene variants affect the activity of cellular DNA repair and platinum conjugation.

The uptake of platinum by cells is not completely understood but there is evidence that decreased accumulation is the most common mechanism of resistance to cisplatin[82]. Platinum uptake by cells is an energy requiring process, but it is not saturable and possibly involves transport by a yet unidentified efflux pump. Once inside the cell, conjugation to glutathione (catalyzed by the enzyme glutathione-*S*-transferase, GST) effectively inactivates platinum compounds before DNA damage is induced. This conjugation reaction is followed by cellular excretion and is therefore related to cellular drug resistance as well. A number of studies indicate an important role of GST in oxaliplatin resistance. A single nucleotide polymorphism (SNP) in exon 5 at position 313 (A→G) in the GSTP1 (π) gene results causes the amino acid change Ile105→Val. The mutant GSTP1 (π) enzyme is less potent in detoxification of carcinogens and individuals with two mutant alleles have shown a significant survival benefit from combined oxaliplatin/5-FU treatment[84]. Other common polymorphisms in the GSTT1 (θ) and GSTM1 (μ) genes include deletions that result in complete loss of enzyme activity in homozygous individuals. However, no association with altered survival or clinical response in patients with advanced colorectal cancer treated with oxaliplatin/5-FU was observed for the GSTT1 and GSTM1 genotypes[85].

Since the primary anti-tumor mechanism of oxaliplatin is the formation of Pt-DNA adducts, polymorphisms in genes involving the repair of these adducts, such as nucleotide excision repair, base excision repair, mismatch repair (MMR) and other post-replicative repair pathways, may affect oxaliplatin efficacy. Induction of the enzymes involved in these systems results in increased DNA repair activity, more efficient adduct removal and hence decreased sensitivity to platinum drugs.

Mismatch repair (MMR) is a DNA repair pathway that corrects base mispairs and small strand loops that occur during replication. Loss of MMR function results in an increased spontaneous mutation rate. The MMR system consists of six different proteins, originating from the hMLH1, hMLH2, hPMS2, hMSH2, hMSH3 and hMSH6 genes. *In vitro* studies showed that MMR is not involved in oxaliplatin induced DNA-damage repair, whereas it serves as an important mechanism in cisplatin and carboplatin adduct repair[86]. The conformational distortion of the oxaliplatin DNA complex is different from the cisplatin and carboplatin adduct and this, together with the less polar properties of the DACH-ligand, contributes to a recognition failure of MMR proteins to detect oxaliplatin adducts. To date, no polymorphisms in the MMR pathway genes are known that influence the anti-tumor effects of oxaliplatin.

Single-strand breaks resulting from exposure to endogenously produced active oxygen, ionizing radiation or alkylating agents are repaired by the base excision repair system. X-ray repair cross-complementing group 1 enzyme (XRCC1) contains a domain which functions as a protein-protein interface that interacts with poly (ADP-ribose) polymerase (PARP). Shen *et al*[87] identified three polymorphisms in the XRCC1 gene. One of these, located in exon 10 of this gene, causes the amino acid change Arg399→Gln in the PARP binding domain. The polymorphic enzyme is supposed to be less capable of initiating DNA repair due to altered binding characteristics. In individuals with the mutant Arg399→Gln codon increased DNA damage marker levels are found due to inadequate repair or increased damage tolerance. Patients with at least one of the mutant alleles have a more than five old risk of combined oxaliplatin/5-FU chemotherapy failure compared to patients with two wild type alleles[88].

Nucleotide excision repair is a pathway involved in the recognition and repair of damaged or inappropriate nucleotides. A wide variety of DNA-damage is repaired by NER, including UV-induced photo-products, helix-distorting monoadducts, cross-links and endogenous oxidative damage. At least six proteins are essential for damage recognition and removal by this repair pathway. The first step in this process is recognition of a damaged or inappropriate base by XPA (xeroderma pigmentosum complementation group A protein) and RPA (replication protein A). The adhesion of XPA and RPA to a DNA strand attracts other repair factors to the site followed by enzymatic unwinding of the helix lesion area by XPD. The XPD gene, also known as ERCC2 (excision repair cross complementing group 2), encodes an ATP-dependent helicase that is a component of transcription factor TFIIH. A significant relationship with clinical response to platinum-based chemotherapy was found for the Lys751 →Gln polymorphism of ERCC2[89]. This SNP causes an amino acid change in exon 23 and apparently affecting protein function but not resulting in an alteration of any of the seven helicase domains. Metastatic colorectal cancer patients treated with oxaliplatin/5-FU showed different tumor response for the various genotypes; 24% responders in the Lys/Lys group, *versus* 10% in the Lys/Gln and 10% in the Gln/Gln groups, respectively[90]. Nevertheless, further studies are necessary in order to confim these data and to establish the real importance of polymorphisms in the gene XPD with regard to resistance to platinum agents.

TARGETED-THERAPIES FOR COLORECTAL CANCER

Targeted therapy is defined as a treatment with a focused mechanism that specifically acts on a well-defined target or biological pathway. The ideal cancer target can be defined as a macromolecule that is crucial to the malignant phenotype and is not expressed significantly in vital organs and tissues bind to cancer cells with high affinity and create anti-tumor effects.

In colorectal cancer, two targets, the process of angiogenesis, and the epidermal growth factor receptor, are exploited by the newest monoclonal antibodies that are available for use in CRC patients (Figure 4).

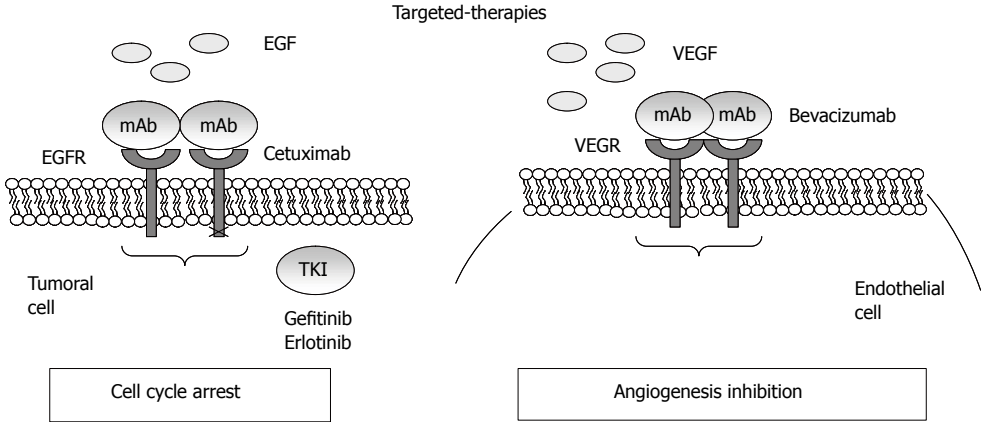

Figure 4 Mechanisms of action for the epidermal growth factor receptor and VEGF.

EGFR-based therapies

EGFR is a tyrosine kinase receptor of the ErbB family that is abnormally activated in epithelial tumors, including 25%-80% of CRCs[91]. EGFR is a 170-kDa cell surface glycoprotein containing three well-identified parts: an extracellular binding domain, a hydrophobic membrane-spanning domain and a cytoplasmic domain containing the tyrosine kinase activity. The bind of specific ligands, EGF and TGFα, to the extracellular domain, leading to dimerization of the receptor with another EGFR (homodimerization) or another member of the EGFR family (heterodimerization). Its activation leads to downstream signaling that stimulates mitogenic and survival pathways such as mitogen-activated protein kinases (MAPKs) and phosphotidylinositol-3 kinase (PI3K)/Akt, which have tumor-promoting activities. Inhibition of these signaling pathways by EGFR antagonists can lead to induction of Bax, activation of caspase-8 and downregulation of Bcl-2 and NF-κB, initiating a cascade of intracellular signaling that ultimately regulates cell proliferation, migration, adhesion, differentiation, and survival[92,93]. Tumor cells that may be activated by ligands such as EGFR and TGFα may then become chemosensitive through EGFR inhibition and activation of these apoptotic pathways.

Agents targeted against the EGFR have been studied extensively in the laboratory, and several have undergone clinical trials, including Cetuximab (Erbitux), a humanized monoclonal antibody directed against the extracellular domain of the EGFR, and the small molecule tyrosine kinase inhibitors (TKIs) Gefitinib (Iressa/ZD1839), and Erlotinib (Tarceva/OSI-774).

Cetuximab binds to the EGFR with high affinity, blocking growth-factor binding, receptor activation, and subsequent signal-transduction events[94]. Preclinical models demonstrated modest *in vitro* and *in vivo* single-agent activity of Cetuximab but significant enhancing activity in combination with cytotoxic chemotherapy[95]. Cetuximab enhanced the antitumor effects of chemotherapy and radiotherapy by inhibiting cell proliferation, angiogenesis, and metastasis and by promoting apoptosis[92]. Several studies have shown that cetuximab is effective in patients with metastasic CRC whose disease has progressed on irinotecan-based chemotherapy. A phase Ⅱ study of cetuximab monotherapy in EGFR-positive advanced CRC patients that failed a previous treatment with irinotecan, obtained 10.5% partial responses and disease stabilization in 35% patients[96]. The result of a multicenter phase Ⅱ study in 246 advanced CRC patients that failed two lines of chemotherapy containing fluoropyrimidines, oxaliplatin and irinotecan have confirmed a partial response of 12% and a disease stabilization rate of 34%. The most important data for the use of cetuximabb, was derived from a large European randomized study, the BOND study, which compared cetuximab with cetuximab in association with irinotecan. Partial response were obtained in 22.9% patients treated with irinotecan plus cetuximab and the time of disease control was 55.5 mo[4].

The development of cetuximab in colorectal cancer was grounded on the premise that EGFR expression by IHC would be prognostic for cetuximab activity, with all trials to date requiring EGFR positivity by IHC. However, Chung *et al*[97] demonstrate no correlation between intensity of EGFR expression and clinical response, challenging this premise. The BOND study results, obtained similar conclusion and the probability or achieving a response was not correlated to the level of EGFR expression in the tumor[4]. On this basis, EGFR-negative colorectal cancer patients would not be excluded from standard protocol treatment with cetuximab on the basis of EGFR status. EGFR analysis by current IHC techniques does not appear to have predictive value, and selection or exclusion of patients for cetuximab therapy on the basis of currently available EGFR IHC does not appear reasonable[98]. This may be due in part to the lack of a standardized protocol and grading system for EGFR expression in clinical samples to technical limitations that are inherent in immunohistochemical methods or, perhaps, to an intrinsically poor correlation between the level of EGFR expression and therapeutic response.

A polymorphic (CA)n dinucleotide repeat is observed in intron 1 of the EGFR gene, which has been shown to be associated with gene expression[99]. It has been demonstrated that as the number of (CA)n repeats increases the level of transcription decreases[100]. However, in CRC cancer, association between the repeat length and EGFR protein expression was not been reported[101]. Neither, polymorphisms of EGFR has been associated with cetuximab therapy.

In addition to cetuximab, several tyrosine kinase

inhibitors have been developed to target EGFR. A recent phase Ⅱ study shown that the combination of capecitabine, oxaliplatin, and erlotinib seems to have promising activity against metastatic colorectal cancer in patients who received prior chemotherapy, with a relatively higher response rate and progression-free survival compared with previous reports of either infusional FU, leucovorin, and oxaliplatin or capecitabine and oxaliplatin in similar patient populations[102].

Skin rash has been the most commonly observed toxicity associated with the various EGFR inhibitors; interindividual differences in the onset, duration and severity of the rash have been observed, and no threshold plasma levels have been linked to the occurrence of the rash. Most intriguing are emerging data demonstrating a significant correlation between skin rash and survival among various patients treated with different anti-EGFR therapies. There are several potential hypotheses being put forward to explain both the variable toxicity and efficacy of EGFR inhibitors. One such hypothesis proposes that variability in clinical observations is related to variable drug exposure. For example, the small-molecule EGFR tyrosine kinase inhibitors gefitinib and erlotinib are metabolized by *CYP3A*, and it is certainly plausible that individuals with variant *CYP3A* alleles might have differences in drug exposure. On the other hand, the previously described CA dinucleotide repeat polymorphism might influence the drug response due to differences in target expression. Data that indirectly lend support to this hypothesis come from a higher response rate observed in Japanese patients compared to Caucasian patients (when treated with gefitinib) two populations with a difference in the frequencies of the *EGFR* dinucleotide repeat variants. However, given the abundant *EGFR* expression in skin tissue, and the observed association between skin toxicity and tumor response; the use of surrogate tissue in this instance might be justified. Nonetheless, this issue highlights an important problem in conducting translational work in this field, since obtaining tumor biopsies in prospective trials for hypotheses generation is not a trivial matter for obvious ethical and practical concerns.

However, robust predictive markers are needed in order to identify the relatively small subsets of patients whose tumours are likely to respond to EGFR-targeted therapies. Candidate markers include phosphorylated EGFR, and phosphorylated effector molecules downstream of the EGFR, such as the mitogen-activated protein kinase (MAPK) and protein kinase B (AKT). However, there are concerns about the stability of phosphorylated proteins in primary tumour samples prior to fixation, and protocols for the collection and processing of clinical material for phosphorylated protein analysis have yet to be validated and standardized. More recently, a work shown that *KRAS* mutation is associated with resistance to cetuximab and a shorter survival in EGFR-positive metastatic colorectal cancer patients treated with this therapy[103]. *KRAS* mutation status might allow the identification of patients who are likely to benefit from cetuximab and avoid a costly and potentially toxic administration of this treatment in nonresponder patients. Prospective randomized study is needed to validate these results that bring a new possibility of targeted therapy adapted to each patient according to its *KRAS* mutation status.

Future issues in the development of EGFR inhibitors include the identification of biologic predictors of response, combination with other targeted agents, and their use in earlier stage malignancies.

VEGF as target for anti-angiogenic therapy

The VEGF family comprises six molecules, the best characterized of which is VEGF-A, which is expressed in at least four isoforms derived by alternative splicing. It is a multifunctional cytokine that acts with receptors expressed on the vascular endothelium to render microvessels hyperpermeable to plasma proteins, alters gene expression, induces endothelial cell migration and proliferation and enhances endothelial cell survival, eventually leading to angiogenesis, permeability and protection against endothelial cell apoptosis and senescence[104,105]. VEGFs mediate their functions by binding to one or more of three tyrosine kinase receptors expressed on endothelial cells: VEGF receptor VEGFR-1 (Flt-1), VEGFR-2 (Flk-1 or KDR) and VEGFR-3 (Flt-4). These receptors have tyrosine kinase activity that initiates intracellular signaling on ligand binding[106]. Other receptors identified (neuropilin-1 and -2) are expressed on numerous cell types, but they do not transmit intracellular signals by themselves after ligand binding[107].

VEGF is a major target for antiangiogenic therapy since its overexpression has been associated with vascularity, endothelial cell migration and invasion, poor prognosis and aggressiveness in most malignancies, including CRC[108]. In CRC, the overexpression of VEGF and its receptor correlated with the development of metastasis[109]. Anti-VEGF strategies include neutralizing antibodies to VEGF or its receptors, ribozymes to receptors and TKIs that block downstream signaling despite ligand binding to VEGFR. Several of these strategies are currently under investigation, including Phase Ⅰ, Ⅱ and Ⅲ trials.

Bevacizumab is a humanized monoclonal antibody that targets and binds to vascular endothelial growth factor-A (VEGF-A), reducing the availability of VEGF and thereby preventing receptor activation[110]. Kabbinavar *et al*[5] reported the first clinical trial of bevacizumab in combination with 5-fluorouracil and leucovorin (5-FU/LV) in previously untreated colorectal cancer patients. Then, different clinical trials shown that Bevacizumab increases survival in association with chemotherapy in the treatment of metastasic CRC. These data led to the FDA approval of bevacizumab for the treatment of metastatic colorectal cancer in February 2004.

As cetuximab, the development of bevacizumab has not included a diagnostic eligibility test and the identification of biomarkers that may predict which patients are most likely to respond to targeted-therapies is of considerable interest. To date, neither direct measurement of VEGF expression nor assessment of tumor microvessel density has been incorporated into the clinical trials or linked to the rates of response to this antibody.

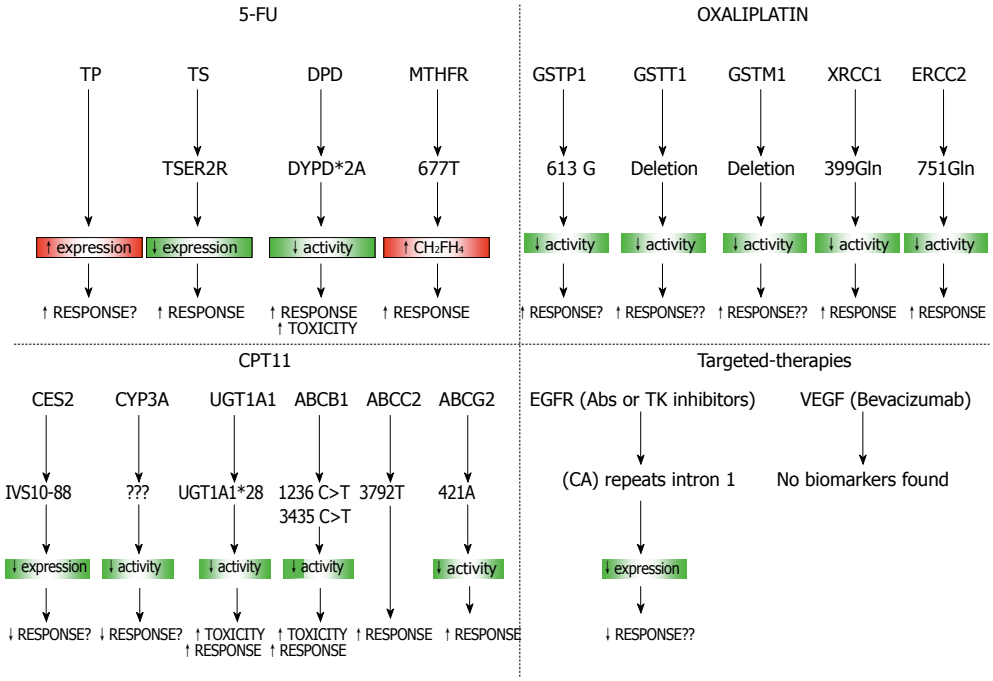

Figure 5 Combination of predictive gene sets for different therapies used in CRC.

Possible biologic surrogates which have been tested in some clinical trials include: DCE-MRI, positron emission tomography scan assessment of tumor blood flow[111], mutations in k-ras, b-raf and p53 genes[112], circulating endothelial progenitors, mature circulating endothelial cells[113], or plasma levels of angiogenic markers, e.g.,VEGF, bFGF. To date, few studies have assessed the potential utility of biomarkers in predicting which patients are more likely to respond to antiangiogenic therapy in the clinic. Tumors may express multiple pro-angiogenic factors and, thus, have different pathways to bypass the VEGF inhibition. Likely, biomarkers that summarize the effects of all angiogenic regulators may better predict patient outcome than the analysis of a single angiogenic factor.

FUTURE PERSPECTIVES

Over recent years, a large number of studies have attempted to define molecular and biochemical markers that may be useful predictors of response to treatment. The introduction of DNA microarray technology has revolutionized our approach to understanding the molecular events regulating the drug-resistant, allowing the simultaneous assessment of thousands of genes. This approach provides a valuable means to identify novel biomarkers of response to treatment as well as novel molecular targets for therapeutic intervention. The candidate gene approach has been widely used to identify the genetic basis for pharmacogenetic traits and becomes increasingly more powerful with the recent advances in genomic technologies. The simultaneous testing of multiple markers predictive of response could help to identify more accurately the true role of these polymorphisms in CRC therapy (Figure 5). High-throughput sequencing and SNP genotyping technologies allow the study of thousands of candidate genes and the identification of those involved in drug efficacy and toxicity. Combination of predictive gene sets identified by gene expression profiling with proteomics and SNPs-array methodologies may enhance the prediction of tumor response to chemotherapy and provide further insights into the molecular characterization of tumor cells. In future studies it will important to combine all these technologies to identify the tumoral response to chemotherapy and finally realize an individualized treatment regimen to each patient.

Abstract

Defining translational research is still a complex task. In oncology, translational research implies using our basic knowledge learnt from *in vitro* and *in vivo* experiments to directly improve diagnostic tools and therapeutic approaches in cancer patients. Moreover, the better understanding of human cancer and its use to design more reliable tumor models and more accurate experimental systems also has to be considered a good example of translational research. The identification and characterization of new molecular markers and the discovery of novel targeted therapies are two main goals in colorectal cancer translational research. However, the straightforward translation of basic research findings, specifically into colorectal cancer treatment and *vice versa* is still underway. In the present paper, a summarized view of some of the new available approaches on colorectal cancer translational research is provided. Pros and cons are discussed for every approach exposed.

Key words: Translational research; Colorectal cancer; Genomics; Proteomics; Targeted therapies

INTRODUCTION TO COLORECTAL CANCER

In the current century, despite the recent achievements in the treatment of advanced colorectal carcinoma (CRC), this tumor remains a major public health concern. In fact, it comprises the third most common cancer type to occur in men and women and was the second leading cause of death among cancer patients in the United States during 2006[1].

Different surgical approaches can guarantee low recurrence rates and high survival expectancy in stages I to Ⅲ colon neoplasm patients[2]. Furthermore, adjuvant chemotherapy administration has been shown to effectively improve those rates[3]. However, the subset of stage Ⅱ colon cancer patients to whom adjuvant therapy should be offered is still to be addressed[4]. In fact, different molecular pathology studies and genomic/proteomic investigations are working on that task[5].

In contrast, metastatic colorectal cancer is still far away from being a curable condition and the main goals in the treatment of stage Ⅳ colorectal cancer are to decrease tumor-related symptoms or, alternatively, to prolong symptom-free survival with tolerable toxicity[6,7]. However, the emergence of the highly selective therapeutic antibodies bevacizumab and cetuximab has definitely improved the survival of patients with metastatic CRC[8,9]. This fact has intensively boosted the search for other targeted therapies directed to other fundamental checkpoints in colorectal tumorigenesis[10,11].

Thus, due to colorectal cancer clinical and economic relevance, its basic and clinical research has become one of the most funded among all tumor types in most developed countries. However, the straightforward translation of basic research findings into colorectal cancer therapies is still underway.

In the present paper, a summarized view of some of the new available approaches on colorectal cancer translational research is provided.

TRANSLATIONAL RESEARCH IN CANCER: DEFINING CONCEPTS

Translation of the exciting novel findings made in basic laboratories into testable hypotheses for evaluation in clinical trials is the ultimate aim of translational research in oncology[12-14]. Between a laboratory breakthrough and a real achievement in the clinic, there must be translational research. Thus, the job of the translational researcher is to take the knowledge gained in the laboratory and lay the groundwork needed to develop a new diagnostic tool for a human tumor or a novel drug to be tested in a clinical trial in human beings (Figure 1).

In other words, in order to improve human health,

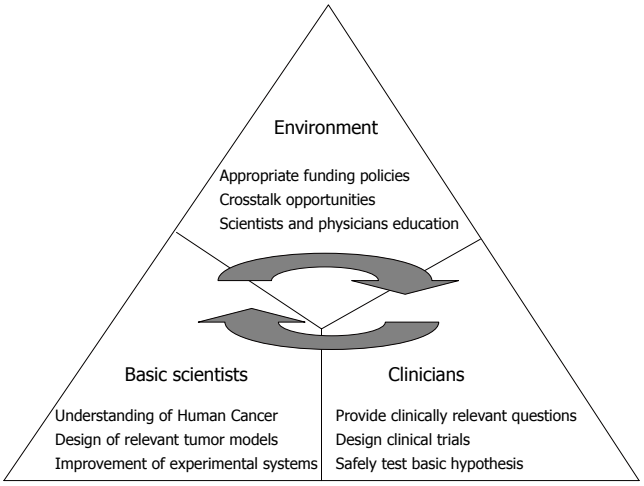

Figure 1 Factors involved in translational research: Interaction between basic scientists, clinicians and the environment.

scientific discoveries must be translated into practical applications. Such discoveries typically start at "the bench" with basic research, in which scientists study disease at a molecular or cellular level[15-19], and then move on to the clinical level, or the patient's "bedside"[20-22]. Scientists are increasingly aware that this bench-to-bedside approach to translational research should really be a two-way highway (Figure 1). Basic scientists provide clinicians with new tools to be used in patients and for assessment of their impact whereas physician-scientists formulate the clinically relevant questions to be tested by basic researchers in a better controlled and more simplified system. Actually, discoveries travel from the clinic to the laboratory in the form of clinical observations, human tissue, diagnostic images, and blood samples, which researchers use to further unlock the molecular and cellular features of cancer (Figure 1).

Often, translational research involves animal studies designed to mimic human conditions[23-26]. Such studies are generally performed with the same care and scrutiny as the best-planned human clinical trials, and comprise a complex set of supporting laboratory techniques that aim to determine how and why the new diagnostic tool or therapy works or fails in these models. Translational research studies may involve many years of investigation on tools and techniques, to try to estimate how safe and how effective the new treatment or diagnostic procedure will be in human trials.

One of the main scopes of translational research in cancer implies the identification and characterization of molecular markers[12]. These can be employed as diagnostic and prognostic tools but also for drug responsiveness assessment or even for targeted therapy design. Molecular markers of tumor responsiveness to drugs would help to select the patient populations that would most likely respond to the drug and identify therapeutic indications. Molecular markers of drug activity in normal tissue would allow pharmacodynamic monitoring of patients that could aid optimization of drug dosing and scheduling to maximize patient response[27]. Furthermore, biological markers involved in tumor initiation and progression can be specifically targeted by new drugs such as therapeutic antibodies[8,9] or anti-tumor vaccines[18].

In fact, another main goal in cancer research is targeted therapy[22]. Translational research is particularly feasible now because of the new understanding of what causes cancer in different individuals, which relates to different combinations of genetic events. This understanding has come primarily from the work of basic research scientists. Until fairly recently, the only effective armamentaria in cancer therapy were surgery, radiation therapy, and chemotherapy. These treatments generally affect neoplastic cells but also non-cancer tissues, leading to the often serious toxicity that characterizes most of traditional cancer treatments[28]. While these standard therapies will continue to play an important role in the treatment of patients with cancer, they can be vastly aided in this process by targeted drugs, which literally target the aberrant molecular pathways that are actually involved in tumor initiation and progression. Therefore, specifically delivering the targeted drug to the malignant cell and its closest environment can significantly relieve cancer treatment related collateral effects[27].

However, since extensive libraries of cytotoxic compounds are being developed for antitumor effect testing, it is becoming more and more common to find new therapies that are successfully developed, tested and commercialized against certain tumors but the ultimate molecular mechanisms involved in tumor response are not clearly known[29]. In those cases, the translational process is rather directed from clinical findings to basic cellular and molecular experiments (from "the bedside" to "the bench"), trying to unravel the complex pathway in which the new compound is playing a definitive role and the specific target or group of them that results inhibited. Therefore, the bidirectional nature of translational research needs to be emphasized[30].

IMPLEMENTING TRANSLATIONAL RESEARCH IN COLORECTAL CANCER

There is still a widening gap between basic research and clinical practice, particularly for colorectal cancer. This might be due to the genetic and molecular complexity of this tumor, the lack of the ideal *in vivo* model for colorectal cancer, and the difficulties found in reproducing animal results into clinical trials in patients.

The principal directions toward which translational research has spread and grown in colorectal cancer in recent years are genomics and proteomics, oncogenic pathways assessment and new targeted therapies discovery (Table 1).

Genomics and proteomics: Searching for new biomarkers and potential target genes

In the last years, there has been an increasingly high effort in the use of genome information in biomedical sciences. This genome information has greatly expanded the insight into the genetic basis of cancer, comprising one of the main fields of interest in translational cancer research. Traditional methods of identifying novel targets involved

Table 1 Translational research technologies in colorectal cancer

Genomics	Proteomics
DNA microarrays	2D-PAGE
	DIGE
	LC-MS/MS
	ICAT
	iTRAQ
	Protein microarrays
	MALDI-TOF
	SELDI-TOF
	Tissue microarrays
Oncogenic pathways	Preclinical models
AS-ODN	Min mice
miRNAs	Msh2, Msh4, Msh6 deficient mice
siRNAs	Apc163 8N mice
	Smad4/Apc mice

in cancer progression were based on studies of individual genes. The following understanding, however, has also shown that gene analysis alone is not sufficient to explain why cancer appears and progresses[31].

Now, the use of DNA microarrays facilitates the analysis of the expression of thousands of genes at the same time and rapidly[32,33]. Microarray analysis has been used for gene expression analysis of different neoplasms[34,35], including CRC[36-39]. However, the application of DNA microarray technology for analysis of CRC is of limited value since it fails to offer direct protein expression measurements[36,40]. In addition, it is already known that important pathways in colon tumorigenesis are regulated at the posttranscriptional level where RNA expression data cannot offer any further information. In fact, due to the alternative splicing of both mRNA and proteins, combined with protein posttranslational modifications, one gene can encode a considerable protein population. Actually, the proteome comprises all proteins that result from the whole genome. In contrast to the genome, the proteome is rather a dynamic parameter constituted by proteins and reflects both the intrinsic genetic program of the cell as well as the impact of its surrounding environment.

However, only a few studies have looked for a further insight into the function and/or importance of individual genes and their application to the proteome research of a tumor. Some of these genes have been proposed as candidate cancer biomarkers[41-43]. More recently a number of proteomic studies have also addressed the identification of potential targets in CRC[44-46].

In the proteomics field, several different technical strategies have been developed and applied to CRC translational research over the last years. Each one has its own advantages and drawbacks that should be considered before deciding the experimental design[47].

The technique leading the field for a long time was the two-dimensional polyacrilamide gel electrophoresis (2D-PAGE)[48]. The 2D-PAGE is based on the separation on a gel of the protein content of a sample in two dimensions according to mass and charge. The gels are stained and spots in samples are compared among different gels. However, a number of serious disadvantages such as its lack of real high-throughput capability (one sample per gel) is responsible for having been replaced by more advanced and capable techniques. Similar to 2D-PAGE, the two-dimensional difference gel electrophoresis (DIGE)[44,46] strengthened the 2D platform by allowing the detection and quantization of differences between three samples resolved on the same gel, or across multiple gels, when linked by an internal standard. Again, it also is a low-throughput technology that does not permit the comparison of many samples in a feasible manner.

Other low-throughput proteomic techniques have recently evolved for cancer protein profiling such as liquid chromatography coupled to tandem mass spectrometry detection (LC-MS/MS)[49], isotope-coded affinity tag (ICAT)[50] and a variation of the latter, isotope tags for relative and absolute quantification (iTRAQ)[51], (both consist of a differential tagging of proteins from samples that are compared using isotope-coded affinity tag in an isotope-dilution mass spectrometry experiment).

A study conducted by Wu *et al*[52] has recently compared some of these diverse proteomic strategies (2D-DIGE, ICAT and iTRAQ) on HCT-116 colon epithelial cells concluding that regarding the number of peptides detected for each protein by each method, the global-tagging iTRAQ technique was more sensitive than the cysteine-specific ICAT method, which in turn was as sensitive as, if not more sensitive than, the 2D-DIGE technique.

Nevertheless, as aforementioned, one of the most important goals in protein profiling in oncology is the discovery of new biomarkers[53]. The use of molecular markers in translational research has expanded considerably during the last 3 decades, and this increased analysis of specific molecular changes has been associated with a concomitant decline in the use of more general and less specific histochemical stains and biochemical assays. Some of the applications for molecular markers include diagnosis, early detection, and prognosis. Also, specific molecular markers are used to study the biology of the disease, to identify targets for novel therapies (e.g., use of Herceptin), and to aid the selection of specific therapies, as previously mentioned.

Therefore, cancer proteomic studies might identify disease-related biomarkers for early cancer diagnosis and new surrogate biomarkers for therapy efficacy and toxicity, but also for guidance of optimal anticancer drug combinations, enabling tailor-made therapy[54]. Furthermore, they could lead to new pharmacological targets. However, a crucial requisite for this purpose is to be able to perform a systematic analysis of a large number of proteins in an easy, reproducible, time-efficient and cost-effective way. High throughput technologies are therefore warranted.

Protein microarrays for instance[55], (targeted proteins bind to spotted probes on a "forward" microarray and specific probes bind to targeted proteins in spotted samples on a "reverse" microarray; bound proteins are detected by direct fluorescent labeling or by labeled secondary antibodies), provide a high throughput approach in terms of number of probes per "forward" array and

number of samples per "reverse" array with the advantage of previously knowing the biomarker identity. On the other hand, the synthesis of many different probes is necessary, the identity of biomarkers has to be known and cross-reactivity of probes along with possible impaired binding of proteins with post-translational modifications (PTM) exists.

In 2002, the Nobel committee acknowledged the advances in mass spectrometry of biopolymers with the recognition of the discovery of electrospray ionization (ESI) mass spectrometry[56,57] and for the discovery of soft laser desorption (SLD) ionization, which led to the development of matrix-assisted laser desorption ionization (MALDI)[58]. These discoveries for peptides, proteins and other macromolecules have been revolutionary, providing easy measurements of molecular weight with unprecedented accuracy. Because the dominant ions generated under SLD and MALDI conditions are singly charged, the technique is most often used in combination with a time-of-flight (TOF) analyzer to extend the m/z range to 100 000 Da and beyond[58]. MALDI-TOF technology is a highly capable tool allowing the measurement of up to 1536 samples per plate, also possessing access to PTM. On the negative side, this technique is unsuitable for high molecular weight proteins (> 100 kDa) and sample fractioning is needed when measuring complex samples.

Surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) technology is a variant of MALDI-TOF in which a selected part of a protein mixture is bound to a specific chromatographic surface and the rest is washed away[47]. Although SELDI-TOF technology only permits 96 samples to be tested by bioprocessor, fractioning of the sample is not necessary and direct application of the whole sample is possible. However, compared to MALDI-TOF, SELDI-TOF provides lower resolution and mass accuracy but requires smaller amounts of starting material. SELDI-TOF is also unsuitable for proteins heavier than 100 kDa.

SELDI-TOF is equally useful for the analysis of cell lysates from cell lines and tissue[59], however, in clinical practice its ultimate value derives from its application to easily accessible body fluids as serum or urine. In fact, in the last years several serum biomarker proteins have been identified through this technical approach[60-62].

In addition, low and high throughput techniques have been shown to be complementary and its combination can lead to a more efficient outcome[63].

In summary, compared to the genome, the proteome provides a more reliable picture of a biological status and is, thus, expected to be more useful than gene analysis for evaluating, for example, disease presence, progression and response to treatment.

A totally different approach for protein profiling has recently emerged in translational cancer research. To evaluate the clinical significance of newly detected potential cancer genes, it is usually required to examine a high number of well-characterized primary tumors. Using traditional methods of molecular pathology, this was a time consuming job that exploited precious tissue resources. However, a high throughput tissue analysis approach, [tissue microarray (TMA) technology], has been developed[64-66]. Using this TMA technology, samples from up to 1000 different tumors are arrayed in one recipient paraffin block, sections of which can be used for all kinds of *in situ* analyses[22,67].

Sections from TMA blocks can then be utilized for the simultaneous analysis of DNA, RNA or protein tumor levels. TMA protein analysis has also been performed in CRC samples for prognostic evaluation[68-72]. However, even though it has been suggested that minute arrayed tissue specimens are representative of their donor tissues, highly heterogeneous cancer types and low levels of protein expression could account for underestimating determined protein expression levels in certain tumors[68,73].

There are multiple different types of TMAs that can be utilized in cancer research including multi tumor arrays (containing different tumor types), tumor progression arrays (tumors of different stages) and prognostic arrays (tumors with clinical endpoints). The combination of multiple different TMAs allows a very quick but comprehensive characterization of biomarkers of interest.

Despite what proteomics have added to translational research in cancer, there are some novel approaches that combine the information provided by genomic and proteomic assays run in parallel in order to complement the translational impact of both procedures[74]. This has also been applied to CRC profiling. Kwong *et al*[75], for instance, studied gene and protein expression performed in parallel across progressive stages of human CRC. For this purpose, they applied cDNA microarray and 2D-PAGE technologies in parallel to analyzed samples collected from 60 CRC cases at various stages of disease progression. Of 47 genes analyzed, 12 (26%) showed significant correlation between mRNA level and protein levels, suggesting that protein abundance is regulated at the transcriptional level. The remaining 31 genes showed either a non-significant correlation between mRNA and protein expression levels or, in 28% of the genes, a negative correlation. Therefore, the authors conclude that posttranscriptional mechanisms play an important role in the regulation of gene products activities in CRC, underline the importance of analyzing gene expression at multiple levels and claim that genomic and proteomic approaches actually complement each other.

In another recent study to identify new biomarkers, Madoz-Gurpide *et al*[76] investigated the feasibility of expressing soluble proteins corresponding to up-regulated genes in surgically resected CRC samples. They used cDNA microarrays (CNIO Oncochip)[77] to identify differentially expressed genes in malignant compared to normal samples isolated from 22 different CRC patients. After investigating different sources of cDNA clones for protein expression, from 29 selected genes, 21 different proteins were finally expressed soluble with, at least, one distinct fusion protein. Additionally, seven of these potential markers were tested for antibody production and/or validation, confirming six of them to be overexpressed in CRC tissues by immunoblotting and TMA analysis[76]. Authors suggest that this kind of approach may provide relevant

biological information of the neoplastic processes and lead to a better characterization of potentially interesting markers in a quite straightforward way for early diagnosis or individualized prognosis assessment.

Oncogenic pathways: Validating target candidates

The previously reviewed development of genomics and proteomics in cancer research has yielded an uncountable number of new potential oncogenic mediators and checkpoints, in CRC, worth further investigating. These novel gene-depending elements, potential new targets for future drugs, are commonly involved in a variety of molecular pathways and their intimate upstream/downstream regulators as well as their crosstalk networks and functional relevance still need to be addressed.

Most widely used experimental methods for molecular pathway research in oncology are performed on fairly well-controlled *in vitro* systems. Recent cell biology achievements and discoveries however, have led to more reliable and physiologically relevant settings where observations on cell behavior and cell fate under particular conditions can be imported into *in vivo* experiments employing animal cancer models and even translating findings into new human therapeutic trials.

In the last few years, several approaches to find molecules able to inhibit the expression of genes (so-called gene-silencing molecules) involved in colorectal cancer progression and therapeutic resistance have been pursued. Sequence-specific gene suppression strategies using antisense oligonucleotides (AS-ODN), ribozymes and deoxyribozymes were initially described and developed[78-82]. AS-ODN derivatives, depending on their type, recruit RNase H to cleave the target mRNA or inhibit translation by steric hindrance. Ribozymes though, directly bind to RNA *via* Watson-Crick base pairing and cleave the phosphodiester backbone of the RNA target by transesterification. Similarly, deoxyribozymes also bind to their RNA substrates *via* Watson-Crick base pairing and specifically cleave the target RNA.

Currently, in addition to their value in target validation studies, different AS-ODN strategies are under evaluation in phase Ⅱ and Ⅲ clinical trials, particularly in hematological malignancies, malignant melanoma and prostate cancer[83,84]. However, consolidating AS-ODN as a broadly applicable functional genomic and therapeutic tool has proven difficult. For instance, difficulties in delivery of the AS-ODN into target tissues, instability of AS-ODN *in vivo*, poor oral availability, uncertainties about the precise mode of action, and toxic effects in animal and human studies have been argued[80,83]. Moreover, a number of class effects are observed with AS-ODN that are unrelated to the specific targeted mRNA sequence. Acute effects include activation of the alternative complement pathway and inhibition of the intrinsic coagulation pathway. In fact, given repeated doses of AS-ODN to animals, accumulation of AS-ODN and/or metabolites occurs in the form of basophilic granules in various tissues, including the kidney, lymph nodes and liver. Although several approaches are known to overcome some of these difficulties[85], very few contributions have firmly supported the use of AS-ODN technology in CRC research[86-88].

But in the field of gene-silencing molecules, the most recent and fascinating tools discovered for studying gene regulation and gene expression control are microRNAs (miRNAs) and small interfering RNA (siRNAs). miRNAs and siRNAs are typically 21 to 25 nucleotide RNA molecules that induce gene silencing by RNA interference (RNAi)[89-91]. Since the description of RNA interference (RNAi) in 1998[92], this gene-silencing technology has been developed into a widely used methodology in basic as well translational research. RNAi was originally discovered as a naturally occurring pathway in plants and invertebrates[92]. Once long double-stranded RNA molecules are inserted into these organisms, they are processed by the endonuclease Dicer into siRNAs. These siRNAs are subsequently incorporated into the multicomponent RNA-induced silencing complex (RISC), which unwinds the duplex and uses the anti-sense strand as a guide to look for homologous mRNAs and degrade them, as previously reviewed by others[93,94]. More strikingly, synthetic short siRNAs (20-25 bp) can be either delivered exogenously or expressed endogenously from RNA polymerase Ⅱ or Ⅲ promoters (in the form of siRNAs or short hairpin (sh)RNAs that are processed by Dicer into functional siRNAs) and used as a new powerful technology for achieving specific down-regulation of target mRNAs in mechanistic research or even therapeutic development in CRC[11,95-98].

Testing targeted therapies: Preclinical modeling in colorectal cancer

Once potential targets are discovered and their expression is successfully inhibited *in vitro*, the safety, efficacy and feasibility of their inhibitors need to be evaluated in animal models in which human disease can be faithfully reproduced. In fact, in the last years, the need of relevant *in vivo* models in colorectal cancer research has prompted many investigators to work on developing reliable, reproducible and human colorectal cancer-mimicking animal models[25,99,100].

However, in colorectal cancer, much has been learned from human inherited syndromes, such as familial adenomatous polyposis (FAP) and hereditary non-polyposis colorectal cancer (HNPCC)[101-103]. That knowledge in fact, has been translated into the design and development of CRC animal models.

Although several rat models have been created for the study of colorectal cancer[104-106], in this review, we will focus our attention on mouse models which have profusely evolved in the last few years because of their abundant genetic/genomic information, and easy mutagenesis using transgenic and gene knockout technology. Genetically engineered mice have become essential tools in both mechanistic studies and drug development in CRC, as previously reviewed by others[107]. In fact, mice provide unique opportunities to define and identify genes that are involved in colorectal cancer progression.

The first mouse model obtained to carry a mutation in the adenomatous polyposis coli (APC) tumor suppressor gene was named multiple intestinal neoplasia (Min)[108].

The Min mutation results in a truncated protein and induces the development of multiple intestinal adenomas (even more than one hundred) and a reduced lifespan of on average 150 d in heterozygous mice. Posterior models carrying mutations in different APC alleles have also been developed and each one possesses its own clinical manifestations. However, the majority of them shows small intestine adenomas and colonic tumors and distant metastases are rarely observed. Interestingly, it has been shown that different mutations in the APC gene, in *Apc1638N* mice for instance, confer distinct tumor susceptibility phenotypes and that fact resembles the heterogeneity observed in human FAP families[109]. Other models of hereditary non-polyposis colorectal cancer (HNPCC) have been developed through the mutation of several mismatch repair genes. One representative example are Msh2 deficient mice that are fertile and develop normally, however, these animals develop T-cell lymphomas early in their life and die because of the disease. Msh2 deficient mice that survive more than 6 months develop gastrointestinal adenomas, carcinomas and skin tumors and can also be used for tumorigenesis studies[110].

Finally, other more recent models have also been developed to better study colorectal cancer. Smad4 heterozygous mice bearing *Apc* mutations present an enhanced progression and a more malignant phenotype[111]. Other combinations responsible for increased gastrointestinal tumorigenesis are APC and oncogenic KRAS that seem to be synergistic in enhancing Wnt signaling[112].

CONCLUSIONS

Translational research is a key developing field in biomedicine. The direct application of basic research findings to the patient's diagnosis and treatment is even more important in cancer. In addition, clinical observations can dramatically contribute to basic research improvement and relevant enhancement. Colorectal cancer, due to its epidemiological importance and economic impact, is one of the main entities in which translational research is a reality today.

However, there still is a long way to go until basic researchers and clinical investigators share information and work together in colorectal cancer research on a daily basis.

Several new technologies and tools have demonstrated a great value in cancer and are in fact responsible for the last crucial pieces of research work allowing a new conception of cancer diagnosis and treatment. Among them, the development of new biomarkers for colorectal cancer combining proteomics and genomics is especially relevant.

Also, anti-sense strategies have recently opened the path for new target-specific therapy development. These new therapeutic discoveries need to be tested in preclinical animal models.

Since extensive validation of the above mentioned research fields is necessary, adequate funding is required. This may imply some adjustments in the current funding policy because it involves non-innovative studies. Furthermore, the pool of researchers/clinicians capable of performing translational research must be increased. Additionally, there should be an enhanced participation of patients in clinical trials and an optimization of the efficiency of these trials using validated surrogate markers. Only when these conditions are fulfilled the 'post-genomic' era of biomedical research will have unprecedented opportunities to innovate and improve therapy for cancer.

COMMENTS

Background

In the present paper, a summarized view of some of the new available approaches on colorectal cancer translational research is provided. Translational research in colorectal cancer comprises the identification and characterization of new molecular markers and the discovery of novel targeted therapies. The better understanding of human cancer and the design of more reliable tumor models and more accurate experimental systems is also part of translational research in cancer.

Research frontiers

The principal directions toward which translational research has spread and grown in colorectal cancer in recent years are genomics and proteomics, oncogenic pathways assessment and new targeted therapies discovery.

Innovations and breakthroughs

To our knowledge, there is no other published paper specifically focused on translational research in colorectal cancer. Therefore, we consider this review as a unique and inspiring one.

Applications

The main objective of this manuscript is to help scientists and physicians working on colorectal cancer determine which findings have been already achieved and which others are still underway and provide a better knowledge of new tools and techniques available for this purpose. This focus might inspire other authors in their own research projects and emphasize the need of a new approach to colorectal cancer research.

Terminology

Translational research: Investigation directed to the link of basic and clinical research in order to better define aims and better control tools and experimental systems. Genomics: Part of the bioscience that studies the genome and its implications in disease appearance, progression and response to treatment. Proteomics: Part of the bioscience responsible for peptide and protein investigation and their role in the diagnosis, treatment and research of disease. Targeted therapies: Group of drugs specifically designed to a certain target of the tumor cell such as growth factor receptors, membrane proteins and others.

Peer review

This manuscript is a very good and complete review of the topic exposed.

Abstract

AIM: To investigate a novel DNA vaccination based upon expression of the HBV e antigen fused to a heat shock protein (HSP) as a strategy to enhance DNA vaccine potency.

METHODS: A pCMV-HBeAg-HSP DNA vaccine and a control DNA vaccine were generated. Mice were immunized with these different construct. Immune responses were measured 2 wk after a second immunization by a T cell response assay, CTL cytotoxicity assay, and an antibody assay in C57BL/6 and BALB/c mice. CT26-HBeAg tumor cell challenge test *in vivo* was performed in BALB/c mice to monitor anti-tumor immune responses.

RESULTS: In the mice immunized with pCMV-HBe-HSP DNA, superior CTL activity to target HBV-positive target cells was observed in comparison with mice immunized with pCMV-HBeAg (44% ± 5% *vs* 30% ± 6% in E: T > 50:1, $P < 0.05$). ELISPOT assays showed a stronger T-cell response from mice immunized with pCMV-HBe-HSP than that from pCMV-HBeAg immunized animals when stimulated either with MHC class Ⅰ or class Ⅱ epitopes derived from HBeAg (74% ± 9% *vs* 31% ± 6%, $P < 0.01$). ELISA assays revealed an enhanced HBeAg antibody response from mice immunized with pCMV-HBe-HSP than from those immunized with pCMV-HBeAg. The lowest tumor incidence and the slowest tumor growth were observed in mice immunized with pCMV-HBe-HSP when challenged with CT26-HBeAg.

CONCLUSION: The results of this study demonstrate a broad enhancement of antigen-specific $CD4^+$ helper, $CD8^+$ cytotoxic T-cell, and B-cell responses by a novel DNA vaccination strategy. They also proved a stronger antigen-specific immune memory, which may be superior to currently described HBV DNA vaccination strategies for the treatment of chronic HBV infection.

Key words: Hepatitis B virus antigen; Dendritic cell; Heat shock protein; DNA vaccine

INTRODUCTION

Chronic hepatitis B virus (HBV) infection continues to be a major human health problem, and there are about 350 million chronic HBV carriers worldwide[1]. Chronic HBV infection is associated with serious complications as a result of long-term sequelae such as liver cirrhosis or hepatocellular carcinoma[2]. The host immune response to HBcAg and HBeAg appears critical in both viral clearance and clinical resolution. The ultimate objective for rational vaccine design is the induction of pathogen immunity. In laboratory animals, DNA vaccine has proven to be a simple and effective method to generate protective immunity against a variety of pathogens, including HBV[3,4]. DNA vaccination that can induce both cellular and humoral immune responses has become an attractive immunization strategy against chronic HBV infection. Although it is known that DNA applied either i.m. or intradermally is primarily taken up by muscle cells or keratinocytes, it has become clear in recent years that professional APCs are essential for priming naive T cells following DNA injection. Accumulating evidence indicates that dendritic cells (DCs), the most potent APCs, play a critical role in the induction of immune responses by DNA vaccines[5-7]. Thus, enhancement of antigen presentation by DCs is an attractive strategy to increase the potency of DNA vaccines. However, a major problem of DNA vaccines is its limited potency, because only a very limited fraction of injected DNA molecules are taken up by DCs.

Recently, heat shock protein (HSP) was observed to elicit protective immunity to cancers and infectious

agents. The abilities of HSP include: (a) to chaperone peptides, including antigenic; (b) to interact with antigen presenting cells through a receptor; (c) to stimulate antigen presenting cells to secrete inflammatory cytokines; and (d) to mediate maturation of DCs, making them a one-stop shop for the immune system[8]. These properties also permit to use of HSP for developing a new vaccine. HSP has been reported to activate innate immune responses, to mediate the maturation of DCs, to upregulate proinflammatory cytokines[9-12], and to induce specific CTL responses[13,14].

In this study, we describe a novel DNA vaccination strategy to enhance uptake and presentation of antigens by DCs. Specifically, we developed a DNA vaccination based upon expression of the HBV e antigen fused to HSP, which are versatile immune regulators that chaperone antigenic peptides for MHC class Ⅰ and Ⅱ presentation by DCs. After vaccination, DNA is taken up by various cells that produce and secrete the antigen-HSP fusion proteins. The secreted fusion proteins, in addition to inducing B-cells, are efficiently captured and processed by DCs *via* receptor-mediated endocytosis, and then presented *via* MHC class Ⅰ and class Ⅱ molecules. This study demonstrates a broad enhancement of antigen-specific $CD4^+$ helper, $CD8^+$ cytotoxic T-cell, and B-cell responses by this DNA vaccination strategy, which may be superior to currently described HBV DNA vaccination approaches for the treatment of chronic HBV infection.

MATERIALS AND METHODS

Mice and cell lines

The mice used were female C57BL/6 and Balb/c mice, aged 4-5 wk. All mice were maintained in the animal facility at Baylor College of Medicine with approval of the Institutional Animal Care and Use Committee. The tumor cell lines EL-4, Trampc-2, and CT26 were purchased from the ATCC. EL-4 and Tampc-2 cells were cultured in DMEM medium and CT26 cells in RPMI 1640 medium both containing 10% heat-inactivated FBS (GIBCO) at 37℃ in an humidified 5% CO_2 atmosphere.

DNA constructs

The pCMV-HBeAg-HSP construct was generated by inserting HBeA (be derived from the precore open reading frame by cleavage of its C-terminus, nucleotide: 1901-2452 of HBV genome) & HSP-70 (StressGen Biotechnologies, Victoria, British Columbia, Canada) plasmid into a pCMV vector (Invitrogen, Carlsbad, CA,USA) with the cloning site HindIII & XbaI. Two control vectors, pCMV-HBeAg & pCMV-HSP, were also generated.

DNA preparation and immunization

Plasmid DNA was amplified in *Escherichia coli* DH5α and purified using an endotoxin-free purification kit (Qiagen) according to a standard protocol. Concentration was determined using the UV/Visible Spectrophotometer (Pharmacia Biotech) at 260 and 280 nm, and the material was adjusted to a final concentration of 1 mg/mL with endotoxin-free PBS (Sigma) and stored at -20℃. Mice were divided into 4 groups, which were immunized with different DNA vaccines including pCMV-HBeAg-HSP, pCMV-HBeAg, and pCMV-HSP. Controls were injected with PBS (C57BL/6 mice) or pCMV (Balb/c mice). Immunization method: mice were injected s.c. (C57BL/6) and i.m. (Balb/c) in quadriceps with 100 μg of DNA in 100 μL, two inoculations were carried out with an interval of 2 wk. Two weeks after the second immunization blood and spleens were collected, and BALB/c mice were challenged with CT26-HBeAg tumor cells.

Elispot for T-cell response assay

Elispot assays were used as a measure for T-cell response. Ninety-six well filtration plates (Milipore, Bedford, MA, USA) were coated with AN18 (anti-mouse IFN-γ, Mebtech) at the concentration of 10 μg/mL and kept at 4℃ overnight. Splenocytes were cultured in 96-well plates (1×10^6 cells/mL and 2×10^6 cells/mL) with RPMI 1640/10% FBS containing HEPES, 2MC, and NEAAS. Splenocytes from mice of different groups were stimulated with HBeAg class Ⅰ peptide (HBcAg93-100 peptide), HBeAg class Ⅱ peptide (HBcAg 120-131), or HBV protein (HBsAg, 227 amino acids, 24kD) (BD Pharmingen, SD, CA, USA) for comparing the effect of different DNA vaccinations on the T-cell response. The splenocytes derived from mice vaccinated with HBeAg-HSP were also stimulated with Trampc-2 class Ⅰ peptide (P117-139, WT1), CT26 class Ⅰ peptide (peptide AH1), Tyrosinase protein, Tyrosinase class Ⅰ peptide (Ty-4), Tyrosinase class Ⅱ peptide (Ty-5), and PMSA4 class Ⅱ peptide as controls. Proteins were added at a final concentration of 60 μg/mL, peptides at a final concentration of 30 μg/mL. All assays were performed in triplicates. After stimulation for 20 h at 37℃, the plate was washed with PBS and the second antibody (anti-mouse IFN-γ, Mebtech Mab R4-6A2 biotin) was added for a further incubation at 37℃ for 2 h. Avidin-HRP was added for 1 h at room temperature after washing, then 100 μL AEC was added to each well for coloring for 4 min after washing. The reaction was stopped by drying the membrane. The results were sent to Zellnet Consulting, Inc. (NY, USA) for test.

CTL cytotoxicity assays

CTL cytotoxic activity was determined using a ^{51}Cr-release assay. In brief, splenocytes obtained from mice 2 wk after the second immunization were cultured in 24 well plates with RPMI 1640/10% FBS containing HEPES, 2MC, NEAAS, and IL-2 (50 U/mL). Splenocytes were stimulated with HBeAg class Ⅰ peptide (HbcAg93-100 peptide) for 7 d, with changing half of the medium every 2 d. Target cell lines were cultured with IFN-γ (100 U/mL) for 24 h. EL-4 cells were pulsed with HBeAg class Ⅰ peptide and HBV protein (HBsAg, 227 amino acids, 24 kDa) as target cells. EL-4 cells pulsed with HBV non-related class Ⅰ peptide such as CT26 and Trampc-2 class Ⅰ peptides, non-pulsed EL-4 cells, and CT26 cells pulsed with HBeAg class Ⅰ peptide served as controls. All target and control cells were labeled with ^{51}Cr for 90 min. Cells were added to the wells at effector-to-target ratios ranging from 100:1 to 6.25:1 in triplicates. Plates were incubated at 37℃ for 5 h, before supernatants were collected and activity was assessed in a Gamma counter (Beckman, Fullerton, CA, USA).

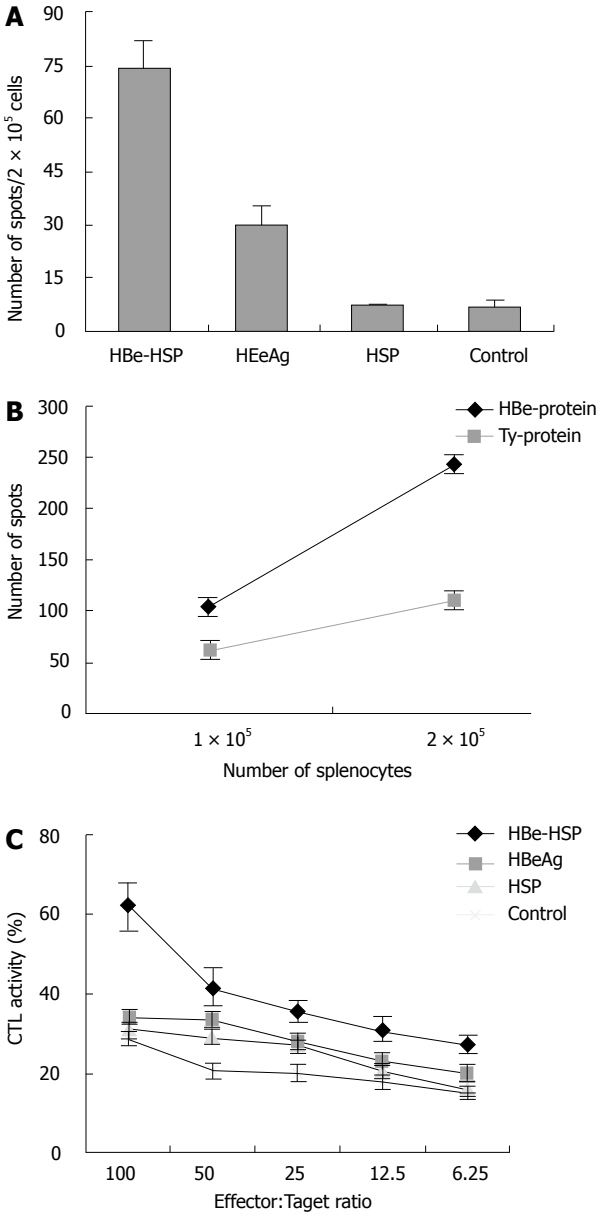

Figure 1 **A**: Comparison of T cell proliferation between different groups after stimulation with HBV protein (C57BL/6 mice); **B**: Comparison of T cell proliferation between stimulation with HBV protein and with non-related protein (Balb/c mice); **C**: Comparison of CTL activity to HBV protein pulsed target cells between different groups (C57BL/6 mice).

Anti-HBeAg antibodies assays

An ELISA assay (BD Biosciences) was used to quantify the antibody response after immunization. Sera were obtained 2 wk after the second immunization. Microtiter plates (Maxisorp) were coated with HBeAg overnight at 4℃. The coated plate was washed with PBS to stop reaction for 1 h at 37℃. Sera were added at different dilutions and the plate was incubated at 37℃ for 2 h. The second antibody was added at 37℃ for 2 h after washing with PBS. Finally, substrate was added and the plate was stored at room temperature for 30 min before stopping reactions with 4N sulfuric acid. Reading of the plate was done in an ELISA reader at 450 nm.

CT26-HBeAg tumor cell challenge test

CT26 cells were transfected with HBeAg using GenePoter reagent (Gene Therapy Systems) according to the manufacture's instructions. Forty-eight hours after transfection, cells were harvested and plated into selective medium in 10 cm dishes, 5×10^4 CT26 cells were plated into 250 μg/mL Geneticin. Two weeks after the second vaccination, 5×10^5 CT26 cells with HBeAg were injected s.c. into mice. Tumor incidence and tumor growth were monitored and tumor size was measured ($v = 1/2ab^2$: v: volume; a: largest diameter; b: smallest diameter).

Statistical analysis

All statistical analyses were performed using student *t*-test. Values of $P < 0.05$ was considered significant.

RESULTS

Enhancement of T cell response and CTL activity by HBeAg-HSP DNA vaccine

To evaluate whether HBeAg-HSP DNA vaccine can enhance immune response *in vivo*, splenocytes were obtained for T cell response and CTL activity. These immune responses were first stimulated with HBV protein and were compared between C57BL/6 and Balb/c mice immunized with different DNA vaccines. In CTL assay, EL-4 cells were pulsed with HBV protein as target cells. ELISPOT showed a stronger T-cell response from the mice immunized with HBeAg-HSP than that from HBeAg immunized mice after stimulation with HBV protein (Figure 1A, spots 74 ± 5 *vs* 31 ± 6, $P < 0.01$). A specific T-cell response was obtained in HBV protein stimulation in comparison with Tyrosinase protein stimulation (Figure 1B). Superior CTL assay to HBV protein pulsed target cell was also observed in mice immunized with HBeAg-HSP in comparison to those immunized with HBeAg (Figure 1C, 46% ± 10% *vs* 35% ± 8% in E: T > 50:1, $P < 0.05$).

We also evaluated the specific stimulating effect of HBV MHC class I peptide on T cell response and CTL activity. After splenocytes were stimulated with HBV MHC class I peptide, ELISPOT showed a stronger T-cell response from mice immunized with HBeAg-HSP than from those which had been immunized with HBeAg (Figure 2A, 76 ± 6 *vs* 29 ± 5, $P < 0.01$). CTL activity to HBV class I peptide pulsed target cells is also stronger in mice immunized with HBeAg-HSP than in mice immunized with HBeAg (Figure 2B, 44 ± 5 *vs* 30 ± 6 in E: T > 50:1, $P < 0.05$). A specific effect on T cell response is also obtained after stimulation with HBV class I peptide in comparison with CT26 class I peptide and TrampC-2 class I peptide stimulation (Figure 2C). A stronger CTL activity to HBV class I peptide pulsed target cells was shown in comparison with target cells pulsed with CT 26 class I peptide and TrampC-2 class I peptide (Figure 2D). T cell response to HBV class I peptide and CTL activity to HBV class I peptide pulsed target cells proved cytotoxic T cell activity.

To evaluate helper T cell activity, the effects of HBV MHC class Ⅱ peptides on T cell response and CTL activity were studied. Splenocytes were stimulated with HBV class Ⅱ peptides for T cell response. A stronger T cell response was obtained from HBeAg-

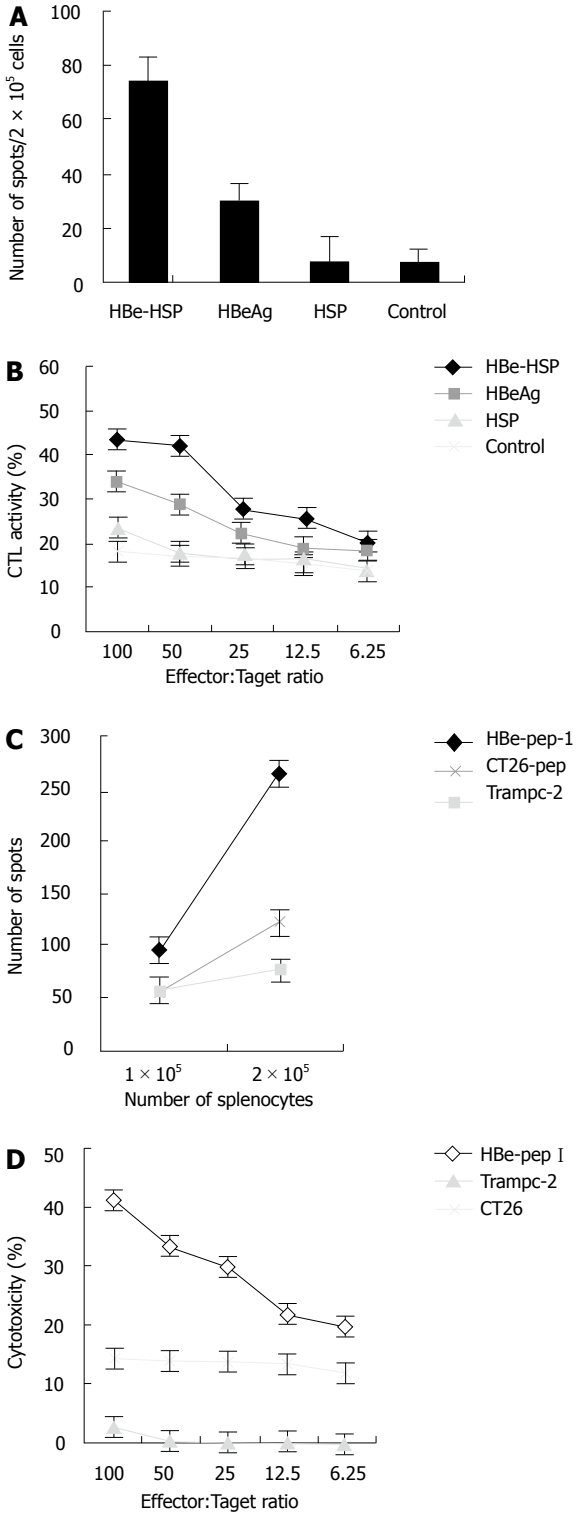

Figure 2 **A**: Comparison of T cell proliferation between different groups after stimulation with HBV class I peptide (C57BL/6 mice); **B**: Comparison of CTL activity to HBV class I peptide pulsed target cells between different groups (C57BL/6 mice); **C**: Comparison of T cell proliferation between stimulation with HBV and with non-related class I peptide (Balb/c mice); **D**: Comparison of CTL activity to HBV class I peptide pulsed target cell between HBV and non-related class I peptide (Balb/c mice).

HSP DNA vaccine immunized mice in comparison with that in mice immunized with HBeAg (A, spots 74 ± 9 *vs* 31 ± 6, $P < 0.01$) and HSP DNA vaccine (Figure 3). A specific stronger T cell response by HBV class Ⅱ peptide stimulation was shown in comparison with that by PSMA4 class Ⅱ peptide, Tyrosin-4 and Tyrosin-5 class Ⅱ peptide stimulation (Figure 3B).

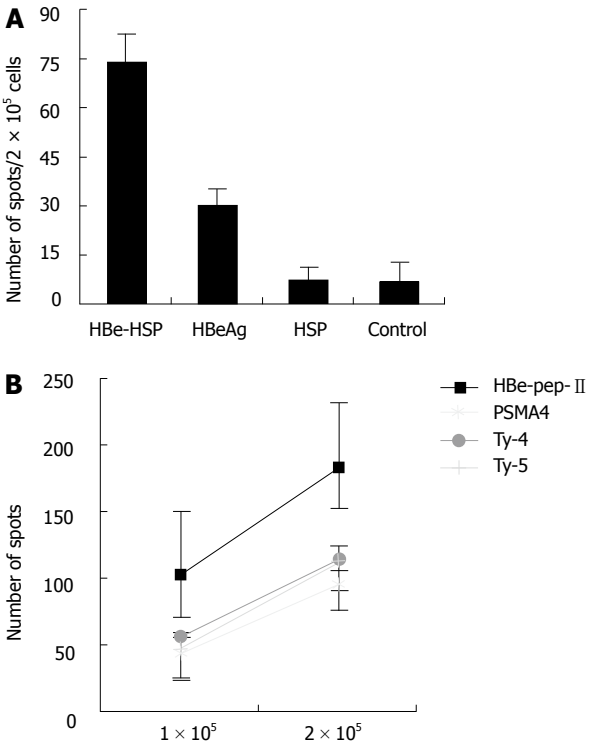

Figure 3 **A**: Comparison of T cell proliferation between different groups after stimulation with HBV class Ⅱ peptide (C57BL/6 mice); **B**: Comparison of T cell proliferation after stimulation with different class Ⅱ peptide (Balb/c mice).

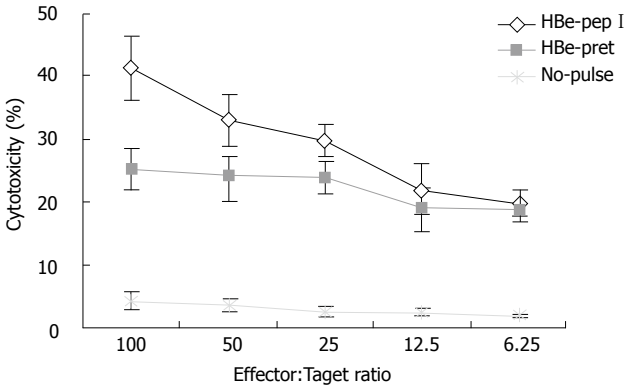

Figure 4 Comparison of CTL activity to target cells pulsed with different agents (Balb/c mice).

We also studied whether HBV related proteins and class I peptides can increase target cell antigenicity. Results suggested that splenocytes from mice immunized with HBeAg-HSP DNA vaccine have a stronger CTL activity to target cells pulsed with HBV protein and HBV class I peptide in comparison to non-target cells and CT 26 cells (Figure 4).

Serum antibody response to HBeAg antigen after DNA vaccination

To determine whether HBeAg-HSP DNA vaccination can also induce an antibody response to HBeAg antigen, we measured serum anti-HBeAg antibody responses by ELISA assay. As shown in Figure 5, antibody levels detected in mice immunized with the HBeAg-HSP DNA vaccine were markedly higher than those immunized with

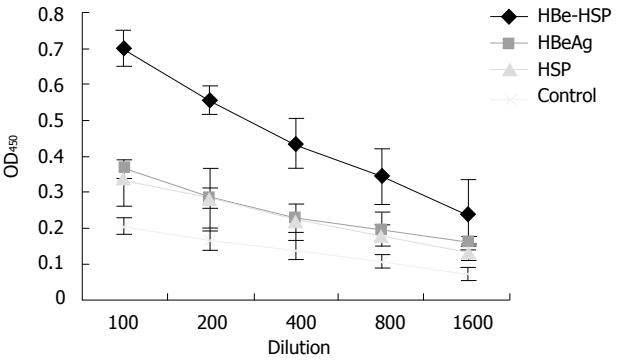

Figure 5 Comparison of antibody titers to HBV between different groups after immunization (Balb/c mice).

the HBeAg or the HSP DNA vaccines ($P < 0.05$). The results indicate the superiority of HBeAg-HSP in inducing humoral immunity.

Systemic immunity enhancement in vivo by HBeAg-HSP DNA vaccine

To evaluate systemic immunity enhancement *in vivo* by the HBeAg-HSP DNA vaccine, Balb/c mice (10 mice/group) were challenged by CT26 cells transfected with HBeAg to observe the antitumor effect after different DNA vaccine immunizations. CT26-HBeAg cells were injected s.c. at 5×10^5/mouse and tumor incidence and tumor growth were monitored. Results showed that there is a low tumor incidence in mice immunized with HBeAg DNA vaccine and a lower tumor incidence in HBeAg-HSP DNA vaccinated mice (Figure 6A), the incidence of tumor are 6/10 in HBeAg-HSP group, 8/10 in HBeAg group and 10/10 in the other two groups. Tumor growth was slowest in mice immunized with the HBeAg-HSP DNA vaccine (Figure 6B). The results suggested that HBeAg-HSP DNA vaccination can induce a stronger immune response to the related antigen.

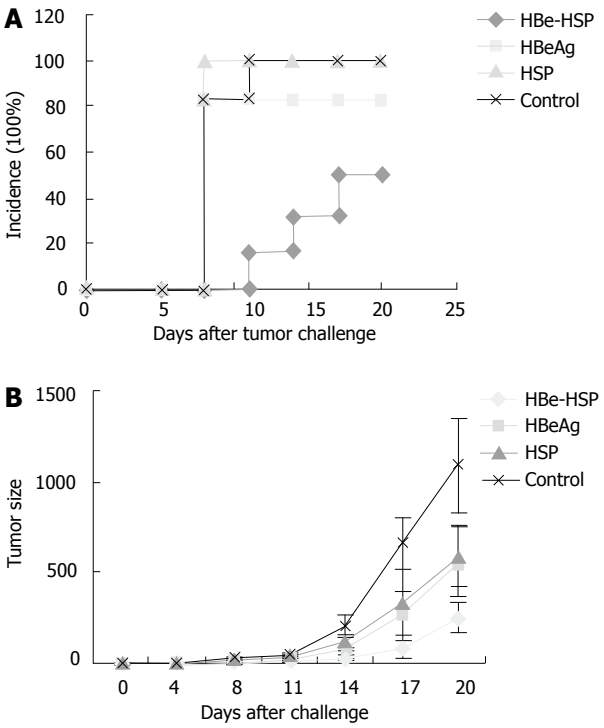

Figure 6 **A**: Tumor incidence after CT26-HBeAg challenge of Balb/c mice; **B**: Tumor growth after CT26-HBeAg challenge of Balb/c mice.

DISCUSSION

HBV infection is a major human health problem and it is associated with a risk of developing liver cirrhosis or hepatocellular carcinoma[1,2]. Thus, effective preventive and therapeutic strategy to chronic HBV infection has been a major exploration[15,16]. Only a small proportion of patients with chronic HBV infection benefit from a treatment with interferon-α (IFN-α)[2]. Antigen-based vaccines have some disadvantages, such as the possibility of reversion to a virulent form, especially in immunocompromised individuals; whole-killed or subunit vaccines do not induce intracellular synthesis of antigen because there is poor or absent presentation of antigen on class I MHC and thus poor induction of a CTL response[17]. DNA-based vaccination is an efficient new technique to stimulate specific immune responses and specific for HBV antigen to induce a strong humoral and cell-mediated immunity against HBV infection[18,19]. HBV(HBsAg, HBc/eAg) DNA vaccine has been popularly studied for prophylaxis or therapy against HBV infection[15,16,20-24].

DNA vaccine has made an attractive alternative to conventional methods of vaccination. HBV DNA vaccination can induce $CD8^+$ T cells as well as a dominant Th1 phenotype among the splenic lymphocytes, so eliciting strong CTL and protective levels of antibody[25-28]. Antigen-presenting cells (APCs) play a key role in induction of immune responses by DNA vaccines. DNA vaccines express native protein antigens in situ which can be recognized by B cells and presented by MHC class Ⅰ and Ⅱ molecules to prime helper T cells and CTLs. Dendritic cells (DCs) are usually thought of as a specific APCs for T cell and B cell activation and regulation of antibody synthesis, presentation of antigen by DCs is a potent stimulus to immune response, particularly to cell-mediated immunity and the development of CTLs. Thus, DCs are critical for initiating and modulating B and T cell responses elicited by DNA vaccination[29-31]. However, only a very limited fraction of injected DNA molecules is taken up by DCs, the intracellular antigens expressed by DCs are difficult to be processed and presented to MHC class Ⅱ[32].

In this study, we designed a novel DNA vaccination strategy to enhance uptake and presentation of antigen by DCs, specifically, we developed a DNA vaccine based upon the expression of the HBV e antigen fused to HSP, which are versatile immune regulators that chaperone peptides for MHC class I and Ⅱ presentation by DCs. The abilities of HSP include: to chaperone peptides, including antigen peptides; to interact with antigen presenting cells through a receptor; to stimulate antigen presenting cells, such as DCs to secrete inflammatory cytokines; and to mediate DC maturation[14]. The HSP70 peptide complex has been shown to elicit $CD4^+$ helper T cells and $CD8^+$ cytotoxic T cells and has been used for inducing antitumor immunity and for therapy of infectious diseases[33-37]. The novel vaccination strategy-HBeAg-HSP we developed

has been shown to induce a stronger CTL activity, T cell proliferative response, and antibody response than that of HBeAg DNA vaccine. Moreover, it also showed a stronger anti-tumor immunity to tumor with HBV antigen challenge than that of the HBeAg DNA vaccine. To date, many kinds of cancer vaccines have been tested worldwide and have shown their own advantages. HSP-based cancer vaccine is one of the outstanding representatives[38]. HSP complexes isolated from tumor have been shown to induce specific anti-tumor immunity, HSP alone can also induce non-specific immunity[39]. Recent works by Enomoto and Chan indicated HSP70 based vaccine possess superior properties such as stimulation of DC maturation and T cell proliferation[40,41]. HSP vaccine has been extensively tested in animals and more recently in clinical trials[42,43]. HSP vaccine can induce immune responses against mutated tumor-specific antigens, as well as normal self-antigens. Immune responses to self-antigens by HSP may thus produce damage to normal tissues, however, there are no reports about toxic side effects in mouse models or clinical trials with HSP[44,45].

It is important that exploit of effective DNA vaccination to induce HBV specific immune response to clear HBV infection. The results of this study demonstrate the broad enhancement of antigen-specific $CD4^+$ helper, $CD8^+$ cytotoxic T-cell, B-cell response, and specific anti-tumor immunity by this DNA vaccination strategy, which may be superior to currently described HBV DNA vaccination for the treatment of chronic HBV infection.

COMMENTS

Background

Chronic HBV infection is associated with serious complications as a result of long-term sequelae such as liver cirrhosis or hepatocellular carcinoma. The host immune response to HBcAg and HBeAg appears critical in both viral clearance and clinical resolution. DNA vaccination that can induce both cellular and humoral immune responses has become an attractive immunization strategy against chronic HBV infection. However, a major problem of DNA vaccine is its limited potency, because only a very limited fraction of injected DNA molecules are taken up by DCs. In this study, we describe a novel DNA vaccination strategy to enhance uptake and presentation of antigens by DCs.

Research frontiers

A DNA vaccination based upon expression of the HBV e antigen fused to a heat shock protein (HSP) was developed, this study demonstrate that this DNA vaccination strategy may be superior to currently described HBV DNA vaccination for the treatment of chronic HBV infection.

Innovations and breakthroughs

DNA vaccine has made an attractive alternative to conventional methods of vaccination. In this study, we designed a novel DNA vaccination strategy to enhance uptake and presentation of antigen by DCs, it may be superior to currently described HBV DNA vaccination for the treatment of chronic HBV infection.

Applications

HSP vaccine has been extensively tested in animals and more recently in clinical trials. The results in this study suggested that HBeAg-HSP DNA vaccine may be superior to currently described HBV DNA vaccination for the treatment of chronic HBV infection.

Terminology

DNA vaccine has made an attractive alternative to conventional methods of vaccination. HBV DNA vaccination can induce $CD8^+$ T cells as well as a dominant Th1 phenotype among the splenic lymphocytes, so elicit strong CTL and protective levels of antibody. The novel vaccination strategy-HBeAg-HSP we developed has been shown to induce a stronger CTL activity, T cell proliferative response, and antibody response than the HBeAg DNA vaccine, and it also showed a stronger anti-tumor immunity to tumor with HBV antigen challenge than that of HBeAg DNA vaccine.

Peer review

The novel vaccination strategy-HBeAg-HSP was studied and it is one of the outstanding representatives for the treatment of chronic HBV infection. Moreover, it will be interesting in the treatment of cancer in future. It is deserved to be published.

Abstract

AIM: To investigate the correlation between systemic hemodynamics and splanchnic circulation in recipients with cirrhosis undergoing living-donor liver transplantation (LDLT), and to clarify how systemic hemodynamics impact on local graft circulation after LDLT.

METHODS: Systemic hemodynamics, indocyanine green (ICG) elimination rate (K_{ICG}) and splanchnic circulation were simultaneously and non-invasively investigated by pulse dye densitometry (PDD) and ultrasound. Accurate estimators of optimal systemic hyperdynamics after LDLT [i.e., balance of cardiac output (CO) to blood volume (BV) and mean transit time (MTT), defined as the time required for half the administered ICG to pass through an attached PDD sensor in the first circulation] were also measured. Thirty recipients with cirrhosis were divided into two groups based on clinical outcomes corresponding to postoperative graft function.

RESULTS: Cirrhotic systemic hyperdynamics characterized by high CO, expanded BV and low total peripheral resistance (TPR) were observed before LDLT. TPR reflecting cirrhotic vascular alterations was slowly restored after LDLT in both groups. Although no significant temporal differences in TPR were detected between the two groups, CO/BV and MTT differed significantly. Recipients with good outcomes showed persistent cirrhotic systemic hyperdynamics after LDLT, whereas recipients with poor outcomes presented with unstable cirrhotic systemic hyperdynamics and severely decreased K_{ICG}. Systemic hyperdynamic disorders after LDLT impacted on portal venous flow but not hepatic arterial flow.

CONCLUSION: We conclude that subtle systemic hyperdynamics disorders impact on splanchnic circulation, and that an imbalance between CO and BV decreases portal venous flow, which results in critical outcomes.

INTRODUCTION

We previously demonstrated that systemic hemodynamics

affecting postoperative graft function are crucial for living-donor liver transplantation (LDLT)[1]. However, the relationship between systemic hemodynamic parameters and splanchnic circulation after LDLT remains to be fully elucidated. In particular, the influence of the systemic hemodynamic state on splanchnic circulation is unclear. Therefore, we carried out a detailed investigation of systemic and splanchnic hemodynamic behavior after LDLT in adult recipients with cirrhosis.

Prior to undergoing LDLT, recipients with cirrhosis generally develop peculiar systemic and splanchnic hemodynamics due to portal hypertension[2-4]. To ascertain correlations between systemic hemodynamics and splanchnic circulation, and to clarify how the systemic hemodynamic state impacts on the local graft circulation, we performed simultaneous assessments of systemic hemodynamics and directly measured splanchnic circulation by systemic dye distribution and ultrasound. We also determined the hemodynamic state required for an excellent clinical outcome corresponding to good graft function.

MATERIALS AND METHODS

Patients

From June 2003 to March 2006, indocyanine green (ICG) pharmacokinetics were analyzed using a non-invasive method in 30 adult recipients (average age 53.1 ± 9.3 years; 25 males, five females) who underwent orthotopic LDLT at Mie University Hospital. As well, splanchnic circulatory parameters were simultaneously assessed using Doppler ultrasound. All 30 patients received a right-lobe liver graft. Clinical diagnoses were 26 cases of liver cirrhosis with hepatitis B or C (18 complicated by hepatocellular carcinoma), two cases of biliary atresia (result of postoperative state of Kasai's operation at childhood), and one case each of primary sclerosing cholangitis and alcoholic liver cirrhosis. All recipients were diagnosed with liver cirrhosis, based on histopathological examination of resected specimens. ABO blood group compatibility was identical in 24 recipients and compatible in six. The operative procedures and immunosuppression protocols used in our institute have been described in detail elsewhere[1,5-8]. All the protocols used in the present study were approved by the Ethics Review Committee for Human Studies of Mie University Graduate School of Medicine (Tsu, Mie, Japan), based on the Ethical Guidelines of the Helsinki Declaration of 1975. Informed consent was obtained from all patients before enrollment.

ICG, pulse dye densitometry (PDD) and analytical procedures

ICG is widely used for analysis of liver function[9,10]. Furthermore, the dye dilution curve of ICG can be used for measuring hemodynamic parameters[9,11]. A non-invasive method for measuring systemic hemodynamic parameters using ICG has been reported[12] and is relatively reliable compared with invasive ones[11,13-15]. It is also advantageous for clinical use because it is simple to use at the bedside, has quick real-time presentation of results and is cost-effective[16,17]. Hence, we used this non-invasive method in the present study.

ICG (Diagnogreen Inj., Daiichi Pharmaceutical, Tokyo, Japan), a non-toxic dye, has no known side effects other than a rare iodine allergy. Although a total of 630 ICG bolus injections were performed in the 30 recipients, no allergic responses or any other side effects were observed.

PDD, which measures the absorption of hemoglobin and ICG, is based on the principle of pulse spectrophotometry; the basic principles of which has been detailed elsewhere[11,12]. A PDD apparatus (DDG-2001; Nihon Kohden, Tokyo, Japan) was used to measure blood ICG concentrations and analyze dye densitography. A sensor was placed on the nose of each patient before ICG injection.

Twenty milligrams of ICG was injected through a peripheral cannula and immediately flushed with 20 mL normal saline[1,9,18]. PPD measurements were obtained before LDLT and from 1 to 14 d and at 21 d and 28 d postoperatively. In particular, measurements were performed every 12 h until 72 h postoperatively, because the hemodynamic parameters showed marked changes during the early postoperative period.

Systemic hemodynamic parameters and ICG elimination rate

The following parameters were measured and calculated using the PDD apparatus with the patients in a settled recumbent position: cardiac output (CO, L/min), cardiac index (CI, L/min per m^2), mean transit time (MTT, s, blood volume (BV, L), heart rate (HR, beats/min) and ICG elimination rate constant (K_{ICG}). MTT was defined as the time required for half the administered ICG to pass through the attached nasal sensor in the first circulation. Details of the above calculations have been described elsewhere[11,12,17]. Measurement of mean arterial pressure (MAP) was performed simultaneously with the PDD. MAP, calculated as MAP (mmHg) = (pulse pressure/3) + diastolic pressure, was measured using a standard manual method[19]. Total peripheral resistance (TPR) was subsequently calculated according to the following formula: TPR (dyne/s^5 per cm) = MAP × 80/CO[19].

Doppler ultrasound and splanchnic hemodynamic measurements

Doppler ultrasound assessment of splanchnic hemodynamic parameters was conducted at the same time as PDD. Portal venous flow velocity (PVFVe), portal venous flow volume (PVFVo), hepatic arterial pulsatility index (HAPI), and hepatic arterial resistance index (HARI) were evaluated as splanchnic circulatory parameters. A Triplex Doppler ultrasound system (Prosound SSD-5000SV; ALOKA, Tokyo, Japan) and a convex probe (2-5 MHz; UST-9119; ALOKA) were used for the Doppler ultrasound assessment. The following parameters were measured at the extrahepatic but post-anastomosis area: (1) PVFVe (cm/s), representing the mean of the maximal flow velocity of the portal vein; (2) PVFVo (mL/min), calculated from a cross-sectional area, assuming a circular portal vein section, and the mean velocity; (3) HAPI,

There were no significant differences between Groups I and Ⅱ in each parameter, respectively ($P > 0.05$, analyzed by Mann-Whitney's U test). Statistical differences between healthy individuals and Group I analyzed by Mann-Whitney's U test ([a]$P < 0.05$, [b]$P < 0.005$, [d]$P < 0.0005$). Statistical differences between healthy individuals and Group Ⅱ analyzed by Mann-Whitney's U test ([e]$P < 0.05$, [f]$P < 0.005$). ICG: Indocyanine green; LDLT: Living-donor liver transplantation; CO: Cardiac output; CI: Cardiac index; BV: Blood volume; MTT: Mean transit time; HR: Heart rate; MAP: Mean arterial pressure; TPR: Total peripheral resistance; PVFVo: Portal veinous flow volume; PVFVe: Portal venous flow velocity; HAPI: Hepatic arterial pulsatility index; HARI: Hepatic arterial resistant index.

calculated from the Doppler trace over one cardiac cycle as: (peak systolic velocity-minimum velocity)/mean of maximal velocities; and (4) HARI, derived from the Doppler spectrum over one cardiac cycle according to: (peak systolic velocity-end diastolic velocity)/peak systolic velocity. The measurement methods for the above indices have been described in detail elsewhere[20-23].

Establishment of normal ranges of systemic hemodynamic parameters, K_{ICG} value and splanchnic circulatory parameters

To establish the normal ranges of the variables we investigated the variables using the above-described methods in seven donors before LDLT and in nine volunteers who agreed to the aims of this study. The data measured in these 16 healthy individuals represent the normal ranges of the parameters, and are shown in Table 1. The control population showed no significant differences in age or body surface area compared with the LDLT recipients (data not shown).

Computed tomographic (CT) volumetry of liver grafts and the standard liver volume (SLV)

In our institution, helical CT studies are routinely performed at 2 and 4 wk after LDLT. All 30 recipients underwent these studies after LDLT. The helical CT studies were conducted using a High Speed Advantage QX-1 (GE Medical Systems, Tokyo, Japan). The scanning parameters were 120 kV, 200 mA, collimation of 5 mm, and a table speed of 15 mm/rotation, with reconstruction increments of 5 mm. Graft volume was calculated by CT volumetry. SLV was calculated according to a previously described formula[24].

Technetium-99m-diethylenetriaminepenta-acetic acid-galactosyl-human serum albumin (99mTc-GSA) liver scintigraphy and ratio of liver to heart-plus-liver radioactivity at 15 min (LHL15)

Since asialoglycoprotein receptors on hepatocytes are characteristic of functional liver cells[25], 99mTc-GSA liver scintigraphy is used as a reliable assessment tool for functional hepatic volume[26]. A total of 60 measurements were performed in the 30 recipients at 2 and 4 wk after LDLT. After intravenous injection of 185 MBq of 99mTc-GSA (Nihon Medi-Physics, Nishinomiya, Japan), dynamic imaging was performed with the patient in the supine position using a large field-of-view gamma camera (GCA7200A; Toshiba, Tokyo, Japan). LHL15 was calculated by dividing the radioactivity of whole liver regions of interest (ROIs) by that of whole liver-plus-heart ROIs at 15 min after injection, as previously described[27].

Histopathological analysis and graft parenchymal damage score

In our institution, needle biopsies are performed after LDLT if necessary. Protocol biopsies are not performed because of the associated risks, such as hemorrhage[28]. In the present study, a total of 30 biopsy specimens from the 30 recipients were assessed within 4 wk after LDLT.

Tissue specimens were stained with hematoxylin-eosin using standard histopathological techniques, and reviewed by an experienced liver pathologist using a semi-quantitative scoring system for features of the graft parenchyma. The graft parenchymal damage score, representing liver damage, was calculated as the total of the following parenchymal feature scores: hepatocyte ballooning (0, no; 1, yes), hepatocyte necrosis (0, none; 1, small foci; 2, confluent areas; 3, bridging necrosis), congestion (0, no; 1, yes), the fraction of hepatocytes that contain microvesicular fat (0, none; 1, < 1/3 of hepatocytes, 2, between 1/3 and 2/3 of hepatocytes; 3, > 2/3 of hepatocytes), neutrophil aggregates (0, none; 1, minimal; 2, moderate; 3, extensive) and cholestasis (0, none; 1, mild; 2, moderate; 3, severe). The graft parenchymal damage score, which was modified from the score according to Neil *et al*[29], has been described in detail elsewhere[6].

Outcomes after LDLT

The clinical courses of all recipients were followed for 996.2 ± 436.5 d, ranging from 32 (patient died) to 1472 d after LDLT. The 30 recipients were retrospectively divided into two groups based on clinical outcomes corresponding to postoperative graft function. Although 25 recipients (Group Ⅰ) presented with a good clinical course and excellent outcome, a subset of five recipients (Group Ⅱ) required long-term intensive management, and finally died because of hepatic or extrahepatic reasons that

Table 2 Clinical profiles before, during and after LDLT

Statistical differences between Groups I and Ⅱ analyzed by Mann-Whitney's U test (NS: $P > 0.05$). LDLT: Living-donor liver transplantation; SLV: Standard liver volume; CT: Computed tomographic; LHL15: The ratio of liver to heart-plus-liver radioactivity at 15 min; 99mTc-GSA: Technetium-99m-diethylenetriaminepenta-acetic acid-galactosyl-human serum albumin.

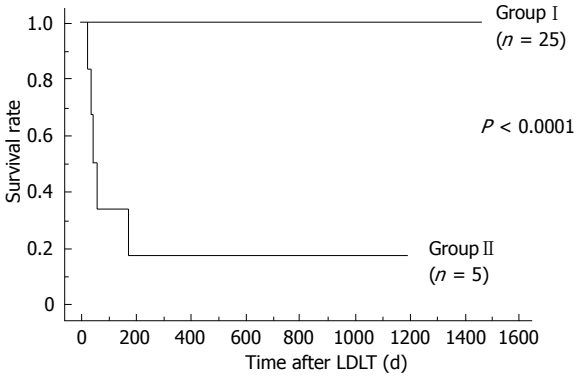

Figure 1 Survival rates after LDLT. The two lines represent the survival rates for Groups Ⅰ and Ⅱ. The P value analyzed by the log-rank test was < 0.0001.

originated from graft dysfunction with prolonged jaundice. Group Ⅱ showed poor clinical outcome, and survival rate differed significantly between the two groups ($P < 0.0001$) (Figure 1).

Clinical profiles before, during and after LDLT

There were no significant differences in the clinical profiles before and during LDLT between the two groups. We considered that high portal venous pressure before removal of the native liver was due to portal hypertension. After LDLT, there was a significant difference in the length of stay in the intensive care unit between the two groups. Although there were no significant differences in SLV, LHL15 and graft parenchymal damage scores both differed significantly between the two groups (Table 2). Because LHL15 and graft parenchymal damage scores accurately reflect functional hepatocytes, these results clearly indicated graft dysfunction in Group Ⅱ during the late postoperative period after LDLT.

Statistical analysis

Results were expressed as means ± SD. For individually, temporally and repeatedly measured data, differences in the changes over time after LDLT between the two groups were analyzed by repeated-measures ANOVA[30,31]. Differences in unpaired discontinuous data between the two groups were analyzed by Mann-Whitney's U test. Survival rates were calculated by the Kaplan-Meier method, and the log-rank test was used for between-group comparisons of recipient survival. All calculations were performed using Stat View-J 5.0 statistical software (SAS Institute, Cary, NC, USA) and values of $P < 0.05$ were considered significant.

RESULTS

Systemic hemodynamic states before LDLT and temporal differences in systemic hemodynamic parameters after LDLT

Cirrhotic systemic hemodynamics have been symbolized as hyperdynamic[1-4,32], and the hyperdynamic state characterized by high CO or CI, large BV, low TPR, mild tachycardia, and low or normal MAP[2,19,32-35]. Although hyperdynamic states were recognized in both groups, there were no significant differences between the two groups before LDLT. Interestingly, CO/BV and MTT were both constant before LDLT (Table 1). There were significant

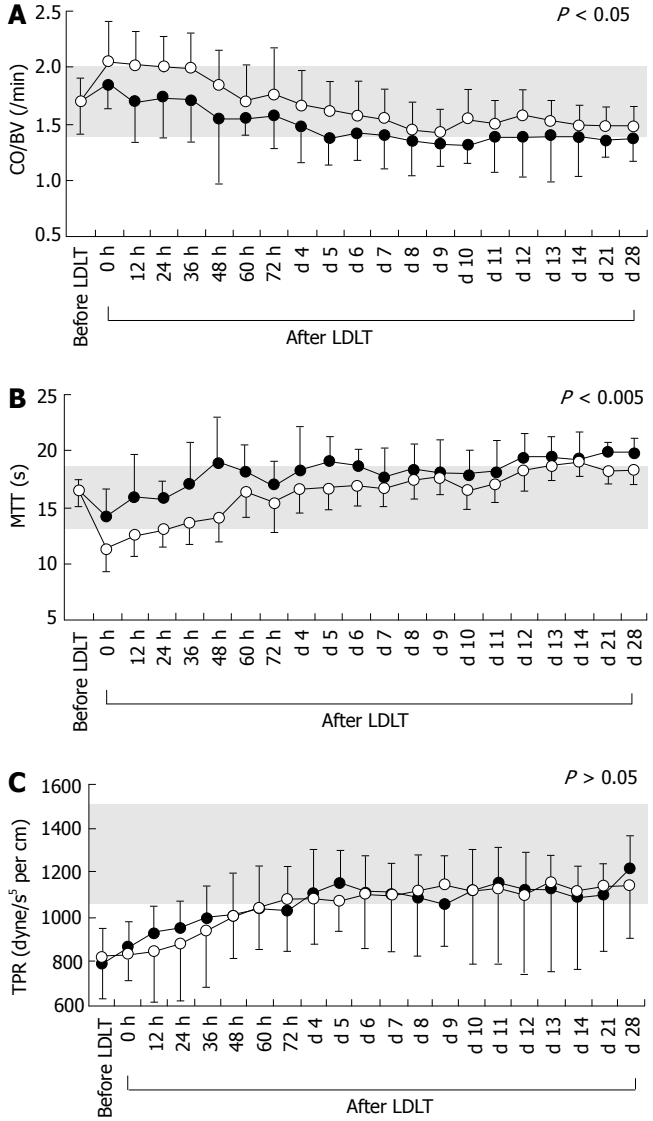

Figure 2 Temporal changes in systemic hemodynamic parameters before and after LDLT. **A:** Temporal changes in the ratio of CO to BV before and after LDLT; **B**: Temporal changes in MTT before and after LDLT; **C**: Temporal changes in TPR before and after LDLT. temporal differences after LDLT between the groups for CO/BV and MTT, but no significant differences in CO, CI, BV, HR, MAP or TPR (Table 3). The actual temporal changes in CO/BV, MTT and TPR are presented in Figure 2. When the absolute values of CO and BV in the recipients were compared with those of healthy individuals, recipients in Group Ⅰ persisted in a hyperdynamic state after LDLT, while those in Group Ⅱ showed a tendency to remain in a hyperdynamic state (actual temporal changes not shown). Thus, regardless of the outcome and graft function, the temporal changes in the absolute values of CO and BV between groups did not reach statistical significance. Therefore, as we have previously determined, detecting subtle disorders of optimal systemic hemodynamics in recipients with cirrhosis by comparing absolute values is not necessarily satisfactory (unpublished data). Indicators for peripheral resistance are thought to precisely reflect cirrhotic vascular alterations and the

presence of collateral vessels and shunts[19,36,37]. It should be noted that the changes in TPR in the two groups exhibited similar patterns with no prompt restoration, despite normalization of the portal pressure after LDLT, and showed quite slow improvement (Figure 2C).

K_{ICG} before LDLT and differences in temporal changes in K_{ICG} after LDLT

Recipients in both groups showed large decreases in K_{ICG} before LDLT (Table 1). Although there were no significant differences in K_{ICG} between the groups before LDLT, K_{ICG} changed significantly after LDLT (Figure 3, Table 3). The K_{ICG} value is dualistic, since it reflects functional hepatocytes and splanchnic blood flow[9,38-40]. However, splanchnic blood flow is a major determinant of K_{ICG} in normal liver[9,41,42]. We have previously demonstrated that K_{ICG} accurately evaluates functional hepatocytes during the late postoperative period, and sharply reflects splanchnic circulation during the early postoperative period, since LDLT restores functional hepatocyte volume drastically and immediately[1]. Extraordinary decreases in K_{ICG} from the early postoperative period were observed in Group Ⅱ, in contrast to the findings for Group I. Therefore, in the present study we verified the detailed splanchnic circulatory parameters measured by Doppler ultrasound.

Splanchnic hemodynamics before LDLT and temporal differences in splanchnic circulatory parameters after LDLT

Cirrhotic splanchnic circulation is symbolized by decreased

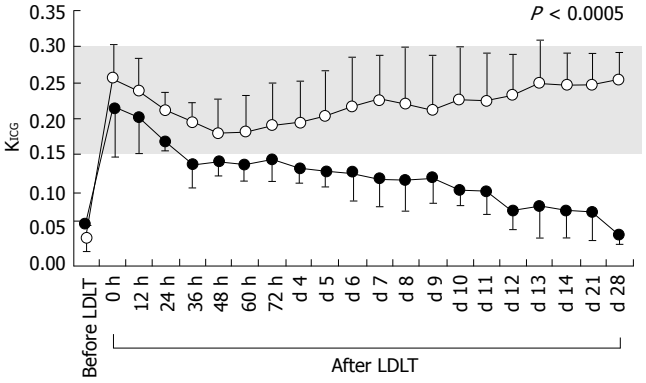

Figure 3 Temporal changes in K_{ICG} before and after LDLT. Open and closed circles represent K_{ICG} values for Groups Ⅰ and Ⅱ, respectively. The shaded area shows the normal range measured in healthy individuals.

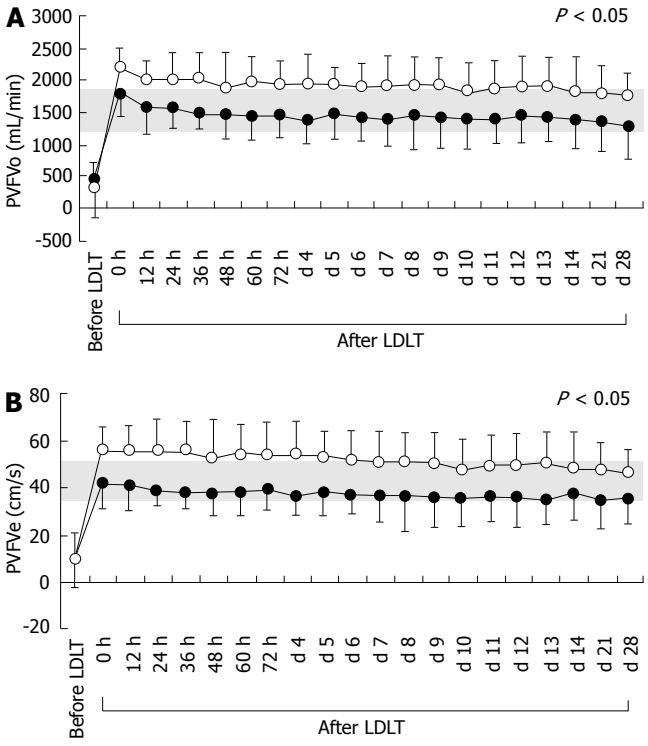

Figure 4 Temporal changes in splanchnic circulatory parameters before and after LDLT. **A:** Temporal changes in PVFVo before and after LDLT; **B**: Temporal changes in PVFVe before and after LDLT. portal venous flow because of portal hypertension, despite a systemic hyperdynamic state. Although all splanchnic circulatory parameters in both groups before LDLT differed significantly from those in healthy individuals, there were no significant differences between the two groups (Table 1). However, after LDLT, there were significant temporal differences in PVFVo and PVFVe, but no significant differences in HAPI and HARI, between the two groups (Table 3). The actual temporal changes in PVFVo and PVFVe are shown in Figure 4. Interestingly, differences in portal venous parameters, but not hepatic arterial parameters, were observed.

DISCUSSION

Almost all adult recipients who undergo LDLT develop liver cirrhosis with long-term portal hypertension. Portal hypertension results in vascular dilatation and collateral pathways. Thus, various alterations in systemic hemodynamics and splanchnic circulation occur, and adult recipients often present characteristic hemodynamics before LDLT. Cirrhotic hemodynamic abnormalities were obviously present before LDLT in the present study.

Several investigators have demonstrated that the systemic hyperdynamic state remains despite normalization of liver function and restoration of portal pressure after LDLT[19,33,36,43-45], and have suggested that most systemic parameters are slowly restored to the normal range after LDLT[19,36]. In agreement with these suggestions, our results demonstrated that vascular alterations do not disappear within 4 wk after LDLT, regardless of the outcome. Thus, we have suggested that optimal persistence of a systemic hyperdynamic state after LDLT is necessary for successful outcomes in recipients with cirrhosis (unpublished data).

A cirrhotic systemic hyperdynamic state is symbolized by expanded BV, high CO and low TPR[3,9,32], and the preload focuses on the balance between CO and BV[46,47]. Thus, we suggest that the balance of CO to BV is an accurate estimator of the optimal stability of the characteristic systemic hyperdynamic state (unpublished data). On the other hand, to determine the systemic hemodynamic parameters related to liver transplantation, the MTT is a rigorous indicator of kinetic behavior circuits[1,9]. MTT values precisely reflect systemic hemodynamics, which are especially influenced by preload factors. That is, a greater CO is proportional to a shorter MTT, and a large BV is proportional to a prolonged MTT. Accordingly, CO/BV and MTT represent mirror images. The results presented here showed significant temporal differences between the two groups in these precise systemic hemodynamic parameters. Thus, we suggest that the recipients in Group Ⅱ showed subtle disorders of the systemic hyperdynamic state after LDLT, in contrast to the recipients in Group Ⅰ.

Other studies have focused on systemic hemodynamics or splanchnic circulation after LDLT, and some investigators have demonstrated that systemic hemodynamics are well correlated with the splanchnic circulation[41,44,48]. Interestingly, the results for the splanchnic circulatory parameters in the current study reveal that subtle disorders of the optimal systemic hyperdynamic state easily influence portal venous flow, rather than hepatic arterial flow. Vascular alterations because of portal hypertension develop in vessels that originally flow into the portal vein under normal portal pressure, and represent one of the causes of a large BV. Hence, we suggest that the imbalance between the greater CO and larger BV after LDLT in Group Ⅱ caused stagnation of the tributary blood flow in the dilated vein and collateral pathways, which resulted in a decrease in portal venous flow. It was also of interest that recipients with cirrhosis with good

outcomes (i.e., Group I) showed a clear tendency toward postoperative portal venous overflow compared with that in healthy individuals. We have previously demonstrated that the persistence of a systemic hyperdynamic state is indispensable for recipients with cirrhosis after LDLT (unpublished data), and therefore consider that excessive portal flow after LDLT seems to be correlated with a postoperative systemic hyperdynamic state. Since portal venous flow has been shown to have a large influence on liver regeneration after LDLT[49], we conclude that successful clinical outcomes in cirrhotic LDLT recipients can be attributed to optimal stability of the systemic hyperdynamic state, which yields sufficient portal venous flow. Based on our results for Group I as compared with Group Ⅱ, we suggest that continuous sufficient portal venous flow, with even a slight surplus, supported by the optimal systemic hyperdynamic state, is necessary for good outcomes after LDLT in recipients with cirrhosis. Since reversible graft damage might begin slowly from the early postoperative period, we suggest that appropriate intensive clinical management of hemodynamics will greatly impact on further improvements in LDLT outcomes.

COMMENTS

Background

Prior to undergoing LDLT, recipients with cirrhosis generally develop peculiar systemic and splanchnic hemodynamics due to portal hypertension. To ascertain correlations between systemic hemodynamics and splanchnic circulation, we performed simultaneous assessment of systemic hemodynamics and directly measured splanchnic circulation by systemic dye distribution and ultrasound.

Research frontiers

We clarify how the systemic hemodynamic state impacts on the local graft circulation in recipients with cirrhosis who underwent LDLT. Vascular alterations due to portal hypertension develop in vessels that originally flow into the portal vein under normal portal pressure, and represent one of the causes of a large BV. Hence, we suggest that the imbalance between the greater CO and larger BV after LDLT caused stagnation of the tributary blood flow in the dilated veins and collateral pathways, which resulted in a decrease in portal venous flow.

Innovations and breakthroughs

We also identified the hemodynamic state required for an excellent clinical outcome after LDLT. Since portal venous flow has been shown to have a large influence on liver regeneration after LDLT, we suggest that successful clinical outcomes in LDLT recipients with cirrhosis can be attributed to optimal stability of the systemic hyperdynamic state, which yields sufficient portal venous flow.

Applications

The methods in this study (PDD and ultrasound) are advantageous for clinical applications because of their simplicity of bedside use, rapid real-time presentation of results, and cost-effectiveness. Hence, we suggest that appropriate intensive clinical management of hemodynamics based on real-time and reliable results measured by non-invasive methods will have a large impact on further improvements in LDLT outcomes.

Terminology

Splanchnic blood flow in this study refers to that in cirrhotic recipients after living-donor liver transplantation.

Peer review

This study builds on previous observations by the same group that hyperdynamic systemic circulation persists following transplantation in patients who previously had cirrhosis, and that this is important for sustaining portal venous flow. The current manuscript focuses on the changes with respect to splanchnic hemodynamics. The authors have demonstrated significant differences in portal venous flow dynamics between a group of 25 individuals that had a good clinical outcome post-transplantation compared with five that had a poor postoperative course. This article has sufficient originality regarding the understanding of post-liver transplant hemodynamics.

Abstract

AIM: To examine the expression of matrix metalloproteinase-1 (MMP-1) and tumor necrosis factor-α (TNF-α) in the colon mucosa of patients with ulcerative colitis (UC).

METHODS: Reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry were used to examine the expression of MMP-1 and TNF-α at both mRNA and protein levels in the colon mucosa of patients with UC. Correlation between MMP-1 and TNF-α and their correlation with the severity of the disease were also analyzed statistically.

RESULTS: The expression of MMP-1 and TNF-α in the ulcerated and inflamed colon mucosa of patients with UC was significantly higher than that in the non-inflamed mucosa of normal controls at both mRNA and protein levels. Furthermore, the expression of MMP-1 and TNF-α in the ulcerated area was significantly higher than that in the inflamed area of patients with UC (0.9797 ± 0.1433 *vs* 0.6746 ± 0.0373, 0.8669 ± 0.0746 *vs* 0.5227 ± 0.0435, $P < 0.05$). There was no statistically significant difference in the non-inflamed area of normal controls. There was a significant correlation between MMP-1 and TNF-α expression (0.9797 ± 0.1433 *vs* 0.8669 ± 0.0746, $P < 0.05$), the correlating factor was 0.877. MMP-1 and TNF-α showed a significant correlation with the severity of the disease (0.0915 ± 0.0044 *vs* 0.0749 ± 0.0032 , 0.0932 ± 0.0019 *vs* 0.0724 ± 0.0043, $P < 0.05$), their correlating factors were 0.942 and 0.890, respectively.

CONCLUSION: Excessively expressed MMP-1 directly damages the colon mucosa by degrading extracellular matrix (ECM) in patients with UC. While damaging colon mucosa, excessively expressed TNF-α stimulates MMPs secreting cells to produce more MMP-1 and aggravates the mucosa damage. MMP-1 promotes secretion of TNF-α in a positive feedback manner to cause further injury in the colon mucosa. MMP-1 and TNF-α correlate well with the severity of the disease, and therefore, can be used clinically as biological markers to judge the severity of UC.

INTRODUCTION

Ulcerative colitis (UC) is a chronic, non-specific inflammatory disease of the colon mucosa with an increasing morbidity due to life pattern changes in China. However, its etiology and pathogenesis are still unknown. Pathophysiologically, ulceration in the mucosal and submucosal areas of patients with UC is due to excessive degradation of extracellular matrix (ECM). In recent years, matrix metalloproteinases (MMPs) and some cytokines have been implicated in the development of a number of diseases, such as multiple sclerosis, rheumatic disease and UC[1-3]. In patients with UC, MMPs participate in tissue repair, vascularization and leucocyte chemotaxis in the ulcerated and inflamed colonic mucosa[3]. MMP-1 produced by cytokine-activated interstitial cells is one of the most important enzymes in degrading ECM[4]. Excessive expression of MMP-1 in the diseased colon mucosa of UC patients causes excessive hydrolysis of the ECM and ulceration[5,6]. It is also believed that imbalance between inflammatory and anti-inflammatory cytokines plays a central role in the development of UC[7]. For example, TNF-α, an important inflammatory cytokine produced by macrophages in the colon, takes part in the pathogenesis of UC[8] and can directly damage the colonic mucosal barrier, causing inflammatory changes in UC. Therefore, in this study we measured MMP-1 and TNF-α transcript and their proteins using reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemistry to explore

their possible role and interrelationship in the pathogenesis of UC.

MATERIALS AND METHODS

Patients and samples

Thirty-six patients with UC confirmed by clinical manifestations, colonoscopy and biopsy were enrolled in this study. Among these patients, 15 were males and 21 were females with their age ranged from 22 to 72 years and averaged 44 years. Samples were taken from the ulcerated, inflamed and non-inflamed areas of the colon mucosa during colonoscopy. There were 4 patients with pan-colon lesions, 3 with hemi-colon lesions, 19 with recto-sigmoid lesions, and 10 with rectal lesions. Based on the clinical manifestations and colonoscopic findings, 8 patients were classified into mild type, 21 into moderate type, and 7 into severe type. Meanwhile, 20 normal subjects were chosen as normal controls, 12 of them were males and 8 were females with their age ranged from 22 to 56 years and averaged 34 years. Biopsy samples were immediately snap frozen in liquid nitrogen and stored at -80℃ for RT-PCR. Biopsy samples were fixed in formalin, embedded in paraffin and cut into 4 μm-thick sections for immunohistochemistry.

Total RNA extraction

Total RNA was extracted from the frozen samples using a RNA isolation kit (Invitrogen Company) following the manufacturer's instructions. Five μL of the extracted RNA was run on 1% agarose gel electrophoresis to identify the extracted products.

RT-PCR for MMP-1 and TNF-α

RT-PCR was performed using the TaKaRa RNA PCR kit 3.0 (AMV) (supplied by Dalian Baosheng Biotechnology Company) following the manufacturer's instructions. Primer sequences used are as follows: MMP-1 (sense: 5'-ATGCGAACAAATCCCTTCTACC-3', antisense: 5'-TTCCTCAGAAAGAGCAGCATCG-3'), TNF-α: (sense: 5'-CTGTAGCCCATGTTGTAGC-3', antisense: 5'-CAATGATCCCAAAGTAGACCT-3'). Primers for β-actin were used as the internal control (sense: 5'-CCTTCCTGGGCATGGAGTCCTG-3', antisense: 5'-GGAGCAATGATCTTGATCTTC-3'). Reverse transcription was carried out at 30℃ for 10 min, at 42℃ for 30 min, at 99℃ for 5 min, and at 5℃ for 5 min. PCR was performed as follows: initial denaturation at 94℃ for 2 min, followed by 35 amplification cycles at 94℃ for 30 s, at 53℃ for 30 s, at 72℃ for 1 min, extension at 72℃ for 10 min. Five μL of PCR products was run on 2% agarose gel electrophoresis.

Immunohistochemistry

Sample sections were washed 3 times with PBS, 3 min each time after initial treatment. Primary antibodies, mouse anti-human MMP-1 monoclonal antibody and rabbit anti-human TNF-α polyclonal antibody (Beijing Zhongshan Biology Company) were added and incubated at room temperature for 1.5 h, washed again and incubated with peroxidase-conjugated secondary antibody for 15 min and washed again. A brown product was developed in diaminobenzidine (DAB) for 10 min.

Result determination and statistical analysis

A bio-imaging system (PALL Company, USA) was employed to analyze the density of the bands of PCR products. MMP-1 mRNA and TNF-α mRNA were semi-quantitatively expressed by the ratios between MMP-1, TNF-α and β-actin OD values. All values were expressed as mean ± SD.

Results of immunohistochemistry were considered positive when brown particles appeared in the cells after DAB staining. An image-pro-plus 4.5 microscopic image analyzing system was used to measure the density of the positive products. Five fields in each section were randomly selected to measure the total density and area. The mean density was determined by calculating the ratio between the total density and area in each section. A bigger ratio value indicates a greater expression of the corresponding proteins.

Student-Neuman-Keuls test was used to compare MMP-1 and TNF-α: mRNAs and their corresponding proteins in different colon samples and in different severity of the disease. Spearman correlation analysis was used to study the relationship between MMP-1, TNF-α and severity of the disease. $P < 0.05$ was considered statistically significant. All statistical analyses were performed using SPSS 11.5 for windows.

RESULTS

Expression of MMP-1 and TNF-α mRNA in different colon areas of UC patients

The expression of MMP-1 and TNF-α mRNA in the ulcerated area of colon was significantly higher than that in the inflamed colon area of patients with UC and non-inflamed colon area of normal controls ($P < 0.05$). The expression of MMP-1 and TNF-α mRNA in the inflamed colon area of patients with UC was also significantly higher than that in the non-inflamed colon area of normal controls ($P < 0.05$), but the extent was not as high as that in the ulcerated area. There was no statistically significant difference in non-inflamed colon area of normal controls (Table 1, Figures 1 and 2).

Expression of MMP-1 and TNF-α mRNA in patients with different severity of UC

The expression of MMP-1 mRNA was significantly higher in different groups of patients than in normal controls ($P < 0.05$). Comparison among the three groups showed that the highest expression of MMP-1 and TNF-α mRNA was seen in the group of patients with severe UC followed by in groups of patients with mild and moderate UC (Table 2).

Correlation MMP-1 and TNF-α mRNA expression

Correlation studies showed that the expression of MMP-1 mRNA was significantly correlated with that of TNF-α mRNA. The correlating factor was 0.877 ($P < 0.01$).

Table 1 Expression of MMP-1 and TNF-α mRNA in samples from different areas of colon of UC patients (mean ± SD)

Samples	MMP-1 mRNA	TNF-α mRNA	*P* value
Ulcerated area	0.9797 ± 0.1433	0.8669 ± 0.0746	< 0.05[a,c,e]
Inflamed area	0.6746 ± 0.0373	0.5227 ± 0.0435	< 0.05[a,c]
Non-inflamed area	0.0071 ± 0.0025	0.0302 ± 0.0299	> 0.05
Normal controls	0.0062 ± 0.0029	0.0280 ± 0.0060	

[a]*P* < 0.05 *vs* non-inlamed area; [c]*P* < 0.05 *vs* normal controls; [e]*P* < 0.05 *vs* inflamed area.

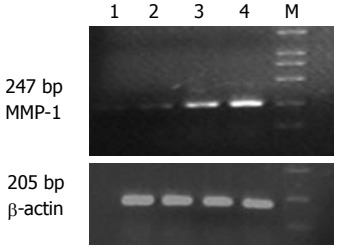

Figure 1 MMP-1 mRNA RT-PCR. Lane 1: Normal controls; lane 2: Non-inflamed area; lane 3: Inflamed area; lane 4: Ulcerated area; lane M: Marker.

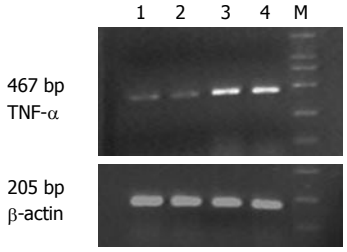

Figure 2 TNF-α mRNA RT-PCR. Lane 1: Normal controls; lane 2: Non-inflamed area; lane 3: Inflamed area; lane 4: Ulcerated area; lane M: Marker..

The expression of MMP-1 and TNF-α mRNA was also significantly correlated with the severity of the disease. The correlating factor was 0.942 and 0.890, respectively ($P < 0.01$).

Results of immunohistochemistry

Immunohistochemistry showed that the expression of MMP-1 and TNF-α in different areas of colon was identical. The expression of MMP-1 and TNF-α in the ulcerated area was significantly higher than that in the inflamed colon area of UC patients and non-inflamed colon area of normal controls ($P < 0.05$). The expression of MMP-1 and TNF-α in the inflamed colon area of UC patients was also significantly higher than that in the non-inflamed colon area of normal controls ($P < 0.05$), but it was not as high as that in the ulcerated area. There was no statistically significant difference in the non-inflamed colon area of normal controls (Figure 3A-D and Figure 4A-D, Table 3).

Protein analysis showed that the expression of MMP-1 and TNF-α in patients with different severity of the disease was identical The expression of MMP-1 and TNF-α was significantly higher in different groups than that in normal controls ($P < 0.05$). Comparison among the three groups showed that the highest expression of MMP-1 and TNF-α was seen in the group of patients with severe UC followed by in groups with mild and moderate UC (Table 4).

Table 2 Expression of MMP-1 mRNA in samples from patients with different severity of UC (mean ± SD)

Samples	MMP-1 mRNA	TNF-α mRNA	*P* value
Ulcerated area	0.9797 ± 0.1433	0.8669 ± 0.0746	< 0.05[ace]
Inflamed area	0.6746 ± 0.0373	0.5227 ± 0.0435	< 0.05[ac]
Non-inflamed area	0.0071 ± 0.0025	0.0302 ± 0.0299	< 0.05
Normal controls	0.0062 ± 0.0029	0.0280 ± 0.0060	

[a]*P* < 0.05 *vs* moderate type; [c]*P* < 0.05 *vs* severe type; [e]*P* < 0.05 *vs* normal controls.

Table 3 Expression of MMP-1 and TNF-α proteins in samples from different areas of colon of UC patients (mean ± SD)

Samples	MMP-1	TNF-α	*P* value
Ulcerated area	0.0891 ± 0.0062	0.0903 ± 0.0054	< 0.05[a,c,e]
Inflamed area	0.0791 ± 0.0047	0.0832 ± 0.0028	< 0.05[a,c]
Non-inflamed area	0.0047 ± 0.0040	0.0036 ± 0.0013	> 0.05
Normal controls	0.0048 ± 0.0016	0.0029 ± 0.0021	

[a]*P* < 0.05 *vs* non-inlamed area; [c]*P* < 0.05 *vs* normal controls; [e]*P* < 0.05 *vs* inflamed area.

Table 4 Expression of MMP-1 and TNF-α protein in samples from UC patients with different severity of the disease (mean ± SD)

Samples	MMP-1	TNF-α	*P* value
Mild type	0.0749 ± 0.0032	0.0724 ± 0.0043	< 0.05[a,c,e]
Moderate type	0.0812 ± 0.0030	0.0840 ± 0.0036	< 0.05[a,e]
Severe type	0.0915 ± 0.0044	0.0932 ± 0.0019	< 0.05[e]

[a]*P* < 0.05 *vs* moderate type; [c]*P* < 0.05 *vs* severe type; [e]*P* < 0.05 *vs* normal controls.

DISCUSSION

Ulcerative colitis (UC) is a chronic, non-specific inflammatory disease with ulceration in the mucosal and submucosal areas of colon. Excessive degradation and insufficient synthesis of extracellular matrix (ECM) are the main pathophysiological events occurring in the process of ulceration. Since matrix metalloproteinases (MMPs) are the major hydrolytic enzymes that degrade ECM, the increased activity of MMPs is responsible for tissue damage of the colon in UC patients. It has been well accepted that inflammatory cytokines including TNF-α participate in the pathogenesis of UC[7]. The relationship between MMPs and inflammatory cytokines remains to be studied when both of them take part in the pathogenesis of UC.

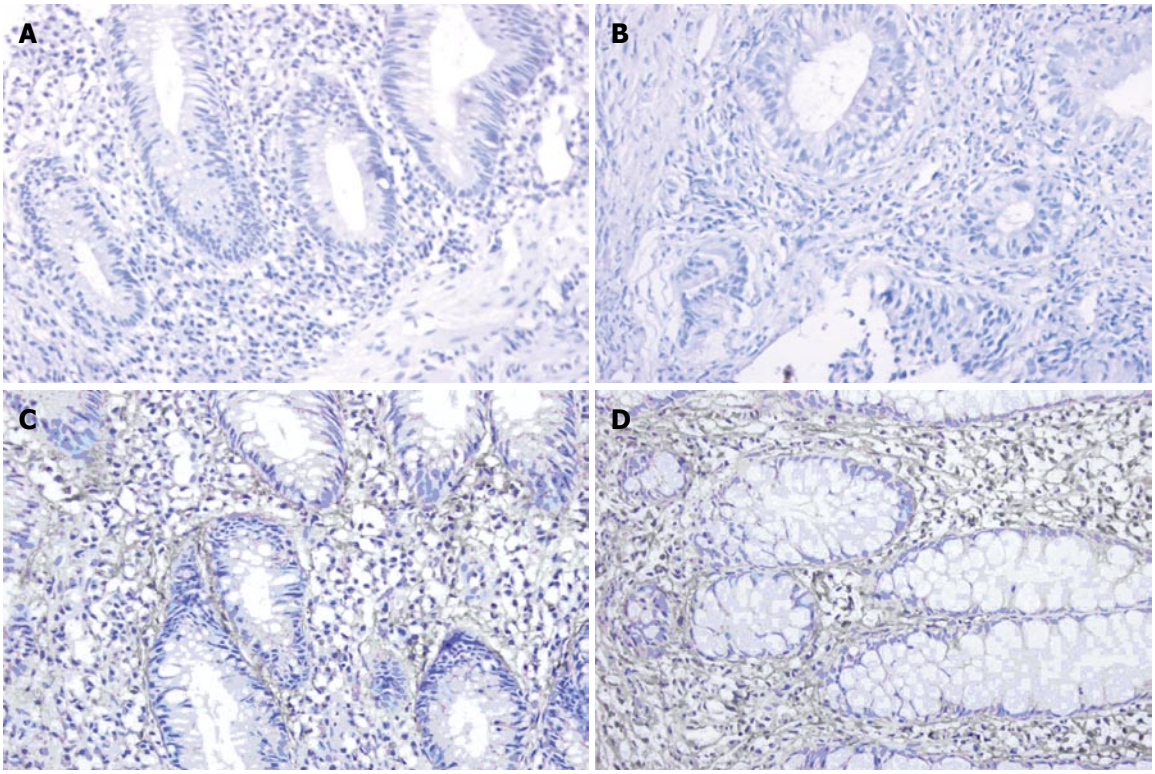

Figure 3 Expression of MMP-1 in normal controls (**A**), in non-inflamed area (**B**), in inflamed area (**C**), and in ulcerated area (**D**).

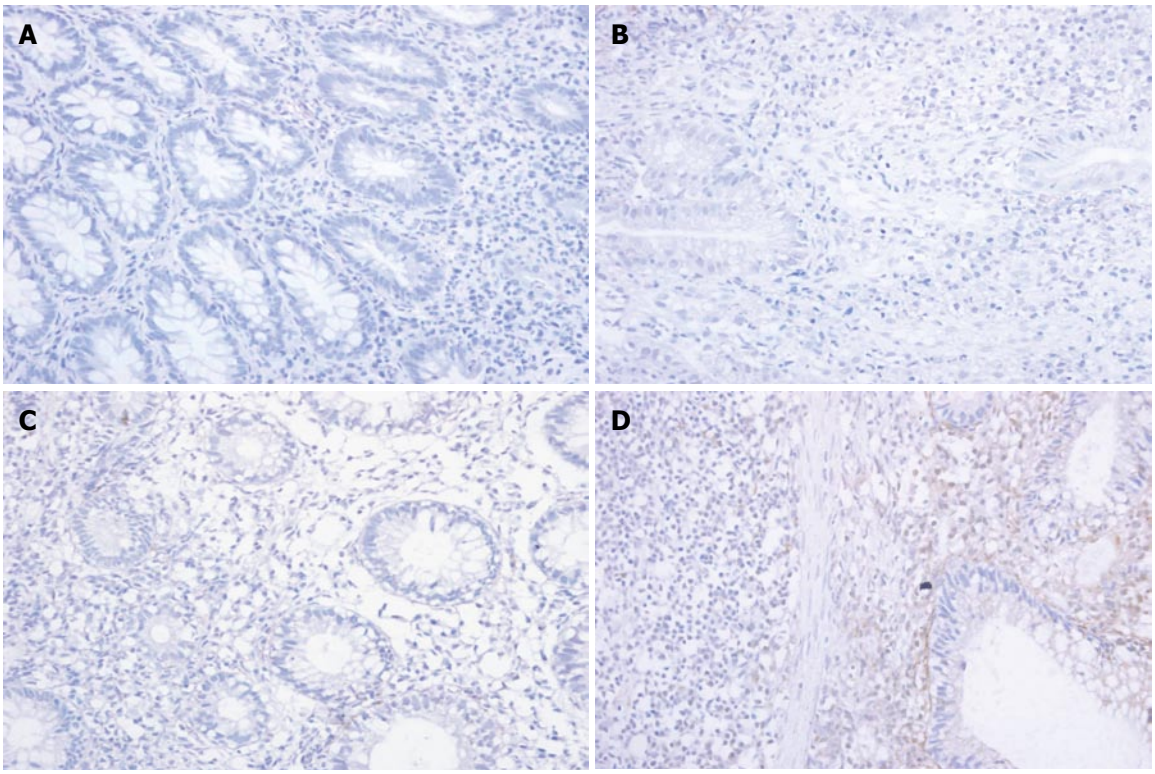

Figure 4 Expression of TNF-α in normal controls (**A**), in non-inflamed area (**B**), in inflamed area (**C**), and in ulcerated area (**D**).

MMPs are a group of zinc-dependent peptidases that degrade ECM. MMP-1, also known as interstitial collagenase, degrades mainly collagen types Ⅰ, Ⅱ, Ⅲ, Ⅵ, Ⅸ and proteoglycan, and plays an important role in degrading ECM in UC patients. Using RT-PCR and immunohistochemistry, we found that at both transcription and protein levels, the expression of MMP-1 in ulcerated and inflamed colon area of patients with UC

was significantly higher than that in non-inflamed colon area of normal controls. Furthermore, the expression of MMP-1 in ulcerated area was significantly higher than that in the inflamed area. In the present study, MMP-1 expression was closely correlated with the severity of the disease (correlating factor was 0.942, $P < 0.05$), indicating that MMP-1 is closely related to colon mucosa damage in UC patients[9,10]. Immunohistochemistry showed that MMP-1 was expressed mainly in the cytoplasm of mono-macrophages, which is consistent with the results reported by Von Lampec *et al*[11]. McKaig *et al*[12] also found that MMP-1 is expressed in damaged tissue vascular smooth muscle cells, indicating that MMP-1 may be related with formation of new blood vessels.

Our results showed that at transcription and protein levels, the expression of TNF-α in the ulcerated and inflamed area of UC patients was significantly higher than that in the non-inflamed area of normal controls. The expression of TNF-α was closely correlated with the severity of the disease (correlating factor was 0.890, $P < 0.05$), indicating that the more severe the disease, the higher the TNF-α expression. Immunohistochemistry revealed that the TNF-α positively stained cells were mainly mono-macrophages. Ishiguro[13] also reported that TNF-α expression in the diseased mucosa of colon in UC patients is significantly higher than that in the unaffected area of normal controls, suggesting that lipopolysaccharide produced by the intestinal flora may directly activate macrophages in the lamina propria, proliferating and producing a series of cytokines including TNF-α which damage the mucosa barrier of colon and produce typical inflammatory changes in UC. Apart from inflammatory cytokines, anti-inflammatory cytokines such as IL-10 also take part in the pathogenesis of UC. Gasche *et al*[14] reported that the expression of IL-10 mRNA is significantly decreased while Niessner *et al*[15] found that IL-10 mRNA is highly expressed in active UC, indicating that the expression of IL-10 mRNA is different in UC patients. Using in situ hybridization and immunohistochemical methods, Autschbach *et al*[16] showed that the number of IL-10 secreting monocytes and the mucosal expression of IL-10 are both significantly increased, but the expression of IL-10 in lanmina propria is relatively low, suggesting that IL-10 cannot effectively inhibit inflammatory cytokines such as TNF-α in lamina propria.

In the present study, MMP-1 was found to be closely correlated with TNF-α, indicating that there is a certain relationship between MMPs and cytokines. There is evidence that multiple cytokines may influence the expression of MMPs during inflammatory responses. Previous studies indicate that IL-1β and TNF-α are potent stimulators of MMP-1 and MMP-3[17,18]. They can regulate the secretion of MMP-1 and MMP-3 produced by mono-macrophages. Sylvia *et al*[19] found that the activity of T cells is correlated with the extent of colon mucosa damage, and that the colon mucosa injury is mediated by endogenously produced MMPs. Some authors believe that anti-inflammatory cytokines, such as IL-4 and IL-10, are able to inhibit the secretion of MMPs by monocytes[20-22]. Qiu *et al*[23] found that MMP-2 and MMP-9 combine with CD44 receptors on the cell membrane to form MMP-1/19-CD44 complex, making the inactivated TGF-β become its active form through hydrolysis and carry out its biological functions. Black *et al*[24] reported that MMPs activate TNF-α on cell membrane through hydrolysis to make it in an active state. MMPs may also block some cytokines, such as IL-6 and TGF-α to down-regulate their activities[25]. It is believed that MMPs not only appear in the down stream of inflammatory responses but also exert a positive feedback effect on cytokines. Therefore, they can be regarded as important "regulators" of inflammatory responses.

MMPs and cytokines play an important role in the process of UC. When infection, diet or other environmental factors act on hereditarily susceptible individuals, abnormal immune responses of the intestine may activate immune cells (such as T cells, lymphocytes and macrophages) to secrete a big amount of cytokines, inflammatory mediators and complements. These substances directly damage the colon mucosa, and induce interstitial cells (including smooth muscle cells, fibroblasts and mono-macrophages) to secrete MMPs. The increased MMPs degrade ECM in the colon mucosa, leading to mucosa damage and ulceration. While cytokines influence MMPs expression, and MMPs themselves are able to up-regulate cytokines through certain ways to cause further damage on the colon mucosa, MMPs can be inhibited by their inhibitors (MMPI) including their natural ones[26], revealing that MMPs have become one of the targets in anti-inflammatory treatment. MMPs inhibitors used in treatment of malignant tumors in clinical phase Ⅲ trial[27] in America and Europe can also be used in the treatment of patients with UC[7], while anti-inflammatory or inflammatory cytokine inhibitors can be used to reduce MMPs expression so as to indirectly reduce tissue damage and ulceration in UC patients. For example, a TNF-α antagonist, Infliximab, has been proved effective against adult and children UC patients[28,29].

In conclusion, excessively expressed MMP-1 directly damages the colon mucosa by degrading ECM in UC patients. While damaging colon mucosa, excessively expressed TNF-α stimulates MMPs secreting cells to produce more MMP-1 and aggravates the mucosa damage. MMP-1 promotes secretion of TNF-α in a positive feedback manner to cause further injury in the mucosa of colon. MMP-1 and TNF-α can be used clinically as biological markers to judge the severity of UC.

COMMENTS

Background

Matrix metalloproteinases (MMPs), their tissue inhibitors (TIMPs) and inflammatory cytokines, e.g., tumor necrosis factor-α (TNF-α) participate in the development of ulcerative colitis (UC) which is a chronic, non-specific inflammatory disease of the colon mucosa with unknown etiology and pathogenesis. This study was to deal with the expression of MMP-1 and TNF-α transcript and their proteins in colonic mucosa of patients with UC and their interrelationships in the pathogenesis of UC.

Research frontiers

Participation and functions of MMPs, TIMPs and inflammatory cytokines in the

pathogenesis of UC have been extensively studied in recent years. Study in this field has become one of the hotspots at present. Previous studies have demonstrated that MMPs and some inflammatory cytokines, such as TNF-α, are responsible for the development of ulceration and inflammation in the colonic mucosa of UC patients. Based on these findings, treatment targeting these proteins, such as anti-TNF-α antibody and exogenous MMPs inhibitors has been designed and studied in animal models. Preliminary results of these studies have shown beneficial and promising effects. Further experimental and clinical studies are needed before certain conclusions can be reached.

Innovations and breakthroughs

The association between MMPs and inflammatory cytokines with UC has been studied previously. However, most of the studies focused on their functions on the development of UC. The relationship between MMPs and other cytokines and the activity of UC remains largely unexplored. This study has bridged this gap and may provide additional targets for therapeutic development.

Applications

Since some basic evidence provided for MMP-1, TNF-α and their relationships in the development of UC, therapeutic approaches targeting MMPs or TNF-α, can be implemented in future study and new methods for treating UC may be developed.

Terminology

Matrix metalloproteinases (MMPs): MMPs are a group of zinc-dependent peptidases that degrade extracellular matrix (ECM). In this family, more than 20 MMPs have been identified. MMP-1, also known as interstitial collagenase, degrades mainly collagen type Ⅰ, Ⅱ, Ⅲ, Ⅵ, Ⅸ, and proteoglycan, and plays an important role in degrading ECM and in leading to colonic mucosa damages in UC patients.

Peer review

This is an informative study demonstrating the association between metalloproteinase (MMP) and tumor necrosis factor (TNF) with disease activity in individuals with ulcerative colitis. The association of TNF with UC is well known but the relationship of other cytokines with disease activity remains largely unexplored. This study is an attempt to bridge this gap and may provide additional targets for therapeutic development. The preliminary conclusion is justified and substantiated by the results obtained.

Abstract

AIM: To combine the benefits of a new thin flexible scope with elimination of excessive looping through the use of an overtube.

METHODS: Three separate retrospective series. Series 1: 25 consecutive male patients undergoing unsedated colonoscopy using the new device at a Veteran's hospital in the United States. Series 2: 75 male patients undergoing routine colonoscopy using an adult colonoscope, pediatric colonoscope, or the new device. Series 3: 35 patients who had incomplete colonoscopies using standard instruments.

RESULTS: Complete colonoscopy was achieved in all 25 patients in the unsedated series with a median cecal intubation time of 6 min and a median maximal pain score of 3 on a 0-10 scale. In the 75 routine cases, there was significantly less pain with the thin scope compared to standard adult and pediatric colonoscopes. Of the 35 patients in the previously incomplete colonoscopy series, 33 were completed with the new system.

CONCLUSION: Small caliber overtube-assisted colonoscopy is less painful than colonoscopy with standard adult and pediatric colonoscopes. Male patients could undergo unsedated colonoscopy with the new system with relatively little pain. The new device is also useful for most patients in whom colonoscopy cannot be completed with standard instruments.

Key words: Colonoscopy; Endoscopy; Colon Cancer; Colon cancer screening

INTRODUCTION

Colonoscopy is typically performed using relatively large-diameter (11-13 mm) pediatric and adult instruments with enough rigidity to permit advancement of the instrument despite multiple turns within the bowel[1-3]. With these instruments, looping of the endoscope is a common difficulty that results in pain for the patient and hinders advancement of the endoscope[4,5]. In an effort to overcome looping, which is particularly common in the sigmoid colon, some practitioners have used stiffening overtubes that are preloaded on the back end of the scope and advanced over the colonoscope after negotiation of the sigmoid colon[6-8]. With the tube in place, further advancement of the instrument can be attained with minimal looping in the sigmoid; the overtube facilitates transmission of force from the endoscopist's pushing hand to the proximal end of the overtube. However, the overtubes employed for colonoscopy in the past have been relatively bulky and rigid devices that accommodate the large diameter of standard colonoscopes.

It is sometimes possible to perform colonoscopy using relatively thin and flexible upper endoscopes[9]. Thinner, more flexible scopes are often more easily advanced through the left colon[10]; this is perhaps the major reason why many endoscopists prefer pediatric colonoscopes over standard adult colonoscopes in female patients and in patients with sigmoid adhesions[2]. However, even pediatric colonoscopes are often associated with more difficulty in advancement through the proximal colon due to excessive looping[2]. These observations suggest that a very thin and flexible scope might facilitate insertion through the distal colon, but a mechanism to prevent excessive looping is important for optimal advancement through the proximal colon. One alternative to conventional colonoscopy that employs this strategy is to perform the procedure using a double balloon enteroscope[11-13]. The double balloon system also employs a very thin scope and an overtube, with the addition of balloons on the scope tip and overtube tip that can be inflated to secure the position by pressing against the bowel wall[14-16]. The double balloon system is used increasingly in patients who have failed conventional colonoscopy, but a major limitation is that the procedure is laborious and time consuming[17-19]. We surmised that by using a standard 160 cm length of scope, rather than the 200 cm long double balloon enteroscope, and a short 60 cm overtube, rather than a 140 cm long double balloon overtube, the procedure would be more efficient.

MATERIALS AND METHODS

The new colonoscopy system consists of a thin 9 mm scope, 170 cm in length, together with a 13 mm diameter 60 cm long overtube. The new 9 mm endoscope has the same outer diameter and instrument channel diameter (2.8 mm) as diagnostic upper endoscopes, but a 170 cm length that is similar to that of standard colonoscopes. The new scope has already received regulatory approval by the U.S. Food and Drug Administration for routine clinical use. The endoscope was provided by the Olympus corporation (Olympus America, Melville, New York, USA). The overtube (TS-13140, Fujinon Corporation, Wayne, New Jersey, USA) has a proprietary coating that reduces friction with the scope when the system is exposed to water; it is available commercially and is widely used in double balloon endoscopy. Because the overtube was too long, we cut off the proximal (near the hub) 100 cm and moved the plastic handle from its original position to the proximal end of the shortened tube (Figure 1). We also removed the inflatable latex balloon at the tip of the overtube because our earlier experience suggested that it is not generally helpful. Prior to each procedure, the overtube was temporarily filled with water to activate the lubrication system inherent in the tube and then back-loaded to the hub of the endoscope, leaving the distal 110 cm of the endoscope free for performing the initial portion of the examination without the overtube in place. After reaching the transverse colon, the scope was reduced, and the overtube was advanced over the scope until the handle on its proximal end was near the buttocks. An assistant then held the handle on the end of the overtube and the scope was advanced to the cecum.

This study consists of 3 retrospective series of patients undergoing colonoscopy at the Veterans Affairs Palo Alto Health Care System. Informed consent was obtained from all patients. The study was approved by the institutional review board of our hospital. All of the procedures were done by a single endoscopist with 8 years of experience performing approximately 1000 colonoscopies per year. The first series consisted of 25 consecutive male patients who were scheduled for unsedated colonoscopy (no medications given for the procedure); the patients were scheduled for unsedated procedures because of patient preference, medical contraindications to sedation, or lack of a driver to take them home after the procedure. The second series consisted of 75 consecutive male patients undergoing routine colonoscopy (3 female patients, 3 patients with previous partial colectomy and 1 patient with inflammatory bowel disease who necessitated a high-resolution magnification scope were not included in the series). An adult (Olympus CF-Q160AL), pediatric (Olympus PCF-Q180AL) and the thin scope/overtube were used in alternating cases. Patients were pre-medicated with lorazepam 2 mg sublingually (1 mg for patients over age 80) 15 min before the procedure. Patients were instructed by the nursing staff to request additional medication if they experienced pain or discomfort. Intravenous fentanyl was administered if the patient requested further sedation. The third series consisted of 35 patients who had incomplete colonoscopies in our endoscopy unit (the cecum was not reached) using any combination of standard adult (Olympus CF-Q160AL) and/or pediatric (Olympus PCF-160AL or PCF-Q180AL) endoscopes. The incomplete colonoscopies were performed by one of eight experienced attending endoscopists who work in our department.

Figure 1 The new 9 mm scope is shown alongside the 60 cm-long overtube.

Statistical analysis

Statistical comparison calculations were performed with two-tailed unequal-variance student's *t*-test[20]. Odds ratios and confidence intervals were calculated with the Newscombe-Wilson method without continuity correction[21].

RESULTS

In the first series, unsedated colonoscopy was successful in 25 consecutive patients at the Veterans Affairs Palo Alto Health Care System using the new device. None of the patients received any medication for the procedure. The indication for colonoscopy was a previous history of adenoma in 14 patients, positive stool occult blood in 3, screening in 2, family history of colon cancer in 2, hematochezia in 2, anemia in 1 and constipation in 1. Patients underwent unsedated colonoscopy for one of three reasons: patient preference (10 patients), inordinately high sedation risk (6) or unavailability of a driver to take them home after receiving sedation (9). All of the patients were male veterans. The age of the patients ranged between 53 and 94, with an average age of 68.1 and a median of 70.

Cecal intubation was achieved in all 25 patients, in a median time of 6 (average 6.4, range 2.5-15) min. Patients rated their maximal pain level during the procedure on a 0-10 scale. The median maximal pain level was 3 (average 2.9, range 0-6.5). Six patients had a maximal pain of 4 or higher. The entire procedure lasted a median time of 13 (average 13.6, range 7-28) min, including at least one snare polypectomy in 8 patients and forceps biopsy in another 2 patients. Small (< 10 mm) areas of mild erythema from passage of the overtube were seen occasionally on withdrawal, but no mucosal disruptions or other signs of trauma were observed. There was one complication:

bleeding one week after endoscopic mucosal resection of a 1.5 cm flat adenoma. The patient underwent urgent colonoscopy with successful clipping of an actively bleeding vessel at the resection site. He did not require blood transfusion or hospitalization.

The second series consisted of 75 male patients undergoing routine screening or surveillance colonoscopy. A standard adult colonoscope, pediatric colonoscope, and the thin scope/overtube system were used alternatingly; 25 procedures were performed with each type of scope. The median age of the thin scope group was 70 ± 10, compared to 69 ± 9 in the adult scope group (P = NS). The median age of the pediatric scope group was 65 ± 8, which was significantly younger than the thin scope group (P = 0.03).

Following premedication with lorazepam, 24/25 procedures with the thin scope were completed without additional sedation medication, compared to 9/25 with the adult scope (odds ratio 43, $P < 0.005$) and 14/25 with the pediatric scope (odds ratio 19, $P < 0.01$). The mean dose of fentanyl (μg) used was 12 ± 60 with the thin scope, compared to 51 ± 53 with the adult scope ($P < 0.05$) and 39 ± 53 (P = NS) with the pediatric scope. The median maximal pain during the procedure on a 0-10 scale was 3.5 ± 2 in the thin scope group, compared to 8 ± 2 in the adult colonoscope group ($P < 0.001$), and 7.5 ± 2.5 in the pediatric colonoscope group ($P < 0.001$). The cecum was reached in all patients, but the adult colonoscope was exchanged for a smaller diameter scope in 2 patients due to acute angulation in the sigmoid, and the pediatric colonoscope was exchanged for another scope in 2 patients due to excessive looping. The median time in minutes to reach the cecum was 5.5 ± 2.5 in the thin scope group, compared to 6.0 ± 2.1 in the adult colonoscope group (P = NS), and 4.0 ± 1.9 min in the pediatric colonoscope group (P = 0.004).

In the third series, 35 patients who had previously undergone unsuccessful colonoscopy (with inability to reach the cecum) had the procedure repeated using the new device. The reasons given by the endoscopist for the inability to reach the cecum were: excessive looping (22 patients), acute sigmoid angulation (11 patients) and acute angulation at the splenic flexure (2 patients). 28 of the patients were male and 7 were female. The age ranged between 33 and 90, with a median age of 65 and a standard deviation of 13. The procedure was successful in 33; the cecum could not be reached in 2 male patients due to excessive looping and double balloon colonoscopy was successfully performed in both of these cases. The median time to reach the cecum in the 33 successful cases was 7 (standard deviation 3.9) min. The median total colonoscopy time, including snare polypectomies in 8 patients and forceps biopsies in 3 patients, was 15 (standard deviation 8.4) min. There were no complications.

DISCUSSION

Sedation practices for colonoscopy vary widely across the world; unsedated colonoscopy is commonly performed in Asia and Finland[2], whereas it is generally very poorly accepted in the United States[22-25]. A major reason is pain due to looping of the endoscope. Small caliber overtube-assisted colonoscopy can potentially decrease looping and pain enough to make unsedated colonoscopy feasible in the general population. The small caliber scope used in this study was easily and rapidly advanced through the distal colon with minimal pain. After reduction of the scope, the thin low-friction overtube was advanced into position without significant resistance. With the overtube in place, it was generally possible to directly advance the endoscope to the cecum with relatively little attention to subsequent loop formation or paradoxical backward motion of the tip upon insertion. Our study suggests that this colonoscopy system could potentially make colonoscopy without intravenous sedation feasible a significant number of patients. The thin scope/overtube system was significantly less painful than conventional adult or pediatric colonoscopes. The 25 patients who required unsedated colonoscopy for a variety of indications all had successful procedures, and only 6 had a maximal pain level of 4 or higher on a 10 point scale. In the second patient series, when routine colonoscopy was performed after premedication with sublingual lorazepam, only 1 of 25 patients in the thin scope/overtube group requested additional sedation, compared to 11 of the patients with the pediatric colonoscope and 16 with the adult colonoscope. This suggests that most male patients undergoing routine screening or surveillance colonoscopy do not require intravenous conscious sedation and would be satisfied with a mild sedative that can be administered by mouth without an intravenous line. This could potentially result in a substantial cost savings by eliminating the need for extensive monitoring of patients receiving conscious sedation, and potentially make colonoscopy feasible for many patients in an office setting.

The thin scope/overtube system offers several benefits compared to standard colonoscopes. The thin scope is generally easily advanced through the sigmoid colon, as demonstrated by the successful performance of colonoscopy in 11 patients in the third series in whom previous colonoscopy was unsuccessful due to acute sigmoid angulations. Once the scope has been advanced through the left colon and reduction of loops has been performed, the overtube is advanced into position and subsequent looping of the scope during advancement through the right colon should theoretically be minimized. We did not specifically measure looping in the procedures we performed, but in our experience once the overtube was in place the scope was easily advanced through the right colon with little effort or attention required to prevent or reduce loops. The median time required to reach the cecum was 6 min in the unsedated group and 5.5 min in the lorazepam premedication group. This suggests that despite the additional step of positioning the overtube, reaching the cecum with the system can still be in an acceptable period of time. The median overall procedure time was 13 and 13.5 min in the unsedated and lorazepam groups, including at least one snare polypectomy in approximately 1/3 of the patients, demonstrating that withdrawal and polypectomy can also be performed efficiently.

Of the 35 patients who had previously failed colonoscopy using standard instruments, 33 had a

successful procedure with the thin scope/overtube system. The median time to reach the cecum in those 33 patients was only 7 ± 3.9 min. Although these cases were subjectively more difficult than routine cases, the patients received conscious sedation, which may facilitate rapid advancement, resulting in a similar overall time to cecum as in unsedated routine cases. This compares very favorably to our prior published experience of using a double balloon enteroscope to successfully complete 19 of 20 patients with previously incomplete colonoscopies, where the median time to reach the cecum was 28 ± 20 min[26]. Based largely on this difference in time, our preference is currently to use the thin scope/overtube system in all cases after failed colonoscopy with standard instruments, and reserve the double balloon enteroscope for those situations when the thin scope/overtube system is unsuccessful.

There are clear limitations to the current study: the retrospective design, the relatively small number of patients in each of the series, the overwhelmingly male patient population, the previously documented tolerance of male American veterans to unsedated colonoscopy[2,27], and the single-center design. Since the study was retrospective, the routine screening colonoscopy patients were not randomized to the new scope or a standard adult or pediatric scope, but rather the scopes were alternated. There were no complications attributable to the thin scope/overtube system in our study (the lone complication in the 3 retrospective series was a post-polypectomy bleed in one of the unsedated patients), but all of the procedures were performed by one experienced endoscopist and it remains to be demonstrated that the system is safe when used by practitioners of varying experience. Given the substantial differences across different institutions and different countries in the performance of unsedated colonoscopy, it is difficult to predict what effect this system could have on colonoscopy practice, but our study does demonstrate the potential for making colonoscopy less painful and better tolerated without dramatically increasing procedure time or complexity.

There are several disadvantages to the small caliber endoscope and overtube system used in this study. The overtube is marketed for single-use and is expensive in its current form (approximately US$200 at our institution); shortening the tube is also cumbersome. It is conceivable that a more reasonably priced short tube could be manufactured or that a reusable version could be developed. The 9-mm scope has a relatively small 2.8-mm channel which is adequate for typical maneuvers such as snare polypectomy and clip placement, but can limit suctioning of stool residue and resected polyps. A water jet port for efficient lavage is not available. The field of view, lighting and optical resolution may be slightly compromised compared to the latest generation of high-resolution adult colonoscopes. However, the potential for reducing pain may outweigh any of these disadvantages. Further studies will also need to address whether some colonoscopies are more difficult with this system, whether there is any increase in the rate of missed lesions, and whether certain therapeutic cases would be better served by using a standard colonoscope. The ultimate goal of reducing pain during colonoscopy enough to make unsedated colonoscopy better tolerated, thereby eliminating both complications due to sedation as well as an estimated 40% of the cost of the procedure[2], is particularly important given the current widespread screening practices in many countries. Additional adjunctive measures, such as using carbon dioxide instead of air for insufflation[28,29], may also play a role in achieving this goal.

COMMENTS

Background

Colonoscopy using standard instruments is often relatively painful and most procedures are done using intravenous sedation. Reduction of pain is a major focus of research because the potential for eliminating conscious sedation may make the procedure safer and less expensive.

Research frontiers

The development of new types of scopes for performance of colonoscopy with less pain and less sedation is a major area of research. Thinner scopes can potentially cause less pain during colonoscopy, but they can also result in more loop formation which can hamper the procedure.

Innovations and breakthroughs

In this article we describe our experience using a new thin scope in combination with an overtube designed to minimize loop formation. We demonstrate that the new system is less painful than standard colonoscopes.

Applications

This study suggests that the combination of a thin scope and an overtube can be useful for unsedated, routine and difficult colonoscopies.

Terminology

Looping: the process where the scope tip does not progress forward when the endoscopist pushes the scope into the patient, but rather the mid-section of the scope bows out, resulting in stretching of the colon.

Peer review

This is an important and well written contribution. Through retrospective comparative study, the authors concluded that small caliber overtube-assisted colonoscopy is less painful than colonoscopy with standard adult and pediatric colonoscopes. Male patients can undergo unsedated colonoscopy with the system with relatively little pain. The new device is also useful for most patients in whom colonoscopy cannot be completed with standard instruments.

Abstract

AIM: To investigate the allelic and haplotypic association of *reg1α* gene with tropical calcific pancreatitis (TCP). Since TCP is known to have a variable genetic basis, we investigated the interaction between mutations in the susceptibility genes, *SPINK1* and *CTSB* with *reg1α* polymorphisms.

METHODS: We analyzed the polymorphisms in the *reg1α* gene by sequencing the gene including its promoter region in 195 TCP patients and 150 ethnically matched controls, compared their allele and haplotype frequencies, and their association with the pathogenesis and pancreaticolithiasis in TCP and fibro-calculous pancreatic diabetes.

RESULTS: We found 8 reported and 2 novel polymorphisms including an insertion-deletion polymorphism in the promoter region of *reg1α*. None of the 5′ UTR variants altered any known transcription factor binding sites, neither did any show a statistically significant association with TCP. No association with any *reg1α* variants was observed on dichotomization of patients based on their N34S *SPINK1* or L26V *CTSB* status.

CONCLUSION: Polymorphisms in *reg1α* gene, including the regulatory variants singly or in combination with the known mutations in *SPINK1* and/or *CTSB* genes, are not associated with tropical calcific pancreatitis.

Key words: Tropical calcific pancreatitis; Lithostathine; Stone formation; Polymorphism; Haplotype

INTRODUCTION

Chronic Pancreatitis (CP) is a continuing or relapsing inflammatory process of the pancreas resulting in exocrine and/or endocrine insufficiency. The cardinal manifestations of CP are pain, steatorrhoea, formation of pancreatic stones, and diabetes mellitus. Recently, mutations in cationic trypsinogen (*PRSS1*)[1], the serine protease inhibitor, Kazal type 1 (*SPINK1*)[2], and cystic fibrosis transmembrane regulator (*CFTR*)[3] genes have been found to be associated with chronic pancreatitis. Tropical calcific pancreatitis (TCP) is an idiopathic, juvenile, nonalcoholic form of chronic pancreatitis with a unique tropical distribution, while fibro-calculous pancreatic diabetes (FCPD) is a condition characterized by the development of diabetes secondary to TCP. A genetic etiology for TCP and FCPD was suggested by Pitchumoni *et al*[4] and confirmed by Mohan *el al*[5], who showed familial aggregation of FCPD with evidence of vertical transmission in some families. We previously reported evidence of its genetic nature, based on clustering of TCP in a few families and its association with SPINK1 mutations[6].

In a previous study we had shown that mutations in *PRSS1* did not play a role in TCP, whereas mutations in *SPINK1* gene were found in the majority of such patients[7]. Recently, we have demonstrated that mutations in pro-peptide region of cathepsin B (*CTSB*) gene are strongly associated with TCP[8]. Irrespective of mutations in different genes, premature intra-pancreatic activation of trypsinogen is believed to play a central role in the pathogenesis of chronic pancreatitis. However, the phenomenon of stone formation continues to be poorly understood. Although various hypotheses have been proposed for stone formation, the development of protein plugs appears to be an important initiating event[9]. It has been proposed that if concentration-dependent precipitation is the cause of protein plug formation, there should be an associated increase in the concentration of some proteins in the pancreatic juice[10].

Lithostathine C was initially isolated as a major

proteic component of pancreatic stones in alcoholic calcifying chronic pancreatitis, and was consequently called pancreatic stone proteic (PSP)[9]. Human PSP or Reg protein is encoded by *reg1α* gene (regenerating gene)[11] as a 166 amino acid pre-proprotein with a 22-residue long signal sequence. A similar protein with 89% homology with PSP is coded by another gene *reg1β* belonging to the same type 1 subclass but has never been isolated and its expression in pancreas remains controversial[12]. Only the Reg1α protein is highly represented in the human pancreatic secretions[13] and is found to be 100% identical to a glycoprotein that is generated by trypsin cleavage resulting in a 133 aa polypeptide previously named pancreatic thread protein (PTP). The mature protein is a soluble glycoprotein existing under 11 isoforms (17-22 kDa)[14], generated by post-translational modification such as glycosylation. Of these isoforms, S2-S5 are believed to inhibit calcite crystal growth *in vitro* and thus stone formation[15,16]. PSP is highly susceptible to trypsin cleavage at Arg11-Ile12 bond resulting in PTP formation, which is known to form fibrilla at neutral pH and is found in protein plugs or stones extracted from pancreatic ducts of CP patients[9,17]. The exact function of Reg1α protein is not clear, but it could stimulate the regeneration and/or growth of pancreatic β-cell[18]. We hypothesized that mutations in the promoter region of *reg1α* may lead to altered expression of the protein. Alternatively, variants in the coding region could predispose the Reg1 protein to increased tryptic cleavage resulting in greater formation of PTP. This may cause precipitation of PTP and obstruction of the pancreatic duct secondary to protein plugs and calculi, resulting in pancreatitis. Since high levels of intrapancreatic trypsin produced both by known mechanisms like *PRSS1* mutations or by as yet unknown mechanisms such as mutations in *SPINK1* and *CTSB* genes is an established fact, it can be speculated that intrapancreatic trypsin may cleave the soluble lithostathine (PSP S2-S5) into insoluble PTP. FCPD is a condition characterized by the development of diabetes secondary to TCP, however, the etiology of diabetes in these patients is not clear, hence we investigated the role of these polymorphisms in the pathogenesis of FCPD. Since, N34S *SPINK1* mutations occur in the majority of these patients and it is not clear whether pancreatitis is the cause or the effect of ductal obstruction, we attempted to investigate the interaction between N34S *SPINK1* mutation and L26V *CTSB* mutations and *reg1α* gene polymorphisms. We also performed haplotype analysis to see if a particular *reg1α* haplotype is associated with the disease.

MATERIALS AND METHODS

Patients and controls

195 unrelated subjects belonging to Australoid ethnicity[19] (134 males and 61 females), diagnosed with tropical calcific pancreatitis at the Asian Institute of Gastroenterology, Hyderabad and 150 age and sex matched individuals (98 males and 52 females) of the same ethnicity but without any evidence of pancreatitis on imaging studies were included as patients and controls respectively[7]. Both the patients and the controls completed a detailed questionnaire and underwent similar investigations including imaging studies. Written informed consent was obtained from all the patients and controls, before the collection of blood samples. The Institutional Ethics Committee of both participating institutes approved the study as per the guidelines of the Indian Council of Medical Research for research on human subjects.

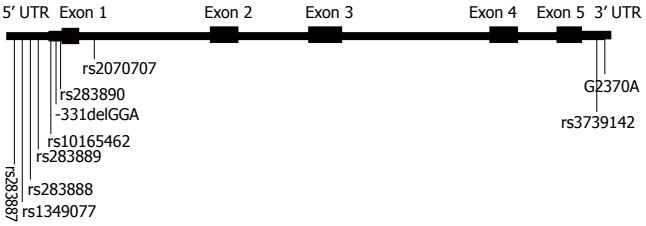

Figure 1 Diagrammatic representation of the *reg1α* gene showing exons (translated), UTRs (untranslated regions) and the location of the polymorphisms studied (constructed on the lines of *reg1α* gene structure as on UCSC genome browser, figure not to scale).

Genetic analysis

Genomic DNA was isolated from patients and healthy volunteers using salting out method[20]. The human *reg1α* gene is located on 2p12 with six exons (5 translated exons, Figure 1) spanning 2962 base pairs and is known to contain TATA and CCAAT box-like sequences that are located at 27 and 100 bp upstream from the transcriptional initiation site[21]. Using the software tool Transplorer (Biobase Biological Databases, Wolfenbuttel, Germany), we attempted to identify transcription factor binding sites in a sequence of about 1600 bases upstream of transcriptional start site, which included the above-mentioned sequence[22]. We screened the complete *reg1α* gene including its exons, introns and 5'- and 3'- untranslated regions by direct sequencing, using 4 sets of primers in 50 patients and 50 controls (Table 1). PCR products were purified and sequenced individually on both the strands using Big-dye terminator cycle sequencing ready kit (Applied Biosystems, Foster City, CA) on an ABI3730 Genetic Analyzer (Applied Biosystems). In case of unclear sequence data, we repeated sequencing under various conditions until the genotype was determined correctly. Six SNPs (Table 2) that

SNP: Single nucleotide polymorphism; n: Number of individuals; OR: Odds ratio; CI: Confidence interval; TCP: Tropical calcific pancreatitis; FCPD: Fibrocalculous pancreatic diabetes; [1]Only SNPs with > 3% minor allele frequency have been presented; The minor allele frequency at each polymorphism was compared between the three groups and *P* value with OR and 95% CI were calculated.

exceeded allele frequency of 3% were screened in another 145 patients and 100 controls from the same ethnic background. N34S and L26V mutations in the *SPINK1* and in *CTSB* genes respectively were analyzed using the methodology as described previously[7,8]. Ten percent of randomly chosen samples were re-genotyped for validation of the data, and no genotyping error was noted.

Statistical analysis

The allele and genotype frequencies were calculated for each polymorphism (Table 2) in the whole cohort as well as in TCP and FCPD patients separately (Table 3). We analyzed any deviation from the Hardy-Weinberg equilibrium, and observed the expected genotype frequencies by Markov simulation based goodness of fit test using Arlequin software version 2[23]. Pearson's Chi-square and Yates corrected chi-square test were used to analyze the statistical significance of the difference in allelic distribution of polymorphisms in patients and controls. Haplotypes were generated with 6 polymorphisms having a minimum allele frequency greater than 3% with the accelerated Expectation-maximization algorithm using Haploview software (Version 3.2) and compared the results between patients and controls[24]. This study was 90% powered to detect a relative risk of 1.60 (http://www.dssresearch.com/). Unless indicated specifically, a *P*-value of 0.05 was considered significant in all the analyses. Chi-square, genotype relative risk, odds ratio and confidence interval were calculated using the PEPI (Programme for EPIdemiologists, ver 4.04) and DeFenetti programs (http://www.ihg.gsf.de/cgi-bin/hw/hwa1/).

RESULTS

We initially sequenced complete *reg1α* gene in 50 patients and an equal number of controls and subsequently, additional patients and controls were screened for six SNPs with rare allele frequency of > 3%. Sequencing results revealed the presence of 8 reported SNPs, one novel SNP and one insertion-deletion polymorphism in the promoter region of the gene (Table 4). We did not observe any significant deviation from Hardy-Weinberg equilibrium ($P > 0.05$) for any of the polymorphisms. The polymorphisms in the promoter region were of prime interest, since the levels of *reg1α* expression differ considerably between the pancreas of patients and controls. Transplorer predicted 3 transcription factor-binding sites (C-Rel, -1513 to -1609; NFκB2, -1527 to -1614; and Hesx1, -15 to -105) within the region +10 to -1600 bp of the putative promoter region[21]. We sequenced the upstream region flanking the 5'-UTR (about 1176 bp upstream of translation start site) along with putative promoter region and found four reported SNPs, G-938A, T-912G, T-385C, T-243G which were equally frequent in patients and controls. A novel insertion-deletion polymorphism at -331 position (-331 to -329) involving

SNP: Single nucleotide polymorphism; n: Number of individuals; OR: Odds ratio; CI: Confidence interval; [1]Minor allele frequency based on N34S *SPINK1* status; [2]Allele frequency based on L26V *CTSB* status.

deletion of GGA (-331delGGA) in the 5'UTR was identified but the frequency of deletion allele was similar in cases and controls. None of the seven polymorphisms in the promoter region altered the transcription-binding site and hence neither any existing transcription binding site was destroyed nor was a new site created. Other SNPs included two in the intronic region and one in the 3' UTR region of *reg1α* gene. All ten polymorphisms had comparable allele frequencies in patients and controls and the difference was statistically not significant (Table 2). Allelic odds ratio and confidence interval did not indicate an association with any of the polymorphisms identified in *reg1α* with TCP (Table 2). Haplotype analysis using the six *reg1α* polymorphisms with greater than 3% minor allele frequency supported the observations made from the allelic and genotypic data at different polymorphisms (Table 5). The patient population was divided into FCPD and TCP patients based on the presence or absence of diabetes, but we failed to observe any association between FCPD and polymorphisms in *reg1α* gene (Table 3). We also dichotomized the patient population based on the presence or absence of N34S mutation in the *SPINK1* gene and L26V mutation in the cathepsin B gene and compared the allele frequency of 6 SNPs in *reg1α* gene of patients having at least one mutant allele with those with the wild type pattern at the above mentioned mutations (Table 6), but could not detect any interaction between them and the *reg1α* variants.

DISCUSSION

TCP is associated with the presence of large calculi throughout the main pancreatic duct[25,26]. However, the mechanism of stone formation is not completely understood[26]. A decrease in tissular pancreatic stone protein mRNA concentration is associated with CCP[27,28]. The role of Reg proteins is debatable but they are known to be associated with pancreatic islet regeneration, diabetogenesis and amelioration of surgical diabetes in animal models[18]. Its role in pancreatic stone formation is not clear with suggestions that lithostathine could promote the nucleation of calcite crystals or may prevent pancreatic lithiasis by inhibiting calcite crystal nucleation and growth in the pancreatic juice[29]. Thus, mutations in *reg1α* gene could play an important role in the pathogenesis of TCP and FCPD.

A previous study, analyzed the exons of *reg1α* gene using a combination of Restriction fragment length polymorphism (RFLP), Single strand conformation polymorphism (SSCP) and sequencing techniques in 50 FCPD patients and controls, but did not identify any nucleotide substitutions and ruled out any contribution

of mutations in the coding regions of *reg1α* gene[30]. However, these workers did speculate about a possible role of regulatory variants in *reg1α* gene. A subsequent study also analyzed only the coding region in 12 Thai FCPD patients and 22 controls and ruled out any association with the disease[31]. T-385C, a polymorphism in exon 1 (5'UTR) with a moderately high allele frequency (0.32 in patients and 0.29 in controls) could have been missed in these studies due to the inherent limitations of techniques like SSCP in detecting any sequence changes. Our study involving extensive analysis of the gene as well as of the promoter region detected several polymorphisms including the promoter variants but the results suggest that there may not be any allelic or haplotypic association between the polymorphisms in *reg1α* and TCP.

As the *reg1α* gene is believed to be involved in islet cell repair and regeneration[18], we examined the association of *reg1α* variants with TCP and FCPD. The etiology and relationship of diabetes mellitus in FCPD are not well understood. Some believe that diabetes in FCPD is secondary to TCP while others suggest there is selective β-cell impairment, the latter hypothesis is supported by the occurrence of FCPD in some patients at a very young age. Evidence showing a preserved pancreatic α-cell function in diabetics with advanced chronic pancreatitis of the tropics indicates the presence of two different pathogenic mechanisms, one causing chronic pancreatitis and the other selective pancreatic β-cell impairment and subsequently diabetes mellitus[32]. However, an independent analysis of the TCP and FCPD patients did not suggest any role for *reg1α* variants in FCPD patients. Although, nearly one-half of the TCP patients carry N34S *SPINK1* mutation and the mutations in *SPINK1* and *CTSB* are the only genetic changes known to be associated with TCP, we did not find any evidence of an interaction between them. Although the present study had limited power to analyse such an interaction, our preliminary observations did not find a statistically significant difference in allele frequency between these groups for any polymorphism, suggesting the lack of epistatic interaction between *SPINK1* and/or *CTSB* with *reg1α* gene.

In conclusion, polymorphisms in *reg1α* gene, including those in the regulatory region are unlikely to contribute to the pathogenesis of pancreaticolithogenesis in tropical calcific pancreatitis. Other genes such as those involved in calcium signaling and regulation, either interacting with *reg* genes or functioning independently may play a role in stone formation in tropical calcific pancreatitis.

ACKNOWLEDGMENTS

The authors express their gratitude to all the patients and normal volunteers for participating in the study and especially for giving informed consent for genetic studies. The help of Dr. Ramakrishna, Asian Institute of Gastroenterology in recruitment of patients and the collection of blood samples is gratefully acknowledged. The financial support of Council of Scientific and Industrial Research, Ministry of Science and Technology, Government of India is gratefully acknowledged.

COMMENTS

Background

Chronic pancreatitis (CP), an inflammatory condition of the pancreas with diverse etiologies, is usually associated with parenchymal calcification and presence of stones in the pancreatic duct. The process of stone formation in chronic pancreatitis is not completely understood. Lithostathine (encoded by *reg1α* gene), identified as a major proteic component of pancreatic stones in patients with alcoholic calcifying chronic pancreatitis, is thought to play an important role in the inhibition of stone formation and its levels are known to correlate with disease severity and is possibly regulated by the *reg1α* variants.

Research frontiers

Tropical calcific pancreatitis (TCP) and fibrocalculous pancreatic diabetes (FCPD; TCP presenting with diabetes) is a type of chronic pancreatitis specific to tropical countries. One of the important features of this condition is formation of large and irregular intraductal stones. Currently, there is considerable interest in understanding the mechanism of stone formation, the factors that inhibit stones, the genes involved in the process of pancreaticolithiasis as well as the effect of various polymorphisms. An additional area of interest is the relationship between the pancreatic inflammation and pancreaticolithiasis as well as the influence of genetic variants that predict susceptibility to the development of chronic pancreatitis.

Innovations and breakthroughs

The present study attempted to open new frontiers in the area of molecular pathogenesis of stone formation in TCP and FCPD by ruling out the role of *reg1α* variants in pancreaticolithiasis.

Applications

The results of the present study propose a new assessment of the pathogenesis of stone formation in TCP and FCPD. Further studies should be designed to elucidate more information.

Terminology

The process of stone formation, lithogenesis, is believed to be initiated by calcite nucleation with the subsequent deposition of proteins leading to protein plug formation; Lithostathine C is known to influence this process.

Peer review

The authors of this manuscript screened the *reg1α* gene including the regulatory region by sequencing and examining the association of the polymorphisms in the gene with pancreaticolithiasis in TCP and FCPD. The authors conclude that neither the previously reported nor novel variants in the *reg1α* gene predict the susceptibility to pancreaticolithiasis in TCP and FCPD.

Abstract

AIM: To investigate the *in-vitro* activation of cytotoxic T lymphocytes (CTLs) by fusion of mouse hepatocellular carcinoma (HCC) cells and lymphotactin gene-modified dendritic cells (DCs).

METHODS: Lymphotactin gene modified DCs (DCLptn) were prepared by lymphotactin recombinant adenovirus transduction of mature DCs which differentiated from mouse bone marrow cells by stimulation with granulocyte/macrophage colony-stimulating factor (GM-CSF), interleukin-4 (IL-4) and tumor necrosis factor alpha (TNF-α). DCLptn and H22 fusion was prepared using 50% PEG. Lymphotactin gene and protein expression levels were measured by RT-PCR and ELISA, respectively. Lymphotactin chemotactic responses were examined by *in-vitro* chemotaxis assay. *In-vitro* activation of CTLs by DCLptn/H22 fusion was measured by detecting CD25 expression and cytokine production after autologous T cell stimulation. Cytotoxic function of activated T lymphocytes stimulated with DCLptn/H22 cells was determined by LDH cytotoxicity assay.

RESULTS: Lymphotactin gene could be efficiently transduced to DCs by adenovirus vector and showed an effective biological activity. After fusion, the hybrid DCLptn/H22 cells acquired the phenotypes of both DCLptn and H22 cells. In T cell proliferation assay, flow cytometry showed a very high CD25 expression, and cytokine release assay showed a significantly higher concentration of IFN-γ and IL-2 in DCLptn/H22 group than in DCLptn, DCLptn+H22, DC/H22 or H22 groups. Cytotoxicity assay revealed that T cells derived from DCLptn/H22 group had much higher anti-tumor activity than those derived from DCLptn, H22, DCLptn+H22, DC/H22 groups.

CONCLUSION: Lymphotactin gene-modified dendritoma induces T-cell proliferation and strong CTL reaction against allogenic HCC cells. Immunization-engineered fusion hybrid vaccine is an attractive strategy in prevention and treatment of HCC metastases.

Key words: Hepatocellular carcinoma; Dendritic cell; Cytotoxic T lymphocyte

INTRODUCTION

Dendritic cells (DCs) are the most important antigen-presenting cells (APCs)[1-3]. DCs-based vaccinations have been demonstrated to be effective in inducing antigen-specific cytotoxic T lymphocyte (CTL) responses[4-9]. Previous studies in mouse tumor models or cancer patients demonstrated that vaccination with hybridomas from tumor cells and DCs induces regression of established carcinomas, lymphomas and myeloma[10-16]. This study was to investigate the *in-vitro* immune effects of fusion of mouse hepatocellular carcinoma (HCC) cells and lymphotactin (Lptn) gene-modified DCs and its antitumor activity.

MATERIALS AND METHODS

Animals, recombinant adenoviruses and cell lines

Five- to six-week old Female BALB/c (H-2K^d) mice were obtained from the Animal Resource Center of Shanghai Institute for Biological Sciences, Chinese Academy of Sciences, and maintained in specific pathogen-free conditions for use at the age of 6-8 wk. Recombinant Ad5 adenoviruses harbouring mouse lymphotactin (AdLptn) or LaZ gene (AdLacZ) were kindly provided by Dr. Cao Xue-Tao. The recombinant adenoviruses were propagated in

human embryonic kidney 293 (HEK293) cells, and purified by cesium chloride (CsCL) density gradient centrifugation. Titers of AdLptn and AdLacZ determined by plaque assay on HEK293 cells were 3.6×10^9 plaque-forming units (PFU)/mL and 4.5×10^9 PFU/mL, respectively. H22 cells, established as a BALB/c mouse origin HCC cell line, were purchased from China Center for Type Culture Collection. All the cells were cultured in RPMI-1640 (H22 cells) or DMEM (HEK293 cells) medium supplemented with 10% heat-inactivated fetal calf serum (FCS), 2 mmol/L glutamine, 100 U/mL penicillin and 100 μg/mL streptomycin.

DC culture

DCs were prepared as previously described[17] with certain modifications. Briefly, bone marrow cells prepared from femora and tibias of normal BALB/c mice were depleted of red blood cells with ammonium chloride and plated in RPMI-1640 plus 10% FCS and 10 ng/mL granulocyte/macrophage colony-stimulating factor (GM-CSF; R&D) with conjunction of 10 ng/mL interleukin-4 (IL-4; R&D) on d 1. On d 3, nonadherent granulocytes, T and B cells were gently removed and fresh media were added. On d 5, loosely adherent proliferating DC aggregates were dislodged and re-plated in the fresh media, and supplemented with 50 ng/mL tumor necrosis factor-α (TNF-α; R&D). On d 7, the released nonadherent mature DCs were harvested. CD11c-positive DCs accounted for more than 80% of the harvested cells as measured by flow cytometry.

Adenovirus transduction

Cultured DCs were pelleted and washed with PBS prior to the addition of virus. Virus stock (stored at -80℃) was thawed at room temperature and diluted in serum-free RPMI-1640 medium. The pellets of DCs were resuspended in serum-free RPMI-1640 and virus was added. After 2 h incubation with virus, cells were washed once in PBS. DCs were resuspended in a cytokine-supplemented medium which was retained after DC culture. Twenty-four hours after gene modification, LacZ gene-modified DCs (DCLacZ) were collected for X-gal staining to evaluate the gene transfer efficiency. Lymphotactin gene-modified DCs (DCLptn) were collected for phenotypic analysis and fused with H22 cells *in vitro*.

Reverse transcription-polymerase chain reaction (RT-PCR)

Total cellular RNA was isolated from cells using the TRIzol reagent (Life Technologies) according to the manufacturer's instructions. cDNA was prepared from total RNA using a hexanucleotide random primer and SuperScrip Moloney murine leukemia virus reverse transcriptase (Life Technologies). PCR primers for the amplification of mouse lymphotactin and beta-actin used are as follows (lymphotactin forward primer: 5'TGGG GACTGAAGTCCTAGAAG3'; reverse primer: 5'TTA CCCAGTCAGGGTTACTGCTGCTGTG3', with the product size of 300 bp. Beta-actin forward primer: 5'TG GAATCCTGTGGCATCCATGAAAC3'; reverse primer: 5'TAAAAGCCAGCTCAGTAACAGTCCG3', with the expected size of 359 bp.). PCR was performed in a Perkin Elmer Cetus DNA thermal cycler using Taq DNA polymerase (Life Technologies). The program consisted of 25 cycles of template denaturation at 94℃ for 1 min, annealing of primers at 60℃ for 1 min and synthesis at 72℃ for 2 min, followed by a final extension at 72℃ for 10 min. The PCR products were analyzed by agarose gel electrophoresis. Controls without reverse transcriptase were used to confirm that the RT-PCR products obtained were not the result of contamination with genomic DNA.

ELISA for measuring lymphotactin in supernatants

Lymphotactin protein in the supernatants from DCLptn was quantitatively determined with a commercial "sandwich" enzyme immunoassay kit (R&D) according to the manufacture's instructions. Briefly, Costar EIA microplates were coated with 100 μL of 2 μg/mL rat-anti-mouse lymphotactin as a capture antibody, incubated overnight at room temperature, and blocked with 1% bovine serum albumin (BSA) in PBS. Then, 100 μL of serially diluted standards or culture supernatant samples was added in triplicate and incubated at room temperature for 2 h. The plates were washed and incubated at room temperature for 2 h with 100 μL of 400 ng/mL biotinylated goat anti-mouse lymphotactin as a detection antibody. After washing, wells were incubated for 20 min in 100 μL of streptavidin- horseradish peroxidase (HRP) solution, and developed with substrate solution.

Cell fusion

DCLptn were fused with tumor cells at a 3:1 (DC: tumor) ratio using 50% polyethylene glycol (PEG, 50% PEG/10% DMSO in PBS, Sigma). In brief, H22 cells were inactivated by 30 μg/mL mitomycin, washed and mixed with DCLptn. After centrifugation, 1 mL of 50% PEG was added to the cell pellets for 2 min at 37℃. Then, an additional 10 mL of warm serum-free medium was added to dilute PEG over the next 3 min with continuous stirring. PEG-treated cells were centrifuged at 400 × *g* for 5 min, resuspended with RPMI-1640 medium supplemented with 20% FCS, 10 ng/mL GM-CSF and 10 ng/mL IL-4, and cultured overnight.

To determine the efficiency of cell fusion, H22 cells were stained with PKH-26 (red fluorescence, Sigma) and DCLptn were stained with PKH-2 (green fluorescence, Sigma). The cells stained with the fluorescence dyes were treated with PEG and cultured overnight as described above. On the next day, the stained cells were analyzed using a FACScan flow cytometer (Becton Dickinson) under a confocal microscope.

Phenotypic analysis

After washing, cells were resuspended in PBS containing 1% BSA, and stained with fluorescence-conjugated monoclonal antibody (H-$2K^d$, I-A^d, CD80, CD86, CD40, CD54) or isotype control antibody for 30 min at 4℃. The stained cells were washed and analyzed using FACS

In vitro chemotaxis assay

Chemotactic responses of lymphotactin to T cells were examined using modified boyden microchemotaxis chambers (Neuro Probe, Gaithersburg) and polyvinyl pyrrolidone-free 5 μm pore size polycarbonate

membranesy. Briefly, spleen cells from naïve BALB/C mice were used as effector cells. The bottom wells of the chamber were loaded with supernants of H22, DC, DCLptn, DCLacZ or RPMI-1640 alone, and the upper wells contained 1×10^5 effector cells. After 1 h incubation and staining, data were obtained by counting five nonoverlapping high power microscopic fields from each well. Cells were considered chemoattracted if the chemotactic index (number of cells migrating in experimental well/number of cells migrating in RPMI-1640 medium only) was greater than 2.

CD25 expression and cytokine production after autologous T cell stimulation

To determine the proliferation and differentiation of lymphocytes, CD25 expression and cytokine production after autologous T cell stimulation were assayed. Briefly, spleen cells from naïve BALB/C mice were passed over nylon wool with their purity determined by FACS (percentage of $CD3^+$ cells near 90%) and used as responder cells at 1×10^5/well in 96-well U-bottom plates. Syngeneic H22, DCLptn, H22+ DCLptn (H22 cells co-cultured with DCLptn at a ratio of 3:1), DC/H22 (H22 cells fused with DC at a ratio of 3:1) and DCLptn/H22 (H22 cells fused with DCLptn at a ratio of 3:1) cells were inactivated with 30 μg/mL mitomycin for 30 min and added to responder cells in varying cell numbers. Cells were cultured at 37℃ in RPMI-1640 medium containing 10% FCS and 5% CO_2 for 2 d. Control wells contained T cells alone. At the end of experiment, supernatants were harvested for cytokine production assay by ELISA and co-cultured T-cells were collected for analyzing CD25 expression by FACS.

CTL assay

Cytotoxic function of the activated T lymphocytes stimulated with DCLptn/H22 was determined by cytotoxicity test. Inactivated cells were co-cultured with spleen T cells separated from naïve BALB/C mice at a 1:10 ratio in the presence of 20 U/mL mouse IL-2 for 7 d. The stimulated T cells were isolated and used as effector cells in lactate dehydrogenase (LDH, Roche) cytotoxicity assay. H22 cells were used as target cells. All steps were performed following the manufacturer's instructions. Briefly, after washed with assay medium (RPMI1640 with 1%BSA), the effector cells were co-cultured at 37℃ with target cells in a 96-well round bottom plate for 6 h, then the plate was centrifuged and the supernatants were transferred to another flat-bottom ELISA plate. One hundred μL of LDH detection mixture was added to each well and incubated at room temperature in the dark for 30 min. Absorbance was measured with an ELISA reader at 490 nm. The spontaneous release of LDH by target cells or effector cells was assayed by incubation of target cells in the absence of effector cells and vice versa, the maximum release of LDH was determined by incubation of the target cells in 1% Triton X-100 in assay medium. The percentage of cell-mediated cytotoxicity was determined by the following equation: cytotoxicity (%) = [(mixture of effectors and targets-effector control)/(maximum-spontaneous)] × 100.

Statistical analysis

Data were expressed as mean ± SD. Experiment results were analyzed using SPSS 10.0 statistical package. Differences among groups were assessed by the Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

Lymphotactin expression and functional assay

DC and H22 did not express any detectable Lptn, which was detected in DCLptn and H22Lptn (Figure 1). The results indicate that adenovirus vector could effectively transducer the Lptn gene.

In order to quantitatively determine Lptn protein in supernatants from gene-modified DCs, culture supernatants were harvested and determined for Lptn production by ELISA. The results showed that about 0.35 ± 0.04 ng/mL Lptn could be detected in the supernatants of DCLptn, while nearly no Lptn could be detected in the supernatants from untransfected DC, DCLacZ and H22 cells.

Consistent with ELISA results, only the supernatant from DCLptn was positive for chemotaxis assay (chemotaxis index = 3.2 ± 0.15), but from DC, DCLacZ, H22 groups was negative. The results indicate that recombinant Lptn secreted from DCLptn had an effective biological activity.

Recognition and characterization of H22 and DCLptn fusion

Fusion was examined by confocal microscopy (Figure 2) and flow cytometry (Figure 3). The fusion cells were yellow under confocal microscope. The fusion efficiency assayed by FACS was 15%-22%.

FACS analysis showed that DCs encoding lymphotactin were positive for H2-K^d, I-A^d, CD80, CD86, CD40, CD54. However, H22 cells expressed a moderate level of I-Ad. The expression levels of H-2K^d, CD80, CD86, CD40 and CD54 were almost negative. Hybrid DCLptn/H22 cells acquired the phenotypes of both DCLptn and H22 cells.

Enhancement of Th1 cytokine production and CD25 expression

Flow cytometry showed that a very high CD25 expression was observed in T lymphocytes generated in autologous mixed lymphocyte reaction with DCLptn/H22 fusions (58.23% ± 11.65%) when compared to T cells either cultured with DCLptn cells (39.12% ± 12. 35%), H22 (10.78% ± 5. 46%), DC/H22 cells (41.55% ± 12.82%), or DCLptn+H22 cells (43.03% ± 10.52%). By *in vitro* cytokine release assay, significantly higher concentrations of IFN-γ and IL-2 were noted in supernatants of DCLptn/H22 co-cultured with T cells compared to those of DCLptn, DCLptn + H22, DC/H22 or H22 co-cultured with T cells. No difference was noted between concentrations of IL-4 or IL-10 in supernatants of all groups (Table 1).

Elicitation of tumor-reactive CTLs by fusion of DCs with H22 cells

Cytotoxic assay revealed that T cells derived from

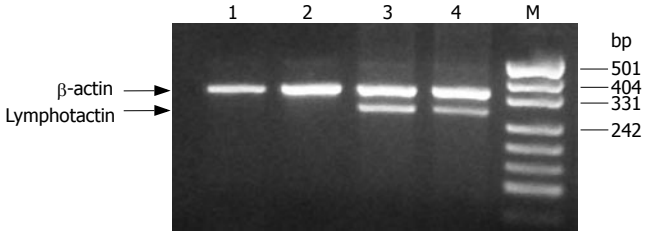

Figure 1 RT-PCR analysis of lymphotactin gene expression in DC, H22, DCLptn, H22Lptn (lanes 1-4). The data shown are representative of three separate analyses for each cell population. M: Marker.

DCLptn/H22 group possessed an extremely higher anti-tumor activity than those derived from DCLptn, H22, DCLptn + H22, DC/H22 groups. Although there were no differences among DCLptn, DCLptn + H22 and DC/H22 groups, the anti-tumor activity of DCLptn, DCLptn + H22 and DC/H22 groups was remarkably higher than that of H22 groups (Figure 4).

DISCUSSION

$CD8^+$ T cells are critical components in immune responses to tumors and can differentiate into cytotoxic T lymphocytes and acquire the ability to lyse tumor antigen expressing cells. Activation of $CD8^+$ T cells requires two steps[18-20]: presentation of antigenic peptides on professional antigen presenting cells and helper function provided by $CD4^+$ T cells *via* Th1/Th2 cytokines. When DCs and HCC cells are fused, antigens are processed and displayed on the cell surface through MHC class I pathway which stimulates $CD8^+$ T cells, and some antigens may be displayed by MHC class Ⅱ molecules, which stimulate $CD4^+$ T cells. On the other hand, mature DCs express MHC Ⅰ, MHC Ⅱ and co-stimulatory molecules that provide necessary signals for the stimulation of naïve T cells[21,22]. Upon stimulation, proliferating $CD4^+$ T lymphocytes differentiate along the Th1 pathway, resulting in increased IFN-γ and IL-2 production, contributing to the activation of tumor-specific CTLs and enhancing the cytotoxic effect. Evidence from cytokine release assays indicates that in cultures with proliferating lymphocytes, the production and secretion of Th1-associated cytokines (IFN-γ, IL-2) but not Th2-associated cytokines (IL-4, IL-10) are increased. In our study, the fusion groups had a higher CTL activity than H22 group.

Activation of lymphocytes is a dynamic, multistep process. Although MHC and costimulatory molecules are critical for successful T-cell activation, signals that regulate this process have not been fully elucidated. It is believed that chemokines are an essential mediator. Migration of DCs to the sites of inflammation where they capture antigens and subsequently migrate to the local lymph nodes is regulated by the expression of different chemokines and their receptors[23,24]. Lymphotactin as a C chemokine produced mainly by T and nature killer (NK) cells, is a chemoattractant both *in vitro* and *in vivo*[25-28]. In our study, DCs and H22 cells did not express Lptn, and the Lptn gene-modified hybridima had a stronger CTL activity

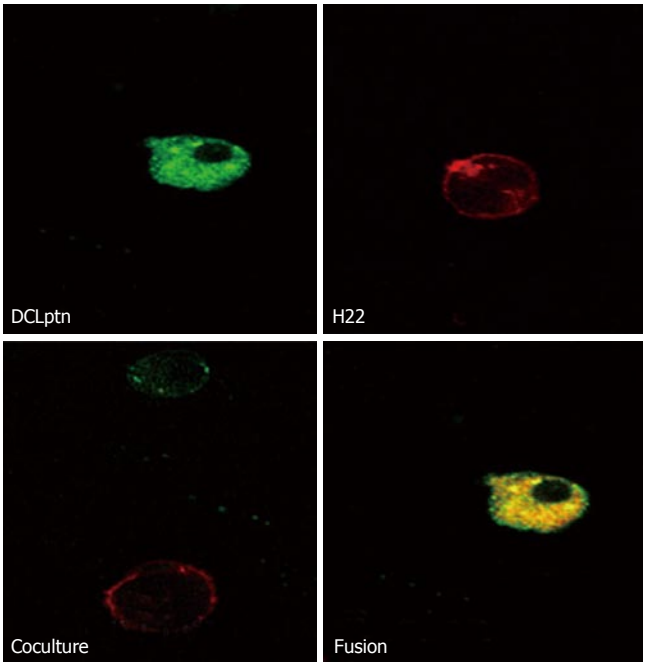

Figure 2 Confocal micrography of DCLptn/H22 fusion cells.

and a higher Th1 cytokine production, suggesting that Lptn modification can improve preferential chemotaxis of hybridoma on T cells and consequently optimize the microenvironment of antigen presentation to T cells.

CD25, α-chain of the IL-2 receptor, is expressed in the early to moderate phase after T-cell activation, the clonal proliferation of activated T cells depends on the expression of this receptor and resting lymphocytes do not express CD25[29,30]. Therefore, CD25 expression is commonly used as a marker for T cell activation. Quantification of surface IL-2 receptor expression on activated lymphocytes by flow cytometry after *in vitro* stimulation with specific antigens is useful in measuring cellular immunity. In the present study, we used this method to assess the lymphotactin gene-modified hybridoma's stimulation on co-cultured T cells. By using this method, we were able to study the effect of stimulation on a heterogeneous cell population without the risk of selective depletion of cells, to exclude non-specific stimulation due to the separation, and to express CD25 at the early to moderate (24-48 h) phase of mixed lymphocyte reaction, thus shortening the co-culture time and keeping the viability of T cells.

In conclusion, lymphotactin gene-modified dendritoma induces potent T-cell proliferation and strong CTL reaction against allogenic HCC cells. Immunization-engineered fusion hybrid vaccine is an attractive strategy in prevention and treatment of cancer metastases.

COMMENTS

Background

Despite recent advances in surgical technique and radio- and chemotherapy, the prognosis of patients with malignant tumors remains dismal. The resistance of these tumors to conventional treatment may stem from their well-documented ability to exert local and systemic immunosuppressive effects. Therefore, alternative treatments are required.

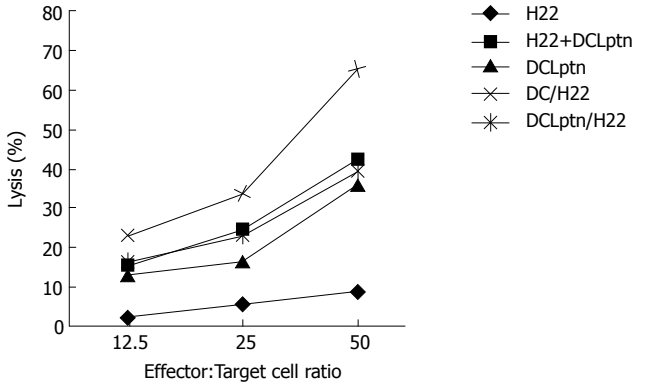

Figure 4 Stimulation of anti-tumor CTLs by DCLptn/H22 cells.

Research frontiers

Dendritic cells are the most potent APC for inducing an antigen-specific CTL response. This property, coupled with the fact that it is now possible to generate, *ex vivo*, a large number of functional dendritic cells from a patient's peripheral blood monocytes or CD34 haemopoietic stem cells, have led to a considerable interest in use of dendritic cell vaccines as a means to induce antitumour immunity. Various strategies have been developed to introduce tumor specific antigens into DCs and thereby to generate cytotoxic T lymphocyte (CTL) responses against malignant cells. One of the important approaches to the induction of primary antitumor immunity is through the generation of tumor cell and DC fusion.

Innovations and breakthrough

Although some effective results have been obtained by vaccinating mice with fusion of DCs and other tumor-cell types, it still remains a challenge. Several parameters must be optimized in order to maximize the efficacy of immunotherapy for dendritoma. In the present study, the authors have found that after Lptn gene modification, activated T cells can acquire more tumor antigens from DCLptn/H22 and have a stronger cytotoxicity to target cells.

Applications

This may be an attractive strategy in prevention and treatment of cancer metastases.

Terminology

Dendritoma: fusion formed by dendritic cells and carcinoma cells.

Peer review

This paper investigated the *in vitro* activation of cytotoxic T lymphocytes by fusion of mouse hepatocellular carcinoma (HCC) cells and dendritic cells modified by transfection of the lymphotactin gene. The authors conclude that lymphotactin modifies dendritoma and induces T cell proliferation and strong reaction of cytotoxic lymphocytes against allogenic HCC cells. These results are of certain interest.

Abstract

We report a case of a poorly differentiated epithelial tumour of the rectum with a highly pleomorphic morphology and an aberrant immunophenotype, including the expression of epithelial markers, the focal parameter of neuroendocrine differentiation, and the unexpected detection of CD-117 overexpression. A 69-year-old man was admitted to our clinic complaining of rectal bleeding and weight loss. Colonoscopy showed an ulcerative bleeding mass located about 8 cm from the anal verge. Abdominal and pelvis CT scans demonstrated a large low-density lesion with extracanalicular growth from the middle rectum, with local lymph-node spread, and without tumour infiltration of other pelvic organs, or evidence of distant intra-abdominal spread. The patient underwent a low anterior resection for rectal cancer together with wide resection of lymph nodes. In immunohistochemical analysis, pankeratin and Epithelial Membrane Antigen (EMA) immunolabeling proved the epithelial nature of the tumor cells. Chromogranin A and Leukocyte Common Antigen (LCA) were negative, whereas CD-56 expression was scanty and Neuron Specific Enolase (NSA) was heavily and diffusely expressed. Ki67 immunoexpression was particularly increased. Interestingly, the intense c-kit immunoreactivity (100%) was a common feature. The above phenotypic and immunohistochemical profile was consistent with an anaplastic carcinoma of the large intestine, with focal neuroendocrine differentiation and diffuse immunoreactivity to c-kit protein. Given the resistance of this tumor to conventional chemotherapy and radiation, the incidence of the c-kit alteration may represent a novel approach to a gene-directed treatment using a c-kit inhibitor (STI571) similar to that which has been proposed in GISTs.

INTRODUCTION

We report a case of a poorly differentiated epithelial tumour of the rectum with a highly pleomorphic morphology and an aberrant immunophenotype, including the expression of epithelial markers, the focal parameter of neuroendocrine differentiation, and the unexpected detection of CD-117 overexpression.

CASE REPORT

A 69-year-old man was admitted to our clinic complaining of rectal bleeding for 2 mo (two episodes of massive rectal bleeding) and weight loss of 5 kg in 4 mo. His past medical history was negative for any surgical procedure or chronic disease, and his family history was also free. He denied any change in bowel habits, urinary urgency, or any other symptoms. Digital examination was normal but proctosigmoidoscopy showed an ulcerative mass bulging over the right rectal wall, and the fecal examination was positive for blood.

Laboratory tests of the peripheral blood revealed microcytic hypochromic anemia (hemoglobin, 11.7 g/dL and hematocrit, 26.6%). The serum levels of carcinoembrionic antigen (CEA), alpha-fetoprotein AFP, and CA19-9 were within normal ranges. Prostate-specific antigen (PSA) was also within the normal range (0.7 ng/dL, PSA free, 0.16 mg/dL).

Colonoscopy showed an ulcerative bleeding mass that was located about 8 cm from the anal verge. An additional abnormality revealed by colonoscopy was the existence of five small polyps along the rest of the colon. Abdominal and pelvis CT scans demonstrated a large low-density lesion with extracanalicular growth from the middle

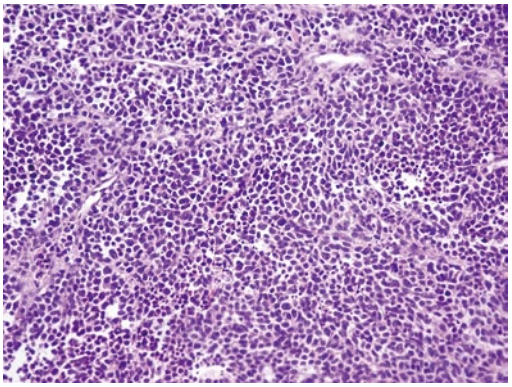

Figure 1 Histological appearance of the colorectal adenocarcinoma (HE, × 20).

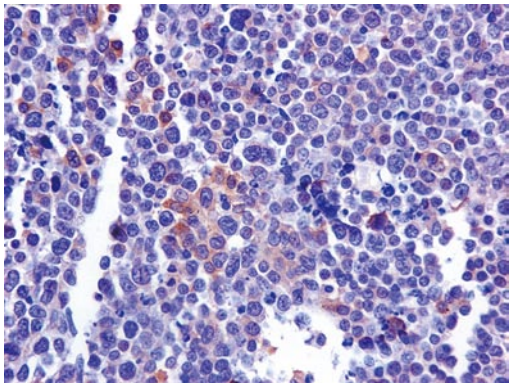

Figure 2 Scanty CD-56 immunohistochemical expression by tumor cells (× 40).

rectum, with local lymph-node spread, and without tumour infiltration of other pelvic organs, or evidence of distant intra-abdominal spread. No metastatic nodules were found in the lung and the liver by diagnostic imaging procedures. The patient underwent a low anterior resection for rectal cancer with a circular stapled low, end-to-end colorectal anastomosis (indicated for tumours situated 6-9 cm above the anal verge), together with wide resection of lymph nodes.

On gross examination, the 14-cm rectosigmoidal surgical specimen manifested as an ulcerative tumor that measured 5 cm in its larger diameter, located 2-5 cm from the distal resection margin.

Under microscopy, the tumor was composed of irregular sheets and scattered tumor cells (Figure 1) with markedly pleomorphic nuclei and prominent nuclei, including giant or multinucleated cell types. The tumor was found to infiltrate the submucosa, the muscularis propria, and the perirectal adipose tissue. Nodal metastasis was found in 2/22 lymph nodes examined.

In immunohistochemical analysis, pankeratin and Epithelial Membrane Antigen (EMA) immunolabeling proved the epithelial nature of the tumor cells. Chromogranin A and Leukocyte Common Antigen (LCA) were negative, whereas CD-56 expression was scanty (Figure 2), and Neuron Specific Enolase (NSA) was heavily and diffusely expressed. Ki67 immunoexpression was particularly increased. Interestingly, the intense c-kit immunoreactivity (100%) was a common feature (Figure 3A and B). The above phenotypic and immunohistochemical profile was consistent with an anaplastic carcinoma of the large intestine, with focal neuroendocrine differentiation and diffuse immunoreactivity to c-kit protein.

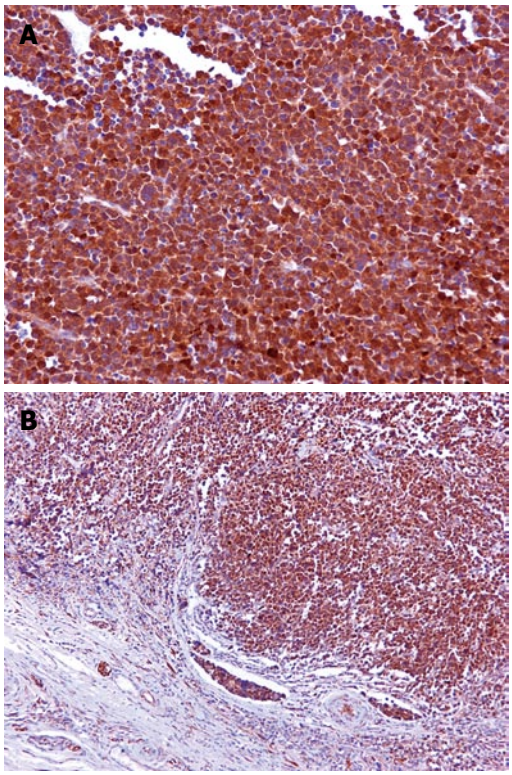

Figure 3 **A**: Intense c-kit immunolabeling (× 20); **B**: intense nuclear cytoplasmic immunolabeling for c-kit protein (× 10).

DISCUSSION

c-kit protein, a 145-kDa tyrosine kinase with oncogenic properties is a transmembrane receptor growth factor known as a stem cell factor (SCF). It is encoded by the c-kit proto-oncogene located on chromosome 4q11-q12[1]. Activation of c-kit by its SCF ligand leads to dimerization of the receptor. The latter activates further signalling cascades that control cell proliferation, adhesion and differentiation[2].

CD-117 is a functionally important protein in hematopoietic stem cells, mast cells, germ cells, some epithelial cells and in Cajal cells. Parenthetically, Cajal cells are known to originate from common intestinal mesenchymal precursor cells[2-5].

Several studies have identified the presence of a c-kit malignant mutation in over half of gastrointestinal stromal tumors (GISTs), as well as in other human tumors, including germ cell tumors, neuroblastoma, melanoma, ovarian carcinoma and breast carcinoma[6-14]. Interestingly, overexpression of c-kit has been found to affect proliferation in human neural, lung, breast, colorectal, skin and prostatic tumors[15].

On the basis of an immunohistochemical study of c-kit expression in 126 colorectal carcinomas, only two

(1.6%) poorly differentiated carcinomas presented with aberrant c-kit positivity, which implies the role of c-kit in tumor progression[16]. Although the functional role of mutated c-kit kinase activity is not fully understood, it seems that in breast, thyroid and ovarian cancer, the malignant transformation seems to correlate with loss of c-kit protein expression[17]. However, Bellon *et al*[12] have reported overexpression of c-kit in human colorectal cancer, and have suggested that c-kit activation is critical for growth, survival, migration and invasive potentional of DLD-1 colon carcinoma cells. Of interest, only 1.6% of colorectal cancers show high cytoplasmic c-kit staining, a fact that is not related definitely to tumorigenesis[16]. Immunohistochemical expression of c-kit protein is a rare event in poorly differentiated carcinomas[16,17].

In the study by Akintola-Ogunremi *et al*[17], who studied 66 cases of primary colorectal neuroendocrine carcinoma, the prognosis did not appear to differ between kit-positive and kit-negative cases. In the view of the limited number of reports in the literature and the lack of follow-up data, c-kit overexpression cannot provide any evidence regarding the biological behavior of the tumor currently described. However, further follow-up, together with c-kit gene mutational analysis may alter the prognostic value of c-kit positivity in these highly aggressive malignancies of the colon. Thus, the immunohistochemical CD-117 alteration in poorly differentiated carcinoma of the rectum remains to be elucidated.

Given the resistance of this tumor to conventional chemotherapy and radiation[18,19], the incidence of the c-kit alteration may represent a novel approach to a gene-directed treatment using a c-kit inhibitor (STI571) similar to that which has been proposed in GISTs[20]. According to the literature, STI571 may inhibit the *in vitro* growth of colorectal carcinoma cell lines, although it has not been tested so far for the treatment of colorectal carcinoma[20].

A long term study of c-kit protein expression in poorly differentiated malignancies of colon may be warranted, although c-kit overexpression can not guarantee tumor response. Thus, a thorough genetic investigation of colorectal malignancy may determine the eligibility of STI571 regimen for potential targeted therapy.

Abstract

To date, antegrade intussusception involving a Roux-en-Y reconstruction has been reported only once. We report a case of acute bowel obstruction due to an intussusception involving two Roux-en-Y limbs in a 40-year-old woman with a history of chronic pancreatitis due to pancreas divisum. Four years preceding this event, the patient had undergone a Whipple procedure, and three years prior to that, a Puestow operation. The patient was successfully treated with bowel resection and a side-to-side anastomosis between the most distal aspect of the bowel and the most distal Roux-en-Y reconstruction, which preserved both Roux-en-Y reconstructions.

Key words: Whipple procedure; Puestow procedure; Pancreas divisum; Intussusception; Bowel obstruction

Gigena M, Villar HV, Knowles NG, Cunningham JT, Outwater EK, Leon LR Jr. Antegrade bowel intussusception after remote Whipple and Puestow procedures for treatment of pancreas divisum. *World J Gastroenterol* 2007; 13(44): 5954-5956

INTRODUCTION

It is a well known fact that intussusception is most often seen in children[1]. Intussusception in adults however is relatively rare, with about 17% of intussusception cases in large reported series having occurred in adults[1]. Surgical sutures or staples along an anastomosis are, among other factors, well-known lead points for the development of intussusception, therefore making abdominal surgical interventions recognized risk factors for the occurrence of this complication[2-6]. Intestinal tract reconstructive surgery involving the pancreas however, has been very rarely linked to the development of intussusception[7]. We report the case of a middle-aged woman who developed intussusception after two major operations that were remotely performed for the therapy of symptomatic pancreas divisum. A brief discussion of the available literature is also presented.

CASE REPORT

A 40-year-old woman presented with abdominal pain, nausea and vomiting of 24 h duration. She was afebrile and normotensive but had tachycardia. Her upper abdomen was visibly distended and a palpable epigastric mass could be felt. The abdomen was severely tender to palpation and peritoneal signs were elicited. Her past history was significant for pancreas divisum and chronic pancreatitis. Four years prior, she underwent a Whipple procedure as therapy for her pancreatic abnormalities. This required surgical revision 1 year later with a Puestow operation, due to stricture of the previously performed pancreatico-intestinal anastomosis. Ever since, she experienced intermittent abdominal pain, for which she was prescribed strong analgesics, with only partial symptomatic relief. Her white blood cell count was 17 000 cells/mm^3. A computed tomography (CT) scan of the abdomen was obtained, which demonstrated jejunal intussusception, with findings suggesting bowel ischemia (Figure 1).

After fluid resuscitation, the patient was subjected to an exploratory laparotomy. A small amount of ascites was encountered. Two loops of dilated small bowel were found inferior to the transverse mesocolon, each measuring about 10 cm in maximal diameter. These loops were identified to be part of the previously performed Roux-en-Y and Puestow procedures, going towards the stomach, bile duct and the pancreatico-jejunostomy reconstruction. Upon further exploration, an intussusception just distal to the most distal Roux-en-Y connection was found, and about 30 cm of non-perforated necrotic small bowel was identified. The intussusception occurred in an antegrade fashion, which obstructed both Roux-en-Y reconstructions. With care, the intussuscepted intestine was reduced. The necrotic bowel was then resected, and a side-to-side anastomosis between the most distal aspect of the bowel and the Roux-en-Y reconstruction that was directed towards the Puestow procedure was performed.

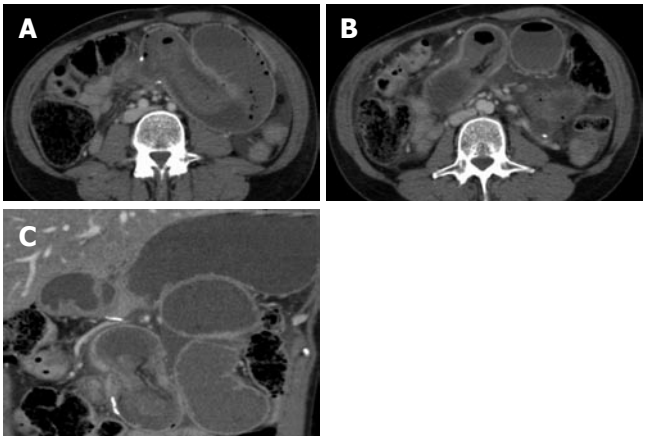

Figure 1 Axial (**A** and **B**) and coronal (**C**) CT images of the abdomen following intravenous contrast administration, which show large dilated loops of small bowel proximal to the intussusception. The intussuscepted bowel entered the more distal jejunum *via* the jejunal anastomotic site, which is evident due to the presence of surgical clips.

Figure 2 Abdominal CT scan from prior hospital visits, which reveals milder bowel intussusception prior to the patient's last admission.

Due to the massive mesenteric vascular engorgement caused by the intussusception, there was an area of bleeding emanating from a bowel mesentery tear. This was localized and controlled. The abdomen was lavaged and closed. Postoperatively, the patient developed clinical evidence of abdominal compartment syndrome and required emergent re-exploration and blood transfusion. The mesenteric tear was again found to be the source of massive bleeding, and was repaired with additional stitches. Temporary skin closure of the abdomen was performed. Final closure was performed 3 d after the first intervention, and she was discharged without complications 8 d later.

DISCUSSION

Pancreas divisum is an anomaly of the pancreatic ducts, which represents the most common congenital variant of the pancreas. It results from the absence of embryological fusion of the dorsal and ventral pancreatic ducts, each keeping their drainage autonomy[8]. The correlation of this abnormality with pancreatic disease is very controversial[9]. Several techniques have been suggested for therapy, including endoscopic papillotomy, open surgical accessory sphincteroplasty, or a Puestow procedure[10]. As a result of the underlying duct anomalies and significant pancreatic head changes, some have suggested treatment with duodenum-preserving pancreatic head resection (Beger's pancreatectomy)[10]. With good patient selection, the outcome of surgical therapy has been shown to be acceptable.

Our patient underwent a Whipple procedure for chronic pancreatitis, which did not achieve symptomatic relief. This was likely due to stenotic involvement of the entire pancreatic duct, and not only the head portion, as well as due to a stricture at the pancreatico-intestinal anastomosis. This was recorded in the patient's old medical records. In consequence, a Puestow operation was subsequently performed, which resulted in symptomatic improvement but incomplete relief. The latter procedure would have likely been a better first modality of therapy for this patient upon her initial presentation, together with a papillotomy of the minor papilla. However, endoscopic retrograde cholangiopancreatography images were not available to us, and it is therefore impossible to give an accurate opinion about her initial treatment.

The chronic nature of our patient's symptoms made her diagnosis challenging. This was due to the fact that she had recurrent symptoms of abdominal pain, nausea and vomiting after both interventions, and that she required large doses of analgesics and antidepressants due to chronic pain. In fact, previously performed CT scans revealed milder degrees of small bowel intussusception in prior hospital visits (Figure 2), which were thought to represent transient short bowel segment intussusceptions.

It has been suggested that altered intestinal motility may contribute to the development of intussusception[2]. In fact, this complication may be an extreme form of the so-called Roux-en-Y stasis syndrome[3]. It has been shown that the myoelectric activity of the Roux limb is often dysfunctional, split and retrograde, and of high amplitude (> 120 mmHg). Therefore it is possible that the intussusception seen in our patient was the result of severe disruption of the normal pacemaker activity in the intestines[3]. This is even more likely given the fact that we did not identify any intraluminal, extraluminal or intramural lesions. Her current presentation with necrotic bowel did not allow us to perform further imaging studies (i.e., small bowel follow through or gastric emptying studies) to demonstrate altered motility and peristaltic motion, and, rather, mandated emergent exploration.

Cases of small bowel intussusception in adults without a lead point have rarely been reported. They are most often seen after gastric bypass is performed for morbid obesity[4,5], but also have been reported exceptionally after biliary reconstruction for choledochal cysts[6], or associated with *Vibrio* infection in a patient with diabetic ketoacidosis[11]. Intussusception occurring after pancreatic duct reconstruction is extremely rare. It was reported for the first time after a pancreatico-jejunostomy in 2003[7]. The latter case reported retrograde intussusception of the efferent limb into the anastomosis of a revised Roux-en-Y bypass of the pancreas, similar to our case. Our patient represents the second reported case of an

antegrade intussusception that occurred after pancreatic reconstruction. The retrograde case that was reported by Whipple and colleagues[7], occurred after a Roux-en-Y revision for an antegrade intussusception after a Puestow procedure performed for chronic pancreatitis.

A lead point is identified in approximately 80% of intussusception cases[7]. In the current case, we were not able to identify a lead point. Interestingly, neither was this noted in the case reported by Whipple *et al*[7].

Our patient unfortunately developed abdominal compartment syndrome due to massive hemoperitoneum. The massive intestinal dilatation accounted for the friability of the bowel mesentery, which, together with an elevated venous pressure caused by blood flow obstruction in the caval-mesenteric veins, due to the mass effect produced by the bowel obstruction, may explain the large amount of bleeding. Permanent abdominal closure after our second intervention was precluded because of bowel edema and disseminated intravascular coagulation after massive resuscitation, due to the large amount of blood loss.

In conclusion, antegrade intussusception in adults after pancreatic duct reconstruction is extremely rare. Our case represents the second report in the literature of such an occurrence. This patient had previous episodes of abdominal pain, nausea and vomiting, which suggests that altered intestinal motility may have contributed to her current presentation. Bowel intussusception should be always considered in cases of small bowel obstruction in adults after pancreatic reconstruction.

Abstract

Lian-Sheng Ma, Editor-in-Chief of *World Journal of Gastroenterology* (*WJG*), warmly met Professor Hugh J Freeman from the University of British Columbia at Peninsula Hotel in Beijing on August 28, 2007. Professor Hugh J Freeman gave much helpful advice toward the further development of *WJG*. He will serve as series editor for a new column called OBSERVER which will start in *WJG* in 2008.

Chang YD. Lian-Sheng Ma, Editor-in-Chief of *WJG*, warmly meets Professor Hugh J Freeman from the University of British Columbia. *World J Gastroenterol* 2007; 13(44): 5957

Professor Lian-Sheng Ma (left), Editor-in-Chief of *WJG*, and Dr. You-De Chang (right) warmly met Professor Hugh J Freeman (middle) at Peninsula Hotel in Beijing. Photograph taken by Mrs. Sally Freeman.

Professor Lian-Sheng Ma, Editor-in-Chief of *World Journal of Gastroenterology* (*WJG*) warmly met Professor Hugh J Freeman, a highly respectable gastroenterologist from the Department of Medicine, University of British Columbia, and his wife Mrs. Sally Freeman during their visit to *WJG* at Peninsula Hotel in Beijing on August 28, 2007. Both sides achieved very fruitful talks and reached a couple of common viewpoints related to future development strategy and management of *WJG*.

Professor Ma gave a detailed introduction to the strategies of both fast peer review and online free access currently taken by *WJG*. "Both fast peer review and online free access are very beneficial and competitive." replied Hugh J Freeman, "It is really just like having a lesson through reading the comments affiliated at the end of an article." He also suggested that *WJG* openly add the names of the peer reviewers at the end of the affiliated comments to make the science communities of authors, reviewers and readers more active and real. "These three aspects have played important roles in ensuring the quality of articles and increasing the public access to *WJG*." he added.

Professor Freeman encouraged with confidence the authors-created, innovation-orientated and readers-benefited publishing system currently conducted by *WJG* with little commercial evolvement. "Over commercial evolvement sometimes misleads the path a journal takes and weakens the decisions a journal makes." Freeman pointed out.

As the second important topic of their talks, Professor Ma invited Professor Freeman to be Associate Editor-in-Chief for a unique column called OBSERVER which will start in *WJG* in 2008. Freeman kindly accepted the invitation. The OBSERVER column will serve as a forum for both gastroenterologists and hepatologists worldwide. Professor Freeman will periodically invite a set of experts from specific research fields to discuss a series of hot topics covering the progress made in both gastroenterology and hepatology, and the challenging questions currently faced by gastroenterologists and hepatologists as well as the possible ideas, ways and techniques to answer these questions. The OBSERVER is an invited editorial for free of publication. For more information, please do not hesitate to contact Professor Freeman at hugfree@shaw.ca and Science Editor Dr. You-De Chang at y.d.chang@wjgnet.com.

On behalf of both Professor Hugh J Freeman and the upcoming OBSERVER column, the *WJG* staff sincerely thank all editorial members, authors and readers from around the world and warmly welcome your coming submissions.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

Ultrasound (US) is often the first imaging modality employed in patients with suspected focal liver lesions. The role of US in the characterisation of focal liver lesions has been transformed with the introduction of specific contrast media and the development of specialized imaging techniques. Ultrasound now can fully characterise the enhancement pattern of hepatic lesions, similar to that achieved with contrast enhanced multiphasic computed tomography (CT) and magnetic resonance imaging (MRI). US contrast agents are safe, well-tolerated and have very few contraindications. Furthermore, real-time evaluation of the vascularity of focal liver lesions has become possible with the use of the newer microbubble contrast agents. This article reviews the enhancement pattern of the most frequent liver lesions seen, using the second generation US contrast media. The common pitfalls for each type of lesion are discussed. The recent developments in US contrast media and specific imaging techniques have been a major advance and this technique, in view of the intrinsic advantages of US, will undoubtedly gain popularity in the years to come.

Key words: Microbubble contrast agents; Ultrasound; Focal liver lesions

Morin SHX, Lim AKP, Cobbold JFL, Taylor-Robinson SD. Use of second generation contrast-enhanced ultrasound in the assessment of focal liver lesions. *World J Gastroenterol* 2007; 13(45): 5963-5970

http://www.wjgnet.com/1007-9327/13/5963.asp

INTRODUCTION

The non-invasive detection and characterisation of focal liver lesions is an important component of cross-sectional imaging studies. Depending on their histological nature, different focal liver lesions vary in their blood supply, with the malignant ones generally having a preferential hepatic arterial supply[1]. The enhancement pattern of a lesion is based on the blood supply and constitutes the mainstay of its characterization with contrast-enhanced computed tomography or magnetic resonance imaging[2].

Ultrasound (US) is often the first imaging investigation for patients with liver disease. The sensitivity and specificity of gray-scale US for the characterization of focal lesions is inferior to that of CT or MRI[3,4]. One of the main reasons for this was the absence, until the 1990s, of US contrast media. The advent of microbubble contrast agents has led to improved characterisation and detection of focal liver lesions since the enhancement characteristics can be visualised in real time over a 5 min period. As a result, recent studies have reported sensitivities and specificities that rival that of CT and MRI[5].

US CONTRAST MEDIA AND SPECIFIC IMAGING TECHNIQUE

Ultrasound contrast agents consist of microbubbles of gas with a protein, lipid or polymer shell. The microbubbles are approximately 1 to 10 μm, which is the size of a red blood cell. These particles are too large to pass through the vascular endothelium and, as such, are considered pure blood pool agents[6]. After several minutes in the circulation, the microbubbles dissolve, the gas is exhaled and the shell is metabolized, mainly in the liver[7]. Furthermore, the microbubbles are well tolerated by patients after intravenous injection and there are very few contraindications to their use.

When subjected to an US wave, the microbubbles respond by changing their size: they expand during the rarefaction phase and contract during the pressure phase. These changes are much greater than the minor changes that occur in the soft tissues. The bubbles, like every oscillating system, have a natural frequency (the resonance frequency) at which their response is maximal.

Fortunately, the bubbles resonate at frequencies used for diagnostic US imaging. This coincidence accounts for their high reflectivity, even when they are present in a small concentration. Furthermore, the expansion of these bubbles during the rarefaction phase exceeds their contraction during the pressure phase. This asymmetric oscillation produces a returning signal (echo) that contains harmonics, i.e. multiples of the driving frequency[8]. The first microbubble-specific imaging technique exploited this property by sending an US pulse into the tissue and selectively detecting echoes at twice that frequency, such that one could theoretically image only the bubbles. However, in practice, soft tissues also produce harmonic echoes. Consequently, the images produced with this technique were of poor quality, in part due to poor tissue suppression.

Subsequently, another mode of imaging with microbubbles was developed using high-power colour Doppler US. When submitted to a high-energy US beam, the microbubbles often break up into much smaller bubbles that dissolve rapidly. As they are disrupted, the bubbles emit a strong, brief echo which is easily detected, a phenomenon known as stimulated acoustic emission (SAE)[9]. The drawback of this technique, however, is that the microbubbles are destroyed by the US beam and therefore real-time imaging is not feasible.

At the present time, the most common imaging technique is based on the principle of phase-inversion, in which two US pulses, 180° out of phase, are sent sequentially. The returning echoes are added up by the US machine[10]. The linear echoes returned by the tissues nullify each other, while the non-linear echoes returned by the microbubbles produce a detectable signal. There are two main advantages of this technique. First, excellent tissue suppression is obtained. Second, a detectable signal is obtained even when a very low-power US beam is employed, consequently, the bubbles are not destroyed. The first generation contrast media, such as Levovist® (Schering, AG, Berlin, Germany), produced a very weak signal when submitted to low mechanical index US beam owing to its fragility and lent itself to use with SAE[11]. Since then, contrast media, such as SonoVue® (Bracco, Milan, Italy), Definity® (Bristol-Myers-Squibb, Billerica, Mass, USA) and Optison® (Nycomed/Amersham, Little Chalfont, UK), which have a strong, non-linear, harmonic response, even when insonated with low acoustic power, were able to provide real-time imaging using low mechanical index (MI) modes[12].

In the following sections we review the common enhancement patterns of the most frequent focal liver lesions seen with the second generation contrast agents.

CONTRAST-ENHANCED US PATTERNS OF FOCAL LIVER LESIONS

The characterization of a hepatic lesion with microbubbles requires careful examination through all phases of contrast enhancement, i.e. arterial (10-20 to 25-35 s after injection), portal (30-45 to 120 s) and late parenchymal (> 120 s) phases[13]. Simply put, the late phase is useful to determine the benign or malignant nature of a lesion while the arterial phase helps in predicting its histology[14-19]. Between 86% to 93% of benign lesions retain the contrast in the late phase, while 78% to 98% of the malignant ones demonstrate wash out of the contrast[14,16,18]. The persistence of the second generation contrast agent in a healthy liver is thought to be the result of a very slow flow through the sinusoid[20]. Consequently, lesions devoid of normal sinusoids do not retain the contrast.

HAEMANGIOMAS

Haemangiomas are the most common solid benign lesion of the liver, with a prevalence ranging from 1% to 20% in the general population[21]. These lesions are more common in females and are frequently located peripherally or adjacent to a large hepatic vein branch. The most common sonographic appearance of haemangiomas is a homogeneously hyperechoic focal lesion, less than 3 cm in size[22]. These characteristic features, when present in a patient at a low risk for malignancy, are usually sufficient to allow a confident diagnosis. In a significant number of patients however, further imaging is required.

The characteristic early arterial nodular enhancement with delayed centripetal fill-in described on CT or MRI[23-25] is the most common appearance of haemangiomas during the arterial phase of contrast-enhanced US, seen in 52% to 88% of cases (Figure 1)[15,16,18,19]. Sustained enhancement has been reported in 83% to 100% during the late phase[16-19]. The real time nature of contrast-enhanced US is particularly useful in diagnosing small, rapidly perfusing (flash-filling) haemangiomas, where the typical enhancement pattern can be appreciated[6]. Complete enhancement does not always occur, especially in lesions larger than 3 cm, which often undergo central thrombosis or fibrosis[6,26,27].

FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia (FNH) is the second most common solid benign hepatic lesion, with a prevalence between 0.9% and 3%[28-30]. This lesion occurs in all age groups and both sexes, but is found predominantly in women (80%-95% of the cases) during the 3rd to 5th decade of life. Oral contraceptive use has been incriminated, but a definite relationship has not been established[31,32]. FNH is not a dysplastic or neoplastic tumour, but is a hyperplastic lesion, probably occuring in response to a pre-existing arterial malformation[33]. FNH does not have a malignant potential, nor is it likely to bleed or rupture[34]. Consequently, differentiation from other lesions, particularly hepatocellular adenoma and carcinoma (especially the fibrolamellar form), is essential since FNH is managed conservatively, whereas the other lesions require surgery. FNH is often discovered incidentally.

The most common sonographic appearance of FNH is that of a homogeneous, near isoechoic lesion; some lesions are detected only because of their mass effect on adjacent blood vessels[32]. A central hypoechoic scar is detected in 20% to 45% of the cases[22,35,36]. In larger lesions, colour Doppler may show a central feeding artery with a spoke-

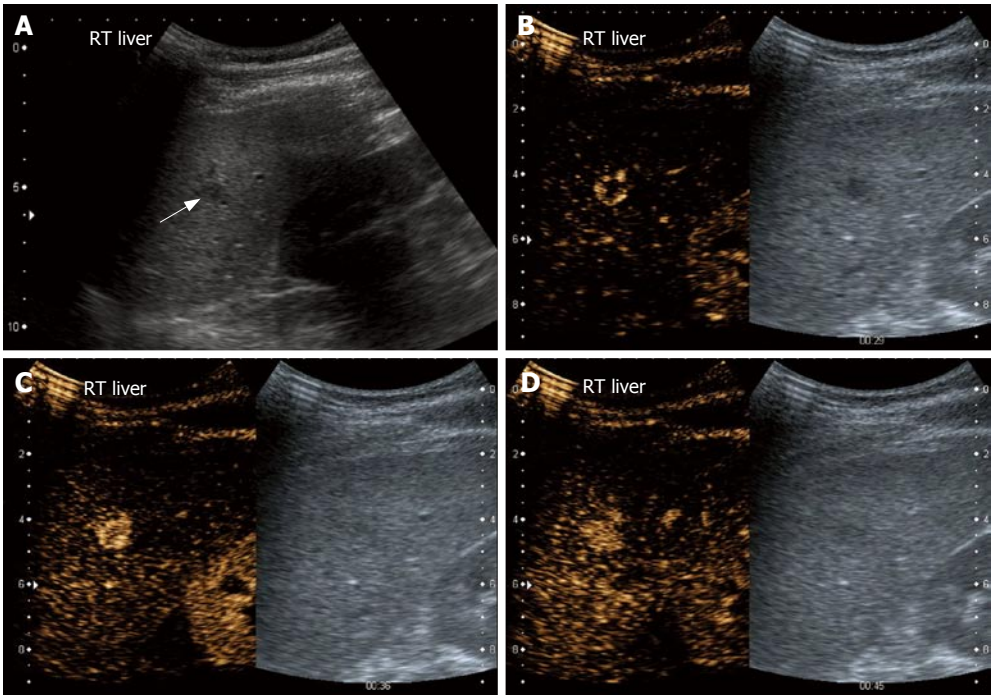

Figure 1 Haemangioma. Gray-scale US image (**A**) and split-screen display images of contrast-enhanced US scan using a low MI technique (**B-D**). The left panel shows the contrast sensitive image while the corresponding gray-scale image is on the right. On gray-scale US, the liver is hyperechoic, consistent with fatty infiltration and an ill-defined hypoechoic lesion is seen (arrow, **A**). On contrast enhanced US, the lesion demonstrates peripheral nodular enhancement during the arterial phase (**B**). At 36 s, the lesion has almost completely filled in (**C**). At 45 s, the lesion is completely enhanced (**D**) and sustained enhancement was observed in the late phase scan (not shown).

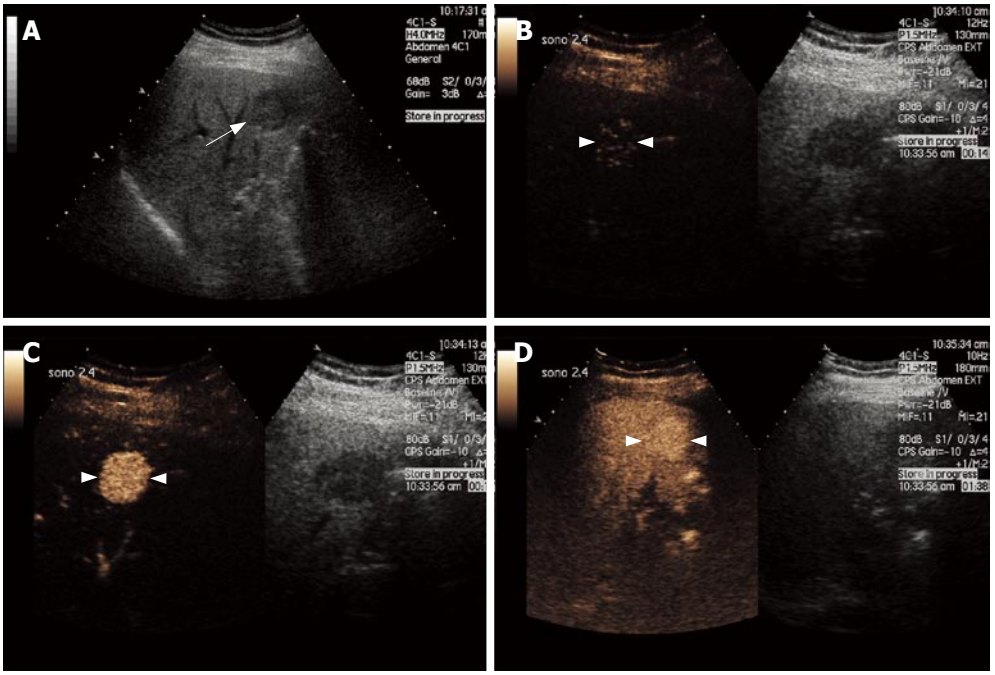

Figure 2 Focal Nodular Hyperplasia. Gray-scale US image (**A**) and split-screen display images of a contrast-enhanced US scan using a low MI technique (**B-D**). The gray-scale US image shows a focal hypoechoic lesion (arrow, **A**) in a diffusely hyperechoic liver in keeping with fatty infiltration. After contrast injection, the lesion enhances avidly in the arterial phase with filling seen from a central feeding vessel, demonstrating the classical spoke-wheel appearance (arrowheads, **B** and **C**). The lesion remains slightly hyperechoic during the portal and late phases (arrowheads, **D**).

wheel pattern of vessels radiating to the periphery.

FNH is a hypervascular tumour and consequently manifests as a strongly and homogeneously enhancing lesion during the arterial phase of contrast enhanced US in nearly 100% of the cases (Figure 2). The central spoke-wheel type of contrast enhancement can be demonstrated in 45% to 89% of FNH. These lesions become isoechoic or slightly hyperechoic, compared with the surrounding liver parenchyma during the portal and late phases of enhancement in 87% to 100% of the time[15-19,37]. The central scar is seen in 23% to 31% of cases[15,17]. However, in contradistinction to the pattern seen on CT or MRI, the central scar stands out as a defect instead of the late enhancement seen with the other imaging modalities. This finding can be explained by the fact that microbubbles are purely intravascular agents and therefore do not diffuse into the interstitium, unlike iodine and gadolinium-based contrast agents used with CT and MRI[6].

In patients with chronic liver disease, caution should be used since well-differentiated hepatocellular carcinoma (HCC) may mimic the enhancement pattern of FNH (see below). In these patients, all hypervascular lesions should be regarded with suspicion.

HEPATOCELLULAR ADENOMA

Hepatocellular adenoma (HA) is a rare, benign neoplasm of hepatocellular origin. Approximately 90% of HAs occur in young women[38]. Up to 90% of females with HA have reported the use of oral contraceptives[39]. HA is also

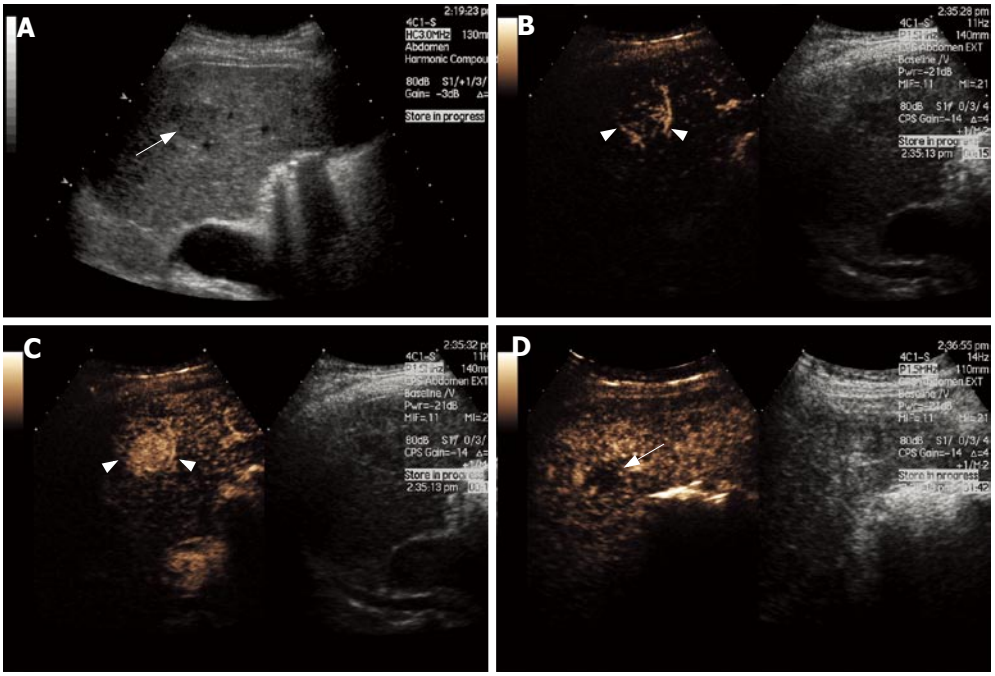

Figure 3 Hepatocellular Carcinoma. Gray-scale US image (**A**) and split-screen display images of a contrast-enhanced US scan using a low MI technique (**B-D**). The gray-scale US image shows a slightly hypoechoic lesion in segment 2 of the liver (arrow, **A**). After contrast injection, the lesion shows marked hypervascularity in the arterial phase with a basket-pattern peripheral network of vessels (arrowheads, **B** and **C**). The lesion becomes isoechoic and finally washes out to leave a defect in the late phase (arrow, **D**).

associated with the use of anabolic steroids in men and in some storage diseases[40]. In contrast to FNH, HA is a true neoplasm.

Management of HA is by surgical resection, in contrast to FNH, because of the risk of malignant degeneration and haemorrhage[41]. Patients with HA may present with pain secondary to its mass effect (40%) or intratumoral/intraperitoneal haemorrhage (40%). Alternatively, the tumour may be discovered incidentally (20%)[22].

The most common sonographic appearance of HA is a well-defined, large, solitary, hyperechoic mass owing to its high lipid content. Since the lesions have a propensity to bleed, HAs are usually heterogeneous in appearance. Colour Doppler findings are non-specific. The typical spoke-wheel pattern of FNH is absent.

The contrast-enhanced US characteristics of HA are relatively non-specific, but these lesions usually enhance during the arterial phase. Smaller lesions are likely to show homogeneous enhancement whereas the larger ones will be heterogeneous owing to previous intratumoral haemorrhage or necrosis. In one study with Sonovue, HAs were iso- or more often hypoechoic in comparison with the surrounding liver parenchyma in the portal venous and late phases of enhancement[37]. Unfortunately, this pattern of enhancement is not unique to HA, as it is also a common appearance of HCC on contrast-enhanced US (see below). In some cases, even the histopathological differentiation of HA from well-differentiated HCC is difficult[42]. The differential diagnosis should include hypervascular metastases which can exhibit similar enhancement characteristics.

HEPATOCELLULAR CARCINOMA

HCC is the most common primary malignancy of the liver. It usually occurs in patients with chronic liver disease, particularly in those with chronic hepatitis B and C infection where the risk is approximately 100 times that of patients with cirrhosis of other aetiologies. Men are affected three times more frequently than women[43]. Early detection is crucial for curative treatment, since patients with small HCC (< 2 cm) who are treated with liver transplantation have a survival rate of about 80%[44], whereas the 5-year survival of untreated HCC is less than 5%.

The gray scale US appearance of HCC is variable and non-specific. Hyperechoic foci related to the presence of fibrosis, haemorrhage and necrosis are found in approximately 50% of large HCCs[22]. On colour Doppler, approximately 75% of HCCs have a fine peripheral network of vessels, surrounding and penetrating the lesion (the so-called basket pattern)[45]. Non-invasive imaging diagnosis of HCC is often based on CT or MRI detection of a hypervascular mass in a patient with chronic liver disease because of the lack of specificity of conventional US.

With the use of contrast-enhanced US, more than 90% of HCCs behave like other hypervascular lesions and enhance avidly during the arterial phase (Figure 3)[15,17-19]. The basket pattern is reportedly seen in about one-third of the cases[19]. Also, like other malignant lesions, the majority (83% to 97%) of HCCs washout the contrast and appear as a defect during the late phase. However, caution should be used since well-differentiated HCCs may not show this washout very reliably. Moreover, it has been observed that the more differentiated a lesion, the more slowly it is likely to washout[46]. Consequently, in a patient with known chronic liver disease, a hypervascular lesion in the arterial phase should not be considered as benign on the sole finding of persistent enhancement during the portal and late phases.

METASTASES

The liver is a frequent site of metastases of extrahepatic tumours, and metastatic disease is one of the most common indications for imaging the liver. The gray-scale sonographic appearances of metastases are varied

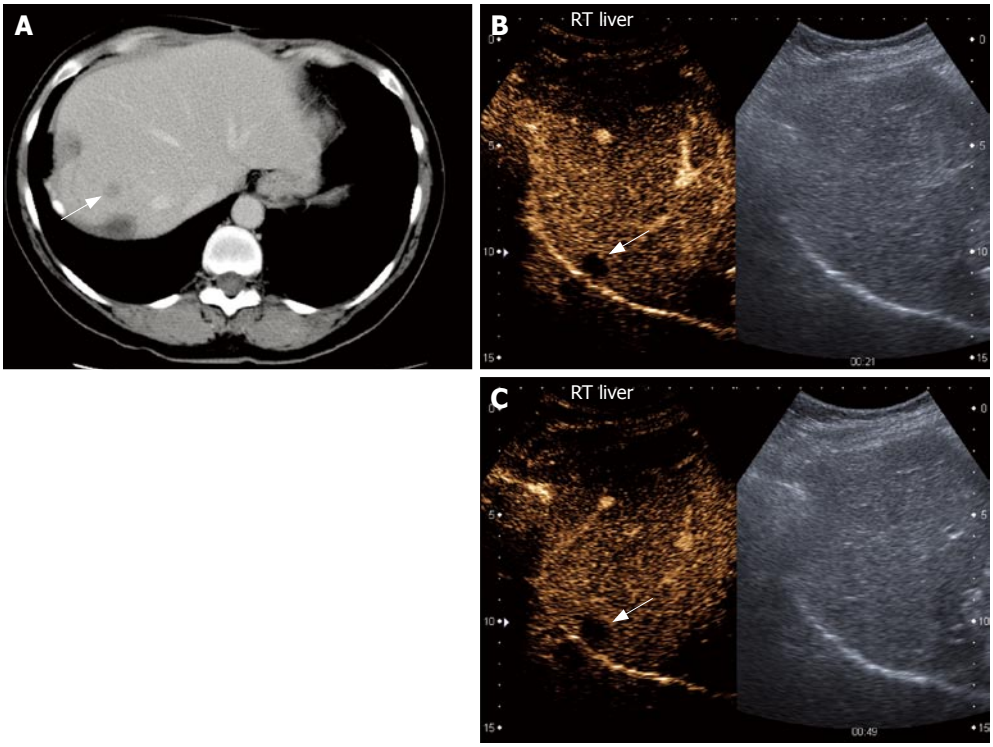

Figure 4 Liver metastasis in a patient with known metastatic colon carcinoma. The patient previously had liver resection and radiofrequency ablation. Contrast-enhanced CT scan image (**A**) and split-screen display images of a contrast-enhanced US scan using a low MI technique (**B** and **C**). On CT, a 1cm lesion is seen in segment 8 (arrow, **A**). The lesion was not visualized on gray-scale US. After injection of microbubbles, a 1 cm hypoechoic rounded lesion is seen as a defect in all the phases of enhancement (arrow, **B** and **C**). These findings are suspicious for a metastatic deposit.

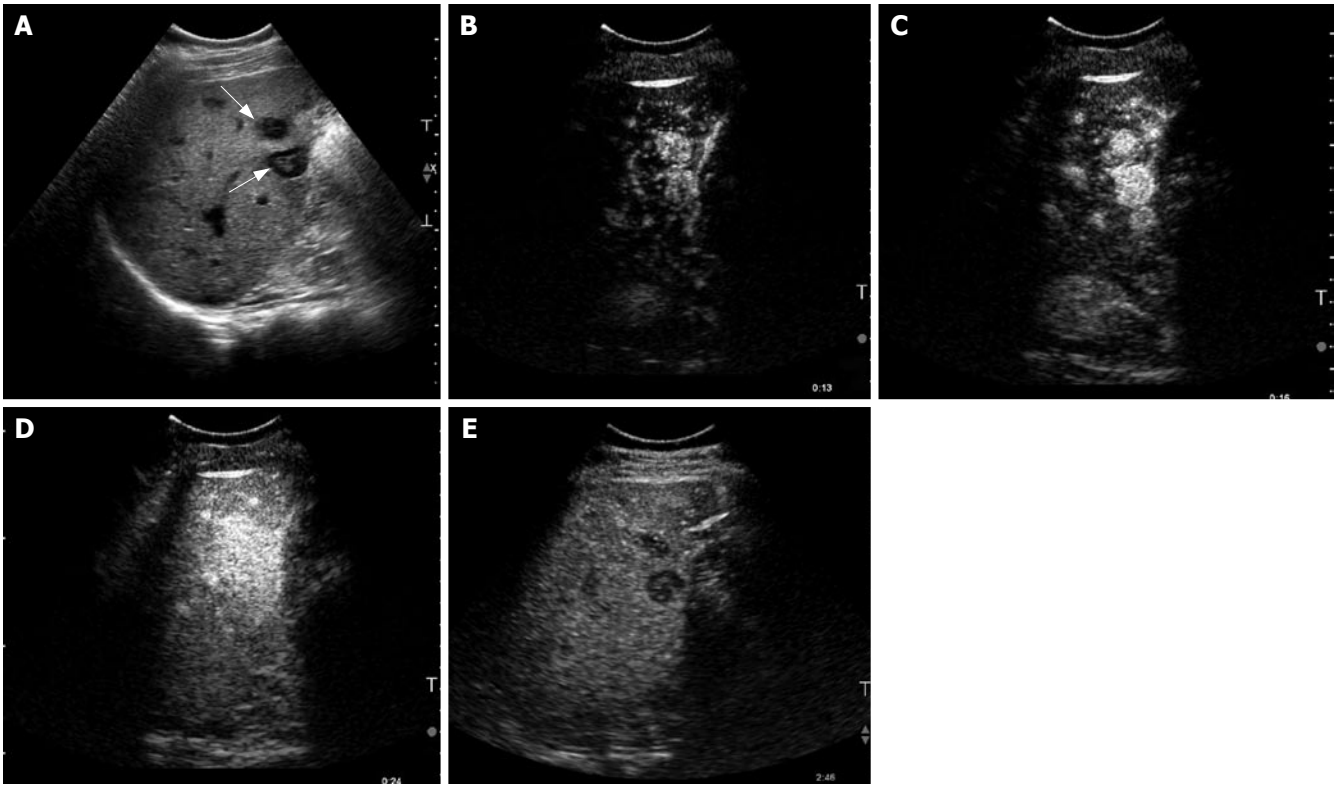

Figure 5 Hypervascular metastases in a patient with a known carcinoid tumour. Gray-scale US image (**A**) and contrast-enhanced US scan images (**B**-**E**) using a microbubble sensitive technique. On the gray-scale image, two hypoechoic target-like lesions are seen (arrows, **A**). After microbubble enhancement, an avid uptake of the contrast medium was seen in the early phase (**B**-**D**). The contrast washed out in the later phases leaving the metastases as defects (**E**).

depending on several factors such as the histology of the primary tumour and the treatment received by the patient. In a patient with a known malignancy with interval development of hepatic masses, the diagnosis is straightforward and characterisation is not an issue. However, when there is no history of malignancy or no previous imaging for comparison, characterisation becomes essential.

The accuracy of US for the assessment of liver metastases is lower than that of CT or MRI[47]. However, the use of first generation US contrast media, improved significantly the sensitivity for the detection of liver

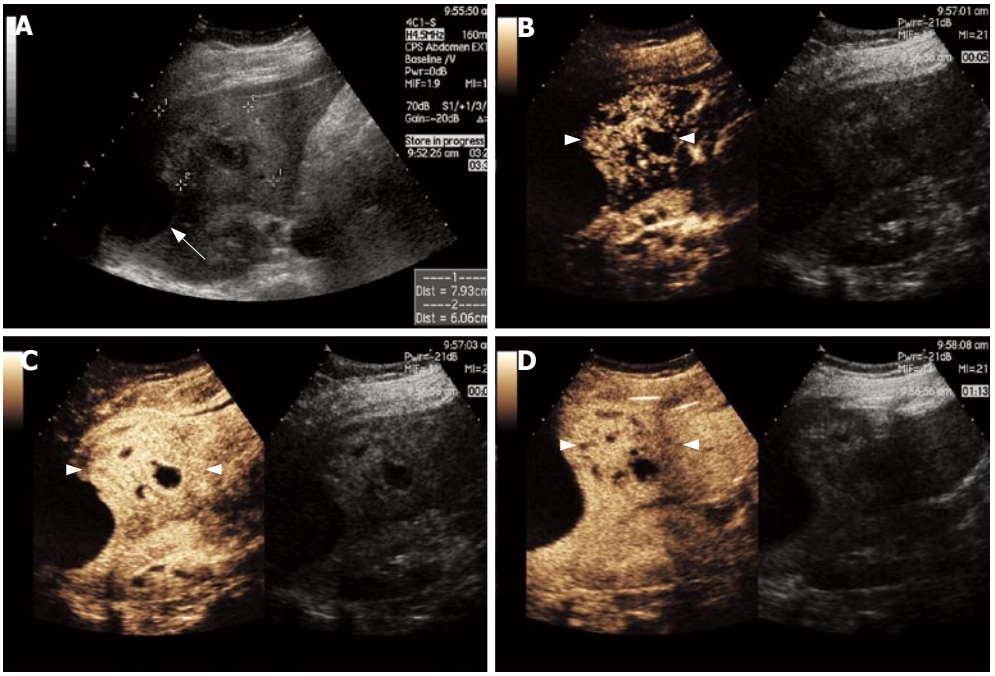

Figure 6 Hepatic abscess. Gray-scale US image (**A**) and split-screen display images of a contrast-enhanced US scan using a low MI technique (**B**-**D**).The gray-scale image shows an ill-defined heterogeneous mass in the left lobe of the liver (between callipers, **A**). A subcapsular anechoic fluid collection is also seen (arrow, **A**). After microbubble injection, regional hypervascularity during the arterial phase is shown (arrowheads, **B**-**D**). The abscess appears as a cluster of non-enhancing collections separated from each other by enhancing septations (**B** and **C**). In the late phase scan (**D**), there is no enhancement of the fluid collections and no wash out of the enhancing portions.

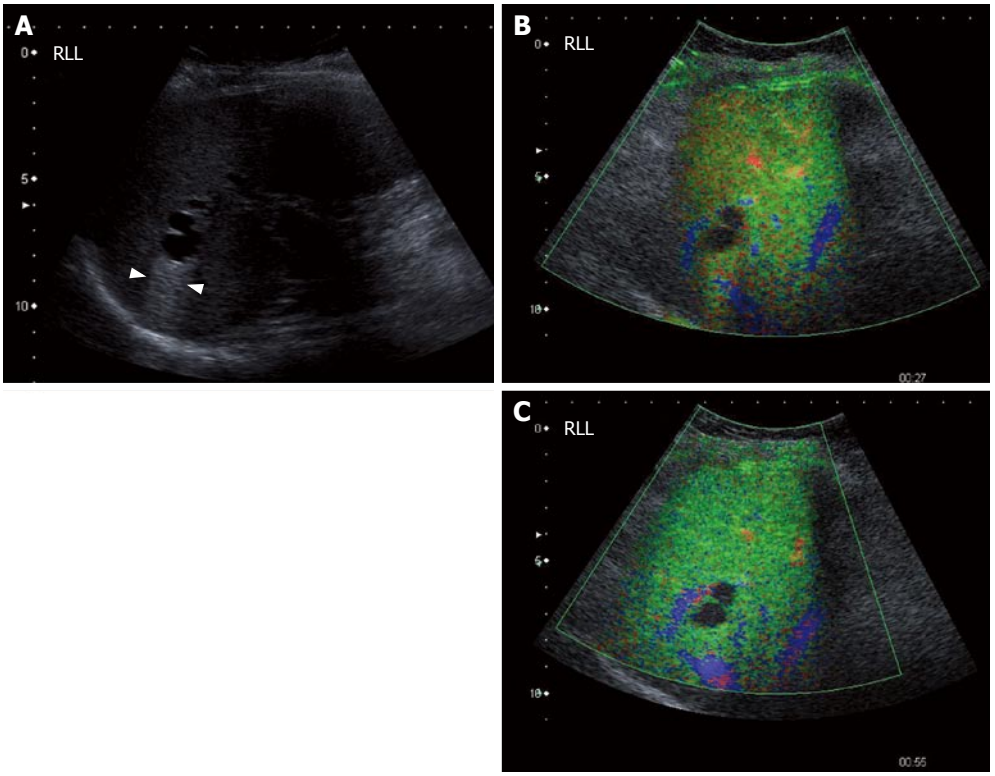

Figure 7 Potential pitfall: simple cysts. Gray-scale US image (**A**) and contrast-enhanced US scan images using a low MI technique (**B** and **C**). The gray-scale image (**A**) shows a typical simple hepatic cyst which is completely anechoic, has a thin wall and posterior acoustic enhancement (between arrowheads, **A**). After microbubble injection, no enhancement of the cyst is seen throughout all phases of enhancement (**B** and **C**). The diagnosis is straightforward if the lesion was recognised prior to contrast injection. If not, it may be misinterpreted as an enhancement defect and be categorized as a malignant lesion.

metastases[48]. It has been proposed by the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) that any US staging study of the liver should be contrast enhanced, although the cost and feasibility of such a recommendation remains a big hurdle[13].

On contrast-enhanced US, metastases show different patterns of enhancement during the arterial phase, depending upon the vascularity pattern of the primary tumour. Regardless of their behaviour during the early phase, metastasis consistently show rapid and complete contrast washout and appear as enhancement defects on late phase scans (Figure 4)[15-17,19]. Recent publications have shown that, with the second generation US contrast media, the vast majority (> 85%) of metastases show some arterial enhancement, often more pronounced in the periphery[15,16,19,49]. This phase of hypervascularity is often not recognized on multiphasic CT or MRI because it is very brief and the lesion starts to washout within 20 s of the injection in most cases, before the arterial phase of CT and MRI, which is around 40 s from the beginning of the injection. The arterial enhancement may be rim-like,

diffuse or mosaic-like. Rim-like enhancement and early and complete washout of the lesion are typical of metastasis, while complete enhancement with a later washout is most suggestive of a HCC. However, when a hypervascular metastasis shows complete enhancement (Figure 5), differentiation from HCC is difficult and correlation with the clinical history and alpha-fetoprotein is often helpful.

OTHER MALIGNANT LESIONS

Other primary malignant lesions of the liver, such as intra-hepatic cholangiocarcinoma and lymphoma, show the typical behaviour of malignant lesions and washout contrast rapidly and appear as defects on the portal and late phases.

Cholangiocarcinoma frequently enhances during the arterial phase[40,49]. The rapid washout of this lesion observed on contrast-enhanced US is discordant with the typical behaviour of the lesion seen on CT and MRI (hypoenhancement with mild peripheral centripetal progression of enhancement over time)[50]. Again, this may be explained by the fact that microbubbles are purely intravascular agents. Some gray-scale features may help in differentiating cholangiocarcinoma from other abnormalities such as biliary duct dilatation.

ABSCESS

Liver abscesses result from bacterial, amoebic or fungal infections. Pyogenic abscess are by far the most frequent (88%)[22]. The gray-scale US findings of pyogenic abscesses vary with the stage of the disease. During early disease, the shape of the lesion is usually irregular and the echogenicity is variable. As the abscess matures the lesion becomes more rounded and hypoechoic, with debris in the middle and thick walls on the outside. Since an abscess is a fluid-filled lesion, there is usually associated posterior enhancement. Internal septations are seen commonly. Bright punctate echoes with "dirty" shadowing are present if there is gas within the cavity.

On contrast-enhanced US, pyogenic hepatic abscesses show areas of increased enhancement relative to the surrounding parenchyma[51]. Mature lesions with fluid show an enhancing rim. The internal septations also show enhancement giving the lesion a honeycomb appearance. Early (solid-appearing) lesions usually enhance diffusely, but heterogeneously. The enhancement appears early and usually persists during the portal and late phases (Figure 6), with no contrast enhancement seen in the liquefied portions. In the arterial phase, a transient peri-lesional enhancement has been reported. In a minority of cases, this is followed by portal venous phase hypovascularity[51]. The main differential diagnosis for a hepatic abscess is a necrotic metastasis. The latter would appear as a punched-out enhancement defects in the late phase, while the former appears as an ill-defined area of decreased enhancement, although, as stated above, this is not a common finding.

LIVER CYSTS

Liver cysts are common incidental findings on liver US. The diagnosis is straightforward when their pathognomonic features (anechoic, thin-walled and posterior enhancement) are present on gray-scale US.

Liver cysts are mentioned in this review because, on contrast-enhanced US, these lesions represent a potential pitfall if they have not first been recognized on gray scale US, since their gray-scale appearances are essential for characterisation. Liver cysts present as enhancement defects on all phases of contrast-enhanced US scan (Figure 7) and can be erroneously mistaken as malignant lesions.

CONCLUSION

The introduction of second generation microbubble US contrast media has allowed real-time imaging of a liver lesion in every phase of enhancement. The ability to observe the complete pattern of enhancement of a lesion has improved significantly the specificity of US for focal liver lesions, and rivals that of CT and MRI, thus reducing the need for further investigations. As a screening tool, US is ideal owing to its relative accessibility and portability. Microbubble agents have extended the utility of US further and are applicable to most imaging departments worldwide.

Abstract

The role of endoscopic therapy in the management of pancreatic diseases is continuously evolving; at present most pathological conditions of the pancreas are successfully treated by endoscopic retrograde cholangio-pancreatography (ERCP) or endoscopic ultrasound (EUS), or both. Endoscopic placement of stents has played and still plays a major role in the treatment of chronic pancreatitis, pseudocysts, pancreas divisum, main pancreatic duct injuries, pancreatic fistulae, complications of acute pancreatitis, recurrent idiopathic pancreatitis, and in the prevention of post-ERCP pancreatitis. These stents are currently routinely placed to reduce intraductal hypertension, bypass obstructing stones, restore lumen patency in cases with dominant, symptomatic strictures, seal main pancreatic duct disruption, drain pseudocysts or fluid collections, treat symptomatic major or minor papilla sphincter stenosis, and prevent procedure-induced acute pancreatitis. The present review aims at updating and discussing techniques, indications, and results of endoscopic pancreatic duct stent placement in acute and chronic inflammatory diseases of the pancreas.

Key words: Chronic pancreatitis; Pancreas divisum; Pancreatic pseudocyst; Pancreatic fistulas; Idiopathic recurrent pancreatitis; Main pancreatic duct stenting; Pancreatic dorsal duct stenting

INTRODUCTION

The role of endoscopic therapy in the management of pancreatic diseases is continuously evolving; at present most pathological conditions of the pancreas are successfully treated by endoscopic retrograde cholangio-pancreatography (ERCP) or endoscopic ultrasound (EUS), or both. After the initial courageous experimental therapy tested in a few centers, pancreatic endotherapy has become an evidence-based method for carefully selected patients; because of the high level of technical skill required and the small numbers of patients who need this approach, pancreatic endotherapy should ideally only be carried out in selected centers where a multidisciplinary team is available.

Endoscopic placement of stents has played and still plays a major role in the treatment of chronic pancreatitis, pseudocysts, pancreas divisum, main pancreatic duct injuries, pancreatic fistulae, complications of acute pancreatitis, recurrent idiopathic pancreatitis, and in the prevention of post-ERCP pancreatitis. These stents are currently routinely placed to reduce intraductal hypertension, bypass obstructing stones, restore lumen patency in cases with dominant, symptomatic strictures, seal main pancreatic duct disruption, drain pseudocysts or fluid collections, treat symptomatic major or minor papilla sphincter stenosis, and prevent procedure-induced acute pancreatitis.

On the assumption that intraductal hypertension caused by obstructive lesions of the main pancreatic duct (MPD) is one cause of the pain often present in either chronic or acute pancreatic diseases, stent insertion beyond the obstruction to decompress the hypertension has a pivotal role in their therapeutic management.

The present review aims at updating and discussing the role of endoscopic pancreatic duct stent placement in acute and chronic inflammatory diseases of the pancreas.

TECHNIQUE OF PANCREATIC STENT PLACEMENT

The technique employed for placing pancreatic stents is similar to that used to place stents in the biliary tract. Once the main or accessory pancreatic duct has been deeply cannulated, a hydrophilic 0.035" (for 5F, 7F, 10F stents) or 0.018" (for 3F stents or when the minor papilla is cannulated) guidewire is introduced into the duct and maneuvred if possible beyond the stricture or leakage. The stent is then introduced over the guidewire (Figure 1). Stents can be placed with or without pancreatic sphincterotomy; pancreatic sphincter can be ablated by using the standard sphincterome in a single step procedure or after biliary sphincterotomy. The multiple step procedure is more time consuming but permits to better control the section of the

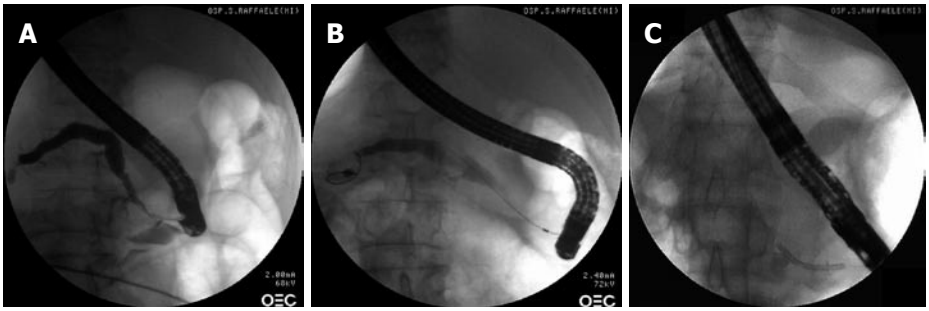

Figure 1 Chronic obstructive pancreatitis involving the head of the gland. **A**: Pancreatography showing a distal stricture of the main pancreatic duct; **B**: Insertion of the guidewire into the main pancreatic duct; **C**: Placement of a 10F plastic stent over the guidewire.

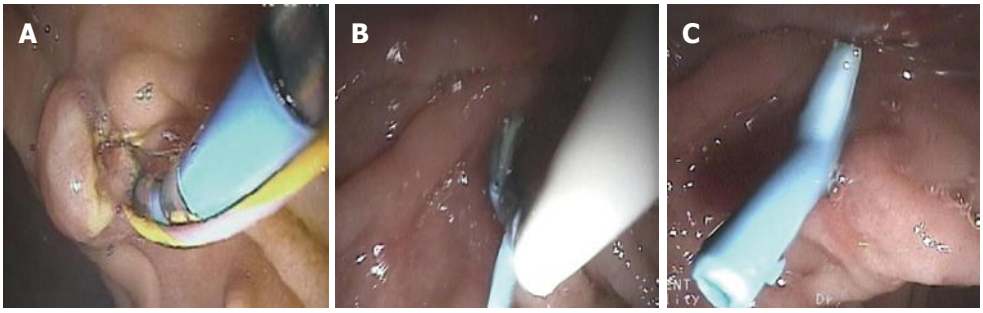

Figure 2 Placement of a pancreatic stent after pancreatic sphincterotomy. **A**: Once biliary sphincterotomy has been performed leaving a guidewire into the common bile duct, pancreatic sphincter ablation is done with the standard sphincterotome; **B**: A plastic stent is then pushed over the guidewire into the main pancreatic duct; **C**: Pancreatic stent in place.

sphincter so it is generally my preferred approach (Figure 2).

Pancreatic stents are generally made of polyethylene and are similar to biliary stents except for side holes along their length to allow flow from side branches. To prevent migration into the pancreatic duct, small-diameter stents have a J or "pig-tail" shape. For transpapillary stenting of a pseudocyst, a double pig-tail stent should be used to prevent displacement outside the cyst cavity. Recently, an S-shaped stent with many side holes has been proposed for MPD stenting in chronic pancreatitis[1]; this stent is made of ethylene vinyl acetate, which is more flexible than polyethylene. The S-shape enables the stent to adapt better to the course of the MPD and reportedly achieves a better outcome in patients with chronic pancreatitis and upstream duct dilatation than in patients treated with the standard straight polyethylene stents (Figure 3).

The diameter of the stent should not exceed the size of a normal downstream duct, so 5F and 7F stents should be used in cases with non-dilated ducts, while 10F and sometimes 11.5F can be used when the ducts are dilated, as in advanced chronic pancreatitis. Sometimes in advanced chronic disease the stricture is too tight to place a stent across it; in these cases the stricture must be dilated with a balloon or bouginage to permit insertion. In some cases the Soehendra stent retriever (5F or 8F) can be used to dilate the stricture and allow insertion.

How long stents are best left in place is not yet known. Pancreatic stents have been left in place for six months and long-term therapy requires multiple stent exchange. However, the duration of a single stent placement depends on the stent diameter: the larger the diameter, the longer the stent can be left in place.

CHRONIC PANCREATITIS

In chronic pancreatitis the MPD may be partially occluded by strictures or stones; the rise of intraductal pressure in the ductal segment above the obstruction causes dilation and obstructive pain. Pancreatic intraductal hypertension occurs regardless of the etiology and whether or not the MPD is dilated; ductal and interstitial hypertension, together with reduced acinar blood flow, may further contribute to the formation of fibrosis and progression toward more severe damage[2]. Removing the barriers to outflow of pancreatic juice may relieve chronic pain or exacerbation of chronic pancreatitis. Obstruction-related reduced outflow of pancreatic juice into the duodenum may also cause mal-digestion of nutrients even in cases with still conserved pancreatic enzyme secretion, or worsening of mal-digestion already present in advanced cases.

Although pancreatic ductal strictures can be treated by catheter or balloon dilation alone, a stent usually has to be inserted because stricture relapse is commonplace. Insertion of a stent beyond the ductal blockage achieves lasting relief of the intraductal hypertension and subsequent pain and possible mal-digestion, also restoring the lumen patency, by dilating the stricture. If a 10F stent or larger is used, the patient generally requires sphincterotomy of both the pancreatic and biliary segments of the sphincter, followed by stricture dilation (Figure 4).

The presence of both obstruction and ductal dilation is vital for predicting which patients are most likely to benefit

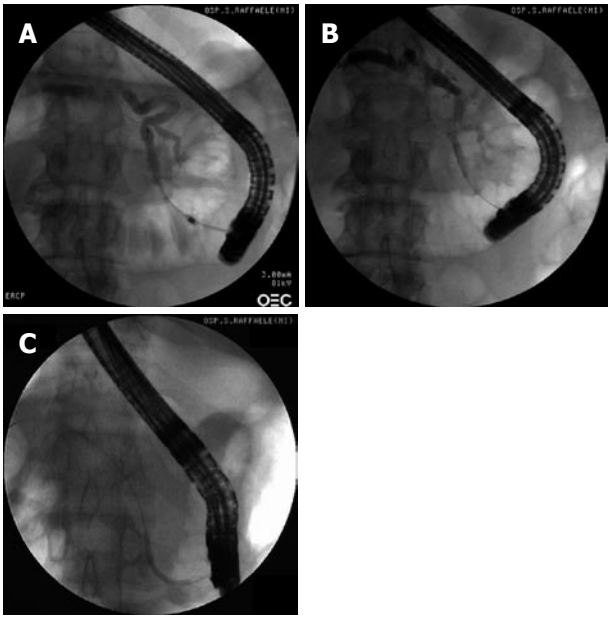

Figure 4 Symptomatic, chronic obstructive pancreatitis at early stage with moderate dilation of the main pancreatic duct. **A**: Mechanical dilation of the pre-papillary stricture by a 10F dilator; **B**: Insertion of the guidewire; **C**: Insertion of a plastic 10F stent throughout the dilated stricture over the guidewire.

from stricture therapy: the best candidates for stenting are those with a distal stricture and upstream dilation (Figure 5).

Most investigators and recent guidelines from the American Society for Gastrointestinal Endoscopy consider endoscopic management to be the preferred interventional approach for chronic pancreatitis in patients selected on the basis of anatomical changes caused by the disease; endoscopic treatment is generally safe, minimally invasive, can be repeated, and does not interfere with eventual surgery[3,4]. Other investigators, however, found surgery superior to endotherapy for long-term pain reduction. Dite *et al*[5], in a prospective randomized trial comparing endoscopic and surgical therapy for chronic, painful, obstructive pancreatitis, reported complete resolution of pain at the five-year follow-up in 37% of patients after surgery and in 14% of those after endotherapy; short-term results were similar in the two groups. Similar data have been recently published by Cahen *et al*[6].

The technical success of endoscopic stricture manipulation can range from 80% to 100% of patients with or without prior pancreatic sphincterotomy. In chronic pancreatitis patients with dominant stricture, pain relief was obtained in 52%-95% of cases over a follow-up ranging from 8 to 72 mo[1,7-19]. Stenting was also associated with weight gain and fewer hospital visits. Good clinical outcomes were related to cessation of alcohol consumption and/or smoking[15]. Early complications were reported in about 17% of cases and were related mainly to pancreatic and/or biliary sphincterotomy, stent clogging (juice infection) and inward migration.

It is not clear how long stents should best be left in place. Although the plastic 10F stents are thought to remain clinically patent for a year on average, generally they are removed and replaced every 6-9 mo. In fact, stent dysfunction leading to pancreatitis, recurrent pain or infection can occur before the scheduled exchange time in about half the cases, so repeated stent exchange is required in the long term. This may make it difficult to ensure compliance with long-term stenting treatment.

Despite encouraging medium- and long-term results, duct stricture may persist or recur after removal of a stent so definitive removal seems impracticable in a subset of patients, because of the recurrence of pain. In an intention-to-treat analysis, a German multicenter study on long-term outcomes in 1000 patients with chronic pancreatitis after pancreatic stenting reported unsatisfactory results in 35%; 16% of these patients continued with endotherapy and 24% opted for surgery[11].

A multiple stenting approach was proposed by Costamagna *et al*[20] in a subset of patients with refractory dominant MPD strictures: they reported lasting stricture dilation in 84% of their patients at 38-mo follow-up. Although placing a mean of three stents within pancreatic strictures may be difficult, this approach appears feasible and safe and could in fact dramatically reduce the need for surgery in the majority of patients with chronic obstructive pancreatitis (Figure 6).

Self-expandible metal stents have been proposed for patients with relapsing dominant strictures to achieve long-term stent patency and avoid the need for stent exchange[21]. The success rate of stent placement was 100% and patients enjoyed immediate relief of symptoms and reduction of duct diameter; however, during follow-up these patients have had high occlusion rates of the stent from mucosal hyperplasia, and it becomes impossible to remove the stent, so this approach has in fact been abandoned.

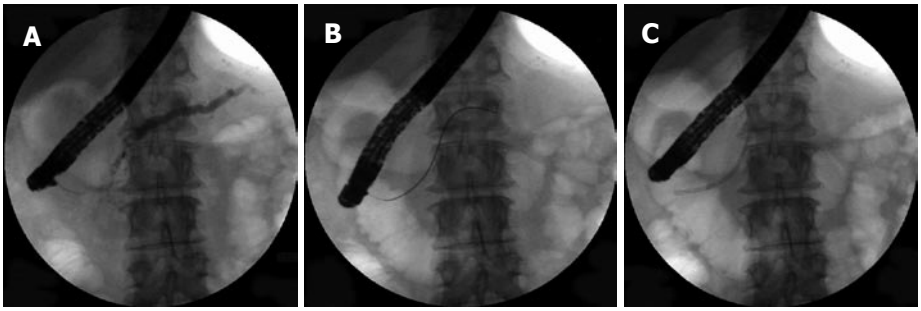

Figure 7 Pancreas divisum with chronic obstructive pancreatitis at early stage. **A**: Extensive dorsal duct stricture with moderate upstream dilation of the pancreatic duct; **B**: Guidewire insertion into the dorsal duct throughout the minor papilla, without sphincterotomy; **C**: 7F plastic stent in place. Long-term stenting rather than minor papilla sphincterotomy appears an appropriate approach in this case with extensive dorsal duct stricture.

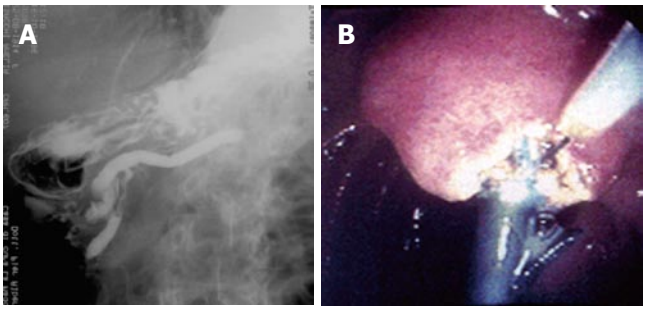

Figure 8 Chronic obstructive pancreatitis in incomplete pancreas divisum. **A**: Minor papilla stenosis associated with diffuse upstream dilation of the pancreatic duct and normal parietal morphology; **B**: Minor papilla sphincterotomy over-the-stent performed with a needle-knife sphincterotome. Minor papilla sphincterotomy rather than long-term stenting appears an appropriate approach in this case with stricture located at the level of the minor papilla.

PANCREAS DIVISUM

Pancreas divisum is present in about 7% of the population; it occurs when the ventral and dorsal ducts of the gland fail to fuse during embryological development. This anatomical variant is asymptomatic in the majority of cases but in some cases it may cause pancreatic pain due to functional obstruction at the level of the minor papilla or recurrent episodes of acute pancreatitis; persistence of the obstruction over time may lead to chronic obstructive pancreatitis. Kamisawa *et al* reported acute recurrent pancreatitis and chronic pancreatitis associated with pancreas divisum in respectively 17.1% and 28.6% of their patients[22].

Endoscopic therapy with minor papilla sphincterotomy and/or stent placement appears to be the treatment of choice at present. Critical issues concerning endotherapy in pancreas divisum are patient selection, difficulty of papillary cannulation, technique for endotherapy (minor papilla sphincterotomy or dorsal duct stenting, or both), stent-induced duct injury, and risks of post-ERCP pancreatitis. Patients with acute recurrent pancreatitis are the best candidates for endotherapy as in this group the predicted sustained response rate is around 75%; the response rate in patients with chronic pancreatitis is 40%-60%, whereas patients with recurrent or chronic abdominal pain respond poorly (20%-40%)[23].

The minor papilla is often difficult to visualize, but its orifice can be easily identified by spraying methylene blue over the duodenal mucosa in the papillary area or injecting it directly into the ventral duct, in cases with incomplete pancreas divisum[24], or by EUS[25], or by enhancing pancreatic secretion with i.v. secretin[26].

Endotheraphy of pancreas divisum includes minor papilla sphincterotomy and dorsal duct stenting with 5F, 7F and 10F stents, depending on the level of obstruction and degree of dilation (Figure 7 and Figure 8). Dorsal duct stenting without sphincterotomy was adopted by McCarthy *et al*[27], Lans *et al*[28] and Ertan[29], who reported satisfactory long-term results in respectively 89%, 90% and 76% of cases. However, Heyries *et al* reported more favorable long-term results with minor papilla sphincterotomy than with stenting[30]; they also observed fewer complications after sphincterotomy (25%) than after stenting (44%). More recently however, 45% of patients with chronic pancreatitis associated with pancreas divisum, undergone successful dorsal duct stenting and followed for a median period of 59.6 mo, required surgery after stent removal because of recurrence of symptoms[31]. Of course, stenting is the only option in cases with dorsal duct strictures proximal to the papillary orifice. A strategy of empiric 3-6 mo dorsal duct stenting may be adopted in patients with recurrent pain or pancreatitis with non-dilated dorsal duct or normal minor papilla motor function, investigated by manometry or MRCP and secretin test, in order to decide whether sphincterotomy would be appropriate. This approach in patients with non-pathological duct morphology, however, could lead to ductal changes consistent with chronic pancreatitis in about one third of cases.

PANCREATIC PSEUDOCYST WITH DUCTAL COMMUNICATION

Pseudocysts complicate acute and chronic pancreatitis in up to 20% of cases; approximately 50% of pseudocysts regress spontaneously within 6 to 12 wk. Pseudocysts that are symptomatic, or become larger on follow-up imaging, or are associated with complications, require a drainage procedure. The pseudocyst communicates directly with the MPD in up to 40%-66% of cases[32]. Pseudocysts with ductal communication can only be resolved by duct drainage[33]. This can be achieved during ERCP by a trans-papillary approach, thus avoiding the usual risks (bleeding and perforation) of endoscopic cysto-gastrostomy or cysto-duodenostomy, especially when endoscopic ultrasound (EUS) guidance is not available. Trans-papillary 5F, 7F or 10F stents can be placed beyond the strictured segment of the MPD but not into the pseudocyst in cases with duct strictures downstream of the pseudocyst, or

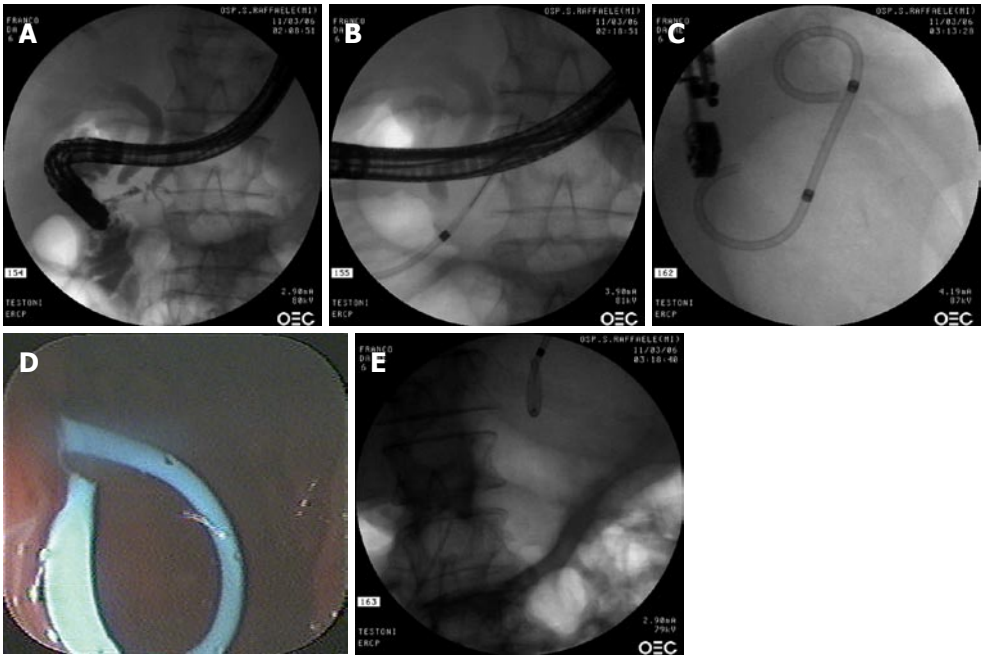

Figure 9 Large pancreatic pseudocyst communicating with the main pancreatic duct: combined endoscopic trans-papillary and trans-gastric drainage. **A**: Contrast injection into the MPD shows a stricture of the main pancreatic duct at the level of the cyst; **B**: After pancreatic sphincterotomy, the stricture is dilated, a guidewire is inserted into the cyst cavity, and a plastic stent is placed; **C** and **D**: Under EUS guidance, a double pig-tail plastic stent is also placed by a single step procedure; **D**: X-ray imaging shows trans-papillary and trans-gastric stents at the end of the procedure.

directly into the pseudocyst cavity if no MPD strictures are found[34], or into the MPD bridging the communication between the duct and the cyst cavity. When the stent is placed directly in the pseudocyst cavity, a double pig-tail stent should be preferred to avoid the risk of displacement. In the presence of a large and symptomatic pseudocyst, MPD drainage is generally associated with a trans-parietal drainage in order to achieve a more rapid decompression of the cyst cavity and resolution of symptoms (Figure 9). EUS-guided pseudocyst drainage has become popular in recent years because it has many advantages compared to the endoscopic approach[35]. Bulging is not required; ultrasound guidance permits assessment of the optimal area to access vascular structures, cyst content and communication with the main pancreatic duct (Table 1). Pseudocyst drainage is feasible even if the distance between the cyst and G.I. lumen exceeds one cm, and the procedure may be performed in a single step.

Stents should be changed routinely every 6-8 wk, to avoid clogging and the risk of infection or pancreatitis.

Features predictive of a successful trans-papillary approach are MPD dilation upstream of the ductal stricture when the stent is placed across the stricture and a non-dilated pancreatic duct when the stent is placed to bridge the communication of the cyst with the pancreatic duct. Placing a stent in the pseudocyst in a case with non-dilated MPD is associated with a higher risk of pancreatitis.

PANCREATIC FISTULAS

Fistulas can occur as a consequence of partial or complete rupture of the pancreatic duct caused by trauma, pancreatic surgery, or complicating severe acute pancreatitis. During an attack of acute severe pancreatitis, ERCP found a pancreatic duct leak in 37% of cases and this was significantly associated with a higher incidence of necrosis and longer hospital stay[36]; the early recognition and treatment of such leaks and eventually associated fluid collections is likely to improve outcomes[37].

At present, the diagnostic approach to pancreatic fistulas and suspected pancreatic duct leaks should be MRCP with secretin stimulation, leaving ERCP and EUS only for therapeutic purposes, once the lesion has been identified and staged. Before planning endoscopic treatment of fistulas or duct leaks several points must be clarified: the location of the lesion within the pancreatic ductal system, the presence and type of pancreatic duct strictures downstream of the lesion, whether pancreatic duct disruption is complete or incomplete, whether there is any communication with a fluid collection, and its anatomical characteristics.

Fifteen years ago Kozarek *et al* reported that bridging a pancreatic duct leakage by trans-papillary stent placement was effective for either internal or external pancreatic fistulas[38]. Transpapillary stenting of the MPD has now become the "gold standard" for the treatment of fistulas and duct leaks, with success rates ranging from 55%[39] to 100%[40], although higher than 80% in most series (Figure 10 and Figure 11). Telford *et al* reported that the position of the bridging stent was the only variable related with a good outcome (92%), while stents placed at the level of

Figure 10 Main pancreatic duct disruption with pancreatic juice leakage (**A**) successfully treated by plastic stent insertion bridging the leak (**B**).

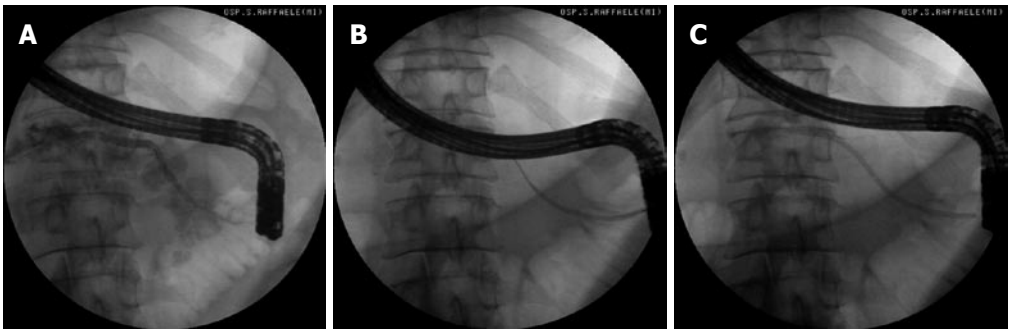

Figure 11 Pancreatic duct leakage at the level of the tail of the gland, following surgical resection of neuroendocrine tumor. **A**: The leakage site is identified by contrast injection into the main pancreatic duct; **B** and **C**: Over a guidewire, a long plastic stent is inserted at the level of the tail of the gland.

the leakage or distally were more often associated with approximately 50% of failures[41]. A partially disrupted MPD, the location of the disruption at the level of the body of the pancreas, the stent positioned to bridge the disruption, and a longer duration of stent therapy were identified as predictors of a favorable outcome in the endoscopic management of duct disruption on a large series of patients[39]. The stent should be left in place for four to six weeks. A shorter period of stenting may involve a higher rate of failure[41], while a longer period may increase the risk of stent occlusion and stent-induced alterations in ductal morphology.

SMOLDERING PANCREATITIS AND IDIOPATHIC RECURRENT PANCREATITIS

"Smoldering" pancreatitis refers to a syndrome in which patients recovering from acute pancreatitis suffer from unremitting abdominal pain, intolerance of food, persistently elevated serum levels of pancreatic enzymes, and persisting inflammatory changes in and around the pancreas at imaging studies. Functional obstruction of the papillary orifice, induced by edema or sphincter spasm, and inflammation-related fibrotic strictures of the MPD may account for the unremitting course in a subset of patients with smoldering pancreatitis. In these cases, insertion of a stent into the MPD provided permanent relief of pain in 91% of patients within a mean of nine days (range 3-20 d) and discontinuation of parenteral nutrition within a mean of 15 d (range 7-39 d); the stents were left in place for a mean of seven weeks (range 2-19 wk)[42].

Today the etiology of acute pancreatitis remains undefined in 2%-30% of cases, despite a careful diagnostic work-up including imaging techniques for pancreatic morphology (CT scan, MRCP, EUS), functional investigation of the sphincter of Oddi (manometry, secretin test), and tests for gene mutations and autoimmune disorders. In these cases the term "idiopathic pancreatitis" is generally adopted and the failure to identify the cause predisposes to further recurrences. Despite the absence of morphofunctional alterations, however, it is generally believed that biliary sludge or microlithiasis or unrecognized transient sphincter of Oddi dysfunction (Type 2) plays a causal role. In a therapeutic protocol study adopted in our institution we found that the placement of a 5F or 7F stent into the MPD in cases with pancreatitis still recurring after biliary sphincterotomy served to identify those patients with residual hypertension of the pancreatic segment of the sphincter of Oddi who benefit from pancreatic sphincterotomy, as documented during a 27-mo follow-up. In these patients with a non-dilated MPD stents were routinely changed every three months. This empiric approach can be suggested for patients with recurrent pancreatitis but no evidence of morphofunctional abnormalities, presenting at least two or three acute attacks over one year, in whom three to six months' stenting can provide a reliable basis for deciding on pancreatic sphincterotomy[43].

Jacob *et al*[44] reported the results of a prospective randomized nonblinded trial evaluating the effectiveness of pancreatic stent placement in preventing attacks of pancreatitis in patients with idiopathic recurrent pancreatitis over a five-year period. The stent group received three stents in one year while the control group underwent selective pancreatic duct opacification without stenting. Pancreatitis recurred in 53% of the control group and in 11% in the stent group. The authors concluded that unrecognized intermittent pancreatic duct sphincter dysfunction or relative outlet obstruction might be a cause of recurrent pancreatitis that can be prevented by stent

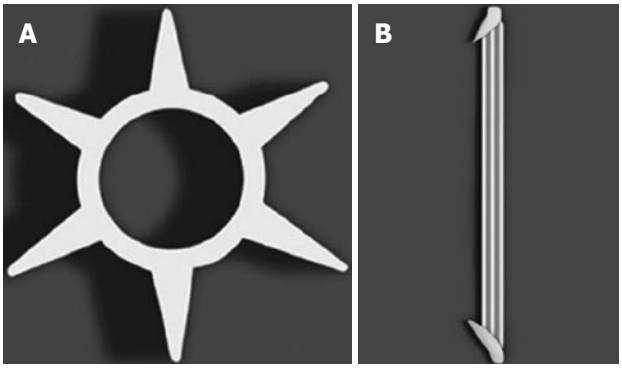

Figure 12 Experimental winged 5 and 7F stents. The new stent design with a wing shape permits an adequate flow of pancreatic juice even alongside the stent and does not compress the duct over its entire circumference, thus avoiding the risk of impaired drainage of pancreatic juice and mechanical trauma to the duct.

placement. However, long-term stenting of the pancreatic duct may in itself cause ductal damage, so only short-term stenting in patients with frequent episodes of pancreatitis is justifiable.

COMPLICATIONS OF STENT PLACEMENT

Several complications have been reported after pancreatic duct stent placement in benign diseases, ranging from 5%-39%. These include inward or outward migration of the stent, occlusion, and anatomic changes of the pancreatic duct[45,46]. The latter limits the long-term use of stents in the treatment of benign disorders especially when pancreatic ducts are non-dilated. Changes of MPD morphology consistent with chronic pancreatitis have been reported after stent placement in 36%-83% of patients; ductal changes of the pancreatogram appear as early as three months and seem not to revert to normal in some cases after removal of the stent. Pancreatic stents placed in dogs were found to induce both radiological and histological changes of chronic pancreatitis in the ductal segment treated with the stent, within eight weeks[47].

Although the mechanism by which changes are induced is not known, there is evidence that stenting the pancreatic duct leads to the formation of intraductal plugs in as little as three weeks even though pancreatograms may remain normal. These protein precipitates have the same composition as plugs removed from patients with chronic pancreatitis. Moreover, the conventional plastic stent does not provide enough side openings for unencumbered drainage at all sites where secondary ducts join the MPD; this obstruction and the pancreatic duct compression along the whole length of the stent induce a fibrotic reaction. A new pancreatic stent design with a wing shape has now been tested in dogs, with encouraging results, since this model permits an adequate flow of pancreatic juice even alongside the stent and does not compress the duct over its entire circumference, thus avoiding the risk of impaired drainage of pancreatic juice and mechanical trauma to the duct[48] (Figure 12).

In conclusion, in about the last 20 years endotherapy of pancreatic disorders has evolved from an experimental approach for some pathological conditions in selected cases where there is a fear of severe complications, to the "gold standard" for most acute and chronic inflammatory disorders involving the gland.

Abstract

Treatment of gastrointestinal bleeding in patients with angiodysplasias and Osler's disease (hereditary hemorrhagic telangiectasia) is clinically challenging. Frequently, vascular malformations occur as multiple disseminated lesions, making local treatment an unfavorable choice or impossible. After local therapy, lesions often recur at other sites of the intestine. However, as there are few therapeutic alternatives, repeated endoscopic coagulations or surgical resections are still performed to prevent recurrent bleeding. Hormonal therapy has been employed for more than 50 years but has recently been shown to be ineffective. Therefore, new therapeutic strategies are required. Understanding of the pathophysiology of angiogenesis and vascular malformations has recently substantially increased. Currently, multiple inhibitors of angiogenesis are under development for treatment of malignant diseases. Experimental and clinical data suggest that antiangiogenic substances, which were originally developed for treatment of malignant diseases, may also represent long-awaited specific drugs for the treatment of vascular malformations. However, antiangiogenics display significantly different actions and side-effects. Although antiangiogenics like thalidomide seem to inhibit gastrointestinal bleeding, other substances like bevacizumab can cause mucosal bleeding. Therefore differential and cautious evaluation of this therapeutic strategy is necessary.

Key words: Angiodysplasias; Osler's disease; Angiogenesis; Gastrointestinal bleeding; Vascular endothelial growth factor

INTRODUCTION

Diseases related to vascular malformation and pathologic vessel growth include benign conditions such as pediatric hemangioma, cutaneous angiectasias and venous malformations. They also include more severe and potentially life-threatening diseases like gastrointestinal angiodysplasias, Osler's disease (hereditary hemorrhagic telangiectasia, HHT) and cerebral arteriovenous malformations, as well as rare syndromes like hereditary dysembryoplasia and pulmonary capillary haemangiomatosis. Vascular malformations and dysfunctional vessels in these diseases result from different disturbances of the angiogenic process, which have only been partially characterized[1-3].

Among these anomalies, arteriovenous vascular malformations that are located on mucosal surfaces are of special clinical relevance because such lesions may cause intense bleeding. Other symptoms of arteriovenous vascular malformation include shunt syndromes, compression syndromes and thrombocytopenia/coagulopathy (Kasabach-Merritt syndrome).

Both Osler's disease and gastrointestinal angiodysplasias can cause recurrent bleeding, which in severe cases can require hundreds of blood transfusions over a period of years[4,5]. Despite diagnostic improvements like wireless capsule endoscopy, treatment of such patients remains a clinical challenge. Multiple lesions disseminated over the small intestine are frequently present, making local treatment an unfavorable choice or impossible[4]. However, as there are few therapeutic alternatives, repeated endoscopic coagulation or surgical resection is performed to prevent recurrent bleeding (although lesions often recur at other intestinal sites after local therapy). Therefore an effective medical treatment for these patients is urgently needed.

Although multiple drugs have been evaluated, there is currently no medical treatment with confirmed efficacy for preventing bleeding from vascular malformations. In this situation, hormonal therapy, which is still the best evaluated treatment option, is frequently employed. Based on observations of cycle-dependent severity of bleeding in some patients, hormonal therapy with estrogens and progesterones has been used for prevention of bleeding since the 1950s. However, there have been no confirming data regarding the effectiveness of hormonal therapy for prevention of intestinal bleeding. The only double-blind, placebo-controlled trial for treatment of nasal bleeding in Osler's disease suggested a moderate effect, but found no

significant reduction in epistaxis from estradiol therapy[6]. In 72 patients with non-hereditary angiodysplasias, a recent randomized placebo-controlled study failed to show an effect from a combination of ethinyl estradiol and norethisterone on the incidence of rebleeding and transfusion requirements[7]. Due to these disappointing results and substantial side-effects, especially in male patients, new therapeutic approaches are clearly required.

MECHANISMS OF BLEEDING

Understanding of the pathophysiology of angiogenesis and vascular malformation has recently substantially increased. Different mutations within the angiogenic signaling cascade indicate that two types of Osler's disease can be differentiated. Mutations of endoglin or activin receptor-like kinase 1 (ALK-1), both receptors for transforming growth factor beta (TGFβ)[1,2], are present in the majority of cases of HHT. Differential stimulation of ALK-1 and ALK-5 is thought to regulate different phases of angiogenesis, thereby activating the angiogenic process, with subsequent increased production of vascular endothelial growth factor [VEGF, initially termed vascular permeability factor (VPF)][8,9]. VEGF, so far the best characterized angiogenic molecule, stimulates proliferation of vascular endothelial cells and increases vascular permeability, and thus is a central mediator of the early phase of angiogenesis[10]. Recent studies have confirmed that both Osler's disease and nonhereditary intestinal angiodysplasias are characterized by increased production of VEGF[11,12]. High serum levels of VEGF that also correlate with severity of bleeding are found in patients with Osler's disease[11].

Intestinal angiodysplasias in patients who have undergone colonic resections because of recurrent bleeding strongly express VEGF along the endothelial lining[12], indicating a proliferative phase of angiogenesis. Expression of VEGF receptor 1 is also observed in bleeding intestinal angiodysplasias[12]. As VEGF receptor 1 is specifically up-regulated by hypoxia, this finding may indicate a role for hypoxia in the pathogenesis of angiodysplasias[13,14]. However, further detailed analyses are necessary to clarify the pathophysiology of gastrointestinal angiodysplasias.

VEGF-mediated effects are presumably also involved in bleeding in inflammatory bowel disease (IBD). The mucosal inflammation in Crohn's disease and ulcerative colitis is characterized by increased production of the proinflammatory cytokines tumor necrosis factor α, interleukin (IL)-1 and IL-6. In experimental models, proinflammatory cytokines have been shown to induce VEGF[15,16], a mechanism which is also likely present in IBD in order to supply the inflammatory infiltrate and thickened bowel wall with microvessels[17]. As a result of permanent VEGF stimulation, sprouting vulnerable vessels are located at the inflamed mucosal surface; thus possibly resulting in intermittent bleeding and so contributing to chronic anemia in Crohn's disease[18,19]. However, a small number of patients with Crohn's disease also suffers from massive recurrent bleeding[20,21]. As such episodes of severe bleeding are not associated with high disease activity[20-22], it can be speculated that the severe bleeding in such patients results from larger superficially located vessels with arteriovenous short circuits. Angiodysplasias have been documented in several of these patients; however they have not been definitely proven to cause this bleeding[20-22].

The initial phase of angiogenesis is characterized by VEGF-dependent formation and the sprouting of vessels consisting of endothelial cells. Within this process, microenvironmental concentrations of VEGF seem to determine whether normal or aberrant angiogenesis is induced[23]. Gene-therapy-induced high local concentrations of VEGF result in vascular malformations[24]. Such lesions resemble the chaotic architecture of haemangiomas or angiodysplasias and are characterized by thin-walled fragile vessels with high permeability, which lack smooth muscle cells and are susceptible to rupture[25]. To mature, such a primitive vascular plexus would have to be remodeled and vessels acquire a smooth muscle layer, a process that requires other angiogenic factors such as TGFβ, platelet-derived growth factor and angiopoietin-1 (which also stabilizes the leakage of VEGF-overexpressing vessels)[25,26]. Angiodysplasias and other vascular malformations like hemangiomas arise from massive local activation of the early stage of angiogenesis, with accumulation of VEGF, which induces primitive endothelial vessel complexes. However, these vessel precursors fail to finally differentiate into complete functional vessels and form net-like labyrinthine complexes. If surrounded by parenchymal tissue or stable epithelial structures, these complexes are generally harmless. However, when located near a mucosal surface, such fragile vessel systems are susceptible to rupture and can cause bleeding.

ANTIANGIOGENIC THERAPY

The observation that different vascular malformations, despite a distinct pathogenesis, are characterized by a pathologic accumulation of VEGF theoretically makes them an attractive target for direct or indirect VEGF-suppressive antiangiogenic therapy. Suppression of VEGF disrupts development of sprouting vessels: in experimental models VEGF withdrawal results in endothelial cell shedding and regression of primitive hemangioblastoma-like vessels[27].

Several antiangiogenic substances have been developed for treatment of malignant diseases. These include monoclonal antibodies against VEGF [Bevacizumab (Avastatin)], VEGF-trap, VEGF-receptor antibodies and antagonists [SU5416 (semaxanib), IMC-IC11, PTK 787 and SU6668], proteins (endostatin and angiostatin), matrix metalloproteinase inhibitors (Marimastat, Primostat and COL-3), thalidomide and its analogues [CC5013 (Revimid) and CC4047 (Actimid)], and several other substances that act during different phases of the angiogenic process[28]. In addition to their therapeutic potential in malignant diseases, some of these substances could also be useful for treatment of bleeding vascular malformations.

THALIDOMIDE-THE FIRST ANTIANGIOGENIC DRUG

The best known-and for four decades unrecognized as

such-inhibitor of angiogenesis is thalidomide, which tragically was used as a sedative and anti-emetic in pregnant women from 1956 until it was withdrawn from the market in 1961 after being recognized to have caused severe birth defects. During these years, in which thalidomide became the most popular sedative in Germany, about 10000 children with phocomelia and other malformations were born[29]. It was only in 1994 that thalidomide was found to inhibit VEGF-and basic fibroblast growth factor-mediated angiogenesis; a detection that resulted from a side-effect-based literature screening in search of drugs with antiangiogenic activity that D'Amato and Folkman presumed should cause both amenorrhea and fetal malformations[30]. The exact mechanism by which thalidomide acts within the angiogenic cascade remains to be determined, but appears to be located upstream of the VEGF level, i.e. reduced expression of integrin genes has been hypothesized[31]. In experimental models, the antiangiogenic activity of various thalidomide metabolites correlates with teratogenicity[30-32], indicating that antiangiogenic effects are also mainly responsible for thalidomide-related birth defects in humans. The antiangiogenic potential of thalidomide is currently being evaluated for treatment of several malignant diseases[29]. Due to promising results in patients with therapy-refractory multiple myeloma, thalidomide is now evaluated as both first-line myeloma therapy and in combination with hematopoietic-cell transplantation[33,34].

It has recently been reported in a number of case studies that thalidomide reduces the incidence of severe bleeding in different gastrointestinal diseases. Eight patients with severe bleeding related to Crohn's disease or angiodysplasias of the small intestine, who had received up to 230 blood transfusions, responded to moderate doses of 100-300 mg thalidomide daily[18,22,35]. Similarly, chronic bleeding unexpectedly resolved in patients with hereditary hemorrhagic telangiectasia, who received thalidomide as antiangiogenic cancer therapy[36,37]. In patients with angiodysplasias, rebleeding was also prevented for more than 2 years after thalidomide treatment had ended[22]. In Crohn's disease with moderate inflammatory activity, severe bleeding stopped during thalidomide treatment, partly recurred after cessation of thalidomide, but was controlled again by retreatment[18,22]. However, in patients with Crohn's disease, it is not clear whether cessation of bleeding is related to antiangiogenic or anti-inflammatory effects of thalidomide. More objective evidence that antiangiogenic effects of thalidomide are responsible for the efficacy on bleeding is found in patients with non-inflammatory diseases. In patients with angiodysplasias or Osler's disease without any evidence of inflammation[22,35,37], the efficacy of thalidomide on bleeding is unlikely to be related to anti-inflammatory or immunomodulating effects. Serum levels of VEGF were found to be suppressed by thalidomide in patients without inflammation[22]. In patients with multiple angiodysplasias of the small bowel, wireless capsule endoscopy has demonstrated that the clinical efficacy of thalidomide is paralleled by a decrease in number, size and color intensity of angiodysplasias, which indicates regression[38].

Although the results of the above case series need to be confirmed in controlled trials, present data indicate that antiangiogenic effects of thalidomide are responsible for reductions in bleeding episodes. However, the side effects of thalidomide are also substantial. Thalidomide is a potent sedative, causes severe birth defects and can also induce sensible peripheral neuropathy, especially at higher cumulative doses[39], therefore, it may not turn out to be the drug for treatment of vascular malformations hoped for by clinicians. Furthermore, in addition to its antiangiogenic activity, thalidomide exerts immunomodulating effects[29]. It is possible that other newly developed antiangiogenics will show more specific inhibition of VEGF or other steps within the angiogenic cascade, with possibly fewer side effects.

NEW ANTIANGIOGENICS

Of the currently developed antiangiogenic substances, most information regarding clinical efficacy and toxicity is available for bevacizumab (Avastatin®), a humanized monoclonal antibody against VEGF. Bevacizumab was recently shown to be effective in the treatment of colonic and renal cancer; present data indicate strong antiangiogenic activity and a favorable side-effect profile[40,41]. However, nose bleeding is frequently observed during treatment (in up to 59% of patients)[42]. The incidence of nose bleeding correlates with higher doses[40], although the reason for this bleeding is not clear. A loss of vascular integrity by bevacizumab-induced endothelial-cell shedding in highly regenerative mucosal tissues with active angiogenesis could be a possible explanation for this dose-dependent effect. Other reported side effects during treatment with bevacizumab include gastrointestinal bleeding and perforations, which were not always tumor-related[41,42].

Bleeding complications do not seem to be a specific feature of bevacizumab. A recent study with IMC-IC11, a humanized monoclonal antibody against VEGF receptor 2, also reported bleeding episodes unrelated to tumor manifestations[43]. Although most bleeding complications are probably of minor relevance in patients with malignant diseases, it is conceivable that abrupt antibody-induced withdrawal of VEGF in proliferating VEGF-dependent endothelial vessels could become critical in pre-existing vascular malformations located on mucosal surfaces.

Therefore, although VEGF-based antiangiogenic therapy is a promising and highly specific therapeutic option for preventing growth of vascular malformations, it seems questionable whether monoclonal antibodies against VEGF or its receptors are also useful for treatment of bleeding from pre-existing vascular malformations. Indeed, some highly effective antiangiogenics could even aggravate bleeding from vascular malformations.

Semaxanib (SU 5416), a small-molecule inhibitor of VEGF receptor 2 tyrosine kinase has recently been used for treatment of hemangioblastoma in patients with von Hippel-Lindau disease (vHLD). In vHLD, a loss of von Hippel-Lindau protein results in an accumulation of hypoxia-inducible factor and subsequently, induction of

VEGF[44]. Some initial studies on semaxanib have reported regression or stabilization, with improvement of macular edema, in patients with hemangioblastoma, which indicates effective inhibition of VEGF[44,45]. Frequently observed side effects of semaxanib include fatigue and headache[47,48]. To date, bleeding complications, like those found for bevacizumab, have not been reported for semaxanib (neither have they been reported for thalidomide, for which side effects have been well documented since its reevaluation for malignant and inflammatory diseases).

In summary, it is remains unclear why some antiangiogenic substances like bevacizumab can cause mucosal bleeding and others like thalidomide do not. This effect may be related to the phase of angiogenesis that is antagonized, or might reflect a particular strong antiangiogenic activity. Detailed analyses of the angiogenic cascade and how thalidomide and other antiangiogenics act within this process will be needed to resolve this issue.

SIDE-EFFECTS AND TOXICITY

Currently, only limited data are available regarding the general toxicity of antiangiogenic therapy. Arterial hypertension has been reported for several agents and is thought to be at least partially related to reduction of VEGF-mediated vascular permeability. As VEGF is also centrally involved in neuroregeneration, neurotoxicity is another possible concern for antiangiogenic treatment[49]. Experimental peripheral neuropathy is reversible by VEGF gene transfer[50]. Reduction of VEGF levels by 25% results in motor neuron degeneration reminiscent of amyotrophic lateral sclerosis[51]. Thalidomide's well-documented neurotoxicity is therefore possibly not drug-specific but could be a general effect of long-term antiangiogenic therapy. Until now, significant neuropathy has not been reported for the new antiangiogenics; however, only very limited data regarding long-term toxicity are available. Furthermore, as these drugs are generally just one part of a polychemotherapeutic regimen, it is often unclear to what extent antiangiogenics contribute to clinically observed neurotoxicity[52].

Finally, VEGF is also crucial for embryonal angio- and vasculogenesis. Loss of a single VEGF allele causes severe embryonic vascular defects[53]. Therefore, not only thalidomide, but any inhibitor of VEGF that crosses the placenta has to be considered a potential teratogen. As antiangiogenics are primarily developed as anticancer agents and designated to be used in combination with chemotherapy, this subject is generally regarded as of minor relevance. However, if antiangiogenic therapy is expanded to benign diseases like angiodysplasias, Osler's disease, and inflammatory diseases like Crohn's disease (which may also improve due to inhibition of angiogenesis)[54-57], and young women are candidates for treatment, teratogenicity becomes a critical issue. Indeed, a single dose of thalidomide is sufficient to cause birth defects[30]. Angiogenesis has a central role in embryo growth and pregnancy-prevention programs cannot completely prevent the birth of children with fetal malformations[58]; therefore, antiangiogenics should only be used under strict surveillance in non-malignant diseases.

CONCLUSION

In summary, antiangiogenic substances like thalidomide hold promise to be not only useful for treatment of malignant diseases, but may also represent the drugs that have been long awaited for the treatment of bleeding from vascular malformations. However, as some antiangiogenics can cause mucosal bleeding, a differential therapeutic approach and careful evaluation are necessary. Moreover, antiangiogenic therapy is also teratogenic and therefore has to be very cautiously considered in women of child-bearing potential.

Abstract

Desmoid tumor is a monoclonal, fibroblastic proliferation arising in musculoaponeurotic structures. This connective tissue hyperplasia infiltrates locally, recurs frequently after resection but does not metastasize. Abdominal desmoid occurs sporadically, in association with some familial syndromes and often represents a clinical dilemma for surgeons. The enigmatic biology and anatomical location of abdominal desmoids make treatment recommendations difficult. This distinct pathological entity is reviewed with a specific focus on aetiology and management.

Key words: Desmoid; Abdomen; Fibromatosis; Familial adenomatous polyposis; Gardner's syndrome

INTRODUCTION

Desmoid tumor, also known as aggressive fibromatosis or musculo-aponeurotic fibromatosis[1], is a monoclonal[2,3], fibroblastic proliferation arising in musculoaponeurotic structures.

Although Mueller in 1838 coined the term desmoid tumor[4] (derived from the Greek *desmos* that means tendon-like), the first description of the tumor is credited to McFarlane, who reported the disease occurring in the abdominal wall of a young woman after delivery in 1832[5].

Histologically, these tumors consist of spindle-shaped cells in a collagenous matrix without the pleomorphic, atypical, or hyperchromatic nuclei of malignancy[1]. The connective tissue hyperplasia infiltrates locally, recurs frequently after resection but does not metastasize[6].

Desmoid tumors have been recently subdivided according to their location into extra-abdominal, abdominal and intra-abdominal, and the latter have been subclassified further into mesenteric fibromatosis and pelvic fibromatosis[7]. This tumor may occur at the site of any fascia, but in particular in muscle, hence the descriptive term musculo-aponeurotic fibromatosis. The most frequent sites involved by these tumors are the torso and the extremities. Many studies have shown that between 37% and 50% of desmoids arise in the abdominal region[6,8,9]. Abdominal desmoid occurs sporadically[8], in association with some familial syndromes[9] and often represents a clinical dilemma for surgeons. Most surgical reports emphasize the difficulty in achieving adequate resection margins, while maintaining acceptable function and cosmesis[10,11]. These are major factors contributing to the high rates of relapse after surgery, especially after conservative resections[12,13].

The enigmatic biology and anatomical location of intra-abdominal desmoids make treatment recommendations difficult. A significant factor limiting the attempted generalization concerning management is the small number of cases available for analysis, reflecting the relative rarity of the disease.

EPIDEMIOLOGY AND ETIOLOGY

Desmoid tumor is a rare lesion representing < 3% of all soft tissue tumors with an estimated incidence of 2-4 new cases per million per year[14].

These tumors have been well characterized from a morphologic standpoint, but their nature and pathogenesis have remained obscure for many years, to the point that Stout[15] defined it as "the most incomprehensible group" of fibromatosis. They have been considered non-neoplastic processes by some authors and well-differentiated low-grade sarcomas by others[2].

An association with familial adenomatous polyposis of the colon (FAP) and Gardner's syndrome has been well documented. Abdominal and extra-abdominal desmoids occur more frequently in FAP patients, with an incidence of 3.5%-32%. In the original Gardner kindred the incidence was 29%[9,16].

The etiology of desmoids has not been well defined. Numerous factors are acknowledged to be strongly associated with their development. An antecedent history of trauma to the site of the tumor, often surgical in nature, may be elicited in approximately 25% of cases[17,18].

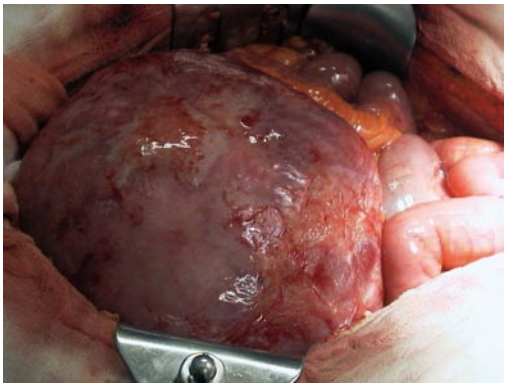

Figure 1 Intraoperative finding of giant retroperitoneal desmoid tumor.

Figure 2 Coronal view of computed tomography scan shows a mesenteric desmoid tumor.

Within the FAP population, there is a strong correlation between prophylactic procto-colectomy and the subsequent development of desmoid tumours[19-22].

Other forms of trauma, such as physiologic trauma associated with pregnancy, are also thought to contribute to the development of desmoid tumors and several papers report an increased association between pregnancy and desmoid tumors[10,14,16,17].

A predominance of the disease in the female population has been reported, with a female to male ratio ranging from 1.4 to 1.8. The peak of incidence is between the ages of 25 and 35 years, even though cases occurring in patients younger than 10 years have been described[10,17,23,24]. The preponderance of cases described afflicting women in reproductive age shows a clear association of this disease with the endogenous hormonal environment and exogenous sex hormones[10,16,17].

Anecdotal reports of tumor regression during menopause[25,26], the development of desmoids in patients taking oral contraceptives[19,27], and reports of tumor regression with tamoxifen treatment[28], serve to underline an evident role of estrogen in the multifactorial pathogenesis of desmoid.

While most of the cases are sporadic, some are associated with familial syndromes (FAP, Gardner's syndrome) and these are most often intra-abdominal[19,29]. There are also cases of familial desmoid tumors at multiple sites, in patients without FAP, often involving one extremity. In both FAP and familial non-FAP tumors, mutations of the adenomatous polyposis coli (APC) gene on the long arm of chromosome 5 have been incriminated. The resultant loss of ability to degrade beta-catenin and elevated beta-catenin levels promotes fibroblastic proliferation through a nuclear mechanism[30].

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

Desmoid tumors most frequently present as a slowly enlarging mass (Figure 1). Symptoms depend on the location of the tumor. Patients with intra-abdominal desmoid may have asymptomatic masses, symptoms of intestinal, vascular and urinary obstruction or neural involvement[6,31,32]. The diagnosis of desmoid is based on clinical suspicion. A history of FAP or of similarly affected family members is frequently elicited. A history of trauma or recent pregnancy is also common.

The role of imaging (computed tomography and magnetic resonance) is to define the degree of extension to local structures and tumor relationship to neurovascular structure[33,34]. This tumor does not metastasize to regional nodes or distant sites so that search for metastatic disease is unnecessary. Biopsy is not usually necessary but does not seem to induce further growth, if performed. At the moment there is no accepted staging system for this disease[35].

MANAGEMENT

The management of desmoid tumors requires special attention. A strong family history of desmoid tumors and a high-risk location of the mutation on the APC gene increase the risk for the development of desmoid tumors[30,36]. Due to a reported 85% recurrence rate of desmoid tumors after surgical excision, surgery should be performed only when absolutely necessary[37,38].

Tamoxifen, toremifene, and sulindac have been used as treatments, but the results are controversial. Reports have suggested that therapy might be associated with an initial benefit but the long-term clinical improvement is minimal[39-41]. Cytotoxic chemotherapy (doxorubicin, dacarbazine, and carboplatin) may be effective in treating aggressive, rapidly growing and unresectable abdominal desmoids[42,43]. Radiation therapy might be effective in selected cases but it is frequently limited by the presence of the small bowel in the radiation field in mesenteric and pelvic desmoids[44,45].

Intra-abdominal desmoid tumors usually involve the mesentery and often involve the mesenteric vessels. They invade the mesentery diffusely, kink loops of bowel and can cause ureters obstruction (Figure 2). This feature requires a complex surgery and often radical resection is impossible to achieve[11]. Therefore the management of intra-abdominal desmoid tumors is complex and is dependant on their clinical behavior.

Given the problems related to the treatment of desmoids, there is a good case for simple observation of many tumors, particularly if asymptomatic. Following diagnosis, a small tumor which is not encroaching on any nearby structures may be followed up by regular clinical

examination (every 6 mo) with or without imaging, usually by CT. Desmoids that are growing slowly or are mildly symptomatic can be treated with sulindac and tamoxifen or with vinblastine and methotrexate, since these are less toxic regimens. Aggressive desmoids are treated with anti-sarcomachemotherapy such as doxorubicin and dacarbazine.

It would thus seem that surgery is a reasonable first-line treatment for abdominal wall tumors, since they are easier to excise than intra-abdominal desmoid tumors, recurrence rates are lower, and morbidity rates associated with the procedure are lower. The excision should be completed with a one cm margin. A mesh can be used to cover the defect if required[46].

For intra-abdominal desmoids surgery should only be used in specific circumstances. These would include tumors which do not appear to involve vital organs and vessels on preoperative imaging, those resistant to drug treatment and in cases where a risky operation is the only possible option in the case of a rapidly growing, life-threatening tumor. High rates of recurrence should be expected and patients must be counseled pre-operatively about the risks of death. Such cases should only be attempted in specialist centers with sufficiently experienced staff.

At the moment one center has also reported a technique where the tumor and small bowel are removed en bloc, perfused and cooled, and the tumor resected on the bench in a bloodless field with subsequent autotransplantation of the small bowel back into the patient[47]. Recently a report has been published where two desmoids (one intra-abdominal) were treated with percutaneous chemical ablation with acetic acid under-radiological guidance[48]. In both cases there was substantial regression of the tumours within a few months.

Unfortunately, despite any treatment, some patients deteriorate, become dependent on TPN, and have life-threatening complications develop. Intestinal transplantation is the only remaining option for these patients[49].

In conclusion the optimal treatment protocol has not yet been established and, in many cases, a multidisciplinary approach including surgery, chemotherapy, and radiation therapy has been employed. The rarity of cases in even major tumor centers has traditionally limited the ability to study this disease. The notion that a specific genotype can predict the development of an aggressive desmoid tumor in a given patient could prove to be valuable in allowing appropriate patient selection for early therapy or even a chemopreventive strategy. Several novel pharmacologic and biologic treatment approaches are actively being developed, although long-term follow-up is needed for their substantiation[50].

Abstract

AIM: To investigate the protective effect of medical ozone (O_3) combined with Traditional Chinese Medicine (TCM) Yigan Fuzheng Paidu Capsules (YC) against carbon tetrachloride (CCl_4)-induced hepatic injury in dogs.

METHODS: Thirty healthy dogs were divided randomly into five groups (n = 6 in each group), namely control, oleanolic acid tablet (OAT), O_3, YC and O_3 + YC, given either no particular pre-treatment, oral OAT, medical ozone rectal insulfflation every other day, oral YC, or oral YC plus medical ozone rectal insulfflation every other day, respectively, for 30 consecutive days. After pre-treatment, acute hepatic injury was induced in all dogs with a single-dose intraperitoneal injection of CCl_4. General condition and survival time were recorded. The biochemical and hematological indexes of alanine aminotransferase (ALT), aspartate aminotransferase/alanine aminotransferase (AST/ALT), serum total bilirubin (TBIL), prothrombin time (PT), blood ammonia (AMMO), and blood urea nitrogen (BUN) were measured after CCl_4 injection. Hepatic pathological changes were also observed.

RESULTS: Compared to the other four groups, the changes of group O_3 + YC dogs' general conditions (motoricity, mental state, eating, urination and defecation) could be better controlled. In group O_3 + YC the survival rates were higher ($P < 0.05$ *vs* group control). AST/ALT values were kept within a normal level in group O_3 + YC. Hepatic histopathology showed that hepatic injury in group O_3 + YC was less serious than those in the other four groups.

CONCLUSION: Medical ozone combined with TCM YC could exert a protective effect on acute liver injury induced by CCl_4.

INTRODUCTION

Medical ozone, a mixture gas of ozone and oxygen, has been used for several decades in the therapy of diabetic foot, arthritis, arterial angiemphraxis and ulcerative colitis[1-9]. It has been used in an empirical fashion in recent years for therapy of viral hepatitis. Rectal insufflation with ozone can reduce hepatic and renal ischemia-reperfusion injury[10-15].

Yigan Fuzheng Paidu Capsules (YC), an empirical formula, is a compound preparation of traditional Chinese medicine (TCM) for treating chronic viral hepatitis. It has been demonstrated experimentally that YC can protect the liver and decrease transaminase level, has anti-lipid peroxidation activity, and *ex vivo* antiviral activity.

This study investigated the effect of medical ozone combined with YC affect on carbon tetrachloride (CCl_4)-induced acute liver injury in order to establish a reliable baseline for clinical application.

MATERIALS AND METHODS

Animals

Thirty healthy mongrel dogs aged 1-2 years, weighing 12-15 kg, were used in the experiments. These dogs received regular feeding, were inspected medically, treated with helminthicide, and acclimatized for at least 1 month prior to the experiments in the Experimental Animal Center of Nanfang Hospital, Southern Medical University. The experiments were carried out in accordance with the animal experiment regulations of the university.

Drugs and reagents

YC was manufactured in the Department of Traditional Chinese Medicine, Southern Medical University (Guang-lian-zhi-zi 2004, No. FPGZ150) with Batch No. 050715. Oleanolic acid tablets (OAT) were produced by Nanguo Biological Pharmacy Co., Guangdong Province, China (Guo-yao-zhun-zi No. H44023537) with Batch No. 040701. CCl_4 was produced by the Chemical Plant of Guangzhou with Batch No. 050317, and mixed with the same amount of peanut oil before use.

Equipment

The medical ozone generator (OZONOSAN alpha Plus 1107, Germany) was registered and licensed for medical therapy by SFDA (registration No. 1570177).

Groups and administration

Thirty healthy dogs were divided randomly into five groups (n = 6 in each group): group control, which received no preconditioning treatment; group OAT, treated with oral OAT at 10 mg/d; group O_3, treated with 8.1 mL/kg medical ozone at 20 μg/mL by transrectal insulfflation every other day; group YC, treated with oral YC at 0.2 g/d; and group O_3 + YC, treated with oral YC at 0.2 g/d plus 8.1 mL/kg medical ozone at 20 μg/mL by transrectal insufflation every other day, for a total of 30 consecutive days. After preconditioning treatment, acute hepatic injury was induced in all dogs with a single intraperitoneal injection of CCl_4 mixture at a dose of 0.9 m/kg body weight.

Measurements

The general condition of the dogs was observed before and after treatment, in terms of motor activity, mental state, eating behavior, urination and defecation. The survival time of each dog was measured accurately in hours.

For biochemical and hematological measurements, intravenous blood was sampled pre- and post-treatment at 24 h, 2, 3, 4, 7 and 14 d. All the blood samples were analyzed immediately by the clinical laboratory of Nanfang Hospital for alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), prothrombin time (PT), serum ammonia (AMMO), and blood urea nitrogen (BUN).

For histopathology, multiple liver tissues were obtained through ultrasound-guided percutaneous needle biopsy from each dog before and after the experiment. The formalin-fixed, paraffin-embedded liver sections (5 μm) were stained with hematoxylin and eosin (HE) and Gomori silver. The degree of necrosis and inflammatory cell infiltrate was evaluated on a four-point scale (Table 1), using 20 random fields at 100 × and 400 × magnification per slide, by a blinded pathologist (MIF)[16].

Table 1 Histological assessment of drug induced acute hepatitis in dogs

Score	Centrilobular necrosis	Inflammation in centrilobular areas
0	None	None
1	Isolated necrotic hepatocytes or single row of hepatocyte drop-out in perivenular areas	Mild: inflammatory infiltrate affecting < 50% centrilobular areas
2	> 1 and up to 3 rows of perivenular necrotic hepatocytes	Moderate: inflammatory infiltrate affecting > 50% and < 75% centrilobular areas
3	> 3 rows of perivenular necrotic hepatocytes with confluent and/or bridging necrosis	Severe: dense inflammatory infiltrate affecting > 75% centrilobular areas

Statistical analysis

Overall survival was evaluated by actuarial analysis using Kaplan-Meier estimates. Independent samples test for comparison of biochemical and hematological measurements, and one-way ANOVA and LSD test for histological assessment were performed by SPSS 13.0. P-values < 0.05 were considered statistically significant.

RESULTS

General condition of the dogs

Pre-treatment, all 30 dogs were in good condition. Eating behavior, feces and urine were normal. Post CCl_4 treatment, all dogs began to vomit and lost balance immediately. Except for the O_3 + YC group, all the dogs in the other four groups appeared to prefer to stay still alone or were pacing up and down restlessly, while some of them showed poor mental health and appetites, and yellow urine. In group O_3 + YC, there were no differences before and after treatment, except for two dogs with yellow urine.

Survival analysis

Log Rank, Breslow and Tarone-Ware tests were used for comparison of survival rate in the five groups of dogs. All three tests showed that the survival rate of group O_3 + YC was significantly higher than that of the control group (P < 0.05), while there were no significant differences between any other two groups (P > 0.05) (Figure 1).

Biochemical and hematological measurements

Pre-treatment, there were no significant differences (P > 0.05) between the control and the other four groups for any of the measurements (AST/ALT was not being analyzed at the time). After CCl_4 injection, all the measurement index in the five groups except for AST/ALT showed a tendency to increase during the first three days and then gradually fall. There were significant differences (P < 0.05) between groups OAT and O_3, OAT and YC, OAT and O_3 + YC for PT, and between groups

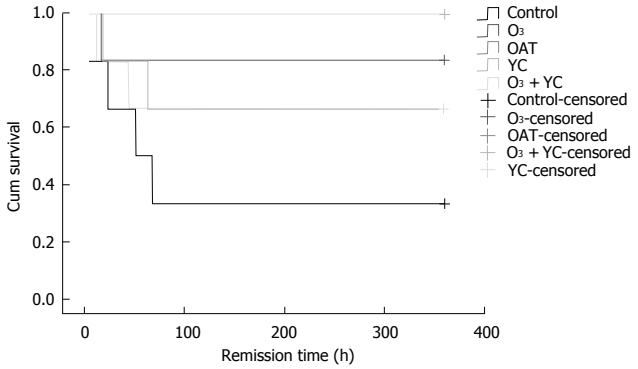

Figure 1 Survival functions of the five groups. The record of each dog's survival time starts at the injection time, and ends in post-360 h (15 d). Plots express the survival rates in different time.

OAT and O_3 + YC, O_3 and O_3 + YC for BUN. In order to compare the measurements post CCl_4 injection, all the index values for each dog were adjusted to the same level. Post CCl_4 injection, the measurement values of ALT, TBIL, PT and AMMO were significantly higher ($P < 0.05$) in the control group than in the other four groups, but there were no significant differences for BUN in all groups ($P > 0.05$). ALT was significantly lower ($P < 0.05$) in group OAT than in group YC, while ALT, TBIL, PT and BUN were significantly higher ($P < 0.05$) in group OAT than in group O_3 + YC. ALT, TBIL, PT and BUN were significantly higher ($P < 0.05$) in group O_3 and YC than in group O_3 + YC. AST/ALT in the control and YC groups showed a little below 1.0 at 24 h after CCl_4 was administrated, then increased to > 1.5 in the control group, and fell to < 0.5 on d 3-4. On d 5-14, AST/ALT in the control group continued to fall (0.1 on d 14). However, in group YC AST/ALT started to increase after 7 d (1.0 on d 14). AST/ALT in the OAT and O_3 groups was approximately 1.0 on first day, fell to approximately 0.4-0.5, and began to increase from d 4 (about 1.0 on d 14) (Table 2).

Liver histopathology

Liver sections from the five groups of dogs, after death or survival for 15 d, were examined and graded for the degree of necrosis and accompanying inflammation, as shown in Table 1. Control group livers demonstrated higher scores for necrosis ($P < 0.05$) and inflammation ($P < 0.05$) compared with the OAT, O_3, YC and O_3 + YC groups (Figure 2).

DISCUSSION

Drug-induced hepatitis is becoming a big problem in clinical practice, and proper management of this problem has not been found so far. For searching new strategy to overcome drug-induced hepatitis, medical ozone and traditional Chinese medicine were first tried in animal model. The effects of medical ozone combined with traditional Chinese medicine on CCl_4-induced acute hepatic injury in dogs were evaluated in this study. The novel method decreased the incidence of jaundice and hepatic encephalopathy and prolonged survival time. Medical ozone combined with YC showed a better effect than OAT, O_3 and YC alone in decreasing transaminases, relieving jaundice and promoting recovery of blood clotting activity.

A number of hepatotoxins have been used to induce fulminant hepatic failure (FHF) in animal models: d-galactosamine, *N*-acetyl-*P*-aminophenol and CCl_4[17,18]. CCl_4 causes serious hepatotoxicity, and has been used extensively and successfully to induce liver damage, including fibrosis[19,20]. CCl_4 is metabolized by cytochrome P450 2E1 in the liver to produce a toxic metabolite. It has been demonstrated to induce liver necrosis, as well as apoptosis[21]. Peroxidation of membrane lipids secondary to the formation of trichloromethyl radicals is believed to be the basis for the toxic effects of CCl_4.

Medical ozone is characterized by its safety and multiple effects in low dose. The main mechanisms of action of ozone pre-conditioning on hepatic injury are as follows. It enhances erythrocyte metabolism[22-26], which can promote the oxygen-carrying capacity of hemoglobin and promote liver oxygenation. Ozone can induce intracellular anti-oxidant enzymes of the liver and scavenging free radicals[14,27-29]. When hepatocytes are equipped with strength against peroxidative radicals by the preconditioning of medical ozone, they can become prone to survival under the attack of toxic CCl_4 radicals. The range of ozone concentrations within which it can exert a therapeutic effect without toxicity is wide from 10 mg/mL to 80 mg/mL[25,30]. YCs have been prescribed clinically for several years. *Astragalus mongholicus*, *Hedyotic diffusa* and *Radix polygoni* prepared as a prescription can promote production of lymphoblasts, regulate the ratio of T-lymphocyte subsets, strengthen immune function, increase activity of lymph active cells and natural killer cells, and induce interferon. Giant knotweed rhizome, *Hedyotic diffusa*, *Rhizome* and *Phyllanthus amatusniruri* have also shown antiviral effects. Honeycomb of paper wasps, red peony root and *Salvia miltiorrhiza* can promote blood flow, mitigate liver injury, and improve hepatocyte oxygenation and promote their recovery. Therefore, the combined effects of O_3 and YC were to up-regulate immune function and promote liver oxygenation. This study may spur the use of a new strategy for the clinical management of some drug-related hepatitis. Clinical trials are needed to confirm the effects of this novel regime.

COMMENTS

Background

Medical ozone has been wildly used, especially in Europe, in surgery and medicine for 50 years. The technique of ozonetherapy, such as major autohemotherapy, rectal insufflation and topical ozonetherapy, were gradually developed in recent decades and served for more than 10 million patients who suffered from skin ulcerative lesion or trauma, diabetic foot, arthritis, arterial obstruction, ulcerative colitis and spinal disk herniation, *etc*. The property of ozone and its therapeutic effects were partially illuminated. Ozone has opposite faces toward human body. It is harmful gas in high concentration or administration by respiratory tract but therapeutic in low concentration. The milestone fact sheets were that: (1) the ozone reacts with red blood cells (RBC) and reactivates RBC metabolism by increasing 2, 3-DPG and ATP concentration; (2) ozone reacts with immunocompetent cells and induces cytokins release, including IL-2, 4, 10, IFN-β, γ, TGF-β1; (3) ozone activates tissue cells' antioxidative enzymes and enhances capacity of radical scavenger. Each discovery mentioned above will mould scientific base for the novel application scope of ozone. For example, the finding of effect of ozone on immune system is the scientific foundation of using

medical ozone to treat infectious diseases, including viral hepatitis B, and to treat rheumatic diseases. Although effort has been done to elucidate the mechanism of ozonetherapy, but its practices in whole still remained in an empirical fashion and have not been accepted by sutra legitimacy medicine.

Research frontiers

Drug-induced liver injury is an increased important problem in modern medical practice. Apart from avoiding using hepatoxic drugs, none of effective methods to prevent drug induced hepatitis are confirmed so far. There are several articles that introduced using medical ozone to prevent liver or renal ischaemia and reperfusion (I/R) injury in animal models. Free radical and reactive oxygen species during I/R process are the main cause of organ I/R injury. The mechanism of some drug-induced hepatitis is the same way as I/R injury. So, the ozone's property of inducing antioxide enzymes and enhancing capacity of radical scavenger should confer preventive effect for protecting liver from hepatoxic drug-induced injury.

Innovation and breakthroughs

This study gives us a new knowledge of medical ozone and impels us to have following deduction, i.e. medical ozone and herb medicine rectal administration may be a new strategy to prevent drug-induced hepatitis. From design point of view, big animal as dog as animal model in this study imitates human being more likely than small canine as mouse. Rectal administration of ozone and herb medicine was proved effective in this experiment, and provided convenient way for future clinical application.

Application

The results from this animal study confirm the protective effect of ozone and prescription of traditional Chinese medicine on hepatoxic drug-induced liver injury. It encourages us to apply medical ozone in preventing some drug-induced hepatitis in the future clinical trials.

Termiology

Medical ozone is a mixture gas of ozone and oxygen. It is made from pure oxygen by an ozone generator. This machine used in medical therapy must have capacity to adjust ozone concentration in a precision and stabilization pattern.

Peer review

This study further confirmed the protective effect of medical ozone and herb medicine on drug-induced hepatitis and was a steady step toward its clinical application. Medical ozone and traditional Chinese medicine are both ancient antiques, its worthiness was not staying in ancient history and its merits are also useful in modern medicine, just simply needs to be added modern decoration, i.e. the evidence based medicine (EBM).

Abstract

AIM: To investigate the role of local colonic mucosal NK receptor-positive T (NKR$^+$ T) cells in the regulation of intestinal inflammation, we analyzed the population and function of these cells in ulcerative colitis (UC).

METHODS: Colonic mucosal tissues were obtained from colonoscopic biopsies of the descending colon from 96 patients with UC (51 endoscopically uninflamed, 45 inflamed) and 18 normal controls. Endoscopic appearance and histologic score at the biopsied site were determined by Matts' classification. A single cell suspension was prepared from each biopsy by collagenase digestion. Two NKR$^+$ T cell subsets, CD56$^+$ (CD56$^+$CD3$^+$) T cells and CD161$^+$ (CD161$^+$CD3$^+$) T cells, were detected by flow cytometric analysis. Intracellular cytokine analysis for anti-inflammatory cytokine interleukin-10 (IL-10) was performed by *in vitro* stimulation with phorbol-myristate-acetate (PMA) and ionomycin.

RESULTS: CD56$^+$ T cells and CD161$^+$ T cells are present in the normal human colon and account for 6.7% and 21.3% of all mononuclear cells, respectively. The populations of both CD56$^+$ T cells and CD161$^+$ T cells were decreased significantly in the inflamed mucosa of UC. In contrast, the frequency of conventional T cells (CD56$^-$CD3$^+$ cells and CD161$^-$CD3$^+$ cells) was similar among the patient and control groups. The populations of NKR$^+$ T cells were correlated inversely with the severity of inflammation, which was classified according to the endoscopic and histologic Matts' criteria. Interestingly, approximately 4% of mucosal NKR$^+$ T cells expressing IL-10 were detected by *in vitro* stimulation with PMA and ionomycin.

CONCLUSION: Selective reduction in the population of colonic mucosal NKR$^+$T cells may contribute to the development of intestinal inflammation in UC.

Key words: Natural killer T cells; Ulcerative colitis; Interleukin-10

INTRODUCTION

Human ulcerative colitis (UC) is a chronic relapsing disorder of ill-defined immunoregulatory dysfunction that leads to inflammation or ulceration of the intestinal tract[1]. Increasing evidence suggests that dysregulation of mucosal T cells may play a key role in the pathogenesis of UC, which results in secretion of proinflammatory mediators, accumulation of inflammatory cells, and tissue damage[2-4]. The pathogenesis of UC remains obscure, but it is now believed that dysfunction of immunoregulatory T cells is considered one of the mechanisms by which intestinal inflammation persists in UC[5].

Human T cells that express natural killer (NK) markers, including CD56 and CD161, were originally discovered in the liver. They differentiate extrathymically and are considered immunoregulatory T cells[6,7]. Hepatic CD56$^+$ T cells and CD161$^+$ T cells can rapidly produce Th1-type and Th2-type cytokines, suggesting that these cells have roles in the regulation of both innate and adoptive immune responses[8-10]. They also have cytotoxic activity against some cancer cell lines[11]. Several investigators reported that hepatic CD56$^+$ T cells and CD161$^+$ T cells are depleted significantly in liver with chronic hepatitis C virus infection[12,13], suggesting that these cells may be involved in the development of hepatic inflammation.

These NK receptor-positive (NKR$^+$) T cells include both conventional major-histocompatibility complex (MHC)-restricted T cells that recognize peptide antigens[14]

and so-called NKT cells, which recognize glycolipid antigens presented by a non-classical antigen-presenting molecule, CD1[15-17]. The latter cell type frequently expresses invariant T cell receptor α-chains (Vα24JαQ in humans and Vα14Jα18 in mice)[9,18].

Recently it was reported that these NKR^+ T cells reside in the human intestine[19], and these populations are reduced in the colonic mucosa of patients with colorectal cancer[20]. However, to date, there have been no reports of the roles of these cells in modulation of intestinal inflammation in UC. Here, we investigated the relation between these cell populations and the severity of colonic inflammation in patients with UC by assessing colonic mononuclear cells in biopsy specimens. We found that a selective decrease in the population of colonic NKR^+ T cells may be involved in the progression of local colonic mucosal inflammation in UC.

MATERIALS AND METHODS

Study groups

Demographic features of the patients and history of drug therapy up to the time of colonoscopy are summarized in Table 1. The diagnosis of UC was based on established endoscopic and histopathologic criteria[21]. Colonic mucosal tissues were obtained from colonoscopic biopsies of 96 patients with UC (45 inflamed, 51 uninflamed). The control group consisted of 18 patients. Ten of these control patients presented with a chief complaint of abdominal pain in which a histological diagnosis was not established. The remaining eight control patients were evaluated endoscopically for hematochezia and found to have solitary adenomatous polyps. All control colonic mucosal samples were taken from a histologically normal portion of the biopsied specimen at least 10 cm away from the involved sites with the polyps. The inflammatory activity of these areas was evaluated endoscopically and histologically according to Matts' criteria with some modifications[22,23]. Inflamed and uninflamed areas were defined as grades 2-4 (and 5 for histologic Matts' criteria) and grade 1, respectively. All biopsy specimens were obtained from the descending colon. Standard 2.8 mm biopsy forceps (Olympus Optical, Tokyo, Japan) were used through all colonoscopes. All samples were obtained with informed consent in accordance with the Helsinki Declaration.

Table 1 Demographic features of participating patients with UC

		Ulcerative colitis	
	Normal	Inflamed	Uninflamed
No. of patients (cases)	18	45	51
Sex (male/female)	11/7	31/14	35/16
Age (yr), mean ± SD	47.5 ± 20.1	35.3 ± 13.6	39.3 ± 14.1
Disease duration (yr)		6.5 ± 6.6	6.2 ± 5.5
Types of colitis			
Total	-	31	10
Left-sided	-	9	14
Proctitis	-	0	24
Others	-	5	3
Treatment			
Prednisolone (PSL) (no/yes)	-	15/30	29/22
Azathioprine (AZA) (no/yes)	-	31/14	42/9

Isolation of lamina propria mononuclear cells

All specimens were weighed prior to isolation of colonic mononuclear cells (MNCs). Five biopsy samples for purification of MNCs and two biopsy samples for evaluation of histology were taken from the same region of each colon, and MNCs were purified as described previously[24]. Briefly, specimens were digested with 150 U/mL of collagenase in RPMI medium (Sigma, St. Louis, MO) containing 10% fetal calf serum (FCS, Sigma), 100 mg/L of gentamicin (Gibco, Gaithersburg, MD), 500 μg/L of penicillin, and 500 μg/L of streptomycin (Gibco) at 37℃ for 90 min. The cells were pelleted and washed with cold phosphate-buffered saline (PBS). Cells were resuspended in 44% isotonic Percoll (Sigma) underlaid with 66% isotonic Percoll and centrifuged for 20 min at 2200 r/min at room temperature. Cells at the interface were collected and washed twice with cold PBS. Cell viability was determined by 0.1% trypan blue dye exclusion, and it was consistently > 90% in all of the patient groups.

Intestinal histology

Intestinal biopsy specimens were fixed immediately in 10% formalin in sodium phosphate buffer and sent to the Department of Pathology at Hiroshima University for processing. Biopsies were embedded in paraffin, and histological sections were stained with hematoxylin and eosin for evaluation. Inflammation was graded according to Matts' classification[22]. The pathologist was blinded to cell surface analysis data.

Flow cytometric analysis

Cells were incubated with a saturating amount of FITC-conjugated anti-human CD3 (UCHT1) mAb and phycoerythrin (PE)-conjugated anti-CD56 (B159) mAb or anti-CD161 (DX12) mAb. All staining reagents were obtained from Becton Dickinson (BD, San Jose, CA, USA). After cells were washed twice with PBS, the stained cells were analyzed on a FACScan (BD), and data were processed with Cell Quest software (BD). The relative proportions of the lymphocyte subpopulations were determined as percentages of the total numbers of cells in a lymphogate defined by forward and side scatter properties. Non-viable cells were excluded by detection of propidium iodide uptake.

Stimulation of cells and staining for intracellular cytokines

Freshly isolated MNCs isolated from a patient with active UC were suspended in complete RPMI medium at a density of 1×10^6 cells/mL and stimulated for 6 h in 96-well plates (Microtest™ 96, BD) at 37℃ in 5% CO_2. Cells were stimulated with 50 ng/mL phorbol-myristate-acetate (PMA) plus 500 ng/mL ionomycin. As controls, unstimulated cells were treated similarly. Interleukin-10 (IL-10) production by NKT cells was examined by a combination of cell-surface and intracytoplasmic mAb staining for IL-10 (JES3-19F1, BD) with Cytofix/Cytoperm Plus™ (BD) and analyzed by flow cytometry.

Statistical analysis

Data were analyzed with StatView software (Japanese version, Hulinks, Tokyo, Japan) on a Macintosh Computer

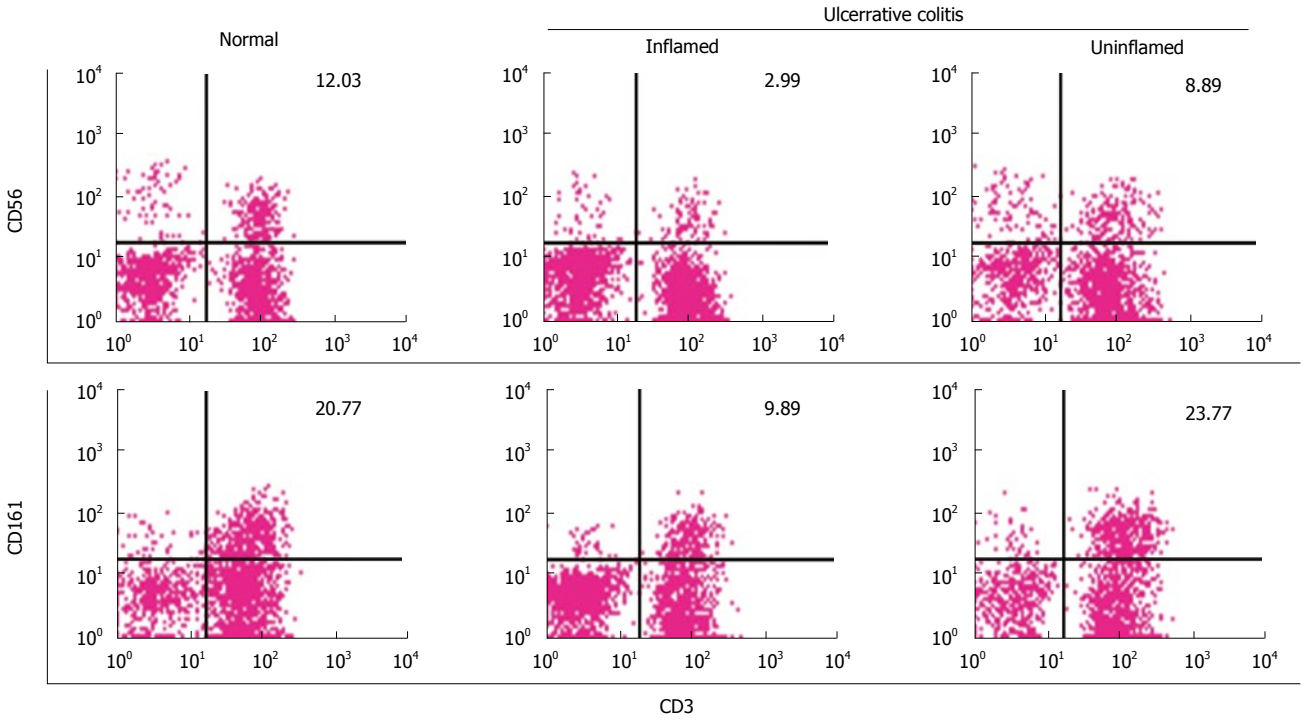

Figure 1 Representative FACS profiles of human colonic mucosal NKT cells. Flow cytometric analysis of CD3 and CD56/CD161 expression on MNCs isolated from colonic samples showing normal mucosa (left), inflamed (Matts' grade 3b) UC mucosa (middle), and uninflamed (Matts' grade 1) UC mucosa (right). The numbers in the top right quadrants denote the percentages of $CD56^+$ T and $CD161^+$ T cells.

(Apple Computer, Cupertino, CA). Data are expressed as mean ± SD. Differences between groups were examined for statistical significance with Student *t* test after analysis of variances (ANOVA). Differences were considered statistically significant at $P < 0.05$.

RESULTS

Decreases in $CD56^+$ T cells and $CD161^+$ T cells in the inflamed colonic mucosa of patients with UC

Representative FACS patterns of NKR^+T cells are shown in Figure 1. Flow cytometric analysis of freshly isolated colonic LPLs revealed that the proportion of NKR^+T cells expressing CD56 was significantly lower in patients with active UC (3.3% ± 1.7%, $P < 0.0001$; Figure 2A) in comparison with controls (6.7% ± 3.2%) and patients with inactive UC (7.5% ± 3.9%). Similarly, the proportion of NKR^+T cells expressing CD161 was significantly lower in patients with active UC (13.4% ± 6.4%, $P < 0.0005$; Figure 2B) in comparison with controls (21.3% ± 7.7%) and patients with inactive UC (21.4% ± 1.5%). The proportion of $CD3^-CD56^+$ NK cells was also reduced significantly in colonic LPL from patients with active UC in comparison with controls and patients with inactive UC (data not shown). No significant differences in the proportions of $CD56^-CD3^+$ and $CD161^-CD3^+$ conventional T cells were observed among these groups (Figure 2C and D), suggesting that mucosal NKR^+ T cells were selectively decreased in the inflamed UC mucosa. Furthermore, when we considered the inflamed mucosa by endoscopic and histologic classifications of Matts' grade, the populations of these NKR^+ T cells decreased as the degree of inflammation increased (Figures 3 and 4A). In contrast, the proportions of $CD56^-CD3^+$ and $CD161^-CD3^+$ conventional T cells were not influenced by the degree of histologic intestinal inflammation (Figure 4B). These results suggest that a relative decrease in the population of colonic NKR^+ T cells may exacerbate intestinal inflammation.

Prednisolone and azathioprine therapies did not affect the percentage of colonic NKR^+ T cells

The percentages of colonic NKR^+ T cells were compared between UC patients treated with or without prednisolone (PSL). We separated the groups into patients with inflamed and uninflamed mucosa because inflammation affects the proportion of NKR^+ T cells. PSL treatment did not influence the proportion of colonic NKR^+ T cells (Figure 5A and B). PSL dose did not influence the population of NKR^+ T cells (data not shown). Treatment with azathioprine (AZA) also did not affect the proportion of NKR^+ T cells (Figure 5C and D).

In vitro stimulation with PMA and ionomycin results in IL-10 production by colonic NKR^+ T cells

To further explore the functional role of NKR^+ T cells, analysis of expression of the anti-inflammatory cytokine, IL-10 was performed. As shown in Figure 6, a subset of colonic NKR^+ T cells from normal colonic mucosa produced intracellular IL-10 when stimulated *in vitro* with PMA^+ ionomycin.

DISCUSSION

In the present study, we observed that the populations of $CD56^+$ T cells and $CD161^+$ T cells were decreased significantly in inflamed lesions on the colonic mucosa

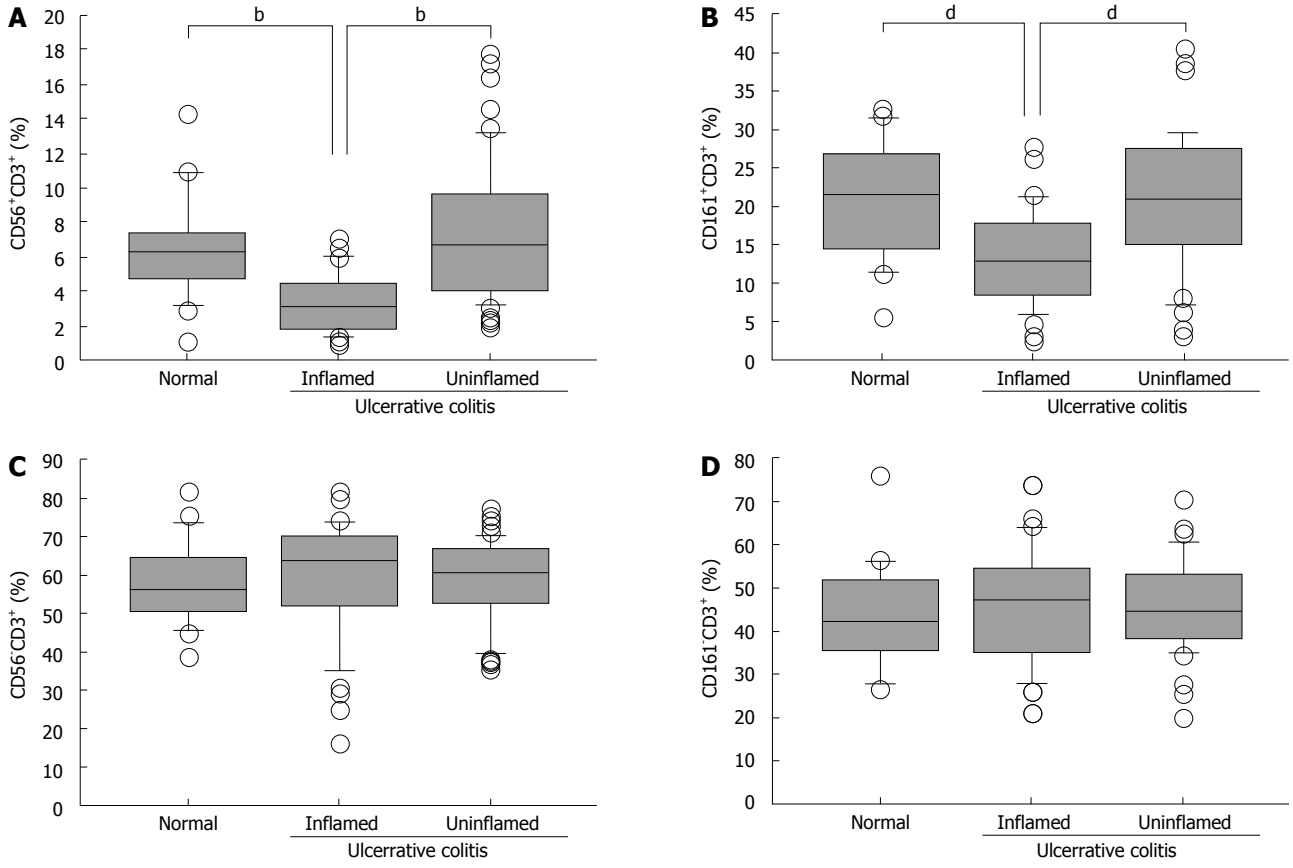

Figure 2 Selective decreases in the proportions of $CD56^+CD3^+$ (**A**) and $CD161^+CD3^+$ (**B**) cells in inflamed colonic mucosa of patients with UC. Box plot graphical representation of the percentage of colonic NKR^+ T cells from normal mucosa of non-UC patients (n = 18), uninflamed mucosa (endoscopic Matts' grade 1, n = 51), and inflamed mucosa (Matts' grades 2-4, n = 45). $^bP < 0.0001$, $^dP < 0.0005$; inflamed mucosa *vs* normal or uninflamed mucosa. (**C, D**) No relation was observed between the percentage of conventional T cells ($CD56^-CD3^+$ or $CD161^-CD3^+$ cells) and the degree of endoscopic inflammation.

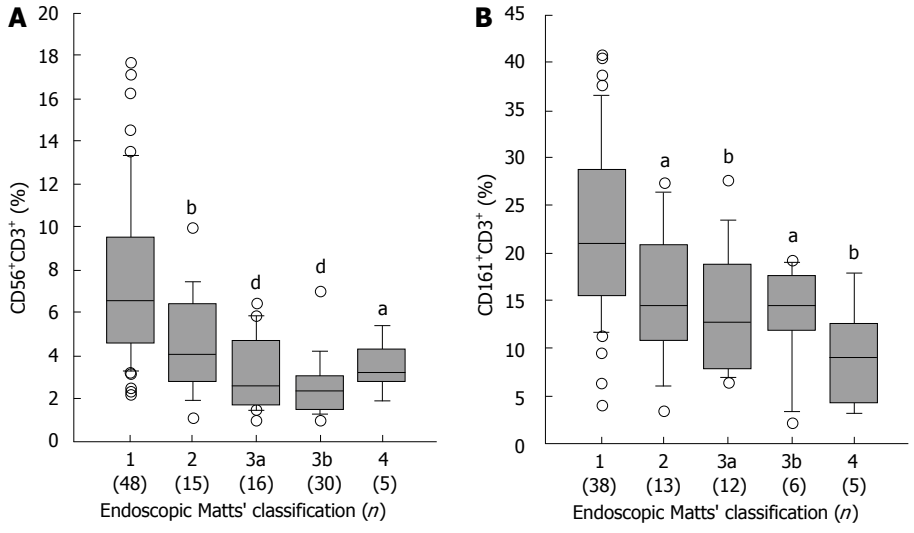

Figure 3 Relation between Matts' scores for endoscopy and the percentage of NKR^+ T cells. Box plot graphical representation of the percentage of colonic NKR^+ T cells in UC patients. The percentage of colonic NKR^+ T cells was compared with the Matts' scores. "n" indicates the number of cases. $^aP < 0.05$, $^bP < 0.01$, $^dP < 0.0001$, *vs* Matts' 1.

in patients with UC. The proportions of these cells were inversely well correlated with the degree of endoscopic and histologic intestinal inflammation. In contrast, the percentages of conventional T cells were similar among our study groups. Our findings suggest that selective decreases in levels of colonic NKR^+ T cells may contribute to the progression of intestinal inflammation.

$CD56^+$ T cells and $CD161^+$ T cells were originally identified in human liver. These cells have an extrathymic origin and have properties of innate lymphocytes[6,7]. These cells are uniquely capable of rapidly producing Th1 and Th2 cytokines upon stimulation[8-10], indicating a broad role for these cells in the activation and regulation of multiple arms of the immune responses. Although the functions of these $CD56^+$ T cells and $CD161^+$ T cells are currently unknown, they express memory T cell phenotypes[15] and homing chemokine receptors[25], suggesting that they may be memory T cells. The proliferation and function of these

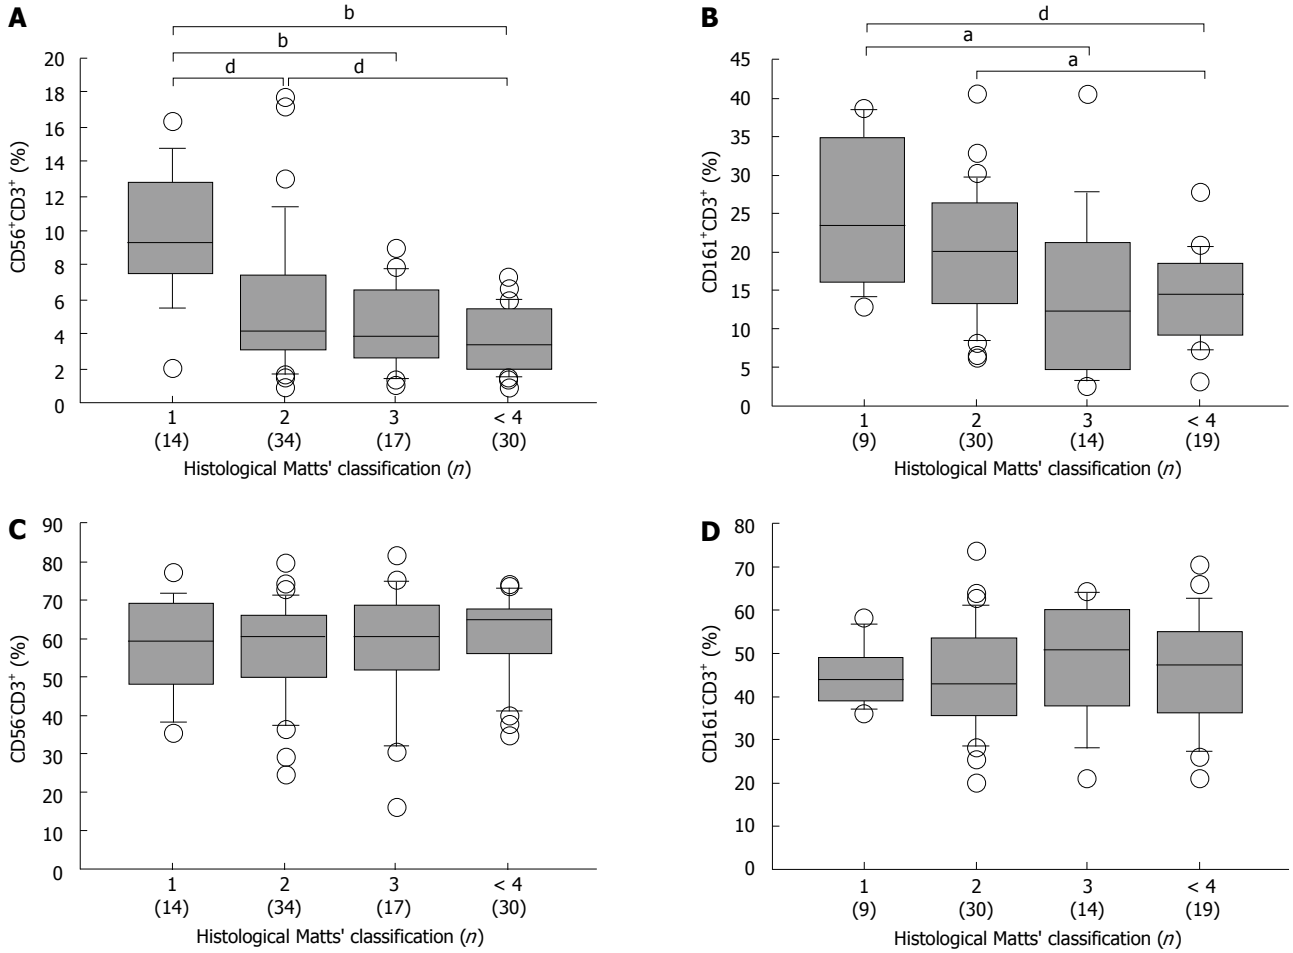

Figure 4 Relation between the histologic Matts' scores and the percentage of NKR$^+$ T cells. Biopsy samples for evaluation of histology were taken from the same regions as samples for MNC purification were taken. The percentage of colonic NKR$^+$ T cells was compared with the histologic Matts' score. Levels of CD56$^+$ T cells (**A**) and CD161$^+$ T cells (**B**) in the colon decreased significantly as a function of the severity of inflammation. "*n*" indicates the number of cases. $^b P < 0.0001$, $^d P < 0.005$ *vs* Matts' 1, $^a P < 0.05$ *vs* Matts' 1 or Matts' 2. No relation was detected between the percentages of conventional T cells (CD56$^-$CD3$^+$ or CD161$^-$CD3$^+$ cells) in the colon and the severity of histological inflammation (**C**, **D**).

cells are regulated by various cytokines, including IL-15 and granulocyte-macrophage colony-stimulating factor[26,27]. These NKR$^+$ T cells include invariant NKT cells that recognize glycolipid antigens presented by the non-classical antigen-presenting molecule CD1[15-17]. CD1d, which is an MHC Class I-like molecule, is expressed by human intestinal epithelial cells[28,29]. Bendelac *et al* reported that Vα24 NKT cells recognize CD1d molecules and act as immunoregulatory cells by producing various cytokines[30]. Blumberg *et al* showed that the CD1d molecule expressed by intestinal epithelial cells is functional because ligation with antibody against CD1d induces production of IL-10 by an intestinal epithelial cell line, T84[31]. Therefore, the interaction between CD1d on intestinal epithelial cells and mucosal CD1d-restricted T cells may be important for maintaining intestinal homeostasis. Whether these NKR$^+$ T cells are CD1d-restricted is currently under investigation.

The role of NKR$^+$ T cells in the development of intestinal inflammation is not clear. A mouse study revealed that CD1d-α-galactosylceramide (αGalCer)-restricted NKT cells are critical for protection against the development of dextran sulfate sodium-induced colitis[32]. The findings of another study suggested that IL-13-producing NKT cells are involved in the development of oxazolone-induced colitis in mice[33]. These data suggest that NKT cells are crucial for eliciting protective immunity against intestinal inflammation.

Although NKT cells are known to have an anti-inflammatory role[34], what is the mechanism by which these cells regulate the immune system? Sonoda *et al* showed that about 5% of NKT cells have the capacity to produce the immunosuppressive cytokine IL-10[35]. We have shown here that some colonic mucosal NKR$^+$ T cells can produce IL-10 when stimulated *in vitro*. IL-10 expression is also important for mucosal immunologic homeostasis. IL-10-deficient mice show enhanced production of colonic proinflammatory cytokines, including IFN-γ, and develop spontaneous chronic enterocolitis[36,37]. The subset of regulatory T cells that produce IL-10 suppresses the development of experimental intestinal inflammation[38]. Furthermore, mice with a macrophage/neutrophil-specific disruption of the Stat3 gene show impaired IL-10-mediated functions and develop chronic enterocolitis[39]. These observations support the idea that mucosal immune homeostasis involves localized production of molecules that promote IL-10 expression by resident immunoregulatory cells in the mucosa. Therefore, decreased IL-10 production due

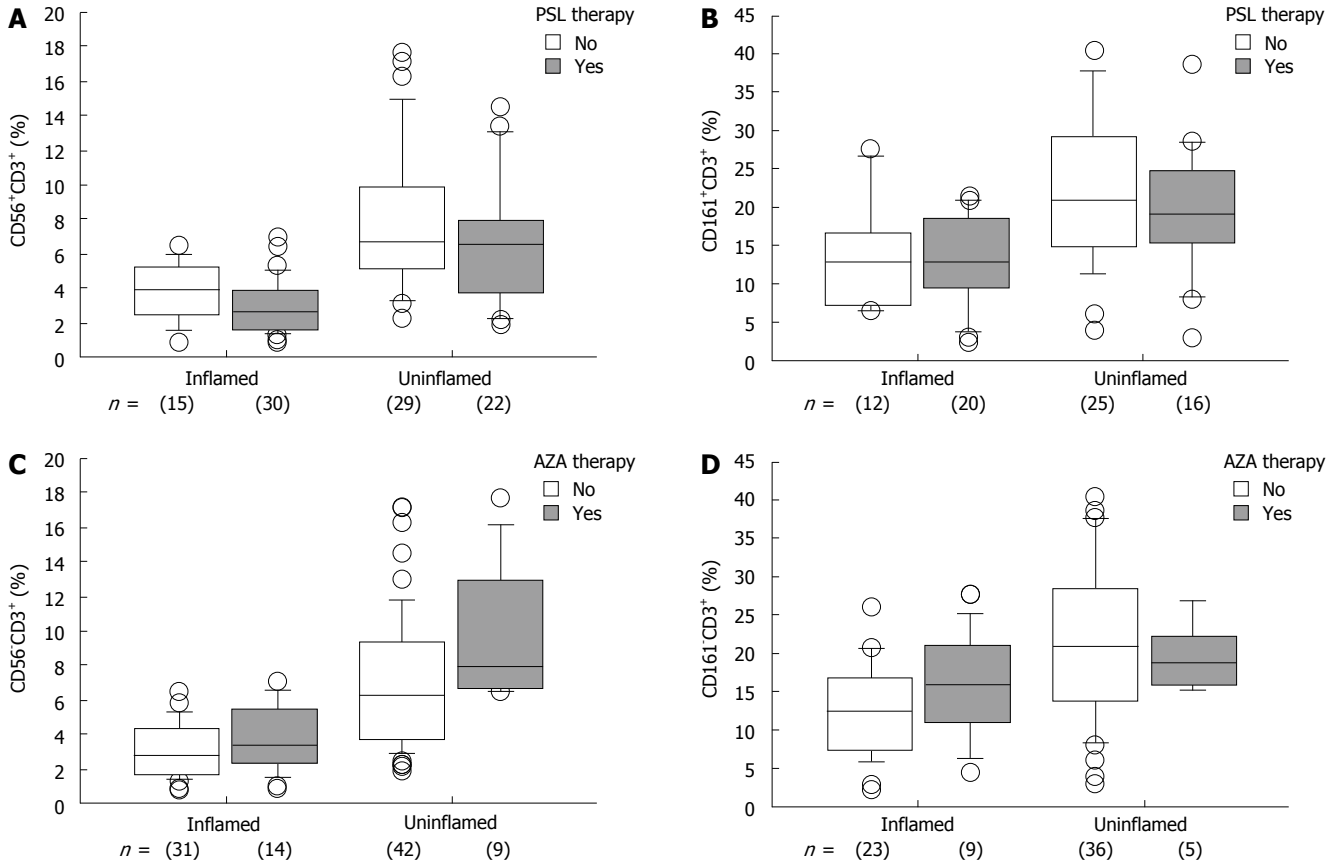

Figure 5 The percentage of colonic NKR$^+$ T cells was not affected by treatment with PSL or AZA. The percentages of colonic NKR$^+$ T cells were compared between untreated UC patients and those treated with PSL (**A, B**). The level of NKR$^+$ T cells was compared between untreated UC patients and those treated with AZA (**C, D**). "*n*" indicates the number of cases.

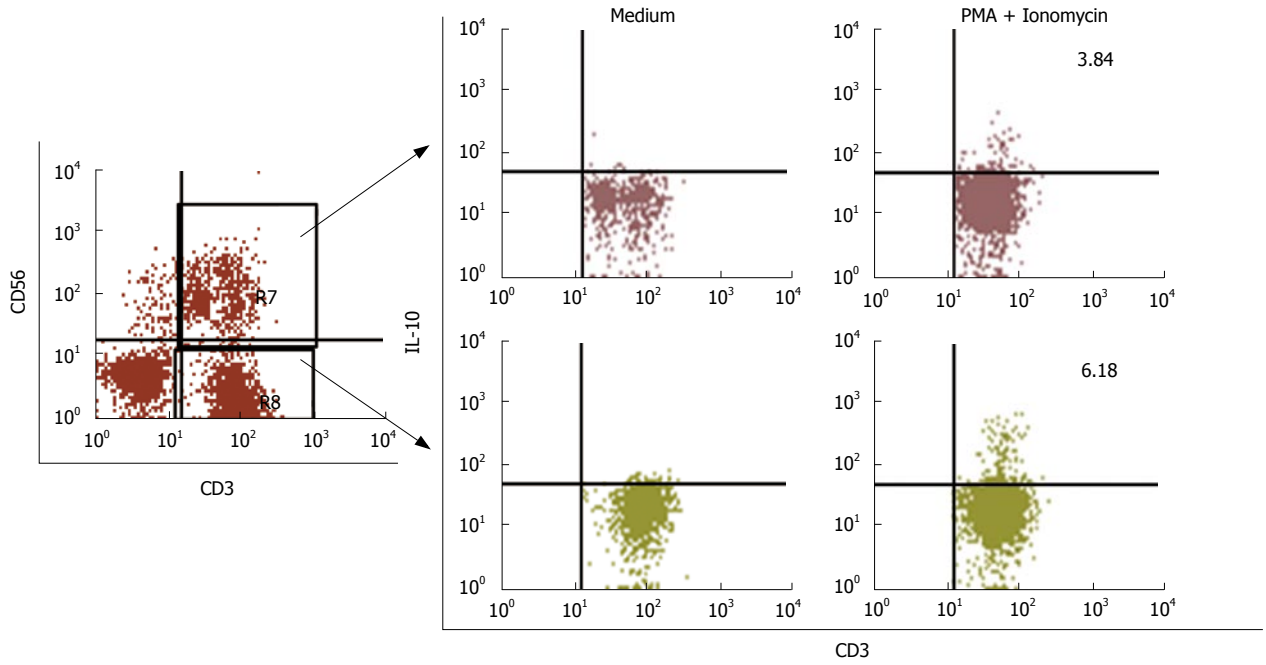

Figure 6 Detection of IL-10-producing NKR$^+$ T cells in the colonic mucosa. Flow cytometric analysis of IL-10 production by *ex vivo*-stimulated colonic MNCs isolated from a patient with active UC. FACScan was gated on CD56$^+$CD3$^+$ cells. The numbers indicate the percentages of CD56$^+$CD3$^+$ cells producing cytokines relative to unstimulated control cells.

to depletion of NKR$^+$ T cells in the colon of human UC as observed in the present study may result in insufficient inhibition of pathologic T cells and activated macrophages. Further studies are needed to compare the percentage of IL-10-producing cells between normal and UC colons.

Several mechanisms may account for the decreased

proportions of NKR^+ T cells in UC. First, the observed depletion of the local colonic NKT cell population may be the result of a continuous process of activation-induced cell death[40]. Second possible mechanism may be the loss of surface NK markers. It was recently reported that NKT cells activated by glycolipid antigens down-regulate NK receptors[41]. Third mechanism may be impaired recruitment of NKR^+ T cells from the peripheral circulation. $CD56^+$ T cells express chemokine receptors such as CCR5 or homing receptors such as $\alpha4\beta7$, a ligand for MAdCAM1 expressed specifically on the intestinal high endothelial venules[25]. These issues are currently under investigation in our laboratory.

In conclusion, human colonic $CD56^+$ T cells and $CD161^+$ T cells are thought to play important roles as anti-inflammatory cells, and the decrease in the proportions of these cells in inflamed lesions of the colon may be one mechanism by which colonic inflammation progresses in UC.

COMMENTS

Background

Human T cells that have natural killer markers are mainly located in the liver and considered immunoregulatory T cells. Recently it was reported that these natural killer receptor (NKR^+) T cells reside in the human intestine. But the exact significance of these cells in the intestine is unknown. This study was aimed at investigating the changes and significance of these cells in human ulcerative colitis (UC).

Research frontiers

Previous studies have demonstrated the significance of NKR^+T cells in human colorectal cancer. However, the role of these cells in the chronic intestinal inflammation is undefined.

Innovations and breakthroughs

The populations of both $CD56^+$ T cells and $CD161^+$ T cells were decreased significantly in the inflamed mucosa of UC. The populations of these NKR^+ T cells were correlated inversely with the severity of inflammation, which was classified according to the endoscopic and histologic Matts' criteria. In contrast, the frequency of conventional T cells ($CD56^-CD3^+$ cells and $CD161^-CD3^+$ cells) was similar among the patients with UC and healthy groups.

Applications

Selective reduction in the population of colonic mucosal NKR^+ T cells may contribute to the development of intestinal inflammation in UC.

Terminology

CD56 and CD161 are known as natural killer cell surface antigens. CD56 was demonstrated to be a neural cell adhesion molecule-1 (NCAM-1). $CD56^+$T cells are believed to be major players in immunosurveillance and antitumor responses. CD161 is a human NKR-P1 family and is recognized as an analogue of murine NKR-P1C. Moreover, $CD161^+$ T cells are also known to play an important role for antitumor immunity. CD161 is also expressed by invariant natural killer T cells that are restricted to CD1d molecule on antigen presenting cells.

Peer review

In this study, the authors demonstrate that the proportion of NKR^+ T cells is selectively decreased in the colonic mucosa of UC patients and that this reduced cell number correlates well with the severity of the disease. These cells are capable of producing an anti-inflammatory cytokine, IL-10. This work adds important information regarding cellular subsets that might be involved in the pathogenesis of UC.

Abstract

AIM: To investigate an association between *N*-acetyltransferase 2 (*NAT2*)-haplotypes/diplotypes and adverse effects in Japanese pulmonary tuberculosis patients.

METHODS: We studied 100 patients with pulmonary TB treated with anti-TB drugs including INH. The frequencies and distributions of single nucleotide polymorphisms, haplotypes, and diplotypes of *NAT2* were determined by the PCR-restriction fragment length polymorphism method, and the results were compared between TB patients with and without adverse effect, using multivariate logistic regression analysis.

RESULTS: Statistical analysis revealed that the frequency of a variant haplotype, *NAT2*6A*, was significantly increased in TB patients with hepatotoxicity, compared with those without hepatotoxicity [P = 0.001, odds ratio (OR) = 3.535]. By contrast, the frequency of a wild-type (major) haplotype, "*NAT2*4*", was significantly lower in TB patients with hepatotoxicity than those without hepatotoxicity (P < 0.001, OR = 0.265). There was no association between *NAT2*-haplotypes and skin rash or eosinophilia.

CONCLUSION: The present study shows that *NAT2* is one of the determinants of anti-TB drug-induced hepatotoxicity. Moreover, the haplotypes, *NAT2*4* and *NAT2*6A*, are useful new biomarkers for predicting anti-TB drug-induced hepatotoxicity.

Key words: Tuberculosis; Anti-tuberculosis drugs; Drug-induced hepatotoxicity; *NAT2*-haplotype; DNA-based diagnosis

INTRODUCTION

Tuberculosis (TB) is a re-emerging infectious disease that was declared a global health problem by the World Health Organization in 1993[1]. Since there were 9 million new TB cases and approximately 2 million TB deaths in 2004, and more than 80% of all TB patients live in sub-Saharan Africa and Asia, the epidemiology and control of TB remain important public health issues[1,2]. However, the management of TB is associated with serious problems, including disease relapse in elderly patients, occurrence

in acquired immunodeficiency syndrome, development of adverse effects of anti-TB drugs, and increase in the prevalence of multidrug-resistant *Mycobacterium tuberculosis*[2-5]. In particular, poor compliance or non-compliance with anti-TB drugs because of adverse effects, such as hepatotoxicity, skin rash, drug fever, peripheral neuritis, eosinophilia, and/or hyperuricemia, may lead to decrease in the quality-of-life of TB patients and appearance of multidrug-resistant *M. tuberculosis*. An important focus of previous studies was drug-induced hepatotoxicity, because it constitutes a major and severe adverse effect in the treatment of tuberculosis. Although the common risk factors for hepatotoxicity include advanced age[6,7], gender[7-10], malnutrition[6,9], complications of diseases[8,10,11], and alcohol intake[6,8,12], genetic factors also have an important impact on the likelihood of the development of drug-induced hepatotoxicity. Case-control studies with candidate genes in the affected populations have identified several possible susceptibility genes, e.g., *N*-acetyltransferase 2 (*NAT2*)[13-17], cytochrome P450 2E1 (*CYP2E1*)[16,18], glutathione *S*-transferase M1 (*GSTM1*)[16,19], glutathione *S*-transferase T1 (*GSTT1*)[16,19], and HLA-DQA1/-DQB1[20].

We focused our research on *NAT2* as a candidate gene associated with drug-induced hepatotoxicity because *NAT2* is the main enzyme involved in isoniazid (INH) metabolism, and is expressed in the liver. Diminution or disturbance of *NAT2* activity could result in the accumulation of precursors, such as hydrazine and acetylhydrazine in the liver, leading to hepatotoxicity[21-23]. Furthermore, the degree of metabolism with regard to *NAT2* varies among individuals, suggesting that genetic variations contribute to the metabolic activation capacity. Although studies on the association between *NAT2* phenotype (slow acetylator)[24] and anti-TB drug-induced hepatotoxicity have been reported from Taiwan[15,18], India[6,16], and Japan[13,14,17], no study has examined the association between hepatotoxicity and haplotypes/diplotypes that are composed of single nucleotide polymorphisms (SNPs). In the present study, we report our findings of the association between *NAT2* haplotypes/diplotypes and anti-TB drug-induced adverse effects, especially hepatotoxicity, in Japanese TB patients.

MATERIALS AND METHODS

Subjects

The study subjects comprised of 100 patients with new onset of pulmonary TB treated with a INH- (400 mg/d) and rifampicin (RFP, 450 mg/d)-containing regimen for six or nine months, between the years of 2003 and 2005 (Table 1). All subjects were Japanese who were recruited randomly from four general health clinics in the Nagasaki area of Japan. The study protocol was approved by the Committee for the Ethical Issue on Human Genome and Gene Analysis in Nagasaki University, and written informed consent was obtained from each patient.

The diagnosis of pulmonary TB was made on the basis of symptoms, chest radiographic infiltrates, and presence of acid-fast bacilli on sputum smear and *M. tuberculosis* on sputum culture. Patients with liver cirrhosis, chronic and acute hepatitis, alcoholic liver disease, and other chronic liver diseases were excluded from the study.

Table 1 Characteristics of pulmonary TB patients included in the study

Characteristics	TB
Number of patients	100
Age range (yr)	22-94
Age (mean ± SD)	64.0 ± 17.4
Gender (male/female)	56/44
Body mass index (kg/m^2)	20.3 ± 2.9

Diagnosis of drug-induced adverse effects

Patients with TB were classified into the following two subgroups: those with adverse effects such as hepatotoxicity, skin rash, and eosinophilia, and those without any side effects. Drug-induced hepatotoxicity was defined according to the criteria of the International Consensus Meeting[25], i.e., development of a two-fold or more increase in serum alanine aminotransferase (ALT) level above the upper limit of the normal range: N ($\leqslant$ 42 IU/L), or a combined increase of over 2 N in serum aspartate aminotransferase (AST, $N \leqslant$ 33 IU/L) and total bilirubin (TB, $N \leqslant$ 1.5 mg/dL). The presence of > 450 eosinophils/mL was defined as eosinophilia.

Determination of NAT2 polymorphisms

Genomic DNA was extracted from peripheral blood leukocytes of each patient using the DNA Extracter WB-Rapid Kit (Wako, Osaka, Japan), according to the manufacturer's protocol. SNPs of *NAT2* deposited in the SNP-database[26] were determined with PCR-restriction fragment length polymorphism (RFLP) method as described previously[27,28]. PCR was performed in a 25-μL reaction mixture containing 20 ng of genomic DNA, 20 mmol/L Tris-HCl (pH 8.4), 50 mmol/L KCl, 1.5 mmol/L $MgCl_2$, 200 μmol/L dNTP, 0.4 μmol/L each of sense and antisense primers, and 1.5 U Taq DNA polymerase (Invitrogen, Carlsbad, CA, USA) with a DNA thermal cycler, GeneAmp PCR System 9700 (Applied Biosystems, Foster City, CA, USA), according to the following protocol: initial denaturation at 95℃ for 5 min; 35 cycles of denaturation at 95℃ for 30 s, annealing at 55℃ for 30 s, and extension at 72℃ for 30 s; and a final extension at 72℃ for 5 min. Subsequently, the PCR product was digested by restriction enzyme (TaKaRa Biomedical, Shiga, Japan) for detection of each SNP. A SNP, C282T, was detected by digestion with *Fok* I. Likewise, C481T, G590A, and G857A were detected by *Kpn* I, *Taq* I, or *Bam* HI, respectively. These fragments were subjected to electrophoresis on a 2% agarose gel, and visualized with UV transilluminator (Alpha Innotech, San Leandro, CA, USA) after ethidium bromide (Invitrogen) staining. Haplotypes were determined to be based on a combination of four SNPs (Table 2)[26,28].

Statistical analysis

Data obtained are shown as mean ± standard deviation (SD). Clinico-pathological parameters were compared between TB patients with and without adverse effect, using the Mann-

Table 2 Five Haplotypes composed of four SNPs in *NAT2*

Haplotype	SNP			
	C282T	C481T	G590A	G857A
*NAT2*4*	-	-	-	-
*NAT2*6A*	+	-	+	-
*NAT2*7B*	+	-	-	+
*NAT2*11*	-	+	-	-
*NAT2*13*	+	-	-	-

Plus or minus symbols for C282T, C481T, G590A, and G857A indicate the presence or absence of SNPs.

Whitney *U* test, χ^2 test with Yates' correction, and Fisher's exact test. Expected allele frequencies were calculated from respective single allele frequencies according to the Hardy-Weinberg equilibrium. The observed and expected allele frequencies were compared by a χ^2 test using SNP Alyze 6.0 standard (Dynacom Inc., Chiba, Japan). To evaluate odds ratio (OR) with 95% confidence interval (95% CI) for the susceptibility to anti-TB drug-induced adverse effects, haplotype and diplotype frequencies were compared between TB patients with and without adverse effects, using multivariate logistic regression analysis. A *P* value of 0.05 or less was considered statistically significant. SPSS 14.0 (SPSS Japan Inc., Tokyo, Japan) program package was used for all statistical analyses.

RESULTS

Frequency of drug-induced adverse effects, and clinico-pathological parameters for susceptibility to the effects

Out of the 100 TB patients enrolled in the study, 50 (50%) patients had anti-TB drug-induced adverse effects, 18 hepatotoxicity, 25 skin rash, and 34 eosinophilia. There were no differences in the clinical characteristics and baseline laboratory data (before chemotherapy) between TB patients with and without adverse effects (Table 3). However, eosinophilia developed less frequently in female patients than male patients ($P = 0.0186$). During TB chemotherapy, patients with hepatotoxicity had 8-times higher serum levels of ALT and AST than those without hepatotoxicity ($P < 0.0001$). Likewise, during therapy, ALT values and eosinophil counts were significantly higher in patients with skin rash compared to those without skin rash ($P = 0.0245$ and $P = 0.0058$, respectively). Moreover, eosinophils in patients with eosinophilia were increased in number compared with those without this complication ($P < 0.0001$).

NAT2-haplotype susceptible to adverse effects

In the 100 TB patients examined, we identified three haplotypes composed of four SNPs (Table 4). One haplotype, "*NAT2*4*" is a wild-type (major type), while the other haplotypes are variants (minor types). Distribution of SNPs and haplotypes among patients corresponded well with the Hardy-Weinberg equilibrium, implying that our samples had a homogeneous genetic background, and was consistent with previous observations[13,14,17]. However, since the frequencies of two haplotypes, *NAT2*11* and *NAT2*13*, were very low, they were not used for further statistical analysis.

Multivariate logistic regression analyses revealed that the frequency of a variant haplotype "*NAT2*6A*", which is composed of two SNPs (C282T and G590A), was significantly increased in TB patients with hepatotoxicity, compared with those without hepatotoxicity ($P = 0.001$, OR = 3.535, 95% CI: 1.648-7.585) (Table 4). By contrast, the frequency of the wild-type (major) haplotype, "*NAT2*4*", was significantly lower in TB patients with hepatotoxicity than those without hepatotoxicity ($P < 0.001$, OR = 0.265). There were no significant differences in the frequency of *NAT2*-haplotypes between TB patients with and without skin rash or eosinophilia (Table 4).

NAT2-diplotype susceptible to adverse effects

We identified six diplotypes composed of three haplotypes (Table 5). Distributions of the diplotypes in our study population were consistent with previous observations [13,14,17]. Of a total of 18 TB patients with hepatotoxicity, 3 (16.6%) had a diplotype, "*NAT2*6A/*7B*"; using multivariate logistic regression analyses, the frequency was significantly higher than in patients without hepatotoxicity (2/82, 2.4%; $P = 0.029$, OR = 8.000, 95% CI: 1.230-52.023) (Table 5). On the other hand, the frequency of another diplotype, "*NAT2*4/*4*", was significantly lower in TB patients with hepatotoxicity than those without hepatotoxicity ($P = 0.032$, OR = 0.272). There was no difference in the frequency of *NAT2*-diplotypes between TB patients with and without skin rash or eosinophilia (Table 5).

DISCUSSION

We have shown that a variant haplotype, *NAT2*6A*, of *NAT2* is associated with susceptibility to anti-TB drug-induced hepatotoxicity, and a wild-type (major) haplotype, *NAT2*4*, is associated with non-susceptibility to hepatotoxicity. These findings suggest that *NAT2* is one of the genetic factors responsible for predisposition to anti-TB drug-induced hepatotoxicity. However, since the number of TB patients in the present study was relatively small, it remains to be confirmed whether this association can be reproduced in a larger number of Japanese TB patients with and without hepatotoxicity as well as in other ethnic populations. Although previous reports have shown a positive association in Japanese TB patients between drug-induced hepatotoxicity and *NAT2* variants with phenotypic activities of *NAT2*, such as rapid, intermediate, and slow acetylators[13,14,17], the present study is the first report demonstrating an association with *NAT2*-haplotype variation.

Three *NAT2* haplotypes, *NAT2*5B*, *NAT2*6A*, and *NAT2*7B*, are believed to be associated with slow acetylators[24,29,30]. We did not detect *NAT2*5B* in our samples, probably because of its low frequency in the Japanese population as described in our previous study[28]. Since *NAT2* is the main enzyme involved in the metabolism of INH and *NAT2*6A* is functionally related to the low activity of *N*-acetylation in the INH metabolic pathway[30], TB patients possessing *NAT2*6A* may fail to metabolize toxic substances, such as hydrazine and acetylhydrazine, generated by INH metabolism in the liver, which therefore accumulate in the body, leading to drug-induced hepatotoxicity[21-23,31,32].

Total number	18	82				25	75				34	66			

A variant diplotype, *NAT2*6A/*7B*, is associated with susceptibility to hepatotoxicity ($P = 0.029$). Although another *NAT2*-diplotype, *NAT2*6A/*6A*, showed a trend towards susceptibility to hepatotoxicity, the results were statistically not significant ($P = 0.121$). However, if a larger number of subjects were analyzed, *NAT2*6A/*6A* as well as *NAT2*6A/*7B* may demonstrate a significant association with hepatotoxicity. Both of these diplotypes are homozygous for variant haplotypes and indicate phenotypically slow acetylators. Therefore, it is likely that some of the slow acetylators who are variant homozygotes possessing the *NAT2*6A* haplotype have susceptibility to anti-TB drug-induced hepatotoxicity. In this context, the results of the present study with regard to *NAT2*-haplotypes/diplotypes are comparable to those of previous reports on the association between *NAT2* phenotypic variation and hepatotoxicity[13-17,32]. Conversely, a wild-type homozygote, *NAT2*4/*4*, is associated with non-susceptibility and resistance to hepatotoxicity.

In conclusion, the haplotypes, *NAT2*4* and *NAT2*6A*, are new biomarkers for predicting drug-induced hepatotoxicity, and may prove useful in achieving optimal treatment of individual TB patients.

ACKNOWLEDGMENTS

We are grateful to TB patients and physicians for participating in this study.

COMMENTS

Background

Tuberculosis (TB) is a re-emerging infectious disease and has been declared a global health problem by the WHO. Adverse effect of anti-TB drugs including

isoniazid (INH) has become a serious problem in the management of tuberculosis. Risk factors associated with the development of adverse effects include both clinical and genetic factors. Recently, genome-wide screening and candidate gene-based association studies have been launched to identify the possible susceptibility genes sensitive to anti-TB drugs.

Research frontiers

Association studies with candidate gene-based approach in Asian and Caucasian patients have identified several possible susceptibility genes, e.g., *N*-acetyltransferase 2 (*NAT2*), cytochrome P450 2E1, glutathione *S*-transferase M1, glutathione *S*-transferase T1, and HLA-DQA1/-DQB1.

Innovations and breakthroughs

There are several reports on the association between *NAT2* polymorphisms and adverse effects, especially hepatotoxicity, of anti-TB drugs from Japan, Taiwan, and India. However, *NAT2* polymorphisms have been analyzed as phenotypic activities of *NAT2*, such as rapid, intermediate, and slow acetylators, but not as *NAT2*-haplotypes. The present study has shown that some phenotypically slow acetylators who are variant homozygotes possessing *NAT2*6A* haplotype have increased susceptibility to anti-TB drug-induced hepatotoxicity. This is the first report on the association with *NAT2*-haplotypes and hepatotoxicity in Japanese TB patients.

Applications

Our findings can be used for DNA-based diagnosis of TB patients before initiating treatment with anti-TB drugs, using *NAT2*6A* as a biomarker. Since patients possessing *NAT2*6A* haplotype have higher susceptibility to anti-TB-drug-induced hepatotoxicity, such individuals should be treated by reducing the dose of INH from 400 to 200 mg, in order to achieve optimal results.

Terminology

NAT2 is the main enzyme in the INH metabolism, and is expressed in the liver. Single nucleotide polymorphism (SNP) is a DNA sequence variation which occurs when a single nucleotide in the genome differs in paired chromosomes of an individual. Haplotype is a combination of alleles at multiple linked loci that are transmitted together. A second interpretation is that a haplotype is a set of SNPs on a single chromatid that is statistically associated. Such information is very valuable in investigating the genetics behind common diseases. Restriction fragment length polymorphism (RFLP) is a laboratory technique designed to distinguish differing nucleotide sequences from two related contexts.

Peer review

This study is well performed and the subject matter is very interesting.

Abstract

AIM: To analyze the spectrum and risk factors of gastroesophageal reflux disease (GERD) based on presenting symptoms and endoscopic findings.

METHODS: A cross-sectional survey in a cluster random sample was conducted from November 2004 to June 2005 using a validated Chinese version Reflux Disease Questionnaire (RDQ) and other items recording the demographic characteristics and potential risk factors for GERD. Subjects were defined as having GERD symptoms according to the RDQ score (> 12). All subjects were endoscopied and the definition and severity of erosive esophagitis were evaluated by Los Angeles classification. The statistical analysis was performed with SPSS13.0 programs.

RESULTS: Of 2231 recruited participants, 701 (31.40%) patients were diagnosed as having GERD while 464 (20.80%) patients had objective findings of reflux esophagitis (RE). Of those 464 patients, only 291 (13.00%) were reported as subjects with GERD symptoms. A total of 528 (23.70%) patients were found to have GERD symptoms, including 19.50% patients with grade A or B reflux esophagitis, 0.90% with grade C and 0.40% with grade D. On multivariate analysis, old age, male, moderate working burden, divorced/widowed and strong tea drinking remained as significant independent risk factors for erosive esophagitis. Meanwhile, routine usage of greasy food and constipation were considered as significant independent risk factors for non-erosive reflux disease (NERD).

CONCLUSION: GERD is one of the common GI diseases with a high occurrence rate in China and its main associated factors include sex, anthropometrical variables and sociopsychological characteristics.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a common disorder with a high incidence rate of 10%-38% of adults in the Western population occurring at least once a week[1,2]. The prevalence of GERD has been increasing[3]. The diagnosis and treatment of GERD are therefore, important because the disease, in addition to the highly disturbing typical symptoms, has a series of known consequences. The presence of GERD may affect the patients' quality of life[4], decrease functional activity[5], increase the economic burden[6] and the risk of esophageal carcinoma in the cases of Barrett's esophagus[7]. With an emphasis on morphological diagnosis, endoscopy has become a major tool to assess the final consequences of GERD, which is especially useful for population-based screening.

Although many investigators have reported the prevalence of erosive esophagitis[8], the prevalence of NERD has not been investigated in China. Our study was designed to analyze the spectrum of GERD subjects based on presenting symptoms and endoscopic findings. In order to determine the risk factors for such disease in outpatients from Zhejiang Province of East China, a cross-sectional survey in a cluster random sample was conducted from November 2004 to June 2005.

MATERIALS AND METHODS

Subjects

From November 2004 to June 2005, outpatients visiting departments of medicine in 10 hospitals from island, mountainous area, plain, city, countryside and suburb, in the Zhejiang Province of East China were recruited to the study. Subjects were excluded if they were not permanent inhabitants of East China, less than 18 years old, and had major psychotic episodes, mental retardation, dementia, severe visual or hearing abnormalities or other illnesses that might render them unable to complete the questionnaire or undergo the endoscopy (e.g. stroke). Excluding criteria also contained a history of peptic ulcer disease and receiving proton pump inhibitors or H_2-blockers over the preceding 2 wk. A total of 2278 individuals who had GI endoscopy were recruited, of which 2231 were eligible with a response rate of 97.9%.

Questionnaire

The gastroesophageal reflux questionnaire, a self-report instrument that to evaluate reflux-associated symptoms during the prior month, included the Chinese version of the Reflux Diagnostic Questionnaire (RDQ)[9] and items concerning the demographic characteristics and probable risk factors for GERD. It comprised the following parts: (1) General information: gender and age. (2) The Chinese version of the Reflux Diagnostic Questionnaire (RDQ): its framework of the RDQ was based on a validated questionnaire previously published[3]. The Chinese version of the RDQ was designed to measure symptoms suggestive of GERD appearing during the previous month. The intraclass correlation coefficient of the Chinese version of the RDQ was 0.9, thus it was validated and found to be a useful screening test for GERD-associated symptoms in China[9]. The symptoms suggestive of GERD in the RDQ included heartburn, substernal chest pain, acid eructation and food regurgitation. The following definitions were used to identify the symptoms in the RDQ: (1) heartburn, a burning sensation located beneath the sternum; (2) substernal chest pain: any pain felt inside in the chest but not including heartburn or any pain that is primarily originated from the abdomen; (3) acid regurgitation, a bitter- or sour-tasting fluid coming into the throat or mouth; and (4) food regurgitation, unpleasant movement of material upwards from the stomach but not vomit. Each symptom was scored according to the frequency and severity (5-point scale). The highest score for one subject was 40. The frequency was measured according to the following scale: 0, no symptom in the past month; 1, less than once a week; 2, once a week; 3, two to three days a week; 4, four to five days a week; and 5, almost daily. Symptom severity was assessed on the following scale:0, none; 1, very mild (symptoms can be easily ignored unless reminded of them); 2, mild (between 1 and 3); 3, moderate (symptoms are obvious and sufficient to influence normal activities, and occasionally need treatment); 4, severe (between 3 and 5); and 5, very severe (symptoms are obvious and sufficient to influence normal activities, and need long-term medication).

The Chinese version of the RDQ has been tested in a multicenter study including 10 hospitals in China. The specificity and sensitivity of the RDQ were evaluated by comparing the results with those of upper gastrointestinal endoscopy and esophageal 24-h pH monitoring. The RDQ score correlated positively with the severity of reflux esophagitis. Esophageal pH monitoring showed that patients with abnormal RDQ scores had higher Demeester scores than those with normal RDQ scores (20.18 *vs* 16.84). Taking 12 as the parameter for the threshold of RDQ score for GERD-associated symptoms, the study group obtained the maximal Youden index, the area under the receiver operating characteristic curve (ROC), was 0.71, the true positive diagnostic rate was 88.07% and the true negative diagnostic rate was 68.42% with a sensitivity of 94.12% and specificity of 50.00%. The subject was defined as a patient with GERD symptoms if his/her RDQ score was higher than 12[9]. Probable risk factors for GERD symptoms included life status: working burden, marital status (married, single, divorced/widowed), constipation, dietary and other personal habits: excessive consumption of acidic beverages, coffee, strong tea, spicy food, greasy food, sweet food, cigarette and alcohol. Definitions: heavy smoker (more than 20 cigarettes per day), excessive alcohol ($\leqslant$ 210 g of alcohol per week), constipation (frequently occurred during last 12 mo), routine use of coffee (more than 100 mL per day on average), acidic beverages and strong tea (more than 200 mL per day on average), dietary habits (taking the food mentioned above more than one time per day on average). The questions about probable risk factors, extra esophageal symptoms and accompanying diseases were all binary: yes or no.

Upper gastrointestinal endoscopy

Patients were examined for the presence of reflux esophagitis. Diagnosis and classification of reflux esophagitis were based on the Los Angeles classification[8]. Barrett's esophagus was diagnosed when columnar epithelium was seen to extend the Z line and confirmed histologically that showed specialized intestinal metaplasia. These criteria were consistently applied and endoscopic diagnosis was confirmed by either of the authors who were present during each endoscopic procedure. Patients who returned for endoscopic reassessment for any reason were excluded from the analysis to prevent duplication of cases.

Survey design and response rate

The cross-sectional survey in a cluster random sample was conducted from November 2004 to June 2005. The present study was based on a standard protocol including routine internal medicine counseling, endoscopy, and a self-reported questionnaire. Consecutive numbers were assigned to each registered subject and a 1:10 ratio of sample was selected using random number tables. All subjects completed the detailed questionnaire before endoscopy. Confirmed consent was obtained from all patients before the questionnaire was administered. All subjects were given the questionnaire.

A subject with GERD symptoms was defined according to the RDQ score (> 12). Patients who were

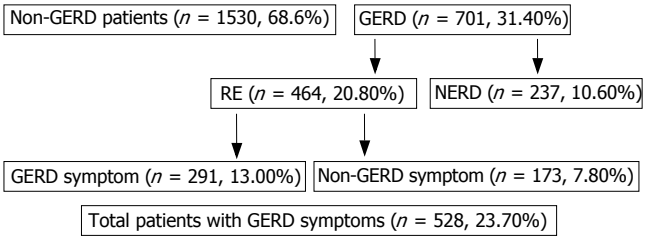

Figure 1 Diagnosis of gastroesophageal reflux disease (GERD) based on symptoms and presence of reflux esophagitis (RE).

Table 1 Grading of reflux esophagitis in 2278 patients

Grade	Total number	%
None	1767	79.20
A	333	14.93
B	102	4.57
C	20	0.90
D	9	0.40
Total	2231	100.00

Table 2 Complications of reflux esophagitis

	Total number	%
Barrett's esophagus	No 1190	98.76
	Yes 15	1.24
Esophageal stenosis	No 1191	98.76
	Yes 15	1.24
Esophagorrhagia	No 1186	98.18
	Yes 22	1.82

suspicious of having GERD but without evidence of reflux esophagitis (RE) were diagnosed as having NERD. GERD was diagnosed based on the presence of reflux esophagitis and/or the presence of predominant reflux symptoms. Because the survey explanation is made according to the RDQ score, all the questions in the RDQ must be answered without omission. In this study, a total of 2231 eligible subjects were recruited.

Ethics

The study was approved by the Ethics Committee of the First Affiliated Hospital, College of Medicine, Zhejiang University.

Statistical analysis

The database was established with Epidata3.0. Statistical analysis was performed with SPSS13.0 programs. Univariate analysis was performed using χ^2 test for categorical variables. Univariate and multivariate logistic regression models were used to identify the potential risk factors of GERD, NERD and reflux esophagitis. The probable risk factors for GERD symptoms were selected by the univariate logistic regression, including life status (labor burden, marital status), dietary and other personal habits such as routine usage of acidic beverage, spicy food, greasy food, coffee, strong tea, sweet food, cigarette and alcohol, and constipation. All risk factors associated with GERD symptoms on univariate analysis were modeled using multivariate forward stepwise logistic regression analysis. To find the best model, a forward elimination stepwise procedure was carried out in a way that the factor would be brought into the analysis if the corresponding P value was less than 0.5. A P value $\geqslant 0.05$ was considered statistically significant and all P values were obtained by two-tailed examination.

Table 3 Comparison between upper gastrointestinal endoscopy and RDQ (χ^2 test)

RDQ	Endoscopy		*P* value
	Negative	Positive	
Negative	1530	173	0.002
Positive	237	291	

$P = 0.002$, there is significant statistical difference between the two investigations.

Total	1767	333	102	20	9	2231		

RESULTS

Sample characteristics

A total of 2231 (56.6% male, 43.4% female) outpatients aged from 18 to 90 years (a median age of 43 years) were recruited to this study.

Prevalence of GERD, reflux esophagitis and NERD

As shown in Figure 1, 701 (31.40%) patients were diagnosed as having GERD and 464 (20.80%) patients were found to have objective findings of reflux esophagitis. Of the 464 patients, only 291 (13.00%) presented with GERD symptoms. Among the 2231 subjects, 528 (23.70%) presented with GERD symptoms.

Distribution of different grades and complications of reflux esophagitis

As shown in Table 1, 435 patients (19.50%) had grade A or B reflux esophagitis while 20 patients had grade C (0.90%) and 9 had grade D (0.40%). The complications of reflux esophagitis are shown in Table 2. The most frequent complication is esophagorrhagia (1.82%).

Comparison between upper gastrointestinal endoscopy and RDQ

As shown in Tables 3 and 4, there is significant difference between the two investigations. The Kappa value was 0.47, $P = 0.000$, demonstrating no predominant consistency between the two diagnostic methods.

Risk factors in GERD and non-GERD patients

GERD: Gastroesophageal reflux disease.

compared to non-GERD patients is shown in Table 5. On univariate analysis, age > 65, male, moderate working burden, divorced/widowed, excessive eating, greasy food, spicy food, strong tea, smoking, alcohol, and constipation were found to be significant participants. On multivariate analysis, old age (OR, 0.57; β, -0.57; 95% CI, 0.40-0.80), male (OR, 0.78; β, -0.25; 95% CI, 0.61-1.00), moderate working burden (OR, 0.58; β, -0.54; 95% CI, 0.39-0.87), divorced/widowed (OR, 1.82; β, 0.60; 95% CI, 1.27-2.60), greasy food (OR, 0.75; β, -0.29; 95% CI, 0.60-0.95), strong tea (OR, 0.67; β, -0.40; 95% CI, 0.50-0.89) remained as significant independent risk factors.

Risk factors in reflux esophagitis and non-GERD patients

The prevalence of various variables in reflux esophagitis patients compared to non-GERD patients is shown in Table 6. On univariate analysis, age > 65, male, moderate working burden, divorced/widowed, spicy food, strong tea, smoking, and alcohol were found to be significant. On multivariate analysis, old age (OR, 1.86; β, 0.62; 95% CI, 1.29-2.70), male (OR, 1.77; β, 0.57; 95% CI, 1.32-2.37), moderate working burden (OR, 1.91; β, 0.65; 95% CI, 1.22-2.97), divorced/widowed (OR, 0.55; β, -0.60; 95% CI, 0.36-0.85), strong tea (OR, 1.62; β, 0.48; 95% CI, 1.18-2.23) were considered as significant independent risk factors.

Risk factors in NERD and non-GERD patients

The prevalence of various variables in NERD patients compared to non-GERD patients is shown in Table 7. On univariate analysis, divorced/widowed, excessive eating,

GERD: Gastroesophageal reflux disease; NERD: Non-erosive reflux disease.

greasy food, spicy food, strong tea and constipation were found to be significant. On multivariate analysis, greasy food (OR, 1.65; β, 0.50; 95% CI, 1.16-2.36) and constipation (OR, 1.51; β, 0.41; 95% CI, 1.01-2.25) were regarded as significant independent risk factors.

DISCUSSION

Traditionally, GERD is defined based on three major diagnostic parameters: (1) ambulatory 24-h esophageal pH monitoring; (2) upper gastrointestinal (GI) tract endoscopic examination for erosive esophagitis; and (3) clinical evaluation by physicians and clinical therapeutic treatment by acid suppression agents. The sensitivity of endoscopic examination is limited, as most patients with GERD do not have obvious mucosa injury. Therefore, most of their disease is categorized as non-erosive reflux disease (NERD). Ambulatory 24-h esophageal pH monitoring also has problems with sensitivity for the intermittent nature of symptoms and daily activities may disturb the placement of a pH probe. Endoscopy can be more easily applied to healthy participants than ambulatory 24-h esophageal pH monitoring. Furthermore, it is more objective in terms of finding reflux disease, which has been investigated in many previous studies. Erosive esophagitis is classified using the LA system, which appears to be the most unambiguous and simple method to apply. However, endoscopic examination alone can not rule out GERD or acid-induced epithelial injury. A variety of questionnaires designed for GERD clinical trials have been developed. The Gastrointestinal Symptom Rating Scale (GSRS)[10] comprises 15 items addressing five symptom clusters (gastroesophageal reflux, abdominal pain, indigestion, diarrhoea, and constipation). The GSRS used graded response categories from "none" to "very severe" without defining what these adjectives meant. This can produce subjective answers, reducing reliability and validity[11]. The "CarlssonDent Self-Administered Questionnaire (QUEST)"[12] had a good face validity, since it incorporated "word pictures" using simple English to describe symptoms of GERD. The GERQ[13] is a self-administered validated instrument that identifies the onset of GERD symptoms and grades the frequency and severity of symptoms over a prior year. It was a long questionnaire containing 80 questions, making it inconvenient for use in clinical trials.

The Chinese version of the Reflux Diagnostic Questionnaire (RDQ): Its framework of the RDQ was based on a validated questionnaire published before[3]. Shaw *et al*[3] found that the RDQ demonstrated validity and reliability and was responsive to change for reflux. The reliability coefficient of the RDQ scales ranged from 0.8 to 0.88, well beyond the acceptable level of 0.70. It was tested in the multicenters and found that it could accurately identify the presence of symptoms suggestive of GERD[9]. It was designed to measure GERD symptoms over the previous month, not the previous year. It was feasible to prevent the recall bias since McColl found that 1-mo was the maximum period over which patients could provide reliable data due to recall errors[14]. Four symptoms were included in the RDQ that may be somewhat different from the definition of the previous studies[10,12-13]. It would be more accurate to include substernal chest pain and food regurgitation to make a diagnosis of GERD[9,15]. Complete satisfaction of multitrait scaling criteria justifies combining the items into scales that can be scored with simple addition, thus eliminating the need for item weighting[16]. As our study confirmed there was no significant statistical difference between the two investigations. The Kappa-value was 0.4-0.75, which demonstrated no predominant consistency between the two diagnostic methods.

GERD becomes more common in Asian countries, resulting in more people coming to the gastroenterology outpatient department for treatment. A 13%-15% prevalence of reflux symptoms has been reported in

Asian GERD patients, which is comparable with results in many Western series. However, the definition of GERD may alter estimated prevalence. In the present study, data for subjects with GERD symptoms (23.70%) support previous prevalence rates[17].

We showed for the first time that the prevalence of NERD in the Chinese is 10.60% (237 of 2231 investigated persons), which is lower than that of erosive esophagitis (20.80%), while the prevalence rate of symptomatic GERD is 10%-30% in Western countries, and more than half of the patients lack endoscopically proven erosive esophagitis[18,19]. In Western countries, the majority of patients with GERD have been reported to have NERD, but not erosive esophagitis, even in cases with severe symptoms[18].

The factors that determine the form of NERD versus erosive esophagitis have not yet been clarified. However, we elucidated differences in the possible causative factors of NERD and erosive esophagitis. By multivariate logistic regression analysis, it was found that old age, male, moderate working burden, divorced and strong tea remained as significant independent risk factors for erosive esophagitis, meanwhile, greasy food consumption, constipation were regarded as significant independent risk factors for NERD.

Several risk factors associated with GERD have been reported as follows. Old age has been shown to be associated with increased risk of erosive esophagitis, Berrat's esophagus, and esophageal adenocarcinoma[20].

The previous studies showed that male gender is a risk factor for erosive esophagitis; whereas female is more likely to be associated with NERD[21,22]. Less parietal cell mass in women may be underlining reasons for the lower risk of GE[23].

Tea drinking has previously only been studied in a case series of reflux episodes[24]. While from another previous population-based study, the tea drinking does not seem to be a risk factor for GERD[25].

Coffee has been reported to be a reduced risk of reflux symptoms among coffee drinkers compared with non-coffee drinkers[25,26]. But previous cross sectional epidemiological studies have been able to establish that coffee drinking is a risk factor for GERD[24]. To accurately evaluate the long term effects of coffee drinking on the risk of reflux, an analysis of prospective exposure data would be necessary.

Smoking has often been cited as risk factors for GERD, although the findings of studies on this matter have been inconsistent[25,27]. Smoking was inversely related to NERD compared with RE[22]. Smoking decreases lower esophageal sphincter pressure and increases the frequency of reflux episodes. In addition, deleterious effects on esophageal defenses such as reduction of esophageal clearance and salivary function have been described[22].

Erosive esophagitis was positively related to alcohol consumption[28]. The mechanism is that alcohol intake induces nausea and vomiting and directly causes mucosal impairment, while food intake at late night elevates the risk of esophagitis[29].

In this cross sectional study, greasy food consumption was associated with an increased risk of GERD symptoms and erosive esophagitis. Several physiological studies of human volunteers have shown increased frequency of transient lower esophageal sphincter relaxation and increased esophageal acid exposure with greasy food consumption[30].

However, a limitation of the current study involves the subject sample. Subjects were outpatients from 10 hospitals and therefore probably represent a population of intermediate GERD severity between subjects recruited from gastrointestinal clinics and those randomly selected from the general population. In addition, other potential risk factors of GERD such as *H pylori*, hiatal hernia and BMI were not assessed in our study. Whether these factors are positively associated with GERD, calls for further observations.

In conclusion, GERD is a highly prevalent disease. Old age, male, moderate working burden, divorced and strong tea remained as significant independent risk factors for erosive esophagitis, meanwhile, midst bodily form, greasy food consumption, and constipation were considered as significant independent risk factors for NERD.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a common disorder with a high occurrence of up to 10%-38% of adults in the Western population at least once a week. The prevalence of GERD has been increasing year after year. The diagnosis and treatment of GERD are important because the disease, in addition to the highly disturbing typical symptoms, has a series of known consequences. The presence of GERD may affect the patients' quality of life, decrease functional activity, increase the economic burden associated and highlight the risk of esophageal carcinoma in the cases of Barrett's esophagus. With an emphasis on morphological diagnosis, endoscopy has become a major tool to assess the final consequences of GERD, which is especially useful for population-based screening.

Research frontiers

The definition or the diagnostic parameters of GERD and the factors that determine the form of NERD versus erosive esophagitis have not yet been clarified.

Innovations and breakthroughs

Although many investigators have reported the prevalence of erosive esophagitis, the prevalence of NERD has not been investigated in China. We showed for the first time that the prevalence of NERD in the Chinese is 10.60% (237 of 2231 investigated persons), which is lower than that of erosive esophagitis (20.80%), While the rate of symptomatic GERD is 10% to 30% in Western countries, and more than half of these patients lack endoscopically proven erosive esophagitis. The factors that determine the form of NERD versus erosive esophagitis have not yet been clarified. However, we elucidated differences in the possible causative factors of NERD and erosive esophagitis.

Applications

Our study was designed to analyze a spectrum of GERD subjects based on presenting symptoms and endoscopic findings. In order to determine the risk factors for such disease in outpatients from department of internal medicine in Zhejiang Province of East China, a cross-sectional survey in a cluster random sample was conducted from November 2004 to June 2005.

Peer review

This is a report designed to analyze a spectrum of GERD subjects based on presenting symptoms and endoscopic findings in Eastern part of China, surveyed by RDQ Chinese version. This clinical study was well designed.The limitation of the study was absence of assessment of the other important risk factors of GERD such as *H pylori*, hiatal hernia, and BMI. It is well known that negative association between *H pylori* and GORD does exist, especially in Asia (Kupcinskas

L, Malfertheiner P. Helicobacter. 2005; 10 Suppl 1: 26-33). In case the other GERD risk factors would be assessed, the results of multivariate analysis could be substantially different.

Abstract

AIM: To estimate the prevalence of small intestine bacterial overgrowth (SIBO) among patients with an earlier diagnosis of irritable bowel disease (IBS) in our geographical area, and to collect information on the use of locally acting non-absorbable antibiotics in the management of SIBO.

METHODS: A non-interventional study was conducted in 73 consecutive patients with a symptom-based diagnosis.

RESULTS: When the patients underwent a "breath test", 33 (45.2%) showed the presence of a SIBO. After treatment with rifaximin 1200 mg/d for seven days in 32 patients, 19 (59.4%) showed a negative "breath test" one week later as well as a significant reduction of symptoms, thus confirming the relationship between SIBO and many of the symptoms claimed by patients. In the other 13 patients, "breath test" remained positive, and a further cycle of treatment with ciprofloxacin 500 mg/d was given for 7 additional days, resulting in a negative "breath test" in one patient only.

CONCLUSION: (1) about half of the patients with a symptomatic diagnosis of IBS have actually SIBO, which is responsible for most of the symptoms attributed to IBS; (2) only a "breath test" with lactulose (or with glucose in subjects with an intolerance to lactose) can provide a differential diagnosis between IBS and SIBO, with almost identical symptoms; and (3) the use of non-absorbable antibiotics may be useful to reduce the degree of SIBO and related symptoms; it must be accompanied, however, by the correction of the wrong alimentary habits underlying SIBO.

Key words: Small intestine bacterial overgrowth; Irritable bowel disease; Breath test; Rifaximin; Hydrogen; Non-absorbable antibiotics

INTRODUCTION

Irritable bowel syndrome (IBS) is a very common diagnosis in gastroenterology that is done on the basis of the Rome Ⅱ symptomatic criteria. The basic clinical pattern is characterized by abdominal pain and changes in bowel habit, on the basis of which three different variants of IBS are recognized (IBS with stipsis, IBS with diarrhea or IBS with alternated stipsis and diarrhea). No matter which variant is diagnosed, 92% of the patients with IBS complain of abdominal bloating, flatulence and meteorism, three symptoms that are, however, more probably related to a small intestine bacterial overgrowth (SIBO) rather than to IBS.

A close relationship exists between the changes in pattern and distribution of gastrointestinal (GI) bacterial flora, and the altered GI motility (changes in bowel habit) and sensorial physiology (abdominal pain and bloating) observed in patients with IBS. It has been demonstrated that the myoelectric activity of intestinal loops are deeply modified by the presence of SIBO, leading to the hypothesis that many of the sensorial and motorial symptoms of IBS are really determined by changes in the GI bacterial flora[1]. Moreover, it is well known that both an acute GI infection[2,3] and the use of systemic antibiotics[4,5] lead to profound changes in GI bacterial flora, and that both the conditions may result in symptoms (such as abdominal bloating and changes in bowel habit), which look like those of IBS[6-9].

Finally, it has been reported that even one single cycle of systemic antibiotics may provoke long-time sustained alterations of GI physiology[10], while a treatment with antibiotics specifically addressed to correction of intestinal

disbiosis is followed by an improvement of IBS- or SIBO-related symptoms[11]. Thus, there is ground to believe that there is a large overlapping between SIBO and IBS, and that many patients with an earlier symptomatic diagnosis of IBS are actually suffering from SIBO. However, the prevalence of SIBO among patients with an initial diagnosis of IBS is not exactly known.

Cuoco and Salvagnini[12] have recently reported in North Italy a 46% incidence of positive "breath test" (increased hydrogen concentrations in the expired air after oral lactulose administration) among 96 patients with IBS. According to USA-based clinicians, this incidence could be higher than 80%[13-15], while European investigators have reported an increased GI bacterial flora in 43% of patients with IBS compared with 12% of matched-control healthy subjects, without any relationship between degree of disbiosis and severity of altered GI motility and symptoms[16].

The different values in SIBO prevalence observed worldwide among patients with an initial diagnosis of IBS are probably due to the different methods employed to detect the bacterial colonization of the small intestine: a typical and simple clinico-laboratory test ("breath test" with lactulose) in the first two studies[14,15], a more rigorous microbiological, but also methodologically more complicated test (GI bacterial count $\geqslant 10^5$/mL) in the third study[16].

Recent studies have provided increasing support for the concept that disturbances in gut flora occur in patients with IBS and that such abnormalities may contribute to IBS-type symptoms[17]. In any case, the overlapping of SIBO and IBS and the role eventually played by SIBO in the pathogenesis of the IBS symptoms, are demonstrated by two double-blind placebo-controlled clinical studies, which have shown respectively a 75% reduction in the GI symptoms and a long-lasting (over 10 wk) clinical improvement in subjects with IBS, after treatment with non-absorbable antibiotics with a topical activity limited to the GI tract[18].

Our study is therefore aimed to estimate the prevalence of SIBO in our geographical area (Campania, South Italy) in patients with IBS diagnosed according to the Rome Ⅱ criteria; the diagnosis of SIBO is established on the basis of a positive "breath test" with lactulose. We have also gathered information on the use of locally active antibiotics in the management of SIBO.

MATERIALS AND METHODS

This study was purely observational. Within a time interval of 27 mo (January 2005-March 2007), we selected patients of both sexes who came to our medical centre for advice, and had a diagnosis of IBS, because of abdominal pain and discomfort complying with the following characteristics: (1) Three months of continuous or recurring symptoms of abdominal pain or irritation that: (a) may be relieved with a bowel movement; (b) may be coupled with a change in frequency, or (c) may be related to a change in the consistency of stools. (2) Two or more of the following present at least 25% of time: (a) change in stool frequency (> 3 bowel movements daily or < 3 bowel movements weekly); (b) noticeable difference in stool form (hard, loose and watery stools or poorly formed stools); (c) passage of mucous in stools; (d) bloating or feeling of abdominal distention; (e) altered stool passage (e.g. sensations of incomplete evacuation, straining, or urgency).

Patients with severe cardiovascular or respiratory or renal diseases and patients with cancer or under treatment with antibiotics and corticosteroids were excluded. All the patients gave their informed consent to the management of personal data according to the "privacy" regulations.

All the symptoms, either GI or not, were recorded during the first medical visit, and the patients were asked to score the global intensity of symptoms by means of Visual Analogue Scale (VAS) 10-cm long (0 = no symptom; 10 = unbearable symptom). Then, all the patients underwent a "breath test", whose concept is based on a non-invasive measurement of hydrogen (H_2) concentrations in the expired air.

In the evening before the examination, the patient was required to eat only boiled rise with no sausage or cheese, and grilled meat, to make a careful oral hygiene and to drink only no-gas water. If stipsis was present, the dietary prescriptions were extended to the three days preceding the exam. On the day of the test, the patient was completely fasted, and smoking was forbidden. Immediately before the test two samples of expired air were taken at a 10-min interval to assay the basal hydrogen concentrations in the still fasted subject; then, 75 g of lactulose were administered and the expired air was sampled every 15 min in the next 3 consecutive hours. In one subject with intolerance to lactose, the "breath test" has been performed by using 50 g of glucose and sampling expired air every 10 min for 2 h.

A positive test required an elevated breath hydrogen concentration higher than 10 ppm over basal values[19]; these concentrations are indicative of a bacterial colonization of the small intestine, where bacteria can metabolize non-absorbable sugars thus producing increased H_2 amounts which are eliminated through respiration[20].

The patients with a positive "breath test", were diagnosed as having SIBO and treated with rifaximin polimorph A (Normix®, Alfa Wassermann) at the daily dose of 1200 mg/die for 7 consecutive days. One week after the end of the treatment, the "breath test" was repeated, and the patients who still showed a positive test, received a further treatment with ciprofloxacin 500 mg/die for additional 7 d. At the end of the second cycle of antibiotic treatment the "breath test" was repeated for the third time.

The demographic characteristics of the patients were described as means and standard deviations (min-max ranges), or frequencies when appropriate. The frequencies of symptoms observed in patients with diagnosis of SIBO and IBS were compared using the χ^2 test, and the frequency of positive "breath test" was analyzed by means of the Fisher exact test.

RESULTS

A summary flow-chart of the employed methodology and the results achieved in our study is shown in Figure 1.

A total of 73 patients with IBS were selected (28 males and 45 females). They were aged between 17 and 87 (mean ± SD, 41.2 ± 15.8 years), and their weight and height were 66.8 ± 12.6 kg and 167.1 ± 9.3 cm,

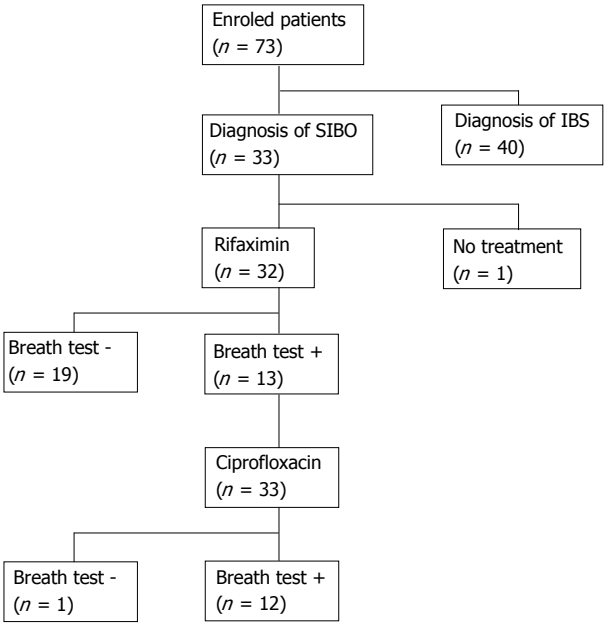

Figure 1 Diagram and synthesis of activities and results in this study.

Table 1 Results of "breath test" with lactulose or glucose in 73 patients with an initial symptoms-based diagnosis of IBS

Definitive diagnosis, *n* (%)		Breath test	Lactulose	Glucose
SIBO	33 (45.2%)	Positive	32	1
IBS	40 (54.8%)	Negative	40	0

The data are reported as frequency and percentage. SIBO: Small intestine bac-terial overgrowth; IBS: Inflammatory bowel disease.

respectively. More than 60% of males and 50% of females were younger than 40, and 10% of both males and females were older than 60 years.

The symptoms more frequently observed were abdominal bloating (83.6%), lower abdominal pain (76.7%), flatulence (65.8%), tenesmus (63.0%) and pain to palpation (50.7%), followed with lower frequencies by chronic diarrhoea, upper abdomen pain, nausea, steatorrhea, reduced body weight and stipsis. It is interesting to note that the most frequently observed symptom ("abdominal bloating") is also the most characteristic symptom of SIBO.

When the patients underwent the "breath test" with lactulose (except one patient with intolerance to lactose who received a "breath test" with glucose), 33 (45.2%) had a positive test, revealing the presence of a clinically relevant bacterial contamination of the small intestine (Table 1).

The symptoms in the patients with a confirmed diagnosis of IBS and those with a diagnosis of SIBO (positive "breath test") are shown in Table 2. The symptomatology was almost superimposable in the two groups, although some symptoms, such as reduced body weight, nausea, pain to palpation, and chronic diarrhoea, were slightly less frequent in subjects with SIBO, while other symptoms, such as tenesmus, were slightly more frequent in the patients with IBS. On the whole, the analysis of the clinical symptoms confirmed that a "breath test" is needed for a differential diagnosis between SIBO and IBS.

Table 2 Frequency of symptoms in 40 and 33 patients with a definitive diagnosis of IBS and SIBO respectively

	IBS (*n* = 40) *n* (%)	SIBO (*n* = 33) *n* (%)	*P*
Chronic diarrhoea	16 (40.0)	17 (51.5)	NS
Upper abdominal pain	17 (42.5)	14 (42.4)	NS
Lower abdominal pain	30 (75.0)	26 (78.8)	NS
Tenesmus	28 (70.0)	18 (54.5)	NS
Pain to palpation	18 (45.0)	19 (57.6)	NS
Abdominal bloating	32 (80.0)	29 (87.9)	NS
Flatulence	24 (60.0)	24 (72.7)	NS
Reduced body weight	7 (17.5)	9 (27.3)	NS
Nausea	9 (22.5)	15 (45.4)	NS
Steatorrhea	3 (7.5)	1	NS
Megaloblastic anemia	1	-	NS
Stipsis	8 (20.0)	9 (27.3)	NS
Fever	1	2 (6.1)	NS
Other (not specified)	1	0	NS

The data are reported as frequency and percentage.

Table 3 Results of "breath test" and symptom score in 32 patients with defini-tive diagnosis of SIBO treated with rifaximin 1200 mg/d for 7 d

	Before treatment	After treatment with rifaximin	
Breath test	Positive	Positive	Negative
	32 (100.0%)	13 (40.6%)	19 (59.4%)
Global symptom score	3.48 ± 0.82	3.24 ± 0.80	0.91 ± 0.06
		NS	*P* = 0.004
		After a further antibiotic treatment with ciprofloxacin	
Breath test		Positive	Negative
		12	1
Global symptom score		3.32 ± 0.95	1.00

The test was repeated one week later and, in the subjects with a still positive "breath test", a further treatment with ciprofloxacin was done (the data are re-ported as frequencies or mean ± standard deviation as appropriate).

Except one patient who refused further treatment, all the patients showing a positive "breath test" were treated with rifaximin 1200 mg/d for seven days. Among them, 19 (59.4%) patients showed the disappearance of the hydrogen peaks in expired air at the "breath test" one week after the treatment. In these patients, the symptom score was significantly reduced from 3.48 ± 0.82 (basal) to 0.91 ± 0.06 after treatment with rifaximin ($P = 0.004$), thus confirming the relationship between SIBO and many of the symptoms claimed by patients (Table 3).

On the contrary, the remaining 13 subjects still showed a positive "breath test" in spite of a treatment with rifaximin, and reported a symptom score (3.24 ± 0.80) that was almost unchanged compared with the basal values. In these patients, a further antibiotic treatment was given with ciprofloxacin 500 mg/d for 7 additional days. At the end of the treatment, only one patient showed a negative "breath test", while in the remaining 12 patients the "breath test" was still positive and the symptom score remained unchanged (Table 3).

No adverse effect or adverse drug reaction was observed in our study during the test and/or the medicinal treatment.

DISCUSSION

The GI tract is colonized by bacteria immediately after birth[21]; *Escherichia coli*, *Streptococci* and *Clostridi* are the first bacteria harboured by the colon, followed by anaerobic *Enterococci*, *Lattobacilli* and *Bacteroidi*[22]. All these bacteria are able to bind the GI mucosa by means of receptors, such as adhesin and lectin, which are expressed either on the host mucosa or other bacteria[23,24], and to resist to the antibacterial activity of many substances that are present in the GI environment, as well as to the gastric acid and GI motility[25].

Many factors affect the type and distribution of the bacteria along the GI tract, starting from the type of delivery[26] and nursing[27] in the first days of life, up to the food habits during adulthood. Normally, bacteria are scarcely present in the acid environment of the stomach while they reach the highest concentrations in the large intestine[28]. Moreover, the pattern of bacterial colonization is different among the different segments of the GI tract, the most prevalent being bacteria represented by aerobes and gram-positive in the duodenum and proximal ileum[28], gram-negative in the distal ileum, and anaerobes (*Bacteroides*, *Bifidobacteri*, *Eubacteri* and *Clostridii*) in the colon[28-30].

The role played by the bacterial flora in the normal physiology of the GI tract is known from animal studies performed many years ago[31-34]. It is quite clear nowadays that the bacterial flora affects the GI motility by means of three different mechanisms: (a) the release of substances produced or metabolized by bacteria; (b) the involvement of neuroendocrine factors; and (c) the involvement of the GI immunological tissue.

The growth of bacteria is controlled by several mechanisms, including gastric acid secretion, immunological factors, diet and bacterial competition[28,29,35]; however, the GI motility is probably the most important factor for control of bacterial growth. It is known that a large part of the bacteria may be eliminated by drugs increasing the GI motility. More importantly, a reduced GI motility leads to bacterial colonization of the small intestine, and many systemic and/or GI diseases characterized by a reduced GI motility have SIBO as one of their consequences[36,37].

In our study, slightly lower than 50% of patients with an initial diagnosis of IBS, are actually affected by a SIBO that is responsible for many of the symptoms earlier attributed to IBS. Our estimate is almost identical to the 46% observed by other clinicians in North Italy with similar methods of investigation[12].

Although other investigators have found a lower prevalence using the direct complex method of the GI bacterial count, it should be noted that the "breath test" with lactulose or glucose, with the determination of the hydrogen concentrations in the expired air, is considered an indirect but highly specific, method for diagnosis of SIBO[38,39]. On the other hand, the symptomatology in both SIBO and IBS is almost identical (Table 2) and, therefore, only a "breath test" can help in the differential diagnosis between the two disorders.

Clinicians should be encouraged to perform a "breath test" to promptly identify a SIBO, because the disorder has several systemic consequences ranging from malabsorption of lipids and liposoluble vitamins and loss of electrolytes[22,28], to a more severe translocation of bacteria (usually, gram-negative and aerobic bacteria, such as *Escherichia*, *Proteus*, *Enterobacter* and *Klebsiella*) from the GI tract to extraintestinal tissues[40], especially in the presence of a pathologically reduced epithelial barrier and immunological defences[41,42]. All these factors may lead to sepsis and multiorgan failure[42-46].

The treatment of SIBO must firstly focus on the correction of wrong food and dietary habits that usually underlie the disorder (e.g. excessive use of fast-food), and then to the reduction of bacterial colonization of the small intestine by means of antibiotics[47,48]. In this regard, the use of locally acting non-absorbable antibiotics would be particularly useful in reducing immediately the bacterial count waiting for the slow-acting beneficial effects of dietary measures.

In our study, the treatment with rifaximin for one week has determined the negativization of "breath test" in 59.4% of treated patients. Our data confirm other reports in the most recent literature: at the dose of 800 mg for four weeks rifaximin significantly reduced the symptoms in 20 patients with IBS and led to a negative "breath test" in almost half of patients[49]; in another series of 23 patients with SIBO and positive "breath test", a treatment with rifaximin 1200 mg/d for 7 d followed by a treatment with probiotics, led to a negative "breath test" in 19 (82.6%) cases and significantly reduced the peak in hydrogen concentrations in the expired air from 40.9 ± 20.4 to 4.78 ± 8.42 ppm[12]. More evidence on the efficacy of rifaximin has been reported in patients with SIBO and acute diverticulitis of the colon[50], and patients with SIBO and celiac disease[51].

It should be noted that further treatment with ciprofloxacin - an antibiotic widely used in the treatment of IBS[52,53] has not given significantly better results than rifaximin in our experience. Valuable alternatives to rifaximin that have been proven to be effective in the treatment of SIBO are represented by norfloxacin and amoxicillin-clavulanic acid[54], gentamycin[55], trimethoprim/sulfamerazin and polymyxin[56], and chlortetracycline[57].

In conclusion, (1) about half of the subjects with a symptomatic diagnosis of IBS have SIBO as a main cause of their claimed symptoms, which have been initially imputed to IBS; (2) only a "breath test" either with lactulose or with glucose in subjects with intolerance to lactose, can provide a differential diagnosis between IBS and SIBO with identical symptoms; (3) the use of non-absorbable antibiotics is useful in reducing the degree of GI bacterial contamination and related symptomatology, although the correction of wrong dietary habit remains the milestone in the management of SIBO if we want to maintain the results achieved with antibiotic treatment for quite some time.

We would like to thank Mr. Diego Pappalardo for his valuable technical assistance.

COMMENTS

Background

The role played by the bacterial flora in the normal physiology of gastrointestinal

(GI) tract is known, and it is quite clear nowadays that the bacterial flora affects the GI motility by means of three different mechanisms: (a) the release of substances produced or metabolized by bacteria; (b) the involvement of neuroendocrine factors; and (c) the involvement of the GI immunological tissues. Recent studies have provided increasing support for the concept that disturbances in gut flora occur in patients with irritable bowel syndrome (IBS) and such abnormalities may contribute to IBS-type symptoms.

Research frontiers

The article provides evidences that in about 50% of patients with a symptom-based diagnosis of IBS, the symptoms are provoked by a small intestine bacterial overgrowth (SIBO).

Innovations and breakthroughs

Clinicians should be encouraged to perform a "breath test" to promptly identify a SIBO, because the disorder has several systemic consequences of malabsorption of lipids and liposoluble vitamins, and loss of electrolytes.

Applications

The treatment of SIBO must firstly focus on the correction of wrong food and dietary habits that usually underlie the disorder (e.g. excessive use of fast-food), and then to the reduction of bacterial colonization of small intestine by means of antibiotics. In this regard, the use of locally acting non-absorbable antibiotics would be particularly useful in reducing immediately the bacterial count waiting for the slow-acting beneficial effects of dietary measures.

Terminology

A standard microbiological definition of SIBO: an increased bacterial count in the small intestine $\geqslant 10^5$ colonic bacteria/mL). A positive "breath test": an elevated breath hydrogen concentration within 90 min, two distinct peaks, and an increase higher than 20 ppm over basal values; these concentrations are indicative of a bacterial colonization of the small intestine, where bacteria can metabolize non-absorbable sugars, thus increasing the H_2 amounts which are eliminated through respiration.

Peer review

This report documents the incidence of small bowel overgrowth in patients with irritable bowel syndrome and how their symptoms respond to appropriate antibiotic therapy and whether or not the overgrowth (documented by serial hydrogen breath tests) is eradicated.

Abstract

AIM: To elucidate the pre-treatment clinical and imaging findings affecting the tumor response to the transcatheter treatment of unresectable hepatocellular carcinoma (HCC).

METHODS: Two hundred cirrhotic patients with HCC received a total of 425 transcatheter treatments. The tumor response was evaluated by helical CT and a massive necrosis (MN) was defined as a necrosis > 90%. Twenty-five clinical and imaging variables were analyzed: uninodular/multinodular HCC, unilobar/bilobar, tumor capsula, hypervascular lesion, portal vein thrombosis, portal hypertension, ascites, platelets count, aspartate transaminases/alanine transaminases (AST/ALT), alfa-fetoprotein (AFP) > 100, AFP > 400, serum creatinine, virus hepatitis C (VHC) cirrhosis, performance status, age, Okuda stage, Child-Pugg stage, sex, CLIP (Cancer of the Liver Italian Program) score, serum bilirubin, constitutional syndrome, serum albumine, prothrombin activity, BCLC (Barcelona Clinic Liver Cancer) stage. Prognostic factors of response were subjected to univariate analysis and thereafter, when significant, to the multivariate analyses.

RESULTS: On imaging analysis, complete response was obtained in 60 (30%) patients, necrosis > 90% in 38 (19%) patients, necrosis > 50% in 44 (22%) patients, and necrosis < 50% in 58 (29%) patients. Ninety-eight (49%) of the 200 patients were considered to have a MN. In univariate analysis, significant variables (P < 0.01) were: uninodular tumor, unilobar, tumor size 2-6 cm, CLIP score < 2, absence of constitutional syndrome, and BCLC stage < 2. In a multivariate analysis, the variables reaching statistical significance were: presence of tumor capsule (P < 0.0001), tumor size 2-6 cm (P < 0.03), CLIP score < 2 (P < 0.006), and absence of constitutional syndrome (P < 0.03). Kaplan-Mayer cumulative survival at 12 mo was 80% at 24 mo was 56%. MN was associated with a longer survival (P < 0.0001).

CONCLUSION: MN after transcatheter treatment is more common in the presence of tumor capsule, maximum diameter of the main lesion between 2 and 6 cm, CLIP score < 2 and absence of constitutional syndrome. The ability to predict which patients will respond to transcatheter treatment may be useful in the clinical decision-making process, and in stratifying the randomization of patients in clinical trials.

INTRODUCTION

Trans-catheter treatment is extensively used to treat hepatocellular carcinoma (HCC) not suitable for surgical resection or percutaneous ablation therapies. Transarterial chemoembolization (TACE), transarterial oily chemoembolization (TOCE) and transarterial embolization

(TAE) have been adopted[1-8]. Prognosis of patients with HCC complicated with cirrhosis mainly depends on the tumor growth, progression of the underlying liver disease, and effectiveness of anti-tumor treatment. Recent meta-analysis showed that the overall survival of patients with well preserved liver function was improved after intra-arterial treatment[9,10]. The primary goal of the trans-catheter treatment is to achieve a massive necrosis, to reduce tumor size, and prevent its dissemination and portal vein invasion. Unfortunately, the tumor response to trans-catheter treatment is heterogeneous with a wide range of necrosis that cannot be accurately predicted. The lack of well-defined prognostic indicators inspired us to perform the present study to analyze the tumor response and the pre-treatment imaging and clinical prognostic factors predictive of response in patients with HCC and compensated cirrhosis who were treated by trans-catheter treatment.

Table 1 Patient and HCC characteristics at admission

Age (mean ± SD, range)	63 ± 8.62 (35-81)
Sex distribution (male/female)	138/62
Liver cirrhosis etiology:	
Hepatitis C	158
Hepatitis B	29
Others	13
Child Pugh score A/B/C	136/59/5
Clip score (0/1/2/3/4/5)	53/79/52/11/4/1
BCLC stage (1/2/3/4)	61/115/14/0
Constitutional syndrome (yes/no)	22/178
Performance status (0/1/2/3)	177/14/8/1
HCC uninodular/multinodular	96/104
HCC unilobar/bilobar	148/52
Tumor capsula: yes/no	83/114
Portal vein thrombosis: absent/partial/complete	185/15/0
Alfa-fetoprotein: < 20/20-100/> 100 ng/mL	83/48/69

MATERIALS AND METHODS

This is a retrospective cohort study based on the analysis of 200 consecutive cirrhotic patients with single or multifocal HCC, treated with intra-arterial therapy and evaluated with follow-up imaging at a single transplant centre. Patients who had at least one image examination (16-slides helical CT scan or triphasic contrast-enhanced MRI) before and after treatment were included into the study. Diagnosis of HCC was based on radiological findings, alfa-fetoprotein level and biopsy according to the Barcelona criteria[11]. Bone metastases were ruled out by bone scintigraphy; lung and abdominal metastases were ruled out by CT scan. Liver function impairment was estimated with routine biochemical parameters reflecting liver function. The cardiac risk was evaluated by EKG and left ventricular ejection fraction (LVEF), as measured by multi-gated angiography scan (MUGA scan) or echocardiography. HCC and patient's characteristics at admission are reported in Table 1. Informed consent was not specifically required for the study, although written informed consent was obtained for each diagnostic and interventional radiology procedure.

All CT scan studies were performed with a 16-slice multidetector CT (Light speed, General Electric Medical Systems, USA) before and 4-6 wk after the intra-arterial treatment. Quadruple-phases protocol was used (unenhanced phase, arterial phase, portal venous phase and late phase).

All CT images were evaluated by at least 2 radiologists. Pre-treatment studies were analyzed without knowledge of the final outcomes of the patients. A consensus of the readers was reached in all cases. The following CT features were evaluated: number of lesions (single, multiple), size of the main lesion (maximum diameter), hepatic distribution (unilobar or bilobar), tumor extension ($\leqslant$ 3 lesions each $\leqslant$ 3 cm or > 3 lesions or one > 3 cm), vascularity of the lesions (hypervascular, hypovascular), tumor capsule, portal vein invasion (lobar, segmental, or subsegmental), signs of portal hypertension (spontaneous splenorenal shunt, patency of umbelical vein, patency of coronary vein), ascites, and necrosis. In post-treatment studies, the presence of arterial enhancement at CT imaging was considered as viable tumor. In patients who underwent TOCE, the complete necrosis was considered only if the lesion had homogeneous Lipiodol uptake without contrast enhancement in arterial phase. In case without clear results, MRI with gadobenate dimeglumine (Gd-BOPTA), using a 1.5T MR scan (General Electric Medical Systems, USA), was performed. The efficacy of intra-arterial treatment was defined according to the amount of tumor necrosis valuable on CT and/or MR follow-up imaging and the WHO recommendations[12]. The presence of non-enhanced tumor areas was defined as tissue necrosis and expressed as percent of the total tumor volume. Tumor necrosis was considered complete when no foci of enhancement were seen within the tumor or at its periphery. In patients with multiple lesions, the necrosis was computed as average of tumor necrosis in each lesion. The response to treatment was classified as: complete response, necrosis > 90%, necrosis > 50%, and necrosis < 50%. In this study, a tumor necrosis > 90% over the treatment interval was classified as massive necrosis (MN).

Intra-arterial treatment was performed in patients with multifocal HCC or single unresectable HCC and contraindications to radiofrequency thermal ablation (RFA).

In our centre, contraindications to RFA are: size of the lesion greater than 4 cm, lesion near to vital organs such as gallbladder, stomach, and colon, lesion adjacent to a big portal or hepatic vein branches at risk of bleeding, subphrenic lesion not easily accessible for RFA and lesion in subcapsular position at high risk of tumor seeding[13].

Exclusion criteria for intra-arterial treatment were HCC volume > 50% of total hepatic volume, complete thrombosis of main portal vein, AST/ALT > 300 U/L, serum bilirubin > 3 mg/dL, serum creatinine > 1.8 mg/dL, white blood cell (WBC) < $2.5 \times 10^3/\mu L$, platelets < $35 \times 10^3/\mu L$, severe ascites and performance status > 3.

TACE was performed using Epirubicine at a dose of 50 mg/m^2 of body surface; the dose was reduced to 50% if serum bilirubin level was > 1.2 mg/dL and < 2 mg/dL and/or white blood cell count (WBC) was $34 \times 10^3/\mu L$;

a dose reduction to 25% was administered if bilirubin was > 2 mg/dL and/or WBC 2.53 × 10^3/μL. Epirubicine was prepared in sterile drip and infused over 30 min using a peristaltic pump. Afterwards, the embolization was performed using Gelfoam (Pfitzer, Belgium) till a stagnation flow was visualized at the fluoroscopy. In patients with acceptable liver function and superselective catherization of the hepatic artery, 2-10 mL of Lipiodol (Lipiodol Ultrafluid, Guebert, Italy) was infused before the gelfoam embolization (TOCE)[14]. No chemotherapeutic agent (TAE) was used in the presence of WBC less than 2.5 × 10^3/μL, previous episodes of neutropenia (< 500/mL), positive HBsAg and HBV DNA[15] and ejection fraction ⩽ 45%. These patients were treated with lipiodol and/or gelfoam. In patients with single HCC, superselective catheterization of the artery supplying the lesion was performed whenever possible, in the other cases the treatment was given in the branch of the right hepatic artery or in the branch of the left hepatic artery supplying the lesion. In patients with multifocal HCC, treatments were given in the right hepatic artery (RHA) or in the left hepatic artery (LHA). In case of multifocal, bilobar HCC, no treatment was given in RHA and LHA during the same session. After the treatment, the patients were carefully observed in a conventional hospitalization room, and analgesics were administered if necessary. Oral intake was reinitiated as soon as possible according to the tolerance of the patients. Usually the day after the procedure, after confirming the absence of clinical abnormalities, the patients were discharged and followed up in the outpatient clinic.

The intra-arterial treatment was repeated every 6-12 wk according to the tumor response based on the follow-up imaging and clinical assessment.

Statistical analysis

Twenty-five clinical and imaging variables were analyzed, including uninodular/multinodular HCC, unilobar/bilobar, tumor capsula, hypervascular lesion, portal vein thrombosis, portal hypertension, ascites, platelets count, AST/ALT, AFP > 100, AFP > 400, serum creatinine, VHC cirrhosis, performance status, age, Okuda stage, Child-Pugg stage, sex, CLIP score, serum bilirubin, constitutional syndrome, serum albumine, prothrombin activity, BCLC stage.

The relationship between these variables and the tumor response was first assessed by univariate analysis using the Chi-square test or Student's *t* test when indicated. For qualitative variables, patients were grouped according to the presence or absence of each variable. For quantitative variables, the cut-off level was determined evaluating the relationship between the sensitivity and the specificity of the MN at different cut-off points from a ROC curve. To identify independent predictors of MN occurrence, all the variables reaching statistical significance in the univariate analysis were subsequently included in a multivariate analysis using the step-wise logistic regression procedure. A *P* value of less than 0.05 was considered significant. Statistical analyses were performed with the SPSS software (SPSS Institute Inc., Cary, NC). Survival curves were modelled using the Kaplan-Meier method.

RESULTS

Patients received a total of 425 sessions of intra-arterial treatments. The mean number of treatment sessions was 2.1 ± 2.0 per patient, range 1-8. Interval of treatment was 76 ± 48 d (range 16-249 d). Type of treatments performed were: TACE 243 (57%), TOCE 126 (30%) and TAE 56 (13%). Technical success was achieved in all the treatments performed. No major life-threatening complications occurred.

On imaging analysis, complete response was obtained in 60 (30%) patients, necrosis > 90% in 38 (19%) patients, necrosis > 50% in 44 (22%) patients, and necrosis < 50% in 58 (29%) patients. In this analysis, 98 (49%) of the 200 patients were considered to have MN. At univariate analysis, significant variables ($P < 0.01$) were: uninodular tumor, unilobar, tumor size 2-6 cm, CLIP score < 2, absence of constitutional syndrome, and BCLC stage < 2. In a multivariate analysis, the variables reaching statistical significance were: presence of tumor capsule (β-coefficient 1.447, $P < 0.0001$), tumor size 2-6 cm (β-coefficient 0.838, $P < 0.03$), CLIP score < 2 (β-coefficient 1.074, $P < 0.006$), and absence of constitutional syndrome (β-coefficient 1.764, $P < 0.03$). Kaplan-Mayer cumulative survival was 80% at 12 mo and 56% at 24 mo. The survival of patients with and without MN was 95% and 75% at 12 mo, and 70% and 55% at 24 mo, respectively. Massive tumor necrosis was associated with a longer survival ($P < 0.0001$).

DISCUSSION

Transcatheter treatment is the most common choice for patients with surgically unresectable HCC and contraindications to percutaneous treatment such as PEI, and RF thermal ablation. The arterial embolization with or without chemotherapy induces tumor necrosis by occlusion of the feeding artery of the HCC, and its clinical efficacy has been documented[3,4,16-21]. The goal of TAE/TACE is to deliver a high dose of chemotherapeutic drug and/or embolizing agent in the HCC, causing tumor necrosis and tumor control, preserving as much normal liver parenchyma as possible. The imaging and clinical factors affecting the tumor response after transcatheter treatment remain to be elucidated. The aim of this study was to identify, by means of multivariate analyses, the pre-treatment variables of independent predictive value of MN in patients with cirrhosis managed with transcatheter therapy.

Our multivariate analysis showed that two tumor-related factors such as tumor capsule and maximum diameter of the main tumor are the only independent factors significantly affecting the tumor response to the transcatheter treatment. The presence of a well-recognizable tumor capsule at the pretreatment CT scan was the most important independent predictive factor of MN after transcatheter treatment. According to our results, previous pathological studies performed on liver resection following transarterial chemoembolization[22,23] demonstrated that encapsulated HCCs are more responsive to the transcatheter treatment than non-encapsulated tumors. Interestingly, a significant correlation

between the thickness of the capsule and the effectiveness of tumor necrosis after chemoembolization has also been documented[24,25]. The reason for the relatively poor necrosis of tumors without capsule is not clear. Wasaka *et al* showed that barium sulfate infused into the portal vein entered into the non-encapsulated tumors but not into encapsulated tumors, suggesting that there is a difference in the type of blood supply that may greatly influence the tumor necrosis after embolization of the feeding hepatic artery[23]. The type of histologic growth pattern at the tumor-nontumor boundary may also affect the necrosis occurrence after transcatheter treatment. HCC is usually the expanding type in encapsulated tumors and replacing type in uncapsulated tumors and chemoembolization appears to be most efficacious for HCC with growth expanding pattern. The poor results expected in the replacing type of HCC may be related to the fact that in the case of tumor, cells replace hepatocytes, the blood spaces communicate with sinusoids supplied by portal blood flow[26,27]. A limitation of the pathological studies is that they were performed weeks or months after the chemoembolization, and the granulated tissue between HCC and normal liver parenchyma, secondary to the treament response, could simulate a true capsule. In this case, the psuedocapsule could be an indicator and not a predictor of tumor response[28]. Our results showed that the naturally formed capsule of encapsulated HCC resulting from condensed reticulin fibers produced by atrophic changes of noncancerous liver tissue and detected at the pretreatment CT scan, is the most important independent predictive factor to obtain MN after transcatheter treatment. However, the capsule seems to form when the tumors are small, and larger tumors are commonly uncapsulated. Finally, in absence of a very well-defined capsule, one must keep in mind the possibility that a negative CT image may not completely exclude the presence of capsule and may give partial information about its integrity. It is known the CT scan is limited in detecting capsular invasion of tumor cells, small satellite nodules, and tumor thrombi of the peripheral portal vein branches that are rather poorly responsive to the transcatheter treatment probably because they receive blood supply from the portal vein[23-25,28].

We obtained MN after transcatheter treatment more frequently in nodules with a maximum diameter of 2-6 cm. Similarly, a previous histologic study evaluating the effect of chemoembolization showed that it is effective for encapsulated HCC measuring between 2.3 and 5.5 cm in diameter[25]. TAE is usually less effective for HCC smaller than 2 cm in diameter[27,29]. The reason for the failure of a complete necrosis of the small tumors is not clear. No significant difference of the predominant lesion vascular pattern was found in this study between patients with or without MN. The apparent discrepancy from previously reported studies[30] might be due to the fact that in our series the hypovascular pattern was very uncommon.

A CLIP score < 2 and the absence of constitutional syndrome are strong independent clinical predictors of MN after transcatheter treatment because these kind of patients have a preserved liver function and multiple treatments might yield a good response.

In conclusion, pretreatment helical CT and clinical findings provide accurate prediction of tumor response in patients with HCC and compensated cirrhosis. The MN (> 90%) is more common in the presence of capsule, maximum diameter of 2-6 cm and in well compensated patients with CLIP score of 1 and without constitutional syndrome. The ability to predict which patients will respond to transcatheter treatment may be useful in the clinical decision-making process, and in stratifying the randomization of patients in the therapeutic clinical trials. The prognostic implications and the survival of patients with massive tumor necrosis require further studies.

COMMENTS

Background

Trans-catheter treatment is extensively used to treat hepatocellular carcinoma in cirrhotic patients to achieve a massive necrosis, to reduce tumor size, and prevent its dissemination and portal vein invasion. Tumor response after trans-catheter treatment cannot be accurately predicted.

Research frontiers

The aim of this study is to analyze tumor response and the pre-treatment imaging and clinical prognostic factors predictive of response in patients with HCC and compensated cirrhosis who were managed by trans-catheter treatment.

Innovations and breakthroughs

This study clearly showed that massive necrosis is more common in presence of capsule, a maximum diameter of 2-6 cm and in well compensated patients with CLIP score of 1 and without constitutional syndrome.

Applications

The ability to predict which patients will response to transcatheter treatment may be useful in the clinical decision-making process and in stratifying the randomization of patients in clinical trials.

Terminology

CLIP (Cancer of the Liver Italian Program) prognostic score includes Child-Pugh stage, tumor morphology and extension, serum alfa-fetoprotein (AFP) levels, and portal vein thrombosis. Costitutional syndrome is characterized by weight loss, malaise and anorexia.

Peer review

This is an interesting study, aiming at identifying the factors predicting tumor response to the trans-catheter treatment in cirrhotic patients with HCC. The authors concluded that presence of tumor capsule, a maximum diameter between 2 and 6 cm, CLIP score < 2 and absence of constitutional syndrome were independent predictors of massive necrosis. The study is well conducted. The results are clearly reported and support the main conclusions.

Abstract

AIM: To investigate the diagnostic efficacy of leukocyte esterase and nitrite reagent strips for bedside diagnosis of spontaneous bacterial peritonitis (SBP).

METHODS: A total of 63 consecutive patients with cirrhotic ascites (38 male, 25 female) tested between April 2005 and July 2006 were included in the study. Bedside reagent strip testing was performed on ascitic fluid and the results compared to manual cell counting and ascitic fluid culture. SBP was defined as having a polymorphonuclear ascites count of $\geqslant 250/mm^3$.

RESULTS: Fifteen samples showed SBP. The sensitivity, specificity, positive and negative predictive values of the leukocyte esterase reagent strips were; 93%, 100%, 100%, and 98%, respectively. The sensitivity, specificity, positive and negative predictive value of the nitrite reagent strips were 13%, 93%, 40%, and 77%, respectively. The combination of leukocyte esterase and nitrite reagents strips did not yield statistically significant effects on diagnostic accuracy.

CONCLUSION: Leukocyte esterase reagent strips may provide a rapid, bedside diagnostic test for SBP.

Key words: Spontaneous bacterial peritonitis; Urinary reagent strip; Leukocyte esterase; Nitrite

INTRODUCTION

Spontaneous bacterial peritonitis (SBP) is a serious and potentially life-threatening complication that can occur in cirrhotic patients with ascites[1,2]. The prevalence of SBP in hospitalized patients with liver cirrhosis and ascites is high, ranging between 10% and 30%. Notably, in-hospital mortality rates range between 30% and 50%[3,4].

SBP requires timely diagnosis that is usually based on cytobacteriological examination of ascitic fluid. A polymorphonuclear leucocyte (PMN) cell count in ascitic fluid > $250/mm^3$, irrespective of the ascitic fluid culture, is currently considered the standard criterion for diagnosis of SBP[1,2]. For this testing, it is of paramount importance that the results of the cytobacteriological examination of the ascitic fluid should be promptly delivered so that appropriate antibiotherapy can be initiated[4,5]. However, because of the organization of facilities in many hospitals, a bacteriological laboratory is not always available for all departments admitting cirrhotic patients with ascites. It follows that alternative methods for rapid diagnosis of SBP are an urgent requirement[6,7].

Use of reagent strip testing for leucocyte esterase has been proposed to reduce the time from paracentesis to a presumptive diagnosis of SBP from a few hours to a few seconds[7,8]. Intriguingly, reagent strips detecting leukocyte esterase activity in biological fluids have been validated for the diagnosis of urinary tract infections[9,10], peritonitis in patients on continuous ambulatory peritoneal dialysis[11], pleural infections[12] and meningitis[13]. The observation that nitrate levels in ascites fluid are raised in patients with SBP is also of interest[14]. Thus far, however, no study has specifically looked at the potential usefulness of nitrite reagent test strips as a diagnostic tool in this patient group.

Therefore, in this study we sought to determine the sensitivity, specificity, and positive (PPV) and negative predictive values (NPV) of nitrite and leukocyte esterase reagent test strips for the diagnosis of SBP in cirrhotic patients with ascites.

MATERIALS AND METHODS

Study sample

This hospital-based study was conducted at the Department of Gastroenterology, Uludag University Medical School, Bursa, Turkey from April 2005 to July 2006. Sixty-three consecutive unselected cirrhotic patients (38 men, 25 women, mean age 59.0 ± 11.6 years) with ascites were included in our study. The general characteristics of the study participants are shown in Table 1. Diagnosis of cirrhosis was established by histological criteria and/or by clinical, laboratory, endoscopic and/or ultrasonographic findings. Only subjects with serum-ascites albumin gradient (SAAG) > 1.1 g/dL were enrolled. Patients with SAAG < 1.1 g/dL were excluded. Subjects with portal hypertension (SAAG > 1.1 g/dL) due to malignancy or tuberculosis were also excluded. The local ethics committee of the Uludag University Medical School approved the study and informed consent was obtained from each participant.

Paracentesis

Paracentesis was performed at admission and during the hospital stay for treatment of ascites or with clinical signs of SBP. Immediately after the paracentesis, ascitic fluid was tested using nitrite and leukocyte esterase reagent strips (Aution Sticks 10 EA; Arkray, Kyoto, Japan). Fresh ascitic fluid was collected in a clean dry container and the strip was immediately immersed in ascitic fluid. The strips were read by two independent research physicians who were unaware of the clinical status of the participants. The strips had a colorimetric 5-grade scale (0-4). A correlation between PMN and a 5-grade scale was suggested by the manufacturer, as follows: grade 0, 0 PMN/mm^3; grade 1, 25 PMN/mm^3; grade 2, 75 PMN/mm^3; grade 3, 250 PMN/mm^3; and grade 4, 500 PMN/mm^3.

Laboratory analysis of the ascitic fluid was performed without delay in all patients. For testing a standard sterile technique was used and included total and differential cell counts, Gram stain and total protein levels. Cultures of ascitic fluid were performed at bedside for all patients using blood culture bottles, including both aerobic and anaerobic media. A minimum of 10 mL of ascitic fluid was inoculated into each bottle.

Diagnostic criteria

The diagnosis of SBP was based on a PMN cell count > 250/mm^3 in ascitic fluid, irrespective of a positive ascitic fluid culture and clinical signs of SBP, and an absence of intra-abdominal sources of infection, inflammation or tuberculosis.

Statistical analysis

Sensitivity was defined as the proportion of patients with a positive reagent strip divided by the number of those with SBP diagnosed by criteria previously defined. Specificity was defined as the proportion of patients with a negative reagent strip divided by the total number of patients without SBP. PPV was defined as the proportion of patients with a true-positive reagent strip divided by the total number of patients with a positive reagent strip. NPV was defined as the proportion of true-negative reagent strips divided by the total number of patients with a negative reagent strip. Data are presented as means ± SD for quantitative variables and as frequencies for qualitative variables. The exact 95% confidence interval for each statistic was calculated from the binominal distribution. SPSS statistical software version 14.0 (SPSS Inc., Chicago, IL, USA) was used for data analysis.

Table 1 General characteristics of the study participants

Characteristics	Study patients (n = 63)
Male gender, n (%)	38 (60.3)
Age (yr)	59 ± 11.6
Child–Pugh classification, n (%)	
B	25 (39.7)
C	38 (60.3)
Etiology of cirrhosis, n (%)	
Chronic B hepatitis	19 (30.1)
Chronic C hepatitis	11 (17.5)
Alcohol abuse	7 (11.1)
Other causes	26 (41.3)

RESULTS

According to the Child-Pugh classification, of the 63 patients there were 25 (39.7%) with Child class B and 38 (60.3%) with Child class C. The etiology of cirrhosis was chronic B hepatitis in 19 (30.1%), chronic C hepatitis in 11 (17.5%), alcohol abuse in 7 (11.1%), and other causes (e.g., autoimmune, primary biliary cirrhosis, cryptogenic) in 26 (41.3%).

SBP occurred in 15 patients (23.8%). Culture of ascitic fluid was positive in 6 cases (40.0%) and negative in 9 (60.0%). Two patients (3.0%) were found to have infected ascites fluid, whereas the remaining 46 (73.0%) had no sign of ascites infection. The bacteria isolated from cultures of ascitic fluid were: *Escherichia coli*, *Klebsiella pneumoniae*, *Staphylococcus warneri*, and *Streptococcus bovis*. PMN counts in ascitic fluid in patients with or without SBP were (mean ± SD/mm^3) 4064 ± 4486 and 69 ± 63, respectively.

Among the 15 patients with SBP, the urine leukocyte esterase strip tested 1+ in the ascitic fluid of one patient and ⩾ 2+ in the remaining 14 individuals. The ascitic fluids of 2 patients with SBP tested positive by the nitrate strips. Detailed laboratory data and urine strip test results of the 15 SBP patients are shown in Table 2. The sensitivity, specificity, PPV and NPV of the leukocyte esterase reagent strips (at a ⩾ 2+ cutoff point) were as follows: 93%, 100%, 100%, and 98%, respectively. The sensitivity, specificity, PPV and NPV of the nitrite reagent strips were 13%, 93%, 40%, and 77%, respectively. The addition of nitrite strips to leukocyte esterase reagent strips did not yield statistically significant effects upon the diagnostic accuracy compared to the leukocyte esterase test alone. Thus the combination of both tests yielded a sensitivity, specificity, PPV and NPV of 93%, 100%, 100%, and 98%, respectively.

DISCUSSION

SBP continues to be an important source of morbidity and mortality in patients with cirrhosis[15]. Under such

circumstances, prompt diagnosis and treatment are crucial to ensure better clinical outcomes in this patient group. However, it has been shown that a positive bacterial culture can be obtained in just 40% of patients with SBP, and that test results may be delayed for several days[16]. Under such circumstances, reagent strips emerge as an attractive means for rapid diagnosis of this clinical entity in patients with cirrhosis and ascites. These tests have the ability to detect esterase activity of PMN cells[16]. Numerous independent studies have evaluated the diagnostic value of reagent strips in settings involving SBP[17-19]. Most have shown high sensitivity and specificity in keeping with our present results.

In a landmark study by Castellote *et al*[8], it has been shown that reagent strips are useful and inexpensive when used in the context of SBP. Specifically, when a cutoff point of 2 or more was selected, overall sensitivity and specificity were 96% and 98%, respectively[6]. More recently, Thévenot *et al*[18] have investigated the utility of two reagent strips, the Multistix test and the Combur 2 test, for the rapid diagnosis of SBP. Both tests showed a high sensitivity and specificity and permitted an accurate laboratory diagnosis of this life-threatening condition. Furthermore, a multicenter study by Sapey *et al*[19] has provided important evidence that two leukocyte esterase reagent strips (Nephur-Test and MultistixSG10) may be of clinical use in the bedside diagnosis of SBP. In light of these results, it has been suggested that in patients with cirrhosis and positive strip test results, antibiotic therapy should be started without delay[17]. Our study confirms and expands previous findings of the potential utility of the leukocyte esterase test as a simple and inexpensive means for testing in settings involving SBP[18-20]. Notably, the selection of a cutoff point $\geqslant 2$ yielded 100% specificity and 100% PPV for the diagnosis of SBP. By contrast, results of a urine strip test of 0 and 1+ yielded a 98% NPV, which excluded SBP in these individuals.

Another aim of our study was to determine whether nitrite reagent strip testing is a useful diagnostic tool in patients with SBP. Previous reports have indicated that nitrate concentration and nitric oxide levels may be raised in ascites from patients with cirrhosis and SBP[14,21]. Since nitric oxide is a diffusible, short-lived, and a reactive free radical gas that is difficult to measure *in vivo*[22,23], most studies have based their conclusions on measurement of nitrite and nitrate in biological fluids[24-26]. In line with this approach, in our study we used Aution Sticks 10EA for the nitrite test strips. This test is based on the Griess Reaction which measures the combined oxidation products for nitric oxide (nitrites and nitrates) after reduction with nitrate reductase[24]. Nonetheless, the sensitivity and PPV of the nitrite reagent strips were low, namely 13% and 40%, respectively. There are several reasons that might explain the low diagnostic performances of the nitrite reagents strips. Nitrite and nitrate levels in body fluids may vary according to a host of confounding factors including the effects of diet-derived nitrate, hepatic synthesis capacity, as well as the occurrence and prevalence of concomitant infections[27-29]. Specifically, it is posited that the limited utility of nitrite strips to screen for SBP in patients with cirrhosis may be due to the low bacterial concentration in ascites fluid[30]. Therefore, for precise bedside diagnosis of SBP in patients with cirrhotic ascites, the highly specific leukocyte esterase strip test remains the method of choice.

Table 2 Results of urine strip test, culture, and ascitic fluid PMN count in 15 patients with SBP

Case number	Reagent strip test		Culture	PMN count (/mm^3)
	Leukocyte esterase	Nitrite		
1	1+	0	Negative	490
2	4+	0	*Escherichia coli*	3860
3	2+	0	Negative	510
4	3+	0	Negative	802
5	3+	0	Negative	311
6	4+	0	*Escherichia coli*	7130
7	4+	1+	*Klebsiella pneumoniae*	16700
8	2+	0	*Staphylococcus warneri*	280
9	4+	0	*Streptococus bovis*	3810
10	3+	0	Negative	9100
11	3+	0	Negative	6120
12	3+	0	Negative	2460
13	4+	0	Negative	5330
14	3+	0	Negative	3790
15	2+	2+	*Klebsiella pneumoniae* plus *Escherichia coli*	270

In conclusion, leukocyte esterase reagent test strips were found to facilitate very rapid identification of patients with SBP and cirrhotic ascites. Specifically, this test can be performed efficiently in order to speed up the bedside diagnostics of this clinical entity. It fits easily into the work flow of a routine gastroenterology department and can be conducted in facilities that do not have the facilities to carry out biochemical and bacteriological tests for diagnosis of SBP.

COMMENTS

Background

SBP is a serious and potentially life-threatening complication that can occur in patients with cirrhosis and ascites. Timely diagnosis is of paramount clinical importance.

Research frontiers

Use of reagent strip testing for leucocyte esterase has been proposed to reduce the time from paracentesis to a presumptive diagnosis of SBP from a few hours to a few seconds.

Innovations and breakthroughs

The leukocyte esterase reagent test strips were found to enable the very rapid identification of patients with SBP in clinical settings involving patients with cirrhotic ascites. This test can be performed efficiently to speed up bedside diagnostics of this clinical entity.

Applications

Leukocyte esterase reagent strip testing fits easily into the work flow of a routine gastroenterology department and can be conducted in facilities that do not or cannot carry out biochemical and bacteriological tests for diagnosis of SBP.

Terminology

Reagent-strip leukocyte esterase: the presence of leukocyte esterase is indirect evidence of the presence of white blood cells in biological fluids.

Peer review

The manuscript "Evaluation of leukocyte esterase and nitrite strip tests to detect spontaneous ascites infection in cirrhotic patiens" is very interesting since it evaluates a test for prompt diagnosis of a disastrous complication of cirrhosis with poor prognosis. In general terms, the study was well performed and the analysis was good.

Abstract

AIM: To assess the effects of mastic administration on cytokine production of circulating mononuclear cells of patients with active Crohn's disease (CD).

METHODS: The study was conducted in patients with established mildly to moderately active CD, attending the outpatient clinics of the hospital, and in healthy controls. Recruited to a 4 wk treatment with mastic caps (6 caps/d, 0.37 g/cap) were 10 patients and 8 controls, all of who successfully completed the protocol. Interleukin-6 (IL-6), tumor necrosis factor-alpha (TNF-α), monocyte chemotactic protein-1 (MCP-1), macrophage migration inhibitory factor (MIF) and intracellular antioxidant glutathione (GSH) were evaluated in peripheral blood mononuclear cells (PBMC) before and after treatment.

RESULTS: Treating CD patients with mastic resulted in the reduction of TNF-α secretion (2.1 ± 0.9 ng/mL *vs* 0.5 ± 0.4 ng/mL, $P = 0.028$). MIF release was significantly increased (1.2 ± 0.4 ng/mL *vs* 2.5 ± 0.7 ng/mL, $P = 0.026$) meaning that random migration and chemotaxis of monocytes/macrophages was inhibited. No significant changes were observed in IL-6, MCP-1 and GSH concentrations.

CONCLUSION: This study shows that mastic acts as an immunomodulator on PBMC, acting as a TNF-α inhibitor and a MIF stimulator. Although further double-blind, placebo-controlled studies in a large number of patients is required to clarify the role of this natural product, this finding provides strong evidence that mastic might be an important regulator of immunity in CD.

INTRODUCTION

Crohn's disease (CD) is a chronic relapsing inflammatory condition of unknown cause[1]. Although the exact pathogenesis of CD is poorly understood, infection, environmental factors, heredity and immunological defects have been proposed as causes[2]. In one or another scenario, a variety of cytokines, such as tumor necrosis factor-alpha (TNF-α), are secreted at the site of inflammation by intestinal lamina propria and attract and activate effector cells[3-5]. Apart from the intestinal mucosa, TNF-α concentration is also raised in serum in patients with active Crohn's disease, compared to normal controls[6,7] and inactive disease[8]. The mechanism through which localized inflammation in the gastrointestinal tract in active CD is associated with systemic manifestations remains unconfirmed, but can involve activated mononuclear cells that migrate *via* the peripheral blood (PBMC) to other tissues. PBMC are highly activated in active CD and secret higher quantities of proinflammatory mediators[9-11]. Altered production of cytokines by PBMC is noted in patients with CD when compared to healthy subjects[12].

As the name implies, monocyte chemotactic protein 1 (MCP-1) acts as a potent chemoattractant and activator of monocytes/macrophages[13], as well as of NK cells, T cells, eosinophils, and basophils[14-17]. During acute inflammatory processes the expression of MCP-1 is increased. Once activated, cells produce an assortment of immunoregulatory cytokines that influence the course of the ensuing immune response. Interleukin 6 (IL-6) expressed among others by T cells and monocytes/

macrophages, stimulates T- and B-cell proliferation and differentiation[18]. The production of IL-6 in these various cells may be regulated by TNF. TNF-α is an important mediator of inflammation, found in substantial amount in the mucosa and stools of subjects with CD. It is a proinflammatory cytokine produced by monocytes, macrophages, and T cells that can affect proliferation, differentiation, and function of every cell type. Therefore, TNF inhibitors, which may be useful in the treatment of CD, have recently been developed[19]. Among these, infliximab has been developed as a therapeutic agent for TNF-α -mediated diseases[20]. Macrophage migration inhibitory factor (MIF) is a cytokine with dissimilar functions; inhibition of macrophage migration[21] or proinflammatory activity[22-25].

Nowadays, various immunosuppressive therapies such as azathioprine, mercaptopurine, and methotrexate, are available. Nevertheless, the treatment of patients with CD still remains a clinical challenge. Furthermore, in view of the increased number of CD patients, there is a considerable scientific and commercial interest in the discovery of novel classes of therapeutic compounds. In particular, plants represent a good source of novel molecules. *Pistacia lentiscus* var. *Chia* (*Anacardiaceae*) is an evergreen shrub widely distributed in the Mediterranean region. Mastic, the resinous exudate, has been reported to possess antioxidant[26] and antibacterial[27] activity, to be effective against peptic ulcers[28], to be hepatoprotective in tetrachloride-intoxicated rats[29] and to suppress the extent of iron-induced lipid peroxidation in rat liver homogenates[30]. We have previously shown that mastic administration resulted in the improvement of the clinical course and in the regulation of inflammatory biomarkers in plasma obtained from mildly to moderate active CD patients[7]. The aim of the present work was to investigate the immunomodulatory effect of mastic treatment on cytokine secretion. Additionally, because inflammation results in oxidative stress and endogenous antioxidants, such as glutathione (GSH), do not counteract it with subsequent mucosal damage, intracellular GSH production from PBMC obtained from patients with mildly to moderately active CD was also measured.

MATERIALS AND METHODS

Setting and participants

Ten consecutive patients with active Crohn's disease and eight healthy controls were included[7]. In brief, clinical evidence of mild to moderate Crohn's disease exacerbation was defined by a score of CD Activity Index (CDAI) 150 < CDAI < 400. Mean CDAI at baseline was 222.9 ± 18.7 (SE), while mean C-reactive protein (CRP) concentration was 40.3 ± 13.1 (SE) mg/mL. Exclusion criteria were elemental diet, parenteral nutrition or antioxidant/mineral supplementation and treatment with immunomodulators (biologic agents-infliximab) and/or corticosteroids. Controls were healthy volunteers, with normal concentrations of CRP [2.4 ± 0.7 (SE) mg/L] and albumin [42.1 ± 1.2 (SE) g/L], without chronic inflammatory disorder, BMI value < 30 (25.8 ± 3.3), none anti-inflammatory drug treatment or antioxidant vitamin/mineral supplementation. Informed consent was obtained from each subject included in the study. The Ethical Committees of both Harokopio University and Saint Panteleimon General State Hospital approved the protocol. Table 1 shows some demographic characteristics of patients and controls.

Table 1 Demographic characteristics and medications of patients with Crohn's Disease and controls

Fistulizing disease	3	-

Intervention

The trial protocol was carried out as previously described[7]. In short, participants were subjected to a 4-wk supplementation with mastic caps (0.37 g/cap, 2 × 3 caps/d, 2.2 g in total). Dietary instructions were given as to maintain consumption of foods rich in anti-inflammatory and antioxidant ingredients low as initially assessed by a food frequency questionnaire and 24 h recall interview and to refrain from mastic and mastic products. Blood samples were obtained prior and after the trial.

Cell cultures

PBMC were obtained from CD patients and controls as previously described[31]. Viability of peripheral blood mononuclear cells (PBMC) was determined by Trypan blue exclusion test. PBMC were resuspended in complete medium consisting of RPMI 1640 medium supplemented with 10% fetal calf serum, 1% L-glutamine and 1% penicillin/streptomycin. PBMC were added to each well of a 24-well plate at a density of 2×10^6 cells/mL and cultures were incubated at 37℃ in a humidified atmosphere containing 5% CO_2 for 18 h. At the end of incubation, conditioned media were collected and stored at -20℃ until assayed, while cells were harvested for GSH measurement. All cultures were run in duplicate.

Cytokine assays

Plasma cytokines from patients with CD and controls were assessed by quantitative, sandwich, enzyme-linked, immunosorbent assays (ELISA) (R&D Systems Abingdon, UK) according to the manufacturer's instructions. Sensitivity of TNF-α ELISA was less than 1.6 pg/mL, of

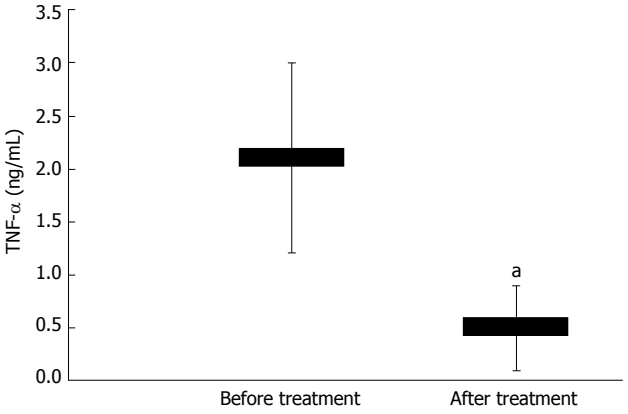

Figure 1 Secretion of tumor necrosis factor-alpha (TNF-α) was decreased in PBMC derived from patients with active Crohn's disease (n = 10) after 4-wk treatment with mastic caps ($^aP < 0.05$). Horizontal bars represent the mean ± SE.

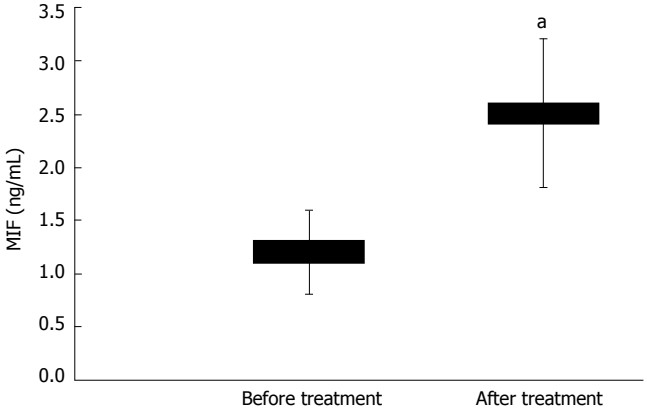

Figure 2 Secretion of macrophage migration inhibitory factor (MIF) was increased in PBMC derived from patients with active Crohn's disease (n = 10) after 4-wk treatment with mastic caps ($^aP < 0.05$). Horizontal bars represent the mean ± SE.

IL-6 was less than 0.70 pg/mL, of MIF less than 0.017 ng/mL and of MCP-1 less than 5.0 pg/mL.

Assay for GSH

At the end of incubation, cells were MPA-treated (5%) and then centrifuged at 2000 × g for 10 min. The resulting supernatant was separated and the GSH assay was performed using the Colorimetric Assay for Glutathione as indicated by the manufacturer (OxisResearch Inc., Portland, USA). GSH concentration was evaluated using a standard curve of Absorbance Units *vs* GSH concentrations and expressed as μmol/L.

Statistical analysis

Results are expressed as mean ± SE. The Mann-Whitney Test was used for comparing differences between patients and controls prior treatment. Differences reported primarily and at the end of the study within individual groups, were tested for significance by the Wilcoxon signed ranks test. A P value below 0.05 was regarded as limit of significance.

RESULTS

Secretion of TNF-α

Our data show that PBMC isolated from patients with active CD exhibited no significant difference in the production of TNF-α compared to controls prior to treatment (2.1 ± 0.9 ng/mL *vs* 1.2 ± 0.3 ng/mL, P = 0.200). TNF-α in controls administered mastic caps was not significantly changed (1.2 ± 0.3 ng/mL *vs* 0.5 ± 0.2 ng/mL, P = 0.173), while in patients it was significantly reduced (2.1 ± 0.9 ng/mL *vs* 0.5 ± 0.4 ng/mL, P = 0.028, Figure 1).

MIF production

MIF production was significantly increased in control group before mastic treatment compared to patients (4.7 ± 1.0 ng/mL *vs* 1.2 ± 0.4 ng/mL, P = 0.038). MIF production in controls administered mastic caps was not altered (4.7 ± 1.0 ng/mL *vs* 4.7 ± 0.7 ng/mL, P = 0.593), while, as shown in Figure 2, it was significantly increased in patients after mastic treatment (1.2 ± 0.4 ng/mL *vs* 2.5 ± 0.7 ng/mL, P = 0.026).

IL-6 and MCP-1

PBMC isolated from patients with active CD exhibited significantly elevated secretion of IL-6 compared to controls prior to therapy (622.5 ± 130.1 pg/mL *vs* 56.7 ± 20.2 pg/mL, P = 0.014). No significant difference was observed in controls before and after treatment (56.7 ± 20.2 pg/mL *vs* 19.9 ± 7.5 pg/mL, P = 0.285). In patients, a trend towards statistical significance was observed in IL-6, before and after treatment although, differences did not reach statistical significance (622.5 ± 130.1 pg/mL to 519.9 ± 176.5 pg/mL, P = 0.068).

In the case of MCP-1, no significant difference was observed between patients and controls prior to treatment (3.0 ± 1.1 ng/mL *vs* 0.7 ± 0.3 ng/mL, P = 0.302). MCP-1 secretion from controls' PBMC (0.7 ± 0.3 ng/mL *vs* 0.6 ± 0.3 ng/mL, P = 0.593) or from patients' PBMC (3.0 ± 1.1 ng/mL *vs* 1.7 ± 1.0 ng/mL, P = 0.463) before and after the trial was not significantly changed.

Intracellular GSH

No significant difference in intracellular GSH was detected between controls and CD patients before mastic treatment (66.4 ± 20.1 μmol/L *vs* 34.0 ± 15.8 μmol/L, P = 0.144). No significant difference was observed in GSH before and after treatment in controls (66.4 ± 20.1 μmol/L *vs* 55.4 ± 9.7 μmol/L, P = 0.285), whereas, even though not statistically significant, a trend towards statistical significance was observed in patients (34.0 ± 15.8 *vs* 56.6 ± 10.3 μmol/L, P = 0.075).

DISCUSSION

Four-week mastic administration has been previously shown to effectively regulate the clinical course, inflammation, and oxidative stress in CD patients. It statistically decreased CD activity index and plasma concentrations of C-reactive protein and IL-6, while it increased plasma total antioxidant potential. Also, nutrition risk index (NRI), one of the most useful measures of nutritional status that incorporates albumin level and body

weight, was improved[7]. In particular, the main element of NRI showing improvement was body weight gain, and since the daily energy intake was unchanged during the trial, increase in body weight and in NRI was attributed to decrease of liquid stools and consequent improvement in nutrient absorption. In two out of ten NRI was > 100 denoting adequate nutrient absorption and absence of nutritional risk. As a continuation of our research to evaluate the effect of mastic on CD and before conducting placebo-controlled studies in large cohorts, in the current study we demonstrated that mastic administration affects cytokine secretion from PBMC obtained from CD patients. Mastic acts as an immunomodulator (a) inhibiting the secretion of TNF-α and (b) inducing the secretion of MIF.

In the report of Grip and coworkers[32] TNF-α was significantly elevated in plasma obtained from CD patients, but not in PMBC, compared to healthy controls. Accordingly, the difference in TNF-α concentrations between patients and controls at baseline was significant in plasma[7], but insignificant in PBMC (present study). Interestingly though, secretion of TNF-α showed a significant decrease in CD patients subjected to mastic treatment (Figure 1). Even though the data reported about TNF-α is conflicting[33,34], the anti-TNF-α treatment in TNF-mediated diseases is developing. The mechanism of mastic's anti-TNF activity in CD may be related to specific blockade of TNF-α secretion. Because cells were always viable in all the experimental conditions, the mechanism including complement mediated lysis of cells expressing membrane bound TNF-α[35], is fairly excluded. A possible approach would be *via* the inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. By blocking HMG-CoA reductase on human monocytes, cells reduce the production of TNF-α[32]. TNF-α is suggested to regulate MCP-1 secretion *via* the activation of nuclear factor-kappa B[36]. Yet, this is rather unlikely to be seen hereby, given that MCP-1 concentration was unaffected in CD patients administered with mastic. It is rather that the nuclear factor-kappa B pathway secondary to the decrease in TNF-α was not activated.

To shed more light on the mechanisms by which mastic might work, we also investigated the potency of mastic caps in affecting MIF secretion. Originally, MIF was described as an inhibitor of migration and chemotaxis of monocytes/macrophages[21]. Our findings of suppressed secretion of MIF in CD mononuclear cells compared to healthy prior treatment indicate that monocytes are sensitized to chemotaxis. Increased secretion after treatment (Figure 2) points to the inhibition of monocyte chemotaxis. The significance of this finding is that migration of chemokine or peptide or nonpeptide stimulated monocytes and differentiation to macrophages into the site of inflammation is limited and further trigger of inflammation is controlled. In some studies it is proposed to have proinflammatory properties and be the first cytokine appearing, followed by others[37]. However, since in our present and previous study[7] mastic administration was not followed by enhanced proinflammatory production, induction of MIF secretion should only be allied with inhibition of chemotaxis.

Even though insignificant, a marginal increment in intracellular GSH concentration ($P = 0.075$) was observed. GSH is the most abundant non-enzymatic antioxidant present in cells that plays an important role in the defence against oxidative-stress-induced cell injury[38]. During inflammatory processes, cells of the immune system are exposed to large amounts of reactive oxygen intermediates, and, thus, an efficient GSH system to neutralize free radicals that otherwise disturb immune functions is essential[39]. Mastic has been proven to induce GSH production in PBMC under oxidative conditions *in vitro*[26], while in CD patients to increase plasma total antioxidant potential *in vivo*[7].

IL-6 is thought to play a crucial role in the pathogenesis of CD[40]. We hereby demonstrated that IL-6 secretion in PBMC from CD patients was significantly elevated compared to healthy controls ($P = 0.014$), evident of the cytokine role in CD inflammation. While in plasma IL-6 was statistically decreased with mastic administration[7], in PBMC insignificant nevertheless decrease ($P = 0.068$) was reported, perhaps due to the small number of samples.

Cytokines play a central role in the modulation of the immune system and they have either proinflammatory, such as TNF-α, or antiinflammatory functions. In CD patients the imbalance between proinflammatory and antiinflammatory cytokines brings about the rationale for "anticytokine" treatment. It is however uncertain whether only one cytokine should be targeted or several pro- and antiinflammatory cytokines, or cytokine synthesis inhibitors, soluble receptors, receptor antagonists or receptor antibodies. In the case of mastic, the activity in CD shown previously[7] and hereby may well be extremely interesting. However, further studies -now in progress- are needed as to determine the target and whether there is one or a class or more than one class of compounds acting synergistically to obtain this effect. As a final point, mastic might serve well in the regulation of immunity in CD patients.

ACKNOWLEDGMENTS

We wish to thank the Chios Mastic Growers Association, especially Dr Christos Kartalis, for the production and kind donation of Chios mastic caps, exclusively for the needs of the trial.

COMMENTS

Background

Mastic administration improves the clinical course and regulates plasma inflammatory and antioxidative mediators of patients with mildly to moderately active Crohn's disease (CD). We aimed to assess the effects of mastic administration on cytokine production of circulating mononuclear cells of patients with active CD.

Research frontiers

The exact pathogenesis of Crohn's disease (CD) is poorly understood; infection, environmental factors, heredity and immunological defects have been proposed as causes. Peripheral blood mononuclear cells (PBMC) are highly activated in active CD and secret higher quantities of proinflammatory mediators. In view of the increased number of CD patients and of the severe side effects of the immunosuppressive therapies available there is a considerable scientific and commercial interest in the discovery of novel classes of therapeutic compounds.

Innovations and breakthroughs

This is the very first study regarding the effect of mastic administration on cytokine production of circulating mononuclear cells of patients with active Crohn's disease.

Applications

Although further double-blind, placebo-controlled studies in a large number of patients is required to clarify the role of this natural product, this finding provides strong evidence that mastic might be an important regulator of immunity in Crohn's disease.

Peer review

This study does provide some new information about a novel possible treatment for Crohn's disease.

Received: June 6, 2007 Revised: September 5, 2007

Abstract

AIM: To observe the prevalence of hepatitis B virus (HBV) infection in maintenance hemodialysis patients.

METHODS: Eighty-eight hemodialysis patients who had been receiving hemodialysis regularly for an average of 39.45 ± 7.57 (range from 36 to 49) mo were enrolled in this study. HBV markers were measured in these patients before hemodialysis and in 100 healthy controls by the chemiluminescent microparticle immunoassay (CMI) method in order to compare the incidence of HBV infection in hemodialysis patients versus normal healthy people. All patients were then divided into two groups: patients positive for HBV markers (i.e. those positive for HBsAg, anti-HBc, HBeAg, anti-HBe, with or without positive anti-HBs) (n = 33), and patients negative for HBV markers (including those only positive anti-HBs) (n = 55). The following information was obtained for all patients: socio-demographic data, number of blood transfusions and some laboratory investigations. After 39.45 ± 7.57 mo follow-up, HBV markers were measured in these patients by CMI.

RESULTS: The incidence of HBV infection in maintenance hemodialysis patients was 37.5%, which was higher than in controls (9%). In the patients positive for HBV markers, there were 13 patients (39.4%) who had a history of blood transfusion, which was more than the number [12 (21.8%), P = 0.04] of patients negative for HBV markers. Eight of the 88 patients negative for HBV markers turned out to be positive, while three of the 33 patients positive for HBV markers turned out to be negative. There was no cirrhosis of the liver or hepatoma occurring in these patients.

CONCLUSION: Maintenance hemodialysis patients have a higher risk of HBV infection than the average population. The number of blood transfusions is associated with an increased prevalence of HBV. While it is hard for hemodialysis patients to eliminate HBV, the prognosis of patients with positive HBV markers is good.

INTRODUCTION

Hepatitis B virus (HBV) infection remains a serious issue in the dialysis population[1-5]. Introduction of HBV vaccination, isolation of HBV positive patients, use of dedicated dialysis machines and regular surveillance for HBV infection has dramatically reduced the spread of HBV in this setting[6-10]. However, the frequency of HBV infection in patients undergoing maintenance dialysis in the industrialized world is low, but not negligible[11-14]. Persistent HBsAg seropositivity is much higher in less-developed countries[15-19], especially in China. The prevalence of HBV infection among hemodialysis patients varies between countries and between dialysis units within a single country. The present study was undertaken to investigate the prevalence of HBV infection among maintenance hemodialysis patients.

MATERIALS AND METHODS

Patients

Eighty-eight patients with ESRD on long-term hemodialysis in the center of blood purification of Beijing Chaoyang Hospital were recruited for this study. There were 42 male and 46 female patients. The median age was 55.46 ± 13.78 (range 25-76) years. The primary cause of ESRD was established in these patients: chronic glomerulonephritis in 35 patients (39.8%), diabetic nephropathy in 22 (25%), hypertension nephropathy in 19 (21.5%), glomerulopathy of unknown origin in 4 (4.5%), tubulointerstitial nephritis in 2 (2.3%), polycystic kidney

Table 1 Variations of HBV markers between hemodialysis patients and healthy controls

Hemodialysis patients	Volunteer controls	HBsAg	Anti-HBs	Anti-HBc	HBeAg	Anti-HBe
18	0			+

7	0		+	+		+
1	0			+		+
2	1	+		+	+	
0	6	+				

disease in 2 (2.3%), and renal cell carcinoma in 2 (2.3%). All patients had been on dialysis for 39.45 ± 7.57 (range from 36 to 49) mo. Hemodialysis was performed two to three times each week, 4-4.5 h per session, using single-use dialyzers with a membrane surface area of 1.3-1.7 m^2. Dialysis membranes were made of polysulfone (36.7%), cellulose acetate (25.4%), or polymethyl-metacrylate (37.9%).

The control group was made up of 100 healthy blood donors and hospital staff [52 males and 48 females, with a median age of 47.25 ± 10.10 (range 35-69) years], whose health status was assessed by periodical general check-ups. These were healthy persons without any infectious, hepatic or kidney diseases.

Methods

Before each patient entered into our blood purification unit, HBV markers were measured, including hepatitis B surface antigen (HBsAg), antibody to hepatitis B surface antigen (anti-HBs), antibody to hepatitis B core antigen (anti-HBc), hepatitis B e antigen (HBeAg), and antibody to hepatitis B e antigen (anti-HBe). These markers were also measured in healthy controls. There were 33 (37.5%) patients positive for HBV markers, i.e. patients positive for HBsAg, anti-HBc, HBeAg, anti-HBe, with or without positive anti-HBs. We therefore divided all patients into two groups: patients positive for HBV markers (n = 33) and patients negative for HBV markers (including those only positive for anti-HBs) (n = 55).

Serum HBsAg, anti-HBs, anti-HBc, HBeAg, and anti-HBe were measured with chemiluminescent microparticle immunoassay (CMI) using an ARCHITECT immunoassay analyzer from the Diagnostics Division of Abbott Laboratories (Abbott Park, IL, United States). Biochemistry data were determined using an AU500 autoanalyzer for blood urea nitrogen (BUN), creatinine, serum albumin, alanine aminotransferase (ALT), aspirate aminotransferase (AST) and alkaline phosphatase (ALP).

RESULTS

Incidence of HBV in maintenance hemodialysis patients

There were thirty-three patients with positive HBV markers at the beginning of the study. The incidence of HBV in maintenance hemodialysis patients was 37.5%, which was significantly higher than that in healthy controls. Nine controls were positive for HBV markers. The incidence of HBV in controls was 9%. The variation of the two groups is shown in Table 1.

Table 2 Clinical characteristics and relevant laboratory data (mean ± SD)

	Positive HBV markers group n = 33	Negative HBV markers group n = 55	P value
Time on HD, months	38.45 ± 9.34	40.55 ± 8.53	0.245
Blood transfusion	13 (39.4%)	12 (21.8%)	0.042
Biochemical data			
BUN, mg/dL	59.53 ± 12.36	56.47 ± 11.43	0.755
Creatinine, mg/dL	59.53 ± 12.36	56.47 ± 11.43	0.755
Serum albumin, g/dL	3.6 ± 0.6	3.7 ± 0.5	0.206
AST, IU/L	26.3 ± 6.9	23.6 ± 7.4	0.052
ALT, IU/L	18.7 ± 8.3	16.5 ± 10.2	0.235
ALP, IU/L	76 ± 15.7	79 ± 13.6	0.072

BUN: Blood urea nitrogen, detected Pre-dialysis; AST: Asparate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; HD: Hemodialysis.

Risk factors of HBV infection

The basic clinical characteristics of the patients are shown in Table 2. In the negative HBV marker group, the mean time on hemodialysis was longer than for the positive HBV marker group, but this difference was not statistically significant. The AST, ALT and ALP levels were, as expected, higher in the positive HBV marker group. The levels of BUN, creatinine, and serum albumin were similar in these two groups. In the positive HBV marker group, there were thirteen patients (39.4%) with a history of blood transfusion, more than the negative group [12 patients (21.8%), P = 0.04].

Turnover and prognosis of the two groups

There were twenty-eight patients positive for HBV markers at the beginning of the study. Three of these became negative, such that the rate was 5.4% (1.8% per year). There were 60 patients negative for HBV markers at baseline, eight of whom turned out to be positive, for a rate of 12.7% (4.2% per year). 39.45 ± 7.57 mo later, chronic cirrhosis and hepatoma had not occurred in these patients.

DISCUSSION

This work shows a high prevalence of HBV infection (37.5%) in maintenance hemodialysis patients (Table 1). The prevalence of HBV infection in hemodialysis patients was higher than that of normal controls (9%) and the general population (9.09%)[20]. This may be attributed to China's high endemic state for HBV infection. A potential contributor to this phenomenon is that significant cellular immune disturbances typically occur in hemodialysis patients. Sharing of supplies, instruments, or medications between hemodialysis patients and reuse of dialyzers would in theory increase the spread of HBV between patients. China, a country hyperendemic for HBV infection, has a higher rate of HBV infection than most industrialized nations. That is why the prevalence rate of HBV infection in our hemodialysis patients is higher than previous observations from western countries (0.9%-5.9%)[11-14] as well as from other developing nations (4%-17%)[15-19].

In order to study the risk of HBV infection, we examined the time on hemodialysis, the biochemical data and the history of blood transfusions of the two groups of patients. We conclude that there is an association between blood transfusions and the prevalence of HBV infection. However, there was no significant difference between time on hemodialysis and HBV infection. In our research, although AST, ALT and ALP levels were higher in the positive HBV marker group, this difference was not statistically significant. As for hemodialysis patients, Hung *et al*[21] revised cutoff values for AST (24 IU/L) and ALT (17 IU/L), which had better sensitivities. In the HBV infected group, the mean values of AST (26.3 IU/L) and ALT (18.7 IU/L) exceeded this criteria, which have important clinical implications in providing benefits of earlier detection and possible prevention of chronic hepatic deteriorations[22].

Because of cellular immune status disturbances, it is hard for hemodialysis patients to eliminate HBV[23-26]. In this study, three patients turned out to be negative, giving a rate of 5.4% (1.8% per year). As for the patients negative for HBV markers, eight turned out to be positive, with a rate of 12.7% (4.2% per year). HBV-related liver disease in patients on long-term dialysis often appears clinically mild, with only modest elevations in AST and ALT levels. Few studies have addressed the natural history of HBV in the dialysis population. Josselson *et al*[27] reported no significant differences in death rates, hospitalizations and hospitalized days between HBsAg-positive and -negative patients on maintenance hemodialysis in the US. However, different outcomes were noted in a retrospective study from India[28]. HBsAg positive patients had a significantly higher mortality rate than negative patients. In our study, the development of cirrhosis, hepatoma and decompensation of liver function is not observed in HBV infected hemodialysis patients. It has been suggested that the hemodialysis procedures lower HBV DNA levels by various mechanisms: the clearance of HBV DNA by the dialysate, the entrapment of HCV DNA particles onto the membrane surface of dialyzers, and the production of cytokines and other substances during hemodialysis sessions. Rampino *et al*[29] have measured a prolonged and marked production of hepatocyte growth factor (HGF) during hemodialysis sessions, and have suggested a beneficial effect of HGF through hepatocyte proliferation and accelerated liver repair. Badalamenti *et al*[30] observed that IFN-alpha levels markedly increase after dialysis using both cellulose and synthetic membranes. This increase in endogenous IFN could contribute to a reduction in viremia in HBsAg patients on maintenance dialysis.

In conclusion, the incidence of HBV in maintenance hemodialysis patients is significantly higher than the average population. The number of blood transfusions is associated with an increased prevalence of HBV. While it is hard for hemodialysis patients to eliminate HBV, the prognosis for patients with positive HBV markers is good.

COMMENTS

Background

Sharing of supplies, instruments, or medications between hemodialysis patients and reuse of dialyzers would in theory increase the spread of HBV between patients. Persistent HBsAg seropositivity is much higher in China than in other countries. In order to get the exact prevalence rate of hepatitis B virus (HBV) infection in maintenance hemodialysis patients, we investigate a dialysis unit in China.

Research frontiers

We studied eighty-eight hemodialysis patients who had been regularly receiving hemodialysis for an average of 39.45 ± 7.57 mo. We measured those patients' HBV markers before hemodialysis and after 39.45 ± 7.57 mo follow-up. We get the prevalence of HBV infection in maintenance hemodialysis patients.

Innovations and breakthroughs

Firstly, this work shows a high prevalence of HBV infection (37.5%) in maintenance hemodialysis patients. Secondly, it concludes that there is an association between blood transfusions and the prevalence of HBV infection. However, there was no significant difference between time on hemodialysis and HBV infection. Thirdly, the main difference from other related articles is that we find three positive HBV-infected patients turned out to be negative.

Applications

The actual application value: the prevalence of HBV infection in maintenance hemodialysis patients in China. The perspective of future application: the further study for the exact mechanisms as to how the hemodialysis patients eliminate HBV.

Terminology

Maintenance hemodialysis patients: The patients who suffer from end-stage renal disease have to receive regular hemodialysis.

Peer review

The authors have estimated the prevalence of HBV infection in a hemodialysis unit. It is concluded that maintenance hemodialysis patients have a higher risk of HBV infection than the average population. The number of blood transfusions is associated with an increased prevalence of HBV. While it is hard for hemodialysis patients to eliminate HBV, the prognosis of patients with positive HBV markers is good.

Abstract

AIM: To investigate if there are changes in serotonin (5-HT) levels, enterochromaffin (EC) cells and mast cells in small intestinal mucosa of patients with irritable bowel syndrome (IBS).

METHODS: Diarrhea-predominant (IBS-D, *n* = 20), or constipation-predominant (IBS-C, *n* = 18) IBS patients and healthy controls (*n* = 20) underwent colonoscopy and peroral small intestinal endoscopy, and mucosal samples were obtained at the descending part of the duodenum, proximal end of jejunum and terminal ileum. High-performance liquid chromatography-electrochemistry and immunohistochemical methods were used to detect 5-HT content, EC cells and mast cells.

RESULTS: (1) There were no differences in the number and distribution of EC cells between IBS patients and the normal group. (2) The mucosal 5-HT contents at the duodenum, jejunum and ileum in IBS-C patients were 182 ± 90, 122 ± 54, 61 ± 35 ng/mg protein, respectively, which were all lower than those in the normal group (256 ± 84, 188 ± 91, and 93 ± 45 ng/mg protein, respectively), with a significant difference at the jejunum ($P < 0.05$). There were no differences in the small intestinal mucosal 5-HT contents between IBS-D patients and the normal group. The mucosal 5-HT contents at the duodenum were significantly higher than those at the ileum in the three groups ($P < 0.001$). (3) The numbers of mast cells in patients with IBS-C and IBS-D at the ileum were 38.7 ± 9.4 and 35.8 ± 5.5/high power field (hpf), respectively, which were significantly more than that in the normal group (29.8 ± 4.4/hpf) ($P < 0.001$). There was no significant difference in the numbers of mast cells at the other two parts between IBS patients and the normal group. The numbers of mast cells in IBS-C, IBS-D, and normal groups were all significantly higher at the ileum (38.7 ± 9.4, 35.8 ± 5.5, 29.8 ± 4.4/hpf, respectively) than at the duodenum (19.6 ± 4.7, 18.5 ± 6.3, 19.2 ± 3.3/hpf, respectively, $P < 0.001$).

CONCLUSION: The changes in the 5-HT signaling pathway at the jejunum of IBS-C patients and the increase in mast cells in patients with IBS at the terminal ileum may offer evidence to explain the pathogenesis of IBS.

INTRODUCTION

Irritable bowel syndrome (IBS) has a very high global incidence nowadays[1,2]. Though it is not fatal, it exerts a strong influence on the quality of human life[3]. Preliminary epidemiological surveys in China had the same suggestions[4,5].

The pathogenesis of IBS is not clear. Studies have found that alterations of many elements in the gastrointestinal mucosa serotonin (5-HT) signaling pathway occurs in IBS patients[6], and this was one of the mechanisms for the disrupted visceral sensation and gastrointestinal motility in IBS patients. It has been shown that mast cells also play a role in the visceral hypersensitivity of IBS patients. Thus, 5-HT content in the mucosa, enterochromaffin cells (EC cells) and mast cells are the most important indicators. Thus far, many studies

on 5-HT content, EC cells and mast cells have been carried out based on samples taken from the ileocecum, colon and rectum. It is not clear whether the small intestinal mucosa 5-HT content, EC cells and mast cells contribute to the pathological and physiological mechanism in IBS patients. The purpose of this study was to compare 5-HT content, the distribution and number of EC cells and mast cells in small intestinal mucosa in order to determine if there are changes in the 5-HT signaling pathways and mast cells in IBS patients.

MATERIALS AND METHODS

Subjects

Following the Rome Ⅲ Criteria[7], 38 IBS patients were selected as subjects, all of whom were outpatients in Department of Gastroenterology, The Second Hospital of Xi'an Jiaotong University from July 2006 to February 2007. Among them, 20 patients (8 male, 12 female, aged 48.7 ± 16.6 years) had IBS-D and 18 IBS-C (9 male, 9 female, aged 41.5 ± 15.1 years). These patients all underwent testing and examinations of their blood, feces, liver function and fasting blood-glucose levels. A colonoscopy and other related procedures were also performed so as to exclude organic diseases. The patients were carefully interviewed about their situations before the onset of the disease to see if they had had any attacks of acute gastroenteritis infectiosa. Those who had were regarded as post-infection IBS (PI-IBS). In this study, the number of PI-IBS samples gathered were not sufficient so they were not included in the analysis and discussion. 20 healthy people were selected as the normal group (9 male, 11 female, aged 39.9 ± 19.5 years). 5 of them underwent examinations because they were suspected of developing malignant diseases caused by familial heredity. 10 of them came to the hospital for reexamination because of intestinal polypi. 5 were volunteers. All the people in the normal group were found to be clear of a history of chronic diseases or symptoms of gastrointestinal diseases such as abdominal pain, diarrhea and constipation. Written consent was obtained from each subject. The study was approved by the Ethics Committee of the Second Hospital of Xi'an Jiaotong University and conducted according to the principle of the Declaration of Helsinki in 1995.

Samples

All the subjects stopped administering any drugs or treatments which might affect the gut movement for at least a week prior to the examinations. The first examination they had was colonoscopy (Pentex EC 3830F) and 6 pieces of mucosa from the terminal ileum, 15 cm from the ileocecal valve, were taken at the same time. After 1 or 2 d for rest, they underwent peroral small intestinal endoscopy (Fujinon EN 450P) and 12 pieces of mucosa were taken, 6 from the descending part of the duodenum, 6 from the proximal end of the jejunum, 15 cm from the ligament of Traitz. For each kind of piece of mucosa, 2 pieces were immediately put into 40 g/L formaldehyde fixatives for use later in immunohistochemistry. Four pieces were put into the plastic tubes and preserved in a refrigerator at -80℃.

Immunohistochemical staining

The mucosa samples were paraffin-embedded in the typical manner and stained with immunohistochemical-SP. For EC cells and mast cells, rabbit anti-human 5-HT antibody (Zhongshan Jinqiao Company, Beijing, Product No. ZA-0231, dilution 1:100) and mouse anti-human tryptase antibody (Maixin_Bio Company, Fuzhou, Product No. MAB-0125, dilution 1:100) were used as primary antibodies. The secondary antibody staining kit was SP9000 of broad spectrum provided by the Zhongshan Jinqiao Company, Beijing. Next, the samples were observed under a powerful optical microscope (× 400). Each piece of mucosa was observed continuously from 6 non-overlapping fields of view and the numbers of positive immunoreactive cells were counted, with each number expressed with "mean ± SD".

Measurement of mucosal 5-HT content

300 μL 0.2 mol/L perchloric acid containing EDTA was added to the small intestinal mucosa samples prior to homogenation. 50 μL of centrifuged supernatant fluid was sent to the Xi'an Institute for Drug Control for determination of the 5-HT content with high-performance liquid chromatography-electrochemistry (HPLC-ECD), which was expressed in ng/mg protein.

Statistical analysis

One-way analysis of variance (ANOVA) was conducted with the SPSS 13.0 software to compare 5-HT content and the number of EC cells and mast cells between the three groups. $P < 0.05$ indicated significant differences.

RESULTS

EC cells

Under optical microscopy, EC cells were distributed in the intestinal gland cavity, mainly in intestinal crypts. They were next to the goblet cells and most of them were in the shape of a cone or rhombus-like. For each field of view under a powerful optical microscope (× 400), the number of EC cells at the descending part of the duodenum in patients with IBS-C and IBS-D was 9.4 ± 3.9/high power field (hpf) and 10.2 ± 3.7/hpf, respectively, 6.7 ± 2.6/hpf and 6.2 ± 2.4/hpf at the proximal end of the jejunum, 2.7 ± 1.4/hpf, 3.2 ± 1.9/hpf at the terminal ileum. Compared with those in the normal group (10.5 ± 3.4/hpf, 6.6 ± 3.4/hpf and 3.1 ± 1.7/hpf, respectively), there were no significant differences ($P > 0.05$, Figure 1). The distribution of EC cells in the small intestinal mucosa in patients with IBS-C and IBS-D was similar to that in the normal group, proportionately decreasing from the descending part of the duodenum to the terminal ileum. In all three groups, the number of EC cells at the descending part of the duodenum was significantly different from that at the terminal ileum ($P < 0.001$). The number of EC cells at the proximal end of the jejunum was significantly less than that at the descending part of the duodenum ($P < 0.05$) and significantly more than that at the terminal ileum ($P < 0.01$). Figure 2 shows the EC cells after staining under a powerful microscope.

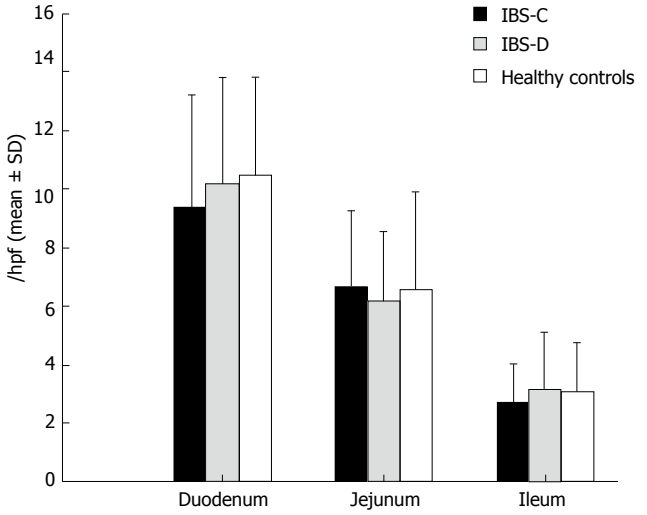

Figure 1 The number of small intestinal mucosal EC cells in IBS patients and the healthy controls. The number and distribution of EC cells in IBS patients are similar to those in the healthy controls. EC cell: Enterochromaffin cells; 5-HT: Serotonin; IBS: Irritable bowel syndrome; IBS-C: Constipation predominant IBS; IBS-D: Diarrhea predominant IBS; hpf; High power field.

5-HT content

The 5-HT content in IBS-C patients at the descending part of the duodenum, proximal end of the jejunum and terminal ileum were 182 ± 90 ng/mg protein, 122 ± 54 ng/mg protein and 61 ± 35 ng/mg protein, respectively, which were all lower than that in the normal group (256 ± 84 ng/mg protein, 188 ± 91 ng/mg protein and 93 ± 45 ng/mg protein, respectively). In addition, the 5-HT content at the proximal end of the jejunum had a significant difference compared with that of the normal group ($P < 0.05$). The P value at the descending part of the duodenum was 0.058, and at the terminal ileum, 0.063. The 5-HT contents in IBS-D patients at the descending part of the duodenum, proximal end of the jejunum and terminal ileum were 220 ± 96 ng/mg protein, 167 ± 58 ng/mg protein and 70 ± 41 ng/mg protein, respectively, which were all lower than those in the normal group, but they did not show statistical significance ($P > 0.05$). Of all the three groups, the 5-HT content at the descending part of the duodenum was significantly higher than that at the terminal ileum ($P < 0.001$), with the 5-HT content at the jejunum falling between them (Figure 3).

Mast cells

Under optical microscopy, mast cells were distributed in the lamina propria, in the shape of an egg or ellipse. They were scattered between the mucous glands with brown cytoplasm. For each field of view under a powerful optical microscope (× 400), the number of mast cells in patients with IBS-C and IBS-D at the terminal ileum were 38.7 ± 9.4/hpf and 35.8 ± 5.5/hpf, respectively, which were significantly more than those in the normal group (29.8 ± 4.4/hpf) ($P < 0.001$). However, the numbers of mast cells in patients with IBS-C and IBS-D did not show significant differences ($P > 0.05$). The number of mast cells at the descending part of the duodenum in patients with IBS-C and IBS-D were 19.6 ± 4.7/hpf and 18.5 ± 6.3/hpf, respectively, and 18.8 ± 5.8/hpf and 19.7 ± 4.8/hpf at the proximal end of the jejunum. Compared with those in the normal group (19.2 ± 3.3/hpf and 20.0 ± 6.9/hpf, respectively), they did not have significant differences ($P > 0.05$, Figure 4). The number of mast cells in the three groups at the ileum were all significantly more than those at the duodenum ($P < 0.001$). However, the numbers of mast cells at the jejunum and at the duodenum did not show significant differences ($P > 0.05$). Figure 5 shows the mast cells after staining under a powerful microscope.

DISCUSSION

The pathological mechanism of IBS is not clear[8]. It is thought that it is associated with alterations in mentality, GI motility, visceral sensitivity, *etc*. The abnormality in the 5-HT content is one of the reasons for the visceral hypersensitivity and gastrointestinal dysmotility of IBS patients[9], and the mast cells have something to do with the visceral hypersensitivity of IBS patients[10]. Because of the difficulty and trouble in taking samples from intestines, many studies on IBS so far have been based on research in mucosa from the ileocecum, colon and rectum, rather than the whole small intestine. To our knowledge, this study is a pioneering one that aims to determine the 5-HT content and number of EC cells and mast cells in the small intestinal mucosa, esp. duodenum and jejunum, in IBS patients. It is also a first study selecting subjects by following Rome Ⅲ Criteria. In order to better understand the mechanism of IBS, patients were divided into two groups, i.e. patients without any attacks of acute gastroenteritis infectiosa before the onset of the disease, and those with PI-IBS, although the number was not sufficient for the analysis.

5-HT is a very important neurotransmitter of the digestive tract; it is essential to the brain-gut connection and related to gastrointestinal motility and visceral sensation. Most of the 5-HT in the digestive tract is stored in EC cells. When EC cells are stimulated, they release 5-HT, which will act upon 5-HT receptors in intestinal nerve fibers and smooth muscle, initiate peristaltic, secretory, vasodilatory, vagal, and nociceptive reflexes, or regulate sensory function by way of vagal spinal afferent nerves. The serotonin-selective reuptake transporter (SERT) terminates the physiological function of 5-HT by taking it back up in the mucosa[11]. When studying the 5-HT signaling pathway, important elements to examine include the number of EC cells, 5-HT content, tryptophan hydroxylase level, 5-hydroxyindoleacedic acid (HIAA), plasma 5-HT concentration and SERT expression[12]. Studies on animals and humans have measured the above elements in gastric and small intestinal mucosa and drawn some meaningful conclusions with regard to the mucosa 5-HT signaling pathway[13-15]. In this study, two important indicators, EC cells and 5-HT content, were used to study the small intestinal 5-HT signaling pathway in IBS patients.

The clinical symptoms of IBS patients include abdominal pain, diarrhea and constipation. 5-HT is closely related to gastrointestinal motility and visceral sensation. Therefore, abnormalities in the 5-HT signaling pathway are regarded as the cause of visceral hypersensitivity, gastrointestinal dysmotility and parasecretion in IBS

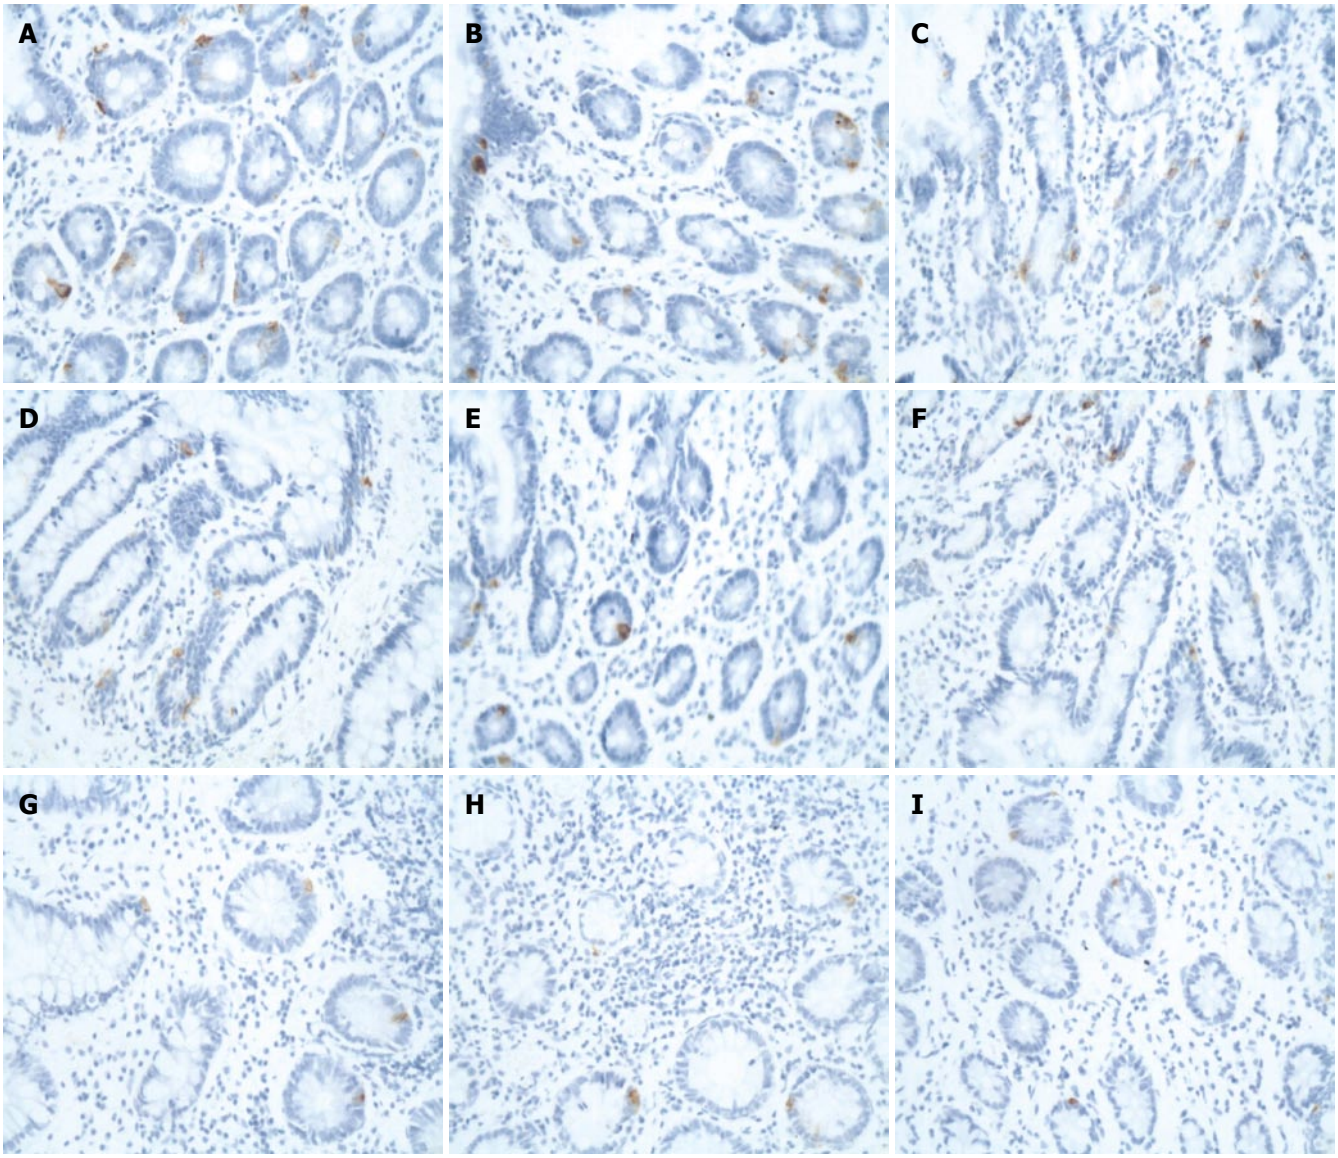

Figure 2 EC cells after being stained by rabbit anti-human 5-HT antibody under a powerful microscope (× 400). **A-C**: EC cells at the descending part of duodenum in healthy controls, IBS-C patients and IBS-D patients, respectively; **D-F**: EC cells at the proximal end of the jejunum in healthy controls, IBS-C patients and IBS-D patients, respectively; **G-I**: EC cells at the terminal ileum in healthy controls, IBS-C patients and IBS-D patients, respectively. EC cell: Enterochromaffin cells; 5-HT: Serotonin; IBS: Irritable bowel syndrome; IBS-C: Constipation predominant IBS; IBS-D: Diarrhea predominant IBS.

patients. A study performed by Coates *et al*[12] suggested that the 5-HT signaling pathway in the mucosa of the rectum in patients with IBS-C and IBS-D had a molecular defect. However, thus far, there have been no studies on 5-HT in the whole small intestine mucosa in IBS patients.

Previous studies on 5-HT content in the colonic mucosa in IBS patients resulted in different conclusions. Coates *et al*[12] thought that the 5-HT content in the rectal mucosa in patients with IBS-C and IBS-D was significantly lower than that of the normal group. A study by Wang *et al*[16] in China suggested that although the 5-HT content in the colonic mucosa in IBS patients was lower than that of the normal group, it did not have statistical significance. In this study, the 5-HT content in various parts of the small intestinal mucosa in IBS-C patients were all decreased, and the 5-HT content at the proximal end of the jejunum was statistically different from that in the normal group ($P < 0.05$). Based on other previous studies, we propose that the decrease in 5-HT results in the weakening of various reflexes, decreasing of secretion and constipation. The fact that there was not much change in 5-HT content in the small intestinal mucosa in IBS-D patients suggested the existence of an abnormality in other 5-HT signaling pathways. Other studies draw different conclusions. Miwa *et al*[17] thought that the increased 5-HT content in colonic mucosa in IBS-C patients relative to normal controls and IBS-D patients suggested that the synthesis of 5-HT was normal, but the release of 5-HT was changed after EC cells were stimulated.

Other studies on EC cells in IBS patients came to different conclusions. The change in EC cells in the intestinal tract in IBS patients was first found in PI-IBS patients. The increase in EC cells was regarded as a characteristic change in PI-IBS patients[18-20], but it was not applied to IBS patients who had had no infection before the onset of the disease. Studies made by Dunlop

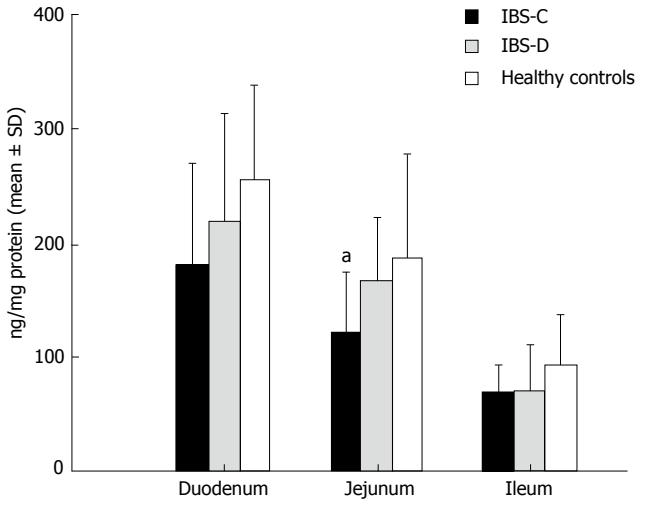

Figure 3 The content of small intestinal mucosal 5-HT in IBS patients and the healthy controls. For each part, the 5-HT content in the IBS-C patients is lower than that in the healthy controls. The 5-HT content at the proximal end of jejunum shows a significant difference compared with that in the normal group ($P < 0.05$). The 5-HT content in the three groups at the descending part of duodenum are all significantly higher than that at the terminal ileum ($P < 0.001$). $^aP < 0.05$ *vs* healthy controls. EC cell: Enterochromaffin cells; 5-HT: Serotonin; IBS: Irritable bowel syndrome; IBS-C: Constipation predominant IBS; IBS-D: Diarrhea predominant IBS.

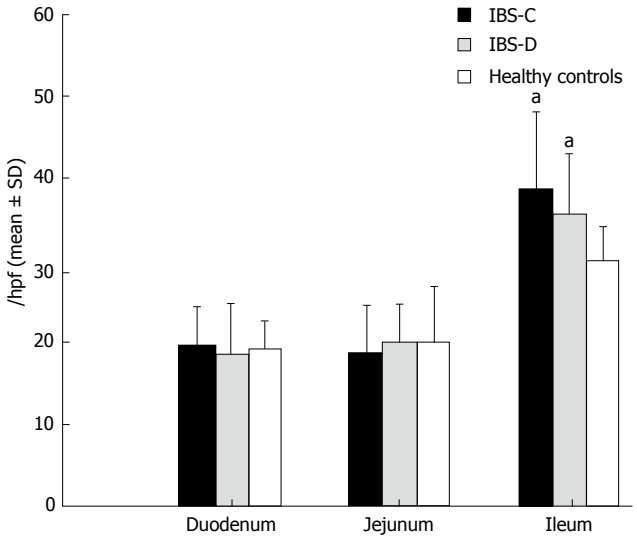

Figure 4 The number of small intestinal mucosal mast cells in IBS patients and the healthy controls. The number of mast cells at the terminal ileum in patients with IBS is significantly different compared with that in the healthy controls ($P < 0.001$). The numbers of mast cells in patients with IBS-C and IBS-D at the other two parts of the intestine do not have significant differences, compared with those in the healthy controls ($P > 0.05$). $^aP < 0.05$ *vs* healthy controls. EC cell: Enterochromaffin cells; 5-HT: Serotonin; IBS: Irritable bowel syndrome; IBS-C: Constipation predominant IBS; IBS-D: Diarrhea predominant IBS; hpf: High power field.

et al[18,19] and Spiller *et al*[20] found no increase in EC cells in IBS patients with no infection before the onset of the disease. Coates *et al*[12] thought that there was no change in the number of EC cells in the rectal mucosa in patients with IBS-C and IBS-D. Li *et al*[21] and Jiang *et al*[22] found that the number of EC cells at the junction of the rectum and sigmoid colon in patients with IBS-C and IBS-D significantly increased, but in the ileocecum it did not. In this study, the number and distribution of EC cells in the small intestinal mucosa in IBS patients did not show significant differences compared with those in the normal group, which suggested there were no obvious pathological changes in the EC cells in the small intestinal mucosa in IBS patients.

Looking at the small intestinal mucosa 5-HT content and the distribution and number of EC cells in IBS patients, we found that the 5-HT content decreased but the number of EC cells remained unchanged compared with that in the normal group, which suggested that the amount of 5-HT released by EC cells in the small intestinal mucosa in IBS-C patients was less than that in the normal group. In IBS-D patients, the 5-HT content and number of EC cells remained the same as those in the normal group, suggesting a difference in 5-HT signaling pathways in IBS-C and IBS-D patients.

Studies have shown that mast cells have something to do with the visceral hypersensitivity of IBS patients[23]. Many agents released by mucosa mast cells can affect intestinal nerve and smooth muscle. Experiments on animals and studies in human beings all proved that mast cells and intestinal nerves are closely connected[24], and in IBS patients, the connection was even closer[25]. The increase of mast cells in IBS patients results in more agents being released by mast cells. All these, together with the close connection between the mast cells and nerve fibers, contribute to the seriousness of abdominal pain.

Many studies have demonstrated that the increase of mast cells in the ileocecum is a characteristic change of IBS[23,26,27]. Park *et al*[23], Dong *et al*[26] and Chen *et al*[27] found an increased number of mast cells in the ileocecum mucosa in IBS patients. Meanwhile, studies suggested the ileocecum might be the site of origin for abdominal pain, bloating, and changes in bowel habits, showing more sensitivity when a balloon dilates[28]. In this study, the number of mast cells at the terminal ileum in IBS patients increased significantly compared with that of the normal group, which is in line with the conclusions drawn from previous studies. It is indicated that the change of mast cell number in the terminal ileum in IBS patients is the characteristic pathological change. Studies on mast cells in other parts of the colonic mucosa (except the cecum) in IBS patients have produced different conclusions. Some found an increase in the number of mast cells[18,23,26], while others did not[19,26]. So far, in China, there have been no studies on mast cells in the duodenum and jejunum in IBS patients. In this study, the numbers of mast cells in the duodenum and jejunum in patients with IBS-C and IBS-D were almost the same as that in the normal group. This study also revealed that the distribution of mast cells in small intestinal mucosa in IBS patients was the same as that in the normal group, i.e. gradually increasing from the duodenum to the ileum.

In conclusion, this study reveals, for the first time, a change in the 5-HT signaling pathway in the jejunum in patients with IBS-C. It also suggests that the increase of mast cells in the ileocecum is the characteristic pathological change in IBS patients. These changes in the mucosa of gastrointestinal tract cause IBS-related symptoms. This

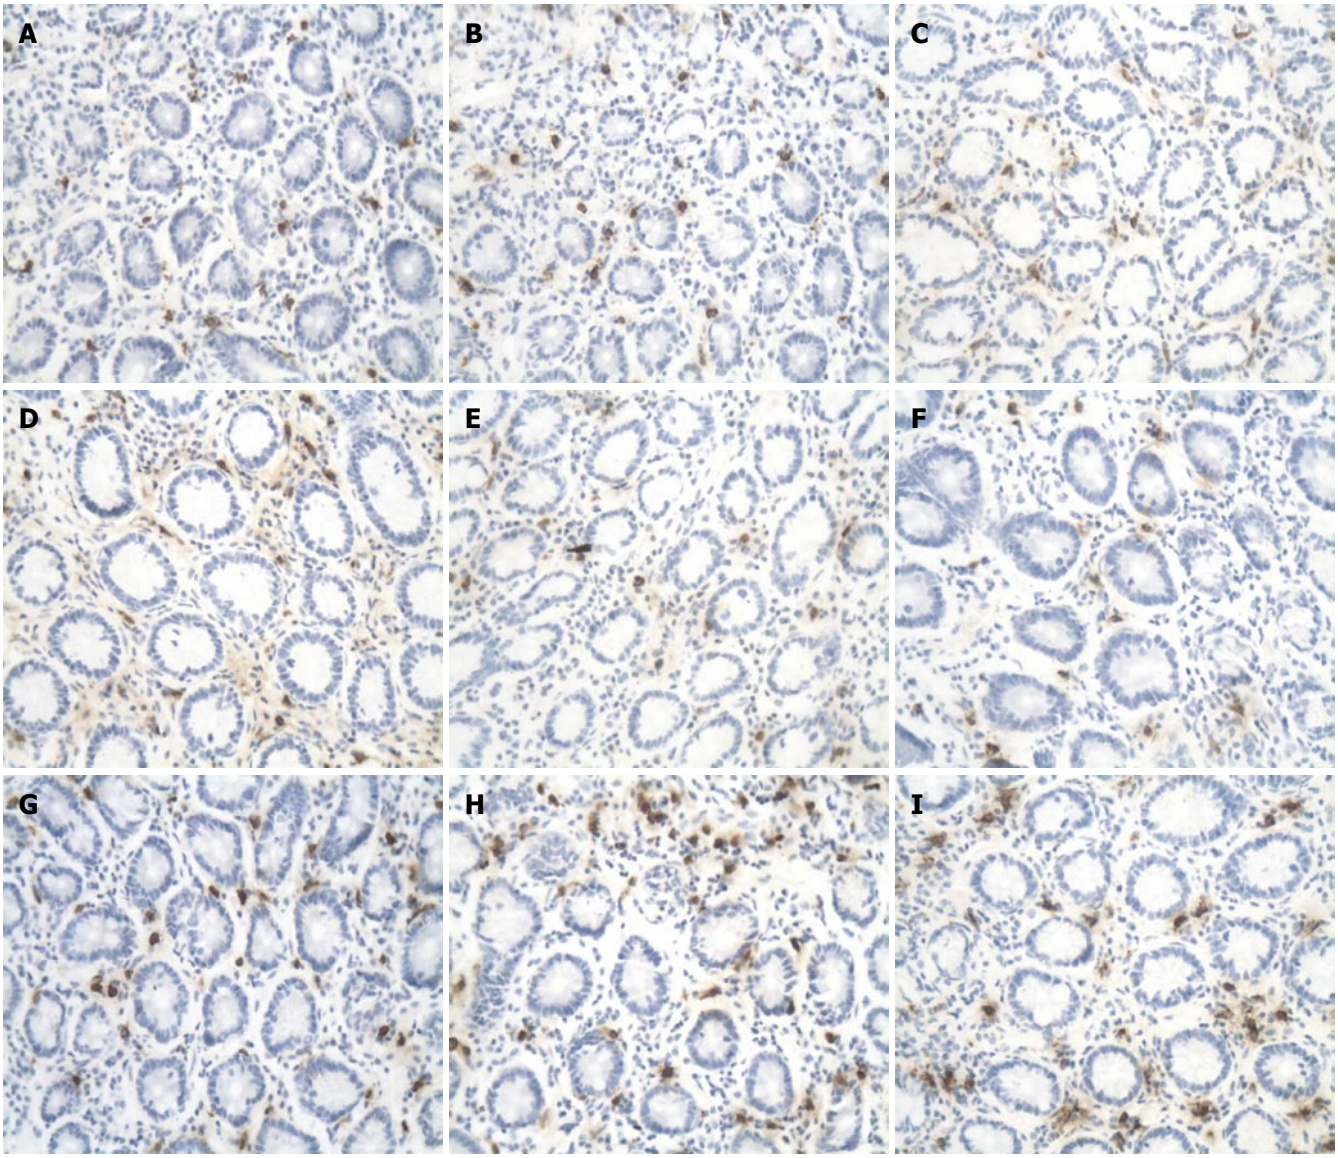

Figure 5 Mast cells after staining by mouse anti-human tryptase antibody under a powerful microscope (× 400). **A-C**: Mast cells at the descending part of the duodenum in healthy controls, IBS-C patients and IBS-D patients, respectively; **D-F**: Mast cells at the proximal end of jejunum in healthy controls, IBS-C patients and IBS-D patients, respectively; **G-I**: Mast cells at the terminal ileum in healthy controls, IBS-C patients and IBS-D patients, respectively. EC cell: Enterochromaffin cells; 5-HT: Serotonin; IBS: Irritable bowel syndrome; IBS-C: Constipation predominant IBS; IBS-D: Diarrhea predominant IBS.

study offers new insight that may be useful for further research into the pathogenesis of IBS.

COMMENTS

Background

Studies have found that abnormal serotonin (5-HT) levels and mast cells are two of the reasons for the disturbance of visceral sensation and gastrointestinal motility in patients with irritable bowel syndrome (IBS). Many studies on 5-HT contents, enterochromaffin (EC) cells and mast cells in IBS have been carried out based on samples taken from mucosa from the ileocecum, colon and rectum, rather than in the whole small intestine.

Research frontiers

The purpose of this study was to compare 5-HT content, the distribution and number of EC cells and mast cells in small intestinal mucosa in order to determine if there were changes in 5-HT signaling pathways and mast cells in small intestinal mucosa in IBS patients.

Innovations and breakthroughs

(1) This study is the first one, to our knowledge, to determine the 5-HT contents, EC cells and mast cells in the small intestinal mucosa, especially the duodenum and jejunum, in IBS patients. (2) It is also the first study on the selection of subjects following Rome Ⅲ Criteria. (3) In order to better understand the mechanism of IBS, patients were divided into two groups; i.e. patients without any attack of acute gastroenteritis infectiosa before the onset of IBS and patients with previous gastrointestinal (GI) infections (post-infection IBS or PI-IBS) although, they could not be used as a group for the analysis due to the small number of cases.

Applications

These changes of 5-HT signaling pathway and mast cells in mucosa of the GI tract will cause IBS-related symptoms. This study offers new insight towards further research into the pathogenesis of IBS.

Terminology

Visceral hypersensitivity: When the GI tract is stimulated by luminal distention and other stimuli, perception of abdominal pain or discomfort is increased. This is widely regarded as the reason for the development of functional gastrointestinal diseases, including functional dyspepsia and irritable bowel syndrome. 5-HT signaling pathways: This refers to the whole process including 5-HT release in the GI tract and central nervous system, binding to its receptors, re-uptake and degradation. Elements involved in the study of the 5-HT signaling pathway include determination of the number of EC cells, 5-HT content, tryptophan hydroxylase

level, 5-hydroxyindoleacedic acid (HIAA), plasma 5-HT concentration and serotonin-selective reuptake transporter (SERT) expression.

Peer review

The study is of interest and permits a better understanding of IBS. It shows that the changes of 5-HT signaling pathway at the jejunum of IBS-C patients and the increase of mast cells in patients with IBS at ileocecum may offer evidence to explain the pathogenesis of IBS.

Abstract

AIM: To evaluate the risk factors for lateral lymph node metastasis in patients with advanced low rectal cancer, in order to make the effective selection of patients who could benefit from lateral lymph node dissection, as well as the relationship of lateral lymph node metastasis with local recurrence and survival of patients with advanced low rectal cancer.

METHODS: A total of 96 consecutive patients who underwent curative surgery with lateral pelvic lymphadenectomy for advanced lower rectal cancer were retrospectively analyzed. The relation of lateral lymph node metastasis with clinicopathologic characteristics, local recurrence and survival of patients was identified.

RESULTS: Lateral lymph node metastasis was observed in 14.6% (14/96) of patients with advanced low rectal cancer. Lateral lymph node metastasis was detected in 10 (25.0%) of 40 patients with tumor diameter $\geqslant$ 5 cm and in 4 (7.1%) of 56 patients with tumor diameter < 5 cm. The difference between the two groups was statistically significant (χ^2 = 5.973, P = 0.015). Lateral lymph node metastasis was more frequent in patients with 4/4 diameter of tumor infiltration (7 of 10 cases, 70.0%), compared with patients with 3/4, 2/4 and 1/4 diameter of tumor infiltration (3 of 25 cases, 12.0%; 3 of 45 cases, 6.7%; 1 of 16 cases, 6.3%) (χ^2 = 27.944, P = 0.0001). The lateral lymph node metastasis rate was 30.0% (9 of 30 cases), 9.1% (4 of 44 cases) and 4.5% (1 of 22 cases) for poorly, moderately and well-differentiated carcinoma, respectively. The difference between the three groups was statistically significant (χ^2 = 8.569, P = 0.014). Local recurrence was 18.8% (18 of 96 cases), 64.3% (9 of 14 cases), and 11.0% (9 of 82 cases) in patients with advanced low rectal cancer, in those with and without lateral lymph node metastasis, respectively. The difference between the two groups was statistically significant (χ^2 = 22.308, P = 0.0001). Kaplan-Meier survival analysis showed significant improvements in median survival (80.9 ± 2.1 m, 95% CI: 76.7-85.1 m *vs* 38 ± 6.7 m, 95% CI: 24.8-51.2 m) of patients without lateral lymph node metastasis compared with those with lateral lymph node metastasis (log-rank, P = 0.0001).

CONCLUSION: Tumor diameter, infiltration and differentiation are significant risk factors for lateral lymph node metastasis. Lateral pelvic lymphadenectomy should be performed following surgery for patients with tumor diameter $\geqslant$ 5 cm. Lateral lymph node metastasis is an important predictor for local recurrence and survival in patients with advanced low rectal cancer.

INTRODUCTION

It is well known that rectal carcinoma is one of the most common carcinomas in China. Since total mesorectal excision was adopted as the standard treatment of patients with rectal carcinoma, improvements have been made in decreasing its local recurrence and prolonging survival of patients[1-8]. However, even having undergone radical resection with total mesorectal excision, about 5%-40% of patients with rectal carcinoma have local recurrence[9-14]. The survival of patients with advanced low rectal cancer

still remains poor. It was reported that lateral lymph node metastasis may be the most important factor for local recurrence and poor prognosis of advanced low rectal cancer[15-18]. In the current study, the data on 96 consecutive patients who underwent curative surgery with total mesorectal excision and lateral lymph node dissection for advanced low rectal cancer at the Department of General Surgery of Guangdong Provincial People's Hospital were retrospectively analyzed. The relationship of lateral lymph node metastasis with local recurrence was identified. The prognostic value of lateral lymph node metastasis for advanced low rectal cancer was also evaluated. Moreover, the risk factors for lateral lymph node metastasis and indications of lateral lymph node dissection remain unclear. Therefore, this study was to explore the risk factors for lateral lymph node metastasis in order to make effective selection of patients who could benefit from lateral pelvic lymphadenectomy. The relation of lateral lymph node metastasis with clinicopathologic characteristics of advanced low rectal cancer was analyzed.

MATERIALS AND METHODS

Patients and methods

A total of 96 consecutive patients who underwent curative surgery with total mesorectal excision and lateral lymph node dissection for advanced low rectal cancer at the Department of General Surgery of Guangdong Provincial People's Hospital were retrospectively analyzed. There were 46 men and 50 women, ranging in age from 25 to 86 years, with a mean age of 65 years. None of these patients received preoperative chemotherapy or radiotherapy. Twenty-one patients (21.9%) had a family history, 40 patients (41.6%) had a high cancer embryonic antigen (CEA) level and a tumor diameter $\geqslant$ 5 cm, 56 had a tumor diameter < 5 cm. According to the Ming's criteria, 42 tumors were classified as expansive type carcinoma, 54 tumors as infiltrative type carcinoma. Fifty-six patients (58.3%) had positive lymph node metastases and 36 patients (37.5%) had positive vessel cancerous emboli. Thirty patients had a poorly differentiated carcinoma, 44 patients had a moderately differentiated carcinoma, 22 patients had a well-differentiated carcinoma. Low anterior resection was performed in 68 patients and abdominal perineal resection in 28 patients. A total of 1776 lymph nodes were dissected from these 96 patients (average 18.5 lymph nodes per patient). Two pathologists who were blinded to the clinicopathological data observed the specimens independently.

Statistical analysis

Statistical analysis was performed by chi-square test to examine the association of lateral lymph node metastasis with clinicopathologic characteristics and local recurrence of advanced low rectal cancer. The relationship between lateral lymph node metastasis and survival in patients with advanced low rectal cancer was evaluated by Kaplan-Meier survival analysis and log-rank test. $P < 0.05$ was considered statistically significant.

RESULTS

Correlation between lateral lymph node metastasis and clinicopathologic characteristics of advanced low rectal cancer

Lateral lymph node metastasis was observed in 14.6 (14/96) of patients with advanced low rectal cancer. Lateral lymph node metastasis was detected in 10 (25.0%) of 40 patients with tumor diameter $\geqslant$ 5 cm and in 4 (7.1%) of 56 patients with tumor diameter < 5 cm. The difference between the two groups was statistically significant (χ^2 = 5.973, P = 0.015). Lateral lymph node metastasis was more frequent in patients with 4/4 diameter of tumor infiltration (7 of 10 cases, 70.0%), compared with patients with 3/4, 2/4 and 1/4 diameter of tumor infiltration (3 of 25 cases, 12.0%; 3 of 45 cases, 6.7%; 1 of 16 cases, 6.3%) (χ^2 = 27.944, P = 0.000). The lateral lymph node metastasis rate for poorly, moderately and well differentiated carcinoma was 30.0% (9 of 30 cases), 9.1% (4 of 44 cases) and 4.5% (1 of 22 cases), respectively. The difference between the three groups was statistically significant (χ^2 = 8.569, P = 0.014). No significant correlation was found between lateral lymph node metastasis and other variables such as gender (χ^2 = 0.168, P = 0.682), age (χ^2 = 0.103, P = 0.749), family history (χ^2 = 0.430, P = 0.512), high CEA level (χ^2 = 0.468, P = 0.494), Ming's classification (χ^2 = 0.430, P = 0.512), lymph node metastases (χ^2 = 0.239, P = 0.625) and vessel cancerous emboli (χ^2 = 0.201, P = 0.654) (Table 1).

Correlation between lateral lymph node metastasis and local recurrence of advanced low rectal cancer

Local recurrence was 18.8% (18 of 96 cases), 64.3% (9 of 14 cases), and 11.0% (9 of 82 cases) in patients with advanced low rectal cancer and those with and without lateral lymph node metastasis The difference between the two groups was statistically significant (χ^2 = 22.308, P = 0.0001).

Correlation between lateral lymph node metastasis and survival in patients with advanced low rectal cancer

In a median follow-up period of 73 (range 16-90) mo, Kaplan-Meier survival analysis showed a significantly improved median survival (80.9 $\pm$ 2.1 m, 95% CI: 76.7-85.1 m *vs* 38 $\pm$ 6.7 m, 95% CI: 24.8-51.2 m) in patients without lateral lymph node metastasis compared with those with lateral lymph node metastasis. The difference between the two groups was statistically significant (log-rank, P = 0.0001) (Figure 1).

DISCUSSION

Lateral pelvic lymphadenectomy for advanced low rectal cancer is controversial[19-25]. In Japan, lateral pelvic lymphadenectomy is routinely performed for patients with advanced low rectal cancer, whereas it is not frequently performed in the Western countries[26-28]. In the current study, a retrospective analysis was performed in 96 patients with advanced low rectal cancer who underwent curative surgery with lateral lymph node dissection. The relations of lateral lymph node metastasis with clinicopathologic

characteristics, local recurrence and survival of advanced low rectal cancer were analyzed.

In our study, lateral lymph node metastasis was observed in 14.6% (14/96) of patients with advanced low rectal cancer, showing a significant correlation with tumor diameter, infiltration and differentiation. Lateral lymph node metastasis was found in 10 (25.0%) of 40 patients with tumor diameter ⩾ 5 cm and in 4 (7.1%) of 56 patients with tumor diameter < 5 cm ($\chi^2 = 5.973$, $P = 0.015$). Lateral lymph node metastasis was more frequent in patients with 4/4 diameter of tumor infiltration (7 of 10 cases, 70.0%) than in patients with 3/4, 2/4 and 1/4 diameter of tumor infiltration (3 of 25 cases, 12.0%; 3 of 45 cases, 6.7%; 1 of 16 cases, 6.3%) ($\chi^2 = 27.944$, $P = 0.000$). The lateral lymph node metastasis rate of poorly, moderately and well differentiated carcinoma was 30.0% (9 of 30 cases), 9.1% (4 of 44 cases) and 4.5% (1 of 22 cases), respectively ($\chi^2 = 8.569$, $P = 0.014$), indicating that tumor diameter ⩾ 5 cm, tumor infiltration and differentiation are risk factors for lateral lymph node metastasis of advanced low rectal cancer. Therefore, lateral pelvic lymphadenectomy should be performed following the management of patients with tumor diameter ⩾ 5 cm, tumor infiltration or differentiation.

It is well known that local recurrence is the most important prognostic factor for rectal carcinoma[29-31]. It was reported that local recurrence can be found in 4%-50% of patients with rectal carcinoma after curative resection, and lateral lymph node metastasis may be the important factor for local recurrence[15,16]. Ueno *et al*[15] reported that patients with lateral node metastases have an increased risk for local recurrence (44% *vs* 11.7%; $P < 0.001$) compared with those without lateral node metastases. Sugihara *et al*[16] also reported that positive lateral lymph nodes are significantly associated with increased local recurrence of rectal cancer. Similarly in this study, lateral lymph node metastasis was significantly correlated with local recurrence of advanced low rectal cancer. The local recurrence rate of advanced low rectal cancer was 64.3% (9 of 14 cases) and 11.0% (9 of 82 cases) in patients with and without lateral lymph node metastasis ($\chi^2 = 22.308$, $P = 0.000$), respectively, indicating that lateral pelvic lymphadenectomy can significantly reduce local recurrence of advanced low rectal cancer.

In the present study, patients without lateral lymph node metastasis had significant improvements in median survival (80.9 ± 2.1 m, 95% CI: 76.7-85.1 m *vs* 38 ± 6.7 m, 95% CI: 24.8-51.2 m) compared to those with lateral

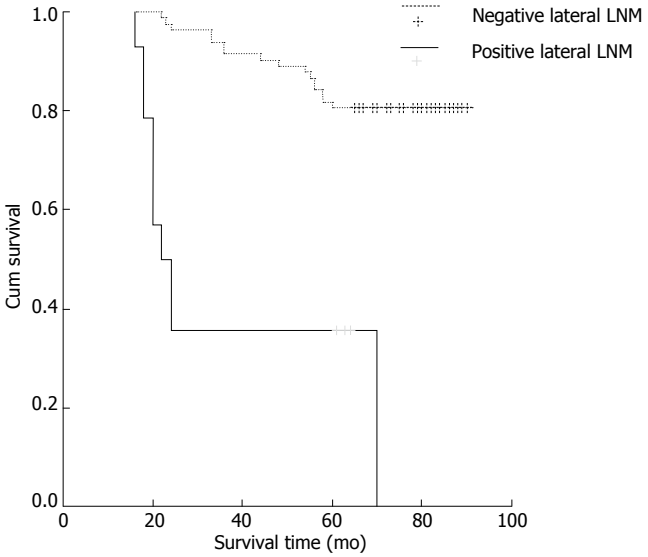

Figure 1 Relations between lateral lymph node metastasis and survival of patients with advanced low rectal cancer (Kaplan-Meier survival analysis). LNM: Lymph node metastasis.

lymph node metastasis. The difference between the two groups was statistically significant (log-rank, $P = 0.0001$), supporting that lateral lymph node metastasis has a significant prognostic value for advanced low rectal cancer. Lateral pelvic lymphadenectomy may effectively improve the survival of patients with advanced low rectal cancer. Ueno *et al*[32] also reported that advanced low rectal cancer patients having lymph node involvement in the lateral pelvic area are likely to benefit from lymphadenectomy.

COMMENTS

Background

Even having undergone radical resection with total mesorectal excision, about 5%-40% of patients with rectal cancer have local recurrence. The survival of patients with advanced low rectal cancer remains poor. Whether patients with advanced low rectal cancer could benefit from lateral lymph node dissection is still controversial.

Research frontiers

At present, lateral lymphadenectomy for advanced low rectal cancer is controversial. However, lateral lymph node metastasis is significantly associated with local recurrence and poor prognosis of advanced low rectal cancer.

Innovations and breakthroughs

The results of this study indicate that tumor diameter $\geqslant$ 5 cm, tumor infiltration and differentiation are risk factors for lateral lymph node metastasis of advanced low rectal cancer. Lateral lymph node metastasis is significantly correlated with local recurrence and prognosis of advanced low rectal cancer.

Applications

Lateral pelvic lymphadenectomy may effectively reduce local recurrence and improve the survival in patients with advanced low rectal cancer.

Peer review

The present study investigated the relations of lateral lymph node metastasis with local recurrence and survival in patients with advanced low rectal cancer. The study design is good and data analysis is extensive. The manuscript is well written.

Abstract

AIM: To understand the role and significance of side population (SP) cells from hepatocellular carcinoma (HCC) in hepatocarcinogenesis, development, relapse and metastasis, we simulated the denutrition conditions that cancer cells experience in clinical therapy, observed the different anti-apoptosis ability of SP cells and non-SP cells under such conditions, and established the possible effects of P53, Bcl-2 and Bax on survival of SP cells.

METHODS: We used flow cytometry to analyze and sort the SP and non-SP cells in established HCC lines MHCC97 and hHCC. We evaluated cell proliferation by methyl thiazolyl tetrazolium (MTT) assay and investigated the expression of p53, bcl-2 and bax genes during denutrition, by RT-PCR and immunofluorescence staining.

RESULTS: The percentage of SP cells in the two established HCC lines was 0.25% and 0.5%, respectively. SP cells had greater anti-apoptosis and proliferation ability than non-SP cells. Expression of Bcl-2 and Bax in SP and non-SP cells differed during denutrition. The former was up-regulated in SP cells, and the latter was up-regulated in non-SP cells.

CONCLUSION: It may be that different upstream molecules acted and led to different expression levels of Bcl-2 and Bax in these two cell lines. There was a direct relationship between up-regulation of Bcl-2 and down-regulation of Bax and higher anti-apoptosis ability in SP cells. It may be that the existence and activity of SP cells are partly responsible for some of the clinical phenomena which are seen in HCC, such as relapse or metastasis. Further research on SP cells may have potential applications in the field of anticancer therapy.

Key words: Side population; Hepatocellular carcinoma; Bax; Bcl-2; Apoptosis

INTRODUCTION

It is believed that cancer is unicellular in origin[1], although cancer cells from a lot of tumors generally exhibit functional heterogeneity in experimental and clinical settings[2]. There are two theories[3,4]. One is the stochastic model, which figures that cancer is composed of a comparatively homogeneous population; only a few cells undergo stochastic events, so that they have the potential to proliferate extensively and form new tumors. The other is the hierarchy model, which suggests that there is some kind of pyramid scale in cancer cells. In this model, the subpopulation cells, which are on acme in the pyramid scale, comprise cancer stem cells (CSCs) that self-renew, generate downstream descendants, and initiate new tumors.

Recently, the latter hypothesis has gained significant recognition. The possible existence of CSCs has been shown in leukemia and some solid tumors, including breast cancer and brain tumors[5-9]. These cells are detected by their own ability to efflux Hoechst 33342 dye through an ATP-binding cassette (ABC) membrane transporter. They are also named side population (SP) cells for their location on flow cytometry charts.

Hepatocellular carcinoma (HCC) is a common malignancy and still has a high mortality rate[10]. Clinical operations and chemotherapy can lead most such cancer cells to death or proliferation inhibition through denutrition. However, there are always some cells that can survive and result in relapse or metastasis, which often leads to therapeutic failure and poor prognosis. The CSC hypothesis offers an explanation for these clinical phenomena. In some studies, it has been found that SP cells are easier to initiate tumors than non-SP cells are in non-obese diabetic/severe combined immunodeficiency (NOD/SCID) mice[11]. Under conditions of denutrition

that are similar to those after clinical treatment, do SP cells survive more easily and have higher anti-apoptosis ability than non-SP cells?

p53, the most frequently mutated gene in human malignancies, is found inactivated in about 50% of tumors in any location and of any histological type. It has been named the "guardian of the genome"[12]. bcl-2 was the first example of an oncogene that inhibits cell death rather than promotes proliferation. According to differences in structure, the Bcl-2 family can be divided into two subgroups. Bax belongs to one subfamily that can oligomerize and integrate into the outer mitochondrial membrane to initiate events during apoptosis. Normally, Bcl-2 inhibits Bax activation. But, when cells are under stress (either oncogenic or genotoxic stress), Bcl-2 is inactivated by P53 as its downstream molecule. As a consequence, apoptotic cell death continues[13,14]. Under denutrition conditions, how are these three genes expressed in SP cells? What is their relationship with the anti-apoptosis ability of SP cells?

Taking clinical and experimental data together, we consider that the understanding of biologic characteristics of SP cells from HCC cells may serve to elucidate the mechanism of hepatocarcinogenesis and lead to novel therapeutic approaches.

In this study we therefore analyzed and sorted SP cells from established HCC cell lines. We observed the anti-apoptosis ability of two cell lines under denutrition conditions by methyl thiazolyl tetrazolium (MTT) assay. We further estimated the expression level of P53, Bcl-2 and Bax in SP cells and non-SP cells by RT-PCR and immunofluorescence during denutrition.

MATERIALS AND METHODS

Cell culture

The human liver cancer cell line MHCC97 was obtained from the Institute of Biochemistry and Cell Biology (Shanghai, China), the hHCC cell line was from the Department of Biochemistry and Molecular Biology of Fourth Military Medical University (Xi'an, China). These cells were cultured in Dulbecco's modified Eagle's medium (DMEM) (Invitrogen Life Technologies, Carlsbad, CA, USA) containing 10% fetal calf serum (FCS) and 1% penicillin/streptomycin (Invitrogen), and incubated at 37℃ in an atmosphere containing 5% CO_2.

SP cell analysis and purification using flow cytometry

Cells were detached from the dishes with trypsin-EDTA (Invitrogen) and suspended at 1×10^6 cells/mL in Hank's balanced salt solution (HBSS) supplemented with 3% fetal calf serum and 10 mmol/L HEPES. These cells were then incubated at 37℃ for 90 min with 20 μg/mL Hoechst 33342 (Sigma, St Louis, MO, USA), either alone or in the presence of 50 μmol/L verapamil (Sigma), which is an inhibitor of verapamil-sensitive ABC transporter. After 90 min incubation, the cells were centrifuged immediately for 5 min at 300 × *g*, 4℃ and resuspended in ice-cold HBSS. The cells were kept on ice to inhibit efflux of Hoechst dye. Then, 1 μg/mL propidium iodide (PI; BD Pharmingen, San Diego, CA, USA) was added to discriminate dead cells. Finally, these cells were filtered through a 40-μm cell strainer (BD Falcon; BD Pharmingen, San Diego, CA, USA) to obtain single suspension cells. Cell dual-wavelength analysis and purification were performed using dual-laser cytometry (FACSVantage; BD Biosciences, Franklin Lakes, NJ. Hoechst 33342 solution was excited at 355 nm UV light; blue fluorescence was collected with a 450/20 band-pass (BP) filter and red fluorescence with a 675-nm edge filter long-pass (EFLP). A 610-nm dichroic mirror short-pass was used to separate the emission wavelengths. PI-positive dead cells were excluded from the analysis.

MTT assay

All cells were maintained in PBS for 3, 6 and 9 h to induce denutrition. Then, cell proliferation was evaluated by MTT assay. MTT solution in PBS was added to a final concentration of 0.5 mg/mL, and cells incubated for 4 h at 37℃. Supernatant was removed and cells were resuspended in 150 μL DMSO for 10 min, and absorbance was measured at 490 nm using a microplate reader (Bio-rad, Japan).

Semi-quantitative RT-PCR

After all cells were induced in PBS for their respective number of hours, total RNA was extracted from SP and non-SP cells using TRIzol reagent (Invitrogen) according to the manufacturer's instructions, and was reverse-transcribed by using a First-Strand cDNA Synthesis Kit (Fermentas, Lithuania), as described in the instructions. RT-PCR was carried out in a 50 μL reaction mixture that contained 1 μL cDNA as template, 1 μmol/L specific oligonucleotide primer pair, and 25 μL Taq mixture that contained 0.5 U Taq DNA polymerase (Tangen, Beijing, China). Cycle parameters for p53, bcl-2, bax and glyceraldehyde-3-phosphate dehydrogenase (G3PDH) cDNAs were 15 s at 95℃, 30 s at 55℃, and 60 s at 72℃ for 33, 32, 30 and 20 cycles, respectively. Primer sequences were as follows: p53, 5'-GTTTCCGTCT GGGCTTCTTG-3' and 5'-CCTGGGCATCCTTGA GTTCC-3'; bcl-2, 5'-ACACTGTTAAGCATGTGCC G-3' and 5'-CCAGCTCATCTCACCTCACA-3'; bax, 5'-GGATGCGTCCACCAAGAA-3' and 5'-ACTCCCG CCACAAAGATG-3'; and G3PDH, 5'-ACCACAGTCC ATGCCATCAC-3' and 5'-TCCACCACCCTGTTGCT GTA-3'.

Immunofluorescence staining

Cells were cultured on coverslips and received the same treatment of induced denutrition in PBS as described above. Cells were fixed in methanol at -20℃ for 20 min and washed in PBS containing 0.1% Tween 20 (Sanland Chemicals, Xiamen, China). After blocking with 10% goat normal serum for 1 h, fixed cells were incubated with primary antibodies, rabbit anti-Bcl-2 (Santa Cruz Biotechnology, Santa Cruz, CA, USA) and mouse anti-Bax (Santa Cruz Biotechnology), in a moist chamber at 4℃ overnight. Cells were washed in PBS containing 0.1% Tween 20, blocked again for 30 min, and treated

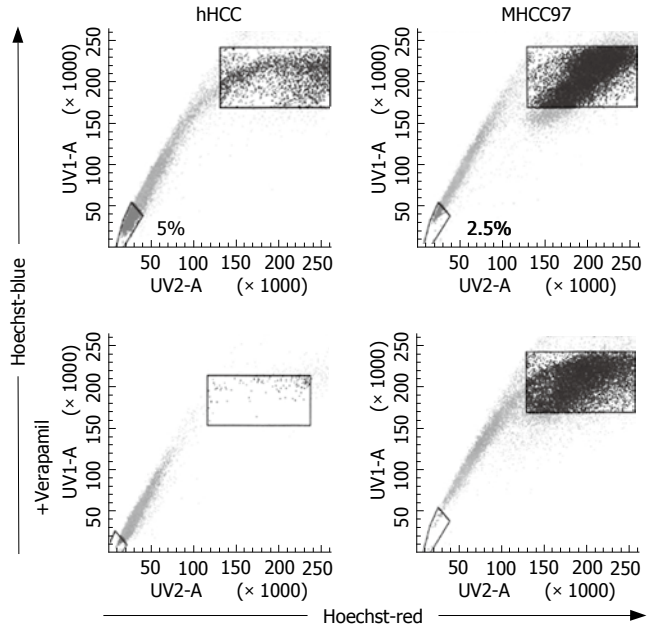

Figure 1 SP cells were detected in 0.25 and 0.5% of MHCC97 and hHCC cells, respectively. The SP cells disappeared with Hoechst 33342 and verapamil co-treatment.

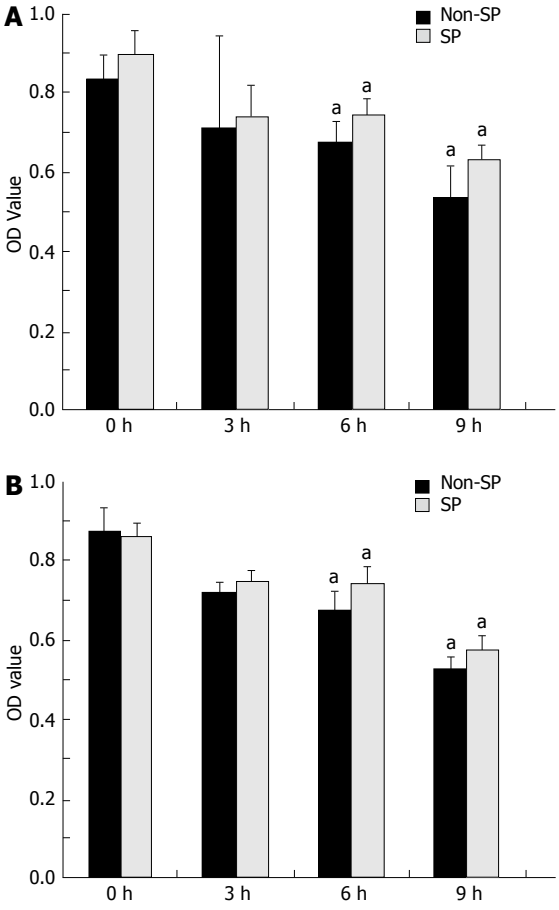

Figure 2 Proliferation of MHCC97 and hHCC cells at 3, 6 and 9 h during denutrition, as observed by MTT assay. SP cells purified from MHCC97 (**A**) and hHCC (**B**) cell lines demonstrated greater viability than the corresponding non-SP cells. $^{a}P < 0.05$.

with TRITC (Tetramethyl Rhodamine Isothiocyanate)-conjugated goat anti-rabbit IgG (Santa Cruz) and FITC (Fluorescein Isothiocyanate)-conjugated goat anti-mouse IgG (Santa Cruz) at 37℃ for 1 h. After washing in PBS, the coverslips were covered on slips with 30% glycerol phosphate buffer and examined under an Olympus IX70 microscope (Olympus, Japan).

Statistical analysis

Bands from RT-PCR were quantified by Smart View Bio-electrophoresis Image Analysis System software (Furi Science & Technology, Shanghai, China). Relative mRNA levels were calculated by referring them to the amount of G3PDH. Numerical data from the MTT assay were presented as the mean ± SEM. The difference between means was measured with Student's *t* test. All statistical analyses were performed using SPSS11.0 software (Chicago, IL, USA). $P < 0.05$ was considered as statistically significant.

RESULTS

Detection of SPs in HCC cells

Flow cytometry analysis with Hoechst 33342 staining demonstrated that MHCC97 and hHCC cells included 0.25% and 0.5% SP cells, respectively. The number of these SP cells was diminished in the presence of Hoechst 33342 and verapamil, a calcium channel blocker. The SP and non-SP cells in MHCC97 and hHCC cells were sorted separately and used for further experiments (Figure 1).

MTT assay

MTT assay was used to determine the proliferation of SP and non-SP cells under denutrition conditions. The results illustrated that denutrition inhibited proliferation of SP and non-SP cells in both cell lines in a time-dependent manner. The data showed that there was a difference between SP and non-SP cells at 6 and 9 h, and it seemed that SP cells had a greater proliferation ability than non-SP cells under denutrition (Figure 2).

RT-PCR

RT-PCR was used to detect mRNA expression levels in SP and non-SP cells in two cancer cell lines. The p53 gene was expressed weakly but steadily during the whole experiment. The bcl-2 gene was up-regulated, while the bax gene was down-regulated in SP cells under denutrition. Interestingly, the regulation of the two genes was reversed in non-SP cells. It may be that the upstream molecule which adjusted these two genes' expression was not P53 (Figure 3).

Immunofluorescence staining

Expression levels of Bcl-2 and Bax proteins were examined by immunofluorescence staining in hHCC and MHCC97 cell lines (Figure 4). It was clear that the expression of Bcl-2 increased in a time-dependent manner in SP cells, in contrast with non-SP cells. Conversely, the expression of Bax increased in non-SP cells in the same manner and decreased in SP cells.

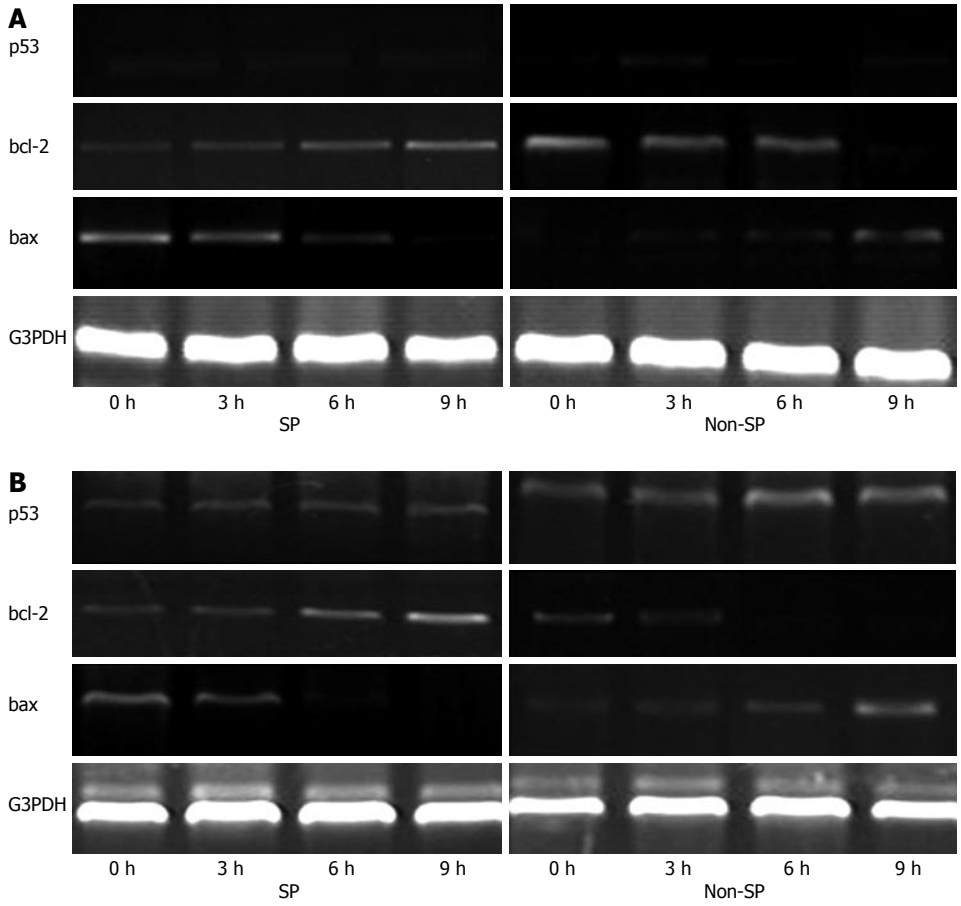

Figure 3 p53, bcl-2 and bax mRNA levels were evaluated by RT-PCR. bcl-2 levels were up-regulated in SP cells from MHCC97 (**A**) and hHCC (**B**) cell lines, and bax levels were down-regulated in non-SP cells during denutrition.

DISCUSSION

HCC ranks among the most common cancers in many countries. A recent estimate indicates that HCC represents the fifth most common cancer in males, and the eighth most common in females, with a total of 560 000 new cases each year, 83% of which occur in developing countries, and more than one-half in China alone. Moreover, because of its very poor prognosis, HCC represents the third leading cause of cancer death worldwide[10].

From the clinical standpoint, there are some conspicuous biological characteristics in HCC, such as anti-apoptosis, chemotherapy resistance, extensive proliferation, and even early metastasis. These characteristics are particularly prevalent in cases of relapse and metastasis.

Recently, it has been reported that CSCs are seen in many kinds of tumors and established cancer cell lines[15-18]. Using the previously described methods, we analyzed and sorted some of these CSCs, namely SP cells, in established HCC cell lines. The proportion of SP cells in the two cell lines was 0.25% and 0.5%, respectively. The MHCC97 (Metastatic Human Hepatocellular cancer 97) cell line was established from a highly metastatic case of HCC in 1997, and the hHCC (human Hepatocellular cancer) cell line was cultured from a case with a high level of chemotherapy resistance, with the proportion of SP cells being a little higher than those reported previously.

In clinic, whatever surgery or chemotherapy, it will bring denutrition directly or indirectly so as to inhibit the proliferation of cancer cells, beside destroy the structure of tumors or kill them. In clinics, surgery, radiotherapy and chemotherapy are used to destroy the structure of tumors, induce denutrition, kill cancer cells directly, and inhibit cancer cell proliferation. However, there are still some cells that can survive in denutrition conditions, and these may lead to relapse and metastasis. What difference is there between these and other cells? What mechanism is behind these phenomena? In our experiment, we simulated the denutrition conditions and observed the anti-apoptosis or proliferation ability of SP cells.

By MTT assay, we found that SP cells had better resistance to denutrition than non-SP cells. Using RT-PCR and immunofluorescence staining, we found that P53 may not be the key molecule that is responsible for the anti-apoptosis ability of SP cells. p53 was one of the most important genes in stabilizing the cell genome. It regulated the expression of numerous pro-apoptotic genes, such as bcl-2 and bax. Our results showed that the normal activity of P53 in the two cell lines may have been inhibited. The expression levels of two members of the Bcl-2 family were clearly altered between SP and non-SP cells; specifically, the expression of Bax was inhibited in SP and activated in non-SP cells, but the expression of Bcl-2 was reversed. Bax was a cytosolic monomer in viable cells but during apoptosis, it changed its conformation, integrated into the outer mitochondrial membrane, and was oligomerized. It provoked the permeabilization of the outer mitochondrial membrane (PT) and contributed to the release of pro-apoptotic factors into the cytosol, such as cytochrome C, which led to formation of the apoptosome and activation of the caspase cascade. However, the anti-apoptotic guardian Bcl-2 could bind Bax strongly, and this interaction

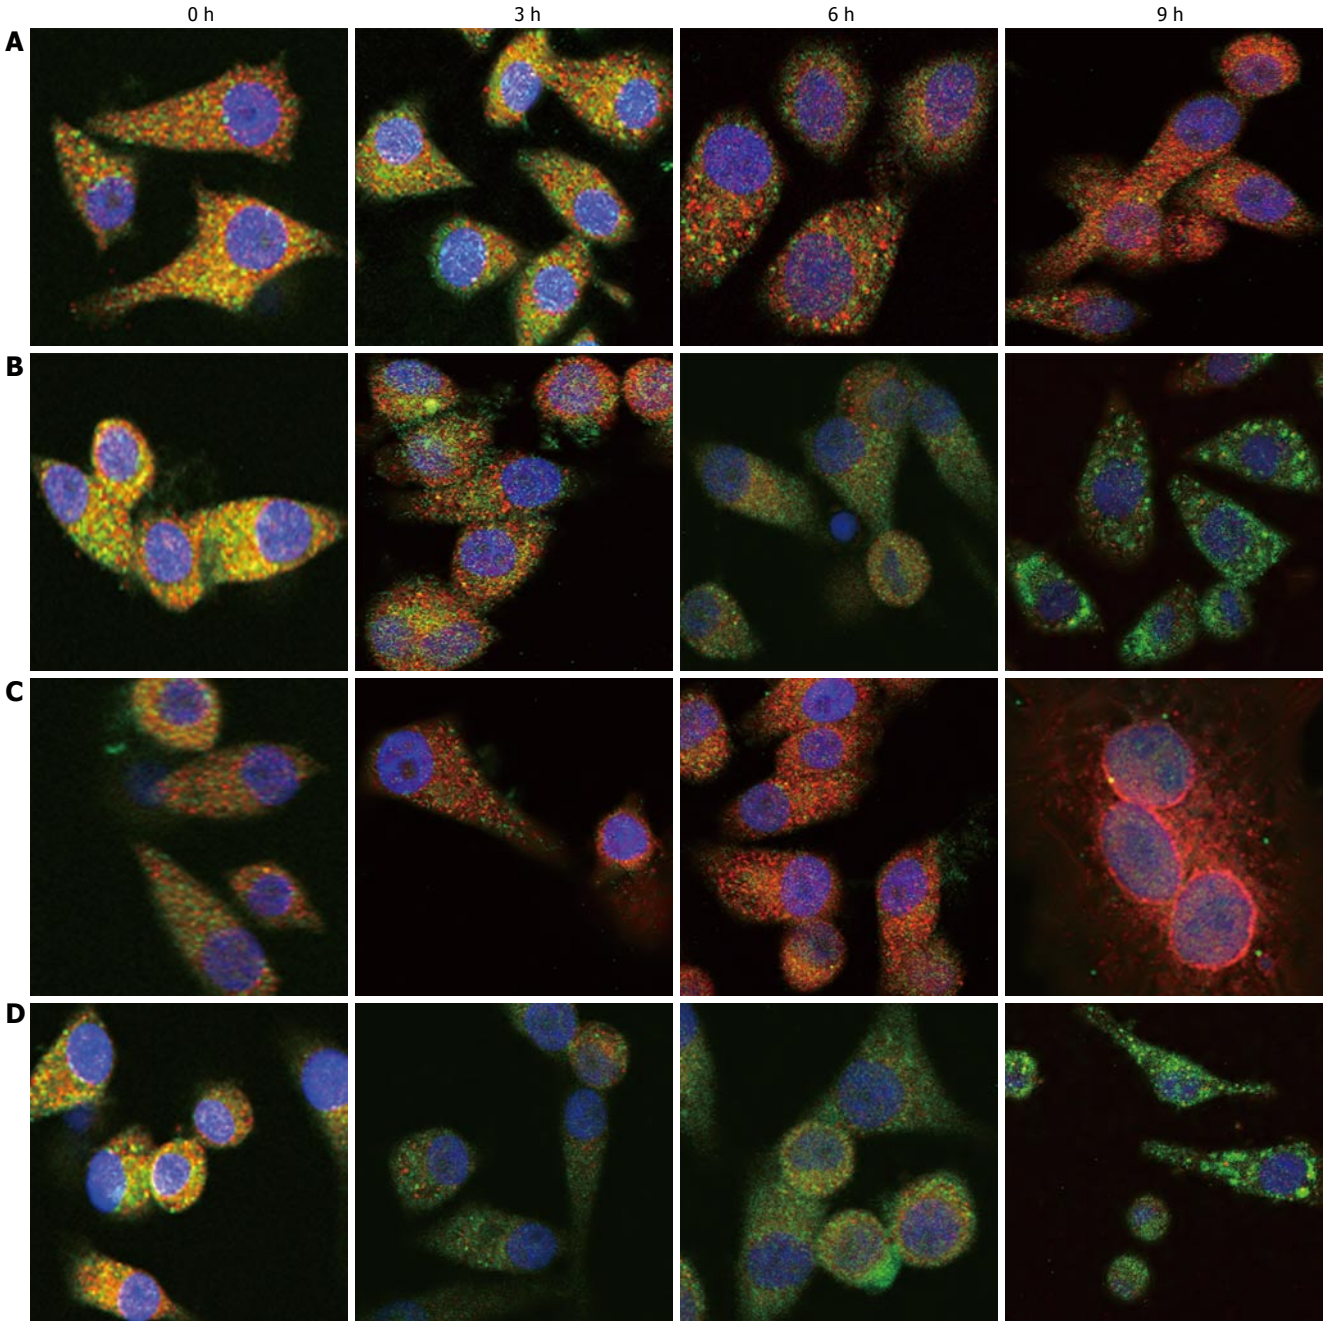

Figure 4 Bcl-2 (red) and Bax (green) expression was examined in SP (**A**) and non-SP (**B**) cells of MHCC97, and SP (**C**) and non-SP (**D**) cells of hHCC cells. The expression of Bcl-2 in SP cells was up-regulated, while Bax was down-regulated.

inhibited Bcl-2 activation, which sustained cell survival. In our study, the up-regulation of Bcl-2 and down-regulation of Bax were effective during the anti-apoptosis in SP cells. In other words, in MHCC97 and hHCC cell lines, SP cells had greater anti-apoptosis or proliferation ability than non-SP cells had. Expression of Bcl-2 and Bax had a pivotal role in the anti-apoptosis procedure during denutrition.

We have previously found that the expression level of alpha-fetoprotein (AFP) in SP cells is significantly higher than in non-SP cells in established HCC cell lines, e.g. MHCC97[19]. AFP is one of the most useful markers, and has been used in clinical diagnosis of HCC. AFP is synthesized in large quantities by the fetal yolk sac and the liver during embryonic development[20,21]. According to clinical experience, if a high level of AFP is found in the serum, the first thought is that the patient has HCC. If this appears after surgery or chemotherapy, it indicates a poor prognosis, such as recurrence or metastasis[22-27]. The ABC transporter for discharging Hoechst 33 342, which is called the breast cancer resistance protein, has a high efflux capacity with a wide substrate range, including mitoxantrone and methotrexate[28]. Further, the higher expression level of ABC transporter on SP cells indicates a possible relationship between them and clinical chemotherapy resistance.

Taking the experimental results and clinical experiences together, we found that the characteristics displayed in SP cells, such as high expression level of AFP and Bcl-2 and

drug efflux capacity, are consistent with the characteristics displayed in tumors, such as high expression level of AFP, high anti-apoptosis ability and chemotherapy resistance. We conclude that perhaps the existence and activity of SP cells are responsible for these clinical phenomena shown in HCC; moreover, it is reasonable to recognize SP cells as CSCs.

ACKNOWLEDGMENTS

We thank Mr. Shi-Liang Ma from Peking University Health Science Center for his patience and dedication during our flow cytometry analysis. We also thank Professor Qing-Chuan Zhao, Professor Zhen-Shun Song and Professor Yong Chen from the Department of Hepatobiliary Surgery for their helpful discussion during the preparation of this paper.

COMMENTS

Background

The theory of CSCs is one of the most significant theory in tumor research. According to the theory, there is some kind of pyramid cell structure in tumor cells, and CSCs are at its apex. They have self-renewal and differentiation abilities, and other cells are their descendents. CSCs have many biological activities, such as anti-drug and greater ability to proliferate. CSC theory also explains some clinic phenomena such as chemotherapy resistance and relapse. Therefore, research on the characteristics of CSCs may be the foundation of future clinical therapy.

Research frontiers

In 1996, Goodell sorted a certain kind of cells from mouse whole bone cells by cytometry, and he found that those cells expressed different biological characteristics, such as higher proliferation and multi-differentiation. Many workers have reported the existence of such cells in different tissues, and they have been collectively named SP cells. SP cells from tumors or tumor cell lines have greater proliferation and tumor formation ability, they resist drugs, and they maintain themselves in whole cells at a rate of a few percent.

Innovations and breakthroughs

The observation of SP cells backs up the theory of CSCs, which was introduced many years ago. Using Hoechst 33342 dye, it is possible to sort the cells by cytometry. SP cells have been found in HCC, brain tumor, prostate cancer and leukemia. By analyzing their biological abilities, it seemed that side population cells existed between the tip and bottom of the pyramid cell structure, and that they had intersection with real CSCs. Thus, though we can not be certain that SP cells are CSCs, it seems that that SP cells have a typical CSC phenotype.

Applications

In clinical cases, there have heretofore been many failures caused by tumor chemotherapy resistance or metastisis. CSC theory and the discovery of SP cells bring new hope for tumor therapy in the future. How to locate these cells in tumors, how to remove them completely by surgery, and how to inhibit or kill them by chemotherapy, are just a few of the clinical questions that need to be answered. Even a small advancement in this research field may result in a new breakthrough in tumor therapy.

Terminology

SP cells were first discovered by Goodell when he analyzed mouse bone cells by cytometry using Hoechst 33342. They were named after their location in 2-D cytometry charts. They display low fluorescence, and are located at the edge of the chart, away from other cells.

Peer review

SP cells from tumors or tumor cell lines are one of the hottest topics in tumor research. This study confirmed their existence and numbers in two human HCC cell lines.

Abstract

AIM: To investigate changes in vasoactive intestinal polypeptide (VIP) and corticotrophin releasing factor (CRF) in the plasma and duodenum of chronic stress-induced depressed rats and the effects of fluoxetine hydrochloride (fluoxetine) treatment on depression-induced changes in VIP and CRF.

METHODS: A Sprague-Dawley rat model of chronic stress-induced depression was produced. Thirty experimental rats were randomly divided into the following groups: control group, saline-treated depressed group, and fluoxetine-treated depressed group. Open-field testing was performed to assess the rats' behavior. VIP and CRF levels in plasma were measured by ELISA. Immunofluorescence techniques combined with laser scanning confocal microscopy (LSCM) were used to investigate VIP and CRF expression in the duodenum.

RESULTS: The open-field behavior, both crossing and rearing, of depression model rats, decreased significantly compared with those of normal control rats over 5 min. Defecation times increased significantly. Compared to the control group, FITC fluorescence of duodenal CRF expression and plasma CRF levels in the depressed rats increased significantly (fluorescence intensity of duodenal CRF: 11.82 ± 2.54 *vs* 25.17 ± 4.63; plasma CRF: 11.82 ± 2.54 ng/L *vs* 25.17 ± 4.63 ng/L, $P < 0.01$), whereas duodenal VIP expression and plasma VIP levels decreased significantly (fluorescence intensity of duodenal VIP: 67.37 ± 18.90 *vs* 44.51 ± 16.37; plasma VIP: 67.37 ± 18.90 ng/L *vs* 44.51 ± 16.37 ng/L, $P < 0.01$). Fluoxetine improved depressed behavior, increased VIP expression and decreased CRF expression in plasma and the duodenal tissue of depressed rats.

CONCLUSION: Chronic stress can induce injury to the duodenum, accompanied by increasing CRF and decreasing VIP in the plasma and duodenum. Treatment with fluoxetine can ameliorate pathological changes in the duodenum of depressed rats, which suggests that antidepressants are an effective therapeutic agent for some duodenal diseases caused by chronic stress. VIP is a potential therapeutic strategy.

INTRODUCTION

In clinical studies, it has become clear that psychological factors, especially anxiety and depression, play an important role in gastrointestinal diseases by precipitating exacerbation of symptoms[1,2]. Several studies have shown that the prevalence of chronic stress disorders in patients with gastrointestinal symptoms is about 60%-85%[3,4]. Stress often worsens the symptoms of gastrointestinal diseases, which might be explained by altered neuroendocrine and visceral sensory responses to stress[5].

In recent years, along with extensive research on the enteric nerve system (ENS), increasing evidence shows that peptidergic neurotransmitters could regulate gastrointestinal diseases. Vasoactive intestinal peptide (VIP), a 28-amino acid peptide, was first discovered, isolated, and purified from porcine intestinal extracts[6]. It was also found in submucous and myenteric plexuses,

as well as the central and peripheral nervous systems[7]. It is now recognized as a major neuropeptide in the brain and gut, with functions ranging from neurotransmission to neuromodulation with neurotrophic properties. Corticotrophin releasing factor (CRF) is a 41 amino-acid peptide which stimulates adrenocorticotropic hormone (ACTH) secretion. Some data strongly suggest that CRF plays an important role in the pathophysiology of gastrointestinal diseases and electrophysiological properties of the brain during visceral perception[8]. Patients with gastrointestinal diseases may have a higher tone of corticotropin-releasing hormone (CRH) in the brain. In common, both central and peripheral nervous pathways are involved in the release of gastrointestinal hormones due to psychological stress, thus modulating gastrointestinal motility[9]. A large body of evidence derived from experiments suggests that CRF can accelerate small intestine transit, while VIP can inhibit it[10].

Fluoxetine is a SSRI (selective serotonin re-uptake inhibitor), which are a class of antidepressants used in the treatment of depression and anxiety disorders. SSRIs increase the extracellular expression of the neurotransmitter serotonin by inhibiting its re-uptake into the presynaptic cell. Serotonin is also involved in the regulation of carbohydrate metabolism. Few analyses of the role of SSRIs in treating depression have covered the effects on carbohydrate metabolism from intervening in serotonin handling by the body. Studies have suggested that SSRIs may promote the growth of new neural pathways or neurogenesis[11]. Also, SSRIs may protect against neurotoxicity caused by other compounds as well as from depression itself. Recent studies have shown that pro-inflammatory cytokine processes occur during depression in addition to somatic disease, and it is possible that symptoms manifested in these psychiatric illnesses are being attenuated by the pharmacological effects of antidepressants on the immune system[12]. SSRIs have been shown to be immunomodulatory and anti-inflammatory against pro-inflammatory cytokine processes[13,14].

However, there has been no report so far concerning the changes in VIP and CRF aroused by depression in plasma and duodenal tissue, and the effect of antidepressants on the duodenum. Therefore, we devised a rat depression model and observed the levels of VIP and CRF in the plasma and duodenum, and the effect of fluoxetine on the duodenum of depressed rats.

MATERIALS AND METHODS

Animals

Forty healthy male Sprague-Dawley rats, weighing 250 ± 30 g, from the Animal Center, Academy of Hubei Preventive Medical Sciences, were employed in the present study. The animals were fed standard rat chow, allowed access to tap water and were acclimated to their surroundings for 1 wk prior to the experiments. After this period, 30 rats were selected according to their open-field behavior.

Reagents

FITC (Fluorescein isothiocyanate)-conjugated goat anti-rabbit IgG, VIP and CRF rabbit anti- mouse antibodies were purchased from Sigma Co., USA. Fluoxetine hydrochloride capsules were purchased from Lilly Co. Ltd., and ELISA kits were purchased from Beijing SUNBIO Biological Technology Co. Ltd. Other reagents used in the study were all of analytical grade.

Experimental protocols (preparation of the rat depression model treated with saline or fluoxetine)

A rat model of chronic stress-induced depression was established[15-17]. The rats received a variety of stressors for 21 d, including tail nip for 1 min, cold water swimming at 4℃ for 5 min, heat stress at 45℃ for 5 min, water deprivation for 24 h, food deprivation for 24 h, 12-h inverted light/dark cycle (7:00 a.m. lights off, 7:00 p.m. lights on), paw electric shock (electric current 1.0 mA 10 s, every 1 min, lasting for 10 s, 30 times), *etc.* Stressors were administered throughout the experiment, could occur at any time of day (or night), and were each applied for a period of between 8 and 24 h. Their sequence was at random in order to be completely unpredictable to the animal. The animals were randomly divided into three groups (10 rats per group): model control, saline + chronic stress-induced, fluoxetine + chronic stress-induced therapy group. The depressed animals were treated with normal saline or fluoxetine (10 mg/kg) by stomach, (once a day, from the 24 h after the depressed model was established until the end of the experiment). A normal control group of rats (10 rats) without receiving any stress was included and housed in a separate room; food and water were freely available in their home cage.

Open field test (OFT)

The open-field test was designed to measure the reaction of rats to a novel environment. In this test, rats were individually placed in the center of a square, wooden, white-colored open-field box with 36 squares measuring 10 cm × 10 cm each. Their activity was assessed for 5 min. The number of squares from which rats crawled out was the total number of crossings. The number of occasions on which the animals stood on their hind legs was the total number of rearings. Defecation times were counted every 5 min. Each rat was housed in one cage and fasted before sucrose intake testing, after which 10 g/L sucrose solution consumption in 24 h was examined.

Assessment of duodenal histological damage

Duodenal tissue was sampled for a variety of determinations after the rats were anesthetized with 200 d/L urethane. Duodenal tissue was fixed in 4% paraformaldehyde, dehydrated, embedded in paraffin, sectioned in 4 μm thick sections, and stained with haematoxylin and eosin. The criteria of the histological score used was a previously validated scoring system from 0 to 4 that depends on the number and size of ulcers as well as the presence or absence of adhesions[18,19]: (1) the infiltration of acute inflammatory cells: 0 = no, 1 = mild increasing, 2 = severe increasing; (2) the infiltration of chronic inflammatory cells: 0 = no, 1 = mild increasing, 2 = severe increasing; (3) the deposition of fibrotin protein: 0 = negative, 1 = positive; (4) submucosa edema: 0 =

Table 1 Open-field activities and sucrose intake test of rats (n = 10, mean ± SD)

Group	Crossing/5 min	Rearing/5 min	Defecation/5 min	Sucrose intake mL/24 h
Control	133.00 ± 11.309	28.53 ± 10.22	3.90 ± 0.57	36.18 ± 10.24
Saline + depressed	51.80 ± 7.441[b]	11.10 ± 5.18[b]	6.80 ± 0.57[b]	8.95 ± 7.39[b]
FH + depressed	76.60 ± 3.534[d]	15.58 ± 7.367[d]	5.10 ± 0.43[d]	18.10 ± 6.43[d]

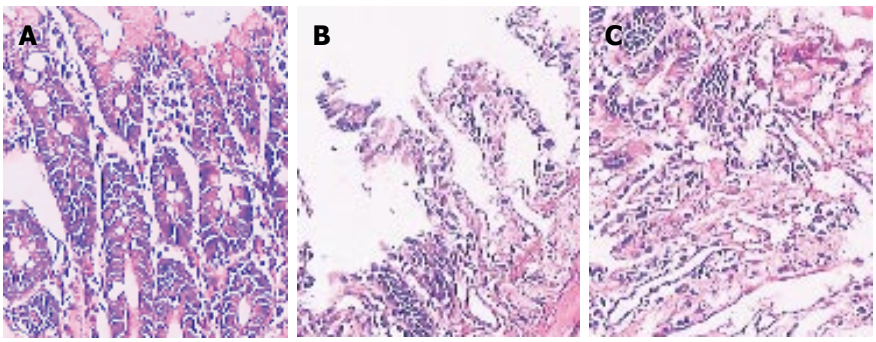

Figure 1 Haematoxylin and eosin staining of duodenum tissues. **A:** No damage in the normal control group (HE, × 200); **B:** Histological changes in the FH + depressed group (HE, × 200); **C:** Histological changes in the saline + depressed group (HE, × 200).

none, 1 = patchy-like, 2 = fusion-like; (5) epithelial necrosis: 0 = no, 1 = limiting, 2 = widening; (6) epithelial ulcers: 0 = negative, 1 = positive. The ulceration, inflammation, lesion and fibrosis were scored and put together as a result ranging between the minimum of 0 and maximum of 10.

Measurement of plasma VIP and CRF

Immediately after the rats were sacrificed, blood samples were collected into chilled tubes containing 0.3 μL ethylenediamine tetraacetic acid (EDTA) and 1000 KIU aprotinin. Blood samples were immediately centrifuged at 3500 r/min at 4℃ for 10 min. The supernatant was aspirated and stored at -70℃ until analysis. VIP and CRF were determined by enzyme linked immunosorbent assays (ELISA) according to the manufacturer's instructions.

Detection of duodenal VIP, CRF expression

Duodenal tissue was fixed in 4% paraformaldehyde for 4 h. One hundred micron sections from the primary tissue were employed in the fluorescent immunohistochemical analysis, which used rabbit anti-rat VIP/CRF antibody, diluted 1:500 in phosphate-buffered saline (PBS). The staining procedure was as follows: (1) the sections were washed in PBS, then pretreated with 0.25% Triton X-100 for 30 min at 37℃ and rinsed in PBS; (2) incubation for 12 h at 4℃ in a 1:500 dilution of the primary antibody of VIP /CRF in PBS; (3) incubation with 1:100 diluted secondary antibodies (FITC -conjugated goat anti-rabbit IgG) in PBS for 30 min at 37℃. The sections were washed three times for 10 min after incubation steps 1 to 3, respectively, and were finally mounted in 50 g/L glycerin.

Detection was carried out according to the kit instructions (Leica SP2 TCS AOBS made in Germany). The specimens were excited with a laser beam at a wavelength of 488 nm (FITC). Five visual fields in three sections of each tissue were randomly selected and observed under a laser scanning confocal microscope (LSCM) and analyzed with a Leica Q500IW image analysis system in terms of FITC fluorescent intensity. This study recorded the relative value of fluorescence intensity for the expression of VIP and CRF.

Statistical analysis

The data were expressed as the mean ± SD and analyzed with SPSS 11.5 statistic software. Statistical analysis was performed by using one-way ANOVA and Student-Newman-Keuls test for multiple comparisons. A P value less than 0.05 was considered statistically significant.

RESULTS

Open-field behavior of depression model rats (both crossing and rearing), was significantly decreased compared with that of the normal control rats (Table 1, $P < 0.01$). Defecation times significantly increased. The consumption of 10 g/L sucrose solution significantly decreased compared with that of the normal control (Table 1, $P < 0.01$). Treatment with fluoxetine hydrochloride (FH) significantly attenuated these effects.

Histological evaluation of the duodenum

No histological damage was seen in the normal control group. Rats with chronic stress-induced duodenitis showed neutrophil, macrophage, lymphocyte and eosinophil infiltration in the mucosa and submucosa. Ulceration and mucosal damage was obvious. Treatment with fluoxetine significantly attenuated the extent and severity of the histological signs. Damage scores of duodenum tissues were as follows: control: 0.39 ± 0.51; saline plus depressed: 7.46 ± 2.14; and FH plus depressed: 4.81 ± 1.37 (Figure 1).

VIP and CRF concentrations in plasma

Plasma VIP levels showed a significant difference among the three groups (Table 2, $P < 0.01$). VIP levels were higher in control and fluoxetine plus depression groups; however, they decreased significantly in the depressed group.

Plasma CRF levels showed a significant difference

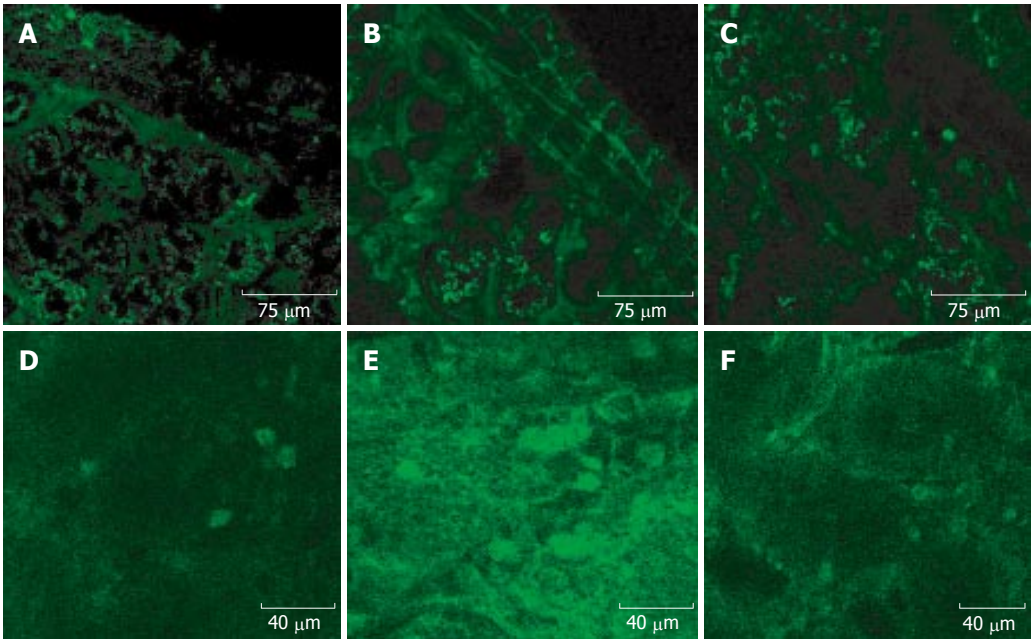

Figure 2 Duodenal tissue staining procedure included: (1) pretreatment with 0.25% Triton X-100; (2) incubation in the primary rabbit anti-rat antibody of VIP/CRF; (3) incubation with secondary antibodies (FITC -conjugated goat anti-rabbit IgG). Expression of FITC-labeled VIP/CRF (green). **A:** Expression of VIP in the control group; **B:** Expression of VIP in the depressed group; **C:** Expression of VIP in the FH + depressed group; **D:** Expression of CRF in the control group; **E:** Expression of CRF in the depressed group; **F:** Expression of CRF in the FH + depressed group.

Table 2 Changes of levels of VIP/CRF in plasma (n = 10, mean ± SD)

Group	VIP in Plasma (ng/L)	CRF in Plasma (ng/L)
Control	67.37 ± 18.90	11.82 ± 2.54
Saline + depressed	44.51 ± 16.37[b]	25.17 ± 4.63[b]
FH + depressed	60.86 ± 19.27[d]	17.05 ± 3.69[d]

[b]P < 0.01 *vs* control group; [d]P < 0.01 *vs* saline-treated depressed group.

among the three groups (Table 2, P < 0.01). CRF levels were lower in control and fluoxetine plus depression groups, but increased significantly in the depressed group.

VIP and CRF alterations and the effects of fluoxetine on the content of VIP and CRF in duodenum tissue of depression model rats

Compared with that of normal control rats, the average fluorescence intensity of duodenal CRF increased significantly, while the average fluorescence intensity of duodenal VIP decreased significantly in chronic stress-induced depressed rats (Table 3, P < 0.01). Furthermore, a significant improvement of the elevated duodenal VIP content and the significant reduction of duodenal CRF content were observed in animals treated with fluoxetine (Figure 2, Table 3, P < 0.01).

DISCUSSION

We found that experimental rats had almost all demonstrable symptoms of depression, consistent with the classic and mature model of depression[16,20]. Our results showed that both crossing and rearing behavior of depressed rats over five minutes significantly decreased compared with that of the normal control rats (Table 1, P < 0.01). Defecation times significantly increased. The consumption of 10 g/L sucrose solution significantly decreased compared with that of the normal control.

Table 3 The average fluorescence intensity analysis of VIP and CRF alterations in duodenum of depression model rats (n = 10, mean ± SD)

Group	Fluorescence intensity of VIP	Fluorescence intensity of CRF
Control	36.28 ± 17.16	10.87 ± 9.28
Saline + depressed	19.07 ± 13.84[b]	50.83 ± 24.66[b]
FH + depressed	28.29 ± 15.02[d]	29.18 ± 17.34[d]

FH: Fluoxetine hydrochloride; VIP: Vasoactive intestinal polypeptide; CRF: Corticotrophin releasing factor. [b]P < 0.01 *vs* control group; [d]P < 0.01 *vs* saline-treated depressed group.

Crossing reflected the degree of animal activity, rearing reflected the degree of curiosity to the novel surroundings, defecation times responded to intestinal function, and sucrose intake tests reflected the animal's response to rewards[21,22]. The chronic stressors caused a generalized decrease in action and responsiveness to rewards, and a functional gastrointestinal disorder. The behavioral changes of the depressed rat were reversed by chronic treatment with fluoxetine hydrochloride (a type of antidepressant).

On the other hand, rats with chronic stress-induced depression showed significant histological damage from duodenitis. For example, a number of neutrophils, macrophages, lymphocytes and eosinophils were found in the mucosa and submucosa; ulceration and mucosal damage could also be observed. No change was seen in the normal control group, and treatment with fluoxetine hydrochloride significantly attenuated the extent and severity of the histological signs. The antidepressant fluoxetine hydrochloride inhibited the extent of inflammation, prevented mucosa injury, minimized the ulceration area, and alleviated the duodenitis seen in the depressed animals.

In this study, we also found that there were different changes in VIP and CRF in the depressed rats' duodenum and plasma. The average fluorescence intensity of duodenal CRF expression of the depression model rats

increased significantly compared with that of the normal control rats, whereas that of duodenal VIP expression decreased significantly.

Brain gut peptides (BGPs) are distributed extensively in the brain and the gastrointestinal tract. Studies have demonstrated that some BGPs including VIP and CRF participate in gastrointestinal motility, secretion and absorption[23]. Several investigations have found that basal CRF levels have increased significantly during stress in patients. Because the gut and the brain are highly integrated and communicate in a bidirectional fashion largely through the ANS and HPA axis, patients also responded with higher expression of ACTH during stress and had higher basal expression of noradrenalin than the normal group. Stress induced exaggeration of the neuroendocrine response and visceral perceptual alterations occur during and after stress by CRF[6]. On the other hand, some studies have indicated that VIP participated in the modulatory effect of drugs on gastrointestinal motility and played an important role in gastrointestinal disorders caused by psychological stress[24]. It had been demonstrated that stress-induced plasma VIP expression decreased gastrointestinal transit disorder beyond a certain intensity range of stress. VIP had potent protective activity against sepsis and increased the survival rate of septic animals[25]. In this study, the significant increase in the expression of CRF possibly suggests that depression could induce an inflammatory response of the duodenum by releasing CRF in rats. The effect of VIP on inflammatory cells could be an additional important mechanism of its potent protective activity on chronic stress-induced duodenitis. The results of our studies suggest that gastrointestinal motility disorders during psychological stress may be partially mediated by release of VIP and CRF.

Our results also show that an antidepressant plays an important role in decreasing symptoms in depressed rats. The behavioral changes of depressed rats were reversed by chronic treatment with fluoxetine. Treatment with fluoxetine significantly attenuated the extent and severity of the histological signs. Fluoxetine at the therapeutic dose of 10 mg/kg was effective in decreasing the expression of CRF and increasing the expression of VIP in the duodenum of depressed rats. Some data has shown that antidepressants may adjust other brain gut peptides or unknown factors, and thus ameliorate the damage of chronic stress-induced gastrointestinal disorders[26-28]. Future serotegenic antidepressants may be made to specifically target the immune system by either blocking the actions of pro-inflammatory cytokines or increasing the production of anti-inflammatory cytokines[29,30].

In summary, brain-gut interaction and psychological factors altered not only the pathology of brain tissue, but also duodenal tissue. The results of our study show that depression can induce injury to the duodenum accompanied by increasing CRF and decreasing VIP. Treatment with fluoxetine can ameliorate pathological changes in the duodenum in depressed rats, suggesting that SSRIs are an effective therapeutic agent for some duodenum diseases caused by psychological factors. We suggest that VIP prevention of inflammatory cell reactivity could be a potential therapeutic strategy for chronic stress-induced gastrointestinal disorders.

COMMENTS

Background

In clinical studies, it has become clear that depression plays an important role in gastrointestinal diseases by precipitating exacerbation of symptoms. Stress often worsens the symptoms of gastrointestinal diseases.

Research frontiers

Some data strongly suggested that corticotrophin releasing factor(CRF) and vasoactive intestinal peptide(VIP) played important roles in pathophysiology of gastrointestinal diseases. Selective serotonin reuptake inhibitors (SSRI's) have been shown to be immunomodulatory and anti-inflammatory against pro-inflammatory cytokine processes.

Innovations and breakthroughs

We set up a rat depression model, and observed the level of VIP and CRF of plasma and duodenum and the effect of fluoxetine on duodenum of the depressed rats.

Applications

The authors of the present study showed that chronic stress can induce injury to the duodenum. This was accompanied by an increase in immunofluorescence staining for CRF and a decrease in immunofluorescence staining for VIP. Treatment with the serotonin reuptake inhibitor, fluoxetine, reversed these changes and in addition reversed the behavioral changes of depressed rats.

Terminology

Vasoactive intestinal peptide (VIP) was found in submucous and myenteric plexus, central and peripheral nervous systems. It is now recognized as a major neuropeptide in the brain and gut. Corticotrophin releasing factor (CRF) stimulates adrenocorticotropic hormone (ACTH) secretion and plays an important role in the pathophysiology of gastrointestinal diseases.

Peer review

The authors of the present study showed that chronic stress can induce injury to the duodenum. This was accompanied by an increase in immunofluorescence staining for CRF and a decrease in immunofluorescence staining for VIP. Treatment with the serotonin reuptake inhibitor, fluoxetine, reversed these changes but in addition reversed the behavioral changes of depressed rats.

Abstract

AIM: To investigate the effect of inducible nitric oxide synthase inhibitor, aminoguanidine, on pancreas transplantation in rats.

METHODS: A model of pancreas transplantation was established in rats. Streptozotocin-induced diabetic male Wistar rats were randomly assigned to sham-operation control group (n = 6), transplant control group (n = 6), and aminoguanidine (AG) treatment group (n = 18). In the AG group, aminoguanidine was added to intravascular infusion as the onset of reperfusion at the dose of 60 mg/kg, 80 mg/kg, 100 mg/kg body weight, respectively. Serum nitric oxide (NO) level, blood sugar and amylase activity were detected. Nitric oxide synthase (NOS) test kit was used to detect the pancreas cNOS and inducible NOS (iNOS) activity. Pancreas sections stained with HE and immunohistochemistry were evaluated under a light microscope.

RESULTS: As compared with the transplant control group, the serum NO level and amylase activity decreased obviously and the evidence for pancreas injury was much less in the AG group. The AG (80 mg/kg body weight) group showed the most significant difference in NO and amylase (NO: 66.0 ± 16.6 *vs* 192.3 ± 60.0, P < 0.01 and amylase: 1426 ± 177 *vs* 4477 ± 630, P < 0.01). The expression and activity of tissue iNOS, and blood sugar in the AG (80 mg/kg body weight) group were much lower than those in the transplant control group (iNOS: 2.01 ± 0.23 *vs* 26.59 ± 5.78, P < 0.01 and blood sugar: 14.2 ± 0.9 *vs* 16.8 ± 1.1, P < 0.01).

CONCLUSION: Selective iNOS inhibitor, aminoguanidine as a free radical, has a protective effect on pancreas transplantation in rats by inhibiting NO and reducing its toxicity.

INTRODUCTION

Pancreas transplantation is frequently complicated by acute pancreatitis, largely due to ischemia/reperfusion injury secondary to cold preservation[1,2]. During the reperfusion period, oxygen-derived free radicals can lead to a severe impairment. Nitric oxide (NO) is a free radical with a strong reactivity, and has a fierce cytotoxicity. However, NO can significantly dilate blood vessels and remit vasospasm of grafts. Therefore, NO plays an ambivalent role in ischemia/reperfusion during pancreas transplantation. In this study, we established a model of pancreas transplantation in rats to investigate the expression of nitric oxide synthase (NOS) isoforms, and the effect of inducible nitric oxide synthase (iNOS) inhibitor (aminoguanidine) on pancreas transplantation.

MATERIALS AND METHODS

Animals

Male Wistar rats weighing 250-300 g (Experimental Animal Center, China Medical University, China) were used as donors and recipients. The animals were kept in standard conditions with free access to water and rodent chow. Diabetes was induced by intravenous injection of streptozotocin at a single dose of 55 mg/kg body weight. Only rats with non-fasting plasma glucose levels of more than 22 mmol/L were used as recipients. We performed recipient transplantation surgery on days 14 and 15 after the injection of streptozocin. A total of 30 recipient animals were randomly assigned to the sham-operation group (n = 6) in which animals underwent midline laparotomy only, transplant control group (n = 6) in which animals underwent transplantation and received a bolus injection of saline instead of aminoguanidine, and aminoguanidine treatment group (n = 18) in which animals

underwent transplantation. Before reperfusion, a bolus injection of aminoguanidine (60 mg/kg, 80 mg/kg or 100 mg/kg body weight) was given *via* the vena dorsalis penis.

Transplantation and collection of specimens

Synergetic pancreaticoduodenal transplantation was performed in diabetic recipients to assess islet cell functions. After overnight fasting with free access to water, the rats were anesthetized and underwent heterotopic pancreaticoduodenal transplantation as previously described[3] with certain modifications. After shaving and disinfecting the abdomen with 75% alcohol, a midline incision was made. The donor pancreas was isolated on an aortic segment branching off the celiac axis and the superior mesenteric artery. The venous outflow was provided by the portal vein. Pancreas grafts were flushed with and stored in cold (4℃) heparinized lactate Ringer's solution. Heterotopic intra-abdominal transplantation was performed by end-to-side anastomosis of the aortic segment of the graft and the recipient infrarenal aorta. The graft portal vein was anastomosed to the recipient vena cava using the same technique. Enteric diversion of exocrine graft secretion was accomplished by end-to-side duodenojejunostomy. The abdomen was closed in two layers with 2-0 silk suture. After a single intramuscular injection of 5 mg cefamandole post-operation, the rats were kept under warming lamps until they became active. The warming and cooling ischemic time was less than 15 min and 25 min, respectively. The animals were killed after 4 h of reperfusion. The pancreas was harvested and divided into two segments with one fixed in 10% PBS formalin and the other preserved at -70℃. The blood was withdrawn without anticoagulant and centrifuged at 2000 r/min for 10 min. The serum was preserved at -20℃.

Determination of serum NO and NOS levels

Nitrate reductase was used to detect the serum NO level and NOS test kit was used to detect the cNOS and iNOS activity in the pancreas.

Determination of serum blood and amylase levels

Serum glucose concentration was measured with an Exac Tech blood glucose meter in samples collected from the cut tip of the tail. Serum amylase concentration was measured with a multianalyzer (Clinilizer, CL-7150, Nippon Denshi, Tokyo, Japan).

Histopathology examination

One pancreas segment was fixed in 10% PBS formalin, dehydrated through a grade ethanol series, washed in xylene and embedded in paraffin. The segment was cut into 4 μm-thick sections. The sections were stained with haematoxylin and eosin and evaluated using light microscope.

Immunohistology

Primary antibody and anti-iNOS polyclonal antibody were produced in rabbits. Strept avidin-biotin complex immunoperoxidase staining system was used, and the positive staining was reddish-brown in color.

Statistical analysis

The data were presented as mean ± SD. All statistical analyses were performed using the SPSS 10.0 software. Differences in groups were tested by analysis of variance (ANVOA). $P < 0.05$ was considered statistically significant.

RESULTS

Serum NO level

The NO level increased significantly in transplant control group and deceased in the sham-operation group ($P < 0.01$) 4 h after reperfusion. After administration of aminoguanidine (AG), a selective iNOS inhibitor, NO level decreased significantly ($P < 0.01$). The effect of AG (80 mg/kg body weight) was obviously better than that of AG (60 mg/kg body weight) ($P < 0.01$). However, the effect of AG (100 mg/kg body weight) was not better than that of AG (80 mg/kg body weight) ($P > 0.05$) (Table 1).

Serum amylase activity

The amylase activity was higher in the transplant control group than in sham-operation group ($P < 0.01$). After administration of AG, the amylase activity decreased markedly, and the effect of AG (80 mg/kg body weight) was better ($P < 0.01$) (Table 1).

Blood sugar level

The blood sugar level decreased after pancreas transplantation, and was the lowest in the AG (80 mg/kg body weight) group ($P < 0.01$) (Table 2).

Activity of NOS isoforms in pancreas tissue

Four hours after reperfusion, the iNOS activity in pancreas tissue increased significantly ($P < 0.01$), but the cNOS activity had no change ($P > 0.05$). After administration of AG (80 mg/kg body weight), the iNOS activity decreased obviously ($P < 0.01$) while the cNOS activity remained normal (Table 3).

Histology

The pancreas was enlarged and swollen in the transplant control group, and appeared relatively normal in all animals of the sham-operation and AG (80 mg/kg body weight) groups. The microscopic pancreatic injury, as indicated by intracytoplasmic vacuoles, interstitial oedema, polymorphonuclear cell infiltrate, venous congestion, and

Table 3 Activity of NOS isoforms in pancreatic tissue 4 h after transplantation (mean ± SD)

Group	*n*	cNOS (U/mL)	iNOS (U/mL)
Sham-operation group	6	5.35 ± 1.01[a]	1.87 ± 0.19
Transplant control group	6	5.91 ± 0.71[a]	26.59 ± 5.78[b]
(AG-80 mg/kg body weight)	6	5.64 ± 0.97[a]	2.01 ± 0.23[d]

[a]$P > 0.05$, [b]$P < 0.01$ *vs* sham-operation group; [d]$P < 0.01$ *vs* transplant control group.

local tissue hemorrhage and necrosis occurred 4 h after transplantation (Figure 1A and B). However, none of the samples from the AG (80 mg/kg body weight) group revealed histological evidence of pancreatic injury (Figure 1C and D).

Immunohistochemistry

Four hours after reperfusion, heavily stained specimens from transplant control group were positive for anti-iNOS, while iNOS staining was mainly localized on the endothelium, vascular smooth muscle, and islet cells (Figure 1E and F). No stained anti-iNOS antibody was detected in all specimens from the AG (80 mg/kg body weight) group (Figure 1G and H).

DISCUSSION

A model of pancreas transplantation in rats was established. Four hours after pancreas graft reperfusion, the expression and activity of iNOS on pancreas increased significantly, serum NO level and amylase activity, leading to severe pancreatitis, whereas cNOS remained normal. After administration of AG, the iNOS activity and NO concentration decreased, the toxicity of NO as free radicals was reduced, and the amylase activity decreased markedly. The severity of ischemia/reperfusion injury and postgraft pancreatitis was reduced, protecting the pancreas graft against ischemia/reperfusion injury.

Ischemia/reperfusion injury remains a major problem in pancreas transplantation. During the reperfusion period, endothelial dysfunction, activation of endogenous enzymes, leucocyte recruitment and activation all lead to generation of oxygen-derived free radicals, promote lipid peroxidation and deplete glutathione and other antioxidation compounds, leading to pancreatitis[4]. Contradictory results about the role of NO in pancreatic ischemia/reperfusion have been reported[5]. NO may lose an electron to form nitrosonium cation (NO^+), which can combine with the superoxide radicals to form peroxynitrite ($ONOO^-$), a highly active free radical with fierce cytotoxicity[5]. In pathological conditions, significant activation of iNOS by the release of inflammatory cytokines, such as tumor necrosis factor α (TNF-α), interleukin-1β (IL-1β), can increase NO concentration[6]. It was reported that endogenous NO is involved in formation of pancreatic edema in L-arginine-induced acute pancreatitis by increasing the vascular permeability and protein extravasation[7]. Treatment with L-NAME significantly reduces amylase activity and edema formation in the pancreas. A study about severe acute pancreatitis has shown a positive correlation between serum NO level and the number of adherent leucocytes[8]. The expression of iNOS is correlated to changes in the pancreatic histomorphology[9-12]. The expression of iNOS during reperfusion following pancreatic ischaemia contributes significantly to the development of acute pancreatitis[13]. Vasoactive mediators, such as bradykinin, platelet activating factor, endothelin and NO, participate in the development of pancreatic microcirculatory failure. Recently, in drug-induced pancreatitis models, some researchers found that there is a correlation among NF-kappaB activation, serum amylase, reactive oxygen species level and tissue damage, suggesting that NF-kappaB and iNOS play a key role in the pathogenesis of acute pancreatitis[14-16]. After treatment with antioxidants or NOS inhibitors, the levels of myeloperoxidase, serum amylase and NO, as well as iNOS activities are decreased significantly, and the pancreatic inflammation is improved[14,15]. Ma *et al*[16] found that the expression of NF-kappaB and iNOS in peritoneal macrophages is significantly higher in rats with severe acute pancreatitis, and anti-inflammatory agents decrease the expression of TNF-alpha, IL-1 and NO in peritoneal macrophages, reducing the severity of pancreatitis. In Folch-Puy's experiment, infusion of a contrast medium into the pancreatic duct could result in an inflammatory process characterized by increased lipase levels in plasma and edema as well as increased myeloperoxidase activity in pancreas, suggesting that activation of NF-kappaB is correlated with iNOS expression in pancreatic cells[17]. It was reported that ischemia/reperfusion provokes severe acute necrotizing pancreatitis with a high mortality rate and leads to systemic inflammatory reaction due to the activation of cytokine cascade and iNOS, indicating that NO overproduction by iNOS corresponds with the apoptotic process in the pancreas and the lung[18,19]. In a study on ischemia/reperfusion injury, Duchen found that calcium overload is associated with NO generation, and their combination leads

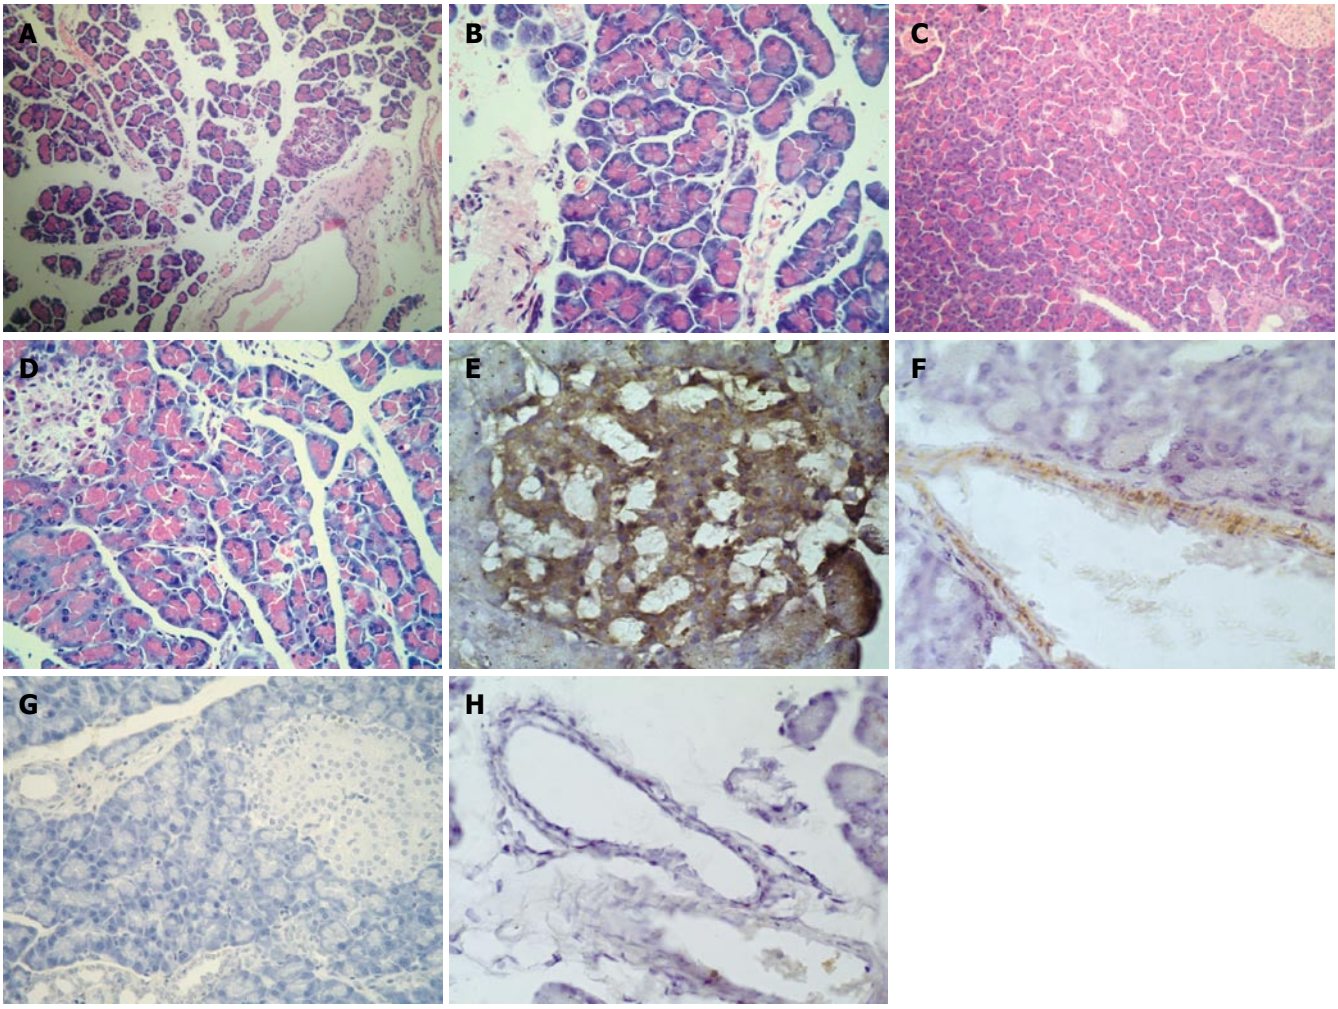

Figure 1 Histology displaying pancreatic injury (**A**, **B**) and no pancreatic injury (**C**, **D**), while immunohistochemistry showing positive anti-iNOS (**E**, **F**) and no stained anti-iNOS (**G**, **H**) in different groups.

to collapse of mitochondrial membrane potential followed by cell death[20]. It was reported that after administration of selective iNOS inhibitors, the iNOS activity and NO concentration are decreased significantly and the severity of pancreatitis is reduced[21]. However, some experiments indicate that NO could activate guanylate cyclase, reduce the activity of platelets and inflammatory cells, relax smooth muscle, and dilate blood vessels[22,23]. Therefore, NO can remit the vasospasm of grafts and decrease the occurrence of vascular crisis. Supplement of NO for donors during reperfusion of pancreatic isografts seems to prevent organ injury because NO attenuates leukocyte-dependent tissue injury[26]. Thus, it remains debatable whether the increased production of NO due to pancreas transplantation is beneficial or detrimental to the tissue.

Based on the findings of this study and present reports, it is very likely that NO plays a dual role in ischemia/reperfusion injury of pancreas. During the early reperfusion period, NO, under the charge of cNOS, can improve postischemic reperfusion. With the prolongation of reperfusion time, NO depletion results in failure of microcirculation, during which supplement of NO or NOS substrate could protect microcirculation against failure[24]. When reperfusion is prolonged (more than 4 h), activation and excessive expression of iNOS due to the release of inflammatory agents such as TNF-α, IL1-β, result in a considerable increase in NO concentration, and the toxic effect of NO as a free radical leads to the development of graft pancreatitis[25]. Therefore, administration of selective iNOS inhibitors can not only reduce the toxicity of NO as a free radical, but also retain vasodilatation effect, and protect the graft against pancreatitis. Aminoguanidine (AG) is a mechanism-based inactivator of NOS isoforms and exhibits a marked specificity for the inactivation of its inducible isoform, which proceeds through multiple pathways of covalent modification of the iNOS protein and heme residue at the active site[26].

At present, some experiments demonstrated that in the transplanted islets, iNOS and toxic NO are produced due to infiltration of inflammatory cells into islets and production of proinflammatory cytokines (such as TNF-α, IL1-β), and an excessive production of NO is deleterious to pancreas β-cells[27-29].

In conclusion, selective iNOS inhibitor, aminoguanidine as a free radical, has a protective effect on pancreas transplantation in rats by inhibiting NO and reducing toxicity.

COMMENTS

Background

Pancreas transplantation is frequently complicated by acute pancreatitis, largely due to ischemia/reperfusion injury. During the reperfusion period, nitric oxide (NO) may form peroxynitrite ($ONOO^-$), a highly active free radical, and has a fierce cytotoxicity. However, NO can significantly dilate blood vessels and remit the vasospasm of grafts, protecting pancreas graft from thrombosis due to transplantation. Therefore, NO plays an ambivalent role in ischemia/reperfusion injury during pancreas transplantation. However, contradictory results about the role of NO in pancreatic ischemia/reperfusion injury have been reported. It remains debatable whether the increased production of NO due to pancreas transplantation is beneficial or detrimental to the tissue.

Research frontiers

Based on the findings of this study and recent reports, it is very likely that NO plays a dual role in ischemia/reperfusion injury of pancreas. During the early reperfusion period, NO under the charge of cNOS, could improve pancreas perfusion. With the prolongation of reperfusion time, NO depletion could result in failure of microcirculation, during which supplement of NO or NOS substrate can protect microcirculation against failure. When reperfusion is prolonged, activation of iNOS due to the release of inflammatory agents, such as tumor necrosis factor α and interleukin-1β, can increase NO concentration. The toxic effect of NO as a free radical can lead to graft pancreatitis. Hence, administration of selective iNOS inhibitors can reduce the toxicity of NO, and protect graft against pancreatitis.

Innovations and breakthroughs

We established a model of pancreas transplantation in rats. Administration of selective iNOS inhibitors could not only reduce the toxicity of NO as a free radical, but also retain vasodilatation effect, and protect graft against pancreatitis. Aminoguanidine (AG) is a mechanism-based inactivator of NOS isoforms and exhibits a marked specificity for the inactivation of its inducible isoform, which proceeds through multiple pathways of the iNOS protein and heme residue at the active site. Our data also suggest that blood sugar level in AG group was much lower than that in transplant control group, indicating that the selective iNOS inhibitor, AG, has a protective effect on pancreas transplantation.

Applications

Pancreas transplantation can give IDDM additional pancreas to take the place of its own, which has lost the function of insulin secreting. Pancreas regulates insulin secretion, and maintains the blood glucose level. At present, nothing else could achieve this object. Factors influencing pancreas functions following transplantation include graft pancreatitis and rejection which are difficult to treat with a poor prognosis. In this study, after administration of selective iNOS inhibitor AG, the iNOS and amylase activity and NO concentration were decreased, the toxicity of NO as a free radical was reduced. The severity of ischemia/reperfusion injury and postgraft pancreatitis was reduced, protecting the graft against pancreastitis.

Terminology

Inducible nitric oxide synthase (iNOS): NO is synthesized from L-arginine by nitric oxide synthase (NOS). iNOS does not express at normal conditions, and produces NO several orders greater than cNOS and may have a more important pathological role. Aminoguanidine (AG) is a mechanism-based inactivator of NOS isoforms and exhibits a marked specificity for the inactivation of its inducible isoform, which proceeds through multiple pathways of the iNOS protein and heme residue at the active site.

Peer review

This study investigated the effect of inducible nitric oxide synthase inhibitor, aminoguanidine, on pancreas transplantation, showing its scientific and clinical values.

Abstract

AIM: To evaluate the effect of polypropylene mesh-reinforced pancreatojejunostomy on pancreatic leakage.

METHODS: Seventeen consecutive patients with paraampullar malignancy received polyprolene mesh-reinforced pancreatodudeonectomy and the Child's method was used to rebuild the alimentary tract.

RESULTS: The mean time of polyprolene mesh-reinforced pancreatojejunostomy was 22 min. Anastomosis could endure 30-500 cm H_2O pressure during operation. All patients recovered without pancreatic leakage.

CONCLUSION: Polyprolene mesh-reinforced pancreato-jejunostomy is a feasible and reliable procedure to prevent pancreatic leakage.

Key words: Pancreatic leakage; Pancreatojejunostomy; Anastomosis; Pancreatodudenectomy

INTRODUCTION

Pancreatic anastomotic leakage is a common lethal complication of pancreaticojejunostomy. The incidence of pancreatic anastomosis leakage depends on multiple factors, among which the anastomotic method is the key factor. Different anastomotic methods in pancreaticojejunostomy have been reported in the literature, but none of them is able to prevent pancreatic leakage. Recently, we designed a new anastomotic method: polypropylene mesh-reinforced pancreaticojejunostomy (MRP), by which the sheath of jejunum is bound to the pancreatic remnant wrapped by a strip of mesh. We have applied this method in 17 consecutive periampullar neoplasm patients, and none of them developed pancreatic leakage.

MATERIALS AND METHODS

Clinical data

Nine male and eight female patients with periampullar malignancy, aged 38-72 years, were included in this study, including 6 patients with carcinoma of the panceatic head, 6 with distal common bile duct cancer, 3 with ampullar carcinoma and 2 with duodenal carcinoma. All the patients received polypropylene mesh-reinforced pancreatoduodenectomy and the Child's method was used to rebuild the alimentary tract. Initial polypropylene MRP was performed on 16 patients, the other patient received end-to-end inviganation anastomosis during the first operation but developed pancreatic leakage after operation. On the 8th postoperative day, the patient developed massive intraabdominal bleeding and received the second laparotomy along with polypropylene MRP.

Technique

The pancreas was transected with a scalpel on the scheduled line. Hemostasis was secured by suture ligatures with 4-0 polyprolene stitches (Ethicon, Somerville, NJ) or electrocautery. A 3.0 cm cut end of the pancreatic remnant was isolated. A 1.0 cm wide polypropylene mesh (Ethicon, Somerville, NJ) strip was tightly wrapped over the pancreatic stump about 1.0 cm from the cut margin with a few stitches. The mesh was fixed if it could not be moved with force. If the main pancreatic duct was identified, a stent tube was inserted into the main pancreatic duct and fixed with suturing thread (Figure 1A). Then, the pancreatic stump and the free margin of jejunum were brought together. A posterior row of continuous running sutures using a 3-0 polyprolene stitch was placed between the inner edge of the mesh and jejunum. The sutures were passed carefully through the

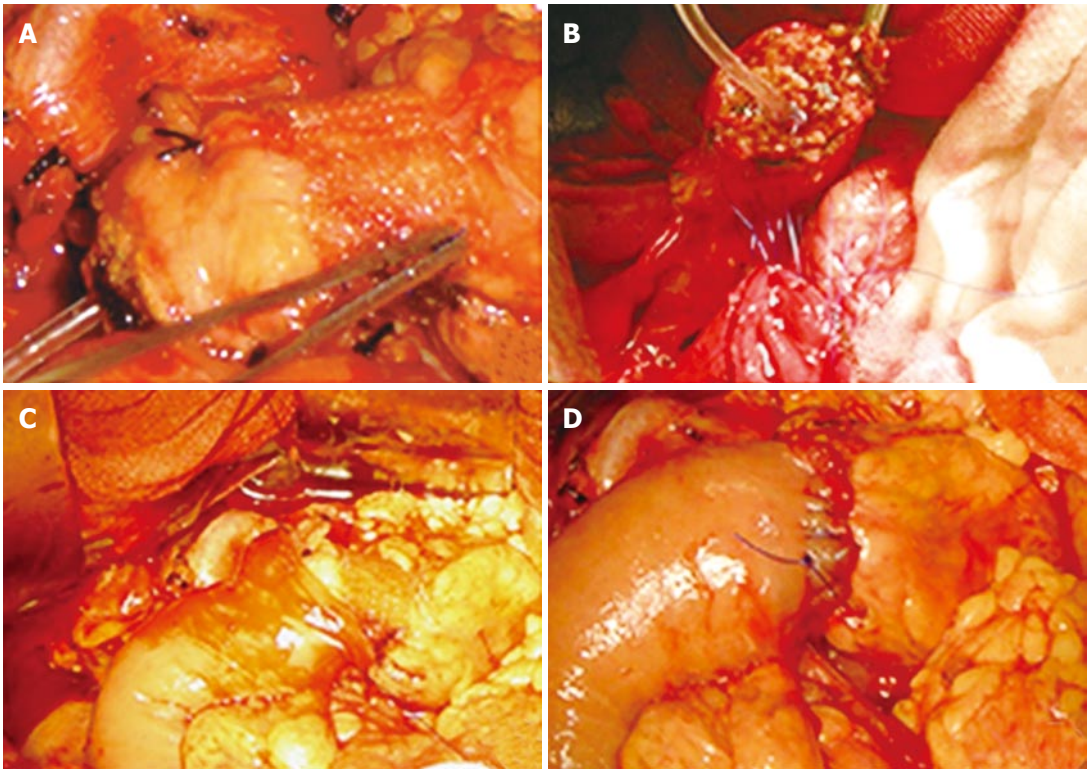

Figure 1 Fixation of mesh around the pancreatic stump (**A**); running suture on the posterior wall of pancreas with a stitch placed between inner edges of the mesh and jejunum (**B**); invagination of the pancreatic stump into the jejunum (**C**); running suture on the anterior wall of the pancreas with a stitch placed between inner edges of the mesh and jejunum (**D**).

mesh, pancreatic capsule and full thickness of jejunum. We began at the farthest point on the cranial side of the pancreatic stump and the caudal side was ligated with six to eight sutures (Figure 1B). After the posterior sutures were completed, they were gently pulled to invaginate the pancreatic stump into the jejunum (Figure 1C). The opposite end of the pancreatic duct stent tube was traversed through sites where bilioenteric anastomosis was performed. Finally, the continuous sutures were extended anteriorly using the same stitch. The sutures were tied after the tightness of the suture line was confirmed. As a result, the jejunal stump invaginated the pancreatic stump of about 2.0 cm (Figure 1D). Care was taken to cover the entire mesh in the jejunal lumen. A urinary catheter was inserted into the jejunum, and saline solution was injected to test for a watertight closure. The seromuscular surface of jejunum 1.0 cm from the margin was anchored to the superior and inferior peritoneal attachments of the pancreatic body to minimize the tension. Biliary anastomosis was constructed in an end-to-side fashion 15 cm distal from the pancreaticojejunostomy. Then a Jackson-Pratt drainage tube was placed near the anastomosis. Daily output and amylase content of abdominal drainage were measured after operation. Pancreatic leakage was defined as the persistent amylase-rich (more than three times the serum concentration) drainage output excess 50 mL/d[1,2]. Prophylactic octreotide was not used.

RESULTS

The mean operative time for polypropylene MRP was 22 min (ranged 10-25 min). No pancreatic leakage was observed under the pressure of 20 cmH_2O during operation. The abdominal drainage output was less than 50 mL in 14 patients, and the amylase content in drainage was within normal range (ranged 46-98 IU/L). The abdominal drainage was removed 4-5 d after the operation, and the patients recovered well and were discharged on the 10th postoperative day. Two patients had a high volume of abdominal drainage during the first 3 postoperative days, but the amylase content in the abdominal drainage was within normal range. The abdominal drainage was removed on the 7th postoperative day and the patients recovered well. A 55-year old male patient received pancreaticojejunectomy for distal common bile duct with an end-to-end invagination anastomosis. The pancreas was soft and fragile. The abdominal drainage output was > 100 mL/d after operation and the amylase content was > 2000 IU/L. Pancreatic anastomotic leakage was identified. The patient had no fever or abdominal pain and received conservative therapy initially. On the 8th postoperative day, fresh blood was drained from the abdominal drainage tube and the patient received the second laparotomy. During the operation, laceration of pancreatic tissue was found on the suture of anastomosis with massive fluid collection. The bleeding came from the splenic artery involved in the fluid collection. After the bleeding was stopped, the pancreas was found to be edematic and fragile. In order to make a direct suture on the pancreas, we decided to perform polypropylene MRP. The patient recovered well after the second operation without pancreatic leakage. All patients were followed up in the outpatient clinic and no adverse events occurred.

DISCUSSION

Since Whipple introduced pancreaticoduodenectomy, it has become a standard procedure for malignant and

benign disorders of the pancreatic head and periampullary region[3-5]. Although the mortality from the surgical procedure has come down considerably during the past three decades[6], it is still higher than that of other radical procedures for abdominal malignancy[7-9]. Pancreatic anastomotic leakage is still the most important determinant of its morbidity, with an incidence of 2%-14%[10,11] and mortality of 28%[12,13]. The etiology of pancreatic anastomotic leakage covers several aspects, including quality of pancreatic tissue, size of major pancreatic duct, exocrinal status of pancreas, general condition and nutritional status of the patient, skill of the surgeon and method of pancreaticojejunostomy[6,14-16]. Among them, method of pancreaticojejunostomy seems to be the key factor[17]. Different methods for pancreaticojejunostomy have been reported in the literature[19], including end-to-side anastomosis, duct-to-mucosa anastomosis, or end-to-end or end-to-side invagination anastomosis. The suturing techniques for anastomosis include running or interrupted suture, single layer or double layers suture[18-20]. But all these methods cannot absolutely prevent the leakage, the incidence of leakage of the most widely applied end-to-side invagination anastomosis is still as high as 11%[21]. No consensus on the choice of anastomotic technique has been reached, and currently each technique finds its application among different groups of surgeons[22].

It is well known that the incidence of pancreatic leakage is higher in patients with a soft and normal pancreatic parenchyma because it is prone to develop parenchymal laceration from shear forces applied during tying of the sutures, especially while performing suturing on the posterior wall of the pancreas. In patients with normal pancreatic parenchyma, the incidence of leakage is 12% to 28%, compared with 5% to 9% in those considered to have pancreatic fibrosis[23]. The efferent loop filled with bile and pancreatic juice also increases the shear force[24]. Some retrospective or prospective studies also suggested that technical modifications may reduce the leakage rate[25-27], suggesting that if the pancreas is soft with a narrow duct, it would be most secure when the pancreaticojejunal anatomosis is intraluminal into the jejunum by invaginating the pancreatic stump.

Polyprolene mesh-reinforced pancreaticojejunostomy was developed based on the binding pancreaticojejunostomy described by Peng *et al*[28,29], who reported a widely invaginated end-to-end anastomosis with ablated jejunal mucosa. Our procedure with single layer continuous sutures is less complicated than the binding pancreaticojejunostomy. The success of this technique may be due to the following four aspects. First, the mesh forms a safe "clothing" around the remnant pancreas for anchoring sutures, thus preventing the possibility of parenchymal laceration and bleeding from the sutures in soft pancreatic parenchyma caused by the suture. We identified the advantages of a new technique in the case where a secondary polypropylene MRP was received for leakage from the first operation site. During the second operation, the pancreatic parenchyma was severely edematic and fragile, making the direct suture impossible. However, it was easy and convenient to perform polypropylene MRP on this patient, and no leakage occurred postoperatively. Second, sine the shape of the pancreatic stump can be modified and reduced by the mesh, it is more convenient to make an invagination. Third, the posterior single layer continuous sutures are simple and require less time. Fourth, it is very convenient to perform polypropylene MRP under different conditions and the time required is less than single end-to-end invagination. The mesh in the anastomosis can promote fibroblast attachment and enhance the anastomotic healing process[30,31]. However, it still needs further confirmation.

An ideal pancreaticojejunal anastomosis should be safe and convenient. Moreover, laparoscopy is more and more widely applied by general surgeons, and the convenience of a surgical procedure should be considered. The use of polypropylene MRP ensures a tight seal for any type of pancreatic stump regardless of the pancreas consistency, thus a more secure and reliable anastomosis can be obtained. The preliminary results are very encouraging. However, an appropriate prospective study in randomized patients is needed. Up to date, we have not observed any adverse effect of polypropylene MRP, but a long following-up time is needed to confirm it.

COMMENTS

Background

Pancreaticoduodenectomy is the standard procedure for malignant and benign disorders of the pancreatic head and periampullary region. Mortality and morbidity of this procedure are still higher than other radical procedures for abdominal malignancy. Pancreatic anastomotic leakage is still the most important determinant of its morbidity.

Research frontiers

The method of pancreaticojejunostomy is the key factor for pancreatic anastomotic leakage. We designed a new technique of polypropylene mesh-reinforced pancreaticojejunostomy to prevent pancreatic leakage.

Innovations and breakthroughs

Up to date, all the existing methods of pancreaticojejunostomy cannot perish anastomotic leakage. Our new method is effective in preventing pancreatic leakage.

Applications

This technique is safe and can be applied in pancreaticoduodenectomy under all conditions even though the pancreas is very fragile. If its advantage and disadvantage can be proved by large clinical trials, it can be used as one of the standard procedures.

Terminology

Pancreaticoduodenectomy: excision of the pancreatic head and the encircling loop of the duodenum to which it is connected. Pancreaticojejunostomy: surgical anastomosis of the pancreatic duct or the divided end of transected pancreas with the jejunum.

Peer review

This article seems to be a challenging artifice to reduce postoperative complication in pancreatic surgery. The results are encouraging and the procedure can be used as a standard method of pancreaticojejunostomy.

Abstract

AIM: To explore the expression of reversion inducing cysteine-rich protein with Kazal motifs (RECK), vascular endothelial growth factor (VEGF) and endoglin (CD105) protein and its correlation with occurrence, development, invasion and metastasis in esophageal squamous cell carcinoma (ESCC).

METHODS: Streptavidin-peroxidase (SP) immunohistochemistry was used to detect expression of RECK and VEGF in 62 cases of ESCC, 31 cases of adjacent atypical hyperplastic epithelium and 62 cases of normal esophageal epithelium. CD105 Mb was used to assess microvessel density (MVD).

RESULTS: The expression of RECK was closely correlated with histological grade, infiltrative depth and lymphatic metastasis in ESCC ($P < 0.05$). The expression of RECK decreased during cancer development: normal esophageal epithelium (85.5%, 53/62), adjacent atypical hyperplastic epithelium (71.0%, 22/31), and carcinoma (59.7%, 37/62). There was a significant difference among the groups ($P < 0.05$). The expression of VEGF protein was closely correlated with infiltrative depth and lymphatic metastasis in ESCC ($P < 0.05$). The expression of VEGF protein increased during cancer development: normal esophageal epithelium (29.0%, 18/62), adjacent atypical hyperplastic epithelium (54.8%, 17/31), and carcinoma (67.7%, 42/62). There was a significant difference among the groups ($P < 0.05$). MVDCD105 increased in accordance with histological grade, but there was no significant difference (grade Ⅰ, 36.92 ± 10.85; grade Ⅱ, 37.65 ± 9.50; and grade Ⅲ, 38.06 ± 12.19). The MVDCD105 was closely correlated with infiltration and lymphatic metastasis in ESCC ($P < 0.05$). The expression of RECK was inversely correlated with the expression of VEGF and CD105.

CONCLUSION: RECK, VEGF and CD105 play important roles in the infiltration, metastasis and carcinogenesis in esophageal carcinoma. Angiogenesis in ESCC may be promoted by over-expression of CD105.

INTRODUCTION

Reversion inducing cysteine-rich protein with Kazal motifs (RECK) is a recently discovered tumor suppressor gene with a special function of inhibiting matrix metalloproteinase (MMP) expression and activity, which serves as an MMP inhibitor[1]. Expression of the RECK gene is closely related to tumor invasion and metastasis and angiogenesis. Previous studies indicate that the level of RECK gene expression is inversely correlated to tumor invasiveness in liver cancer, pancreatic cancer, mammary cancer and pulmonary carcinoma, and for patients with higher RECK gene expression, the prognosis is sometimes apparently better than that of patients with low expression[2-5]. No studies have been published in China or abroad on the correlation of the RECK gene with invasion and metastasis of esophageal cancer, and the relationship between RECK, vascular endothelial growth factor (VEGF)

and endoglin (CD105) expression. The streptavidin–peroxidase (SP) immunohistochemistry method was used to perform a combined test on expression of RECK, VEGF and CD105 gene in tissues from 62 cases of esophageal squamous cell carcinoma (ESCC), 31 cases of para-carcinoma atypical hyperplasia, and 62 specimens of normal esophageal mucous membrane, to establish the role of RECK, VEGF and CD105 in the generation and development of esophageal cancer, so as to ascertain the molecular index for early diagnosis and prognosis judgment.

MATERIALS AND METHODS

Materials

Resection specimens from 62 cases of esophageal cancer were collected from the Municipal Cancer Hospital of Anyang, Henan Province, China from 26 February to 16 March, 2006, which is one of the most epidemic regions for esophageal cancer. No patients had a history of chemotherapy, radiotherapy or immunotherapy. The specimens were taken from 36 male and 26 female patients aged 38-75 years (average 60.6 ± 9.5), who were all verified to have ESCC by histopathological examination. The histological grading included Class Ⅰ (15 cases), Class Ⅱ (25 cases) and Class Ⅲ (22 cases); 20 cases were accompanied with lymphatic metastasis, and 42 cases had no lymphatic metastasis. The depth of invasion was divided into two groups that consisted of seven cases with invasion of the superficial muscularis, and 55 with invasion of the deep muscularis or fibrous membrane. All the samples were taken from within 3 cm of the tumor focus, as well as from three areas of distal normal mucous membrane, and were fixed with 40 g/L paraformaldehyde solution, normally dehydrated, embedded in paraffin, and serial sections were cut to a thickness of 4-6 μm, and used for hematoxylin and eosin and immunohistochemistry staining. Mouse anti-human RECK monoclonal antibody (mAb) and anti-human VEGF mAb were all purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA), and mouse anti-human CD105 single clone antibody and the SP immunohistochemistry kit were purchased from Beijing Zhongshan Golden Bridge Biotech Development (China).

Methods

The SP immunohistochemistry SP method was employed. RECK, VEGF and CD105 mAbs were diluted 1:100, stained with diaminobenzidine, and counterstained with hematoxylin, strictly in accordance with the instructions, and PBS solution was used as a negative control replacing primary antibody. RECK- and VEGF-positive signals all show brown granule-like materials that are located in the cytoplasm. Under a high-power magnifying glass, five fields of vision (FOVs) were randomly selected (for each FOV, there were no fewer than 200 cells), and the results were interpreted in accordance with the percentage of cells and depth of stain[6]. (1) Scored in accordance with depth of staining of cells in a section: 0, no cell coloration; 1, light yellow; 2, brown; 3, tan. (2) Scored in accordance with the percentage of positive cells in like-kind cells: 1, < 30%; 2, 30%-70%; 3 > 70%. The product of (1) and (2) was used as the total score, where 0-1 indicates a negative score (-), 2-3 a weak positive score (+), and ⩾ 4 a positive score (++). Tumor MVD measurement was done using the methods reported by Weidner[7], i.e. any brown endothelial cell or cell cluster is used as a vessel. We first observed all the FOVs for a given section under a low-power magnifying glass to find the highest density area of tumor vessels, and then we counted the number of microvessels in three FOVs under a high-power magnifying glass; the average values were then used as the MVD.

Statistical analysis

SPSS 10.0 statistical software was used and the χ^2 test, single factor analysis of variance, *t* test were applied, correlation test was applied, Spearman correlation analysis. The test level was $\alpha = 0.05$.

RESULTS

RECK expression in ESCC tissues and correlation with clinical and biological behavior

RECK expression was mainly located in the cytoplasm of tumor cells, and appeared as light to dark yellow (Figure 1A). RECK expression increased sequentially as ESCC developed: normal tissue (59.7%, 37/62), para-carcinoma atypical hyperplastic tissue (71.0%, 22/31), and ESCC (85.5%, 53/62), and comparison between the groups indicated a significant difference ($\chi^2 = 10.331$, $P < 0.01$) (Table 1). RECK expression was related to histological grading, invasion depth and lymphatic metastasis (the respective values of χ^2 were 10.422, 8.550 and 4.751; average $P < 0.05$) (Table 2).

VEGF expression in ESCC tissues and correlation with clinical and biological behavior

VEGF staining was located in the cytoplasm, and appeared as light to dark yellow (Figure 1B). VEGF expression decreased sequentially as ESCC developed: normal mucous membrane (67.7%, 42/62), para-carcinoma atypical hyperplastic tissue (54.8, 17/31), and carcinoma (29.0% 18/62); and comparison between the groups indicated a significant difference ($\chi^2 = 18.994$, $P < 0.05$) (Table 1). VEGF expression was not related to histological grading ($P > 0.05$), but was related to depth of invasion and lymphatic metastasis (the respective values of χ^2 were 10.319 and 6.693; average $P < 0.05$) (Table 2).

Correlation of MVDCD105 with differentiation and metastasis in ESCC

CD105 expression was mainly located in the cytoplasm of vascular endothelial cells of tumor stroma, and appeared as light to dark yellow granules (Figure 1C). In grade Ⅰ, Ⅱ and Ⅲ ESCC tissues, MVDCD105 tended to increase as the degree of cancer tissue differentiation decreased: grade Ⅰ, 37.87 ± 3.60; grade Ⅱ, 37.44 ± 3.99; and grade Ⅲ, 39.00 ± 4.47), but there was no significant difference between the results ($F = 0.885$, $P > 0.05$) (Table 1). In cancer tissues with lymphatic metastasis, MVD (41.00 ±

3.26) was higher than that without metastasis (36.33 ± 3.76). MVD (38.80 ± 3.60) of cancer tissues with invasion of the deep muscularis was higher than that of the superficial muscularis (32.57 ± 3.46), and the difference was significant (Table 3).

Correlation of RECK, VEGF and CD105 expression in ESCC

RECK expression was inversely correlated to that of VEGF. In tissues with positive RECK expression, VEGF expression rate was 51.4% (19/37), and in tissues negative for RECK expression, VEGF expression rate was 92.0% (23/25). Comparison between the groups indicated a significant difference (γ_s = -0.427, $P < 0.01$). In tissues with positive RECK expression, MVDCD105 was 35.76 ± 9.42, and tissues negative for RECK expression, MVDCD105 was 41.59 ± 10.80. Comparison between the groups indicated a significant difference (t = -2.969, $P < 0.01$) (Table 4).

DISCUSSION

The RECK gene were discovered by Takahashi *et al*[1] in NIH3T3 cell lines transfected by the v-Ki-Ras gene, which is located on chromosome 9p13-p12 and encodes a membrane-anchored glucose protein with a relative molecular mass of 110 000. RECK gene has high expression in normal tissues, but no expression in various tumor cell lines and cells affected by cancer genes such as Ras. Many cancer genes such as ras, fos and myc can all decrease the expression of the RECK gene[8,9], which indicates that the RECK gene may be a negatively adjusted target jointly acted upon by cancer genes, and the proper expression of the RECK gene can inhibit angiogenesis[10-12]. It has been shown that the RECK gene is closely related to the prognosis of liver cancer, pancreatic cancer and mammary cancer, and prognosis of patients positive for RECK expression is better than that of those with negative expression[2-5]. The effects of RECK during the course of tumor generation and metastasis may be more widespread than has been discovered to date. It is now considered that RECK may affect tumor invasion and metastasis through inhibiting tumor angiogenesis, and is thus a cancer-inhibiting gene[12-14]. The results of this experiment indicate that the RECK gene is expressed in normal esophageal tissues, esophageal para-carcinoma atypical hyperplastic

tissues and cancer tissues, but its expression level in cancer tissue is significantly lower. This indicates that tumors with low RECK expression have greater invasive capacity.

VEGF is a polypeptide cell factor discovered in recent years (also called vascular permeability factor), which has a double function: (1) it directly stimulates vascular endothelial cell reproduction through its receptor, and induces production of the proteolytic enzyme interstitial collagenase and tissue factor to promote angiogenesis; and (2) it increases vascular permeability, promotes exosmosis of fibrinogen to cause tumor interstitial edema and extracellular matrix changes, and consequently provides a basis for tumor invasion and metastasis[15,16]. VEGF is an angiogenic factor that has been studied at the most with the most specific effect at present, and which is related to generation and metastasis of various human tumors[17-23]. The results of this study show that VEGF expression is inversely related to ESCC lymphatic metastasis, i.e. the positive protein rate of VEGF for the lymph metastasis group significantly higher than that of no lymph metastasis group, which indicates that the positive protein expression of VEGF maybe correlated with metastasis of ESCC lymph. The results of this study also show that VEGF expression is not obviously related to the degree of tumor differentiation, which indicates that VEGF expression is not related to ESCC histology.

CD105 is a gene located in human chromosome 9q34, which is a homotype dipolymer membrane glycoprotein with a molecular mass of 180 kDa, participating in signal transmission inverting growth factor β (TGF-β) receptor and angiogenesis. Previous studies indicate that strong expression of CD105 in tumor-related, newly generated vascular endothelium is a more accurate index for judging endothelial reproductive state, and it is closely related to tumor generation and metastasis[24-27]. Contrasting with endothelial cell markers such as CD31, CD34 and Ⅷ factor-related antigens, the difference is that CD105 as a marker of angiogenesis is only strongly expressed in vascular endothelial cells of tumor tissues at the reproduction stage (i.e. newly generated vascular endothelium), but it is not expressed in the blood vessels of normal tissues[28-30]. A quantitative test has been carried out on the MVD of newly generated vessels in ESCC with anti-CD105 single clone antibody, the results of which indicated that MVD is positively correlated with depth of invasion and lymphatic metastasis in ESCC. That is, the MVD of tumors with deep invasion is significantly higher than that with superficial invasion, and the MVD of tumors with lymphatic metastasis is significantly higher than that of those without metastasis; however, MVD is not related to histological grading. Thus, the fixed vessel quantity in tumors is considered as a significant and separate prognosis index. The level of angiogenesis in cancer can be evaluated through MVD measurement[31], and MVD measurement in ESCC may help to judge its potential for invasion and metastasis. The MVD in tumor tissues was tested with CD105, the results of which indicate that RECK expression is inversely related to tumor angiogenesis; further, MVDCD105 for tumors with high RECK expression is obviously lower than that for those with low RECK expression, which indicates that RECK can inhibit angiogenesis. There is a co-adjustable mechanism between MVDCD105 and RECK.

Angiogenesis inhibition by RECK has also been verified in some clinical studies that have discovered that MVD in tumor tissues is inversely related to RECK expression[10,32]. However, such an inverse correlation only occurs when the expression of VEGF is much higher, i.e. for tumors with higher expression of VEGF, the influence of RECK also increases, which indicates that RECK can inhibit VEGF-induced angiogenesis. The results indicate that RECK expression is closely related to tumor prognosis. Also, the inhibitory effects of RECK on tumor angiogenesis have a certain pertinence. The results of this study indicate that positive expression of RECK is inversely correlated with VEGF expression and MVD. In cases with negative RECK expression, VEGF expression and MVD are significantly higher than in cases with positive RECK expression ($P < 0.05$). This indicates that decreasing or losing RECK expression may increase VEGF expression, which consequently promotes tumor angiogenesis, and provides the conditions for the generation and metastasis of ESCC. This study also discovered that VEGF expression is consistent with MVD, i.e. if VEGF expression is high, MVD will rise accordingly ($P < 0.05$), and the VEGF's positive stained cells at the front of tumor infiltration, which are consistent with CD105's expression positions, which further verifies that VEGF is an angiogenesis factor with specific effects, and can specifically promote tumor angiogenesis. This study shows that decreasing or losing RECK expression and increasing VEGF expression are two of the significant events during the generation and development of ESCC, and RECK, as a cancer-inhibiting gene, may inhibit angiogenesis in ESCC, through affecting the signal transmission path of VEGF expression. The combined test on RECK, VEGF and MVD can be used as an

objective index to determine the invasion and metastasis capabilities of ESCC, which is of great significance for judging prognosis.

COMMENTS

Background

The RECK gene was discovered by Takahashi *et al* in NIH3T3 cell lines transfected by the v-Ki-Ras gene, which plays an important role in regulating MMPs and participating in tumor invasion, metastasis and angiogenesis.

Research frontiers

No studies have been published in China or abroad on the correlation of the RECK gene with invasion and metastasis of esophageal cancer, and the relationship between RECK and expression of VEGF and CD105.

Related publications

Expression of RECK gene is closely related to tumor invasion and metastasis and angiogenesis. Previous studies indicate that RECK gene expression is inversely correlated with tumor invasiveness in liver cancer, pancreatic cancer, mammary cancer and pulmonary carcinoma, and for patients with higher RECK gene expression, the prognosis is apparently better than that of patients with low RECK expression. Therefore, RECK is considered to be an cancer-inhibitory gene, which can affect tumor metastasis through inhibiting the activity of MMPs and angiogenesis.

Innovations and breakthroughs

No reports on this subject have been published in China or abroad. The immunohistochemistry SP method was used to perform a combined test on expression of RECK, VEGF and CD105 genes in 62 cases of ESCC, 31 specimens of para-carcinoma atypical hyperplastic tissues, and 62 specimens of normal esophageal mucous membrane, to ascertain the role of RECK, VEGF and CD105 in the generation and development of esophageal cancer, so as to establish a molecular index for early diagnosis and prognosis judgment.

Applications

The further investigation of RECK helps us understand more about the biological behavior of esophageal carcinoma and it gives us a new guide for earlier diagnosis and therapy of esophageal carcinoma. RECK may be a molecular target for the early diagnosis and prognostic judgment of esophageal carcinoma.

Terminology

RECK is a new cancer-inhibiting gene first discovered in NIH3T3 cell lines transfected by v-Ki-Ras.

Peer review

This manuscript reports expression of three genes in ESCC, in which they appear to have prognostic value as they are correlated with histological grade, lymphatic metastasis and invasion.

Received: May 16, 2007 Revised: September 10, 2007

Abstract

AIM: To investigate the correlation between C/T single nucleotide polymorphism (SNP) in the promoter of the DNA methyltransferase 3B (*DNMT3B*) gene and risk for development and progression of primary hepatocellular carcinoma (HCC).

METHODS: One hundred case subjects were selected consecutively from Tongji Hospital (Wuhan, China). from March to November 2006. They did not receive radiotherapy or chemotherapy for newly diagnosed and histopathologically confirmed HCC. One hundred and forty control subjects having no history of cancerous or genetic diseases were healthy volunteers to Wuhan Blood Center in the same period. Frequency was matched for sex, age, alcohol consumption and cigarette smoking status of the case subjects. C/T polymorphism of the *DNMT3B* promoter was analyzed using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) and sequencing analysis. The association between genotypes of *DNMT3B* and clinicopathological parameters among cases was also studied.

RESULTS: The CC genotype was not detected in both HCC patients and controls. In control subjects, the frequency of TT and CT genotypes was 99.3% and 0.7% respectively, and that of T and C alleles was 99.6% and 0.4% respectively. The frequency of CT genotype was higher in HCC (3.0%). The frequency of T and C alleles was 98.5% and 1.5% respectively. However, the genotype and allelotype distribution in HCC patients was not significantly different from that in controls.

CONCLUSION: C/T polymorphism is not associated with the increased risk of HCC. *DNMT3B* genetic polymorphism is variable in different races, ethnic groups or geographic areas. Further study is needed to clarify the role of *DNMT3B* SNP in the development of HCC among other populations.

INTRODUCTION

Primary hepatocellular carcinoma (HCC) occurs frequently in Southeast Asia, especially in China. It ranks second and approximately accounts for 42.5% of all malignancies worldwide[1].

Although hepatitis B virus (HBV) is the major cause of HCC, only a fraction of patients with chronic HBV infection develop HCC during their lifetime, suggesting that genetic and epigenetic factors are important in determining individuals' susceptibility to HCC.

DNA methylation plays an important role in chromatin structure stability, genome integrity, modulation of tissue-specific gene expression, embryonic development, genomic imprinting, X-chromosome inactivation and is essential for the development of mammals[2,3]. DNA methylation is mediated by DNA methyltransferases (DNMTs), of which three active forms have been identified: DNMT1, DNMT3A and DNMT3B. DNMT1 is thought to be primarily responsible for maintaining pre-existing methylation patterns after DNA replication because of its preference to hemimethylated DNA substrates and targeting replication foci. DNMT3A and DNMT3B have an equal preference to hemimethylated and unmethylated DNA substrates, and therefore they are believed to be principally required for *de novo* methylation[4-6]. Recent studies have shown that three different mechanisms play a role in the effect of methylation: global hypomethylation, hypermethylation of individual gene segments and deregulated expression of DNA methyltransferases. Changes in the methylation pattern correlate with the

development of cancer. *De novo* hypermethylation in promoter CpG islands has been identified as a possible mechanism for tumor suppressor gene and DNA repair gene inactivation of in human cancer cells[7-12]. DNMT3B, regarded as a *de novo* DNA methyltransferase, is thought to play an important role in the generation of aberrant methylation in carcinogenesis[13,14].

DNMT genes are up-regulated in various human cancers, including HCC[15-20]. Significant over-expression of DNMT3B is observed in tumor tissues while over-expression of DNMT1 and DNMT3A is more modest[15,18,20].

A C-to-T transition polymorphism (C46359T, GenBank accession no. AL035071) in the promoter region of the *DNMT3B* gene, -149 base pairs from the transcription start site, is reported to greatly increase promoter activity. Many reports have shown that the C/T polymorphism is associated with an increased risk for lung cancer and decreased postsurgical survival in patients with small cell carcinoma of the head and neck. Carriers of T allele, particularly heterozygotes, have a significantly increased risk for such cancers[21-24].

Several polymorphic genes are reported to be correlated with modification of susceptibility to HCC. To our knowledge, the association between *DNMT3B* polymorphism and development of HCC has not been reported. Since the *DNMT3B* promoter polymorphism that is responsible for regulating genomic methylation is possibly associated with an increased risk for cancers, we evaluated the relationship between *DNMT3B* C46359T polymorphism and risk of HCC in a hospitalization-based case-control study in a Chinese Han nationality population.

MATERIALS AND METHODS

Subjects

One hundred case subjects were selected consecutively from Tongji Hospital (Wuhan, China) from March to November 2006. They did not receive radiotherapy or chemotherapy for newly diagnosed and histopathologically confirmed HCC. One hundred and forty control subjects having no history of cancerous or genetic diseases were healthy volunteers to Wuhan Blood Center in the same period. Frequency was matched for sex, age, alcohol consumption and cigarette smoking status of the case subjects. All the cancer patients and control subjects were unrelated Han nationality individuals from Wuhan or from its surrounding regions. Blood was taken from all recruits who consented to the epidemiology survey. Each subject was scheduled for an interview after informed consent was obtained, and a structured questionnaire was used to collect information on demographic data and risk factors, such as hepatitis B infection history and family history of any cancers.

DNMT3B genotyping

Genomic DNA was extracted from peripheral blood lymphocytes by proteinase K digestion and phenol-chloroform extraction. DNMT3B C/T polymorphism was determined by PCR-RFLP. The primers of 5'-TGCTGT GACAGGCAGAGCAG-3' (nt 46151-46170) and 5'-GG TAGCCGGGAACTCCACGG-3' (nt 46530-46511) were synthesized as previously described[21]. This 380-bp target DNA fragment contains the upstream region and the first exon of the *DNMT3B* gene. Amplification reaction was carried out in a 25 μL PCR mixture containing 50-200 ng of genomic DNA, 12.5 pmol of each primer (Shanghai Sangon Company), 0.1 mmol/L each deoxynucleotide triphosphate, 1 × PCR buffer (50 mmol/L KCl, 10 mmol/L Tris-HCl, and 0.1% Triton X-100), 2.0 mmol/L $MgCl_2$, and 1.25 U Taq polymerase (Beijing Sbsbio Company). The PCR profile consisted of an initial denaturation at 95℃ for 5 min, 35 cycles of denaturation at 95℃ for 30 s, annealing at 65℃ for 30 s and extension at 72℃ for 30 s and a final extension at 72℃ for 10 min. The 380-bp product was then digested with *Bln* I (TaKaRa Biotechnology Company) for 12-16 h in 37℃ bath water. The digested product was separated by vertical electrophoresis at 200V of constant voltage for 1.5 h through 8% polyacrylamide gel (29:1) and silver staining, and then determined under ultraviolet irradiation. The variant T allele has a *Bln* I restriction site that results in two bands (207 bp and 173 bp), and the wild-type C allele lacks the *Bln* I restriction site, thus producing a single 380-bp band (Figure 1). More than 10% of the samples were randomly selected for repeated assays, and the results were 100% concordant. Restriction fragment length polymorphism (RFLP) analysis was confirmed by PCR-based sequencing with an Applied Biosystem automated sequencer (Figure 2).

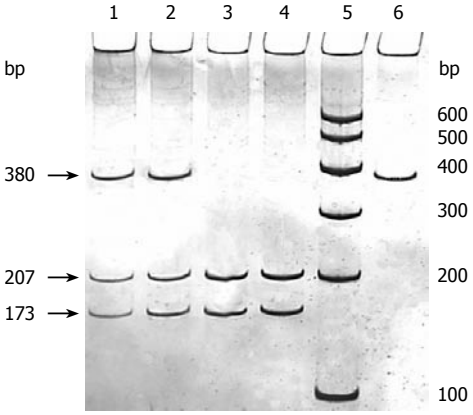

Figure 1 PCR-RFLP-polyacrylamide gel electrophoresis for genotyping of DNMT3B promoter C46359T. Lanes 1 and 2: CT heterozygote; lanes 3 and 4: TT genotype; lane 5: 100 bp molecular marker; lane 6: PCR product.

Statistical analysis

Data were presented as mean ± SD. A database was developed by Epi Info 6.0 and the analysis of data was accomplished using SPSS 10.0 software. The difference in frequency distributions of genotypes and allelotypes between the two groups was detected by chi-square test. *P* values of less than 0.05 were considered statistically significant.

RESULTS

The characteristics of 100 HCC case patients and 140 control subjects are summarized in Table 1. In the case group, the age ranged 18-70 years, the mean age was (55.86 ± 10.12) years, and the gender ratio was 4:1 while the mean

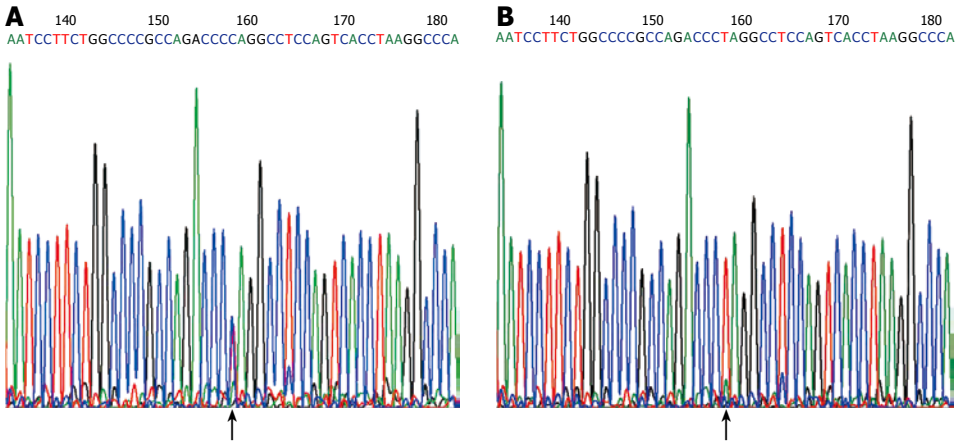

Figure 2 CT genotype (**A**) and TT genotype (**B**) Sequencing-confirmed.

Table 1 Frequency distributions of selected variables in HCC patients and control subjects, *n* (%)

Variable	Case (*n* = 100)	Control (*n* = 140)
Sex		
Male	80 (80)	114 (81.4)
Female	20 (20)	26 (18.6)
Age (yr)	55.86 ± 10.12	57.12 ± 10.01
Smoking status		
Current smoker	60 (60.0)	92 (65.7)
Former smoker	21 (21.0)	26 (18.6)
Non smoker	19 (19.0)	22 (15.7)
Pack/year	11.26 ± 6.25	14.89 ± 7.56
Alcohol consumption		
Current drinker	55 (55.0)	70 (50.0)
Former drinker	19 (19.0)	29 (20.7)
Non drinker	26 (26.0)	41 (29.3)
Alcohol/year	10.01 ± 5.21	13.58 ± 5.09

Table 2 *DNMT3B* genotype and allele frequencies in case patients and control subjects and their association with HCC, *n* (%)

Genotypes	Case patients (*n* = 100)	Control subjects (*n* = 140)
CT	3 (3)	1 (0.7)
TT	97 (97)	139 (99.3)
C allele	3 (1.5)	1 (0.4)
T allele	197 (98.5)	279 (99.6)

$\chi^2 = 1.86$, $P = 0.17$ (genotype); $\chi^2 = 1.84$, $P = 0.17$ (allele).

time of alcohol consumption and cigarette smoking was (10.01 ± 5.21) years and (11.26 ± 6.25) years, respectively. In the control group, the age ranged was 15-68 years, the mean age was (57.12 ± 10.01) years, and the gender ratio was 4.4:1 while the mean time of alcohol consumption and cigarette smoking was (13.58 ± 5.09) years and (14.89 ± 7.56) years, respectively. The two groups had a similar frequency of distribution in age, sex, alcohol consumption and cigarette smoking status. In addition, 95% of the case patients had a chronic infection with HBV but others had no infection with any hepatitis virus.

The *DNMT3B* T allele frequency and genotype distributions in the case patients and control subjects are summarized in Table 2. Only one genotype of CT was found in 140 control subjects (0.7%) and three in 100 case subjects (3.0%), respectively. The variant C allele frequency was 1.5% for the case patients and 0.4% for the control subjects. The CC genotype was not detected in both HCC patients and controls. Although the frequency of CT genotype and C allele was higher in HCC patients than in control subjects, but there was no significant difference ($P > 0.05$).

DISCUSSION

Alterations in DNA methylation can cause changes in gene transcription patterns and also promote mutational events leading to malignant tumors. Recent studies have shown that several mechanisms, including DNA hypomethylation on pericentromeric satellite regions, DNA hypermethylation on CpG islands of genes such as *p16*, *E-cadherin*, and *HIC-1* (hypermethylated-in-cancer), over-expression of DNA methyltransferases, and reduced expression of methyl-CpG-binding proteins play a role in hepatocarcinogenesis[25-27]. It was reported that genetic disruption of both *DNMT1* and *DNMT3B* in human cancer cells results in global and gene-specific demethylation, and abrogation of silencing of tumor suppressor genes. Both the wild type and catalytically inactive *DNMT3B* mutant can suppress rDNA promoter irrespective of its methylation status[28,29], suggesting that altered activities of DNMTs contribute to the generation of aberrant methylation in cancer.

Single nucleotide polymorphisms (SNPs) are the most common form of human genetic variation. SNPs in the promoter region of genes may affect either the expression or the activity of enzymes and therefore may be mechanistically associated with cancer risk. The *DNMT3B* gene contains a C-to-T transition polymorphism (C46359T) in a novel promoter region, -149 bp from the transcription start site, which in *in vitro* assays confers a 30% increase in promoter activity[23]. It was postulated that the T variant might up-regulate *DNMT3B* expression, resulting in a predisposition towards aberrant *de novo* methylation of CpG islands in tumor suppressor and DNA repair genes. These findings encouraged us to examine the relationship between a novel polymorphism in the human *DNMT3B* promoter and risk of HCC.

To select China as a research field to analyze the relationship between *DNMT3B* genetic polymorphisms and HCC is a new attempt. In this study, the *DNMT3B* genetic polymorphism was not susceptible to HCC. The

CC genotype was not detectable in both HCC patients and controls, while the T allele was predominant. In control subjects, the frequency of TT and CT genotypes was 99.3% and 0.7% respectively, while that of T and C alleles was 99.6% and 0.4% respectively. The frequency of CT genotype was higher in HCC (3.0%), while that of T and C alleles was 98.5% and 1.5%. Although the frequency of CT genotype and C allele was higher in HCC patients than in control subjects, but there was no significant difference.

The frequency of *DNMT3B* genotypes is much different from the reported frequency in Caucasians[21]. In the control group, the frequency of TT, CT and CC was 23.2%, 41.8% and 35.0% respectively, while the T allele frequency was 44.1%. C allele was very common. The frequency of TT, CT and CC in lung cancer patients was 21.0%, 56.7% and 22.3% respectively, indicating that a different race has a different genetic composition.

The *DNMT3B* allele frequency of people in North China is slightly different from that of people in other areas of China[30]. In the present study, the CC genotype was also not detectable. In control subjects, the frequency of TT and CT genotypes was 94.9% and 5.1% respectively, while that of T and C alleles was 97.4% and 2.6% respectively, suggesting that *DNMT3B* genetic polymorphism is variable in the same race living in different geographic areas. Only the TT genotype was detectable in all control subjects as compared with other ethnic groups such as Japanese[31], also suggesting that a different ethnic group has a different genetic composition.

The PCR product was digested with *Bln* I for 12-16 h to complete the reaction of restriction enzyme. Since the sensibility of electrophoresis through polyacrylamide gel is much higher than that of electrophoresis through agarose gel, we chose the former to separate the DNA fragments.

In our study, only one of the case subjects with CT genotype had a family history of HCC, but HBsAg, HBeAb and HBcAb in the other case subjects remained positive for a period of over 10 years without any treatment. Although we designed experiments to assess the correlation of the distribution of *DNMT3B* genotypes to the transcription and expression of *DNMT3B* and HBV infection status in selected tumor and normal hepatic tissues, we could not carry out the experiments due to the insufficient number of samples with CT genotype in our study.

The very similar distribution of *DNMT3B* genotypes in HCC patients and healthy controls suggested that the C/T polymorphism of *DNMT3B* gene might not independently affect the risk for HCC. A study in North China showed that *DNMT3B* SNPs are not associated with the susceptibility to gastric cardiac adenocarcinoma[30], although this polymorphism has been demonstrated to be associated with the susceptibility to cancers of the lung, head, neck and breast.

Recently, several candidate SNPs in the *DNMT3B* gene have been deposited in public databases (http://www.ncbi.nlm.nih.gov/SNP). Although the functional effects of these polymorphisms have not been elucidated, we hypothesize that some of these variants, particularly their haplotypes, may influence DNMT3B activity on DNA methylation, thereby modulating the susceptibility to HCC. The C/T SNP (C46359T) in the promoter of the *DNMT3B* gene may not be associated with up-regulation of DNMT3B and an increased risk of HCC as observed in this study, but probably there are other polymorphisms in *DNMT3B* which are susceptible to HCC.

In the present study, the *DNMT3B* gene was not negligible in the study of hepatocarcinogenesis in different areas. Whether *DNMT3B* SNPs are associated with different tumor types needs to be further studied in China. To clarify the role of *DNMT3B* SNP in the development of HCC, investigations in other populations need to be performed as well. The potential usefulness of *DNMT3B* genotyping needs further studies on a larger scale.

Saito[32] has found that over-expression of a splice variant of DNMT3B, DNMT3B4, which may lack DNA methyltransferase activity and compete with DNMT3B3 for targeting pericentromeric satellite regions, results in DNA hypomethylation on these regions, even at precancerous stages, and plays a critical role in the development of human HCC because of chromosomal instability and aberrant expression of cancer-related genes. Further investigation on the mechanism of aberrant expression of DNMT3B in tumors, including HCC, should be performed.

ACKNOWLEDGMENTS

The authors thank Ping Xiong (Department of Immunology, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei Province, China) for the technical advice on genotyping assays, Dr. Wan-Guang Zhang (Hepatic Surgery Center, Tongji Hospital) for the assistance in recruiting study subjects.

COMMENTS

Background

Genetic and epigenetic factors are important in determining individuals' susceptibility to hepatocellular carcinoma (HCC). Alterations in DNA methylation can cause changes in gene transcription patterns and also promote mutational events leading to malignant tumors. DNA methylation is mediated by DNA methyltransferases (DNMTs), of which three active forms have been identified: DNMT1, DNMT3A and DNMT3B. DNMT3B, regarded as a *de novo* DNA methyltransferase, is thought to play an important role in the generation of aberrant methylation in carcinogenesis.

Research frontiers

Studies have shown that significant over-expression of DNMT3B is observed in tumor tissues while over-expression of DNMT1 and DNMT3A is more modest. A C-to-T transition polymorphism (C46359T) in the promoter region of the *DNMT3B* gene, -149 base pairs from the transcription start site, greatly increases promoter activity and is associated with an increased risk of cancers, such as cancer of the lung, head and neck. Carriers of the T allele, particularly heterozygotes, have a significantly increased risk foe such cancers.

Innovations and breakthroughs

Since the *DNMT3B* promoter polymorphism that is responsible for regulating genomic methylation is possibly associated with an increased risk for cancer, we evaluated the relationship between *DNMT3B* C46359T polymorphism and risk of HCC using PCR-RFLP and sequencing analysis.The PCR product was digested with *Bln* I for 12-16 h to complete the reaction of restriction enzyme. Since the sensibility of electrophoresis through polyacrylamide gel is much higher than that of electrophoresis through agarose gel, we chose the former to separate the DNA fragments.

Applications

C/T polymorphism of the *DNMT3B* gene may not independently affect the risk for HCC and probably there are other polymorphisms in *DNMT3B* which are susceptible to HCC. Whether *DNMT3B* SNPs are associated with different tumor types and different races needs to be further studied. The potential usefulness of *DNMT3B* genotyping needs further studies in a large scale.

Terminology

Single nucleotide polymorphisms (SNPs) represent a natural genetic variability at a high density in the human genome. A synonymous expression is "biallelic marker" corresponding to the two alleles that may differ in a given nucleotide position of diploid cells. A single SNP represents an alternative nucleotide in a given and defined genetic location at a frequency exceeding 1% in a given population. This definition does not include other types of genetic variability like insertions and deletions, and variability in copy number of repeated sequences. SNPs are considered the major genetic source to phenotypic variability that differentiates individuals from one another within a given species. Restriction fragment length polymorphism (RFLP) is a technique by which organisms may be differentiated by analysis of patterns derived from cleavage of their DNA. If two organisms differ in the distance between sites of cleavage of a particular restriction endonuclease, the length of fragments produced differs when DNA is digested with a restriction enzyme. The similarity of patterns generated can be used to differentiate species (and even strains) from one another.

Peer review

Dr. Wu and co-investigators looked at C/T SNP in the promoter region of *DNMT3B*. They could not demonstrate a significant difference in C/T polymorphism between HCC patients and normal Chinese population. However, *DNMT3B* gene is not negligible in study of HCC in different races, ethnic groups or geographic areas as well as in study of different tumor types.

Abstract

Amoxicillin/clavulanate is associated with liver injury, mostly of a cholestatic pattern. While outcomes are usually benign, progression to cirrhosis and death has been reported. The role of immunosuppressive therapy for patients with a protracted course is unclear. We report the case of an elderly patient who developed prolonged cholestasis secondary to amoxicillin/clavulanate. Vanishing bile duct syndrome was confirmed by sequential liver biopsies. The patient responded to prednisone treatment, but could not be weaned off corticosteroids, even when azathioprine was added. Complete withdrawal of both prednisone and azathioprine was possible by using mycophenolate mofetil, an inosine monophosphate dehydrogenase inhibitor. Sustained remission has been maintained for more than 3 years with low-dose mycophenolate mofetil.

Key words: Amoxicillin and clavulanate; Drug-induced cholestasis; Ductopenia; Mycophenolate mofetil; Vanishing bile duct syndrome

INTRODUCTION

Acute liver injury caused by amoxicillin/clavulanate occurs in 1.7 cases per 10000 prescriptions written and is mostly of a cholestatic type[1]. Outcomes are usually benign with resolution of cholestasis in 1-4 mo following drug withdrawal[2]. However, some patients develop prolonged drug-induced cholestasis, defined as the persistence of jaundice for more than 6 mo or persistently high alkaline phosphatase and gamma-glutamyl transpeptidase for more than 1 year, despite withdrawal of the causative drug, and in the absence of pre-existing liver or biliary tract disease[3]. Patients who develop progressive destruction of the small interlobular bile ducts ("vanishing bile duct syndrome") may ultimately require liver transplantation[4,5], given the lack of effective treatment. As an immunological reaction is suspected, corticosteroids have been used empirically[6], although the precise mechanism of amoxicillin/clavulanate-induced cholestatic hepatitis is unknown. We report a case illustrating that mycophenolate mofetil can be a successful and safe alternative to corticosteroids for amoxicillin/clavulanate-induced prolonged cholestasis.

CASE REPORT

A 69-year-old man presented with fatigue, upper abdominal discomfort and a pruritic rash involving his torso. He had a history of long-standing and well-controlled polycythemia vera. His medications included aspirin and hydroxyurea, and he drank alcohol sparingly. Three weeks prior to this examination, he had undergone a course of amoxicillin/clavulanate, 875 mg twice daily, for treatment of bronchitis. Physical examination revealed a fine maculopapular rash on his torso. The liver edge was palpable under the costal margin, and was smooth and not tender. No hepatosplenomegaly was noted. Initial laboratory data showed: alkaline phosphatase 624 U/L, aspartate aminotransferase (AST) 89 U/L, alanine aminotransferase (ALT) 82 U/L, total bilirubin 1.6 mg/dL, direct bilirubin 1.0 mg/dL, gamma glutamyl transpeptidase (GGT) 360 U/L, and albumin 3.3 g/dL. Abdominal ultrasound examination showed that the liver had a heterogeneous texture, with normal bile ducts and gallbladder. Over the next 2 weeks, he became jaundiced, with a peak of alkaline phosphatase of 988 U/L, total bilirubin 7.4 mg/dL, direct bilirubin 6.7 mg/dL, AST 235 U/L, and ALT 310 U/L. Prothrombin time (PT)/international normalized ratio (INR) remained normal. Autoimmune and viral serologic studies were all negative. Iron studies and alpha-1-antitrypsin levels were within normal ranges. Endoscopic retrograde cholangiography was normal. Liver biopsy, performed 5 mo after

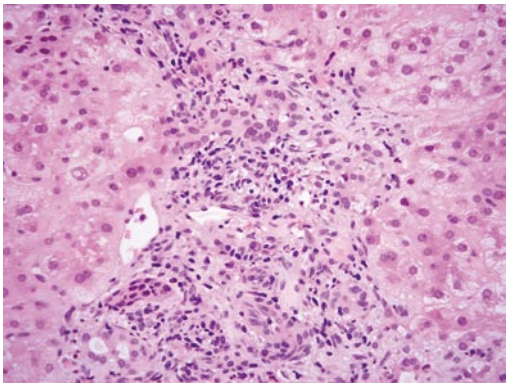

Figure 1 Initial biopsy. The triad is expanded by portal and periportal fibrosis, and there is a mixed inflammatory infiltrate. Injured bile ducts are present (bottom left and top center) and there is a marked ductular reaction.

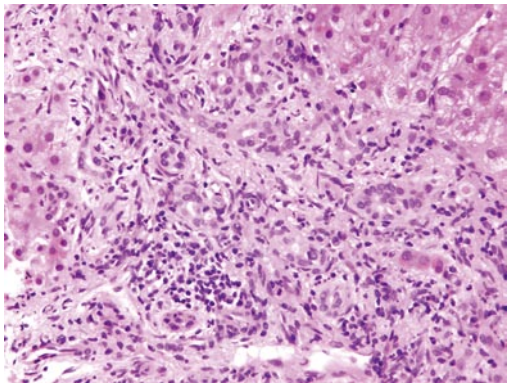

Figure 2 Second biopsy. The portal tracts appear similar to those seen in the initial biopsy, but with greater fibrous expansion ands more inflammation, including a loose aggregate of plasma cells and lymphocytes (bottom left). There is ductopenia and a prominent ductular reaction.

exposure to amoxicillin/clavulanate, showed destructive cholangiopathy of the small/medium-sized bile ducts, with ductopenia, duct proliferation, and bilirubinostasis. An infiltrate of lymphocytes and plasma cells was mostly confined to the portal tracts. Portal, periportal and focal bridging fibrosis were present, but hepatic architecture was preserved (Figure 1).

Treatment with prednisone 30 mg/d and ursodiol 1200 mg/d resulted in marked clinical and biochemical improvements. Tapering off the prednisone dose was attempted over the next few months, but resulted in increased alkaline phosphatase, AST and ALT, every time the prednisone dose was decreased to 12 mg/d. Azathioprine, titrated to 100 mg/d for several months, could not achieve prednisone tapering.

A second liver biopsy, taken after more than 1 year of treatment, showed chronic destructive cholangiopathy, persistent portal inflammation, and progression of fibrosis, with portoportal bridging and distorted hepatic architecture (Figure 2). Repeat endoscopic retrograde cholangiopancreatography (ERCP) revealed no extrahepatic biliary abnormalities.

Mycophenolate mofetil was added at a dose of 1 g twice daily and the patient was rapidly weaned off azathioprine. Over the next 6 mo, prednisone was successfully tapered, with liver tests remaining normal, except for a mild elevation in alkaline phosphatase (Figure 3). Over 1 year, the dose of mycophenolate mofetil was reduced to 250 mg twice daily, without adverse effects. Efforts to withdraw treatment completely resulted in recurrence of mild cholestatic abnormalities.

DISCUSSION

About 30 drugs, including amoxicillin/clavulanate, have been reported to cause vanishing bile duct syndrome with protracted clinical courses, the prototype being chlorpromazine[4]. Ductopenia, when interlobular bile ducts are absent from at least 50% of the small portal tracts, carries a poor prognosis[7]. The mechanism of progression from acute liver injury to ductopenia is unclear. However, it is suggested that bile ducts, as complete epithelium-lined tubes, are only rarely reconstructed once they have been completely destroyed[8]. A patient's unique immune response likely plays a role in the intensity and duration of injury, as certain HLA haplotypes have been found to be markedly overrepresented in patients who develop drug-induced cholestatic hepatitis[9,10].

Our case had the typical characteristics of amoxicillin/clavulanate-induced liver injury. These include advanced age, male sex, a cholestatic pattern of liver injury, delay between cessation of therapy and onset of jaundice, repeatedly negative tests for viral, autoimmune and metabolic diseases, and negative imaging studies[2,11-14]. Primary biliary cirrhosis and autoimmune cholangiopathy were considered unlikely, given the patient's age, gender, repeatedly negative serology, and histopathology.

A distinctive feature of our patient was his first liver biopsy that showed destructive cholangiopathy with portal and periportal fibrosis. The second biopsy, obtained 1 year later, revealed persistence of the destructive cholangiopathy but worsening fibrosis, with portoportal bridging and architectural distortion. In our patient, early fibrosis at 5 mo after exposure to amoxicillin/clavulanate may explain the prolonged cholestasis and immunosuppressant dependency. Patients reported complete recovery from prolonged amoxicillin/clavulanate-induced cholestasis did not have fibrosis on liver biopsy[2,11-14]. By contrast, in Degott's review of drug-induced cholestasis, all patients with persistent cholestasis had moderate to severe fibrosis[15].

Given the small number of patients reported with drug-induced vanishing bile duct syndrome and the unpredictability of its occurrence, there have been no clinical trials of treatment regimens. Short courses of corticosteroids have been used[6], based on a suggested immune pathogenesis of drug-induced cholestatic hepatitis. Mycophenolate mofetil, a non-competitive inhibitor of purine synthesis that acts by inhibiting inosine monophosphate dehydrogenase, blocks T- and B-lymphocyte proliferation. Approved for prophylaxis of rejection in solid organ transplantation, it is used against various immune-mediated diseases. Small clinical trials have reported its efficacy as a corticosteroid-sparing agent in autoimmune hepatitis[16,17], but it has not been evaluated for use in drug-induced liver disease. Our case illustrates

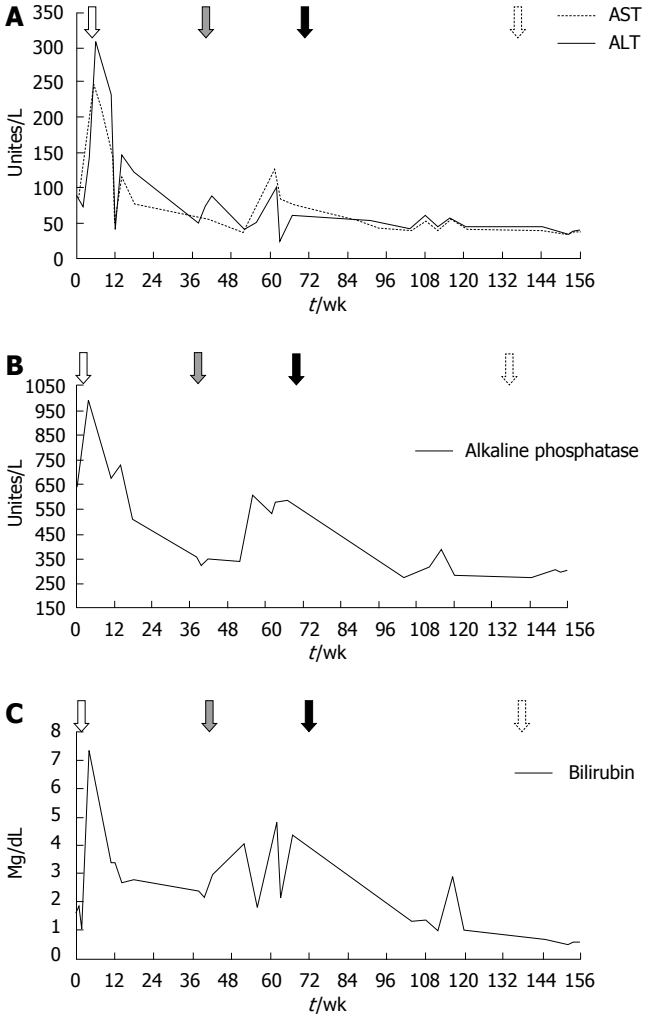

Figure 3 Three-year follow-up: liver enzymes and bilirubin during treatment with prednisone (white arrow), azathioprine/prednisone (grey arrow), and mycophenolate mofetil/prednisone (black arrow). Prednisone was stopped at wk 140 (dashed arrow). **A**: AST/ALT; **B**: alkaline phosphatase; **C**: bilirubin.

that mycophenolate mofetil can be a successful and safe alternative to corticosteroids for drug-induced prolonged cholestasis. Our patient has, at the time of this report, maintained normal liver function for over 3 years on low-dose mycophenolate mofetil, though efforts to withdraw treatment completely resulted in recurrence of mild cholestatic abnormalities.

In summary, we reported a case of severe amoxicillin/clavulanate-induced cholestatic hepatitis that resulted in progressive bile duct destruction and development of bridging fibrosis. Clinical and biochemical resolution was achieved using long-term immunosuppression, initially with prednisone and finally with low-dose mycophenolate mofetil. This suggests that cautious use of immunosuppressive therapy may be of benefit in those rare cases with persistent cholestasis. Further studies are needed to determine if early therapy can prevent irreversible bile duct injury, and to identify patients in whom such therapy is indicated.

Abstract

We describe the first case of sirolimus-induced drug fever in a female liver transplant recipient, with a history of hepatitis C-induced end-stage liver cirrhosis in 1999. In 2005, six years after transplantation, she developed calcineurin inhibitor-induced renal function impairment. Immunosuppression was switched from tacrolimus to sirolimus. Two days after the intake of sirolimus, she developed daily fever spikes, but no infectious focus was found. Antibiotic therapy had no influence on the fever. After fourteen days, sirolimus was switched back to tacrolimus and the fever disappeared. In history, the patient developed ciclosporin-induced generalized seizures eleven days after liver transplantation, followed by the development of a motoric speech disorder. Magnetic resonance imaging (MRI) findings were consistent with leucoencephalopathy, therefore immunosuppressive therapy was changed from ciclosporin to tacrolimus and the neurologic symptoms improved significantly. Our case is the first reported case of sirolimus-induced drug fever. In addition, the patient showed the rare occurrence of ciclosporin-induced leukencephalopathy with seizures.

INTRODUCTION

Ciclosporin and tacrolimus are very potent immunosuppressive drugs which have been used in organ transplantation for more than 10 years. Both are calcineurin-inhibitors and have the same mode of action. They are mainly metabolized by cytochrome P450 3A4 in bowel and liver[1]. The main side effects of ciclosporin and tacrolimus are renal toxicity, neurotoxicity, arterial hypertension, diabetes mellitus and hyperlipidemia[2]. Combination therapy of these two drugs is therefore not useful. Until now, many immunosuppressive regimens contain either ciclosporin or tacrolimus in combination with other immunosuppressive drugs. For several years, the mammilian target of rapamycin (mTOR) inhibitor, sirolimus (Rapamune®), has also been used as an immunosuppressive drug in organ transplantation. Similar to ciclosporin, it is also metabolized in bowel and liver by cytochrome P450 3A[1]. The main advantage of sirolimus is its virtual lack of nephrotoxicity. The main side effects are hyperlipidemia, anemia, and thrombocytopenia. Ciclosporin and sirolimus are substrates of the efflux-transporting pump P-glycoprotein, which is among others localized in gut and liver[3]. Ciclosporin and sirolimus have different modes of action and synergistic effects[4]. Therefore, in patients with renal impairment, combination therapy allows a dose reduction of both drugs which results in reduced side effects, especially on renal toxicity. Ciclosporin, tacrolimus as well as sirolimus can be given as monotherapy or in combination with other drugs. Patients with progressive impairment in renal function due to ciclosporin- or tacrolimus-induced nephrotoxicity can be switched to sirolimus monotherapy to prevent further loss of renal function[5].

CASE REPORT

We present the case of a 63-year-old female patient, who was first diagnosed with chronic hepatitis C virus infection in 1996 (genotype 1b). Infection was most likely due to several blood transfusions which were necessary after resection of a cyst of the left ovary in 1973. In 1997

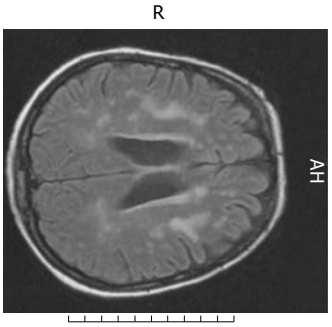

Figure 1 Magnetic resonance imaging (MRI) of the head showing almost symmetric periventricular white matter lesions consistent with leucoencephalopathy and a beginning encephalitis (FLAIR TR 8000 ms, TE 110 ms).

histopathological liver examination was performed for the first time and showed inflammation grade Ⅳ, as well as fibrosis grade Ⅲ (Ishaak-Score). Therefore, interferon monotherapy was given for one year (relapse after end of treatment). Six months later, she presented with decompensated liver cirrhosis and esophageal bleeding due to varices grade Ⅲ. After re-compensation she was listed for liver transplantation in January 1999. Neurologic status was normal prior to liver transplantation. Liver transplantation was successfully performed in August 1999. The explanted liver demonstrated complete cirrhosis (716 g). The liver graft showed no histological damage and normal perfusion as judged by duplex sonography. Immunosuppressive therapy was started with a combination therapy of ciclosporin, azathioprine and steroids. Eleven days after the start of immunosuppressive therapy, she developed a generalized seizure, which could be stopped with diazepame. Several focal and generalized epileptic fits followed and the patient developed a motoric speech disorder which finally resulted in dysarthria and complete aphasia. The patient showed no other neurologic symptoms. A magnetic resonance imaging (MRI) of the head showed periventricular white matter lesions consistent with leucoencephalopathy and a beginning encephalitis (Figure 1). The described symptoms were interpreted as side effects of ciclosporin medication. Therefore, immunosuppressive therapy was changed from ciclosporin to tacrolimus (FK 506, Prograf®) and antiepileptic therapy was initiated with 400 mg gabapentin four-times a day. The dysarthric disorder improved significantly, but residuals still existed with no occurrence of further seizures at the time when this report was written. During the treatment with steroids and tacrolimus, the patient developed an insulin-dependent diabetes mellitus.

In December 1999, transplant reinfection with hepatitis C virus was diagnosed. In July 2001, liver histology showed a beginning fibrosis of the liver graft with little infiltration of inflammatory cells, corresponding to chronic hepatitis (Yano classification: grading 4, staging 3). Therefore, antiviral therapy with interferon alpha (1.5 Mio units/wk) and ribavirin (600 mg/d) was initiated. Due to pancytopenia azathioprine medication, ribavirin was stopped one year later. Hepatitis C virus re-infection was controlled by 90 μg pegylated interferon alpha 2a once a week subcutaneously. In 2003, a control MRI showed no deterioration of leukencephalopathy.

In September 2005, the patient presented with progressive renal impairment and peripheral oedema. Serum creatinine (193 μmol/L, normal range 44-80 μmol/L) and urea levels (15 mmol/L, normal range 2.0-8.3 mmol/L) were elevated. Urinary tests confirmed chronic renal failure with a creatinine clearance of only 20 mL/min. Therefore, immunosuppressive therapy was changed from tacrolimus (Prograf®) to sirolimus (Rapamune®). Two days after starting sirolimus, the patient developed fever of 38℃, which reached up to 39℃ on the next day. No reason for the fever was found either with blood cultures or with urine examination, or with X-rays. The patient showed no other specific clinical symptoms (e.g. diarrhea, skin lesions, pharyngitis). Leucocytes (3.8/nL, normal range 4.8-10.8/nL) and thrombocytes (96/nL; normal range 130-440/nL) were reduced, most likely due to interferon therapy and splenomegaly. Erythrocyte sedimentation rate (ESR) and C-reactive protein were normal and cytomegalovirus and Epstein Barr virus screening was negative. Antibiotic therapy with piperacilline and sulbactame was given for 6 d, but did not result in any improvement of the daily spikes of fever, which occurred every evening (Figure 2). After 14 d, the fever disappeared when sirolimus was switched back to tacrolimus in combination with mycophenolate mofetil. Thus, sirolimus-induced drug fever was diagnosed.

At the time when we wrote this report, the patient was in a good clinical condition, neurologic status remained stable but dysarthria still existed, and renal function (133 μmol/L serum creatinine) improved with dose reduction of tacrolimus and intake of 3 litres fluid per day.

DISCUSSION

The clinical and radiological features demonstrated in this patient are consistent with those of leukoencephalopathy, a rare condition previously described in patients treated with ciclosporin and tacrolimus[6,7]. In our patient as in most patients previously described, leukoencephalopathy associated with immunosuppression occurred early during therapy and was reversible with good recovery. One case of late-onset leukoencephalopathy with a fatal outcome has been reported[8]. In the reported case, the symptoms due to leukoencephalopathy improved after withdrawal of ciclosporin, but unfortunately, did not completely disappear. The patient also suffered from seizures, which disappeared after withdrawal of ciclosporin and initiation of antiepileptic therapy with gabapentin.

Neurologic symptoms represent serious complications following orthotopic liver transplantation and may be caused by various perioperative factors or may develop due to drug-specific toxicity of immunosuppression. The incidence of neurotoxicity seems to be higher in patients treated with tacrolimus than in patients treated with ciclosporin in the early postoperative period, after retransplantation as well as in the late phase[9]. Watson *et al*[10] described two patients who suffered from neurological events, one with encephalopathy and the other with recurrent seizures. Both patients were on sirolimus and ciclosporin after orthotopic liver transplantation and stabilized after withdrawal of ciclosporin. Choi *et al*[11] reported that of the 367 patients who received OLT, 48 suffered from neurological complications, 17

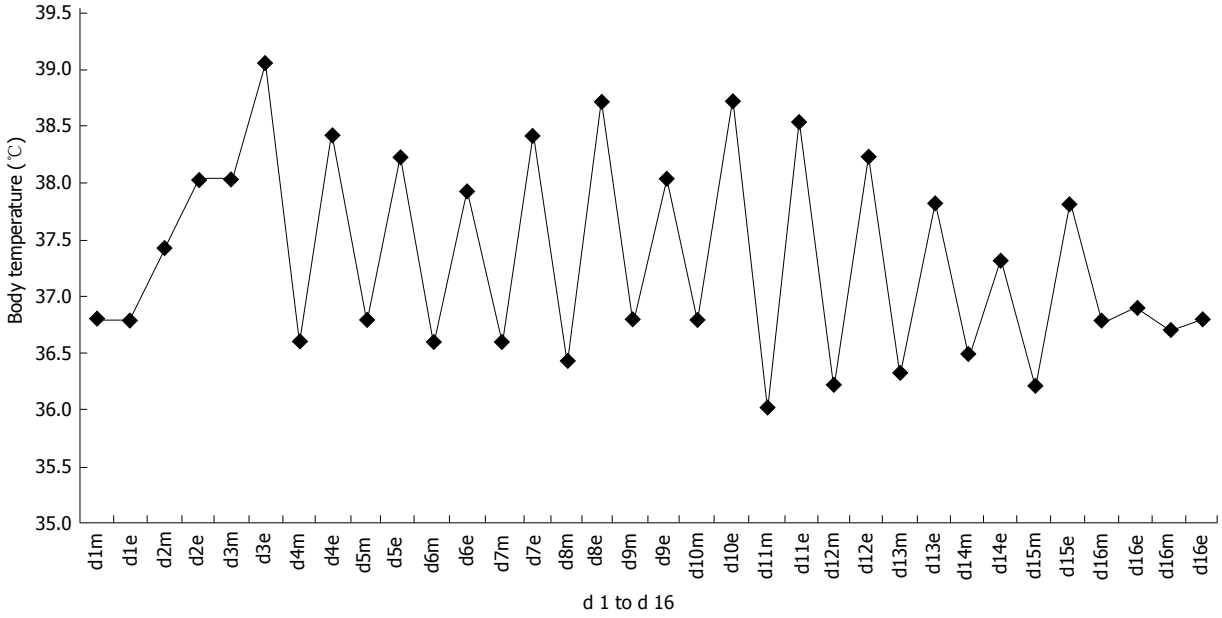

Figure 2 Temperature curve before, during (14 d) and after sirolimus therapy. Antibiotic therapy with piperacilline and sulbactame given from d 3 to 9 showing no effect. m: morning; e: evening.

developed seizures (status epilepticus occurred in two patients, generalized tonic-clonic seizures in five patients). Although neurotoxicity is not a frequent side effect of ciclosporin medication, the described cases in the reports are in accordance with our patient's symptoms (seizures and consecutive motoric speech disorder) which could be interpreted as side effects of ciclosporin medication. The motoric dysarthric disorder improved significantly after a change of the immunosuppressive regimen, but residuals still existed.

Idilman *et al*[12] described two cases of reversible posterior leukoencephalopathy manifested as headache, nausea and seizures associated with the use of immunosuppressive drugs following liver transplantation. One case of a 29-year old patient treated with ciclosporin after a liver transplant for primary sclerosing cholangitis showed late-onset progressive leucoencephalopathy due to immunosuppressive therapy and died three years later. These reports suggest that neurological side effects should be cautiously observed when alteration of immunosuppressive therapy is considered.

Although ciclosporin is an immunosuppressive agent widely used in the management of liver transplant recipients, neurological complications have been described in only few cases. The two different neurological side effects found in our patient are probably associated with ciclosporin medication.

Side effects of sirolimus include delayed wound healing, oral ulcers, hypertension, interstitial pneumonitis, infections, and most importantly, hyperlipidemia and myelosuppression[13]. Concerning the central nervous system, it has been shown that sirolimus can alter cell metabolism of primary astrocytes, thus resulting in similar neurotoxicity as experienced by tacrolimus and ciclosporin[14]. Perhaps the greatest potential benefit of sirolimus for liver transplant recipients is its lack of nephrotoxicity as compared to calcineurin inhibitors[15,16]. At present, no single immunosuppressive regimen can offer a clear advantage over another with regard to prevention of cellular rejection, graft survival, and patient survival[17]. In our patient, immunsuppression was switched from ciclosporin to sirolimus due to nephrotoxicity of ciclosporin. We clearly could show that the fever in our patient was not related to infection, but most likely to sirolimus. Two days after starting immunosuppression with sirolimus, our patient developed fever with no infectious focus found in blood cultures, urine tests or in radiologic examinations. Even the antibiotic therapy did not show any improvement of the daily spikes of fever in the evening. Due to the diagnosis of sirolimus-induced drug fever, the immunosuppressive medication was changed back to tacrolimus in combination with mycophenolate mofetil and no more fever spikes occured. To our knowledge, this is the first reported case of drug-fever obviously related to sirolimus. Two years ago, Dorschner *et al*[18] described a 2-year drug-related fever caused by everolimus, a sirolimus-derived immunosuppressant (Certican®). Their patient was 66 years old and received a cardiac transplant due to dilatative cardiomyopathy. The immunosuppressive regimen consisted of steroids, ciclosporin, and everolimus. Two weeks after the replacement of everolimus with azathioprine, all the patient's symptoms disappeared.

This is the first report of a liver transplant recipient with rare immunosuppressant-induced side effects. Until now, we could not unravel the mechanism(s) responsible for these side effects. A mutation in cytochrome P450 3A or FK-binding protein 12 (FK-BP12) seems to be unlikely, because our patient had no side effects under medication with tacrolimus, which is also metabolised by cytochrome P450 3A and bound to FK-BP12. Since ciclosporin, tacrolimus and sirolimus are substrates of the ATP-binding efflux pump P-glycoprotein, located in several organs like bowel and liver, it seems to be impossible that this protein might cause the several drug-side effects in our

patient. Therefore, we speculate that immunosuppressant drugs may have some influence on proteins in the central nervous system.

In conclusion, ciclosporin is an immunosuppressive agent widely used in the management of solid organ transplantation. Sirolimus is a powerful immunosuppressant used to prevent acute rejection episodes in patients who have undergone transplantation, particularly when nephrotoxic effects of calcineurin inhibitors become problematic.

Abstract

A 74-year-old woman presented with symptoms consistent with hyperadrenocorticism and hypercatecholaminism. She had a cushingoid appearance and her cortisol level was elevated. Her serum dopamine and noradrenalin levels were also elevated. Computed tomography detected a left adrenal mass measuring 3.5 cm × 3.0 cm in diameter. Metaiodobenzylguanidine scintigraphy was negative. Unexpectedly, the serum Serum carcinoembryonic antigen (CEA) level was elevated. Fluorodeoxyglucose positron emission tomography showed increased uptake in the adrenal tumor only, with a maximum standardized uptake value of 2.8. Selective venography and blood sampling revealed that the concentrations of cortisol, catecholamines and CEA were significantly elevated in the vein draining the tumor. A diagnosis of CEA-producing benign adenoma was made. After preoperative management, we performed a combined lateral and anterior transperitoneal laparoscopic adrenectomy. Her vital signs remained stable during surgery. Histopathological examination revealed a benign adenoma. Her cortisol, catecholamine and CEA levels normalized immediately after surgery. We present, to the best of our knowledge, the first case of CEA-producing adrenal adenoma, along with a review of the relevant literature, and discuss our laparoscopic surgery techniques.

INTRODUCTION

Serum carcinoembryonic antigen (CEA) level is widely used as a reliable tumor marker in cancer patients. CEA level is rarely elevated in benign disease, and to the best of our knowledge there have been no reports of CEA-producing benign adrenal tumors. We present the first reported case of a CEA-producing adrenal adenoma, along with a review of the relevant literature, and discuss a useful technique for the removal of adrenal tumors.

CASE REPORT

A 74-year-old Japanese woman was referred to our hospital

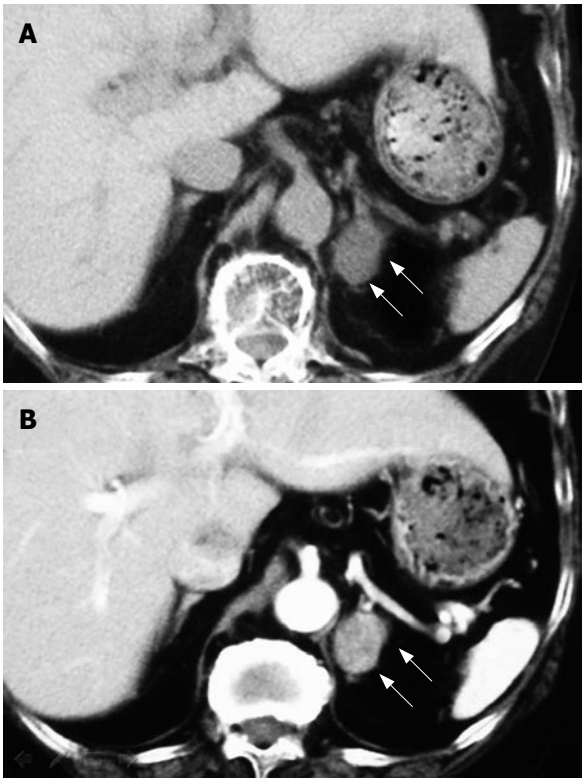

Figure 1 Abdominal CT. Plain (**A**) and enhanced (**B**) CT revealed a left adrenal mass (white arrows) measuring 3.5 cm × 3.0 cm in diameter.

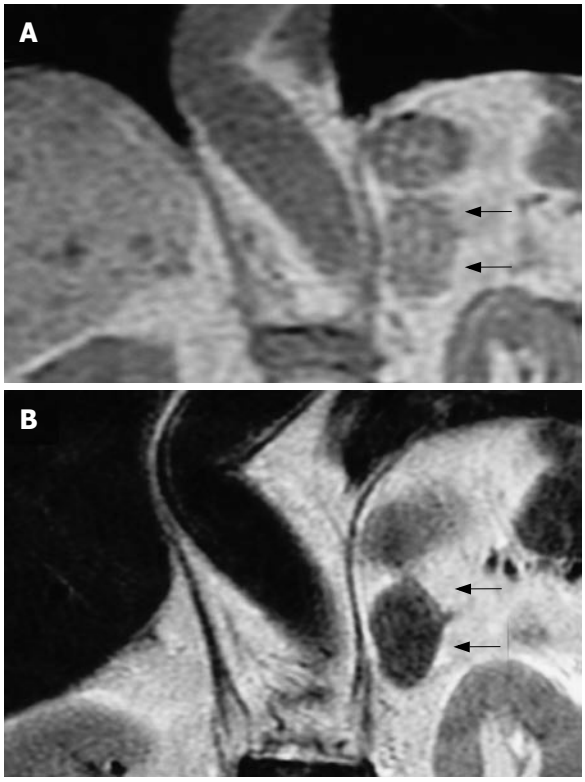

Figure 2 Abdominal MRI. MRI showed an adrenal mass (black arrow) with slightly low intensity on T1-weighted images (**A**) and low intensity on T2-weighted images (**B**).

because of fatigue and frequent episodes of palpitations, sweating, headache and weight gain over the past year. She had a history of hypertension and hyperglycemia, for which she had been treated at another hospital for 18 years. Although the number of medications and their dosages had slowly increased during the year before this consultation, her diseases and symptoms were not well controlled. Physical examination showed truncal obesity, moon face, buffalo hump and proximal muscle weakness. On admission, her blood pressure was 202/108 mmHg, and pulse rate 96 beats/min. X-ray images revealed osteoporosis. Serum biochemistry showed elevated levels of glucose (243 mg/dL; normal, 70-109 mg/dL), Hemoglobin A1c (HbA1c) (8.9%; normal, 4.3-5.8%) and total cholesterol (271 mg/dL; normal, 50-149 mg/dL), and reduced levels of total protein (5.5 g/dL; normal, 6.5-8.3 g/dL) and albumin (3.2 g/dL; normal, 3.7-5.3 g/dL). Abdominal computed tomography (CT) showed a left adrenal mass measuring 3.5 cm × 3.0 cm in diameter (Figure 1). Magnetic resonance imaging (MRI) showed an adrenal mass with slightly low intensity on T1-weighted images and low intensity on T2-weighted images (Figure 2). Her physical appearance was cushingoid, as described above. Adrenal cortical hormone analysis revealed a markedly elevated cortisol level, but aldosterone and estradiol levels were normal. The regulatory factors for these hormones were all within normal ranges (Table 1). Catecholamine analysis revealed markedly elevated dopamine and noradrenalin (NA) levels but the adrenalin level was within the normal range. The levels of catecholamine-breakdown products homovanillic acid (HVA) and vanillylmandelic acid (VMA) were both increased (Table 1). ^{123}I-metaiodobenzylguanidine scintigraphy showed no adrenal or extra-adrenal hot spots.

Unexpectedly, the CEA level was also found to be elevated (Table 1), although other tumor markers including carbohydrate antigen (CA) 19-9, CA125, CA15-3, alpha-fetoprotein and squamous cell carcinoma antigen were all normal. Upper gastrointestinal and colorectal endoscopy, neck/chest CT, and genital and breast examination did not reveal any abnormal findings. F-18 fluorodeoxyglucose (FDG)-positron emission tomography (PET)/CT revealed increased FDG uptake in the left adrenal gland (Figure 3). The maximum standardized uptake value was 2.8, and there was no FDG uptake elsewhere. We performed selective venography and blood sampling at various locations around the inferior vena cava to measure the concentrations of factors not within a normal range. The left adrenal vein (AV) was the drainage vein of the tumor and flowed into the left renal vein (RV). Results from the selective blood sampling clearly showed that the concentrations of these factors were dramatically increased in the left adrenal 'drainage' vein. This revealed that the left adrenal tumor was an obvious source of the CEA (Figure 4).

We diagnosed the tumor as a benign adrenal adenoma, which caused hyperadrenocorticism and hypercatecholaminism[1] and produced a large amount of CEA. After preoperative management[2], we removed the tumor by combined lateral and anterior transperitoneal laparoscopic adrenectomy (LA). The patient was placed in the right lateral position. A trocar was inserted at the umbilicus, and a carbon dioxide pneumoperitoneum (10 mmHg) was established. We introduced one trocar into the abdominal cavity through the lateral abdominal

Table 1 Time course of serum endocrine profiles and CEA levels before and after surgery

	Normal range	Before surgury	Postoperative day

CEA (ng/mL)	< 5.0	12.6	4.5	2.5	2.1	2.2

Values outside the normal range are underlined.

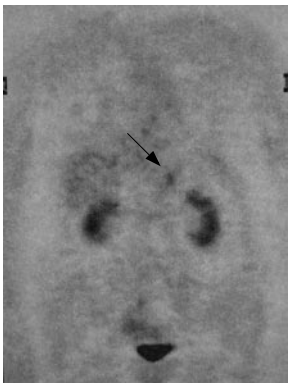

Figure 3 FDG-PET/CT. FDG uptake in the left adrenal gland (black arrow). The maximum standardized uptake value was 2.8, and no FDG uptake was seen anywhere else.

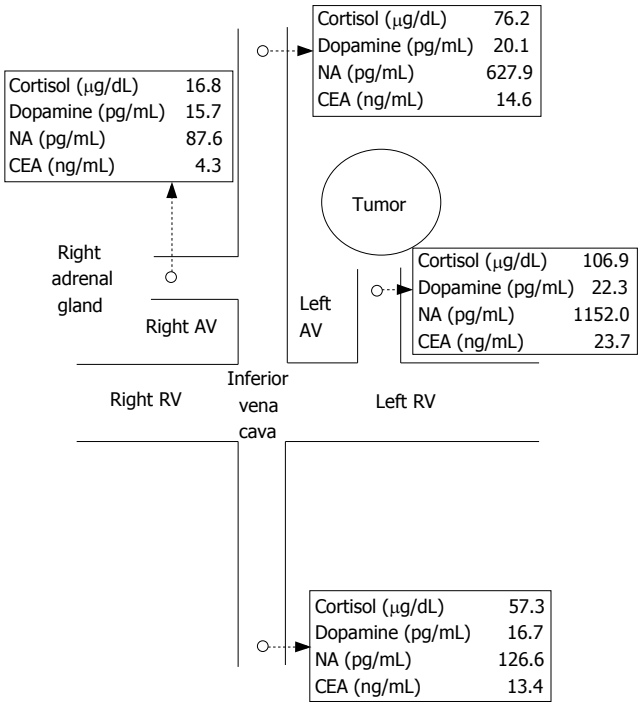

Figure 4 Selective venography and direct blood sampling. Measurements of serum cortisol, dopamine, NA and CEA were performed at four locations (proximal and distal inferior vena cava and both AVs). White circles represent sampling points.

wall, and two trocars through the subcostal wall. Using an electrothermal vessel sealing system (LigaSure, Tyco Healthcare, CO, USA), we isolated the spleen and distal pancreas by resecting the phrenic, colic and renal ligaments. The left RV and splenic vein were exposed by retracting the distal pancreas, spleen and left kidney. The left AV was separated from the surrounding tissue and ligated at its entry into the RV using a clip. The tumor was found to be located as indicated on preoperative imaging studies, without adhesion to the adjacent organ, and was removed with complete hemostasis. Vital signs remained stable during LA. Operative time was 2 h 45 m, and total blood loss was 85 mL. Histopathological examination of the resected specimen confirmed a benign adenoma. Chromaffin staining was negative. Cortisol, catecholamine and CEA levels normalized immediately after surgery (Table 1).

DISCUSSION

Based on hormonal evaluations of the adrenal cortex, we considered that this patient's hyperadrenocorticism was adrenocorticotrophic hormone-independent and renin-angiotensin-system-independent. Phenylethanolamine N-methyltransferase (PNMT), which is found in the adrenal glands, is required for the conversion of NA to adrenalin during catecholamine synthesis[3]. Catecholamine metabolism produces the breakdown products HVA (from dopamine) and VMA (from NA). Hormonal evaluations of the adrenal medulla suggested that this adrenal

adenoma either lacked PNMT or the optimal environment for the activation of PNMT.

LA was first performed in 1992[4,5], and this safe and effective treatment is now used worldwide for the management of functioning and non-functioning adrenal tumors for many reasons[6]. The minimal skin incisions provide a sufficient surgical field, anastomosis and reconstruction are not required, hemostasis can be achieved using laparoscopic devises, and the resected tumor can be removed through the small skin incision. Many previous reports on LA have already described the advantages and shortcomings of the transperitoneal and retroperitoneal approaches. There are two transperitoneal approaches, lateral and anterior[7]. Especially in left adrenal tumors and cases with more retroperitoneal fat, we have a clear impression that the combined lateral and anterior transperitoneal LA has the advantage of providing a sufficient surgical field and anatomical orientation in a timely manner. Surgery for catecholamine-releasing tumors differs from that for non-functioning tumors, because of the risk of intraoperative hypertensive and tachycardiac events[8]. In the present case, the combined approach allowed easy and early ligation of the drainage vein, which was the source of the catecholamines. We suggest that this procedure is effective for avoiding intraoperative iatrogenic complications.

CEA, the first tumor-associated antigen to be described, has many features that make it attractive for active vaccination against cancer. This useful biomarker is expressed in > 50% of all human cancers[9], including colorectal, lung, stomach, breast, pancreas, gallbladder, biliary tract, cervix, uterus, ovary, head/neck, bladder, kidney and prostate cancer. In the present study, we performed FDG-PET/CT to rule out adrenal cancer and to search for extra-adrenal tumors to explain the raised CEA level, as the conventional investigations for evaluation of an elevated CEA level showed no significant findings. We eventually hypothesized that the left adrenal tumor was producing a large amount of CEA, and performed selective venography and direct blood sampling of the drainage vein of the tumor to verify this. This method was useful for detecting the source of CEA in the present case. Previous reports have demonstrated that smoking, inflammatory diseases and benign tumors uncommonly produce CEA; but that benign tumors rarely progress to become malignant[10,11]. We are unable to explain how this patient's benign adenoma acquired the ability to secrete CEA, even after reviewing the relevant literature. This appears to be the first reported case of a CEA-producing adrenal adenoma. As a benign adrenal adenoma rarely secretes CEA, more cases need to be studied to better understand CEA production in benign adrenal tumors.

Abstract

Ectopic pancreas is defined as pancreatic tissue found outside the usual anatomic location of the pancreas. It is often an incidental finding and can be found at different sites in the gastrointestinal tract. It may become clinically evident when complicated by pathologic changes such as inflammation, bleeding, obstruction, and malignant transformation. In this report, a 40 years old woman with epigastric pain due to ectopic pancreatic tissue in the stomach is described. The difficulty of making an accurate diagnosis is highlighted. The patient has remained free of symptoms since she underwent wedge resection of the lesion three years ago. Frozen sections may help in deciding the extent of resection intraoperatively. Although ectopic pancreas is rare, it should be considered in the differential diagnosis of a submucosal gastric tumour.

INTRODUCTION

Pancreatic heterotopia was first described in 1727 when it was found in an ileal diverticulum[1]. It is a rare entity, defined as the presence of extrahepatic tissue without any anatomic or vascular continuity with the pancreas. It may occur at a variety of sites in the gastrointestinal tract having a propensity to affect the stomach and small intestine. Usually, it is a silent anomaly but it may become clinically evident when complicated by inflammation, bleeding, obstruction or malignant transformation[2]. We report a case of a 40-year-old female with an ectopic pancreatic lesion in the antrum of the stomach.

CASE REPORT

A 40-year-old woman was admitted to our hospital due to a 2-mo history of recurrent episodes of epigastric pain, nausea and vomiting. Physical examination, routine blood tests including amylase, plain chest and abdominal X rays along with abdominal ultrasound were unremarkable. Esophagogastroduodenoscopy revealed a sessile polypoid mass with benign features located in the gastric antrum to the posterior wall measuring approximately 2 cm in diameter. The mucosa appeared normal throughout the stomach. Biopsy confirmed the presence of a normal gastric mucosa over the lesion. Computed tomography was not performed.

A decision was made to proceed with surgery. Endoscopic injection with methylene blue was performed to mark the lesion preoperatively.

The patient underwent exploratory laparotomy. Through a small midline incision a gastrotomy was performed. The lesion was clearly stained with methylene blue 4 h after the endoscopy. It was located approximately 10 cm from the pylorus to the greater curvature. In palpation the lesion was rubber like, fixed to the surrounding mucosa giving the feeling 'like a breast fibroadenoma'. Its dimension was approximately 5 cm × 3 cm × 4 cm. By using a stapler device a wedge resection of the lesion was performed with macroscopically clear margins. Frozen sections excluded malignancy and the possibility of ectopic pancreatic lesion. The surgical margins were clear.

The patient had no postoperative complications and was discharged 4 d later. She has remained free of symptoms with negative endoscopy since then.

Histopathologic examination of the lesion showed heterotopic pancreatic tissue in the gastric antrum with a lobular architecture characteristic of ectopic pancreas. The pancreatic lobules were located mainly in the gastric submucosa (Figure 1A) and partially in the muscularis propia (Figure 1B). They contained a mixture of pancreatic acini, ducts and islets of Langerhans. The overlying gastric mucosa was normal.

DISCUSSION

Ectopic pancreas is defined as pancreatic tissue that lacks anatomical or vascular communication with the normal

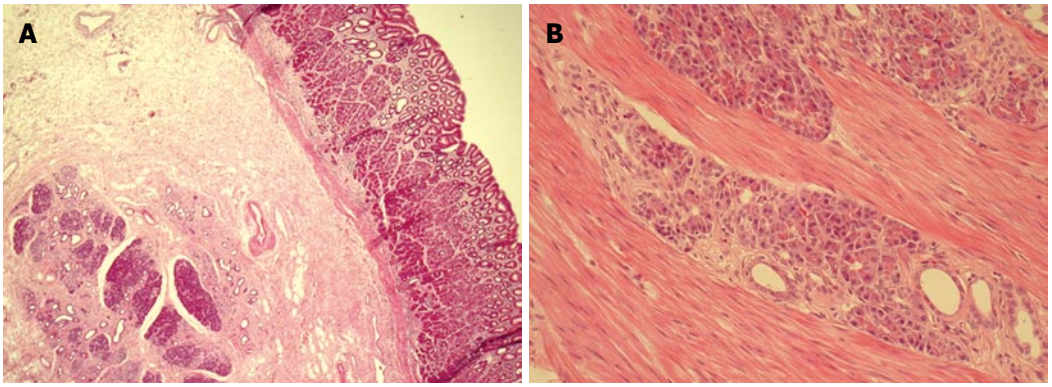

Figure 1 Heterotopic pancreatic lobules occupying the submucosa under an intact normal gastric mucosa (HE, x 100) (**A**) and between smooth muscle fibers of the gastric muscularis propria (HE, x 200) (**B**).

body of the pancreas[3]. Heterotopic pancreas has a genetic make-up, physiologic function, and local environmental exposure similar to that of the pancreas[4]. The incidence in autopsies ranges 0.5%-13.7%, being more common at the age of 30-50 years with a male predominance[3].

Of the 105 gastrectomies performed in our institution over the last five years, ectopic pancreatic tissue was found in only one case (1/105, 0.9%).

Several theories have been proposed to explain the pathogenesis and occurrence of pancreatic heterotopia. The most tenable theory implicates that during the development of normal pancreas from several evaginations, originating from the wall of the primitive duodenum, one or more evaginations may remain in the bowel wall. Migration of this embryonic remnant along with the development of the gastrointestinal tract gives rise to the ectopic pancreatic tissue[5]. Another theory suggests that during embryogenesis pancreatic metaplasia of the endodermal tissues localized in the gastric submucosa may occur[5].

Histopathologically, it is not a diagnostic problem when pancreatic acini, ducts, islets of Langerhans and intervening connective tissue are present. The most characteristic gross feature is a central ductal orifice[6].

Specifically in the stomach, the involvement of submucosal layer, muscularis and subserosal layer is 73%, 17% and 10%, respectively[7]. In the presented case the pancreatic tissue involved both the submucosa and muscularis propria. Heinrich in 1909 proposed three types of heterotopic pancreas but his classification was modified by Gaspar-Fuentes in 1973 acquiring its final form. Type Ⅰ heterotopia consists of typical pancreatic tissue with acini, ducts, and islet cells similar to those seen in normal pancreas (Figure 1). Type Ⅱ heterotopia is composed of pancreatic ducts only, referred as canalicular variety. Type Ⅲ heterotopia is characterized by acinar tissue only (exocrine pancreas). Type Ⅳ heterotopia is made up of islet cells only (endocrine pancreas)[8].

The usual location is in the stomach in 25%-38% of the cases, duodenum in 17%-36%, jejunum in 15%-21.7% and rare in the esophagus, gallbladder, common bile duct, spleen, mesentery, mediastinum and fallopian tubes. Gastric lesions are discovered in the antrum in 85%-95%, either on the posterior or anterior wall, being more common along the greater curvature[5].

The pancreatic ectopic tissue is usually silent but can also undergo complications that occur in normal pancreatic tissue such as acute or chronic pancreatitis, abscess and pseudocyst formation[9]. Malignant transformation may rarely occur. Up to 15 cases have been reported so far[10]. In order to be described as arising from heterotopic pancreas, the diagnosis of a carcinoma should fulfil three criteria: (1) the tumour must be located within or very close to the ectopic pancreatic tissue, (2) transition between pancreatic structures and carcinoma must be identified and (3) the non-neoplastic pancreatic tissue must comprise fully developed acini and ducts[11]. Adenocarcinomas arising from ectopic pancreas seem to have a somewhat better prognosis than those arising from the pancreas itself, probably due to earlier presentation[10].

Symptoms depending upon the anatomical location, such as gastric outlet obstruction in a pre-pyloric rest or obstructive jaundice in a bile duct focus, may originate from the mass effect of the tumour[12] and are also related to the size of the lesion. Lesions greater than 1.5 cm in diameter are more likely to cause symptoms[12]. Pain is one of the most common symptoms. The possible explanation is that the pain is due to endrocrine and exocrine function of the heterotopic pancreatic tissue, and relates to the secretion of hormones and enzymes, being responsible for inflammation or chemical irritation of the involved tissues[13]. Haemorrhage due to mucosal erosion, ulcer formation and perforation especially localized in the small intestine have also been reported[12].

Barium swallow study may show a typical image of a rounded filling defect with central indentation. The reported sensitivity and specificity are 87.5% and 71.4%, respectively[14]. Upper GI endoscopy can demonstrate a broad based umbilicated submucosal lesion. In the majority of cases, biopsies are superficial and non diagnostic. However, positive biopsies can establish the diagnosis[15]. Endoscopic ultrasonography has proven to be a useful adjunct in identification of pancreatic rests, localizing in the submucosa and ranging 0.5-2 cm. The combination of endoscopic ultrasonography with fine-needle aspiration allows cytologic evaluation of submucosal gastrointestinal lesions, having a sensitivity ranging 80%-100%[16,17].

Computed tomography findings are usually non specific. However, multi-slice spiral CT with oral and portovenous phase Ⅳ contrast may demonstrate the lesion which enhances similarly with the normal pancreatic tissue. CT can localize lesions with normal pancreatic tissue but cannot distinguish ectopic pancreas from other submucosal tumors[18,19].

In our case, since neither CT nor endoscopic ultra-

sonography was performed and the biopsy showed normal gastric mucosa, the diagnosis was made based on the benign endoscopic features of the lesion.

The diagnosis may be sometimes difficult intraoperatively due to the gross similarity of pancreatic heterotopia with gastrointestinal stromal tumour (GIST), gastrointestinal autonomic nerve tumour (GANT), carcinoid, lymphoma or even gastric carcinoma. If in doubt, frozen section is very helpful to establish the diagnosis intraoperatively and to avoid unnecessary extensive operations.

In conclusion, although pancreatic heterotopia is rare, it should be always considered in the differential diagnosis of extramucosal gastric lesions. Despite the development of modern diagnostic modalities, its diagnosis remains challenging. Surgical excision provides symptomatic relief and is recommended especially if diagnostic uncertainty remains. If in doubt, frozen section can help to avoid unnecessary radical operations.

Abstract

Echinococcal disease remains a problem within some endemic areas. Echinococcal cysts usually involve the liver and lungs, but any other organ can potentially be involved. Extrahepatic localization is reported in 14%-19% of all cases of abdominal hydatid disease. We report the case of a large echinococcal cyst localized in the lower pelvis. A 28-year-old woman was admitted to a surgical ward with lower abdominal pain and discomfort lasting for a month. Ultrasonography and computed tomography scanning revealed a large retroperitoneal cystic mass (9 cm × 4 cm) in contact with the left ovary and left ureter. There were no cysts in any other location. Serological tests were positive for Echinococcus. The patient was operated on and the entire cyst was excised intact. Histopathological results confirmed the diagnosis of echinococcosis. Antihelminthics were administered postoperatively and the patient was discharged after 6 d, and is now being closely followed up. Total cystectomy when possible represents the treatment of choice for large extrahepatic echinococcal cysts.

INTRODUCTION

Echinococcal disease, which produces unilocular cystic lesions, is an infection of humans caused by the larval stage of *Echinoccocus granulosus*. It is prevalent in the Middle East, the Mediterranean region, particularly in Greece and Lebanon, Australia, Argentina and Africa. Confirmed hosts are dogs that pass eggs into their feces. Intermediate hosts, e.g. sheep, cattle, humans, goats and horses, ingest the eggs and develop cysts[1]. Echinococcal cysts are mostly found in the liver (60%-70% of cases), followed by the lungs (10%-25%), spleen, ovaries, kidneys, brain, bones and heart, but rarely elsewhere in the body[1]. Hydatid disease in extrahepatic locations usually remains asymptomatic unless the cyst grows and produces symptoms due to pressure, rupture to the pleural or peritoneal cavity, secondary infection, or an allergic reaction[2]. We report the rare case of a 28-year-old woman with a large hydatid cyst in her lower pelvis, without hepatic or any other involvement.

CASE REPORT

A 28-year-old woman was admitted to our surgical ward with vague abdominal pain localized in the hypogastrium, and severe constipation, which had lasted for the previous 20 d. Her gynecologist had diagnosed a large cystic mass adjacent to the left ovary. She did not report episodes of fever, vomiting or diarrhea. Neither did she note any alterations in her menstrual cycle. Blood tests showed mild leukocytosis (12 000 white blood cells). Plain abdominal X-rays did not show any specific diagnostic findings. Abdominal ultrasonography (US) revealed a large cystic mass (9 cm × 4 cm) in contact with the left ovary and left ureter. Computed tomography (CT) confirmed the US findings (Figure 1). There were no cysts in any other location. Serological tests were positive for echinoccocal disease. The patient underwent a laparotomy, and a large cystic mass was identified retroperitoneally, firmly attached to the sacrum and in contact with the left ovary, left ureter and the sigmoid colon. Total cystectomy was performed en block with a portion of the mesosigmoid. The sigmoid vasculature remained intact, and there was no evidence of intraoperative colon ischemia. Postoperatively, antihelminthics were administered and the patient was discharged after 6 d. She had been closely followed up for 3 mo, without any abdominal pain and with significant improvement of constipation.

DISCUSSION

Echinococcosis remains a problem in endemic areas. *E.*

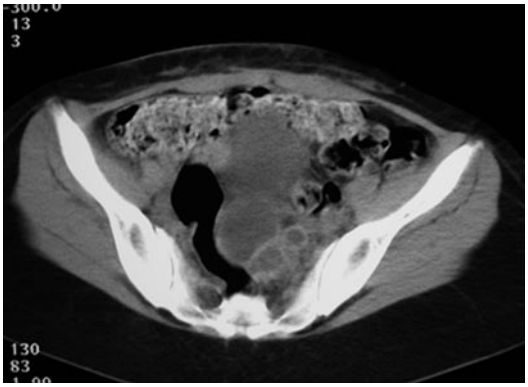

Figure 1 CT image of a large retroperitoneal echinococcal cyst in contact with the left ovary and left ureter.

granulosus is a 5-mm long worm, with a lifespan of 5-20 mo within the jejunum of dogs. When eggs are ingested by an intermediate host, the embryos escape, penetrate the intestinal mucosa, enter the portal circulation, and are then trapped in the liver[3]. A small number escape the hepatic filter, enter the systemic circulation, and are scattered to other organs. Larvae develop into fluid-filled unilocular hydatid cysts that consist of an external membrane and an inner germinal layer. Daughter cysts originate from the inner layer[3,4]. Slowly enlarging echinococcal cysts generally remain asymptomatic. Five to 20 years elapse before cysts enlarge sufficiently to cause symptoms. Abdominal pain, hepatomegaly or a palpable mass in the right upper quadrant are the most common symptoms for patients with liver echinococcosis[1]. Bile-duct compression or leakage of fluid into the biliary tree may mimic cholelithiasis. Biliary obstruction can result in jaundice. Generalized toxic reaction due to hydatid cyst rupture and secondary infection are among the most common complications[5].

Cysts in the peritoneal cavity account for 10%-16% of cases and are mainly the result of the rupture of concomitant hepatic cysts[2]. Extrahepatic locations of the echinococcus include the lungs (10%-15%), spleen (0.9%-8%), kidneys (1%-4%), pancreas (0.25%-0.75%), brain, heart, ovaries, bones and abdominal wall. Symptoms in such cases occur because of pressure or complications including rupture, allergic reaction and secondary infection[6]. Radiography, US and CT studies are important for a diagnosis of echinococcal disease. Plain abdominal X-rays may show calcifications of the cystic wall[7]. US is the method of choice for the detection of hepatic and extrahepatic echinococcal cysts. Hydatid cysts are classified by ultrasound into six categories.

Type I are defined as univesicular and < 50 mm in diameter. Type Ⅱ are univesicular with a prominent laminated layer, and tend to be seropositive. Type Ⅲ are subdivided into Ⅲa, defined as cysts with a prominent lamination that contains daughter cysts, and Ⅲb, characterized by lamination but a lower number of daughter cysts. Both Ⅲa and b are highly seropositive. Type Ⅳ appear as solid masses. Type Ⅴ are characterized by degeneration with calcifications. Type Ⅵ are defined as multiple cysts that may be univesicular and laminated, with daughter cysts involving one or more organs[8]. The sensitivity of US ranges from 93% to 98%[5].

CT confirms the diagnosis by revealing the presence of daughter cysts and plaque-like calcifications in the cystic wall. It is important as it provides information regarding the exact location of extrahepatic cysts in relation to neighboring structures. CT sensitivity ranges from 90 to 97%[5,9].

Serological tests contribute to diagnosis. Immunoglobulin G antibody detection by ELISA has a sensitivity of 95% and a specificity of 94%[8]. The sensitivity of indirect hemagglutination test has been found to be 87.5%[8,10].

Therapy for extrahepatic echinococcal disease is based on considerations regarding the size, location and manifestations of the cysts, and the overall health status of the patient. Asymptomatic small cysts once diagnosed can be treated with antihelminthic drugs, administered for 28 d in one to eight repeating cycles, separated by drug-free intervals of 2-3 wk[11].

For symptomatic or large hydatid peritoneal cysts, surgery, when feasible, is the principal method of treatment. Surgical treatment can be either radical or conservative. Total cystectomy, whenever possible, is the gold standard. For peritoneal cysts firmly attached to intraperitoneal viscera, unroofing and drainage has been proven to be a safe method[11,12]. It is important that the abdominal cavity is isolated with gauzes soaked in 20% hypertonic saline solution to avoid secondary hydatosis and allergic reaction[11].

In our case, to eradicate the disease, total cystectomy was carried out with meticulous dissection of the left ureter, gonadal vessels, hypogastric nerve plexus and the mesosigmoid vasculature. Thus, the sigmoid remained intact, free from compression, and constipation was greatly improved postoperatively.

In conclusion, a diagnosis of extrahepatic echinococcal disease is more accurate today because of the new imaging techniques available. The treatment of choice for small asymptomatic hydatid cysts is conservative by administration of antihelminthic drugs. Large or symptomatic echinococcal cysts need to be treated by total cystectomy, or unroofing and drainage followed by adjuvant antihelminthic therapy.

Abstract

Dysphagia associated with esophageal mechanical obstruction is usually related to malignant esophageal diseases. Benign lesions are rarely a cause for this type of dysphagia, and usually occur either as an intramural tumor or as an extrinsic compression. Mediastinal tuberculous lymphadenitis is rare in adults, and even more rarely causes dysphagia. We report two cases of dysphagia in adult patients caused by mediastinal tuberculous lymphadenitis, presenting radiologically and endoscopically as an esophageal submucosal tumor. Based on the clinical and imaging diagnosis, the patients underwent a right thoracotomy, and excision of the mass attached to and compressing the esophagus. Pathological examination of the specimens showed a chronic granulomatous inflammation with caseous necrosis, which was consistent with tuberculous lymphadenitis.

INTRODUCTION

In the esophagus, squamous cell adenocarcinoma as the most common type of malignant tumors and leiomyoma as the most common type of mesenchymal neoplasms, represent the frequent causes for dysphagia. However, dysphagia associated with esophageal mechanical obstruction can be caused by several conditions, mainly endoluminal/mucosal lesions, intramural tumors or extrinsic compression.

Despite technological improvements in the diagnostic work-up, the definitive diagnosis of some of these entities, particularly differentiation of submucosal parietal lesions from extrinsic lesions compressing the esophagus, may only be established after surgery[1].

Mediastinal diseases such as sarcoidosis[2], lung cancer, lymphoma, distant metastases[3,4] or mediastinal inflammatory lymph nodes[1,5-9] are the conditions that rarely compress the thoracic esophagus and cause dysphagia.

Some causes for dysphagia should always be considered in the differential diagnosis of dysphagia, because some of them if diagnosed and treated in time will completely cure the patient. We herein report two cases of dysphagia caused by mediastinal tuberculous lymphadenitis (MTL), presenting as esophageal intramural tumors.

CASE REPORT

Case 1

A 40-year-old woman who complained of a six-month history of dysphagia for solid food and paroxystic odynophagia, was admitted to our hospital for further evaluation of a submucosal mass-like lesion seen on an upper gastrointestinal (GI) endoscopy taken in another hospital. She had no other digestive symptoms, denied weight loss, fever, cough, sputum and night sweating. Her past medical history was unremarkable, namely exposure to tuberculosis and her family history was also unremarkable. Clinical examination was irrelevant, and her hematological and biochemical tests were normal.

A chest X-ray did not show any parenchymal and pleural change or mediastinal pathology. A barium swallow esophagogram (Figure 1A) disclosed a two-centimeter protruding lesion on the left lateral aspect of the mid-esophagus, distal to the aortic arch and with a smooth surface. An upper GI endoscopy (Figure 1B) showed a

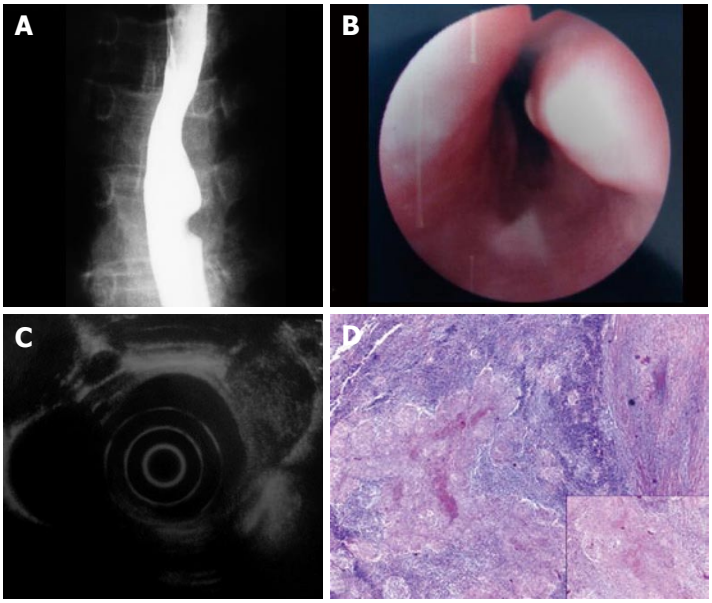

Figure 1 Barium swallow showing a two-centimeter protruding lesion on the left lateral aspect of the mid-esophagus (**A**), and endoscopic view of a two- centimeter protruding lesion covered by normal mucosa and with firm consistency (**B**), endoscopic ultrasonography revealing a two-centimeter solid hypoechoic lesion in the third layer (**C**), and lymph node parenchyma extensively occupied by necrotizing epithelioid granulomas (HE, × 40) (**D**). Insert: typical tuberculous granuloma with central caseous necrosis and multinucleated cells of Langhans type (HE, × 200).

two- centimeter deformity of the esophageal wall, covered by normal mucosa and with firm consistency, located 25 centimeters from the anterior incisor teeth. An endoscopic ultrasonography (Figure 1C) suggested that the lesion described by the other methods was an extramucosal mesenchymal tumor of the esophagus. A CT scan showed no pulmonary lesions or enlargement of mediastinal lymph nodes. The patient underwent a right thoracotomy, and excision of the mass attached to and compressing the esophagus. Surgery was performed with some difficulty due to surrounding fibrosis.

Pathological examination of the specimen showed a conglomerate of lymph nodes surrounded by chronic granulomatous inflammation with caseous necrosis. Zielh-Neelsen stain of the specimen, however, failed to disclose acid-fast bacilli (Figure 1D).

The symptoms of dysphagia and odynophagia disappeared after excision of the mass and post-operative treatment with a three-regimen anti-tuberculous chemotherapy with isoniazid, ethambutol hydrocloride and rifampicin.

A follow-up barium swallow esophagogram revealed a normal esophagus and the patient was in good health 6 years after an uneventful operation and subsequent discharge.

Case 2

A 54-year-old woman was referred to our hospital with a five-month history of dysphagia for solid food and a diagnosis of a submucosal lesion in the middle third of the esophagus. She had no other digestive symptoms, denied weight loss, fever, cough, sputum and night sweating. Her past medical history was unremarkable, namely exposure to tuberculosis and her family history was also unremarkable. Clinical examination was irrelevant, except for a palpable right supra-clavicular lymph-node. In spite of a repeatedly high erythrocyte sedimentation rate (30-73 mm in the first hour), sputum examination to disclose acid-fast bacilli and all the other routine laboratory tests revealed no abnormal findings.

Fine needle cytology of the supra-clavicular lymphadenopathy showed a necrotic lesion, without malignant cells. Zielh-Neelsen stain was negative. A barium swallow esophagogram (Figure 2A and B) disclosed a four-centimeter protruding smooth lesion on the right lateral aspect of the mid-esophagus, with apparent integrity of mucosa. An upper gastrointestinal (GI) endoscopy (Figure 2C) showed a two-centimeter deformity of the esophageal wall covered by normal mucosa and with firm consistency, located 22 centimeters from the anterior incisor teeth. An endoscopic ultrasonography (Figure 2D) revealed a two-centimeter hipoecogenic mass with well-defined limits, which was apparently dependent on the fourth ecographic layer of the esophagus, suggesting a leiomyoma. A chest X-ray and a CT scan did not show any lung parenchymal or pleural change, but the CT scan revealed enlargement of some mediastinum and pulmonary hilum lymph nodes, even though they did not form conglomerates.

Through a right thoracotomy, the mass compressing the esophagus was removed, in fact, an enlarged lymph node, and some other lymph nodes adherent to the esophageal wall were also removed.

Pathological examination of the specimen showed lymph nodes surrounded by a chronic granulomatous inflammation with caseous necrosis. Zielh-Neelsen stain of the specimen disclosed acid-fast bacilli (Figure 2E).

The patient began a postoperative three-regimen anti-tuberculous treatment with isoniazid, ethambutol hydrocloride and rifampicin.

The symptoms of dysphagia disappeared after treatment and a follow-up barium swallow esophagogram (Figure 2F) revealed a normal esophagus. The patient was in good health 4 years after discharge.

DISCUSSION

The ethiology of dysphagia associated with esophageal mechanical obstruction is usually referred to as

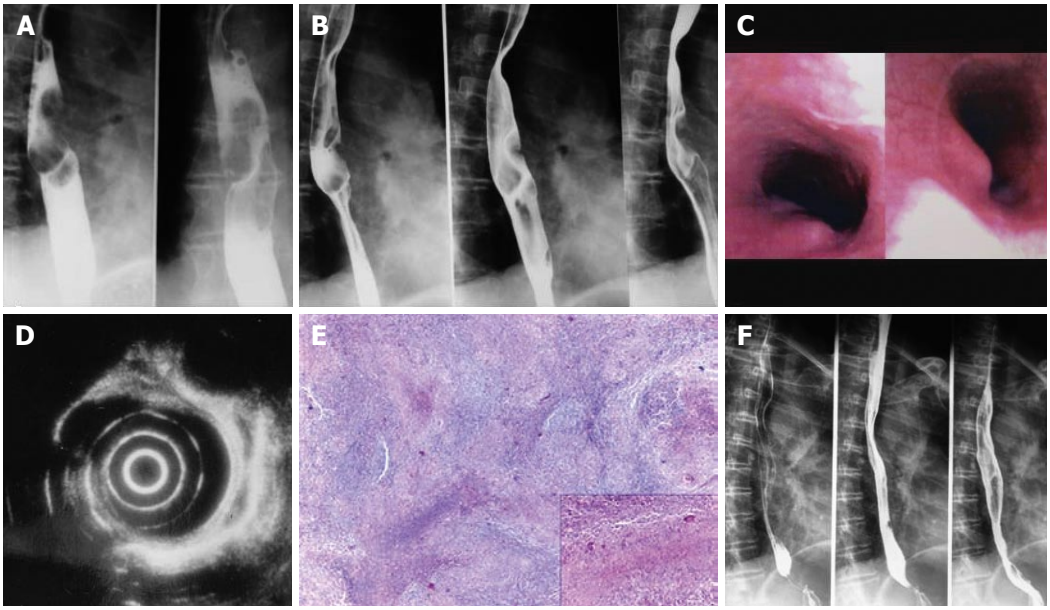

Figure 2 A barium swallow esophagogram disclosing a four-centimeter protruding smooth lesion with apparent integrity of mucosa on the mid-esophagus (**A**, **B**), esophagoscopy showing a two-centimeter deformity of the esophageal wall covered by normal mucosa and with firm consistency, twenty-two centimeters from dental arch (**C**), endoscopic ultrasonography revealing a two-centimeter well defined solid tumor in the fourth layer (**D**), lymph node parenchyma extensively occupied by necrotizing epithelioid granulomas (HE, × 40) and typical tuberculous granuloma with central caseous necrosis and multinucleated cells of Langhans type (HE, × 200) (**E**), and a two-month follow-up after surgery revealing no filling defect at the same level (**F**).

endoluminal/mucosal, intramural or extrinsic, in accordance with the location of the initial lesion in the esophageal wall. Malignant tumors of the esophagus are the most frequent cause, not only for primary dysphagia, but also for dysphagia caused by lesions originating from the esophageal mucosa[10].

Obstructive dysphagia caused by benign lesions is rare and usually results from intramural or extrinsic lesions. Even though rare, benign lesions leading to dysphagia are of great concern in the clinic. In fact, these lesions, if not treated, can lead to death due to progressive obstruction of the esophagus or pulmonary complications, but they almost always allow a curative surgical resection[10].

The endoscopic and radiological characteristics of a submucosa tumor are the endoluminal protusion of the digestive tube wall, usually covered by a normal looking mucosa. However, such features may also be caused by organ lesions or structures that extrinsically compress the digestive wall. EUS is described as the diagnostic method with a greater capacity of distinguishing between intraparietal and extrinsic lesions compressing the digestive wall, with a diagnostic accuracy superior to CT-scan and barium swallow[11,12]. Although EUS-guided fine needle biopsy is possible in these lesions, the material retrieved is sometimes insufficient for a diagnosis and, particularly for evaluation of the malignant potential of the lesions[12-15].

In our cases, even though the diagnosis of an extrinsic compression on the esophagus could not be excluded, barium swallow revealed an image compatible with a submucosa tumor protruding into the lumen. In fact, the angle between the esophageal wall and margin of the mass was almost perpendicular, which is in accordance with an intramural lesion, rather than an extrinsic compression on the esophagus[16]. Furthermore, all of the other diagnostic examinations pointed towards the diagnosis of a submucosal tumor-like intraluminal protruding mass. For these reasons, the patients were operated on with a probable diagnosis of a leiomyoma of the esophagus, suggesting that this is the most frequent intraparietal benign tumor of the esophagus.

One of our patients had a supraclavicular adenopathy and a persistently high erythrocyte sedimentation rate. The lymph node biopsy revealed necrotic material, but no Zielh-Neelson stained bacilli. Even though central necrosis of a lymph node is a frequent finding in tuberculous lymphadenitis[17], this fact does not give us a diagnosis of tuberculosis. In our cases, pulmonary Rx and CT scan of the thorax did not reveal lesions compatible with the diagnosis of pulmonary tuberculosis.

Mediastinal inflammatory lymph nodes, particularly tuberculous lymphadenitis[1,6-9] is a condition compressing the thoracic esophagus and causing dysphagia. Although mediastinal tuberculous lymphadenitis is rare, it is increasing in adults[18-20]. On the other hand, tuberculosis is an infectious disease with a rising incidence particularly in Asian and Eastern European countries and also a rising prevalence in association with HIV infection[21]. In 1993, tuberculosis was declared as a global emergency, by the World Health Organization[22].

Mediastinal tuberculous lymphadenitis should be included in the differential diagnosis of dysphagia, but it should be realized that it can present with various endoscopic and radiological findings. In fact, mediastinal tuberculous lymphadenitis can affect the esophagus by compressing the esophagus externally, causing rupture in the mediastinum and leading to an inflammatory process with secondary involvement of the esophagus, invading

the esophagus, ulcerating the mucosa and draining caseum into the esophageal lumen[9], as well as resulting in an esophageal fistula in some cases[23].

Dysphagia in mediastinal tuberculous lymphadenitis is due to the external compression on the esophagus, but the pain during swallowing - odynophagia occurring in one of our patients, suggested that the esophagus is directly involved in the inflammatory process. Interestingly, Ghmire and Walker[7] reported a case of mediastinal tuberculous lymphadenopathy who had painful dysphagia without significant involvement of the esophagus endoscopically and radiologically. They assumed that the contiguous inflammation of paraesophageal tissues resulted in disturbed esophageal motility of the patient.

In cases of tuberculous adenitis with esophageal mucosal lesion, confirmation of diagnosis should be done by histological or microbiological examination of the specimen obtained by endoscopic biopsy. In our cases without lesion of the mucosa, but with a strong suspicion that the cause for dysphagia is of tuberculous origin, EUS and endoscopic fine needle biopsy can play a role in diagnosing mediastinal masses that produce esophageal symptoms[5]. Other authors prefer biopsies guided by mediastinoscopy or thoracoscopy, when there is no mucosal lesion[24]. Nevertheless, when it is impossible to reach the affected lymph nodes through these approaches, surgery may be necessary in order to establish a diagnosis[1].

At present, minimally invasive surgery should be attempted to remove lesions diagnosed pre-operatively as probable leiomyomas. However, it was difficult, in the first case, to localize the lesion immediately below the aortic arch, on the left side of the esophagus associated with the surrounding fibrosis. In fact, it is hard to isolate the lesion in the presence of mediastinitis fibrosis resulting from rupture of an affected lymph node[25-27]. Medical treatment of most patients with tuberculosis consists of a short course in chemotherapy, using 3 or 4 essential anti-tuberculosis drugs (isoniazid, rifampicin, ethambutol, pyrazinamide and streptomycin). Anti TB regimen consists of an initial intensive phase and a continuation phase[22]. It was reported that most patients can be successfully treated with a three-drug anti-tuberculosis chemotherapy regimen[6,8,9,28]. If the diagnosis of mediastinal tuberculous lymphadenitis is made pre-operatively, such a treatment may lead to favourable outcomes[16,24]. Surgery should be reserved for patients with no pre-operative diagnosis, as in our cases, and those who develop complications, such as mediastinal abscess that is unresponsive to non operative management[1].

Since the diagnosis of a small esophageal submucosal lesion or an intraparietal lesion is usually difficult, surgery is necessary. Even though rare, the diagnosis of mediastinal tuberculous lymphadenitis should be highly considered in the presence of an uncertain esophageal lesion[29]. This is particularly important because a diagnostic non surgical approach is possible and an adequate treatment can completely cure mediastinal tuberculous lymphadenitis with or without tuberculous esophagitis[16].

Abstract

Malakoplakia, typically involving the urinary tract, is an uncommon form of chronic inflammation caused by chronic infections and characterized by accumulation of macrophages. It has also been found in many other sites such as the gastrointestinal tract, pancreas, liver, lymph nodes, skin, respiratory tract, adrenal gland, vagina and brain. We present a case of a 64-year-old man referred to our hospital with cachexia and radiologic evidence of metastatic tumor of the liver. Colonoscopy revealed a large malignant - appearing polypoid mass of the ascending colon and multiple distinct polyps throughout the rest of the colon. Biopsies of the ascending colon mass confirmed the diagnosis of adenocarcinoma. Histological examination of two of the other polyps revealed malakoplakia which was characterized by aggregates of granular histiocytes with Michaelis - Gutmann bodies and histochemically confirmed with periodic acid-Schiff and von Kossa stains. This is a rare case diagnosed on endoscopic samples. The majority of reported cases were found in surgical specimens. In addition, the endoscopic appearance of multiple polyps is unusual in malakoplakia.

INTRODUCTION

Malakoplakia, typically involving the urinary tract, is an uncommon form of chronic inflammation caused by chronic infections and characterized by accumulation of distinct macrophages[1,2]. It has also been found in various sites such as the gastrointestinal tract, pancreas, liver, lymph nodes, skin, respiratory tract, adrenal gland, vagina and brain[3]. We describe a case of a 64-year-old man with end-stage carcinomatosis which originated from the ascending colon and was associated with colonic malakoplakia. The endoscopic appearance of malakoplakia was very unusual, mimicking multiple polyps throughout the large bowel.

CASE REPORT

A 64-year-old man was admitted to our hospital with cachexia, ascites and multiple liver metastases, according to an abdominal CT scan. He reported a three-month history of fatigue, shortness of breath, altered bowel habits, weight loss and progressive abdominal distension. On examination he was pale and cachectic, and had a bulging abdomen with flank and shifting dullness. Blood pressure was 100/65 mmHg and pulse rate 94 beats/min. Hemoglobin was 8.1 g/dL and hematocrit 25%. Blood chemistry revealed cholestasis and 2.6 g/dL albumin and normal CEA levels. Abdominal CT scan revealed widespread hepatic metastases and a large quantity of ascetic fluid. Abdominal paracentesis and ascetic fluid cytology were compatible with peritoneal carcinomatosis. Colonoscopy revealed a large malignant polypoid lesion, almost obstructing the lumen of the ascending colon, as well as multiple (13) distinct polyps throughout the rest of the colon (5 rectal, 5 sigmoid, 3 transverse). The polyps were sessile, soft, ulcerated and hemorrhagic, measuring 5-15 mm in diameter (Figure 1). Two of them were removed in order to exclude a familial polyposis syndrome. The patient received only supportive treatment and subsequently died of liver failure-generalized carcinomatosis two weeks after hospitalization. Biopsies of the ascending colon mass confirmed the diagnosis of adenocarcinoma.

Histological examination of two of the other polyps revealed malakoplakia characterized by aggregates of granular histiocytes (Figure 2A). Several of these histiocytes contained intracytoplasmic Michaelis - Gutmann bodies (Figure 2B), which were confirmed

Figure 1 Endoscopic appearance of distinct polyps of the colon.

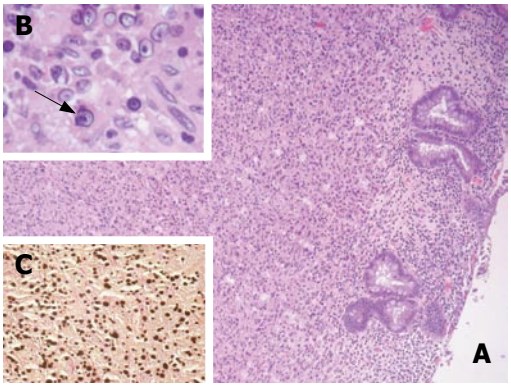

Figure 2 Aggregates of granular histiocytes in the lamina propria of large bowel mucosa (HE, × 200) (**A**), Michaelis - Gutmann bodies (HE, × 400) (**B**) and (Von Kossa, × 200) (**C**).

histochemically with periodic acid-Schiff and von Kossa stains (Figure 2C).

DISCUSSION

Malakoplakia, derived from the Greek adjective malakos (soft) and plaka (plaque), was first described in 1902 by Michaelis and Gutmann[4]. It occurs predominantly in the genitourinary tract (about 75% of the reported cases)[2]. The second most common site is the gastrointestinal tract (11% of the cases), and the majority of these cases involve the rectum and colon[5,6]. The remaining cases affect the brain, lungs, lymph nodes, adrenals, tonsils, conjunctiva, skin, bone, abdominal wall, liver, pancreas and retroperitoneum[3]. An increasing number of cases have been correlated with immunosuppression[7,8].

Definitive diagnosis of the lesion can be made by histopathologic examination. Malakoplakia is characterized by aggregates of histiocytes with abundant eosinophilic cytoplasm known as von Hansemann cells, intermingled with lymphocytes, plasma cells and neutrophiles. Finding the well-known Michaelis-Gutmann bodies is diagnostic for malakoplakia. These bodies are phagolysomes that have become encrusted with calcium and iron salts. They vary in size from 2 μm to 10 μm, have targetoid appearance due to concentric laminations and are stained with periodic acid-Schiff and von Kossa calcium stains. At the ultrastructural level, disintegrated bacteria have been occasionally observed in the Michaelis-Gutmann bodies. The origin of Michaelis - Gutmann bodies is most likely an abnormal response resulting in incompletely digested bacterial fragments and subsequent mineralization[1,9].

Indeed, malakoplakia is related to chronic bacterial infections, such as E*scherichia coli, Proteus mirabilis, Staphylococcus aureus, Mycobacterium Tuberculosis* and *Shigella boydii*. Fungi such as *Paracoccidiodes brasiliensis* and viruses have also been implicated[1,9,10]. In patients with AIDS, *Rhodococcus equi* has also been reported[11]. The pathogenesis of malakoplakia remains unknown. Three possible pathogenetic mechanisms have been suggested: an unusual causative organism, an abnormal or altered immune response and an abnormal macrophage response due to defective lysosomal function[12].

Colonic malakoplakia was first described by Terner and Lattes in 1965[13] and has been reported to occur in conjunction with tumors and non-tumoral conditions[14-16]. Since 1965 about 95 cases of colonic malakoplakia have been published. Notably, 24 of them had a coexistent colonic adenocarcinoma, similarly to our case[6]. All of the reported cases were found in surgical specimens, most of them in conjunction with the tumor. Half of the cases occured as a pericolic mass and only 3 cases as a single nodule or a microscopic focus[15].

However, our patient is a rare case in which the diagnosis of malakoplakia was made preoperatively on biopsy samples as previously described[17,18]. The additional biopsies were prompted by the presence of multiple small polyps in addition to the main cancerous one. The coexistence of multiple colonic polyps related to malakoplakia has not been described previously, the previously reported endoscopic appearances have been described as unifocal or nodular lesions and large masses, and the presence of a pericolonic mass associated with a fistula has been noted[6].

Notably, von Hasselman histiocytes can mimic adenocarcinoma cells in frozen sections. A helpful clue for the correct diagnosis is the presence of Michaelis-Gutmann bodies which are not seen in mucin vacuoles.

Our case may serve as a reminder of the clinical significance of malakoplakia coexisting with colonic adenocarcinoma, which increases the risk of over-staging the tumor and over-treating the patient.

Abstract

There are no reports regarding perforation of the colorectum induced by anorectal manometry. We report two cases of colorectal perforation that occurred during manometry in the patients undergoing restorative proctectomy for distal rectal cancer. In the first patient, computed tomography showed an extraperitoneal perforation in the pelvic cavity and a rupture of the rectal wall. A localized perforation into the retroperitoneum was managed conservatively. In the second patient, a 3 cm linear colon rupture was detected above the anastomotic site. A primary closure of the perforated colon and proximal ileostomy were conducted, but the patient died 2 wk later. We hypothesize that the perforation induced by anorectal manometry may be associated with the relative weakening of the proximal bowel wall due to anastomosis, decreased compliance, and abnormal rectal sensation. We suggest that measurement of the maximum tolerable volume should not be routinely performed after restorative proctectomy for distal rectal cancer.

Key words: Iatrogenic perforation; Anorectal manometry; Rectal cancer; Low anterior resection

INTRODUCTION

Anorectal manometry is an objective test for evaluating a patient's resistance to spontaneous defecation provided by the sphincter mechanism, as well as the sensory capabilities of the rectum in terms of the sensation of imminent defecation[1]. Currently, anorectal manometry is widely performed for the tracking of anorectal physiological changes occurring after low anterior resection for rectal cancer, as the test allows for a numerical value evaluation of pre- and post-operative anorectal function, including rectoanal inhibitory reflex, rectal compliance, and anal resting pressure[2-4]. This procedure is generally thought to be safe, and the incidence of critical complications associated with anorectal manometry has not been reported. We recently encountered two unusual cases of iatrogenic perforation occurring following anorectal manometry in rectal cancer resection patients.

CASE REPORT

Case 1

A 72-year-old male patient received ultra-low anterior resection with coloanal anastomosis for the treatment of rectal cancer 22 mo ago. The patient's primary tumor was located 4 cm from the anal verge. He complained of frequent defecation in excess of 10 bowel movements a day, as well as urgency and tenesmus. We performed anorectal manometry in order to measure changes in the patient's anorectal function. Anorectal manometry (Model UPS-2020 Stationary GI Motility System, MMS, Netherlands) was conducted using the water-perfusion technique, with an 8-channel micro tip catheter connected to a perfusion pump. We evaluated the rectal sensation *via* inflation of a latex balloon with an air flow of 1 mL per second. The threshold volumes for the first minimum sensation, defecatory desire, urge, and maximum tolerance were determined. In this study, the maximum resting pressure (48.25 mmHg) determined was significantly lower than that observed in the normal controls (normal value:

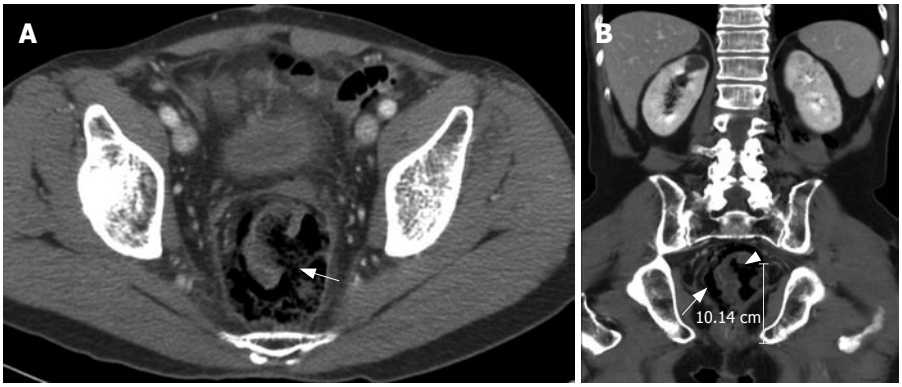

Figure 1 Abdomino-pelvic CT at the level of acetabula showing air bubbles mixed with small solid particles surrounding both lateral aspects of the rectum (arrow) (**A**) and coronal view of extraluminal air in the pelvic cavity (arrow) and rupture of the left lateral wall of the rectum (arrow head) (**B**).

53-90 mmHg), and the maximum squeezing pressure (117 mmHg) was not reduced in comparison with the normal controls (normal value: 100-200 mmHg). During the test, the patient complained of slight discomfort in the lower abdomen during measurement of the maximum tolerable volume. When the balloon catheter was removed, however, the surface of the balloon observed was slightly blood stained. As the patient had normal vital signs and appeared to be relatively healthy, he was discharged after examination. Seven hours later, the patient revisited the emergency room because of persistent lower abdominal pain, anal pain, and a sensation of "chilling". Upon physical examination, the patient experienced mild lower abdominal tenderness with palpation but no symptoms of generalized peritonitis. His temperature was 39.2℃ initially, and decreased within three hours to 38.5℃. His heart rate was 110 per minute and no hypotension was found. The most noteworthy feature of his laboratory studies was an elevated white blood cell count of 17 000/mm^3. Upright chest and abdomen films were normal. However, abdominal CT showed a moderate amount of extraperitoneal air in the pelvic cavity and a rupture of the rectal wall (Figure 1A and B). Perforation into the retroperitoneum was localized, and no signs of intraperitoneal perforation were observed. The patient was hospitalized and received no treatment by mouth, total parenteral nutrition, and intravenous broad-spectrum antibiotics. Daily physical examinations were conducted. We verified improvement in radiologic signs on a CT examination conducted seven days later. The patient was discharged on the 14th d of hospitalization.

Case 2

A 78-year-old female patient underwent an ultra-low anterior resection and coloanal anastomosis following preoperative radiotherapy (50.4 Gy during 5 wk) coupled with infusion of 5-FU for low rectal cancer 23 mo ago. The patient had a history of angioplasty due to unstable angina 4 years ago. She presented at the hospital for frequent defecation and urgency to defecate, which persisted after surgery. We performed anorectal manometry to measure the function of her anorectum in the same manner as in Case 1. No abnormalities were detected with the exception of loss of rectoanal inhibitory reflex and a reduction in resting pressure. However, when the rectal balloon was gradually inflated with 130 mL air for measurement of the maximum tolerable volume, a steep fall in intra-balloon pressure (from 130 mmHg to 65 mmHg) was detected, and the examiner could actually feel her resistance against the decrease in air injection. During the test, she complained of an abrupt discomfort in the abdomen and abdominal distension. An urgent CT scan of the abdomen and pelvis was conducted, which evidenced a large quantity of free intraperitoneal gas and fluid within the abdomen consistent with the perforation of a gas-containing viscous body (Figure 2). Emergency laparotomy was immediately conducted, and a 3 cm linear colon rupture was detected above the coloanal anastomosis suture area. Accordingly, primary closure of the perforation site and a diverting ileostomy were performed. The patient's underlying heart condition deteriorated rapidly after surgery, and she died two weeks later, despite aggressive resuscitation.

Figure 2 Abdomino-pelvic CT at pelvis level showing a large amount of extraluminal air (arrow heads) mixed with a complicated collection of fluids, probably primary extraluminal feces (arrow).

DISCUSSION

We experienced two iatrogenic colorectal perforations (0.13%) in 1501 anorectal manometry tests in the past three years. Both patients had a history of rectal cancer resection. Anorectal manometry has been widely adopted as a means for evaluating physiological changes in the anus and rectum of patients undergoing low anterior resection. To our knowledge, no iatrogenic perforation has been reported as a complication arising from anorectal manometry conducted following low anterior resection[3,5-7].

We consider that this colorectal perforation is

associated with certain characteristics of the neorectum following low anterior resection and anastomosis, including relative weakening of the proximal bowel wall due to anastomosis, decreased compliance, and abnormal rectal sensation. The pressure of balloon inflation can exert undue stress on the weakened proximal bowel wall to fibrotic anastomosis, causing rupture on the neorectum. The vulnerable part, which evidences low compliance, can be readily ruptured by the application of physical force via artificial balloon inflation. As the rectal balloon is inflated, patients are instructed to inform the examiner of the rectal sensation according to changes in the air injection level. However, patients with dull rectal sensation are not able to appropriately express it. In the case of the aged, who undergo rectal surgery or to whom radiotherapy is administered, there is some risk that the balloon may be inflated over the actual maximum threshold volume.

In treatment of iatrogenic colonic perforation, nonoperative management of colonic perforation is advocated for patients who are clinically stable with no evidence of peritonitis[8-10]. For selected patients with incidental intramural or small retroperitoneal perforations but no evidence of barium spillage, favorable results have also been reported as the result of conservative treatment consisting of bowel rest combined with total parenteral nutrition, intravenous fluid treatment, and broad-spectrum antibiotics[11,12]. On the basis of our experience with the two cases, this indication for conservative management after iatrogenic perforation may also be applied to perforation occurring during anorectal manometry. However, we believe that there may be a higher risk for perforation during anorectal manometry than for other types of perforation because (1) anorectal manometry is conducted without reasonable bowel preparation and (2) diagnostic delays are likely to occur as physicians tend not to recognize the possibility of perforation. Therefore, a more cautious approach should be taken when selecting patients who can receive conservative treatment for perforation occurring during anorectal manometry.

In order to avoid iatrogenic perforations during anorectal manometry, it is important to assess the high risk factors associated with perforation prior to anorectal manometry. History taking should focus on age, previous rectal surgery, bowel inflammation, and bowel obstruction. Meticulous digital rectal examination preceding anorectal manometry, for the detection of unsuspected anorectal abnormal lesions, is necessary for patients with a history of rectal surgery. This facilitates catheter insertion and provides information on anorectal conditions. We believe that the process of measuring the maximum tolerable volume may be omitted in patients following low anterior resection and anastomosis for distal rectal cancer. The maximum tolerable volume may be highly distorted in patients undergoing rectal resection in comparison with patients with normal rectum, as sensations of rectal distension differ in accordance with the patterns and rates of balloon inflation, which are dependent on examiners and laboratories[13]. We suggest that measurement of the maximum tolerable volume should not be routinely performed in patients undergoing restorative proctectomy for distal rectal cancer.

Abstract

We report a 55-year-old male who developed advanced hepatic metastasis and peritoneal carcinomatosis after resection of remnant gastric cancer resection 3 mo ago. The patient only received epidermal growth factor (EGF) receptor antibody (Cetuximab) plus recombinant human endostatin (Endostar). Anti-tumor activity was assessed by ^{18}F-fluorodeoxyglucose (^{18}F-FDG) positron emission tomography/computer tomography (PET/CT) at baseline and then every 4 wk. The case illustrates that ^{18}FDG-PET/CT could make an early prediction of the response to Cetuximab plus Endostar in such clinical situations. ^{18}FDG-PET/CT is a useful molecular imaging modality to evaluate the biological response advanced hepatic metastasis and peritoneal carcinomatosis to Cetuximab plus Endostar in patients after remnant gastric cancer resection.

Key words: Hepatic metastasis; Remnant gastric cancer; Cetuximab; Recombinant human endostatin; ^{18}F-fluorodeoxyglucose; Positron emission tomography/computer tomography

INTRODUCTION

The activity of epidermal growth factor (EGF) and its receptor (EGFR) has been identified as the key driver in the process of cell growth and replication. There is now a body of evidence that EGFR-mediated drive is increased in a wide variety of solid tumors, including non-small cell lung cancer, prostate cancer, breast cancer, gastric cancer, colon cancer, ovarian cancer and tumors of the head and neck[1]. EGFR antibody (Cetuximab, Erbitux, Merck and Imclone Systems) has been approved by the Food and Drug Administration (FDA)[2] for use in treatment of colorectal cancer. Angiogenesis is the formation of new capillaries from existing blood vessels. The recognition of tumor angiogenesis as a therapeutically useful target is based on experimental evidence that tumor growth and progression are dependent on new blood vessel formation. Endostatin has been shown to inhibit potently angiogenesis *in vitro* and *in vivo* and Endostar (Medgenn Bioengineering Co. Ltd. Yantai, Shandong, P. R.China.) has been approved by the State Food and Drug Administration (SFDA)[3]. In this case, we used ^{18}FDG-PET/CT to monitor the early response of advanced hepatic metastasis and peritoneal carcinomatosis to Cetuximab plus Endostar in patients after remnant gastric cancer resection.

CASE REPORT

A 55-year-old male, with a history of subtotal gastrectomy for gastric ulcer 20 years ago, received remnant gastric cancer resection 3 mo ago. Immunohistochemistry revealed adenocarcinoma of the stomach with expression of EGFR. Episodes of fever above 40℃ appeared without evidence of infection and mild jaundice developed with weight loss of 10 kg within 1 mo. A palpable liver and tenderness of the left upper abdominal quadrant were found during physical examination. Laboratory findings during the first admission showed 55 g/L HGB, 41.4 μmol/L TBIL, 12.9 μmol/L DBIL, and 28.5 μmol/L IBIL. Advanced hepatic metastasis and peritoneal carcinomatosis were confirmed by ^{18}F-fluorodeoxyglucose positron emission tomography/computer tomography (^{18}F-FDG PET/CT) and biopsy guided by ^{18}F-FDG PET/CT. These findings were supportive for tumor-associated cachexia because his overall performance status was significantly reduced (Karnofsky index: 40%). Conventional chemotherapy was not considered the first choice of

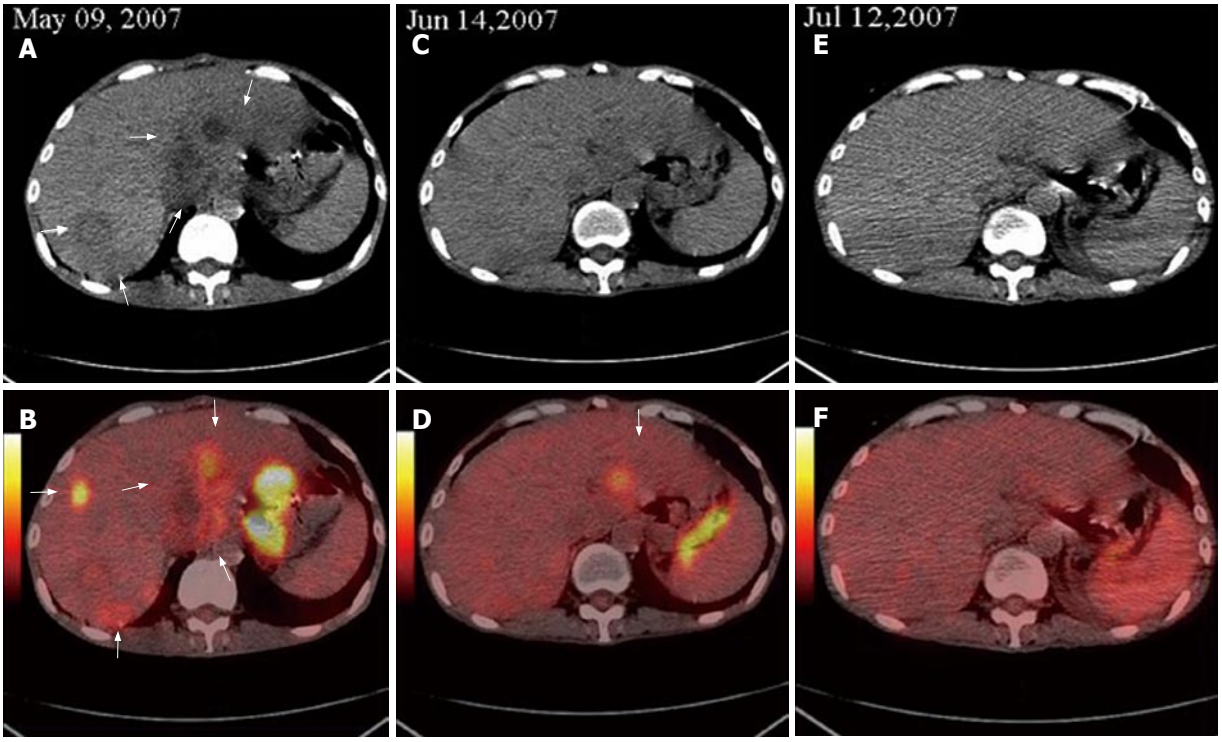

Figure 1 Base line FDG PET/CT detecting a highly metabolic metastasis in liver (white arrows, **A** and **B**), second FDG PET/CT demonstrating the decreased number and metabolism level of liver metastases and one highly metabolic metastasis in the left lobe of liver (white arrows, **C** and **D**), third FDG PET/CT displaying no lesion at the same position (**E** and **F**).

treatment for the patient. After giving informed consent, the patient received Cetuximab weekly at 400 mg/m^2 iv loading dose, followed by at 250 mg/m^2 iv maintenance dose for 8 wk, together with but separately used Endostar daily at 15 mg iv loading dose and maintenance dose for over 8 wk. Anti-tumor activity was assessed by ^{18}F-FDG PET/CT at baseline and then every 4 wk. During the 8-wk follow-up period of time, ^{18}F-FDG PET/CT was performed 3 times to monitor the treatment response. His temperature returned to normal slowly after 4 wk of treatment. Cetuximab exhibited only mild skin toxicity, and hepatic metastasis and peritoneal carcinomatosis lesions had a partial response to Cetuximab treatment (> 30% reduction, according to RECIST) after 4 wk (Figure 1 and Figure 2). Main laboratory tests showed 70 g/L HGB, 21.4 μmol/L TBIL, 13.9 μmol/L DBIL, 16.5 μmol/L IBIL. Karnofsky index was 70%. Due to responses to the treatment without serious complications, after the second treatment cycle, hepatic metastases were almost completely gone on the third ^{18}F-FDG PET/CT (Figures 1 and 2). However, a few metastatic lymphoid nodes in the abdomen could be detected (Figure 3). In parallel, main laboratory tests showed 90 g/L HGB, 20.4 μmol/L TBIL, 12.9 μmol/L DBIL, 15.5 μmol/L IBIL. Karnofsky index was 80%. Due to the confirmed responses to the treatment, the third cycle of treatment was going on when this paper was completed.

DISCUSSION

Multiple cellular pathways involved in the growth and metastatic potential of tumors may create heterogeneity, redundancy, and the potential for tumors to bypass signaling pathway blockade, resulting in primary or acquired resistance. Combined therapies are more effective in inhibiting different signaling pathways and can overcome tumor resistance[4]. Vascular endothelial growth factor (VEGF) and EGFR inhibitors have become the key components of therapies for several tumor types. There is a close relationship between these two factors. VEGF signaling is up-regulated by EGFR expression while VEGF up-regulation independent of EGFR signaling seems to contribute to resistance to EGFR inhibition. Therefore, inhibition of both pathways improves anti-tumor efficacy and overcomes resistance to EGFR inhibition[5].

EGFR belongs to a family of receptors known as the ErbB family (ErbB tyrosine kinase receptors), which comprises four proteins encoded by the c-erbB proto-oncogene. EGFR can activate a cascade of multiple signaling pathways that facilitate tumor growth process[6]. The EGFR signaling pathway regulates cell differentiation, proliferation, migration, angiogenesis, and apoptosis, all of which are down regulated in cancer cells. In a study, EGFR immunoreactivity was detected in one (3.8%) of the 26 early gastric carcinomas and in 33 (34.4%) of the 96 advanced gastric carcinomas, respectively, the incidence of expression between the two groups was significantly different[7]. In gastric cancer, the management of peritoneal dissemination in the peritoneal cavity is extremely important. However, peritoneal dissemination in the final stage of gastric cancer remains untreatable. VEGF is correlated with peritoneal metastasis from gastric cancer, and has been reported as a useful indicator of peritoneal recurrence[8].

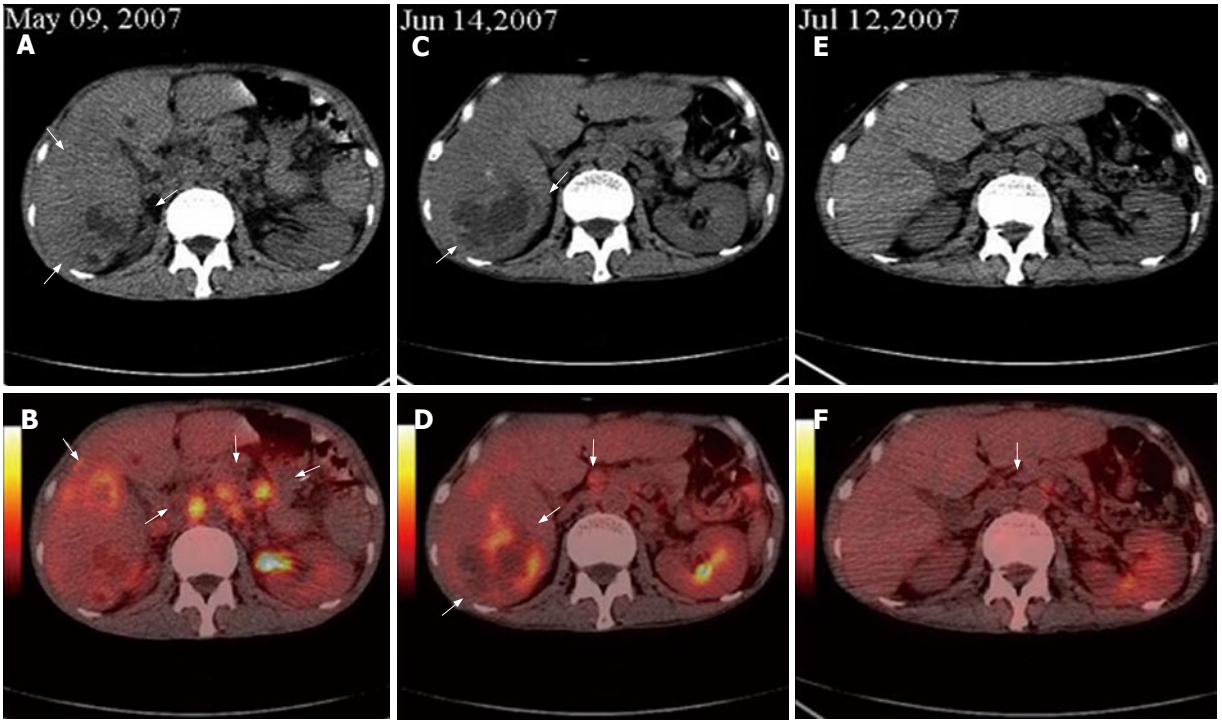

Figure 2 Base line FDG PET/CT detecting huge metastases in the right lobe of liver and highly metastatic lymphoid nodes in abdomen (white arrows, **A** and **B**), second FDG PET/CT demonstrating huge metastases in the right lobe of liver and the decreased number, size and metabolism level of metastatic lymphoid nodes (white arrows, **C** and **D**), third FDG PET/CT displaying the disappeared huge metastases in the right lobe of liver and the normal size of metastatic lymphoid nodes (**E** and **F**).

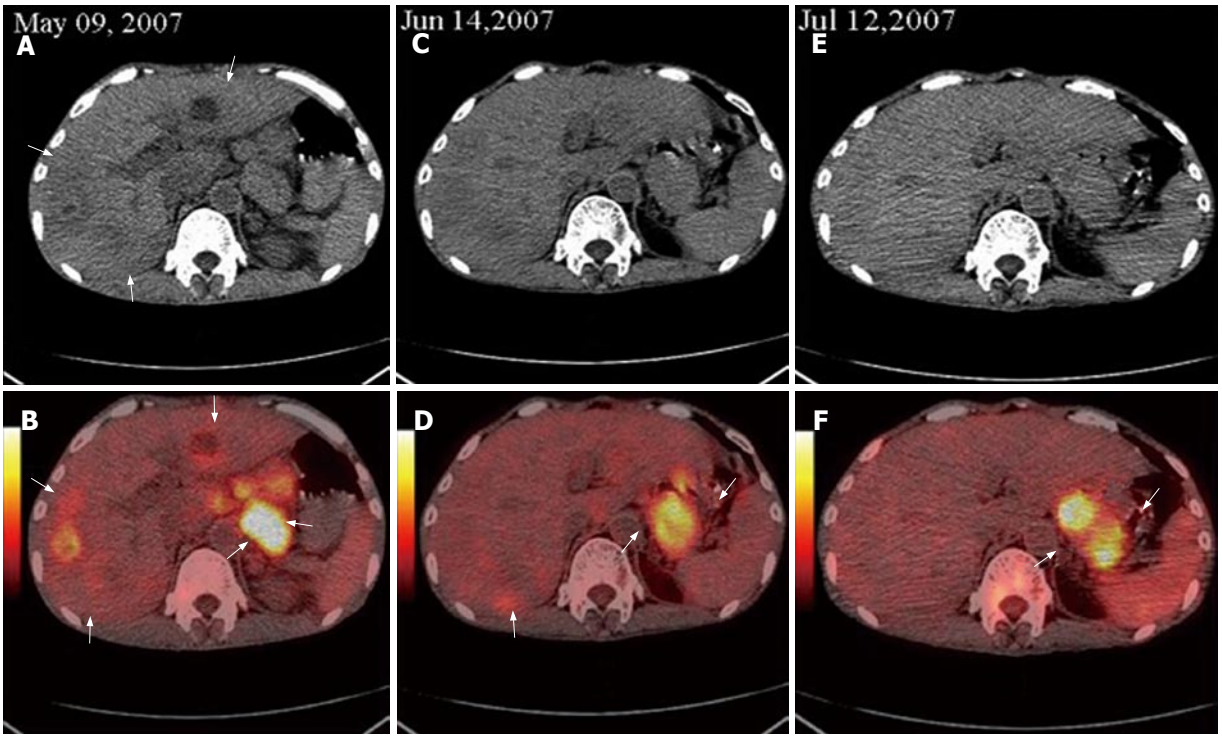

Figure 3 Base line FDG PET/CT detecting multi high metastases in both lobes of liver and highly metastatic lymphoid nodes in abdomen (white arrows, **A** and **B**), second FDG PET/CT demonstrating multi high metastases in the liver and the decreased number, size and metabolism level of metastatic lymphoid nodes (white arrows, **C** and **D**), third FDG PET/CT displaying disappeared liver metastasis and metastatic lymphoid nodes (**E** and **F**).

Cetuximab is a chimeric IgG1 monoclonal antibody and binds to EGFR with a high specificity and a higher affinity than either EGF or TGF-α, thus blocking ligand-induced phosphorylation of EGFR. Second line therapies with Cetuximab for colorectal cancer after failure of first-line regimes have shown a response rate of 17%-23% and an overall survival (median) of 8.6 mo[9]. Endostar is a new recombinant human endostatin developed by Medgenn

Bioengineering Co. Ltd (Yantai, Shandong, China) in 2005. A preclinical study indicated that endostar could inhibit tumor endothelial cell proliferation, angiogenesis and tumor growth, and results from prospective trials addressing the response of colorectal cancer to Cetuximab containing regimes have confirmed its efficacy in clinical practice[10].

Modern cancer care is critically dependent on imaging technologies, which are used to detect early tumors and guide their therapy or surgery[11]. Molecular imaging technologies provide information about the functional or metabolic characteristics of malignancies, tumor stage and therapeutical response, and tumor recurrence, whereas conventional imaging technologies predominantly assess the tumor's anatomical or morphologic features including its size, density, and shape, *etc*. Since conventional imaging technologies reveal morphology of lesions with nonspecific features, differentiation between malignant and benign lesions could be improved by molecular imaging. As our knowledge about the molecular basis of cancer increases, imaging methods that provide clinicians with telling details about the molecular environments of patients' tissues are needed. By using standard anatomic imaging technologies combined with molecular imaging technologies such as PET/CT, we can detect disease processes at the anatomic, physiologic, metabolic, and molecular levels, thereby, allowing earlier detection of diseases, monitoring of therapies, and better prognostication of disease progression[12].

The precise tailoring of treatment for patients with cancer is a challenge. PET/CT and SPECT/CT help achieve better results[13]. PET with the glucose analog ^{18}F-FDG is increasingly used to monitor the effectiveness of therapy for patients with malignant lymphomas and solid tumors. Quantitative assessment of therapy-induced changes in tumor ^{18}F-FDG uptake can predict tumor response and patient outcome early in the course of therapy. Treatment may be adjusted according to the chemosensitivity and radiosensitivity of tumor tissue in an individual patient. Thus, ^{18}F-FDG PET has a potential to reduce the side effects and costs of ineffective therapy[14]. The use of integrated PET/CT instead of PET in treatment monitoring poses some methodologic challenges against the quantitative analysis of PET scans. However, it may provide the opportunity to integrate morphologic and functional information. This integration may define new parameters for assessment of tumor response and facilitate the use of PET in studies as well as in clinical practice[14]. In our case, a partial response (> 30% reduction, according to RECIST) of hepatic metastasis and peritoneal carcinomatosis lesions was achieved after 4 wk of treatment with Cetuximab plus Endostar.

In conclusion, our case demonstrates that molecular imaging could monitor molecular treatment and combination of EGFR-specific antibodies with VEGF-specific antibodies may be a promising treatment modality. Further prospective trials are mandatory to confirm its effects and discriminate Cetuximab-induced response from Endostar-associated response. The potential of this novel approach to anticancer therapy should be elucidated in large clinical trials.

Abstract

Eosinophilic cholecystitis is an infrequent form of cholecystitis. The etiology of eosinophilic cholecystitis is still obscure, and it is sometimes accompanied with several complications, but a simultaneous onset with pericarditis is very rare. We would like to make an alternative interpretation of our recent report "Kaji K, Yoshiji H, Yoshikawa M, Yamazaki M, Ikenaka Y, Noguchi R, Sawai M, Ishikawa M, Mashitani T, Kitade M, Kawaratani H, Uemura M, Yamao J, Fujimoto M, Mitoro A, Toyohara M, Yoshida M, Fukui H. Eosinophilic cholecystitis along with pericarditis caused by Ascaris lumbricoides: A case report. World J Gastroenterol 2007; 13: 3760-3762."

Key words: Cholecystitis; Visceral larva migrans; Parasite; *Ascaris suum; Toxocara canis*

TO THE EDITOR

Eosinophilic cholecystitis is an infrequent form of cholecystitis. The etiology of eosinophilic cholecystitis is still obscure, and it is sometimes accompanied by several complications, but a simultaneous onset with pericarditis is very rare[1-3].

We would like to make an alternative interpretation of our recent report "Kaji K, Yoshiji H, Yoshikawa M, Yamazaki M, Ikenaka Y, Noguchi R, Sawai M, Ishikawa M, Mashitani T, Kitade M, Kawaratani H, Uemura M, Yamao J, Fujimoto M, Mitoro A, Toyohara M, Yoshida M, Fukui H. Eosinophilic cholecystitis along with pericarditis caused by Ascaris lumbricoides: A case report. *World J Gastroenterol* 2007; 13: 3760-3762." We reported that this rare clinical manifestation was caused by *Ascaris lumbricoides*. However, from the serological diagnosis, it was likely that these clinical symptoms were visceral larva migrans (VLM) caused by *Ascaris suum* or *Toxocara canis* rather than by *Ascaris lumbricoides*. While a definitive diagnosis of parasitic diseases is established after the detection of worms or eggs from the patient, the direct detection of the worm is quite rare. As we described in the report, we could not make a direct detection of the worm either. Generally, food-borne parasitic infection can be diagnosed based on the raw food intake history, laboratory data such as hypereosinophila, and the presence of antibody against the parasite in the serum. Our patient revealed a higher titer of antibody against *Ascaris suum* and *Toxocara canis* by enzyme-linked immunosorbant assay by 150 and 100 fold as compared with the control serum. Nevertheless, we can not rule out the possibility that it is caused by *Ascaris lumbricoides*. *Ascaris lumbricoides* also could penetrate the gastrointestinal tract.

In conclusion, since the title was too high in our study, we had to consider other alternative possibilities of VLM caused by *Ascaris suum* or *Toxocara canis* as described above, and we believe that this letter would help make our previous report more easily understood and legible for the readers.

Abstract

News release to the latest science findings is beneficial to both researchers and their served institutions as well as the public. It will help to set a bridge of communication between researchers, the public and media, and publishers, making the latest research findings well known to the public. *World Journal of Gastroenterology* has currently freely opened the News Release Service System (*WJG*-NRSS) for original articles with potential significance and novelty for news release to mass media to broaden the findings to the public.

Chang YD. Science news release and its benefits to your research. *World J Gastroenterol* 2007; 13(45): 6120-6121

http://www.wjgnet.com/1007-9327/13/6120.asp

News release to your research findings before publication in mass media is beneficial to both researchers and their served institutions. It will help to bridge the communication among researchers, the public and media, and publishers, particularly making the latest findings of the researchers well known to the public. An investigation from The New England Journal of Medicine shows that the citation rate of an article increase seven times when the findings of an article have been reported by New York Times.

World Journal of Gastroenterology (*WJG*) has currently freely opened the News Release Service System (*WJG*-NRSS) for the authorized reporters for news release in mass media such as EurekAlert!. As one of the registered members with identity of an international peer reviewed journal, *WJG* has been authorized to release science news on EurekAlert! (Figure 1).

As an online, global news service operated by AAAS, the science society, EurekAlert! is one of the central places through which *WJG* can bring the authors' latest findings to the media and public. *WJG* science news features the resources focused on all original articles with both significance and novelty. EurekAlert! has 923 registered entities including *WJG*, and has timely delivery of the released news to the public and its 5400 journalists worldwide.

Figure 1 *WJG* as a registered member to EurekAlert! with an identity of an international peer reviewed journal.

WJG has encouraged those articles with both significance and novelty to release news before its publication on EurekAlert! so that more readers could share the researcher's latest findings and ongoing research. The sample science news released by *WJG* on EurekAlert! are shown in Table 1. The number of hits shows that the four science news with amusive titles have been very attractive to readers.

An excellent news is very essential to achieve the expectations. In addition to basic guidelines for general news writings, we recommend some specific guidelines for our reporters in *WJG* science news writings. News titles may be different from the original article but should be attractive and informative. The main body of news is less than 1000 words with a summary of both less than 75 words. Interesting pictures are also strongly recommended. The deadline for news submission is about one week before publication. Since most readers to science news are not experts, journalists should avoid scientific jargon and use everyday language in news writings regardless of the topic or content. Finally but importantly, be sure the science news is lawful and ethical.

Global Collaboration for Gastroenterology

For the first time in the history of gastroenterology, an international conference will take place which joins together the forces of four pre-eminent organisations: Gastro 2009, UEGW/WCOG London. The United European Gastroenterology Federation (UEGF) and the World Gastroenterology Organisation (WGO), together with the World Organisation of Digestive Endoscopy (OMED) and the British Society of Gastroenterology (BSG), are jointly organising a landmark meeting in London from November 21-25, 2009. This collaboration will ensure the perfect balance of basic science and clinical practice, will cover all disciplines in gastroenterology (endoscopy, digestive oncology, nutrition, digestive surgery, hepatology, gastroenterology) and ensure a truly global context; all presented in the exciting setting of the city of London. Attendance is expected to reach record heights as participants are provided with a compact "all-in-one" programme merging the best of several GI meetings. Faculty and participants from all corners of the earth will merge to provide a truly global environment conducive to the exchange of ideas and the forming of friendships and collaborations.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

Treatment of chronic pancreatitis has been exclusively surgical for a long time. Recently, endoscopic therapy has become widely used as a primary therapeutic option. Initially performed for drainage of pancreatic cysts and pseudocysts, endoscopic treatments were adapted to biliary and pancreatic ducts stenosis. Pancreatic sphincterotomy which allows access to pancreatic ducts was firstly reported. Secondly, endoscopic methods of stenting, dilatation, and stones extraction of the bile ducts were applied to pancreatic ducts. Nevertheless, new improvements were necessary: failures of pancreatic stone extraction justified the development of extra-corporeal shock wave lithotripsy; dilatation of pancreatic stenosis was improved by forage with a new device; moreover endosonography allowed guidance for celiac block, gastro-cystostomy, duodeno-cystostomy and pancreatico-gastrostomy. Although endoscopic treatments are more and more frequently accepted, indications are still debated.

Key words: Chronic pancreatitis; Endoscopic treatment

Heyries L, Sahel J. Endoscopic treatment of chronic pancreatitis. *World J Gastroenterol* 2007; 13(46): 6127-6133

METHODS

Endoscopic treatment needs a team (operator, anaesthesiologist) aware with Endoscopic Retrograde Cholangiopancreatography (ERCP) procedures. Specific material is necessary: good fluoroscopy with the possibility to magnify pictures, and a duodenoscope with a 4.2 channel allowing insertion of high calibre stent (10 Fr). Moreover, a wide variety of endoscopic ancillary instruments is essential: metallic and hydrophilic guide-wire, sphincterotomes, Dormia basket, balloon dilatators and bougie dilatators (5-11.5 Fr), but also very thin guide wire (0.025 inches), fine-tipped sphincterotomes, Soehendra extractors (cf infra)[1]. Impaction of stones in pancreatic ducts needs the use of extracorporeal shock wave lithotripsy before endoscopic stone extraction[2]. Endoscopic treatment also needs naso-pancreatic drains and pancreatic stents that are either polyethylene or Teflon. The choice of length, pattern or external calibre of the stent is decided according to the anatomy of pancreatic ducts. Usually, straight stents with proximal and distal external flaps (to avoid internal or external migration), are used. Other stents like single or double pig-tail stents can be used also.

Endoscopic pancreatic sphincterotomy (PS)

Firstly described by Fuji[3], PS is generally performed as the first step in order to improve access to the pancreatic duct. A short (5-6 mm) sphincterotomy is oriented at 13 h with a pure section cutting. Narrowness of pancreatic ducts has justified using special device (thin 0.025 guide-wire, fine-tipped sphincterotome). Biliary sphincterotomy, which was firstly recommended before PS, seems not to be systematically performed because, contrary to the firstly experience, PS alone is not associated with a secondary biliary stenosis[4].

Complications of PS occur in 4.2%-12.6% of cases[4,5]. The morbidity rate also depends on other endoscopic procedures done at the same time such as pancreatic stenting or stricture dilatation. It also depends on the inclusion of patients presenting with recurrent attacks of pancreatitis secondary to sphincter of Oddi dysfunction. In this case, morbidity rate is higher, reaching 12.5%[6]. PS is probably no more or no less harmful than a biliary sphincterotomy which is associated with a morbidity rate of 5.4%-9.8% of cases[7-9]. Morbidity of PS seems also lower in case of post-PS drainage with a naso-pancreatic drain or a pancreatic stent[6]. In case of complete obstruction of the main pancreatic duct in the head, it is sometimes possible to access to the body of the pancreatic duct through the accessory papilla.

Treatment of pancreatic duct strictures by dilatation and stenting

The procedure consists in setting a 3-4 m length, hydrophilic-top guide wire deep inside the main pancreatic duct to realise a stricture dilatation with balloon or dilatators in order to insert a stent the calibre (5-10 Fr) and length (3-12 cm) of which depends on pancreatic duct anatomy. The length of the stent is adapted to bridge the stenosis (duct stricture and/or stone); the calibre of the stent depends on the highest calibre of dilatator successfully inserted through the duct stricture.

In practice, chronic pancreatitis duct strictures are more difficult to pass than biliary stenosis. They are usually associated with an impacted stone which may prevent deep insertion of the guide-wire into the main pancreatic duct. Moreover, pancreatic duct strictures are often narrow and tight because of expanding pancreatic fibrosis. For these reasons, a high rate of failure of dilatation of pancreatic stricture has been reported. Recently, a new technique of dilatation has been reported by Brand *et al*[1]. who used a device (*Soehendra extractor*) previously designed for the extraction of migrated biliary stents. Forage is realised by screwing this instrument through pancreatic duct stenosis on the guidance of a guide-wire. The morbidity rate is low (0%-13%) because forage is realized in a fibrotic area. Finally, among patients with a stricture which could not be passed with a 7 Fr dilatator, this device (7 Fr or 10 Fr) allowed to pass over the stenosis in all cases[1,10].

Plastic stents are clogged by lithostatine precipates, carbonate of calcium and bio bacterial film in a mean time of four to six mo[11,12]. Therefore, stents have to be retrieved or exchanged every four mo during a variable stenting length of time according to the main series (2-12 mo)[13]. Some authors prefer to leave the pancreatic stent and to exchange it only in case of recurrence of symptoms or infection but this strategy is associated with a risk of complications[14]. Metallic stent has been proposed because of a longer time of patency but those stents could also be completely obstructed by intra-luminar inflammatory granuloma with a risk of septic complication[15]. The morbidity rate of pancreatic stenting is widely varied in series. Early complications (before d 30 after ERCP) are distinct of late complications (> 30 d). The main early complication is acute pancreatitis (5%-39%), most of cases are benign, oedematous, spontaneously resolutive forms. A few cases of pancreatic abscess or cholangitis have been reported in the preliminary publications[15,16]. Late complications are stent-related: although stent migration is rare (5%), stent occlusion is very frequently encountered. Ductal lesions after stenting (dilatation, irregularity, stenosis) have been reported in 21%-80% of cases[17]. These lesions are associated with endosonographic parenchymal signs in 68% of cases[18]. In fact, in more than half of the cases, stenting-ductal lesions will regress four mo after retrieval of the stent[17].

Pancreatic stones extraction and lithotripsy

Pancreatic stones may be retrieved only after a previously PS. Since pancreatic stones are often impacted in the pancreatic duct upstream a duct stenosis, extraction of pancreatic stones is more difficult than extraction of biliary stones. Many difficulties have to be solved before: stenosis above stones have to be dilated, stones have to be fragmented with extracorporeal shock wave lithotripsy (ESWL). After good results obtained for biliary and kidney stones, ESWL has been firstly proposed for pancreatic stones in 1987[2]. There are three kinds of lithotripter generators: electro magnetic, electro hydraulic and piezo-electric. Stones are visualised under fluoroscopic or ultrasonographic guidance or both, treatment is realized in pro-cubitus position, under general analgesia or sedation.

Results of the major series are reported on Table 1.

Table 1 Results of extracorporeal shock wave lithotripsy

Total	264	1.6-4.6	17-79	85-100	50-75

Without ESWL, complete clearance of pancreatic stones was less than 40%. ESWL is successful in 85%-100% of cases and wash-out of stones was obtained in 50%-75%. Pain disappeared in 17%-79% of cases[19-23]. Morbidity of ESWL is difficult to distinguish from the morbidity related to other endoscopic procedures. Nevertheless, main adverse events of ESWL are abdominal pain and attack of acute pancreatitis. Success factors are more dependant of the site than the size of the stone: juxta-papillary and main pancreatic duct stones are easier to extract than stones located in the tail or in the side branches. Large stones seem easier to break because easier to localize. Duct stenosis is often associated with a pancreatic stone and is a factor of recurrence of pain despite a complete clearance. Fragments of stones are retrieved through PS during a new ERCP, using an extractor-balloon or a Dormia basket; a naso-pancreatic drain is sometimes left to wash the pancreatic ducts during 48 h[22].

Endoscopic drainage of pancreatic cysts and pseudo-cysts

Drainage of pancreatic cysts is realised through the stomach wall (gastro-cystostomy) or duodenum wall (duodeno-cystostomy) in case of trans-mural drainage or through the papilla in case of trans-papillary drainage. The trans-mural way is dedicated to bulging cysts into the stomach or duodenum. A diathermic puncture is realized perpendicularly on the site of maximal bulge. After insertion of the catheter deep inside the cyst cavity, a sample of cyst fluid is taken for bacteriologic, biochemical and cytological analysis. A guide-wire is inserted in the cavity in order to realise multiple loops. Then, a careful cystostomy of 5-8 mm with a papillotome or by balloon dilatation is realised. Large cystostomies appear to be associated with a higher risk of haemorrhage than balloon dilatation. Finally, one or two double-pig-tail stents are inserted. In case of infected cyst or large amount of necrotic tissues which could occlude the stent, a naso-cystic drain for washing seems more adapted than a stent.

Trans-papillary drainage is dedicated to communicating cysts. After a selective cannulation of the pancreatic duct, a guide-wire deeply inserted and a pancreatic sphincterotomy, a dilatation of the tract between the pancreatic ducts and the cyst (a down-stream duct stenosis usually being associated), is performed. A stent is inserted into the pancreatic duct in order to bridge the area of communication between the ductal system and the cyst. The mean time of drainage is usually two mo but depends on the persistence of the cyst on the morphologic explorations[24]. In case of co-existence of pancreatic duct

lesions, a long-term pancreatic stenting is necessary to prevent a recurrence of the cyst.

Endo-ultrasonography

Interventional endo-ultrasonography (EUS) is particularly interesting in three issues: treatment of pain by coeliac neurolysis, drainage of pseudo cysts and trans-gastric pancreatic drainage. Coeliac block is associated with a low morbidity (diarrhoea in 3.5% of cases)[25,26]. Treatment of pancreatic cysts under EUS guidance is dedicated for pseudo cysts which are not bulging in the gut[27-32]. In case of complete obstruction of the pancreatic duct, a pancreatico-gastrostomy can be achieved under EUS guidance[33,34].

RESULTS AND INDICATIONS OF ENDOSCOPIC TREATMENT

The aim of endoscopic treatment is improvement of pain. Analysis of the literature is difficult because (a) the variability of pain during the time and between patients[35-37] (b) the pain during CP is multifactorial: ductal or interstitial pancreatic hyperpression, inflammatory infiltration of peri pancreatic nerves ("pancreatic neuritis") or pseudo-cysts. Other complications of CP could also be associated with pain: duodenal stenosis, duodenal cystic dystrophy, biliary stenosis or duodenal ulcer[35]. Moreover, endoscopic methods are different: biliary sphincterotomy is not always associated with a pancreatic sphincterotomy, time of pancreatic stenting (two months to undetermined), or number of stents. In fact, there are several methods of treatment which aim to obtain a satisfactory drainage of a pancreatic and/or biliary duct.

Treatment of pancreatic pain

Drainage of pancreatic duct is reported in numerous articles[11,13,14,23,38-45]. Technical success was obtained in 85% of cases (58%-96%). Stents are left during variable length of time, from two mo to endless. Short-term improvement of pain was obtained in 81% of cases (62%-100%). After a follow-up of 30 mo (14-60 mo), improvement of pain dropped to 61% of cases (24%-95%). There was no clinical predictive factor of success despite of an early stage of CP reported in three series[13,41,43]. Communicating cyst and juxta-ampullary stenosis were the two reported morphological predictive factor of success. Surprisingly, stop of alcohol intake did not seem to modify results of the endoscopic treatment. Nevertheless, alcohol intake has to be stopped because morbidity and mortality of CP are more attributed to toxic habits (alcohol or tobacco) than to CP itself[46]. In cases of complete obstruction of pancreatic duct preventing access *via* the papilla, EUS-guided pancreatico-gastrostomy can be done. Results of this method are preliminary: a short series of four cases has reported good results in one case, recurrence of pain in two cases managed with another endoscopic treatment (stenosis of the pancreatico-gastrostomy in one case, disruption and spontaneous migration of the stent in the other case), and failure in one case (12 mo of follow-up)[33]. An additional factor of pain is peri-pancreatic inflammatory infiltrate of nerves: a prospective randomized comparison of endoscopic ultrasound and computed tomography-guided celiac plexus block has reported better results under EUS whereby an immediate improvement of pain occurred in 50% of cases but this result dropped to 30% after six months of follow-up. Efficiency appeared significantly more prolonged in the EUS-group and the ratio cost-efficiency was also better in this group[47]. More recently, a prospective study including 90 patients reported an immediate improvement of pain in 55% and in 10% after six months of follow-up[25]. Young age or previously pancreatic surgery were factors of poor results. Indication of celiac plexus block is limited in CP because of a relative immediate efficiency and especially a frequently recurrence of pain after six mo of follow-up (Table 2).

Treatment of pancreatic cysts and pseudo cysts

Evaluation of patient and collection are the first step to decide strategic therapy. Ultrasonography, computed-tomography, MRCP and EUS make it possible for clinician to determine the two major risks of endoscopic treatment which are haemorrhage and perforation. Haemorrhage depends on the presence of pericystic or peridigestive vessels, segmental portal hypertension and the haemorrhagic content of the cyst. Perforation depends on the distance between the digestive-wall and

the cyst which should not exceed 10 mm. Results of transmural drainage were reported in six series between 1989 and 1992 including 191 cysts (Table 3)[48-53]. Mean rate of healing, failure and recurrence were respectively 78% (51%-82%), 5.5% (0%-16%) and 6.5% (3%-13%). Secondary surgical procedure was necessary in 14.9% of patients (12%-30%). Morbidity was 15.5% including, according to increasing rates of frequency, haemorrhage, perforation, and infection. Haemorrhage seems more frequent in case of gastro-cystostomy than for duodeno-cystostomy[51]. The only death reported concerned a patient who presented cirrhosis complicated by portal hypertension and associated with haemorrhagic pancreatic ascitis[51]. Long-term results of transmural drainage are not well-known, follow-up not exceeding 31 mo. A recent study including 34 patients followed 46 mo, reported good results in 62% of cases (in intent to treat) with only 71% of initially technical success[54]. Three cases of recurrence were reported, of whom two cases were successfully managed endoscopically.

Results of trans-papillary drainage have been also reported in six series from 1991 to 1995 including 121 cysts (Table 4)[48,53,55-57]. Symptom-free rates were 87% (76%-87%) and healing rates of cysts were 84% (76%-94%). Recurrence of cyst was 9.2%, morbidity was 10% with essentially septic complications and post-ERCP acute pancreatitis. A secondary surgical procedure was necessary in 10.8% of cases (9%-50%). Endoscopic drainage is intended for symptomatic cysts. In the other cases, drainage is necessary if the size of the cyst is more than 4 cm, particularly if the cyst is localized out of pancreatic area because, in this case, it uncommonly collapses spontaneously[58]. Trans-papillary drainage appears a first choice treatment in case of CP because pancreatic stent treats also pancreatic ductal lesions down stream the cyst and because it is less invasive than transmural way. Transmural drainage is especially reserved to large cysts but must be avoided in presence of segmental portal hypertension. Results of EUS-guided pseudo-cysts drainage have been recently reported in six series including 69 cases[27-32]. The most important monocentric study included 35 patients of whom 20 pancreatic abscess: after 27 mo of follow-up, drainage was successful in 94% of cases, a pneuperitoneum occurred in a case and has been managed conservatively, recurrence of cyst occurred in three cases of whom two abscess, surgical drainage was necessary in four cases of whom were four abscess. This method seems satisfying but has to be more evaluated in larger series[31].

Endoscopic treatment of biliary stenosis

Long-term results of biliary stenting have been reported in three series including 102 patients[59-61]. Although initial improvement was reported in 100% of cases, the rate of symptom free patients decreased to 17.5% (10%-28%) after 10 mo (14-49 mo) of follow-up; moreover, 68% of patients underwent a surgical bili-digestive diversion or were still stenting. Plastic stents temporarily improve cholestasis but are not able to dilate adequately common bile duct. In contrast with the previous series, a recent study including 25 patients using balloon dilatation before biliary stenting has reported excellent results in 80% of cases after 13 mo of follow-up[62]. These recent optimistic results attributed to the balloon dilatation, have to be confirmed. Morbidity is low (8%-9%) except migration or obstruction of the stent observed in respectively 14/25 and 18/25 patients of series of Deviere *et al* and Vitale *et al*[59,62]. Draganov *et al* tried to improve results by using several stents: nine patients underwent a biliary stenting with 2-($n = 3$) or 3-($n = 6$) 10 French-stent; 48 mo after

Table 5 Results of endoscopic biliary stenting of biliary stenosis associated with chronic pancreatitis

Smits[61]	58	100	62	7	27	10
Vitale[62]	25	100	56		80	13

retrieval of stents, biliary stenosis recurred in only 55% of cases, absence of cephalic pancreatic stones was a factor of success[63]. Because plastic stent are not adapted for a long-term drainage, Deviere *et al* tested metallic expansive stent with an excellent result in 18/20 patients, after 33 mo of follow-up[64]. Nevertheless, the two remaining patients presented an obstruction of the stent secondary to epithelial hyperplasia in contact with the stent. More recently, a study including 13 patients presenting a biliary stenosis and unfit for surgical procedure, reported good results in 9/13 (69%) patients after 50 mo of follow-up, mean time of stent patency was 60 mo[65]. A single stent was enough in five cases, obstruction of the stent was managed by insertion of a plastic stent inside the metallic stent (n = 3) or by an extractor balloon (n = 1). In four (21%) cases, biliary drainage was not effective because of occluded stent (n = 3) or duodenal migration of the stent (n = 1). Three patients died for a cause not related to the biliary stenosis. Nevertheless, those metallic stents being not extractable, after a long-term follow-up, there is a possibility of stent occlusion by granulation reaction against a foreign body (Table 5).

Management of pancreatic exocrine and endocrine functions

Although improvement of pancreatic exocrine and endocrine functions is frequently discussed in surgical series, this notion is seldom reported in endoscopic series[13,22]. This is probably due to the difficulties to correctly explore the pancreatic exocrine function and also to the relatively short-term follow-up of endoscopic series in compared with surgical series. A temporary improvement of diabetes mellitus has been reported in 10% of cases after endoscopic treatment, while aggravation was noted in 12%[22]. Although another series reported an improvement in 26% of cases[13], most of the series did not noted any improvement[42,44]. Therefore, diabetes mellitus alone should not be an indication of endoscopic treatment of CP.

Evaluation of the effects of endoscopic treatment on pancreatic exocrine function is also seldom precise. A few studies report a gain of weight but this gain probably reflects more improvement of pain than improvement of exocrine function[13]. Evaluation of pancreatic exocrine function with a C^{14} breath test reports a 50%-60% improvement after endoscopic treatment[22].

Endoscopic treatment of pancreatic fistulas

Three major series included 39 patients presenting with a pancreatic fistula after acute pancreatitis (n = 19) and associated with CP (n = 12)[55,66,67]. Treatment consisted in a trans-papillary drainage of pancreatic duct in 34 cases, associated with a transmural drainage of a cyst in four cases. Rate of success was 92 %, with complications occurring in seven cases (17%). Complications included mainly acute pancreatitis and sepsis. Seven (17%) patients underwent surgical procedures 11 to 16 mo after endoscopic treatment. Few isolated cases of pancreatico-pleural fistula successful treated by endoscopic drainage, have been reported[68]. Trans-papillary drainage is also reported as a successful treatment for pancreatico-peritoneal fistulas.

ENDOSCOPIC TREATMENT AND SURGICAL PROCEDURES

Up to now, few randomised series have covered this topic. A recent study concludes in favour of surgery[69]. This study randomized 72 patients and after a follow-up of five years, although incomplete improvement of pain was equivalent in the two groups (46% *versus* 52%), a significant difference appeared for the complete resolution of pain (37% in the surgical group *versus* 14% in the endoscopic group). Nevertheless this series presents a bias because 80% of patients in the surgical group underwent a resection procedure and only 20% underwent a derivation procedure. Therefore, results of endoscopic treatment have to be compared with surgical procedure of derivation. Moreover, half of patients accepted randomization between surgery and endoscopy, this high rate of refusal emphasizes the difficulties in comparing the two methods and to set-up this kind of study. Nevertheless, more recently, another prospective series reported that surgical drainage of the pancreatic duct was more effective than endoscopic treatment[70]. Thirty-nine symptomatic patients having CP with distal obstruction of the main pancreatic duct and without inflammatory mass were randomized: 19 underwent endoscopic trans-papillary drainage (16 of whom also underwent ESWL) and 20 had operative pancreatico-jejunostomy. After 24 mo of follow-up, patients who underwent surgery had a significant ($P < 0.001$) lower pain score compared to endoscopic drainage. Moreover, complete or partial pain relief was achieved in 75% of patients of "surgical group" and only 36% of patients of "endoscopic group" ($P = 0.007$). Morbidity rate and length of hospital stay were similar in the two groups but there were more procedures in the "endoscopic group" than in "surgical group" (a median of 8 *vs* 3). To conclude, strategy depends on the expertise of the local teams, endoscopic treatment could be proposed as a first line treatment, before surgical procedure.

CONCLUSION

Endoscopic treatment of CP has certainly improved during the last two decades. Although results are clearly accepted as excellent for pancreatic cysts and pancreatic fistulas, long-term improvement of biliary and pancreatic ducts stenosis remains controversial.

Abstract

Smoking is an important environmental factor in inflammatory bowel disease (IBD), having different effects in ulcerative colitis (UC) and Crohn's disease (CD). A recent meta-analysis partially confirmed previous findings that smoking was found to be protective against ulcerative colitis and, after onset of the disease, might improve its course, decreasing the need for colectomy. However, smoking increases the risk of developing Crohn's disease and worsens its course, increasing the need for steroids, immunosuppressants and re-operations. Smoking cessation aggravates ulcerative colitis and improves Crohn's disease. Data are however, largely conflictive as well as the potential mechanisms involved in this dual relationship are still unknown. In this review article, the authors review the role of smoking in inflammatory bowel diseases.

Key words: Smoking; Crohn's disease; Ulcerative colitis; Phenotype

INTRODUCTION

The pathogenesis of ulcerative colitis (UC) and Crohn's disease (CD) has only been partly understood. Inflammatory bowel disease (IBD) is a multifactorial disease with probable genetic heterogeneity[1,2]. In addition, several environmental (eg, diet, smoking, measles or appendectomy) risk factors may contribute to its pathogenesis.

During the past decades, the incidence pattern of both diseases has changed significantly[3], showing some common but also quite distinct characteristics for the two disorders. Differences in geographic distribution, and particularly changes in incidence over time within one area, may provide insight into possible etiological factors[4]. It is very unlikely however, that these rapid changes attributed to variations in the genetic factors. On the contrary, environmental factors are likely to play an important role. Diet, as a luminal antigen, was thought to be an important factor in the pathogenesis of IBD[1,5]. In the last two decades, there has been a shift in the lifestyle in Eastern Europe, Asia, and Central America, as the lifestyle, including the diet, became more "Westernized". This possibility is further supported by the differences in incidence and prevalence found within one region.
