Abstract

AIM: To investigate the multicellular resistance of human hepatocellular carcinoma HepG2 cells in three-dimensional culture to delisheng, 5-fluorouracil and adriamycin, and the possible molecular mechanisms of delisheng.

METHODS: Human hepatocellular carcinoma HepG2 cells were cultured with a liquid overlay technique. After the formation of multicellular spheroids, morphology was analyzed by phase contrast microscopy, scanning electron microscopy and transmission electron microscopy. Sensitivity of HepG2 cells to delisheng, 5-fluorouracil and adriamycin was investigated by MTT assay in multicelluar spheroids and monolayers. Vascular endothelial growth factor (VEGF) and endostatin expression were analyzed in multicellular spheroids treated with delisheng, 5-fluorouracil, adriamycin and negative control PBS, with immunohistochemical staining.

RESULTS: Multicellular spheroids exhibited structural characteristics somewhat different to those in monolayers. The cells in three-dimensional cell culture turned out to be less sensitive to delisheng, 5-fluorouracil and adriamycin than the cells cultured in monolayer. This showed that delisheng had a satisfactory cells inhibition ratio compared to 5-fluorouracil and adriamycin. Immunohistochemical staining showed that VEGF and endostatin expression was positive during growth as multicellular spheroids, and endostatin expression in spheroids with treatment of delisheng was higher than that with 5-fluorouracil, adriamycin and PBS (139.35 ± 7.83, 159.23 ± 10.34, 162.83 ± 3.47 and 148.48 ± 11.06, $P < 0.05$).

CONCLUSION: Chinese medicine compound delisheng has satisfactory anti-tumor activity in HepG2 cells in three-dimensional culture, and the effects are associated with up-regulation of endostatin.

Key words: Delisheng; Ginseng; Three-dimensional culture; Multicellular resistance; Endostatin

INTRODUCTION

Hepatocellular carcinoma (HCC) is a highly malignant tumor with a very high morbidity and mortality, and a poor prognosis. Its incidence is increasing both in Asian countries and in the USA. A majority of HCC patients presents with advanced or unresectable disease. Even for those with resected disease, the recurrence rate can be as high as 50% at 2 years. Despite extensive efforts by many investigators, systemic chemotherapy for HCC has been quite ineffective, as demonstrated by low response rates and no survival benefits[1-4]. With the continuous development of the traditional Chinese medicine industry in recent years, it has been proven that traditional Chinese medicines (TCMs) have a marked effect on treating HCC, with unique advantages, and have gained wide acceptance as a safe, palliative and effective treatment in China[5-9]. Delisheng is a Chinese medicinal compound and is usually used in combination with chemotherapy for HCC. Furthermore, it has been reported that it can improve the clinical symptoms and quality of life, without severe adverse reactions, in patients with late-stage HCC. It is composed of ginseng, milk vetch root, secretion bufonis and Cantharidium. As delisheng is attractive as a natural product for medicinal use, increasing attention is being

paid to its scientific evaluation and its possible molecular mechanisms.

Three-dimensional cell culture has been widely used for studying the various molecular processes and the development of therapy in recent years, for subtle changes in phenotypic expression and biological activity not demonstrated in conventional monolayer culture. In contrast, multicellular spheroids of tumor cells provide an excellent three-dimensional *in vitro* model to facilitate detailed investigations, including the response to various antineoplastic agents and their possible molecular mechanisms, since spheroids mimic the solid tumors more closely than monolayers do[10]. Tumor resistance to anticancer drugs is a real phenomenon, partly because of the so-called multicellular resistance (MCR), and it may be the most important obstacle to cancer treatment[11]. The resistance encountered in cells cultured as spheroids seems to be analogous to the natural resistance observed in patients, so the usage of three-dimensional cell culture may provide a model for studies on the development of anti-cancer drugs.

In this study, cells were cultured with a liquid overlay technique[12,13]. After the formation of multicellular spheroids, morphology was analyzed by phase contrast microscopy, scanning electron microscopy and transmission electron microscopy. Sensitivity of human hepatocellular carcinoma HepG2 cells to delisheng, 5-fluorouracil and adriamycin was investigated by MTT assay in multicelluar spheroids and monolayers. Vascular endothelial growth factor (VEGF) and endostatin expression was analyzed in multicellular spheroids treated with delisheng, 5-fluorouracil, adriamycin and negative control PBS, with immunohistochemical staining.

MATERIALS AND METHODS

Human hepatocellular carcinoma cell line

The human hepatocellular carcinoma cell line used in the present study was HepG2 preserved in The Center of Molecular Biology of Xi'an Jiaotong University.

Monolayer and three-dimensional cell cultures

Each HepG2 cell line was maintained in DMEM (Gibco, USA) medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin, 100 U/mL streptomycin in 5% CO_2/95% air at 37℃. Cell cultures were maintained in the exponentially growing state by passaging twice weekly. Exponentially growing cells were harvested in a monolayer cell culture, while for three-dimensional cell culture obtained by liquid overlay technique, a single cell suspension in complete medium was seeded in each culture flask coated with 2% agarose. The conditions for three-dimensional cell culture were exactly the same as for monolayer culture, except for the presence of an agarose layer. After 3 or 4 d incubation, multicellular spheroids were obtained from each culture flask.

Scanning electron microscopy

After 3 or 4 d culture, monolayer cells and multicellular spheroids were observed by phase contrast microscopy. After which, samples were washed with PBS, pH 7.4, and fixed with 2.5% glutaraldehyde for 2 h at 4℃. After three washes in PBS, they were post-fixed with 1.0% osmium tetroxide in PBS for 2 h at 4℃, then washed once in PBS, followed by dehydration with an increasing ethanol series (30, 50, 70, 90 and 100%). The samples were then treated with isoamyl acetate for 10 min, dried to the critical point, and coated with gold. Finally, the samples were observed with a scanning electron microscope (JEOL, JSM-840, Japan).

Transmission electron microscopy

Additional samples were fixed and dehydrated as described for scanning electron microscopy, and embedded in Epon812 epoxy resin. Thin sections were prepared and examined with a transmission electron microscope (HITACHI, H-600, Japan).

MTT assay

The Chinese medicinal compound delisheng was dispensed into a physic liquor to give a clinical dosage of 80 mL (recommended dose is 50-100 mL/d). Delisheng was attenuated with Hanks balanced salts solution, and the final concentration was 12.5, 25, 50, 100 and 200 μL/mL. MTT [3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide] (Sigma, St. Louis, MO, USA) was dissolved in PBS at 5 mg/mL and sterilized by filtration. After treatment with 12.5, 25, 50, 100 or 200 μL/mL delisheng; 6.25×10^{-3}, 12.5×10^{-3}, 25×10^{-3}, 50×10^{-3} and 100×10^{-3} g/L 5-fluorouracil; 0.15625×10^{-3}, 0.3125×10^{-3}, 0.625×10^{-3}, 1.25×10^{-3} and 2.5×10^{-3} g/L adriamycin in monolayer and three-dimensional cell culture for 48 h, the cells were freshly disaggregated by enzymatic dissociation, and the cell number was determined with a hemocytometer. A cell suspension (150 μL) of each sample was added to a 96-well plate. The cell number per well was approximately 2×10^5, Each well was added to stock MTT solution (20 μL, 5 mg/mL). After incubation in the presence of 5% CO_2 and 95% air at 37℃ for 4 h, the supernatant was discarded. DMSO (150 μL) (Sigma) was added to each well and mixed thoroughly to dissolve the dark blue crystals. After 30 min at room temperature to ensure that all crystals were dissolved, the plates were read with a Micro Elisa plate reader at a wavelength of 492 nm. All samples were read five times. The cell inhibition rate was calculated by the following formula: cell inhibition rate (%) = (1-OD of treated cells)/(OD of control cells) × 100%.

Immunohistochemical staining

Antibody staining was performed with multicellular spheroids. The monoclonal anti-VEGF antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA) was used at a dilution of 1:25. The monoclonal anti-endostatin (Santa Cruz Biotechnology) was used at a dilution of 1:25. Spheroids treated with delisheng (25 μL/mL), 5-fluorouracil (40×10^{-3} g/L), adriamycin (1×10^{-3} g/L) and negative control PBS for 48 h were washed in PBS, and fixed in 4% paraformaldehyde in PBS at 4℃ for 1 h, placed in a small tissue processing cassette full of 3%

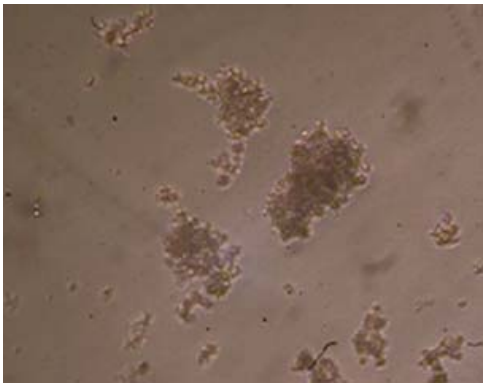

Figure 1 Multicellular spheroids of hepG2 cells observed with the phase contrast microscope (× 100).

Figure 2 Monolayer of hepG2 cells observed with the phase contrast microscope (× 100).

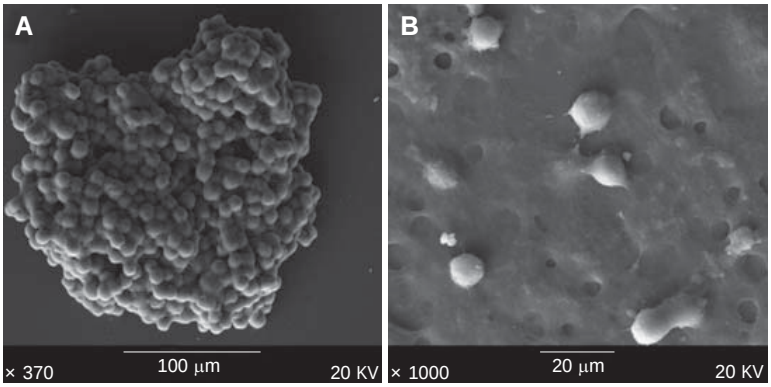

Figure 3 Scanning electron microscopy of hepG2 cells. **A**: The multicellular sphere was irregular with a diameter up to 1.0-2.0 mm, tight cell junctions were observed; **B**: Monolayer cells spread dispersively and cell junctions were hardly observed.

agarose for 1 h, then dehydrated and embedded in paraffin. Four-micrometer sections from the representative blocks were immunohistochemically stained with mouse anti-human monoclonal antibodies against VEGF, and rabbit anti-human monoclonal antibodies against endostatin. Four-micrometer thick sections were deparaffinized, rehydrated and washed in PBS for 15 min, before endogenous peroxidase activity was blocked. Primary antibody was substituted by normal mouse and rabbit serum as a negative control .Then endogenous peroxidase activity was blocked by 30 min incubation in 3% hydrogen peroxide solution. The specimens were washed with PBS, pH 7.5. Non-specific binding was blocked by incubating the slides with normal goat serum in PBS for 15 min at 37℃, then incubated overnight at 4℃ with the primary antibodies. After washing three times with PBS, the sections were incubated with secondary antibody, biotinylated antibodies for 40 min at 37℃. After washing three times with PBS, the sections were immunostained with avidin-biotin complex for 40 min at 37℃. Visualization of the immunoreactions was conducted with 3, 3'-diaminobenzidine (DAB, Sigma, UK) for 5 min. Finally, sections were counterstained with hematoxylin. The degree of the expression of immunohistochemical products was classified into negative (< 10% of cells had a positive reaction) and positive (> 10% of cells had a positive reaction). Simultaneously, VEGF- and endostatin-positive staining particles were quantitatively analyzed by a LeicaQ550cw imaging analysis system (Germany) to determine the mean grey values, the lower mean grey values, and the stronger substrate coloration. The mean grey values are an inverse ratio with the protein expression quantity.

Statistical analysis

Data were reported as means ± SE. The *t* test was used for statistical analysis, $P < 0.05$ was considered statistically significant.

RESULTS

Cell morphology (phase contrast microscopy, scanning and transmission electron microscopy)

Multicellular spheroids and monolayer cells were observed with phase contrast microscopy. The cells were oval spheroids in three-dimensional cell culture (Figures 1 and 2).

Scanning electron microscopy showed that the multicellular spheroids were irregular, with a diameter of up to 200 μm at 3-4 d. The cells were oval spheroids or polyhedrons, with tight cell junctions, compared to monolayer cells that were spread in a dispersed manner and had few cell junctions (Figure 3).

Transmission electron microscopy showed that desmosome and intermediate junctions were observed in three-dimensional cell culture, but such structures were rarely observed in monolayer cell culture. Multicellular spheroids of approximately 200 μm diameter showed no obvious signs of extensive central apoptosis or necrosis,

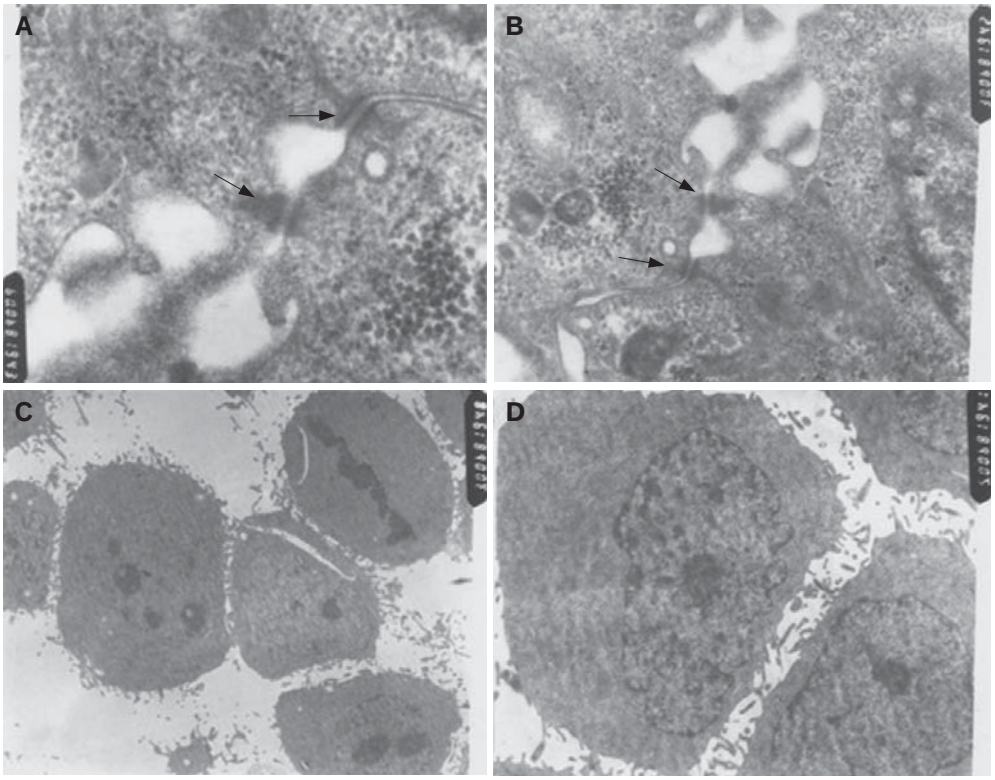

Figure 4 Transmission electron microscopy of hepG2 cells: **A** (× 60 000); **B** (× 30 000): desmosome junctions and intermediate junctions were observed in three-dimensional cell culture; **C** (× 3000); **D** (× 5000): cell junctions were hardly observed in monolayer cells with more microvilli on the surfaces.

Table 1 Test sensitivity of delisheng in 3d and 2d cell culture

Concentration (μL/mL)	Inhibition ratio (%)		*P* value
	3-d	Monolayer	
12.5	11.73 ± 11.58	33.81 ± 10.54	0.014
25	20.94 ± 8.29	37.79 ± 9.55	0.018
50	25.45 ± 5.62	46.01 ± 6.32	0.001
100	36.69 ± 5.37	75.65 ± 10.47	< 0.001
200	43.93 ± 7.81	84.62 ± 3.24	< 0.001

Table 2 Test sensitivity of 5-fluorouracil in 3d and 2d cell culture

Concentration (g/L)	Inhibition ratio (%)		*P* value
	3-d	Monolayer	
6.25×10^{-3}	18.25 ± 7.85	33.89 ± 9.41	0.021
12.50×10^{-3}	17.51 ± 7.28	39.08 ± 7.74	0.002
25.00×10^{-3}	18.18 ± 11.34	43.18 ± 5.92	0.002
50.00×10^{-3}	17.87 ± 10.93	67.72 ± 2.18	< 0.001
100.00×10^{-3}	36.42 ± 10.54	81.17 ± 2.81	< 0.001

although there was some swelling and there were fewer microvilli on the surface of multicellular spheroids compared to monolayer cells (Figure 4).

Response to delisheng, 5-fluorouracil and adriamycin exposure

The sensitivity of monolayer and three-dimensional cell cultures to delisheng, 5-fluorouracil and adriamycin was investigated by MTT assay. The cell inhibition ratio in three-dimensional cell culture treated with delisheng, 5-fluorouracil and adriamycin was lower than that in monolayer culture ($P < 0.01$) (Tables 1-3, Figures 5-7), which indicated the HepG2 cells in three-dimensional culture became resistant to delisheng, 5-fluorouracil and adriamycin. Cell inhibition ratio increased with concentration of delisheng, 5-fluorouracil and adriamycin. The results showed that delisheng had a satisfactory cell inhibition ratio compared to 5-fluorouracil and adriamycin.

Table 3 Test sensitivity of adriamycin in 3d and 2d cell culture

Concentration (g/L)	Inhibition ratio (%)		*P* value
	3-d	Monolayer	
0.15625×10^{-3}	11.40 ± 2.71	10.39 ± 5.07	0.705
0.31250×10^{-3}	12.17 ± 6.49	21.31 ± 2.85	0.02
0.62500×10^{-3}	18.61 ± 9.41	25.69 ± 8.19	0.24
1.25000×10^{-3}	29.45 ± 5.26	41.66 ± 6.52	0.012
2.50000×10^{-3}	38.09 ± 20.71	84.56 ± 7.97	0.002

Data were reported as means ± SE ($n = 5$).

Immunohistochemistry staining

VEGF and endostatin protein expression were confirmed in multicellular spheroids in three-dimensional culture. Immunohistochemical analysis demonstrated that VEGF and endostatin were expressed in the cytoplasm. Endostatin expression in spheroids treated with delisheng was higher than that with 5-fluorouracil, adriamycin and negative control PBS ($P < 0.05$). However, VEGF expression in spheroids treated with delisheng was similar with 5-fluorouracil, adriamycin and PBS ($P > 0.05$) (Tables 4 and 5; Figure 8).

DISCUSSION

HCC is one of the most common types of human

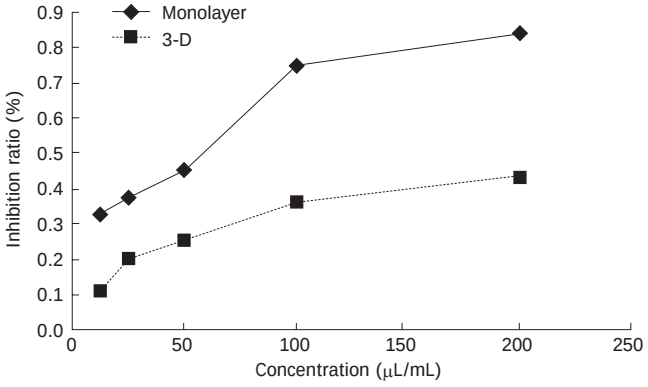

Figure 5 Sensitivity of HepG2 cells to delisheng determined by the MTT assay. After the treatment with 12.5, 25, 50, 100 and 200 μL/mL delisheng for 48 h, the cells in three-dimensional cell culture and monolayer culture were cultured with MTT solution and cell inhibition ratio was determined. The cells in monolayer culture were more sensitive to delisheng ($P < 0.01$).

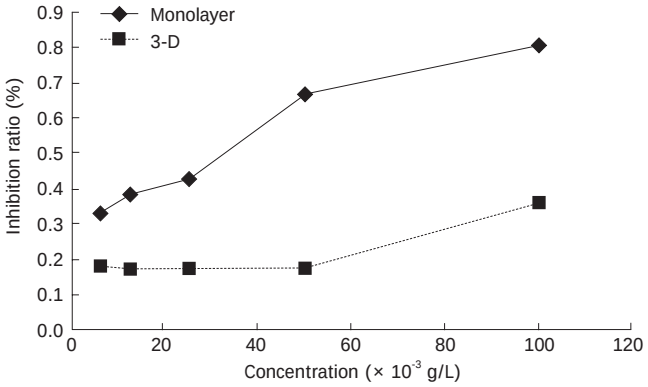

Figure 6 Sensitivity of HepG2 cells to 5-fluorouracil determined by the MTT assay. After the treatment with 6.25, 12.5, 25, 50 and 100 × 10^{-3} g/L 5-fluorouracil for 48 h, the cells in three-dimensional cell culture and monolayer culture were cultured with MTT solution and cell inhibition ratio was determined. The cells in monolayer culture were more sensitive to 5-fluorouracil ($P < 0.01$).

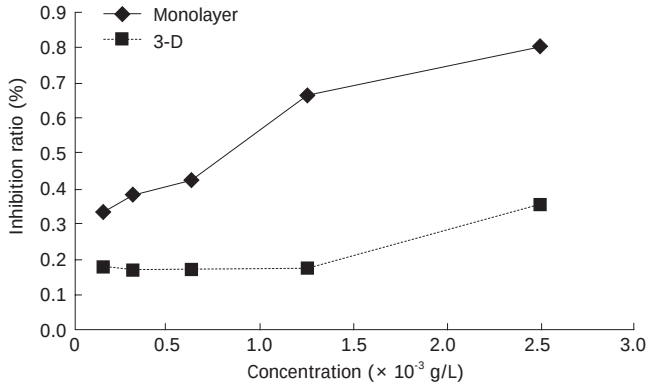

Figure 7 Sensitivity of HepG2 cells to adriamycin determined by the MTT assay. After the treatment with 0.15625, 0.31250, 0.62500, 1.25000, 2.50000 × 10^{-3} g/L adriamycin for 48 h, the cells in-three dimensional cell culture and monolayer culture were cultured with MTT solution and cell inhibition ratio was determined. The cells in monolayer culture were more sensitive to adriamycin ($P < 0.01$).

malignancy worldwide. The prognosis in patients with untreated HCC is very poor, with a median survival of 6 mo in patients who receive no specific treatment[14]. Curative therapy such as surgery, liver transplantation[15], or percutaneous treatments benefit only 25% of patients. Systemic chemotherapy has been widely used in an attempt to prolong this short survival time or to provide symptomatic relief[16], but it appears to be less efficient, possibly because it is used when metastases are already present, and the tumor is large and spreading; moreover, anticancer drug resistance is frequent. Tumor resistance to anticancer drugs is a real phenomenon, but the most prevalent mechanism may not correspond to multidrug resistance[17]. Instead, the so-called MCR, first described in 1972 by Durand and Sutherland may be the most important obstacle to cancer treatment. The resistance encountered in cells cultured as spheroids seems to be analogous to the natural resistance observed in patient tumors. Tumor cells often form compact multicellular spheroids when maintained in a three-dimensional culture system. Various changes in molecular expression and even in biological activity have been reported to exist between the three-dimensional and conventional monolayer cultures[18,19].

There are abundant resources in TCMs that have been used clinically for > 5000 years in China and Asia, and increasing attention is being paid to their scientific evaluation. With continuing development of TCM, it has a marked effect on the treatment of several, including tumors, with unique advantages. Delisheng is a common Chinese medicinal compound, whose composition includes ginseng, milk vetch root, secretion bufonis and Cantharidium. Satisfactory effects of delisheng have been reported in patients with late-stage HCC that may improve clinical symptoms and quality of life, without severe adverse reactions. However, the mechanisms responsible for this treatment are unknown. Many kinds of solid tumors *in vivo* and tumor cells in three-dimensional cell culture *in vitro* exhibit intrinsic or acquired resistance to

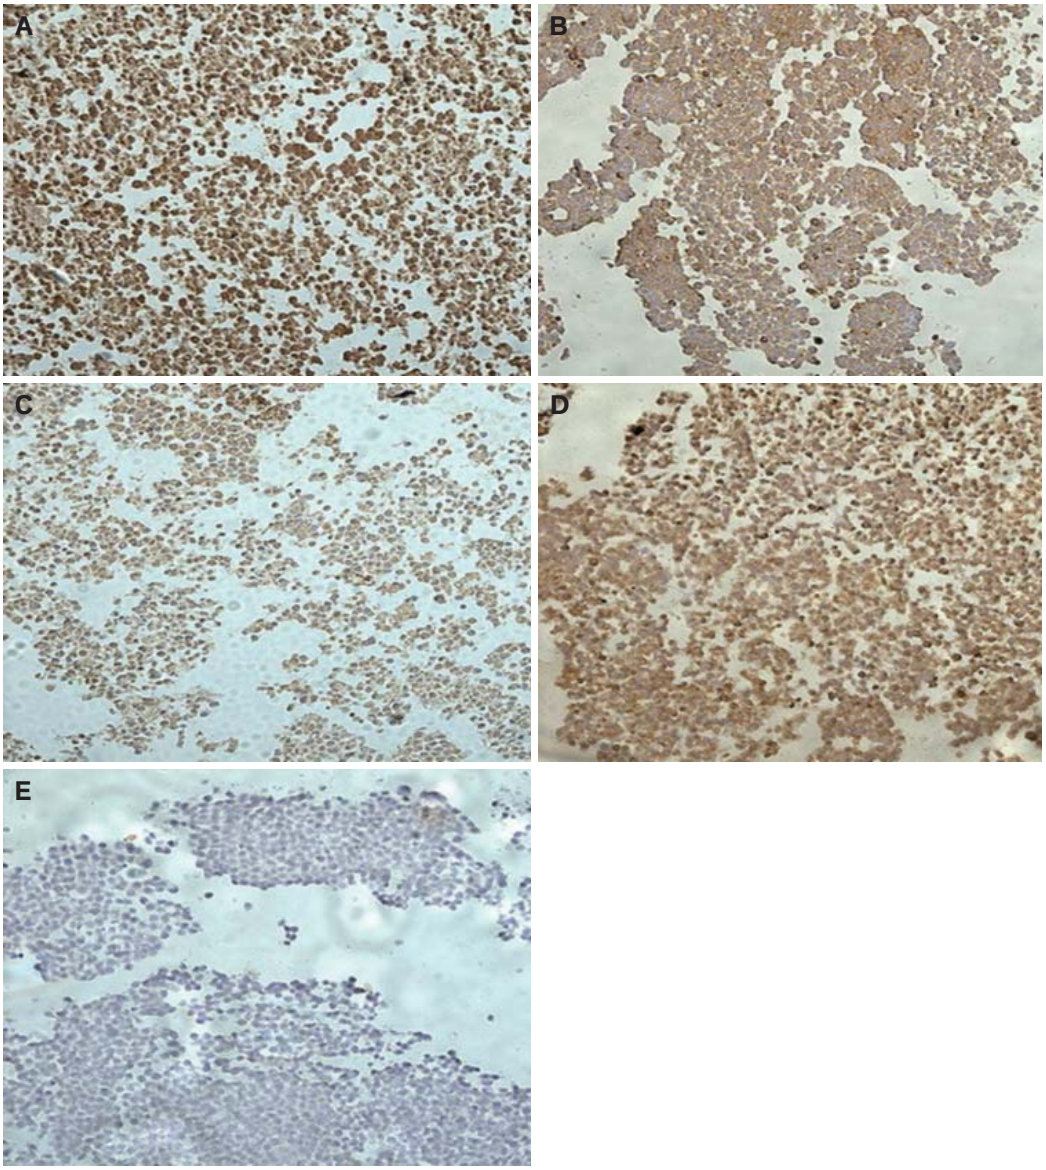

Figure 8 Immunohistochemical staining patterns of formalin-fixed and paraffin-embedded multicellular spheroids of HepG2 cells (× 200) [**A**: delisheng; **B**: adriamycin; **C**: 5-fluorouracil; **D**: negative control PBS; **E**: negative control (Primary antibody was substituted by normal rabbit serum)]. cytotoxic drugs, which is one of the major obstacles to clinical treatment.

In this study, human HepG2 cells were cultured with a liquid overlay technique to form multicellular spheroids. The results indicated that the cells were oval spheroid or polyhedral, with fewer microvilli on the surface and more desmosome and intermediate junctions, compared to monolayer cells. The cells in three-dimensional culture turned out to be less sensitive to delisheng, 5-fluorouracil and adriamycin than those cultured in monolayer. Some studies have indicated that more cells in multicellular spheroids shift into a quiescent state. However, the majority of conventional cytotoxic anticancer drugs preferentially kill cycling cells. The increase in quiescent cells might result in decreased sensitivity. VEGF and endostatin expression were confirmed in three-dimensional culture. The data indicated that endostatin expression in spheroids treated with delisheng was higher than that with 5-fluorouracil and adriamycin and negative control PBS, and a previous study has shown that delisheng has a satisfactory cell inhibition ratio compared to 5-fluorouracil and adriamycin. This suggests that the satisfactory effects of delisheng on HCC were associated with the up-regulation of endostatin. As we know, one of the components of delisheng, ginseng, has some antiangiogenic activity. Recent studies have reported that ginseng extract exerts anti-tumor activity through its effect on the vascular system; furthermore, some investigators have suggested that ginsenoside Rg3, a saponin extracted from ginseng, alone or combined with cyclophosphamide (CTX), inhibits growth and angiogenesis of ovarian cancer by decreasing the microvessel density (MVD value) and VEGF expression[20-23]. Endostatin as an angiogenesis inhibitor has been shown to inhibit VEGF-induced endothelial cell migration *in vitro*, and to have anti-tumor activity *in vivo*[24,25]. Some investigators have studied tumor growth in transgenic mice overproducing endostatin specifically in the endothelial cells (a 1.6-fold increase in the circulating levels), and found that tumor growth was 3-fold slower than in wild-type mice[26-30]. Therefore, we think that the endostatin up-regulation induced by delisheng in our experiment was possibly due to the antiagiogenic activity of its ginseng component, and this may explain why delisheng has satisfactory anti-tumor

activity too. Although major emphasis has been placed on the down-regulation of VEGF, the potential role of endostatin increase induced by ginseng as an endogenous inhibitor of angiogenesis in tumor growth inhibition can not be ignored.

Further understanding of the mechanisms involved in the activity of delisheng will help in the development of new approaches to therapy of HCC. The satisfactory activity of delisheng on HCC was associated with ginseng up-regulation of endostatin expression.

ACKNOWLEDGMENTS

We would like to offer special thanks to the Department of Medical Oncology, The First Affiliated Hospital of The School of Medicine of Xi'an Jiaotong University and The Center of Molecular Biology of Xi'an Jiaotong University for their help with these experiments.

COMMENTS

Background

HCC is a highly malignant tumor with a very high morbidity and mortality. Despite extensive efforts by many investigators, systemic chemotherapy for HCC has been quite ineffective. Delisheng is a Chinese medicinal compound and is often used in conjunction with chemotherapy for HCC, with satisfactory results. Our work tried to establish the mechanisms for these effects of delisheng on HCC. Three-dimensional cell culture has been widely used for studying the various molecular processes, since spheroids mimic solid tumors more closely than monolayers do, so the use of three-dimensional culture provides a model for the development of anti-cancer drugs. In this study, cells were cultured with a liquid overlay technique. After the formation of multicellular spheroids, we used the model to perform our experiments.

Research frontiers

With the continuous development of TCM in recent years, it is been demonstrated that it can have a marked effect on treating HCC, with unique advantages, and it has gained wide acceptance as a safe, palliative and effective treatment in China. Delisheng is a Chinese medicinal compound and is often used in conjunction with chemotherapy for HCC. Furthermore, it has been reported in patients with late-stage HCC that delisheng may improve the clinical symptoms and quality of life, without severe adverse reactions. As delisheng is attractive as a natural product for medicinal use, increasing attention is being paid to its scientific evaluation and its possible molecular mechanisms. Three-dimensional cell culture has been widely used for studying the various molecular processes and development of therapy in recent years, as it detects subtle changes in phenotypic expression and biological activity not seen in conventional monolayer culture. In contrast, multicellular spheroids of tumor cells provide an excellent three-dimensional *in vitro* model to facilitate detailed investigations, including the response to various antineoplastic agents and their possible molecular mechanisms, since spheroids mimic solid tumors more closely than monolayers do. The resistance encountered in cells cultured as spheroids seems to be analogous to the natural resistance observed in patient tumors, so the usage of three-dimensional cell culture may provide a model for developing anti-cancer drugs.

Innovations and breakthroughs

We used three-dimensional cell culture to study a Chinese medicine and its anti-cancer effects. We showed that delisheng had satisfactory anti-cancer effects on HCC, and these were associated with the up-regulation of endostatin. This was possible because of the presence of ginseng in delisheng.

Applications

We confirmed that three-dimensional cell culture was suitable for the study of a traditional Chinese medicine, and this may help other researchers to find a better model for drug development. We also found that delisheng had satisfactory anti-cancer effects on HCC, and these were associated with the up-regulation of endostatin. This was made possible by one of delisheng's components, ginseng, and this may provide a new method of therapy for HCC.

Terminology

Three-dimensional cell culture: this has been widely used for studying the various molecular processes and development of therapy in recent years, because it can detect subtle changes in phenotypic expression and biological activity not seen in conventional monolayer culture. This is because spheroids mimic solid tumors more closely than monolayers do. Delisheng: a Chinese medicinal compound that is often used in conjunction with chemotherapy for HCC. Furthermore, it has been reported in patients with late-stage HCC that it can improve clinical symptoms and quality of life, without severe adverse reactions. Its composition includes ginseng, milk vetch root, secretion bufonis and Cantharidium.

Peer review

The article provides a new model to study TCM, and explains the test outcome rationally; furthermore, it introduces the Chinese medicinal compound delisheng and indicates its further applications.

Abstract

The aetiology of primary sclerosing cholangitis (PSC) is not known. A more than 80-fold increased risk of PSC among first-degree relatives emphasizes the importance of genetic factors. Genetic associations within the human leukocyte antigen (HLA) complex on chromosome 6p21 were detected in PSC 25 years ago. Subsequent studies have substantiated beyond doubt that one or more genetic variants located within this genetic region are important. The true identities of these variants, however, remain to be identified. Several candidate genes at other chromosomal loci have also been investigated. However, according to strict criteria for what may be denominated a susceptibility gene in complex diseases, no such gene exists for PSC today. This review summarises present knowledge on the genetic susceptibility to PSC, as well as genetic associations with disease progression and clinical subsets of particular interest (inflammatory bowel disease and cholangiocarcinoma).

INTRODUCTION

Primary sclerosing cholangitis (PSC) is a chronic inflammatory condition of unknown aetiology, characterised by progressive strictures of the intra- and extrahepatic bile ducts and eventually liver cirrhosis and liver failure[1,2]. No effective medical treatment is currently available[3,4], and PSC is the major indication for liver transplantation in the Scandinavian countries as well as the fifth leading indication for liver transplantation in the United States[5,6]. Population-based studies of disease frequency are available from Norway, Great Britain and The United States[7-9], and indicate comparable incidence (0.9-1.3 per 100 000/year) and prevalence (8.5-14.2 per 100 000) rates for these populations. The prevalence of PSC is probably lower in Southern European and Asian populations[10]. In contrast to the female predominance of many autoimmune diseases, approximately 2/3 of the PSC patients are male[11]. Affected individuals are young (less than 40 years at time of diagnosis), and median survival from time of diagnosis by cholangiography to death or liver transplantation is approximately 12 years[11].

Up to 80% of the PSC patients of Northern European origin have concurrent inflammatory bowel disease (IBD)[10]. The frequency in Southern Europe and Asia is lower (around 50% and 35%, respectively)[12-14]. According to standard criteria[15], the IBD phenotype in PSC has mainly been classified as ulcerative colitis (UC), although an association with colonic Crohn's disease also exists[16,17]. The increased frequency of a variety of other autoimmune diseases (e.g. type 1 diabetes) among patients with PSC does not seem related to the increase in IBD[18]. There is also an increased risk of cancer among the patients with PSC, not only cholangiocarcinoma of the biliary tract (approximately 13%-14% in Scandinavia)[19,20], but also other gastrointestinal malignancies (i.e. pancreatic and colorectal cancer)[19]. The diagnosis of cholangiocarcinoma is difficult because the cholangiographic changes may look similar to those found in PSC without cholangiocarcinoma[21]. As a result, the cancer is often recognised at an advanced stage when treatment by liver transplantation does not improve survival[22].

Smoking is the only environmental factor known to influence PSC susceptibility and is associated with a reduced risk of the disease[23]. Several genetic risk factors, however, have been repeatedly described throughout the 25 years since they were first detected[24,25]. The present editorial aims to summarise present knowledge on statistical associations between genetic variants and risk of PSC or particular characteristics of PSC. In genetic epidemiology, disease characteristics under study are called phenotypes. Etymologically, the pheno-prefix refers to "visible" or "evident". Phenotypes, also referred to as traits, may be dichotomous (e.g. PSC/healthy) or quantitative (e.g. the level of alkaline phosphatase in a blood sample from a PSC patient). The clinical definition of a disease is primarily made to decide whether a

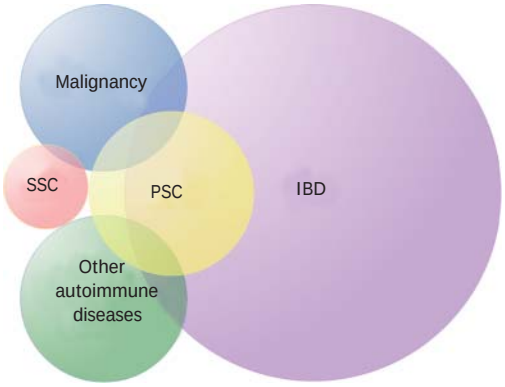

Figure 1 Primary sclerosing cholangitis (PSC) is a patchwork of different phenotypes in addition to the bile duct involvement. Most important are inflammatory bowel disease (IBD), malignancy and other autoimmune diseases. PSC is distinct from secondary sclerosing cholangitis (SSC).

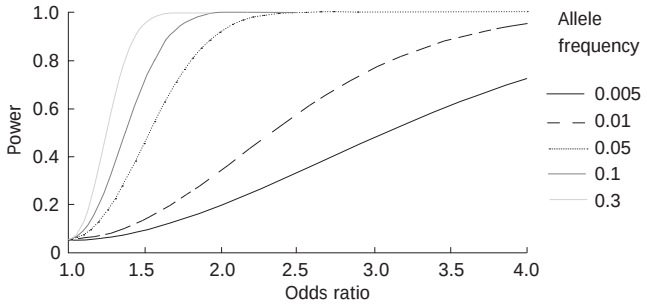

Figure 2 Statistical power (α = 0.05) for different odds ratios and allele frequencies in a study of 365 patients and 365 controls, i.e. the number of alleles in each group is 2 n = 730.

particular treatment or follow-up may be indicated for a patient or not. This practical aspect means that PSC as a clinical "diagnosis" does not necessarily equal the ideal "phenotype" for genetic association studies. The disease phenotype in such studies should be as homogeneous as possible, simply because the presence of irrelevant phenotypes in a study population will reduce the strength of effects to be identified. The clinical phenotype of PSC is compound (Figure 1).

In other diseases, susceptibility genes have been identified through genome-wide linkage scans followed by fine-mapping[26-28]. In PSC, the lack of families with affected sibling pairs has not allowed such studies to position susceptibility loci[28]. The search for PSC susceptibility genes has thus focused on plausible candidates with regard to function[25]. As a general basis for interpreting candidate gene association studies, an introduction to important concepts of such studies will be given, followed by a presentation and discussion of studies performed in PSC. We searched PubMed for relevant articles published up until the end of April 2007. We have also reviewed the reference lists of identified articles, as well as the reference lists of major immunogenetic- and hepatology conferences held over the last 2 years.

GENETIC CONSIDERATIONS

In genetic terms, PSC is considered a complex trait, meaning that polymorphisms in several genes along with environmental factors are required for disease development[27]. Heritability for a disease is measured by (a) concordance rates in monozygotic versus dizygotic twins and (b) relative risk in siblings of a patient (λ_s = prevalence among siblings divided by the general population prevalence). For monogenic disorders, λ_s ranges from several hundreds to several thousands, whereas values in complex traits are usually below 100. A strong genetic contribution to overall risk of PSC is supported by λ_s values of approximately 100[29], as compared with values of 15-35 for Crohn's disease and 6-9 for UC[30].

Polymorphisms are genetic variants that have arisen from mutational events in DNA[31]. Conventionally, to be denominated a polymorphism, a mutant variant should occur at a frequency of > 0.01 in the general population. A particular nucleotide (or nucleotide sequence) at a polymorphism is defined as an allele. The combination of alleles on the two chromosomes is termed the genotype of the individual at that position. A distinct combination of two or more alleles of polymorphisms that occur together on the same chromosome is defined as a haplotype.

When a mutation arises in a chromosomal region, it does so on a background of particular DNA variants that are already present in the population, i.e. the mutation is linked to these surrounding alleles by the integrity of the DNA molecule. Over time, recombination tends to separate a mutant allele from the alleles of the surrounding DNA. At the population level, the positive association that remains between particular alleles at linked polymorphisms is called linkage disequilibrium (LD), meaning that these alleles occur more frequently together than would be expected from their population frequencies. Recombination ultimately leads to loss of LD unless there is a selective advantage of particular allele combinations.

The relationship between disease phenotype and three of the genetic concepts described (polymorphisms, alleles and haplotypes), is the subject of *genetic association studies*. That is, the aim of genetic epidemiology is to identify alleles (or in diploid terms, genotypes) of polymorphisms that are associated with an increase or decrease in risk of disease or a particular characteristic of a disease. The advantage of LD is that all polymorphisms in a genetic region do not have to be genotyped to detect an association. This is because the causative variant will reside on the same haplotypes as other polymorphisms and can be indirectly detected by typing for these. The disadvantage of LD is that it may be almost impossible to determine which of a series of alleles in LD on a haplotype that is actually the causative variant. Most of the genetic variation (> 99%) in the human genome is believed to be without any phenotypic consequence[32].

STATISTICAL CONSIDERATIONS

Because of the low prevalence, a major limiting factor for statistical power in studies of PSC susceptibility genes is sample size. Figure 2 illustrates the statistical power as a function of the effect size (odds ratio; OR) and allele

frequency of a genetic variant for studies performed in the largest PSC population in which studies have been performed so far (n = 365)[33]. Two issues require mentioning. First, very weak effects (OR ≈ 1.0-1.3) are likely to be missed, even for populations of this size. Second, rare variants of importance for PSC susceptibility (allele frequency < 0.01) are likely to be missed unless the OR of the variant is very high (or low; ORs < 1 were not plotted for clarity).

An important controversy regarding the prospects of mapping the genetic predisposition to complex diseases is not related to statistical power, but the possible complexity of allelic variation at a susceptibility locus. Supporters of the "common-disease/common-variant" hypothesis argue that common diseases arise due to polymorphisms that are common (i.e. allele frequency > 0.10[34]) in the background population. Supporters of the "multiple rare variants" hypothesis point to the complexity observed at susceptibility loci in monogenic disorders, where multiple rare alleles define a similar phenotype (e.g. the hundreds of disease causing alleles at the cystic fibrosis transmembrane-conductance regulator locus)[35]. Possibly, susceptibility genes in complex diseases that are defined by multiple rare variants cannot be identified using regular LD based approaches[36]. Although PSC is relatively rare, the main HLA haplotypes that confer risk are relatively common (e.g. the frequency of the PSC associated ancestral HLA haplotype 8.1 is > 0.10 in Scandinavia[37]).

The abundance of false positive genetic association studies (i.e. type I statistical errors) represents a problem of legitimacy for this type of study design[38]. Simply using a P-value < 0.05 as "evidence" to distinguish between a "positive" and "negative" finding in these studies can be questioned[39]. The problem is partly related to the many statistical tests performed in these studies. The so-called Bonferroni correction (multiplying P-values with the number of comparisons that have been performed) is the most widely accepted strategy to account for this problem.

The Bonferroni approach has limitations. Due to the many tests that are theoretically possible throughout the genome, it can be argued that conservative significance levels of 10^{-5} or even 10^{-8} should be used for all tests[38,40]. Achieving such significance levels would require patient collections simply not available for rare diseases like PSC. The most recent proposal is that so-called permutation testing (in Latin, "permutare" means "change completely") within a dataset is the preferable strategy to take account of multiple testing[41]. In permutation tests, case/control assignment is shuffled randomly using a computer and tests are run over and over again to count how often the permuted dataset achieves the effect observed in the correctly ordered dataset. If the permuted dataset achieves an effect equal to or stronger than that observed in the original dataset in 500 out of 10 000 analyses, this means that the probability of a type I error for a finding is 5%.

The problem of statistical significance in genetic association studies philosophically relates to the problem of causality for which criteria relevant to modern medicine were proposed by Sir Austen Bradford Hill in a classic essay in 1965[42]. These criteria point to factors in addition to the probability from statistical association tests (e.g. biological plausibility) that are required for a causal relationship to be established. This is also argued for in so-called Bayesian statistics, where the prior probability of a genetic variant to be associated (e.g. non-synonymous polymorphism in a gene which function is relevant to the disease phenotype), is accounted for when deciding on the posterior probability of whether or not a finding is valid[38]. In sum, circumstantial evidence (from functional studies or mouse models) is required to support findings if a genetic variant should be considered causative in terms of contributing to a disease phenotype[28], whatever the statistical evidence is available.

THE HLA COMPLEX AND GENETIC ASSOCIATIONS OBSERVED IN PSC

The HLA complex stretches across 7.6 million base pairs (bp) of DNA on the short arm of chromosome 6 and contains 252 expressed protein-coding genes, of which 28% are potentially related to immunological functions[43]. Throughout evolution of this genetic region[44], duplications have led to several gene clusters containing genes of similar function (Figure 3)[43]. HLA class I molecules (i.e. HLA-A, -B and -C) are expressed on all nucleated cells in the body and present intracellular/endogenous antigens to $CD8^+$ T-lymphocytes. HLA class I molecules also serve as ligands for inhibitory killer immunoglobulin-like receptors (KIRs) on natural killer (NK) cells and γδ T-lymphocytes[45,46]. HLA class II molecules are expressed on antigen presenting cells (e.g. macrophages and dendritic cells) and present extracellular/exogenous antigens to $CD4^+$ T-lymphocytes[45].

Sequence-based HLA-nomenclature was established in 1987[45]. The locus name is followed by an asterisk and two pairs of digits. The first pair of digits denominates the main type and is often similar to the serological type (e.g. DRB1*03 is the same as serological DR3, but DRB1*13 is only one of the DR6 alleles). The second pair of digits denominates the subtype (e.g. DRB1*0301 and DRB1*1301). Further definition is possible, since null alleles are suffixed by "N", and polymorphisms that do not alter the amino acid sequence of the peptide binding groove give rise to the fifth, sixth and seventh digits. In result, a complete sequence-based HLA allele name represents the haplotype of all alleles at all polymorphisms within the HLA gene at that chromosome.

LD between alleles at the HLA class I and II loci defines ancestral HLA haplotypes (AHs) and are named after which HLA-B allele they contain (e.g. the most common haplotype with HLA-B*08 is called AH8.1)[44]. Alleles of other genes are in LD with these ancestral haplotypes, and the co-occurrence of particular alleles across the entire HLA complex on one chromosome is called an extended HLA haplotype[47]. At the population level, the degree of conservation varies between different extended HLA haplotypes[48]. As examples of this phenomenon, an extended HLA haplotype with the HLA-B*08 and DRB1*0301 alleles (i.e. the AH8.1) is remarkably conserved in the Northern European population, whereas haplotypes carrying DRB1*04 alleles

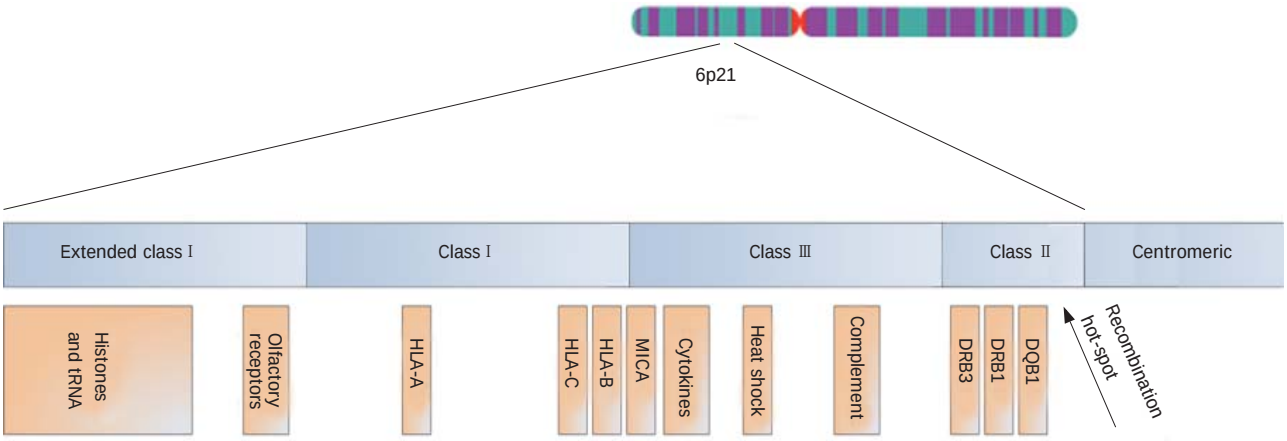

Figure 3 Schematic outline of the HLA complex on chromosome 6. Distances are arbitrary. By convention, the extended HLA complex stretches from the centromeric border of the HLA class Ⅱ loci (HLA-DP) to the telomeric limit of the histone gene cluster more than 4 million bp from HLA-A[43,120]. Centromeric to the HLA-DQ loci, a region with intense recombination can be found ("recombination hot-spot")[132].

are considerably less conserved and may not even qualify for the denomination "extended haplotypes"[49].

A HLA association in PSC was first identified for HLA-B8 (i.e. HLA-B*0801) and DR3 (i.e. DRB1*0301)[24,50]. Later studies have verified that PSC associations exist also for the other alleles of the AH8.1 (the HLA-A1 allele[51], the HLA-C7 allele[52], the major histocompatibility complex class I chain-related A (*MICA*) *008/5.1 allele[53,54], and the tumour necrosis factor alpha (*TNF*α) promoter -308 A allele[55,56]). This haplotype is associated with a wide range of autoimmune diseases[57,58]. A cross-European study (Norway, Sweden, Great Britain, Italy and Spain) concluded that a consistent, positive HLA class Ⅱ association in PSC probably exists also for a haplotype that carries the DR6 (i.e. DRB1*1301) allele[37]. In individuals negative for DR3 and DR6, an association with haplotypes that carry the DR2 (i.e. DRB1*1501) allele can be found. Negative associations with HLA class Ⅱ alleles have been reported for the DR4, DR7 and DR11 alleles[37,59,60], although primarily in populations of Northern European origin[56]. In Southern Europe, the picture is even more complex, since the DR4 allele seems to be consistent in LD with a predisposing variant in Italy[37,56], whereas a protective effect is noted in Spain[37].

Due to strong LD, an important question in HLA genetics is whether genetic associations are due to variation in the HLA class I or Ⅱ genes (meaning that they arise because the patients are able to present particular antigens to the T-cell receptor)[61], or due to variation in neighbouring genes[62]. There is some degree of amino acid sequence similarity between several of the PSC associated HLA class Ⅱ polypeptide variants[59,63]. However, no consistency has been found regarding these similarities[59]. The proposal of leucine at position 38 of the DRβ polypeptide as a critical determinant for PSC susceptibility relies heavily on the strong DRB3*0101 association in Northern European populations[63]. An early suggestion that a common denominator between haplotypes with the DRB1*0301 and DRB1*1301 alleles could be the DRB3*0101 allele (serologically DRw52a) was later withdrawn[64,65]. Another study found that the DRB1*1301-DRB3*0202 haplotype association is as strong as the DRB1*1301-DRB3*0101 association[37]. Taken together, the most interesting proposal of a single amino acid position in defining risk of PSC may rather relate to a protective effect in carriers of proline at position 55 of the DQβ polypeptide, which is common for DQ3 alleles known to be in LD with the protective DR4, DR7 and DR11 alleles[59]. However, no consistent risk allele is defined by this position[59], and to what extent the HLA class Ⅱ molecules are of primary importance in the PSC pathogenesis should probably not be concluded based on present evidence.

The PSC-associated MICA*008/5.1 allele has been proposed as a common denominator between the PSC-associated A*01-C*07-B*08-DRB1*0301-DQB1*0201 and A*03-C*07-B*07-DRB1*1501-DQB1*0602 haplotypes[53,59]. MICA functions as a ligand for the activating NKG2D receptor on NK cells[66]. It was recently recognised that the two risk haplotypes in question share alleles not only at *MICA*, but also at the neighbouring *HLA-B* and *-C* loci, when these are defined according to the KIR binding properties of the HLA class I molecules[67]. The PSC-associated *HLA-B* and *-C* KIR ligand genotypes may result in decreased inhibition of NK cells and several subsets of T-lymphocytes that express KIRs[46,68]. Such combinations of KIR and HLA class I ligand variants have been shown to increase susceptibility to other autoimmune diseases[46]. How the PSC-associated MICA*008/5.1 allele may cause disease is not known. This allele is also associated with an increased risk of other autoimmune conditions[69,70], and may thus also result in an increased activity of cells expressing the NKG2D receptor, acting in synergy with the loss of inhibition resulting from the PSC associated HLA class I ligand genotypes. The fact that the MICA 5.1 allele was recently shown to confer protection against cholangiocarcinoma is in line with an activating effect[71]. Some studies report an increased frequency of NK cells in the portal infiltrate of patients with PSC when compared with other liver diseases[72,73], and also in the intestinal mucosa of patients with PSC without IBD compared with IBD patients without liver

Table 1 Candidate gene studies performed in PSC

Gene	Chromosome	N (PSC)	Primary finding	Reference	Replication finding	Reference
IL-1	2q	40	Negative	[76]	Negative	[77]
IL-10	1q	96	Negative	[77]	Negative	[55]
MMP1	11q	165	Negative	[78]	NA	-
MMP3	11q	111	Positive	[79]	Negative	[78]
CCR5	3p	71	Positive	[80]	Negative	[33]
ICAM-1	19p	104	Positive	[81]	Negative	[82]
CFTR	7q	29	Negative	[83]	Negative	[84,85]
MDR3	7q	37	Negative	[86]	Negative	[87]
BSEP	2q	37	Negative	[86]	NA	-
AIRE	21q	60	Negative	[88]	NA	-
NRAMP1	2q	40	Negative	[89]	NA	-
CTLA4	2q	144	Negative	[90]	NA	-
FOXP3	X	195	Negative	[91]	NA	-

Interleukin-1 and -10 (IL-1 and -10), MMP1 and 3 (matrix metalloproteinase 1 and 3), CCR5 (chemokine receptor 5), ICAM-1 (intercellular adhesion molecule 1), CFTR (cystic fibrosis transmembrane conductance regulator), MDR3 (multidrug resistance gene 3), BSEP (bile salt export pump), AIRE (autoimmune regulator), NRAMP1 (natural resistance-associated macrophage protein 1), CTLA4 (cytotoxic T-lymphocyte-associated protein 4), FOXP3 (forkhead box P3). NA: Not available.

disease[74]. Taken together with the genetic findings in this region of the HLA complex (Figure 3), further studies on the role of these cells in PSC seem warranted.

In sum, the HLA association in PSC is likely to be complex. Multiple risk variants may exist[25], some of which may be associated not only with PSC, but autoimmunity in general.

PSC ASSOCIATIONS WITH POLYMORPHISMS IN GENES OUTSIDE THE HLA COMPLEX

Summarising the published genetic association studies in PSC, it seems proven beyond doubt that one or more genetic variants located within the HLA complex are important. The true identities of these variants, as discussed above, are not known. The situation is even less clear with regard to other susceptibility loci. Given the large number of protein coding genes in the human genome (25-35 000)[32], selecting candidate genes for association studies is an extremely difficult task. According to strict criteria for what may be denominated a susceptibility gene in complex diseases (consistent statistical evidence, functional consequence of identified mutation, relevant tissue expression, *etc.*)[28], no such gene exists for PSC. A summary of studies performed is given in Table 1. So far, most attention has been given to genes known to be of importance in other autoimmune diseases. The association between PSC and IBD has also inspired some of the studies, as well as the observation of PSC-like changes in cystic fibrosis[75].

Two of the negative findings are of particular interest and will be discussed in greater detail. First, studies in limited populations ($n < 50$) have pointed to a non-significant increase of particular multidrug resistance gene 3 (*MDR3*) variants among PSC patients as compared with healthy controls[86,87]. Knock-out mice for this phospholipid transporter gene (called *mdr2* in mice) spontaneously develop hepatic lesions resembling PSC[92], possibly due to loss of protection of the biliary epithelium from toxic bile acids. Second, it cannot be formally ruled out that the 32 bp deletion of the chemokine receptor 5 (*CCR5*) gene and the E/E genotype of the K469E SNP in the intercellular adhesion molecule 1 (*ICAM-1*) gene may confer population specific effects[80,81,93]. Both genes are plausible candidate genes in PSC. The CCR5 may be involved in the recruitment of intestinally activated lymphocytes *via* portal expression of CCR5 ligands (e.g. the macrophage inflammatory protein-1α and β), and ICAM-1 may play a similar role in recruiting leukocytes to an inflamed liver by interacting with the β2-integrin ligand. The negative findings in the replication series referred to in Table 1 state it unlikely that genetic variants of these receptors are of primary importance in the pathogenesis of PSC. The receptors may, however, still be involved in the disease process along with other CCRs and adhesion molecules [e.g. CCR9 and the mucosal addressin cell adhesion molecule 1 (MAdCAM-1)[94,95]].

GENETIC ASSOCIATIONS WITH CLINICAL SUBSETS OF PSC PATIENTS

The most prominent features of PSC along with the biliary changes are inflammatory bowel disease, cholangiocarcinoma and other autoimmune diseases (Figure 1).

The increased frequency of autoimmune diseases among patients with PSC is possibly due to the increased frequency of the AH8.1 among the patients[58,96]. Similarly, an increased frequency of IBD risk alleles among patients with PSC could contribute to the co-occurrence of these two phenotypes. Several IBD susceptibility genes have been identified during the last 6 years through the application of genome-wide linkage screens and subsequent fine-mapping approaches[26]. To determine if the high frequency of IBD among patients with PSC could be due to genetic risk factors shared with IBD in general, we recently genotyped key polymorphisms of known IBD susceptibility genes in a large cohort of Scandinavian PSC patients[97]. The following genes were studied: caspase activating recruitment domain 15 (*CARD15*), toll-like receptor 4 (*TLR-4*), caspase activating recruitment domain 4 (*CARD4*), solute carrier family 22, member 4 and 5 (*SLC22A4* and *SLC22A5*), Drosophila discs large homolog 5 (*DLG5*) and multidrug resistance gene 1 (*MDR1*)[26,98]. No significant PSC associations were detected for any of the investigated polymorphisms[97]. These negative findings add to notions that the IBD phenotype in PSC may be a "third" IBD phenotype[99], possibly distinct from UC and Crohn's disease not only in clinical presentation, but also with regard to genetic susceptibility.

It is of interest to know whether genetic associations detected in PSC may be of particular importance for the IBD phenotype among the PSC patients or patients with IBD in general. In a recent study of HLA alleles in

PSC and UC patients of the same ethnicity[100], the only parallel association detected was a protective effect of the DRB1*0404 allele, more pronounced among the PSC patients than among the patients with UC without liver disease. No association with any of the main PSC risk alleles (DRB1*0301, DRB1*1301 or DRB1*1501) was found among the regular UC patients. Interestingly, a non-significant trend towards a higher frequency of the DRB1*1501 allele was noted among the patients with PSC and concurrent IBD compared with PSC patients without IBD, and the possibility should be held open that this HLA haplotype may harbour genetic variants of particular importance for the IBD phenotype in PSC. A similar notion can be made with regard to the MMP3 5A allele association detected by Satsangi *et al*[79]. Although the replication study by Wiencke *et al*[78] failed to confirm an overall association with PSC susceptibility, a significant association was evident when PSC patients with UC were compared with UC patients without liver disease.

The study by Wiencke *et al*[78] also detected a possible association between cholangiocarcinoma and the MMP1 1G allele. Although the number of patients with cholangiocarcinoma in this series was too small for conclusive statistics to be performed (n = 15), the 100% occurrence of this allele among the cholangiocarcinoma patients warrants future replication attempts in other study populations. Recently, a highly significant association between polymorphisms in the *NKG2D* gene and cholangiocarcinoma in PSC was detected[71]. Previous studies have highlighted the importance of this activating NK cell receptor in protection against other cancer types[66]. Persistent exposure to effector molecules of inflammatory pathways (e.g. IL-6[101]), along with chronic cholestasis[102], is probably important for the malignant transformation of cholangiocytes. The study by Melum *et al*[33] points to the possible role of NK cell activity in protection against neoplastic cells. Polymorphisms of the *NKG2D* gene along with other parameters may also prove important in identifying PSC patients at a particular low risk of developing cholangiocarcinoma.

MODIFIER GENES IN PSC

There is an increasing interest in so-called "modifier genes" in complex diseases (as compared with "susceptibility genes"), initiated by the recognition of the influence of such genes on disease expression (e.g. severity) in monogenic disorders like cystic fibrosis and haemochromatosis[103-105]. Modifier genes may point to biochemical and physiological systems of relevance to prognosis and are therefore of great clinical interest. Although PSC should be considered a progressive condition culminating in death or liver transplantation in most cases[106], the clinical course for each individual patient varies considerably[107,108]. In terms of disease course, indicators of PSC severity (e.g. portal hypertension and need for liver transplantation) are more likely to represent a particular disease stage than to serve as valid measures of disease progression. The most precise strategy for performing enquiries on effects from genotypes on disease course in PSC is thus to compare absolute survival time (defined as time from diagnosis until death or liver transplantation) using Kaplan-Meyer analyses, or calculating the relative risk for death and/or liver transplantation from Cox regressions[109,110].

We have recently observed that genetic variants of the steroid and xenobiotic receptor (SXR) are associated with a more aggressive disease course in PSC[110]. The SXR is a ligand-dependent transcription factor known to mediate protection against bile acid-induced liver injury in cholestatic animal models[111,112]. In this perspective, our data may suggest that the activity of bile acid detoxification systems could be of importance for disease progression in PSC. Interestingly, the SXR ligand rifampicin has been used in the treatment of cholestatic pruritus[113], and it has also been shown that ursodeoxycholic acid is able to activate SXR in human hepatocytes[114]. However, the SXR may also influence inflammatory pathways *via* the pro-inflammatory transcription factor nuclear factor kappa B (NF-κB)[115], as well as liver fibrogenesis and thus cirrhosis *via* direct effects on hepatic stellate cells and Kuppfer cells[116]. Further studies are needed to clarify the functional consequences of various polymorphisms of the *SXR* gene in patients with PSC.

The SXR variants associated with death or liver transplantation in our study were not associated with PSC susceptibility[110]. However, also for some of the disease-associated variants in the HLA complex, modifier effects have been observed. The first notion was made by Gow *et al*[117] who described an unusually aggressive disease progression in four patients carrying the DR4 allele. Later, Boberg *et al*[109] found that DR4 positive patients have an increased risk of cholangiocarcinoma, but do formally not experience an accelerated disease progression. In this study, an increased risk of death or liver transplantation was observed in patients heterozygous for the DR3-DQ2 haplotype. As long as the causative variants along the HLA haplotypes in question have not been identified, one can only hypothesize upon a biological explanation for these observations. Given the complexity of the HLA associations in PSC, it is even possible that other variants within this region may be important for disease progression than those primarily important for disease susceptibility. However, for the same reasons it has been difficult to pinpoint susceptibility genes in this region (strong LD, multiple genes of immunological relevance, *etc*.), such modifier genes may prove hard to identify conclusively.

FUTURE STUDIES AND CONCLUDING REMARKS

Although several important findings have been made during the past 25 years since the first genetic association study in PSC was performed[24], PSC remains an enigmatic disease and future studies are warranted. With an ever increasing availability of methods for efficient genotyping of polymorphisms[118], a critical limitation for such studies in PSC is the availability of well-characterised patient materials. Collaborative efforts will be necessary to achieve patient collections required for detecting the modest effects (Figure 2), as well as for replicating results of

uncertain validity[33]. Such collaborations are now being undertaken in other diseases[119], and have successfully aided in clarifying genetic associations found in PSC[37].

In terms of future research strategies, several proposals can be made. First, dissection of the widely replicated HLA-associated susceptibility to PSC should be considered a priority. Detailed maps of genetic markers in this region are now available[120]. It is anticipated that the systematic application of such marker maps in populations of an appropriate size may lead to the identification of true, disease causing variants in this difficult region[62].

Second, some biological pathways are pointed to by existing findings (e.g. the possible importance of bile acid homeostasis in influencing disease progression), and further candidate gene studies of critical components of these systems may identify additional risk factors. There is increasing awareness of the importance of interaction between polymorphisms in functionally related genes in complex diseases, i.e. epistasis[121,122]. In some cases, epistatic considerations have proven necessary for the detection of effects from genetic variation on a phenotype of interest[123,124]. These observations have implications for study design in future candidate gene studies in PSC. Polymorphisms not only in single genes, but in relevant panels of several genes encoding proteins with closely related functions, should be investigated.

Finally, two recent advances in the genetic research field now make genome-wide studies feasible also for case-control materials. First, the human haplotype map project (HAPMAP) was recently completed[125]. In the project, 3.9 million SNPs have been genotyped in families of three different ethnicities (at the time of writing). Results from the project enable researchers worldwide to efficiently select SNPs throughout the genome that are prone to cover genetic variation of interest to a project[126,127]. Second, although costs are high, genotyping technology now allows for the typing of 100 000's of SNPs simultaneously in the same DNA sample[118]. Emerging reports provide proof-of-concept for genome-wide case-control studies[128,129]. However, there are still statistical problems to be solved regarding the many tests performed and risk of false positive results[130]. As evident from Figure 2, only strong effects may be detectable, and prospects may not yet justify the costs. However, sooner or later genome-wide studies seem warranted, also in PSC. Possibly, PSC susceptibility genes will be identified that would otherwise never have been included in hypothesis-driven candidate gene studies of the type performed so far[131].

Abstract

AIM: To investigate the anti-viral mechanism of combination therapy of interferon (IFN)-α and ribavirin in patients with chronic hepatitis B.

METHODS: Twenty patients were assigned to receive either IFN-α plus ribavirin (group A, *n* = 14) or no treatment as a control (group B, *n* = 6). Patients were analyzed for T-cell proliferative responses specific for hepatitis B virus (HBV)-antigen and cytokine production by peripheral blood mononuclear cells (PBMCs).

RESULTS: Combination therapy induced HBV-antigen specific CD4+ T-cell proliferative responses in four patients (28.6%). Production of high levels of HBV-specific IFN-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-12 by PBMCs was found in five patients (35.7%), who showed significantly lower HBV DNA levels in serum at 12 mo after treatment ended (P = 0.038) and at 24 mo of follow-up (P = 0.004) than those without high levels of cytokine production.

CONCLUSION: HBV-antigen specific CD4+ T cells may directly control HBV replication and secretion of anti-viral T helper 1 (Th1) cytokines by PBMCs during combination therapy of chronic hepatitis B with ribavirin and IFN-α.

Key words: Hepatitis B; Interferon-alpha; Ribavirin; CD4+ T cells; Th1

INTRODUCTION

More than 400 million people worldwide have chronic hepatitis B virus (HBV) infections[1]. Chronically infected patients with active liver disease have a high risk of developing cirrhosis and hepatocellular carcinoma[2]. However, therapeutic options against HBV still present a major clinical challenge. The goal of treatment is HBV DNA suppression, normalization of alanine aminotransferase (ALT) levels and reduction in liver necroinflammation. Currently available therapies against HBV are mainly interferon (IFN)-α and nucleoside analogs, which are well tolerated and induce a decrease in serum HBV DNA levels and normalization of serum ALT levels. However, the efficacy of IFN-α[3,4] or nucleoside analogs for treatment of hepatitis B varies in different clinical situations[5-12]. IFN-α shows seroconversion from hepatitis B e antigen (HBeAg) to antibody to HBeAg (anti-HBe), concomitant with HBV DNA negativity in just one-third of patients treated, and is both costly and induces adverse effects[3]. It has been well established that IFN-α has potent antiviral activity against DNA and RNA viruses, and that it also acts as an immunomodulatory agent[13]. Some reports have suggested that ribavirin shows antiviral and immune effects against various infections[14], including hepatitis B and C. Both drugs have the capacity to modulate systemic as well as virus-specific T-cell responses, along with the potential to shift the profile of cytokine secretion[15,16].

Recent reports have suggested that combination therapy with IFN-α plus ribavirin for chronic hepatitis B significantly reduces viremia[17,18] and induces lasting CD4+ T-cell proliferation and Th1 cytokine release at the site of infection, which may lead to sustained HBV eradication[18]. These preliminary data in anti-HBe-positive patients refractory to IFN-α treatment appear to be promising[18]. Thus, in the present study, we investigated the mechanism involved in the control of HBV replication, utilizing combination therapy with ribavirin and IFN-α.

MATERIALS AND METHODS

Patients

Twenty patients with chronic hepatitis B (14 men and 6 women; mean age 42 years), positive for both anti-HBe and HBV DNA in the serum, and who had failed previous IFN-α treatment were enrolled in this prospective trial. None had human immunodeficiency virus, hepatitis

C virus, or hepatitis D virus infections, hepatocellular carcinoma, or had received nucleoside analogs. Six healthy controls were also analyzed (mean age 38 years). Table 1 shows patient characteristics at enrollment. This study conformed to the ethical guidelines of the Declaration of Helsinki and was approved by institutional ethics committee. Informed consent was obtained from all patients prior to inclusion.

Therapeutic and analytic schedule

The patients were divided into two groups: group A (n = 14) for combination therapy with IFN-α plus ribavirin, and group B (n = 6) for untreated controls. Patients in group A received 5 million U IFN-α2b three times a week for 12 mo, plus ribavirin (1000 mg/d) orally for 12 mo[17]. Patients were followed for 12 mo after the end of treatment. Blood chemistry, blood cell counts, and HBV DNA were measured at the beginning of treatment, and then every 1-2 mo during treatment and follow-up periods. HBeAg and anti-HBe were measured at the beginning of treatment, and then at 6-mo intervals. Blood samples for immunological analysis were collected before therapy and at 3, 6, 9, 12, 18 and 24 mo after the commencement of therapy. Serum HBV DNA was quantified, using transcription-mediated amplification and a hybridization assay. The concentration of HBV DNA in the samples was expressed as the logarithm of genome equivalents per milliliter (LGE/mL). Biochemical and hematologic parameters were measured by standard methods. All patients completed treatment and follow-up.

Cell preparation

The methods of cell preparation used here were nearly identical to those of Ren *et al*[19] in their report focusing on therapeutic vaccination against chronic hepatitis B. Peripheral blood mononuclear cells (PBMCs) from 20 patients were separated from heparinized blood by density-gradient centrifugation with lymphoprep (Nycomed Pharma AS, Oslo, Norway). B cells were removed from PBMCs by negative depletion, by incubating the cells with mouse anti-$CD19^+$ antibodies coated on magnetic beads (Danal, Olso, Norway). CD4+ or CD8+ T cells were then removed from the resultant T cells in the same manner, using mouse anti-human CD4+ or CD8+ antibodies coated on magnetic beads (Danal), respectively. CD4+ cells were also blocked with CD4+ antibodies (Caltag Laboratories, Burlingame, CA, USA). The purity of the T-cell subpopulation was monitored by immunolabeling with anti-$CD3^+$ antibodies (Becton Dickinson, San Jose, CA, USA). Flow cytometry revealed a > 95% purified T-cell subpopulation. PBMC or lymphocyte subsets were resuspended with 2 mmol/L l-glutamine, 10 mmol/L HEPES, 100 kU/L penicillin, 100 mg/L streptomycin, and 50 mL/L human AB serum (complete medium).

Proliferation assay

The proliferation assay used in this study was nearly identical to that of Ren *et al*[19]. T cells (1.5×10^6 cell/L in 0.2 mL complete medium) were cultured in triplicate wells of 96-well round-bottom microplates with medium alone, were stimulated with 10 mg/L phytohemagglutinin (PHA: Sigma) and 3 mg/L HBV antigens: HBsAg protein, synthetic entire preS1, HBeAg, and hepatitis B core antigen (HbcAg) (Virostat, Portland, ME, USA). After 4 d of culture at 37℃ in an atmosphere of 50 mL/L CO_2 in air, the cells were labeled for 18 h with 37 kBq of [^{3}H]-thymidine (Amersham, Little Chalfont, UK). DNA-incorporated radioactivity was measured by scintillation counting. Data were expressed as the stimulation index (SI), calculated as the ratio of the mean cpm of triplicate cultures obtained in the presence of antigen to cpm obtained without antigen. SI > 3 was considered significant. The proliferative responses were not tested with PBMCs from patients in control group B.

Table 1 Clinical characteristics of patients at enrollment

Patient No.	Age (yr)	Gender	ALT (nkat/L)	HBV DNA (10^3 LGE/L)	Type of response (end of treatment)

P > 0.05, Group A *vs* Group B.

Cytokine assay

The cytokine assay used in this study was nearly identical to that of Ren *et al*[19]. PBMCs (1.5×10^6 cell/L in 0.2 mL complete medium) were cultured in triplicate wells of 96-well round-bottom microplates with medium alone, and stimulated with 10 mg/L PHA or with 3 mg/L HBsAg, HBeAg, HBcAg or preS1. After 3 d of culture at 37℃ in an atmosphere of 50 mL/L CO_2 in air, culture supernatants were collected. Concentrations of IFN-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-4, IL-10 and IL-12 p70 were determined using commercial ELISA kits (Genzyme, Cambridge, MA, USA). Production levels after antigen stimulation were expressed as the ratio of the mean cytokine concentration of triplicate cultures obtained in the presence of antigen to that obtained without antigen.

Statistical analysis

Results are expressed as mean ± SD. Differences in proportions were tested by the χ^2 test. Mean quantitative values were compared using the Mann-Whitney U test. All reported P values were two-tailed and $P \leqslant 0.05$ was considered significant.

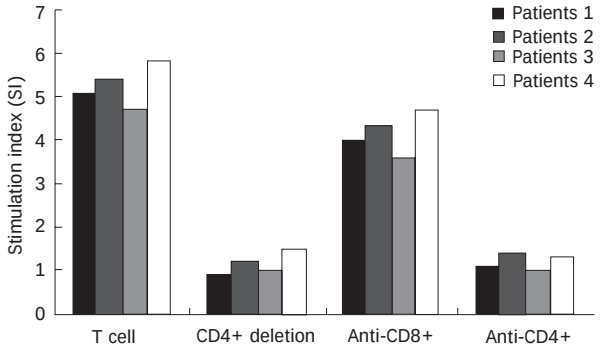

Figure 1 Abrogation of antigen-specific T-cell proliferative responses from patients 1-4 at 12 mo ([b]$P < 0.01$ *vs* T cell and Anti CD8+).

RESULTS

Clinical outcome

HBV DNA levels decreased, with a significant reduction at 9 mo and thereafter, as compared to those at baseline, in the combination therapy patients. Serum HBV DNA levels were also significantly lower in the combination therapy patients than in the controls at 12 and 24 mo. At 12 mo, four patients in group A (28.6%) (patients 1-4) had undetectable HBV DNA levels, and also showed sustained normalization of ALT; they were thus considered sustained responders, as previously reported[17,18]. The remaining 10 patients at 12 mo had detectable HBV DNA and elevated ALT levels.

Induction of T-cell proliferation response to HBV antigens

Proliferative responses of T cells during combination therapy and the follow-up period are summarized in Table 2. Four patients (1-4) showed significant proliferative responses at 12 mo, and these responses were sustained until 24 mo (the end of follow-up). These proliferative responses were always specific to both HBV antigens. Thus, this combination therapy was found to have induced proliferative T cell responses specific to the antigen contained in these four patients (28.6%). Patient 5 also showed a strong proliferative response at 24 mo. However, whether the combination therapy induced this response is unclear because it occurred at 12 mo after completion of therapy.

T-cell proliferative responses were also examined for patients 1-4 after incubation with anti-CD4+ antibodies or removing CD4+ or CD8+ cells. Depletion of CD8+ cells did not clearly inhibit the proliferative responses, while depletion of CD4+ cells or blocking with anti-CD4+ antibodies completely abrogated the proliferative responses of the patients (Figure 1).

HBV-specific cytokine production in PBMCs

HBV-specific cytokine production levels of PBMCs are shown in Figure 2. Cytokine production showed a Th1-like pattern characterized by secretion of IFN-γ, TNF-α, and IL-12 in the absence of IL-4 and IL-10 in five patients (1-5, defined as responders). Patients 1-4 exhibited remarkable increases in IFN-α, TNF-α, and IL-12 production at 3, 6 or 9 mo, as compared to patient 5 who showed mild, but not significant, proliferative responses (Table 2). These responses were sustained until the end of the observation period. Production of Th1 (IFN-γ, TNF-α, and IL-12) and Th2 (IL-4 and IL-10) cytokines did not increase, or remained unchanged in the patients who received other combination therapy (patients 6-14, defined as non-responders).

The mean serum HBV DNA level was lower in responders than in non-responders at 12 mo (4.3 ± 1.1 *vs* 6.0 ± 1.1, $P = 0.038$) and 24 mo (3.8 ± 0 *vs* 5.7 ± 1.2, $P = 0.004$). It is noteworthy that HBV DNA fell to under the detection limit at 24 mo in all responders. The decrease in serum HBV DNA level was almost coincident with the increase in IFN-γ production by HBV antigen-specific T cells, but was not preceded by any increase in serum ALT levels in four responders (patients 2-5).

DISCUSSION

In the present study, a significant decrease was found in serum HBV DNA levels at 9 mo and thereafter, along with significantly lower levels of HBV DNA in the combination therapy patients than in the controls at 12 and 24 mo. IFN-α plus ribavirin therapy appeared to inhibit

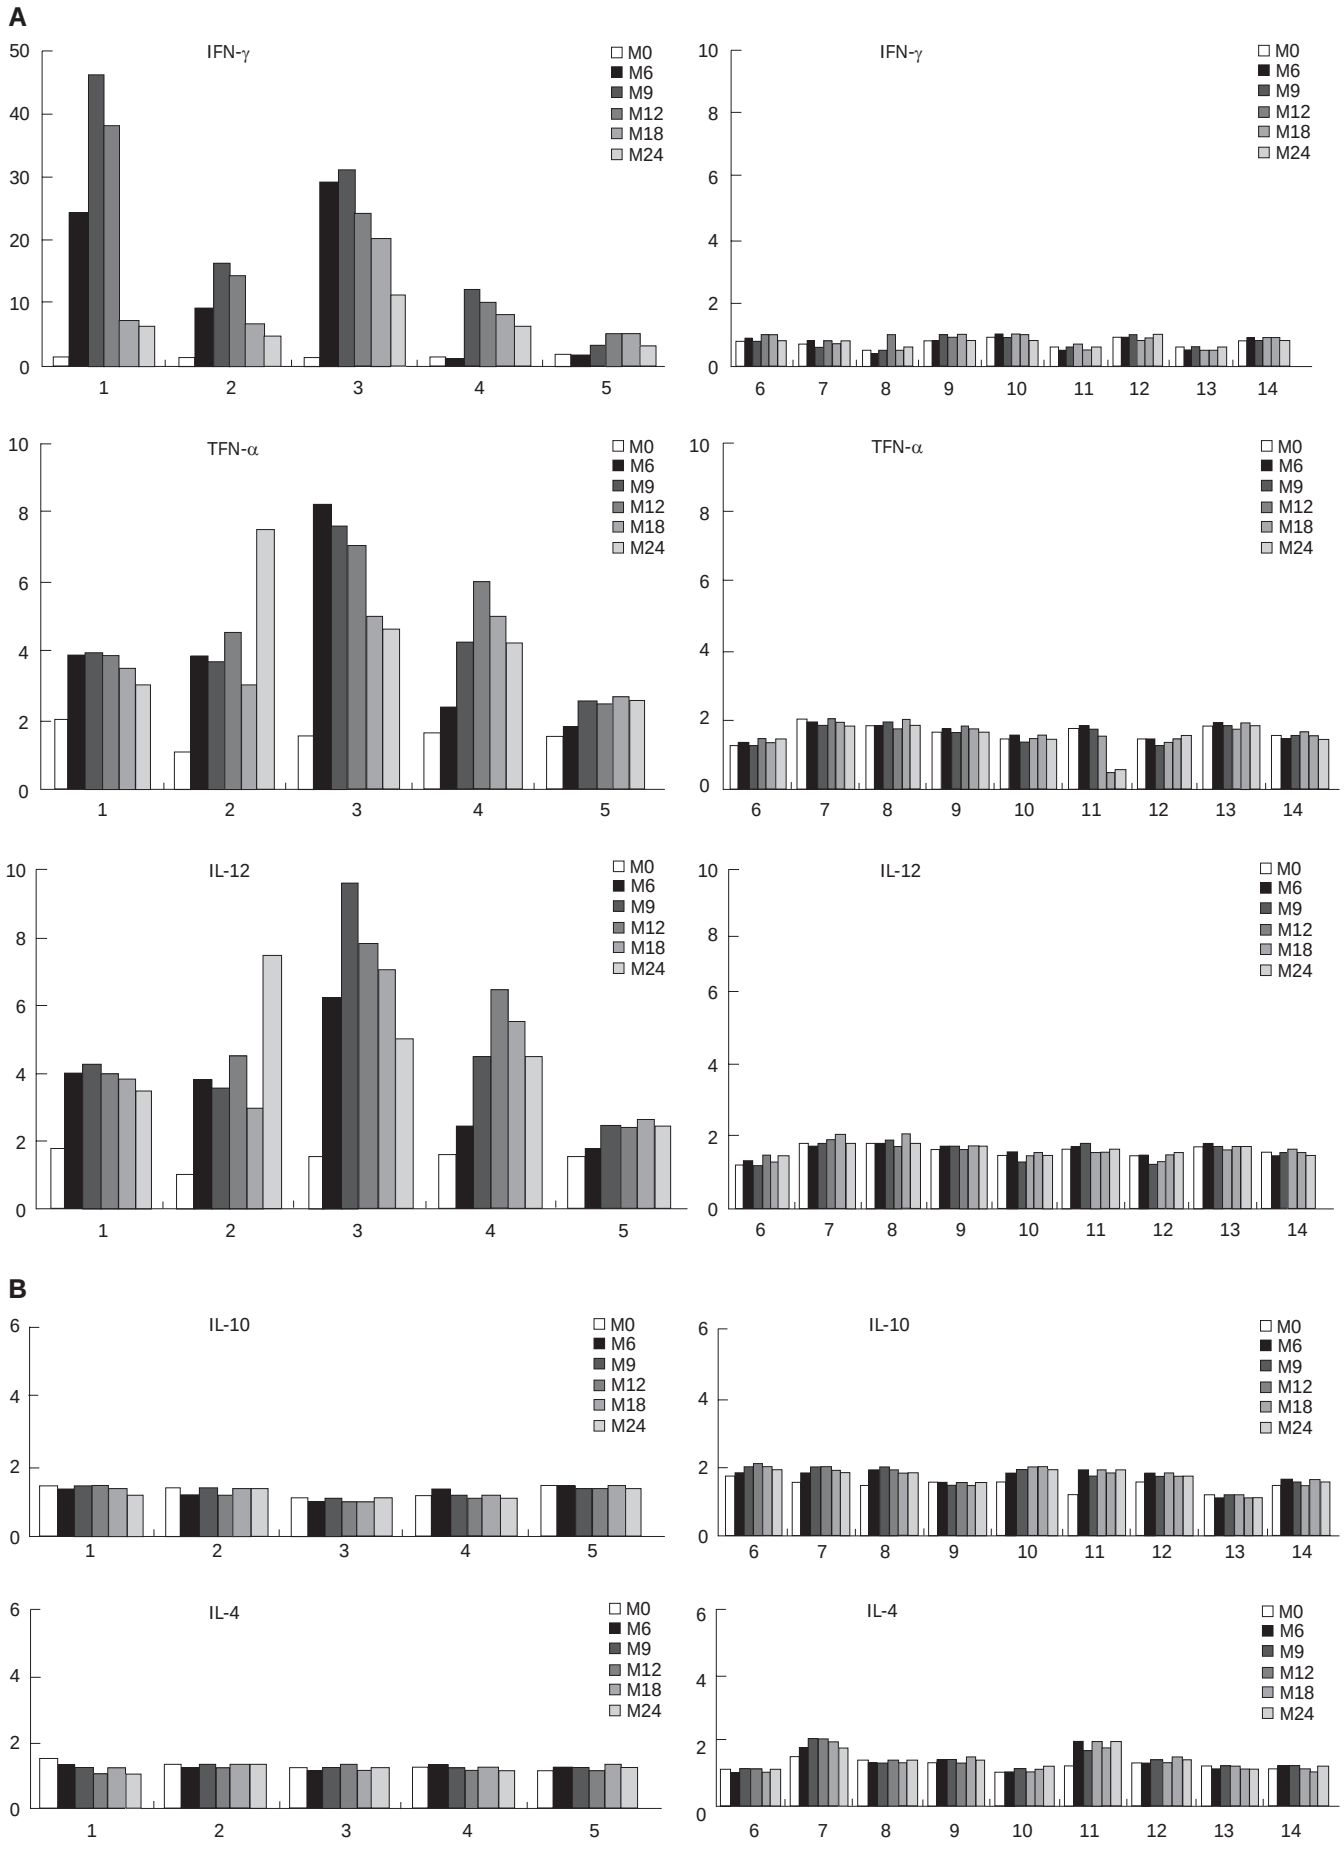

Figure 2 Cytokine production levels in PBMCs in combination therapy patients. The vertical axis represents the ratio of the mean cytokine concentration of triplicate cultures obtained in the presence of antigen to that obtained without antigen. The numbers in the horizontal lines represent the patients. **A:** Th1 cytokine production in PBMCs in combination therapy patients; **B:** Th2 cytokine production in PBMCs in combination therapy patients.

HBV replication in some patients, since serum HBV DNA levels were significantly lower at 12 and 24 mo in responders who showed HBV-antigen-specific IFN-γ, TNF-α and IL-12 production *in vitro* in PBMCs that was augmented in responders. The production of HBV-antigen-specific Th1 (IFN-γ, TNF-α, and IL-12) and Th2 (IL-4 and IL-10) cytokines did not increase, or remained unchanged in non-responders. Cytokine production showed a Th1-like pattern, as well as induction of PBMCs, and was consistent with the results of Rico *et al*[18].

CD4+ T cells are necessary for the maintenance of the effector functions of CD8+ T cells during chronic viral infection[20]. Activated CD8+ cytotoxic T cells can kill virus-infected cells by utilizing both perforin-dependent and Fas-mediated cytotoxic mechanisms[21]. CD8+ T cells can also secrete anti-viral cytokines such as IFN-γ and TNF-α[22]. The HBV-antigen-specific T-cell reactivity observed in our study may be relevant for the outcome of the infection, because it may be crucial to provide help to CD8+ cytotoxic T-cell responses to lyse and clear HBV-infected cells[23-27]. Nevertheless, eradication of HBV may be accomplished by other cells non-cytolytically by transcription and replication of HBV[28,29]. Based on our results, it is not possible to establish the mechanism contributing to HBV clearance (in this study we did not investigate CD8+ cytotoxic T cells in the cytotoxic assay). However, the decrease in serum HBV DNA levels was almost coincident with the increase of IFN-γ production by antigen-specific CD4+ T cells and was not preceded by an increase in serum ALT levels (as represented by patient 2, data not shown). These results suggest that cytotoxic T cells are unlikely to contribute to the control of HBV replication in combination therapy with ribavirin and IFN-α; results that are supported by those of Rico *et al*[18]. CD4+ T cells appear to directly participate in the anti-viral response (by producing anti-viral cytokines) rather than indirectly (by helping cytotoxic T cells) in this combination therapy of ribavirin and IFN-α. A role for Th1 cells in controlling viral infection is supported by experiments showing that they can clear influenza[30,31] and vaccinia virus[32] infections in a cytotoxic-T-lymphocyte-independent manner. Further, a direct, cytokine-dependent anti-viral role for CD4+ T cells, which produce Th1 cytokines (Th1 cells), has been shown in HBV transgenic mice[33,34]. These reports support our concept that the increased production of anti-viral cytokines by PBMCs plays a crucial role in the control of HBV replication in combination therapy with IFN-α and ribavirin. This combination therapy for chronic hepatitis B not only significantly reduced viremia levels but also induced lasting CD4+ T-cell proliferation and Th1 cytokine release at the site of infection, which may have led to sustained HBV eradication, as suggested by Rico *et al*[18]. Further studies will be needed to ascertain whether the anti-viral mechanism of combination therapy is by a route different from the one normally employed.

In conclusion, the present study indicated that combination therapy with ribavirin and IFN-α for anti-HBe-positive patients significantly reduces viremia, and induces CD4+ T-cell proliferation and Th1 cytokine secretion in patients with chronic hepatitis B.

COMMENTS

Background

Some recent reports have suggested that ribavirin shows antiviral and immune effects against various infectious diseases, including hepatitis B and C. It is suggested that combination therapy with IFN-α plus ribavirin for chronic hepatitis B significantly reduces viremia; however, the mechanisms involved remain unclear.

Research frontiers

Previous studies have suggested that combination therapy with IFN-α plus ribavirin for chronic hepatitis B significantly reduces viremia; however, the mechanism is unclear. In the present study, we investigated the anti-viral mechanism of combination therapy with IFN-α and ribavirin against chronic hepatitis B by analyzing T-cell proliferative responses in patients and determining Th1 cytokine levels.

Innovations and breakthroughs

In this study, we analyzed HBV-specific CD4+ T-cell proliferative responses and determined Th1 cytokine levels in PBMCs. Our results indicated that combination therapy of patients with chronic hepatitis B with ribavirin and IFN-α significantly reduced viremia, and induced CD4+ T-cell proliferation and Th1 cytokine secretion.

Applications

This study indicates that combination therapy with ribavirin and IFN-α for chronic hepatitis B significantly reduces viremia; thus, this combination may represent an alternative treatment option to achieve sustained eradication of HBV in patients with chronic hepatitis B refractory to IFN-α treatment.

Peer review

This is an interesting report of combination therapy with IFN-α plus ribavirin against chronic hepatitis B. The results suggest that HBV-antigen-specific CD4+ T cells may directly control HBV replication and secretion of anti-viral Th1 cytokines by PBMCs, utilizing combination therapy with ribavirin and IFN-α against chronic hepatitis B.

Abstract

AIM: To examine genetic variation of nucleotide oligomerization domain 1 (*NOD1*) and *NOD2*, their respective influences on Crohn's disease phenotype and gene-gene interactions.

METHODS: (*ND1+32656*1*) *NOD1* polymorphism and *SNP8*, *SNP12* and *SNP13* of *NOD2* were analyzed in 97 patients and 50 controls. *NOD2* variants were determined by reaction restriction fragment length polymorphism analysis. *NOD1* genotyping and *NOD2* variant confirmation were performed by specific amplification and sequencing.

RESULTS: The distribution of *NOD1* polymorphism in patients was different from controls (P = 0.045) and not altered by existence of *NOD2* mutations. In this cohort, 30.92% patients and 6% controls carried at least one *NOD2* variant (P < 0.001) with R702W being the most frequent variant. Presence of at least one *NOD2* mutation was inversely associated with colon involvement (9.09% with colon *vs* 36.4% with ileal or ileocolonic involvement, P = 0.04) and indicative of risk of penetrating disease (52.63% with penetrating *vs* 25.64% with non-penetrating or stricturing behavior, P = 0.02). L1007finsC and double *NOD2* mutation conferred the highest risk for severity of disease (26.3% with penetrating disease *vs* 3.8% with non-penetrating or stricturing behavior presented L1007finsC, P = 0.01 and 21.0% with penetrating disease *vs* 2.5% with non-penentrating or stricturing behavior carried double *NOD2* mutation, P = 0.007). Exclusion of patients with *NOD2* mutations from phenotype/*NOD1*-genotype analysis revealed higher prevalence of *1*1 genotype in groups of younger age at onset and colonic location.

CONCLUSION: This study suggests population differences in the inheritance of risk *NOD1* polymorphism and *NOD2* mutations. Although no interaction between *NOD1*-*NOD2* was noticed, a relationship between disease location and Nod-like receptor molecules was established.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract. Although the etiopathogenesis of this disease remains poorly understood, both genetic and environmental factors have been suggested to predispose to CD. Various disease phenotypes, including age at diagnosis, sex, family history, location of disease, response to medical therapies and behavior of the disease may be genetically determined.

Experimental and observational data suggest that intestinal inflammation arises from abnormal immune reactivity to bacterial flora in the intestine of individuals who are genetically predisposed[1]. The analysis of the molecules that participate in the response of commensal organisms revealed that gastric and intestinal cells are

largely deficient in TLR signaling and must rely on alternative systems, such as Nod-like receptors (NLRs) for the detection of pathogens. The mammalian NLR family is composed of more than 20 members that share a modular domain organization of a C-terminal leucine-rich repeat (LRR) domain, a central nucleotide-binding site domain and a N-terminal protein-protein-interaction domain composed of a CARD (caspase activation and recruitment domain), pyrin domain or Bir domain[2].

The first NLRs reported to have a direct function as intracellular pattern recognition molecules were Nucleotide oligomerization domain 1 (*NOD1*) (*CARD4*) and *NOD2* (*CARD15*); both proteins detect distinct substructures from bacterial peptidoglycan. *NOD1* detects a unique tripeptide motif found in Gram-negative bacterial peptidoglycan and also in specific Gram-positive bacteria such as *Listeria* and *Bacillus* spp[3]. *NOD2* detects muramyl dipeptide, the largest molecular motif common to Gram-negative and Gram-positive bacteria[4]. It is expressed in intestinal epithelial cells, with high expression in Paneth cells in the small intestine, intestinal myofibroblasts, granulocytes, endothelial, and monocyte-derived cells[5,6].

Identification of *NOD2* as the first susceptibility gene for CD was a breakthrough in understanding inflammatory bowel disease (IBD) pathogenesis. *NOD2* gene is located at the CD susceptibility locus (*IBD1*) on chromosome 16q12[7,8] and it has more than 60 sequence variants. Although, disease-associated *NOD2* mutations linked to Blau syndrome and early onset of sarcoidosis have been found in the region encoding the nucleotide-binding site domain[9,10], the three common genetic mutations linked to CD are mapped within or adjacent to the LRR region of *NOD2* (leading to protein changes at R702W, G908R, L1007finsC)[7,8]. These mutations are associated with an altered NF-κB activation and the linkage is particularly strong with ileal and ileocolonic CD[11,12]. *NOD2* variants are associated with early surgery due to stenosis, postsurgical recurrence, familial CD[13] and stricturing and penetrating forms of CD[14].

CD association with *NOD2* has been widely replicated. However, investigations into the inheritance of the three risk alleles in *NOD2* associated with susceptibility to CD have demonstrated a remarkable heterogeneity across ethnicities and populations with regional variation across Europe[15,16].

The discovery of *NOD2*-related innate immune defects in certain CD cases has led to speculation about defects in other pattern recognition receptors and downstream signaling molecules. The gene encoding *NOD1* (*CARD4*) is located within the chromosome 7p14 IBD locus, a region that contains an IBD susceptibility locus in British families[17]. An association between a complex insertion/deletion polymorphism (*ND1+32656*1*) in *NOD1* and susceptibility to IBD has been described. Particularly, this polymorphism has been associated to age at diagnosis and to the presence of IBD extraintestinal manifestations[18]. This *NOD1* polymorphism has also been associated to increased susceptibility to asthma[19,20]. In both diseases, the mutation has been found to be an insertion/deletion polymorphism in an intron of *NOD1*. Convincing replication of these findings is pending, since no evidence of association between *ND1+32656*1* and IBD was found in two recent well-powered data sets[21,22].

The present study examines the genetic variation in *NOD1* and *NOD2* and their respective influences on the CD phenotype (age at diagnosis, disease location and behavior) in a cohort of well-characterized CD patients. Since *NOD1* and *NOD2* share structure and functions, a potential interaction between *NOD1* and *NOD2* variants in CD phenotype was analyzed. After stratifying patients by their *NOD2* genotype, the distribution of *NOD1* polymorphism was determined and the contribution of each genotype was studied in regard to the disease phenotype.

MATERIALS AND METHODS

Patients

Ninety-seven CD patients attending the IBD outpatient clinic of Hospital Sant Pau (Barcelona, Spain) were prospectively included in the study. Fifty healthy controls matched for age, sex and geography were also evaluated. CD diagnoses were based on clinical, radiologic, endoscopic and pathologic bases. Patients with CD were classified according to Montreal classification for age at onset, disease location and behavior[23]. All patients and healthy controls gave informed consent and the study was approved by the local ethics committee.

Genotyping

Analysis of *NOD2* variants was performed as previously described, using genomic DNA extracted from blood samples by Qiagen kit (Qiagen, Heiden, Germany). A panel of 3 single nucleotide polymorphisms (*SNP8*, *12* and *13*) was detected by a polymerase chain reaction (PCR)-restriction fragment length polymorphism analysis (PCR-RFLP)[7]. Each *NOD2* variant was initially amplified by PCR using specific primers (Table 1). The PCR products were subsequently analyzed by restriction enzyme cleavage and gel electrophoresis. For assay of the SNP8, the PCR product (185 bp) was digested with MspI, resulting in the following fragments: 20, 35, 54 and 76 bp in R702 homozygous; 20, 35 and 130 bp in 702W homozygous and 20, 35, 54, 76, and 130 bp in heterozygous. For assay of the SNP12, the PCR product (163 bp) was digested with HhaI, resulting in the following fragments: 163 bp in G908 homozygous; 27 and 136 bp in 908R homozygous and 27, 136 and 163 in heterozygous. In order to detect the SNP13, the PCR product (151 bp) was digested with ApaI, resulting in the following fragments: 151 bp for Leu1007 homozygous; 20 and 131 bp in 1007Pro homozygous and 20, 131 and 151 bp in heterozygous.

Genotyping of *NOD1* (*ND1+32656*) polymorphism and confirmation of the three *NOD2* mutations were performed by specific amplification with the primers described in Table 1 and the subsequent sequencing of the amplified products. Sequencing reaction was performed using ABI PRISM BigDye terminator v1.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA) and analyzed by Genescan analysis on an ABI Prism 3100 Genetic Analyser according to the manufacturer's protocol (Applied Biosystem).

[1]ORs and probability values for disease status associated with carriage of at least 1 mutant allele (heterozygous, compound heterozygous and homozygous were grouped together). [2]*P*-values were calculated with the Fisher's Exact test when comparing controls and CD patients.

Statistical analysis

Genotype and allele frequencies of the patients and controls were compared by the χ^2 test or Fisher exact test in 2×2 contingency tables with at least 1 expected value < 5. Odds ratios (ORs) and 95% confidence intervals (CIs) were calculated to estimate relative risks. A two-tailed *P* value $\leqslant 0.05$ was considered significant. Statistical analysis was performed using the Statistical Package for the Social Sciences (SPSS) version 14.0 for Windows (SPSS Inc., Chicago, Ⅲ).

RESULTS

Frequencies of three NOD2 mutant alleles and one NOD1 polymorphism in CD patients and healthy controls

NOD2 gene mutations (R702W, G908R and L1007finsC) were determined in 97 CD patients and 50 healthy controls. Frequencies are summarized in Table 2. The distribution of genotypes at each mutation was significantly different in CD patients versus controls. R702W was the most frequent variant in CD and controls (21.65% and 4%, respectively, $P = 0.004$), and the only homozygous mutant patient in this cohort was found for this SNP8. Carriage of R702W was associated to the highest risk for CD in our cohort of patients (OR = 7.04; 95% CI: 1.58-31.30). Genotype frequency of the L1007finsC variant was lower than R702W, but showed a tendency to be higher in CD patients than in controls (8.25% *vs* 2%, $P = 0.167$; OD 4.40, 95% CI: 0.53-36.25). The *NOD2* variant with the lowest frequency in CD patients and in controls was G908R (5.15% *vs* 0%, $P = 0.166$). No homozygous *NOD2* mutant was found for L1007finsC or G908R. In this CD cohort, 30.92% of patients carried at least one variant of *NOD2* compared with 6% of healthy controls ($P < 0.001$) (Table 3), conferring a high risk for CD (OR 7.01; 95% CI: 2.02-24.30). Six CD patients but no controls carried two *NOD2* variant alleles.

NOD1 complex insertion/deletion polymorphism (*ND1+32656*) was examined in the same cohort of patients and controls (Table 4). Fifty-two percent of controls were *1*1, 34% were *1*2 and 14% were *2*2, whereas 59.79% of CD patients were *1*1, 37.11% were *1*2 and only 3.09% were *2*2. The distribution of *NOD1* genotype according to the *ND1+32656* polymorphism in CD patients and controls was statistically different ($P = 0.045$). Frequency of CD patients carrying *1 allele was 96.8% whereas in controls it was 86%, conferring a significant risk to develop the disease (OR 5.10; 95% CI: 1.25-20.68, $P = 0.032$).

Distribution of *NOD1* genotype according to WT or mutant *NOD2* was analyzed in CD patients to assess potential interactions between NOD1 and NOD2 (Table 4). Among those patients carrying at least one *NOD2* mutant allele, 60% of the patients were *1 *1, 36.66% were *1 *2 and 3.33% were *2 *2. Similarly, 59.70% of NOD2 WT/WT were *1 *1, 37.31% were *1 *2 and 2.98% were *2 *2. The presence of *NOD2* mutant alleles had therefore no influence on the *NOD1* polymorphism distribution ($P = 0.99$), suggesting no gene-gene interactions.

Clinical characteristics of CD patients according to the NOD2 genotype

CD patients were classified according to Montreal classification, with minor modifications as indicated in Table 5. The association of *NOD2* mutations to each CD phenotype was analyzed using each mutant genotype. The presence of at least one risk allele or the joint analysis of

	Mutant	3	3 (100)	0	0

CD: Crohn's disease; WT: Wildtype. [1]Number of CD patients or controls; [2]Results are expressed as number of CD patients (% of CD patients); [3]NOD2 mutant was considered any subject that inherited at least one copy of the variant allele.

compound heterozygous and homozygous for *NOD2* mutations were considered as a single independent variable.

A high proportion of patients in this cohort were diagnosed under the age of 40 (A1 + A2, *n* = 2 + 78), whereas 17 patients were diagnosed over 40 years (A3). All 6 patients with 2 mutant *NOD2* alleles were diagnosed before 40 years of age.

To study the association between genotype and disease location, one L1 + L4 patient was included in the L1 group (*n* = 34, 35.05%), and another L2 + L4 patient was included in the L2 group (*n* = 23, 23.71%). *NOD2* WT/WT patients were similarly distributed in L1, L2 and L3 groups: in 21.65% patients disease location was terminal ileum (L1), in 20.62%, it was colonic (L2), and in 26.80%, it was ileocolonic (L3). However, location of disease in *NOD2* mutant patients was not identical to *NOD2* WT/WT patients (*P* = 0.08). Despite the fact that R702W polymorphism was the most frequent in this cohort, only one patient with colon location carried this mutation (the patient had a double *NOD2* mutation). The presence of at least one mutant *NOD2* gene was inversely associated with exclusively colonic involvement (L2) (*P* = 0.04, OR 0.26; 95% CI: 0.07-0.96). When analyzing compound heterozygous and homozygous *NOD2* mutations, 2.06% of patients were L1, 1.03% of patients were L2 and 3.09% of patients were L3, indicating a comparable distribution.

Similarly to location, behavior groups in CD patients were simplified as follows: B1 group included 4 patients B1p (*n* = 37, 38%), B2 included 4 patients B2p (*n* = 41, 42%) and B3 included 4 patients B3p (*n* = 19, 19.5%). Distribution of *NOD2* mutations was different depending on disease behavior (*P* = 0.003). The presence of at least one mutant *NOD2* allele was indicative of risk of penetrating disease (B3) (*P* = 0.02, OR 3.22, 95% CI: 1.14-9.06) with the allele L1007finsC being indicative of the highest risk (*P* = 0.007, OR 8.92; 95% CI: 1.91-41.68). The frequency of double *NOD2* mutants was significantly higher in the B3 group than in the B2 and B1 groups (66% of the double *NOD2* mutants were B3, 33.3% were B2 and non-double *NOD2* mutants were B1). Presence of two *NOD2* mutant alleles was therefore indicative of risk for severity of disease (*P* = 0.01, OR 10.13; 95% CI: 1.70-60.40). The exam of the behavior through the course of disease showed an expected changing pattern[24]. There was a progressive reduction in the proportion of patients in the group B1 (51.6% patients with 5 years of disease, 34.9% patients with 6-9 years of disease and 21.7% patients with 10-15 years of disease). Inversely, there was a progressive increase in the proportion of patients in the groups of more complicated forms, B2 (34.5% patients with 5 years of disease, 44.2 patients with 6-9 years of disease and 52.2% patients with 10-15 years of disease) and B3 (13.8% patients with 5 years of disease, 20.9% patients with 6-9 years of disease and 26.1% patients with 10-15 years of disease). Selecting the group of patients with 6-9 years of disease (*n* = 43), the presence of at least one NOD2 mutation was indicative of risk of penetrating disease (the B3 group) (*P* = 0.046, OR = 5.55, 95% CI: 1.14-27.01) and 66.7% of the double *NOD2* mutants were included in the B3 group. Twelve patients with perianal disease (B1p, B2p, and B3p) were analyzed separately. Four of these patients presented one *NOD2* mutation, one was a compound heterozygous and the rest were *NOD2* WT/WT.

Clinical characteristics of CD patients according to the NOD1 genotype

Phenotype of CD patients was analyzed according to the *ND1+32656* polymorphism of *NOD1* gene. Distribution of *NOD1* genotype according to older age at diagnosis (A3 *P* = 0.64), location (L1 *P* = 0.28, L2 *P* = 0.56 and L3 *P* = 0.26) and behavior (B1 *P* = 0.55, B2 *P* = 0.99 and B3 *P* = 0.99) of the disease were not different from healthy controls. Similarly to a previous report, ND1+32656 genotype distribution in the group of early-onset CD (A1 + A2) was different from that observed in healthy controls. Only 2.5% of CD patients in the early-onset group had *2*2 genotype compared to 14% of healthy controls (*P* = 0.04).

Since *NOD2* mutations have a strong association with some CD clinical characteristics, and in particular with the ileal location, 30 CD patients that presented at least one *NOD2* mutation were excluded from the phenotype/genotype study to prevent any influence of *NOD2* (Table 6). When comparing the distribution of *NOD1*

Table 5 Clinical characteristics of CD patients according to *NOD2* genotype

CD: Crohn's disease; WT: Wildtype. [1]Number of CD patients in each subgroup; [2]*P*-values, odds ratios and confidence intervals refer to the comparison of presence versus absence of the at least one mutant *NOD2* allele; [3]Results are expressed as number of CD patients (% of CD patients).

polymorphism in each phenotype group with healthy controls, a higher prevalence of *1*1 was observed in the group A1 + A2 ($P = 0.04$). Interestingly, there was a clear tendency of the colonic group (L2) to have a higher frequency of *1*1 and lower frequency of *1*2 and *2*2 than controls, but the distribution of the *ND1+32656* polymorphism was not statistically different because the low number of cases decreased the power of the test. Distribution of this *NOD1* polymorphism in the other clinical subgroups of CD patients was comparable to healthy controls. Seven of the 12 patients with perianal disease (B1p + B2p + B3p) were *NOD2* WT/WT. In this subgroup of patients, *NOD1* polymorphism analysis showed that three of them were *1*1 and four were *1*2.

DISCUSSION

The frequency of *NOD2* mutant alleles associated to CD in our cohort of patients was within the European range, but deviated somewhat from populations of nearby geographic regions[25,26]. The frequency of R702W was one of the highest described in Caucasian populations, whereas the frequency of L1007finsC was lower than in other studies[27]. This observation is consistent with marked racial and regional differences described in the inheritance of the three risk *NOD2* alleles[16].

As expected, carriage of *NOD2* mutations conferred a high risk for developing CD, but this was neither necessary nor sufficient for CD development. The three *NOD2* mutations were not equally involved in CD susceptibility. The presence of R702W showed the strongest risk for CD in our cohort of patients. However, this mutation was not associated to CD in Galician, Finnish or Scottish populations[26]. The mutation with the strongest CD association in several familial and non-familial studies was L1007finsC[14], but this was not so in our cohort. Although the frequency of L1007finsC was noticeably elevated in CD patients, the absence of controls with this genotype precluded a statistical comparison.

We found an association between the polymorphism located at the intron IX-exon IX boundary of *NOD1* and susceptibility to CD in our cohort of patients. These results confirm a previous report associating this *NOD1* polymorphism with early IBD-onset and extraintestinal manifestations[18]. Although one recent study did not show a significant association with IBD[21], this *NOD1* non-coding polymorphism showed a strong association with asthma and the presence of elevated IgE levels in three independent panels of subjects[20]. Other *NOD1* polymorphisms in the coding sequence have been previously examined and showed no influence in CD susceptibility[28]. Mutations with phenotypic effects should be predominantly found at the coding sequence but complex disease susceptibility is often mediated through regulatory polymorphisms. In this case, *ND1+32656* may affect the binding of an unknown nuclear factor[20]. The involvement of *NOD1* gene is not surprising, since *NOD1*, similarly to *NOD2*, is involved in the recognition of intracellular bacterial pathogen-associated molecular patterns[29] and the two molecules share structure and functional similarities. Certain polymorphisms and

mutations in these molecules may, therefore, result in abnormalities during bacterial recognition with direct implications for CD pathogenesis. Given the importance of these results, further confirmatory studies are warranted in more and larger IBD populations. In order to maximize the opportunities to compare clinical subgroups, location was kept simple and genotyping was specifically blinded to clinical status. Mutations of the *NOD2* gene were rare among our patients with disease limited to the colon (L2). This is in accordance with recent studies showing that *NOD2* mutations (particularly L1007finsC) are strongly related to an increased risk of developing ileal CD. In our cohort of patients we only found this association after combining ileal and ileocolonic patients. This could be the consequence of the low rates of limited ileal CD in our cohort of patients compared to other studies (ranging from 40% to 50% in CD patients)[25,26]. Since location remains relatively stable during the course of the disease[24], the low rates of ileal CD seen in our patients could be attributable to the impact of interobserver disagreement[30], variation of disease location among different backgrounds[31] and even differences in diagnostic techniques. The present study suggests a relationship between disease location and different Nod-like receptor molecules, with relevant clinical implications. Distinctive subcellular location, trafficking, and expression of each Nod-like receptors could be confining the association of *NOD1* and *NOD2* with location of the disease at different parts of the gastrointestinal tract. In healthy humans, *NOD2* is expressed in Paneth cells within the crypts of the small intestine but not in colonic epithelium[6]. On the other hand, colon intestinal epithelial cells constitutively express *NOD1*[32]. *NOD1* or *NOD2* prevalence in colon or ileum could also be due to the predominance of different intracellular organisms or enteroinvasive bacteria for which they are receptors[33]. Further studies are needed to better clarify this subject.

A higher genetic load of *NOD2* mutations increased the susceptibility to CD and determined an aggressive course of the disease. Although CD behavior is a dynamic process progressing towards complicated forms in 80% of patients[24], the presence of *NOD2* variants could predict a stricturing and penetrating disease[14]. In addition, *NOD2* variants have been associated with early surgery due to stenosis and with CD recurrence after surgery[13]. No association was established between the *NOD1* polymorphism and disease behavior.

When comparing these results with other published genotype/phenotype associations, potential confounding factors should be taken into account to understand the differences. Agreement in Montreal classification, modification of the phenotype during follow-up, as well as the mixture of populations in some studies could be masking the particularities of each population. Our study adds two novel approaches to previous studies. First, two functionally related genes were analyzed for the first time in the same population, and second, the association phenotype/*NOD1* genotype was established after ruling out the strong influence of *NOD2*. Although this work emphasized the importance of *NOD1* and *NOD2* on CD disease phenotype, the complexity of IBD genetics should not be ignored. Individual combinations of genetic risk factors from other molecules such as OCTN, DLG5, TUCAN, MDR1, TNF and TLRs[34-40] would depict a specific clinical picture for each CD patient.

ACKNOWLEDGMENTS

We thank Carolyn Newey for editorial assistance and Ignasi J Gich for advice in the statistical analysis.

COMMENTS

Background

Crohn's disease (CD) is a chronic inflammatory disorder of the gastrointestinal tract. Genetic and environmental factors have been suggested to predispose to CD. CD association with *NOD2* mutations has been widely replicated but with remarkable heterogeneity across populations. Similarly to *NOD2*, *NOD1* has a direct function as intracellular pattern recognition molecules but detecting different substructures from bacterial peptidoglycan. The present study examines the genetic variation in *NOD1* and *NOD2* and their respective influences on the CD phenotype in a cohort of well-characterized CD patients.

Research frontiers

Individual combinations of genetic risk factors from *NOD2*, *NOD1* and other molecules, such as OCTN, TNF and TLRs, would depict a specific clinical picture for each CD patient.

Innovations and breakthroughs

This study adds two novel approaches to previous studies. First, *NOD2* and *NOD1* were analyzed for the first time in the same population and second, the association phenotype/*NOD1* genotype was established after ruling out the strong influence of *NOD2*. The present results suggest a relationship between disease location and different Nod-like receptor molecules.

Applications

This is an association study that compares the allele or genotype frequencies of two genes between affected and unaffected individuals of Crohn's disease. Exploring new gene variants associated with inflammatory bowel disease would make possible the identification of proteins located in certain pathophysiological pathways.

Terminology

NODs are cytosolic proteins that contain a nucleotide-binding oligomerization domain (NOD). As sensors of bacterial components, *NOD1* and *NOD2* are triggered by host recognition of specific motifs in bacterial peptidoglycan and, upon activation, induce the production of proinflammatory mediators.

Peer review

This is a very well written paper. Authors examined genetic variation of *NOD1* and *NOD2*, their respective influences on Crohn's disease phenotype and gene-gene interactions. This study suggests population differences in the inheritance of risk *NOD1* polymorphism and *NOD2* mutations.

Received: June 27, 2007 Revised: August 17, 2007

Abstract

AIM: To validate an optimized ^{13}C-urea breath test (^{13}C-UBT) protocol for the diagnosis of *H pylori* infection that is cost-efficient and maintains excellent diagnostic accuracy.

METHODS: 70 healthy volunteers were tested with two simplified ^{13}C-UBT protocols, with test meal (Protocol 2) and without test meal (Protocol 1). Breath samples were collected at 10, 20 and 30 min after ingestion of 50 mg ^{13}C-urea dissolved in 10 mL of water, taken as a single swallow, followed by 200 mL of water (pH 6.0) and a circular motion around the waistline to homogenize the urea solution. Performance of both protocols was analyzed at various cut-off values. Results were validated against the European protocol.

RESULTS: According to the reference protocol, 65.7% individuals were positive for *H pylori* infection and 34.3% were negative. There were no significant differences in the ability of both protocols to correctly identify positive and negative *H pylori* individuals. However, only Protocol 1 with no test meal achieved accuracy, sensitivity, specificity, positive and negative predictive values of 100%. The highest values achieved by Protocol 2 were 98.57%, 97.83%, 100%, 100% and 100%, respectively.

CONCLUSION: A 10 min, 50 mg ^{13}C-UBT with no test meal using a cut-off value of 2-2.5 is a highly accurate test for the diagnosis of *H pylori* infection at a reduced cost.

Key words: *H pylori*; ^{13}C-urea breath test; Diagnosis; Accuracy; Cost

INTRODUCTION

H pylori infection is present in around 50% of the world population[1], with higher prevalence rates in developing countries where it is the most frequent chronic infection in human kind[2].

H pylori infection has been associated with the pathogenesis of gastric disorders such as gastritis, duodenal and gastric ulcer, gastric cancer and MALT lymphoma[3], and a variety of extradigestive disorders including hematologic, such as iron deficiency anemia[4], pernicious anemia[5], autoimmune neutropenia[6], Schönlein-Henoch purpura[7], thrombotic thrombocytopenic purpura[8] and idiopathic thrombocytopenic purpura[9]. It has also been implicated in the pathogenesis of traditional autoimmune diseases, including rheumatoid arthritis[10], Sjögren syndrome[11] and autoimmune thyroiditis[12], dermatologic diseases such as rosacea[13] and urticaria[14], and cardiovascular events[15,16] among others.

Diagnosis of *H pylori* infection can be established by either invasive or non-invasive techniques. Invasive techniques, by means of endoscopy, are expensive[17], cause patient discomfort and introduce the risk of cross-infection[18,19]; moreover, there is morbidity and mortality associated with the procedure[20] and is not indicated in all cases where the *H pylori* status must be determined[21,22]. Non-invasive methods include serology[23] ^{14}C-urea or ^{13}C-urea breath test (UBT)[24,25], stool antigen test[26] and blood urea test[27].

The principle of the ^{13}C-UBT relies upon the ability of the urease, produced by *H pylori* in the gastric mucosa, to hydrolyze the orally administered ^{13}C-urea. This enzyme breaks down any urea in the stomach to ammonia and carbon dioxide (CO_2), which is absorbed into the blood stream and then released from the lungs. The labelled carbon dioxide ($^{13}CO_2$) is detected in breath samples[28].

The aim of the present study was to standardize and validate an assay that is cost-effective, while preserving excellent diagnostic accuracy. Two simple protocols were validated against the standard European protocol[29], which included modifications in the dose, formulation and *via* of urea administration, sample collection times and test meal. Appropriate cut-off values for these assays were also established.

MATERIALS AND METHODS

Subjects

The study population included 70 volunteers with no gastrointestinal symptoms. The volunteers were informed about the study and the tests, and signed an informed consent in accordance with the Helsinki Declaration[30]. The study was classified as a research study with no biological, physiological, psychological or social risks by the Health Ministry of Colombia[31]. Because of the nature of the study in healthy volunteers, it was considered non-ethical to perform invasive tests such as biopsy, culture or endoscopy.

Protocols

Reference protocol: *H pylori* infection status of individuals was determined by the ^{13}C-UBT, according to the European protocol described before[29] and using commercial kits (TAU-KIT, Isomed SL, Madrid, Spain) that provide both a sensitivity and specificity close to 100%[25]. This protocol was standardized and was validated for our region, with over 15000 assays performed, and used as the gold standard. The ^{13}C-UBT was analyzed by means of continuous flow-isotope ratio mass spectrometry (ABCA, SerCon, Cheshire, UK) at the Laboratorio Clínico Hematológico® in Medellín, Colombia.

The reference protocol was performed as follows: After fasting for at least 8 h, individuals were given 4.2 g of citric acid dissolved in 200 mL of water. Ten minutes later, a duplicate basal breath sample was collected. Immediately after, individuals were given 100 mg of ^{13}C-urea dissolved in 125 mL of water. After 30 min, a duplicate post-urea breath sample was collected. Results over 2.5 delta-over-baseline (DOB) were considered positive for *H pylori* infection.

Protocol 1: After fasting for at least 8 h, a first basal breath sample was collected. Individuals were given 50 mg of ^{13}C-urea (99%, Isotec, Miamisburg, Ohio, USA) dissolved in 10 mL of water, taken as a single swallow. Immediately after, individuals were given 200 mL of water (pH 6.0). Volunteers, with a final volume of 210 mL, were asked to make a circular motion around the waistline for a few times to homogenize the aqueous solution and allow contact of the ^{13}C-urea with the entire gastric mucosa. Additional breath samples were collected afterwards at 10, 20 and 30 min.

Protocol 2: Same as Protocol 1, except that 4.2 g of dehydrated citric acid were added to the 200 mL of water.

The performance of both protocols was analyzed at various cut-off values from 0.5 to 5.5, at the different time intervals (10, 20 and 30 min).

Statistical analysis

The χ^2 test was used to analyze associations between qualitative variables. For quantitative variables, the Wilcoxon's signed rank sum tests and Student's *t*-test were applied. Normality of the distribution of the data was assessed with the Wilk-Shapiro test. Sensitivity, specificity, positive predictive value, negative predictive value, accuracy, Youden index, likelihood ratios for a positive (LR+ve) or negative (LR-ve) test were calculated against the defined gold standard. The effectiveness of each protocol was evaluated by ROC analysis. Processing and analysis of data were done with the SPSS (Statistical Product for Service Solutions) version 12.0 and EPIDATE Version 3.0. A value of $P < 0.05$ was considered statistically significant.

RESULTS

This study included 70 individuals, 24 (34.3%) males and 46 (65.7%) females, with an average age of 39.63 (SD ± 12.58) years for males and 34.33 (SD ± 10.17) years for females. There were no significant differences between the mean age for males and females ($P = 0.061$). According to the reference protocol, 46 (65.7%) individuals were positive for *H pylori* infection and 24 (34.3%) were negative. When assessed by gender, 17 (70.8%) males and 29 (63%) females were positive for *H pylori*; this association was not statistically significant ($P = 0.515$).

Table 1 shows the performance of the protocols in terms of sensitivity, specificity, accuracy, positive and negative predictive values, Youden index and likelihood ratios for a positive (LR+ve) or (LR-ve) test with the different DOB cut-off values at 10, 20 and 30 min. Only Protocol 1 (with no test meal) achieved accuracy, sensitivity, specificity, positive and negative predictive values of 100%. The highest values achieved by Protocol 2 were 98.57%, 97.83%, 100%, 100% and 100%, respectively.

There were no significant differences in the ability of both protocols to correctly identify positive and negative *H pylori* individuals at 10 ($P = 0.32$), 20 ($P = 0.32$) and 30 min ($P = 0.32$). These results were confirmed by ROC analysis (Figure 1). The areas under the ROC curves for both protocols were as follows: for Protocol 1, 1.0 at 10, 20 and 30 min; for Protocol 2, 0.9837 at 10 and 30 min, and 0.9873 at 20 min. Although these results were not statistically different, Protocol 1 shows the maximum optimal values for an assay.

Table 2 shows the distribution of the DOB values at 10, 20, 30 min for *H pylori* positive and negative individuals for Protocols 1 and 2. For Protocol 1, the median DOB for *H pylori* infected individuals at 10 min was 13.64, while for Protocol 2 was 12.02. There was no statistically significant difference between these 2 values (Wilcoxon, $P = 0.121$). In contrast, median DOB values at 20 and 30 min for both protocols showed significant differences ($P = 0.006$ and $P = 0.001$, respectively). In addition, for non-infected individuals there were no statistically significant differences in the median DOB values at 10, 20 and 30 min ($P = 0.710$, $P = 0.440$ and $P = 0.346$, respectively) between both protocols.

DISCUSSION

The ^{13}C-UBT has become the gold standard of the non-invasive tests for diagnosing *H pylori* infection, before and after eradication treatment. Recently, The Maastricht Ⅲ Consensus Report has recommended the ^{13}C-UBT as the best option to establish the diagnosis of *H pylori* infection, especially in patients in whom endoscopy is not indicated[22].

Table 1 Performance of protocols (P1 and P2) in terms of sensitivity, specificity, accuracy, positive and negative predictive values, Youden index and likelihood ratios for a positive (LR+ve) or (LR-ve) test with the different DOB cut-off values at 10, 20 and 30 min

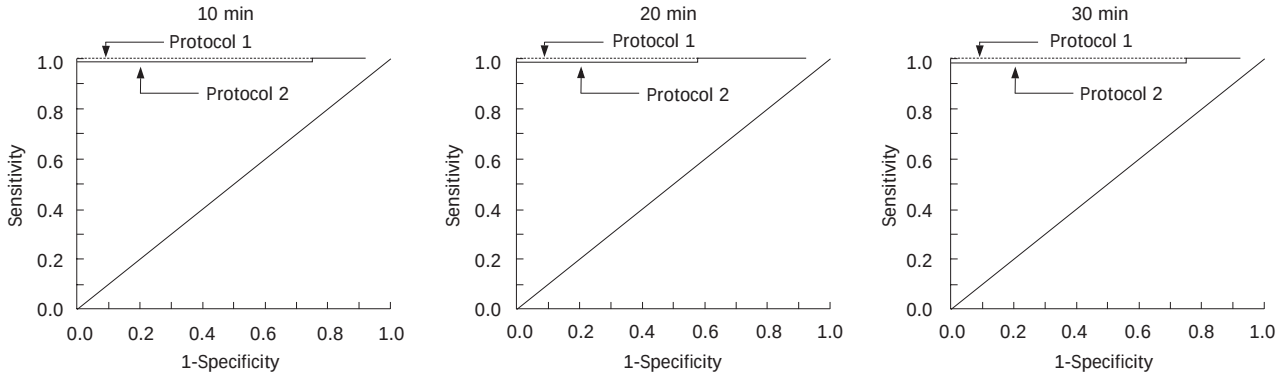

Figure 1 ROC curves for protocols 1 and 2 at 10, 20 and 30 min to establish the diagnosis of *H pylori* infection.

Table 3 shows a selection of 40 studies from the literature where relevant variations to the original ^{13}C-UBT protocol[28] have been implemented. From each study, the protocol with the best diagnostic performance was selected[32-71]. Of these, 12 (30%) yielded sensitivities and specificities of 100%[33,37,43,45,47,56,61,63,65,67-69].

Based on the results after reviewing the literature, the present study introduced several variations to simplify even further the technique and make it more cost-efficient, without compromising the high standards of sensitivity, specificity, positive and negative predictive values of the test. Below is a brief review of the evolution of the assay, since its first description, which led to the designing of the protocols evaluated in the present study.

Urea dose

Originally, the ^{13}C-UBT was described with a dose of ^{13}C-urea of 5 mg/kg of bodyweight[28]. Later on, doses of

Table 2 Distribution of DOB values in *H pylori* positive and negative individuals for both protocols at 10, 20 and 30 min

H pylori-positive individuals

DOB: Delta-over-baseline.

125[35,72] and 100 mg[36,40,47,48,51,54,57,60,62,65,73-83] were validated by several American, European and Asian groups, and more recently 75 mg[32,37,43-45,49,50,55,72,84-93], 50 mg[52,56,58,94,95], 38 mg[96], 25 mg and even 10 mg[69] of ^{13}C-urea have proved to be sufficient.

Test meal

From the beginning, there has been a belief that a delay in gastric emptying is necessary for optimal performance of the test, to allow enough time for the *H pylori*-urease to react in the gastric mucosa, if present. Initially individuals were given a meal consisting of one can of "Sustacal" pudding or 120 mL of 25% glucose polymer, followed 10 min later by a polycose solution containing the ^{13}C-urea[28]. Through the years there have been numerous modifications to the test meal, including the use of citric acid alone before administering the urea[37,62,67,79,84,85,97], or mixed with the ^{13}C-urea at the time of administration[43-45,88,91,98], or as a presentation in combination with the ^{13}C-urea[42,61,72,94,99]. Several alternatives to citric acid have also been tested, including orange juice[43,49,67,90,95] and apple juice[100], as well as other types of food such as milk[48,58,101,102] and a pudding test meal[34,46], and even water[41,103]. As shown in Table 3, the majority of the test meals have provided reliable results. Even the complete absence of a test meal has shown little, if any, variation in the diagnostic performance of the assay[35,40,47,53,56,59,60,102,104].

Via of administration and formulation of ^{13}C-urea

Another issue that has been addressed by different groups is the interference of other urease-producing bacteria in the oral cavity and oropharynx[105,106], leading to an increase in false positive values. As a result, there have been different approaches in the formulation and way of administration of the labeled urea, including the development of ^{13}C-urea tablets[42,61,63,64,95], capsules[68,96,99,107], and even the intragastric instillation of the urea through the endoscope[80,108,109]. Some have also suggested mouth rinsing before and after urea administration[39-41,48,51,52,54,58,60,68,110].

Sample collection times

The ^{13}C-UBT was originally described with a basal sample and 18 post-urea samples taken during the following 180 min[28]. Rapidly the assay was modified and currently only 2 samples are obtained: pre and post-urea. Sampling times, although shorter than initially, have differed among protocols.

Ways of reducing the cost of the ^{13}C-UBT could include decreasing the amount of ^{13}C-urea used, reducing the duration of the test, and improving the ease with which the test can be administered and tolerated. The conventional European ^{13}C-UTB protocol used in our region is sensitive and specific enough (values close to 100%), but it takes 40-45 min to complete and is performed using 100 mg of ^{13}C-urea. For the present study we decided to use 50 mg of ^{13}C-urea to reduce the cost of the assays by half, a dose that has proved to be as accurate as higher doses[52,56,58,61,63,68]. The ^{13}C-urea was administered diluted in 10 mL of water and taken as a single swallow, to try to avoid cross-contamination with urease-producing oropharyngeal bacteria. Immediately after 200 mL of water (pH 6.0) with 4.2 g of citric acid (Protocol 2) and without citric acid (Protocol 1) were administered, and volunteers were asked to make a circular motion around the waistline for a few times to homogenize the aqueous solution and allow contact of the ^{13}C-urea with the entire gastric mucosa. It has been shown that *H pylori* urease operates in a pH range from 3.1 to 10, with an optimal activity at pH 6.0[111,112]. By utilizing water at pH 6.0, activity of the *H pylori* urease was optimized for Protocol 1, where no citric acid was used. Acid solutions have been used by many to delay gastric emptying and to provide a higher acidic environment to induce *H pylori*-urease activity[43,98], although it has been demonstrated by Pantoflickova *et al*[100] that the emptying is determined by the caloric density of the test meal rather than by its pH. Finally, in order to reduce the duration of the test, both protocols were tested at different sampling times: 10, 20 and 30 min.

This study included 70 individuals, 34.3% males and 65.7% females, with an average age of 39.63 ± 12.58 years for males and 34.33 ± 10.17 years for females. According to the reference protocol, 46 (65.7%) individuals were positive for *H pylori* infection. No statistically significant association was found between gender and presence of *H pylori* infection ($P = 0.515$).

There were no significant differences in the ability of both protocols to correctly identify positive and negative *H pylori* individuals at the various sampling times. However, only Protocol 1, with no test meal, yielded a test with sensitivity, specificity, positive and negative predictive values, and accuracy of 100% when compared to the gold standard, when using a DOB cut-off value between 2 and 2.5 at 10 and 20 min, and a DOB cut-off value of 1.5 at 20 and 30 min. For Protocol 2, with citric acid, the highest accuracy (98.57%) was achieved at 10 min using a DOB cut-off value of 2.0, at 20 min a DOB cut-off value of 2.0, and at 30 min with a DOB of 2.5.

Median DOB for *H pylori* infected individuals at 10 min was 13.64, while for Protocol 2 was 12.02. There was no statistically significant difference between these 2 values (Wilcoxon, $P = 0.121$). However, median DOB values at 20 and 30 min for both protocols showed significant differences ($P = 0.006$ and $P = 0.001$, respectively). These results are in accordance with those by Atherton *et al*[113]

Table 3 ^{13}C-UBT protocol with best diagnostic performance from each study with samples obtained within 30 min of ^{13}C-urea administration: Review of literature

and Gisbert *et al*[47], who showed that the test meal did not affect ^{13}C-UBT results at 10 min, but increased the values thereafter.

In conclusion, an optimal laboratory test should be non-invasive, easy to perform, highly reproducible, cost-efficient and with a sensitivity and specificity close to 100%. When compared to other protocols published in the literature, the present conditions of Protocol 1 have further optimized the ^{13}C-UBT assay, as this is the only protocol with a sampling time of 10 min, a ^{13}C-urea dose of 50 mg and no test meal that can yield a test with 100% accuracy for the diagnosis of *H pylori* infection. These variations provide a protocol that can reduce the cost of the ^{13}C-UBT assay, is innocuous, well tolerated, has no restrictions and could be implemented for all patients in whom endoscopy is not an indication[21,22] and as a screening test for *H pylori* epidemiological studies. Further studies are underway to try to decrease the ^{13}C-urea to an even lower dose, using biopsy as the gold standard.

ACKNOWLEDGMENTS

To all volunteers that willingly participated in the study and to the medical technologists at Laboratorio Clínico Hematológico, in particular to Gloria Elsy Escobar-Gallo and Luz Marina Valencia-Zuluaga. To Victor Calvo-Betancur for his assistance with the statistical analysis. To Ana I. Toro, for her insightful discussions and help with the English translation.

COMMENTS

Background

H pylori infection is present in around 50% of the world population and has been associated with the pathogenesis of gastric disorders such as gastritis, gastric ulcer and MALT lymphoma, and a variety of extradigestive diseases, including idiopathic thrombocytopenic purpura, iron deficiency anemia and autoimmune thyroiditis, among others. Diagnosis of *H pylori* infection can be established by either invasive techniques, by means of endoscopy, or non-invasive techniques such as the ^{13}C-urea breath test.

Research frontiers

The ^{13}C-urea breath test relies upon the ability of an enzyme (urease), produced by *H pylori* in the stomach, to break down the administered urea. Patients swallow the urea labelled with a non-radioactive isotope (^{13}C). After a few minutes, the isotope-labelled carbon dioxide ($^{13}CO_2$) is exhaled in the breath if there is presence of *H pylori* urease in the stomach. The difference in the $^{13}CO_2$ values before and after ingestion of the labelled urea will determine the presence of infection.

Innovations and breakthroughs

Many have attempted to lower the high cost of the ^{13}C-urea breath test, while preserving excellent diagnostic accuracy. For this purpose, modifications in the

dose, formulation and way of administration, sample collection times and test meals have been evaluated.

Applications

A low cost ^{13}C-urea breath test for the detection of *H pylori* infection before and after eradication treatment will make this non-invasive assay more accessible for patients, especially in developing countries.

Terminology

^{13}C-UBT: Breath test that includes urea labelled with ^{13}C, a non-radioactive isotope. DOB: Delta over base line, units used to express the amount of $^{13}CO_2$ contained in the breath sample.

Peer review

This is a well written and comprehensively referenced article. The methods section is adequately described and the results clearly presented. The conclusions are a fair interpretation of the results.

Abstract

AIM: To investigate the poor prognosis of HCC with PVTT, we evaluated the efficacy by a new combination chemotherapy for advanced hepatocellular carcinoma (HCC) with portal vein tumor thrombus (PVTT).

METHODS: From 2002 to 2007, a total of 10 consecutive patients with Stage IVA HCC accompanied by PVTT were studied prospectively to examine the efficacy of treatment by intra-arterial infusion of a chemotherapeutic agents consisting of etoposide, carboplatin, epirubicin and pharmacokinetic modulating chemotherapy by 5-FU and enteric-coated tegafur/uracil.

RESULTS: The mean course of chemotherapy was 14.4 (range, 9-21) mo. One patient showed complete response (CR) with disappearance of HCC and PVTT after treatment, and the two patients showed partial response (PR), response rate (CR + PR/All cases 30%). The median survival time after the therapy was 457.2 d. The one-year survival rate was 70%. Adverse reactions were tolerable.

CONCLUSION: Although the prognosis of most patients with Stage IVA HCC by PVTT is poor, our combination chemotherapy may induces long-term survival and is an effective treatment and produced anti-tumor activity with tolerable adverse effects in patients for advanced Stage IVA HCC accompanied by PVTT.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide including Japan[1]. Although the development of imaging modalities has made the early diagnosis of HCC possible, surgically resectable cases are relatively uncommon because of a hepatic function reserve and/or an advanced stage at presentation. Several modalities, such as percutaneous ethanol injection (PEI), transcatheter arterial embolization (TAE), chemolipiodolization, microwave coagulation therapy (MCT), and radiofrequency ablation therapy (RFA) are reportedly useful in treating patients with unresectable disease[2,3]. However, unfortunately, many hepatocellular carcinoma patients have tumor recurrence. Furthermore, HCC has a predilection for portal vein invasion, which has been shown to be a poor prognostic factor. An effective therapy regimen is needed for advanced HCC with portal vein tumor thrombus (PVTT). Recent trials have been reported that combination therapy of intra-arterial 5-FU and systemic interferon for HCC with PVTT is effective[4,5]. However, portal venous invasion is a crucial factor that can worsen the prognosis of patients with HCC. It often leads to extensive spreading of the tumor throughout the liver, and can increase portal venous blood pressure, resulting in the fatal rupture of esophageal varices, and can decrease portal flow which causes ascites, jaundice, hepatic encephalopathy, and liver failure. Previous studies have

reported that the median survival time of patients with portal venous invasion was 2.7-4 mo if left untreated[6,7].

As systemic therapy of HCC, we had previously achieved complete remission of multiple HCC associated with hepatitis C virus-related decompensated liver cirrhosis by oral administration of enteric-coated tegafur/uracil[8]. Furthermore, we reported that oral administration of enteric-coated tegafur/uracil induces long-term survival and is an effective treatment for Stage Ⅳ-A HCC[9]. However, this therapy by single agent is not effective HCC with PVTT. Therefore, there is an urgent need for new method and active drugs for PVTT from HCC.

The aim of this study is to evaluate the usefulness by intra-arterial infusion of a chemotherapeutic agents consisting of etoposide, carboplatin, epirubicin and pharmacokinetic modulating chemotherapy by 5-FU and enteric-coated tegafur/uracil for HCC with tumor thrombosis of the main trunk of the portal vein.

MATERIALS AND METHODS

Ethics

The study protocol was reviewed and approved by the Hospital Ethics Committee. Informed consent was obtained from each patient who entered a randomized controlled trial and from family member(s).

Patients

A group of 10 consecutive patients with HCC accompanied by portal vein tumor thrombus (PVTT) were enrolled in the therapeutic trial between April 2002 and April 2007. The diagnosis of HCC was made by histologically and/or imaging study.

All patients received intra-arterial regional chemotherapy carried out at the Department of Gastroenterology and Hepatology, Saiseikai Niigata Second Hospital and gave their informed consent according to our situational guidelines, and the study received ethical approval.

Eligibility criteria for patients in this study included the following: (1) diagnosed Stage ⅣA HCC with PVTT (2) unresectable carefully assessed by the individual experts; (3) no recent active treatments including surgery, radiotherapy, chemotherapy, transarterial embolization, percutaneous ethanol injection, or other regional treatment within six month; (4) HCC with PVTT diagnosed by total image systems such as computed tomography (CT) or magnetic resonance imaging (MRI). (5) the ability to manage the indwelling catheters and implanted injection ports; (6) adequate hematologic function (white blood cell count > 3000/L, platelet count > 80 000/L, and hemoglobin level > 9.5 gm/dL); adequate renal function (serum creatinine < 1.5 mg/dL and a creatinine clearance > 60 mL/min); (7) adequate hepatic function, (8) a performance status less than 3 at pre-treatment, (9) portal tumor thrombi located the first portal branch, or the main portal trunk, and (10) informed consent.

Treatment schedule and follow up

For intra-arterial regional chemotherapy, catheters were introduced into the proper or common hepatic artery placed *via* the right femoral artery using the Seldinger method. The gastroduodenal artery and the right artery were occluded by a steel coil as indicated to prevent gastroduodenal injury from the anticancer agents. Intra-arterial regional chemotherapy was performed by puncturing a thin needle percutaneously into the port. Before every infusion, we confirmed that the catheters were patent, either by checking the blood back-flowing in the catheter or by injecting a contrast medium under fluoroscopy. Using an infusion pump (Syringe Pump, Terumo Co. Ltd., Osaka, Japan), 50 mg/body of etoposide (VePesid, Bristol-Myers Squibb Co. Ltd., Tokyo, Japan), 300 mg/body of carboplatin (Paraplatin, Bristol-Myers Squibb Co. Ltd., Tokyo, Japan) and 60 mg/body of epirubicin (Farmorubicin, Kyowa Hakko Kogyo Co. Ltd., Tokyo, Japan) were infused from each catheter over a 30-minute period. Subsequently, a continuous arterial infusion of 5-FU (500 mg/m^2) (5-FU, Kyowa Hakko Kogyo Co. Ltd., Tokyo, Japan) was given for 24 h. Before the needle was removed from the port, both the port and connected catheter were filled with undiluted heparin (1000 U/mL). An antiemetic and an H2-receptor antagonist were given intravenously. This treatment was repeated once weekly for 3 consecutive weeks of every 4 wk or biweekly, mainly at our outpatient clinic, for as long as possible. All patients were given also enteric-coated tegafur/uracil (Taiho Pharmaceutical, Co. Ltd., Tokyo, Japan) at a dose rate of 200 mg/body twice daily. Treatment was continued for a minimum of 8 wk and given until patient withdrawal or death even after the progression of disease.

Studies during follow-up included a physical examination, complete blood count, platelet count, and determination of levels of AFP, PIVKA-Ⅱ, amylase, liver transaminase, urea nitrogen, and creatinine. Either an ultrasonogram or a computed tomogram of the abdomen was obtained at least every two months, to determine the size of HCC and PVTT.

Evaluation of therapeutic response

The therapeutic clinical response of the liver was assessed in accordance with the World Health Organization Criteria. Clinical responses were graded as follows. Complete response (CR) was defined as disappearance of all measurable lesions in the liver, continuing for at least 4 weeks when assessed by both computed tomography and ultrasonography. Reduction of tumor size by more than 50%, continuing for at least 4 wk, was regarded as partial response (PR). No change (NC) was determined as tumors showing a decrease in size of less than 25%. Progressive disease (PD) was defined as tumors that had grown over 25%.

Statistical analysis

Survival curves were calculated by the Kaplan-Meier method and the difference between survival curves was evaluated using the log-rank test.

Statistical analyses were performed using Stat View-J4.11 software (Abacus Concepts; Berkeley, California) to assess the relative prognostic importance

Table 1 Characteristics of the patients

10 patients
Age mean 60.20 y.o (range 35-70)
Sex: Male/Female 7/3
Child-Pugh's stage: A,B/C 8/2
"Virus: HBsAg/anti-HCV 8/2"

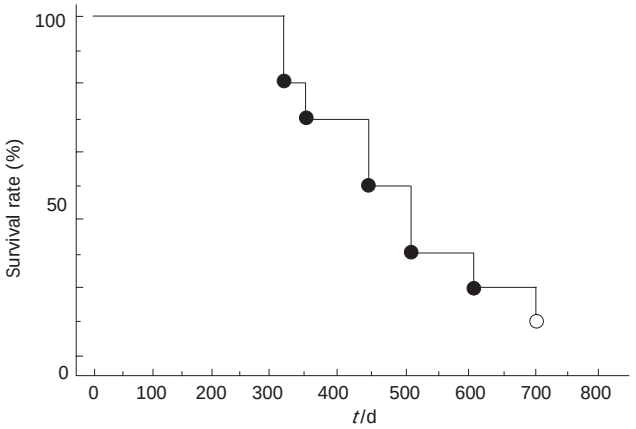

Figure 1 Cumulative survival of patients with hepatocellular carcinoma accompanied by PVTT who treated combination therapy.

of variables in predicting the survival rate. Differences at $P < 0.05$ were considered significant.

RESULTS

Background clinical and laboratory data of patients

Patients' profiles before the combination chemotherapy are listed in Table 1. Seven men and three women, with a median age of 60.2 years, were treated. Positive HBsAg was found in 70% of patients, while anti-hepatitis C virus (HCV) serology was positive in 30% of patients.

Child-Pugh Grade A/B was 2/6, the remaining patients had Grade C. Only 2 patients received the full courses of chemotherapy. The median number of cycles received per patients was 15.3. Dose reduction was required in 80% of the patients, mainly due to profound bone marrow suppression from the previous cycle.

Cumulative survival rate of patients by Kaplan-Meier survival curves

Of the 10 patients in the treated group, a total of 3 (30.0%) were classed as CR or PR, and a total 7 (70.0%) were classed as NC or PD. At the time of the final analysis (April 2007) 2 patients (from the treatment group) were alive. A total of 153 treatment cycles were administered.

The overall survival curve for all 10 patients is shown in Figure 1. The median survival was 457.2 d. The survival rates at the end of 1-year and 2-year were 70.0% and 20.0%, respectively. Of the 10 patients studied, 8 had died by the time of this analysis. The survival curves for clinical responders (CR or PR) and the others (NC or PD) are shown in Figure 2. The 6-mo and one-year survival rates were 100% and 100.0%, respectively, in the responders

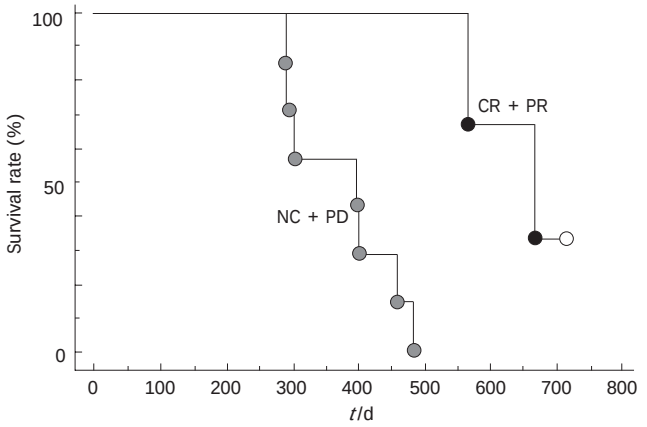

Figure 2 Survival of patients with hepatocellular carcinoma accompanied by PVTT according to the response and control (*Log-rank P < 0.05)*. CR: Complete response, PR**;** Partial response, NC; No change, PD; Progressive disease.

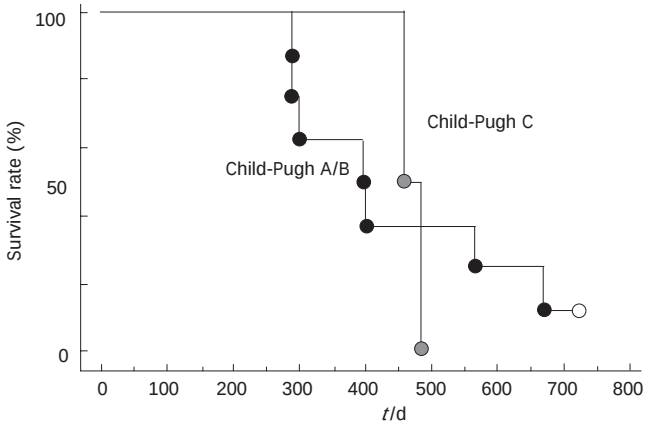

Figure 3 Survival of patients with hepatocellular carcinoma accompanied by PVTT according to Child-Pugh's stage (*Log-rank P = 0.98)*.

and 100% and 57.1%, respectively, in the non-responder. There was a significant difference in survival between the two groups ($P < 0.01$).

However, there was not a significant difference in survival rates between Child-Pugh A/B group and Child-Pugh C group (Figure 3).

Side effects and complications due to regional chemotherapy

The side-effects and complications encountered during therapy are summarized in Table 2. Local complications at the femoral artery entry sites did not occur in any patient. No serious complications that necessitated intensive care were encountered during therapy. The side-effects included oral dryness, diarrhea and liver dysfunction, and bone marrow suppression. Mild oral dryness was noted at the beginning of the treatment in 40.0% of patients, but this subsided as treatment continued. Mild diarrhea was noted at the beginning of the treatment in 30.0% of patients, but this also subsided with time. Such symptoms resolved spontaneously or after appropriate therapy. The complications experienced by patients treated with regional chemotherapy were well tolerated. No other serious

Table 2 Main clinical side effects observed during the treatment (*n* represents the number of patients having experienceed the effect in any of the courses)

	Grade of toxicity			
	1	2	3	4
Oral dryness	3	1	0	0
Diarrhea	1	2	0	0
Vomiting	1	0	0	0
Liver dysfunction	1	2	0	0
Fever	0	0	0	0
Hair loss	1	0	0	0
BM suppression	4	4	0	0

complications, such as gastric ulcer, liver damage, renal damage, vascular complications, or cardiac toxicity were encountered. However, dose reduction was required in 80% of the patients, mainly due to profound bone marrow suppression from the previous cycle. There were no treatment-related deaths from administration of regional chemotherapy.

DISCUSSION

Patients with HCC are highly compromised by failing liver function. HCC is associated with a high risk of portal vein involvement. PVTT is one of important prognostic factors in patients with HCC. However, HCC with PVTT is refractory to treatment. The treatment of HCC with PVTT is still problematic and major challenge item for oncologists because of its high and dismal outcomes. None of the reported treatment regimens can be considered to be standard treatment for HCC with PVTT.

Meanwhile, regional hepatic arterial infusion chemotherapy is a reasonable drug delivery system for patients with advanced HCC because the tumors derive most of their blood supply from the hepatic artery, whereas the portal vein supplies the normal parenchyma[10]. Furthermore, chemotherapy combined with interferon is reported to be effective for HCC with PVTT.

Combined treatment with 5-FU and alpha-interferon for HCC patients was first reported by Patt, *et al* in 1993[11]. The response rate was reportedly 22%. Urabe *et al*[12] treated 16 patients with HCC and PVTT in the main trunk or the major branches of the portal vein by intrahepatic infusion of methotrexate, 5-FU, and cisplatin, and administered alpha-interferon subcutaneously. The response rate and median survival time were 46.7% and 7 mo, respectively.

Moreover, combined intra-arterial 5-FU and subcutaneous alpha-interferon therapy for 8 patients with HCC accompanied by PVTT in the major portal vein was reported by Sakon *et al*[5]. The response rate was 63%. In another study by this group in 2005, 55 patients received this treatment, and 8 (14.5%) showed a complete response, 16 (29.1%) showed a partial response, 4 (7.3%) showed no response, and 27 (49.1%) showed progressive disease[13]. The median survival time and 5-year survival rate were 11.8 mo and 16.4%, respectively. Using this combination protocol, Obi *et al*[4] treated 116 patients with unresectable HCC accompanied by PVTT in the main trunk or the 1st branches of the portal vein. The survival rates at 1 and 2 years among overall patients were 34% and 18%, respectively, in contrast to 15% and 5% among the historical controls. Survival rates at 1 and 2 years were 81% and 59% among complete responders, respectively, and 43% and 18% among partial responders. The median survival time was prolonged to 11 mo in patients with an active response, although there appears to be no benefit in patients without an active response.

However, it is chaotic to determine whether the combination chemotherapy with interferon is effective or not for HCC accompanied by PVTT.

We previously reported[8,9] that administration of enteric-coated tegafur/uracil induces long-term survival and is an effective treatment for Stage Ⅳ-A HCC. However, single agent such as enteric-coated tegafur/uracil was not effective for HCC with PVTT. So, combination chemotherapy is needed for HCC with PVTT.

The choice of the anticancer agent is important in achieving favorable clinical results. We selected etoposide, carboplatin, epirubicin and pharmacokinetic modulating chemotherapy by 5-FU and enteric-coated tegafur/uracil.

Firstly, etoposide is agent which has shown significant antitumor against HCC[14-16]. It could be suggested as part of intensive multidrug regimens for HCC and high-risk HBV[17-19]. Though response rates to cisplatin and etoposide[20] given systemically as single agents are 5 and 15%, intra-arterial combination chemotherapy using cisplatin and etoposide produces a high rate of objective tumor remissions in patients with HCC[21].

However, cisplatin has been reported that it has a lot of nephrotoxic and emetic effects. To the contrary, carboplatin has demonstrated antitumor activity comparable to cisplatin and has been shown to have fewer nephrotoxic and emetic effects. In fact, carboplatin is thought to be a useful anticancer agent in patients with HCC treated with TACE. Furthermore, it is reported that carboplatin is effective for HCC[22-24].

So we selected carboplatin as combination with etoposide. In addition, a combination of epirubicin and etoposide appears to be an active and tolerable therapeutic option for HCC patients who are not candidates for surgical or locoregional procedures[19,25-27].

Recently, Kusunoki *et al* reported that pharmacokinetic modulating chemotherapy, based on the concept that the benefit of a continuous venous 5-fluorouracil infusion can be potentiated by low-dose oral tegafur/uracil is useful for a variety of cancers[28,29].

In fact, it is reported that modified pharmacokinetic modulating chemotherapy had no severe side effect and was effective for advanced unresectable HCC[30].

Based on these facts, we tried combination chemotherapy for HCC with PVTT. In our series, the treatment resulted in an objective response rate of 30% and a median survival of 457.2 d. Only the three patients who had an objective response had a survival of long duration.

As our group was small, we did not perform a statistical analysis to determine a predictive factor for response. However, our results are comparable with those of most interferon combination chemotherapy.

In our study, the toxicity of this therapy was low despite the fact that all of the patients had cirrhosis. It is noteworthy that there were no patients showing overt liver toxicity. Moreover, there was no treatment-related death.

In this study, no hepatotoxicity due to this combination chemotherapy was observed. The side effects of this regimen were minimal and well tolerated.

In conclusion, this chemotherapeutic regimen ameliorated the survival of patients with advanced HCC without serious adverse effects.

We suggest that, in the near future, this chemotherapy method should be subjected to a prospective randomized controlled study for HCC with PVTT. Further prospective randomized clinical trials of chemotherapy for HCC with PVTT will be needed.

COMMENTS

Background

Portal venous tumor thrombus (PVTT) is a crucial factor that can worsen the prognosis of patients with hepatocellular carcinoma (HCC). It often leads to extensive spreading of the tumor throughout the liver, and can increase portal venous blood pressure, resulting in the fatal rupture of esophageal varices, and can decrease portal flow which causes ascites, jaundice, hepatic encephalopathy, and liver failure. However, there is not effective useful therapy for HCC combined with PVTT. Therefore, there is an urgent need for new and active drugs and combination chemotherapy of advanced HCC.

Research frontiers

HCC has a predilection for portal vein invasion, which has been shown to be a poor prognostic factor. An effective therapy regimen is needed for advanced HCC with PVTT. Combination chemotherapy is needed for HCC with PVTT urgently. The choice of the anticancer agent is important in achieving favorable clinical results. The authors selected etoposide, carboplatin, epirubicin and pharmacokinetic modulating chemotherapy by 5-FU and enteric-coated tegafur/uracil. Progress in implantable drug delivery systems has made possible the repeated arterial infusion of chemotherapeutic agents for patients with advanced HCC recently. Therefore, hepatic arterial infusion chemotherapy has been often selected as a therapeutic option for advanced HCC with PVTT.

Innovations and breakthroughs

The authors investigated the efficacy, the feasibility, usefulness, and complication rate of arterial combination therapies for HCC with PVTT.

Applications

Intra-arterial combination chemotherapy is useful and inducing long-term survival for advanced HCC accompanied by PVTT. Further prospective randomized clinical trials of chemotherapy for HCC with PVTT will be needed.

Terminology

PVTT: Portal vein tumor thrombus meaning tumor thrombus locating the first portal branch, or the main portal trunk.

Peer review

This is an interesting manuscript reporting the strategy for HCC with PVTT. This new information is certainly worthy of publication.

Abstract

AIM: To investigate the systemic hemodynamic effects of two surgical procedures largely employed for treatment of schistosomal portal hypertension.

METHODS: Thirty-six patients undergoing elective surgical treatment of portal hypertension due to hepatosplenic mansonic schistosomiasis were prospectively evaluated. All patients were subjected to preoperative pulmonary artery catheterization; 17 were submitted to esophagogastric devascularization and splenectomy (EGDS) and 19 to distal splenorenal shunt (DSRS). The systemic hemodynamic assessment was repeated 4 d after the surgical procedure.

RESULTS: Preoperative evaluation revealed (mean ± SD) an increased cardiac index (4.78 ± 1.13 L/min per m^2), associated with a reduction in systemic vascular resistance index (1457 ± 380.7 dynes.s/cm^5.m^2). The mean pulmonary artery pressure (18 ± 5.1 mmHg) as well as the right atrial pressure (7.9 ± 2.5 mmHg) were increased, while the pulmonary vascular resistance index (133 ± 62 dynes.s/cm^5.m^2) was decreased. Four days after EGDS, a significant reduction in cardiac index (3.80 ± 0.4 L/min per m^2, $P < 0.001$) and increase in systemic vascular resistance index (1901.4 ± 330.2 dynes.s/cm^5.m^2, $P < 0.001$) toward normal levels were observed. There was also a significant reduction in pulmonary artery pressure (12.65 ± 4.7 mmHg, $P < 0.001$) and no significant changes in the pulmonary vascular resistance index (141.6 ± 102.9 dynes.s/cm^5.m^2). Four days after DSRS, a non-significant increase in cardiac index (5.2 ± 0.76 L/min per m^2) and systemic vascular resistance index (1389 ± 311 dynes.s/cm^5.m^2) was observed. There was also a non-significant increase in pulmonary artery pressure (19.84 ± 5.2 mmHg), right cardiac work index (1.38 ± 0.4 kg.m/m^2) and right ventricular systolic work index (16.3 ± 6.3 g.m/m^2), without significant changes in the pulmonary vascular resistance index (139.7 ± 67.8 dynes.s/cm^5.m^2).

CONCLUSION: The hyperdynamic circulatory state observed in mansonic schistosomiasis was corrected by EGDS, but was maintained in patients who underwent DSRS. Similarly, the elevated mean pulmonary artery pressure was corrected after EGDS and maintained after DSRS. EGDS seems to be the most physiologic surgery for patients with schistosomal portal hypertension.

INTRODUCTION

In Brazil, mansonic schistosomiasis is an endemic disease, and its hepatosplenic form, which is characterized by presinusoidal portal hypertension with preserved liver function and marked splenomegaly, is a major cause of portal hypertension[1-3]. Upper digestive tract hemorrhage due to esophageal varices rupture is the most feared complication[4].

The development of portal hypertension, regardless of its etiology, is a consequence of increased vascular resistance, mostly due to an architectural distortion of

the liver parenchyma secondary to fibrosis, but also due to a diminished endothelial nitric oxide release from the hepatic endothelium[5]. Increased portal venous inflow due to mesenteric arteriolar vasodilatation, and determined by increased levels of vasodilators, also contributes to portal pressure increase[6].

The pathophysiology of portal hypertension in hepatosplenic mansonic schistosomiasis also displays a systemic hyperdynamic state[2]. We have previously reported that this hyperdynamic circulatory state seems to be corrected in the intraoperative period during esophagogastric devascularization and splenectomy (EGDS)[7]. However, to the best of our knowledge, there are no data in the literature regarding postoperative systemic hemodynamics after surgical treatment of schistosomal portal hypertension.

The purpose of this study was to prospectively investigate the postoperative systemic hemodynamic effects in two different surgical procedures largely employed for treatment of schistosomal portal hypertension.

MATERIALS AND METHODS

Thirty-six patients with portal hypertension and a history of previous upper digestive tract bleeding, due to esophageal varices rupture secondary to hepatosplenic mansonic schistosomiasis, were prospectively studied before and after elective surgical treatment between June 1998 and March 2005. Eighteen patients were male and eighteen female, with a mean age of 39 (range 22-56) years. Laboratory data and arterial blood gases are expressed in Table 1. Transthoracic echocardiography was performed in all patients before surgery. The Hospital Ethics Committee approved the study protocol, and all patients signed their informed consent. Immediately before surgery, patients underwent a right internal jugular vein puncture with the introduction of a pulmonary artery catheter (Edwards Swan-Ganz TM, caliber 7F, model 93A-131H; Baxter Corporation, USA) for invasive systemic hemodynamic assessment. Patients were randomized for two different elective surgical procedures: 17 were subjected to esophagogastric devascularization and splenectomy (EGDS) and 19 to distal splenorenal shunt (DSRS). A mean pulmonary artery pressure greater than 25 mmHg was considered as an absolute contraindication for DSRS.

EGDS consisted of ligation of the splenic artery close to the body of the pancreas, followed by splenectomy and devascularization of the distal 5-7 cm of the esophagus, and of the upper two thirds of the stomach proximal to the incisura angularis. DSRS consisted of dissection of the splenic vein from the splenic hilum until its junction with superior mesenteric vein, and ligating all small vessels between the pancreas and the splenic vein (splenopancreatic disconnection). Left renal vein anterior and superior surfaces were dissected, the splenic vein was transected near it's junction with the superior mesenteric vein, and an anastomosis between the splenic and renal veins was performed with a running suture. No immediate complications were observed and there was no intra- or postoperative mortality.

Four days after surgery, when the surgical effects had worn off, the systemic hemodynamic assessment was repeated and the pulmonary artery catheter was removed. There were no complications related to pulmonary artery catheterization.

Table 1 Preoperative laboratory and arterial blood gases data

	Mean ± SD	Normal values
ALT (IU/L)	31.7 ± 16.8	7-45
AST (IU/L)	31.6 ± 20.5	7-45
Gamma GT (IU/L)	46.2 ± 25.5	7-50
ALP (IU/L)	118.5 ± 46.3	60-122
BUN (mg/dL)	25.5 ± 5.75	10-50
Cr (mg/dL)	0.78 ± 0.16	0.6-1.4
TP (g/dL)	7.45 ± 0.71	6-8
ALB (g/dL)	4.18 ± 0.48	3.5-5.0
PT (s)	14.2 ± 2.9	14 ± 2
PTT (s)	29.8 ± 6.26	30 ± 2
TBIL (mg%)	1.16 ± 0.73	1.4
IBIL (mg%)	0.79 ± 0.67	0.8
Hb (g/dL)	11.2 ± 2.4	12-18
Ht (%)	34.4 ± 7.2	36-54
WBC (10^3/mm^3)	3.63 ± 2.2	4-10
PLT (10^3/mm^3)	88.74 ± 56.24	150-400
pH	7.41 ± 0.05	7.37-7.44
pO_2 (mmHg)	91.4 ± 6.5	80-100
pCO_2 (mmHg)	34.9 ± 3.2	34-45
SaO_2 (%)	97.1 ± 0.95	96-98

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; Gamma GT: Gamma glutamil transpeptidase; BUN: Blood urea nitrogen; Cr: Creatinine; PT: Prothrombin time; PTT: Partial thromboplastin time; Hb: Hemoglobin; Ht: Hematocrit; WBC: White blood cells; PLT: Platelets; pO_2: Arterial oxygen tension; $PaCO_2$: Arterial carbon dioxide tension; SaO_2: Arterial oxygen saturation; ALP: Alkaline phosphatase; TP: Total serum protein; ALB: Aalbumin; TBIL: Total serum bilirubin; IBIL: Indirect bilirubin.

Statistical analysis

Statistical analysis was accomplished by the paired *t* test, and $P < 0.01$ was considered as statistically significant, with a 99% confidence interval.

RESULTS

The results of the transthoracic Doppler echocardiography are shown in Table 2. No ventricular hypertrophy or segmental contraction abnormality was observed, and no patients presented valvular lesions or pericardial effusions. All patients presented normal systolic and diastolic ventricular function. In two patients, echocardiography revealed an estimated pulmonary artery pressure of 60 and 40 mmHg, respectively, accompanied by a discrete dilatation of the right ventricle. These two patients were subjected to EGDS.

Pre- and postoperative hemodynamic evaluation data are shown in Table 3 and Figure 1. Preoperative hemodynamic evaluation revealed an increased mean cardiac index (4.78 ± 1.13 L/min per m^2) and a reduction in the systemic vascular resistance index (1457 ± 380.7 dynes.s/cm^5.m^2). The systolic index (60.24 ± 12.8 mL/beats per m^2), left cardiac work index (6.14 ± 1.43 kg.m/m^2), left ventricle systolic work index (76.6 ± 17.8 g.m/m^2), right cardiac work index (1.22 ± 0.5 kg.m/m^2) and right ventricle systolic work index (15.25 ± 6.4 g.m/m^2)

Table 2 Preoperative transthoracic echocardiography in patients with portal hypertension due to hepatosplenic mansonic schistosomiasis

	Preop (mean ± SD)	Normal range
Ao	30.7 ± 1.9	20-35 mm
LA	38.1 ± 4.6	20-40 mm
LVDD	49.7 ± 3.9	35-55 mm
FDV	125.4 ± 29.6	50-150 mL
LVSD	30.9 ± 2.8	20-35 mm
SV	30.1 ± 8.1	50-150 mL
DD	37.6 ± 3.3	30%-40%
EF	75.9 ± 4.5	65%-80%
Se	8.9 ± 0.6	7-11 mm
Pw	8.4 ± 0.5	7-11 mm
V/M	65.1 ± 6.8	45%-75%

Ao: Aorta; LA: Left atrium; LVDD: Left ventricular diastolic diameter; FDV: Final diastolic volume; LVSD: Left ventricular systolic diameter; SV: Systolic volume; DD: Shortening fraction; EF: Ejection fraction; Se: Septum wall thickness; Pw: Left ventricular wall thickness; V/M: Left ventricular volume/mass relationship; E/A: Ratio between wave E and A.

Table 3 Pre- and postoperative hemodynamic parameters in patients with portal hypertension due to hepatosplenic mansonic schistosomiasis

	Preop	EGDS	DSRS	Normal values
HR	80.2 ± 11.4	83.1 ± 10.6	86.7 ± 17.9	80-100 beats/min
MABP	91.4 ± 12.5	93.6 ± 14.4	92.36 ± 13.75	80-100 mmHg
RAP	7.9 ± 2.5	7 ± 2.4	7.26 ± 2.4	0-7 mmHg

CI	4.78 ± 1.13	3.8 ± 0.4[d]	5.2 ± 0.76	2.5-4 L/min per m^2
SI	60.24 ± 12.8	46.2 ± 8.6[d]	59.64 ± 10.5	41-51 mL/beat per m^2
SVRI	1457 ± 380.7	1901.4 ± 330.2[d]	1389 ± 311	1970-2390 dynes.s/cm^5.m^2
PVRI	133 ± 62	141.65 ± 102.9	139.7 ± 67.8	225-315 dynes.s/cm^5.m^2
LCWI	6.14 ± 1.43	4.9 ± 0.7[b]	6.94 ± 1.3	3.4-4.2 kg.m/m^2
LVSWI	76.6 ± 17.8	59 ± 12.6[b]	82.65 ± 17	50-62 g.m/m^2
RCWI	1.22 ± 0.5	0.79 ± 0.4[b]	1.31 ± 0.35	0.54-0.60 kg.m/m^2
RVSWI	15.25 ± 6.4	9.45 ± 4.8[b]	16.3 ± 6.3	7.9-9.7 g.m/m^2

[b]P < 0.01 between EGDS and PREOP; [d]P < 0.001 between EGDS and PREOP. Values are expressed as means ± SD. EGDS: Esophagogastric devascularization and splenectomy; DSRS: Distal splenorenal shunt; HR: Heart rate; MABP: Mean arterial blood pressure; PAP: Mean pulmonary artery pressure; RAP: Mean right atrium pressure; PCWP: Pulmonary capillary wedged pressure; CI: Cardiac index; SI: Systolic index; SVRI: Systemic vascular resistance index; PVRI: Pulmonary vascular resistance index; RCWI and LCWI: Right and left cardiac work indexes, LVSWI and RVSWI: Left and right ventricular systolic work indexes.

were all increased. Heart rate (80.2 ± 11.4 beats/min), mean arterial blood pressure (91.4 ± 12.5 mmHg) and pulmonary capillary wedge pressure (10.2 ± 2.7 mmHg) were all within normal limits. Mean pulmonary artery pressure (18 ± 5.1 mmHg), as well as right atrial pressure (7.9 ± 2.5 mmHg), was increased, while the pulmonary vascular resistance index (133 ± 62 dynes.s/cm^5.m^2) was decreased.

Four days after EGDS, there was a significant decrease in cardiac index (3.8 ± 0.4 L/min per m^2) and a significant increase in systemic vascular resistance index (1901.4 ± 330.2 dynes.s/cm^5.m^2) toward normal levels. The systolic index (46.2 ± 8.6 mL/beats per m^2), left cardiac work index

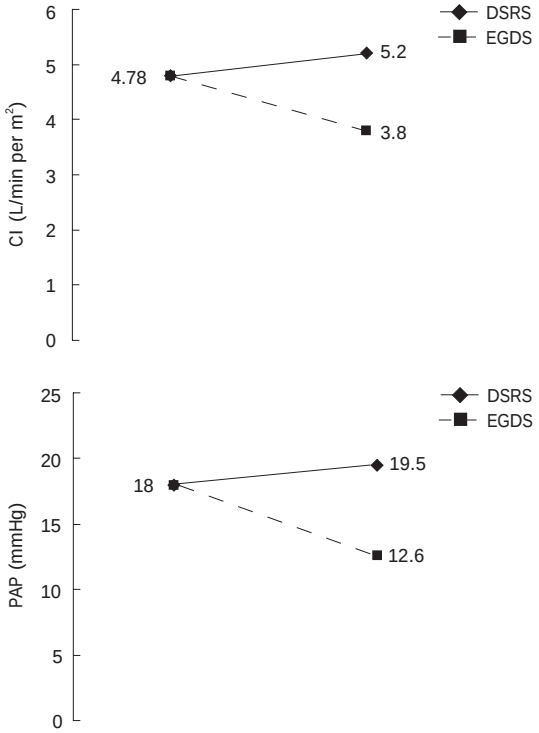

Figure 1 Schematic illustration showing important differences in cardiac index (CI) and pulmonary artery pressure (PAP) before and after EGDS (dashed line) and DSRS (continuous line).

(4.9 ± 0.7 kg.m/m^2) and left ventricle systolic work index (59 ± 12.6 g.m/m^2) also significantly decreased toward normal levels. There was no significant alteration in heart rate (83.1 ± 10.6 beats/min), mean arterial blood pressure (93.6 ± 14.4 mmHg), pulmonary capillary wedge pressure (9.1 ± 3 mmHg) and right atrial pressure (7 ± 2.4 mmHg). There was also a significant reduction in pulmonary artery pressure (12.65 ± 4.7 mmHg), right cardiac work index (0.79 ± 0.4 kg.m/m^2), right ventricle systolic work index (9.45 ± 4.8 g.m/m^2), and a non-significant increase in pulmonary vascular resistance index (141.65 ± 102.9 dynes.s/cm^5.m^2).

Four days after DSRS, there was a non-significant increase in cardiac index (5.2 ± 0.76 L/min per m^2), and a non-significant decrease in systemic vascular resistance index (1389 ± 311 dynes.s/cm^5.m^2). The systolic index (59.64 ± 10.5 mL/beats per m^2), left cardiac work index (6.94 ± 1.3 kg.m/m^2) and left ventricle systolic work index (82.65 ± 17 g.m/m^2) remained above normal levels. There were non-significant increases in heart rate (86.7 ± 17.9 beats/min) and mean arterial blood pressure (92.36 ± 13.75 mmHg), and non-significant decreases in pulmonary capillary wedge pressure (9.55 ± 2 mmHg) and right atrial pressure (7.26 ± 2.4 mmHg). In addition, there were non-significant increases in pulmonary artery pressure (19.84 ± 5.2 mmHg), right cardiac work index (1.31 ± 0.35 kg.m/m^2), and right ventricle systolic work index (16.3 ± 6.3 g.m/m^2), with no significant alteration in pulmonary vascular resistance index (139.7 ± 67.8 dynes.s/cm^5.m^2).

DISCUSSION

Hemodynamic changes after the surgical treatment of schistosomal portal hypertension with disconnection or

shunt procedures may contribute to the understanding of the hyperdynamic circulation observed in these patients with portal hypertension and preserved liver function. Twenty-nine patients (80.5%) showed an elevated cardiac index in the preoperative evaluation, which characterized a hyperdynamic circulatory state[8,9]. Although easily clinically recognized in patients with cirrhosis by peripheral arterial vasodilatation, hypotension and tachycardia, which are usually related to progressive liver failure, in schistosomal patients, these alterations are completely absent because they are less intense and liver function is preserved[10].

We have previously demonstrated that hepatosplenic schistosomiasis presents mild pulmonary hypertension and induces a hyperdynamic circulatory state, which is corrected after EGDS[2,7]. We have suggested that these changes are correlated with the portosystemic collateral circulation, especially as a consequence of splanchnic hyperflow[7]. Our group, as do Wattanasirichaigoon *et al*[8], believes that portosystemic collateral circulation mimics an arteriovenous fistula, in which the high-pressure portal blood connects with the lower pressure systemic venous circulation, which decompresses the portal circulation, but increases portal blood flow. As portal blood flow increases, so does collateral flow, and it is almost totally shunted with the systemic circulation. These observations should be considered particularly in patients with hepatosplenic schistosomiasis, in whom large splenomegaly induces splenic hyperflow, which plays an important role in the origin and maintenance of hyperdynamic circulation[3]. In the present study, 15 patients subjected to EGDS (88.2%) presented normalization of cardiac and systemic vascular resistance indexes, which suggested that EGDS corrected the hyperdynamic circulation. In cirrhosis, physical exercise and pharmacological stress determine an increase in left ventricular end diastolic pressure and a fall in cardiac stroke index and left ventricular ejection fraction, which indicates an abnormal ventricular response[9,11,12]. In these patients, the reduced vascular resistance may mask left ventricular failure. In contrast, the correction of hyperdynamic circulation without elevation of filling pressure, and the normal pre-operative echocardiographic parameters strongly suggest an absence of cardiomyopathy in patients with portal hypertension due to hepatosplenic mansonic schistosomiasis.

On the other hand, patients subjected to DSRS maintained a hyperdynamic circulation. These observations suggested that splenic flow through the venous shunt maintained a low-resistance circuit and hence, the hyperdynamic circulation. These findings are corroborated by the increases in heart rate, systolic, left cardiac work and left ventricle systolic work indexes observed in these patients. Studies that assess the hemodynamic pattern in a later period after EGDS or DSRS are necessary to confirm the findings of our study.

Portopulmonary hypertension (PPHTN) is defined as an increase in mean pulmonary artery pressure greater than 25 mmHg, increased pulmonary vascular resistance (greater than 120 dynas/cm^5), and pulmonary capillary wedge pressure lower than 15 mmHg, in the presence of portal hypertension[13-15]. There are several mechanisms proposed for its development, including an increased production of vasoconstrictors[16-18], increased pulmonary blood flow leading to vascular endothelial damage and remodeling[19], excess of pulmonary vascular volume[20], cirrhotic cardiomyopathy with myocardial thickening and diastolic dysfunction[21], and in situ microthrombosis[22]. Interestingly, to date there are no data showing any correlation between the extent of PPHTN and the intensity of portal pressure, severity of liver disease or degree of shunting[23].

Arterial blood gases and left (systolic and diastolic) ventricular function were within normal limits and, pulmonary capillary wedge pressure was < 15 mmHg in all patients during the hemodynamic study, which provided evidence of normal cardiopulmonary function.

In the present study, 23 patients (63.8%) presented with pulmonary artery pressure greater than 15 mmHg; 13 (36.1%) between 15 and 20 mmHg, eight (22.2%) between 20 and 25 mmHg. In two patients (5.5%), pulmonary artery pressure was > 25 mmHg, which demonstrated a tendency toward pulmonary hypertension in schistosomal portal hypertension, as previously described by our group[24].

After EGDS, we observed a significant reduction in pulmonary artery pressure in 88.2% of the patients. There was also a significant reduction in right cardiac work and right ventricular systolic work indexes, without significant increase in pulmonary vascular resistance index. The two patients without pulmonary artery pressure reduction showed a normal preoperative pulmonary artery pressure (< 15 mmHg). These findings suggest that pulmonary hyperflow may contribute to the elevated pulmonary artery pressure observed in these patients. The reduced pulmonary vascular resistance may be an accommodation of pulmonary vasculature to the hyperflow, in an attempt to maintain normal pulmonary artery pressure. Nevertheless, this adaptation seems ineffective, since pulmonary artery pressure was elevated in the majority of the patients studied. The two patients with PPHTN subjected to EGDS showed reduction of both cardiac index and mean pulmonary artery pressure.

These findings were confirmed by the hemodynamic pattern of patients subjected to DSRS, with which, 16 patients (84.2%) showed a slight increase in pulmonary artery pressure, right cardiac work and right ventricular systolic work indexes. In fact, we have previously reported the cases of two young asymptomatic patients with normal cardiovascular preoperative assessment (electrocardiography, thoracic X-ray and transthoracic echocardiography) who died 4 and 7 d after DSRS, and necropsy showed signs of acute pulmonary hypertension and right ventricular failure[25]. We hypothesized that these patients had undiagnosed preoperative elevated mean pulmonary artery pressure that caused acute pulmonary hypertension after the splenorenal shunt, due to pulmonary hyperflow. The importance of preoperative hemodynamic evaluation in hepatosplenic schistosomiasis is to identify patients with raised pulmonary artery pressure, and consequently, to choose EGDS rather than DSRS as the ideal surgical treatment.

In conclusion, the hyperdynamic circulatory state present in hepatosplenic mansonic schistosomiasis was corrected by EGDS, but it was maintained by DSRS.

Similarly, the raised mean pulmonary artery pressure was corrected by EGDS and maintained by DSRS. EGDS seems to be the most physiologic surgical alternative for patients with schistosomal portal hypertension, because of its tendency to lead to immediate normalization of the systemic and pulmonary hemodynamic parameters. Cardiomyopathy present in cirrhotic portal hypertension seems to be absent in hepatosplenic mansonic schistosomiasis. Hemodynamic studies to evaluate the late circulatory pattern in these patients are necessary to confirm our findings.

COMMENTS

Background

To the best of our knowledge, there are no data in the literature regarding postoperative systemic hemodynamics after surgical treatment of schistosomal portal hypertension. The purpose of this study was to prospectively investigate the postoperative systemic hemodynamic effects in two different surgical procedures largely employed for treatment of schistosomal portal hypertension.

Research frontiers/Innovations and breakthroughs

Hemodynamic changes after the surgical treatment of schistosomal portal hypertension with disconnection or shunt procedures may contribute to the understanding of the hyperdynamic circulation observed in these patients with portal hypertension and preserved liver function. This knowledge may be useful in deciding on the best surgical option for each patient.

Applications

The importance of preoperative hemodynamic evaluation in hepatosplenic schistosomiasis is to identify patients with raised pulmonary artery pressure, and consequently, choose EGDS rather than DSRS as the ideal surgical treatment. EGDS seems to be the most physiologic surgical alternative for patients with schistosomal portal hypertension, due to its tendency to lead to immediate normalization of the systemic and pulmonary hemodynamic parameters.

Terminology

Schistosomal portal hypertension: presinusoidal portal hypertension in patients with preserved liver function.

Peer review

This study examines in patients with pre-hepatic portal hypertension, caused by schistosomiasis, the short-term effects of two different interventions, EGDS and DSRS, on hemodynamic cardiac parameters derived from transthoracic echocardiography and direct measurement of pulmonary artery pressure. The study shows that EGDS lowers cardiac output and mean pulmonary artery pressure (probably as a result of splenectomy), while DSRS has no effect on these parameters.

Abstract

AIM: To evaluate the frequency of neural cell adhesion molecule (NCAM)-180 expression in fresh tumor tissue samples and to discuss the prognostic value of NCAM-180 in routine clinical practice.

METHODS: Twenty-six patients (16 men, 10 women) with colorectal cancer were included in the study. Fresh tumor tissue samples and macroscopically healthy proximal margins of each specimen were subjected to flow-cytometric analysis for NCAM-180 expression.

RESULTS: Flow-cytometric analysis determined NCAM-180 expression in whole tissue samples of macroscopically healthy colorectal tissues. However, NCAM-180 expression was positive in only one case (3.84%) with well-differentiated Stage Ⅱ disease who experienced no active disease at 30 mon follow-up.

CONCLUSION: As a consequence of the limited number of cases in our series, it might not be possible to make a generalisation, nevertheless the routine use of NCAM-180 expression as a prognostic marker for colorectal carcinoma seems to be unfeasible and not cost-effective in clinical practice due to its very low incidence.

Key words: Neural cell adhesion molecule-180; Colorectal cancer; Prognosis; Flow-cytometry

INTRODUCTION

Cancer is currently one of the major causes of morbidity and mortality in humans. Tumor progression to local invasion and metastasis are clinically the most relevant processes for prognosis. However the molecular pathways involved in tumor progression are the least well defined at the cellular level, which represents one of prime challenges in cancer research. Tumor suppressor genes are the major target for treatment modalities in most malignant diseases, including gastrointestinal neoplasies. For colon carcinoma, Deleted in Colon Carcinoma (DCC) accounts for one of the best described tumor suppressors involved in adhesive interactions. DCC is a member of the immunglobulin (Ig) superfamily. The neural cell adhesion molecule (NCAM, CD56) is another member of this family possessing structural and sequence homology to DCC[1,2]. Members of the Ig family of cell adhesion molecules (CAMs) play an important role in progression to tumour malignancy and metastasis. NCAM is an embryologic adhesion molecule and a cell membrane protein that modulates neuroendocrine cell growth, migration, and differentiation[3]. NCAM mediates cell-cell and cell-matrix adhesion, contact inhibition and tissue morphogenesis and also is proposed to be critical in signal transduction[3,4]. The major variants of NCAM are classified based on the sialic acid content as either NCAM-H (high-sialic-acid content) or NCAM-L (low-sialic-acid content). The properties of NCAM-H molecules are the following: relative molecular weight between 200-250 kDa, more prevelant in embrionic tissue, blocks adhesion-binding sites and fascilitates cell migration during embriogenesis[5-7]. Therefore, cell-cell or cell-matrix adhesions can be altered by downregulation of NCAM molecules or by upregulation of sialic acid content within the NCAM protein. NCAM-L with a molecular weight of 120-180 kDa predominates in adult tissue and is expressed in three major isoforms, resulting from alternative mRNA splicing and depending on cell type and stage of differentiation[5,8,9]. The major

isoforms have the 5-distal immunoglobulin and 2-membrane proximal fibronectin (FN)-Ⅲ domains. NCAM-120 is glycophosphatidylinositol-linked to the plasma membrane by a sequence encoded by exon 15[9]. NCAM-140 has the basic NCAM-120 structure with a transmembrane sequence and a short (40-kDa) intracellular tail. NCAM-180 has a longer intracellular tail (90 kDa) encoded by exons 17, 19, and unique to this isoform, exon 18. The intracellular component of NCAM-180 anchors the molecule to the cytoskeleton. NCAM-180 is believed to be an important structural molecule that mediates cell-cell adhesion by providing a mechanical linkage between the cytoskeleton and the extracellular adhesive end of the molecule resulting in tissue stabilisation[10]. NCAM-180 was found to be expressed in normal colonic epithelium villous tips and the expression was demonstrated to be lost in highly aggressive colon cancers[7,11]. This study was undertaken to further evaluate the frequency of NCAM-180 expression in fresh tumor tissue samples by flow-cytometric analysis and to discuss the prognostic value of NCAM-180 in colorectal carcinoma in routine clinical practice.

MATERIALS AND METHODS

Patients and tumor samples

Fresh tumor tissue samples were obtained at operation from 26 patients with colorectal cancer who underwent surgery between January 2002 and January 2006. Two samples from each case, one of which was chosen directly from the center of a main tumor lesion and the other from the macroscopically healthy proximal margins, were transferred to flow-cytometric analysis immediately. The remaining specimen was fixed in 10% phosphate buffered formaldehyde, and embedded in paraffin for histopathological analysis. Patient characteristics are shown in Table 1. Oncologic follow-up was performed in each case within 6-12 mo periods. Clinical data were obtained by direct interviews with patients as a part of oncologic follow-up. Patients were defined as having an aggressive clinical course if they presented with an obstructing or perforating lesion or had metastatic disease. Death within 18 mo of presentation was also classified as having an aggressive clinical course. Participation in the study was voluntary and all patients gave their informed consent to participate. The study was approved by the Local Ethics Committee of Zonguldak Karaelmas University Hospital, Zonguldak, Turkey.

Table 1 Background of 26 cases of resected colorectal carcinoma

Case	Gender	Age (yr)	Location	Tumour

Flow-cytometric analysis

All biopsy materials were dissociated mechanically with Medimachine (Becton Dickinson, CA, USA). The dissociated cells were prepared as single cell suspension in PBS (phosphate buffered salt solution) .The cell number was calibrated as 10×10^6/mL. Each 100 μL sample incubated with 10 μL anti-CD56-PE (phycoerythrin conjugated NCAM monoclonal antibody) for 15 min at room temperature. Samples were processed by a Coulter Q Prep Workstation and run with a Beckman-Coulter Epics XL MCL flow cytometer (Beckman coulter, Florida, USA). At least 20000 events were acquired for each sample. Data analysis was performed using EXPO32 (Beckman-Coulter) software. Only CD45 negative population gated were used for NCAM analysis. The upper limit of background fluorescence was set such that no more than 1% of the events with the matched isotype was in the positive region.

Histological classification

Pathologic stagings were performed based on the TNM staging system developed by the American Joint Committee on Cancer[12]. Histologic tumor typing was applied according to the classification system indicating poor, moderate or well differentiation. Macroscopically healthy proximal margins were verified to be tumor free by histopathologic examination.

RESULTS

Of the 26 patients, 16 (61.5%) were male and 10 (38.5%) were female. The mean age was 65.04 ± 13.60 (range, 37-88) years. Tumors were found to be localized in colonic segments in 19 (73.07%) and in rectum in the rest 7 (26.93%) cases. Four patients died because of cardiovascular or pulmonary complications following surgery. No patients died during follow-up. The mean follow-up period was 19.05 ± 12.33 (range, 4-56) mo. Histopathologic stage, differentiation status, NCAM-180 expression and postoperative survival periods are shown in Table 2. The number of patients in Stage Ⅰ, Ⅱ, Ⅲ and Ⅳ disease were 3 (11.53%), 7 (26.92%), 9 (34.61%), and 7 (26.92%), respectively. Tumors were detected to be well-differentiated in 4 (15.38%), moderately-differentiated in 15 (57.69%) and poorly-differentiated in 7 (26.92%) cases. Flow-cytometric analysis determined NCAM-180 expression in whole tissue samples of macroscopically

Table 2 Results of histopathologic evaluation and flow cytometric analysis of NCAM-180 status

Case	pTNM	Stage	Histology	NCAM-180	Outcome
1	T3N0M0	Ⅱ	Moderate	-	No active disease at 21 mo follow-up
2	T4N1M1	Ⅳ	Poor	-	Died of metastatic diesease 8 mo postresection
3	T4N2M1	Ⅳ	Moderate	-	No active disease at 9 mo follow-up
4	T3N0M0	Ⅱ	Well	-	No active disease at 20 mo follow-up
5	T4NIM1	Ⅳ	Poor	-	Died of cardiopulmonary complication postoperatively
6	T3N1M0	Ⅲ	Moderate	-	No active disease at 6 mo follow-up
7	T2N0M0	Ⅰ	Moderate	-	Metachrone colonic disease at 15 mo
8	T2N0M0	Ⅰ	Moderate	-	No active disease at 15 mo follow-up
9	T4N2M0	Ⅲ	Moderate	-	Died of metastatic diesease 18 mo postresection
10	T3N2M0	Ⅲ	Moderate	-	No active disease at 18 mo follow-up
11	T2N0M0	Ⅰ	Moderate	-	Died of cardiopulmonary complication postoperatively
12	T3N0M1	Ⅳ	Poor	-	Died of cardiopulmonary complication postoperatively
13	T3N1M0	Ⅲ	Moderate	-	No active disease at 32 mo follow-up
14	T3N1M0	Ⅲ	Moderate	-	No active disease at 20 mo follow-up
15	T3N0M0	Ⅱ	Poor	-	No active disease at 16 mo follow-up
16	T3N1M0	Ⅲ	Well	-	No active disease at 19 mo follow-up
17	T3N0M0	Ⅱ	Well	+	No active disease at 30 mofollow-up
18	T3N1M0	Ⅲ	Well	-	No active disease at 44 mo follow-up
19	T4N2M1	Ⅳ	Poor	-	Died of metastatic diesease 5 mo postresection
20	T4N2M1	Ⅳ	Poor	-	Died of metastatic diesease 4 mo postresection
21	T3N0M0	Ⅱ	Moderate	-	Died of metastatic diesease 56 mo postresection
22	T4N1M1	Ⅳ	Moderate	-	Died of metastatic diesease 15 mo postresection
23	T4N1M0	Ⅲ	Moderate	-	Died of cardiopulmonary complication postoperatively
24	T3N0M0	Ⅱ	Poor	-	No active disease at 18 mo follow-up
25	T3N0M0	Ⅱ	Moderate	-	No active disease at 16 mo follow-up
26	T4N1M0	Ⅲ	Moderate	-	No active disease at 14 mo follow-up

healthy colorectal tissues. However, NCAM-180 expression was positive in only one case (3.84%) with well-differentiated Stage Ⅱ disease, and this patient experienced no active disease at 30 mo follow-up.

Correlation between NCAM-180 expression in colorectal cancer and other parameters

It is not possible to compare overall survival outcomes in this series with only one (3.84%) positive NCAM-180 expression. However, NCAM-180 expression was positive in a well-differentiated Stage Ⅱ tumor with an uneventfull clinical course for 30 mo following surgery. Considering well-differentiated tumors, one of three patients without NCAM-180 expression experienced a longer disease free survival period (44 *vs* 30 mo). Moreover, NCAM-180 epxression was not detected in both moderate or poor differentiated tumors. Evaluation of the patients with stage Ⅱ disease demonstrated that one of six patients without NCAM-180 expression survived 56 mo after diagnosis and no active disease was detected in the other 5 patients within a mean follow-up period of 18.2 (range, 16-21) mo.

DISCUSSION

Tumoral invasion and metastasis are the most critical and complex processes in aggressive human cancers and are one of the major causes of cancer deaths. Cell adhesion molecules, including the immunoglobulin superfamily, play a crucial role in determining tumor development and the metastatic cascade[13,14]. Variations in cell-cell and cell-matrix adhesion accompany the progression from benign tumours to invasive, malignant cancer and the subsequent metastatic dissemination of tumour cells. The hallmark of neoplastic and metastatic growth is thought to be reduced adhesiveness between cells and also between cells and the extracellular matri[3]. Several groups of adhesion molecules are importantly involved in regulation of tumor invasion and metastasis.

NCAM (CD56) is a calcium independent cell adhesion molecule, which mediates homotypic and heterotypic cell-cell and cell-matrix adhesion[15-17]. NCAM has been found to be a significant factor for survival in various solid tumors. A correlation between reduced NCAM expression and poor prognosis has been reported for some cancer types[11,18,19]. The existence of NCAM-180 has been proposed to be a good prognostic criterion in colorectal carcinoma[11]. Previous studies have demonstrated that NCAM-180 is present in normal colonic epithelium and in benign colonic tumors and loss of NCAM-180 expression might result in defective intracellular adhesion between colonocytes in aggressive colon carcinoma[7,11]. In this study we investigated the NCAM-180 expression rate in fresh tumor tissue samples of colorectal carcinoma and the association of an aggresive clinical course with loss of this expression.

NCAM expression has been investigated in various solid and neuroendocrine tumours. There is a consensus that presence of its polisialiated (embryonic) form, which is less adhesive than the adult form [that contains a relatively low polisialic acid (PSA) content], is associated with a poor prognosis. Correlation between N-CAM expression and perineural spread has been confirmed in a variety of human carcinomas. The existence of the polisialiated form of NCAM in Wilms' tumor, neuroblastoma, pituitary tumor, small cell lung cancer, gallbladder and bile duct cancer,

squamous cell cancer of head and neck, and prostat cancer results in perineural invasion and agrressive metastatic behaviour with a poor clinical outcome[20-28]. As the expression of the polisialiated form of NCAM correlates with tumor growth and invasiveness because of its role in cell disassociation, ıt was considered to be a poor prognostic criterion in pituitary tumors and rhabdomyosarcoma[22,29]. Polysialation has been proposed to involve steric inhibition of membrane-membrane apposition and cell adhesiveness, based on the biophysical properties of the polisialic acid[30]. In renal cell carcinoma, NCAM expression was suggested to be a risk factor for tumor metastasis[31]. Moreover, NCAM is not polysialylated in renal cell carcinoma suggesting that it plays another role in these tumors involving homophilic adhesion[31]. Conversely, for other tumors like pancreatic adenocarcinomas, reduced levels of NCAM expression were found to correlate with increased tumor malignancy[19]. This result was also observed in a transgenic mouse model of β-cell pancreatic carcinoma by crossing these mice with NCAM knockout mice[32]. The hypothesis was reduced levels of NCAM could increase cell dissociation from primary tumors. Moreover, an overall decrease in the NCAM level has been observed in another subset of tumors including colon carcinoma and astrocytoma. In these tumors NCAM expression is markedly down-regulated, and the loss of NCAM correlates with poor prognosis[7,11,18,33]. In gastrointestinal neoplasia, when pancreatic, colorectal and gastric cancer were considered, poorly differentiated tumors had lower levels of NCAM than well or moderately differentiated tumors[18].

Previous studies have demonstrated that NCAM-180 is present in normal colonic epithelium and NCAM-180 expression was found to be absent in clinically aggressive colon carcinomas[11]. Consistent with this thesis, colorectal carcinomas expressing NCAM-180 should experience a good clinical course with longer disease free survival. In other words, overexpression of the polysialylated form of NCAM or reduced expression of NCAM-180 has been suggested to decline intracellular adhesion, facilitating metastatic behavior in cancer. This study was designed to determine the rate of NCAM-180 expression in fresh colorectal tumour tissue and correlation of NCAM-180 expression with clinical course. In our series of 26 colorectal carcinoma, we determined NCAM-180 expression in only one patient (3.84%) (pathologic stage Ⅱ-well differentiated tumour) with a good clinical course during a follow-up period of 30 mo. This was an expected finding according to the previous literature[7,11]. However, we detected that 6 of the other patients with the same clinical and pathological stage at diagnosis and surgery, experienced either similar or a better clinical course during follow-up as well. Moreover, 2 patients without NCAM-180 expression and in an advanced pathological stage at diagnosis survived more than the patient with NCAM-180 expression. These are controversial results predicting that attribution of NCAM-180 expression as a good prognostic criterion in colorectal carcinoma is something to be interrogated before acceptance.

NCAM-180 has been proposed as a candidate tumor supressor in colorectal carcinoma previously and might play a crucial role in tumor behaviour by mediating colonic epithelial integrity and preventing tumour invasiveness and metastasis due to cellular adhesive properties. When colorectal cancer is considered, loss of NCAM-180 expression might lead to reduced homotypic binding between cancerous cells, resulting in detachment from the primary cancerous mass and invading other organs, acting systematically. However, in our series the NCAM-180 expression rate was only 3.84% and statistical correlation analysis of survival with NCAM-180 expression was not possible according to this low frequency. Moreover, the comparision according to tumor differentiation and stage revealed that loss of NCAM-180 expression in either well-differentiated or stage Ⅱ disease did not result in a worst clinical course. As a consequence of the limited number of cases in our series, it might not be possible to make a generalisation, nevertheless the routine use of NCAM-180 expression as a prognostic marker for colorectal carcinoma seems not to be feasible and cost-effective in clinical practice due to being present at a very low frequency. Further studies with a greater number of cases are thus called for to study the underlying mechanisms of tumor metastasis and prognosis in colorectal carcinoma.

Presented in "Turkish National Surgery Congress" 24-28 May, 2006.

COMMENTS

Background

Cancer being one of the most mortal disease worldwide, tumor markers and prognostic criterions attract a great enthusiasm above researchers. Tumor suppressor genes and cell adhesion molecules are considered to play a crucial role in tumor pathophysiology.

Research frontiers

Neural cell adhesion molecule (NCAM-CD56) mediates cell-cell and cell-matrix adhesion, contact inhibition and tissue morphogenesis and also proposed to be critical in signal transduction. The major variants of NCAM are classified based on the sialic acid content as either NCAM-H (high-sialic-acid content) or NCAM-L (low-sialic-acid content). NCAM-L with a molecular weight of 120-180 kDa, predominates in adult tissue and is expressed in three major isoforms. NCAM-180 is believed to be an important structural molecule that mediates cell-cell adhesion by providing a mechanical linkage between the cytoskeleton and the extracellular adhesive end of the molecule resulting in tissue stabilisation.

Innovations and breakthroughs

A correlation between reduced NCAM expression and poor prognosis has been reported for some cancer types. NCAM-180 expression has been demonstrated to be lost in highly aggressive colon cancer and proposed to function as a tumor supressor. From this point of view we aim to evaluate the frequency of NCAM-180 expression in fresh tumor tissue samples by flow-cytometric analysis and to discuss the prognostic value of NCAM-180 in colorectal carcinoma in routine clinical practice.

Applications

The most critical deficit in the ability to treat cancer effectively is the lack of knowledge about cellular basis and markers for early diagnosis. The verification of an association between various types of malignancies and adhesion molecules might provide novel targets to cancer therapy by indicating the accurate goals.

Terminology

Neural cell adhesion molecule (NCAM-CD56) is a well identified cell membrane protein and a member of immunoglobulin superfamily, possessing structural and sequence resemblance to Deleted in Colon Carcinoma (DCC), which is another member of the same superfamily.

Peer review

The authors evaluated the frequency of NCAM-180 expression in fresh tumor tissue samples by flow-cytometric analysis and found that NCAM-180 expression in whole tissue samples of macroscopically healthy colorectal tissues, but only in one case (3.84%) with well-differentiated Stage Ⅱ disease. As discussed by the authors that the limited number of cases in the series, it is impossible to make a generalization. Further study with a large series of cases should be carried out to evaluated the clinicopathological significance of NCAM-180 expression in colorectal cancers.

Abstract

AIM: To investigate serum alanine aminotransferase (ALT) levels in relation to the clinical, biochemical, ultrasonographic and histological characteristics of patients with hepatitis C virus.

METHODS: Duration of disease, HCV-RNA, liver steatosis, and the hepatitis activity index (HAI) were correlated with serum ALT in 36 patients with HCV. ALT values were also investigated in 16 control subjects without any liver diseases.

RESULTS: In bivariate analyses, ALT levels correlated with duration of HCV infection ($P < 0.01$), HCV-RNA ($P < 0.05$), and the HAI ($P < 0.01$). Among the components of the HAI, ALT concentrations were significantly associated with periportal bridging/necrosis ($P < 0.01$) and fibrosis ($P < 0.05$). In multivariate analysis, periportal bridging/necrosis ($\beta = 0.508$; $P < 0.01$), duration of HCV infection ($\beta = 0.413$; $P < 0.01$), and HCV-RNA ($\beta = 0.253$; $P < 0.05$) were independently associated with ALT activity. The normal ALT activity for men and women was < 23 IU/L and < 22 IU/L, respectively.

CONCLUSION: In patients with HCV, alterations in the liver tissue as reflected by ALT elevation are mainly associated with periportal bridging/necrosis, viral load and duration of disease. A cut-off value < 23 IU/L distinguished with high diagnostic accuracy healthy controls from patients with HCV.

Key words: Hepatitis C virus; Disease duration; Viral Load; Inflammation; Normal alanine aminotransferase

INTRODUCTION

Hepatitis C virus (HCV) is a major cause of chronic liver disease, frequently progressing to cirrhosis and increased risk of hepatocellular carcinoma[1-3]. Chronic hepatitis C is often silent, most of the times discovered only by routine serologic or biochemical testing[4-6]. Many attempts to identify the natural history and progression of hepatitis C infection have been made, but several aspects remain to be elucidated[7]. In individuals with chronic hepatitis C, viral load and elevated serum alanine aminotransferase (ALT) levels may have clinical relevance[8-10]. When parenchymal liver cells are damaged, aminotransferases leak from the liver into the blood, resulting in elevated levels of these enzymes in the bloodstream. The exact definition of the normal levels of serum ALT activity is crucial for screening and follow-up studies in hepatitis C infection[11,12]. It should be noted, however, that half of the untreated patients with chronic HCV infections display normal or minimally elevated serum ALT levels[13,14]. Accordingly, several studies have recently questioned whether previously established values to define normal ALT range are clinically accurate[11,12]. In this regard, it has been posited that the limits of normal for serum ALT should be revised accordingly[12].

In the present study, we sought to investigate serum ALT levels in relation to the clinical, biochemical, ultrasonographic and histological characteristics of patients with hepatitis C. We also aimed to study the normal level of ALT in Turkish healthy adults at low risk for chronic liver diseases. This information, in addition to daily clinical practice, may be clinically useful for research studies of hepatitis C and chronic liver diseases in Turkey.

MATERIALS AND METHODS

Study sample

A total of 36 patients (24 females, 12 males; mean age: 47.9 ± 13.2 years) with HCV infection were studied before the treatment with antiviral drugs. Patients with hemochromatosis, Wilson's disease, autoimmune hepatitis,

primary biliary cirrhosis, sclerosing cholangitis, biliary obstruction, alpha-1 antitrypsin deficiency, or malignancies were excluded from the present study. None of the subjects was using any medications, including estrogens, amiodarone, steroids, tamoxifen, or herbal supplements. Furthermore we excluded patients with daily alcohol intake exceeding 20 g/d. For control purposes, 16 healthy age- and gender-matched volunteers (9 females, 7 males) were recruited. All controls were judged to be in good health and confirmed as having normal liver by ultrasound. Subjects with a consumption of alcohol > 20 g/d or who were taking any medication were not included in the control group. All subjects underwent physical examination, anthropometric measurements and biochemical screening.

A written informed consent was obtained from all participants. Our study was in accordance with the ethical standards for human experimentation and approved by the Ethics Committee of the Uludag University Medical School.

Laboratory and virology assessment

Blood samples for the evaluation of alanine aminotransferase (ALT), and biochemical parameters were obtained after overnight fasting. Routine biochemical tests were carried out using commercially available kits (Hitachi, Tokyo, Japan). The HCV-RNA was determined in the sera using an RT-PCR assay (Amplicor, Roche, Mannheim), with a sensitivity of 70 copies/mL.

Ultrasound assessment

Liver ultrasound (US) scanning was performed to assess the degree of steatosis. All US procedures were performed by the same operator. Liver steatosis was assessed semi-quantitatively on a scale of 0 to 3:0, absent; 1, mild; 2, moderate and 3, severe.

Histological analysis

Ultrasonography-guided liver biopsies were performed under conscious sedation using a 16-gauge Klatskin needle. The length of histological specimens was not smaller than 2.5 cm. All biopsy specimens were placed in formalin solution for fixation and embedded in paraffin blocks. Serial sections (sectioned at 4 μm intervals) were stained with hematoxylin-eosin and Masson's trichrome. The hepatitis activity index (HAI), designed by Knodell and Desmet[15,16], was used to grade the severity of the necroinflammatory process and fibrosis. HAI comprises four separate scores, including periportal necrosis with or without bridging necrosis (0-10), intralobular degeneration and focal necrosis (0-4), portal inflammation (0-4) and fibrosis (0-4).

Statistical analysis

Variables are presented as counts and percentages, mean ± SD. Correlations among the study variables were assessed by means of the Pearson's correlation coefficients. Multivariate stepwise regression models were used to assess the independent predictors of ALT levels in patients with HCV infection. Cut-off values for serum ALT values were determined by means of the ROC curve analysis with the use of the MedCalc statistical software (Mariakerke, Belgium). A $P < 0.05$ was considered statistically significant. All computations were made using SPSS 11.0 (SPSS Inc., Chicago, IL, USA).

RESULTS

Bivariate analysis of serum ALT levels in patients with HCV infection

The characteristics of individuals with HCV infection are given in Table 1. The estimated median duration of HCV infection was 58 (interquartile range: 24-120) mo. Steatosis was present in 22 (61%) of the 36 HCV infected patients, of whom 8 (22%) had grade 1, 11 (30%) grade 2, and 3 (9%) grade 3. The histological findings of the study participants are shown in Table 2. In bivariate correlation analyses, ALT levels correlated with duration of HCV infection (r = 0.46, $P < 0.01$, Figure 1), HCV-RNA (r = -0.33, $P < 0.05$, Figure 2), and the HAI (r = 0.44, $P < 0.01$, Figure 3). Among the components of the HAI, ALT concentrations were significantly associated with periportal bridging/necrosis (r = 0.50, $P < 0.01$) and fibrosis (r = 0.37, $P < 0.05$).

Multivariate analysis

Multivariate stepwise regression analysis was used to

Table 2 Liver histology in the 36 study participants with HCV infection

Variable	Score
Hepatitis activity index	9.5 ± 3.7
Periportal necrosis with or without bridging necrosis	3.7 ± 2.2
Intralobular degeneration and focal necrosis	2.7 ± 1.1
Portal inflammation	3.0 ± 1.0
Fibrosis	1.9 ± 1.2

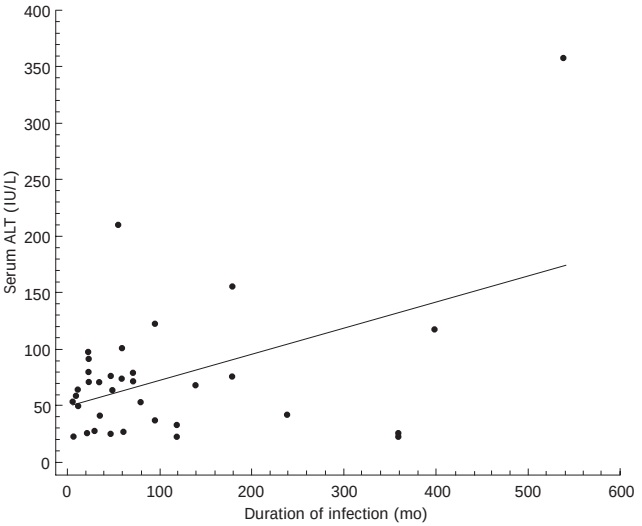

Figure 1 Scatter diagram and regression line showing a significant positive relationship between duration of HCV infection and serum alanine aminotransferase (r = 0.46, P < 0.01).

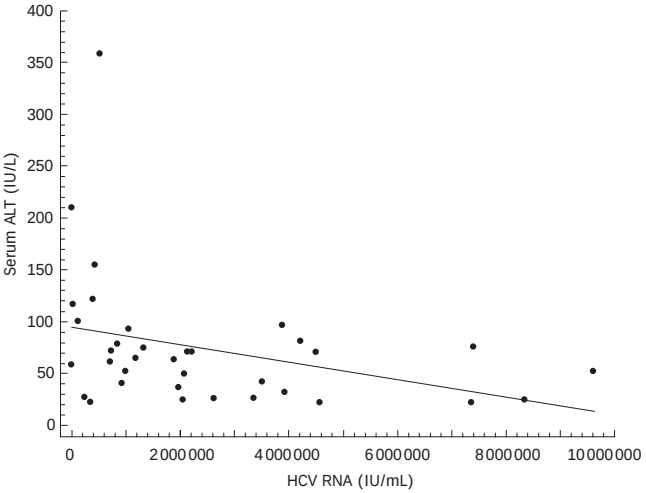

Figure 2 Scatter diagram and regression line showing a significant inverse relationship between viral load and serum alanine aminotransferase (r = -0.33, P < 0.05).

identify independent predictors of ALT levels in our patients with HCV infection. Serum ALT activity was considered as the dependent variable. All variables listed in Table 1 were entered into the multivariate model as independent variables. The results of this analysis showed that periportal bridging/necrosis (β = 0.508; P < 0.01), duration of HCV infection (β = 0.413; P < 0.01), and

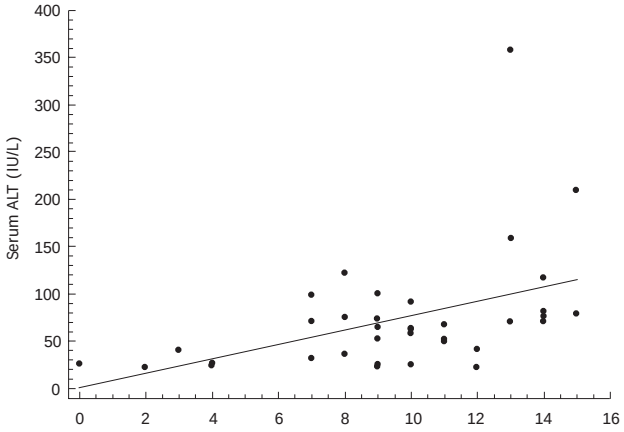

Figure 3 Scatter diagram and regression line showing a significant positive relationship between the Histology Activity Index and serum alanine aminotransferase (r = 0.44, P < 0.01).

HCV-RNA (β = 0.253; P < 0.05) were, in the order they entered into the model, independently associated with ALT levels.

Identification of a cut-off value for serum ALT levels according to gender

In order to establish a better cutoff value for ALT in hepatitis C screening in our Turkish population, the ALT levels were measured in 16 healthy age- and gender-matched volunteers. ALT levels in the control population were 18.2 ± 3.6 IU/L. The cutoff value was identified by construction of a ROC curve (receiver operating characteristic) in each gender. In females, the better cutoff value for ALT was at 22 IU/L, with sensitivity of 87.5% and specificity of 100% in identifying subjects without HCV infection (Figure 4). In males, the better cutoff value for ALT was at 22 IU/L, with sensitivity of 100% and specificity of 100% in identifying subjects without HCV infection (Figure 5).

DISCUSSION

This study provides insights into the correlates of ALT levels in the setting of patients with HCV infection. We found that, in our sample of Turkish patients, serum ALT levels were significantly and independently correlated with periportal bridging/necrosis, viral load and duration of HCV infection.

Serum ALT levels, as a measure of biochemical hepatitis activity, increased significantly with periportal bridging/necrosis, and this association was stronger than for other components of the HAI index. Our findings are in line with previous studies showing a statistically significant linear relationship between the degree of ALT elevation and the amount of liver injury based on the HAI score[17]. In our study, viral load was significantly and inversely correlated with mean ALT levels. This result is in keeping with the findings of Ito *et al*[18], who showed that mean viral load was significantly higher in chronic HCV patients with persistently normal ALT levels. In this regard, it has been hypothesized that immune response to HCV

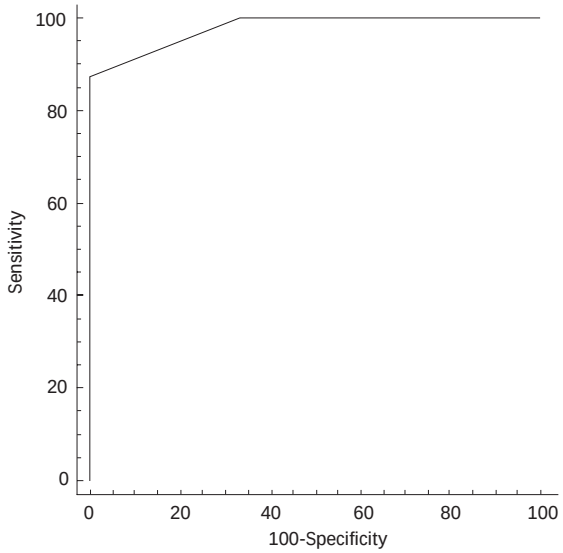

Figure 4 ROC curve of serum ALT for discriminating female HCV patients from women without liver disease. The better cutoff value for ALT was at 22 IU/L, with sensitivity of 87.5% and specificity of 100% in identifying subjects without HCV infection.

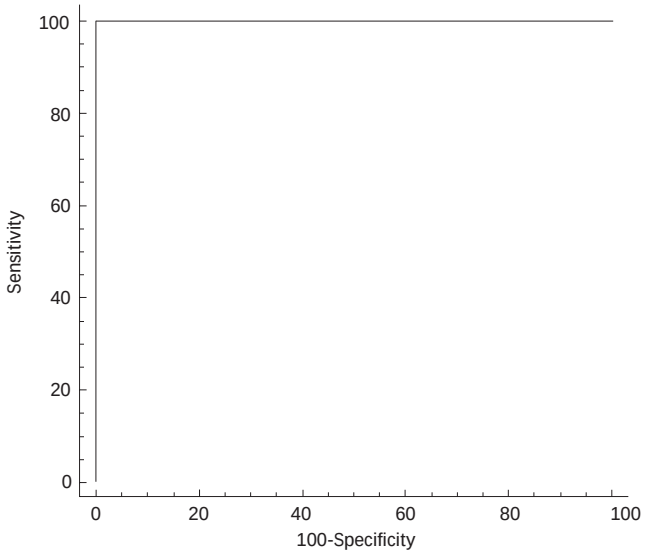

Figure 5 ROC curve of serum ALT for discriminating male HCV patients from men without liver disease. The better cutoff value for ALT was at 23 IU/L, with sensitivity of 100% and specificity of 100% in identifying subjects without HCV infection.

could play a role in rendering viral load smaller[18]. It should be noted, however, that some authors have reported higher ALT levels in patients with high viral load[19]. Another group has suggested that no significant difference in viral load exists between patients with abnormal ALT levels and those with normal ALT levels[20]. Although the reasons for conflicting data remain to be clarified, the discrepancies in the literature may be due at least in part to the presence of potential confounders such as ethnicity or different sample sizes. The duration of HCV infection may be of importance for the development of cirrhosis and patients with longer periods of infection may be more likely to have higher ALT levels[20]. In our study we found a positive association between ALT activity in the serum and duration of HCV infection. Some authors, however, have failed to demonstrate such a relationship[21]. In any case, it should be kept in mind that the onset of HCV infection may be difficult to establish in some patients, thereby rendering disease duration undefined.

Growing evidence has suggested that up to 25% of patients with chronic hepatitis C virus infection have persistently normal aminotransferase levels (10% to 40%, according to different studies)[22-24]. The normal range for ALT level was set in the 1950 s and has changed little since then. However, several recent studies have questioned whether previously established reference values to define normal ALT range are really accurate. Under these circumstances, it has been repeatedly suggested that the limits of normal ALT activity should be revised[25-27]. In most countries, the cutoff value for ALT is defined as twice the upper limit of the normal range of healthy individuals[28]. The normal ALT activity for men and women is < 23 IU/L and < 18 IU/L, respectively[28]. In order to gain more insights on the normal level of ALT in Turkish healthy adults at low risk for chronic liver diseases, we measured ALT activity in a control population from our country. By ROC curve analysis, we found that the optimal cutoff point in our population was 23 IU/L in males and 22 IU/L in females. Using our newly calculated cutoff value, we found that the sensitivity and specificity for detection of subjects without HCV infection were 100% and 100% in men and 87.5% and 100% in women, respectively. Hopefully, these new data obtained in the Turkish population should contribute to the ongoing discussion regarding new reference systems for the measurement of the catalytic activity of ALT in the clinical practice[29,30]. Given the small sample size, we believe that our findings may stimulate future studies on a larger number of patients.

In conclusion, we have provided evidence that the main correlates of ALT levels in HCV patients are periportal bridging/necrosis, viral load and duration of HCV infection. A cut-off value < 23 IU/L in males and 22 IU/L in females may distinguish with high diagnostic accuracy healthy control subjects from patients with HCV.

COMMENTS

Backgrounds

The exact definition of the normal levels of serum ALT activity is crucial for screening and follow-up studies in hepatitis C infection. However, half of the untreated patients with chronic HCV infections display normal or minimally elevated serum ALT levels. Accordingly, several studies have recently questioned whether previously established values to define normal ALT range are clinically accurate.

Research frontiers

Recent evidence has suggested that the limits of normal for serum ALT should be revised. In the present study, we sought to investigate serum ALT levels in relation to the clinical, biochemical, ultrasonographic and histological characteristics of patients with HCV.

Innovations and breakthroughs

We have provided evidence that the main correlates of ALT levels in HCV patients are periportal bridging/necrosis, viral load and duration of HCV infection.

Applications

A cut-off value < 23 IU/L in males and 22 IU/L in females may distinguish with high diagnostic accuracy healthy control subjects from patients with HCV.

Terminology

ALT elevation: aminotransferases leak from the liver into the blood when parenchymal liver cells are damaged.

Peer review

The study is of particular interest to the practical medicine. The results provide sufficient evidence that the activity of ALT correlates with histological changes, viral load and duration of infection in patients with HCV.

Abstract

AIM: To determine the prevalence and symptoms of gastroesophageal reflux disease (GERD) in a healthy general population in relation to demographic, lifestyle and health-seeking behaviors in Shiraz, southern Iran.

METHODS: A total of 1978 subjects aged > 35 years who referred to Gastroenterohepatology Research Center and who completed a questionnaire consisting of 27 questions for GERD in relation to demographic, lifestyle and health-seeking behaviors were included in this study for a period of five months. The validity and reliability of the questionnaire were determined.

RESULTS: The prevalence of GERD was 15.4%, which was higher in females (17.3%), in rural areas (19.8%), and in illiterate subjects (21.5%) and those with a mean age of 50.25 years. The prevalence was significantly lower in subjects having fried food (14.8%), and fruit and vegetables (14.6%). More symptoms were noticed in subjects consuming pickles (22.1%), taking aspirin (21%) and in subjects with psychological distresses (27.2%) and headaches (22%). The correlation was statistically significant between GERD and halitosis (18.3%), dyspepsia (30.6%), anxiety (19.5%), nightmares (23.9%) and restlessness (18.5%). Their health seeking behavior showed that there was a significant restriction of diet (20%), consumption of herbal medicine (19%), using over-the-counter drugs (29.9%) and consulting with physicians (24.8%). Presence of GERD symptoms was also significantly related to a previous family history of the disease (22.3%).

CONCLUSION: GERD is more common in females, rural and illiterate subjects and correlated with consumption of pickles, occurrence of headache, psychological distress, dyspepsia, halitosis, anxiety, nightmare and restlessness, and a family history of GERD and aspirin intake, but the correlation was negative with consumption of fat and fiber intake.

Key words: Reflux; Risk factors; Prevalence; Southern Iran

INTRODUCTION

Symptoms of gastroesophageal reflux disease (GERD) represent one of the most frequent health problems in the western world[1]. Approximately 10% of the American population suffer from daily heartburn and about one third have periodic symptoms[2]. Based on the population studied, the prevalence of the primary GERD symptoms, heartburn (a burning feeling behind the breast bone) or acid regurgitation (an acid taste in the mouth) varies between 9% and 42%[3]. The relationship between GERD and lifestyle habits, e.g. cigarette smoking, alcohol and coffee consumption, ingestion of medications such as aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), and diet has not been firmly established, and inconsistent results have been obtained from population-based studies[1,4-8].

As there are few population-based data on GERD in Asia[9-12], this study was performed for the first time in Shiraz, southern Iran with the aim of determining the prevalence of GERD symptoms and describing the demographic, lifestyle and health-seeking behaviors associated with GERD.

MATERIALS AND METHODS

Materials

This study was carried out in a group of GERD patients.

Table 1 Frequency of GERD symptoms and their correlation with different characteristics of subjects in Shiraz, Southern Iran (*n* = 1978)

Characteristics		GERD Symptoms (%)		*P* value

	Obese	18.8	81.2	
Age (mean) (yr)		50.25	49.83	0.547

GERD: Gastroesophageal reflux disease.

Methods

In a population-based study, 3600 subjects were selected by cluster random sampling method based on postal code division of Shiraz, southern Iran into 17 districts. After clarifying the research project for each subject, he/she received an invitation letter to refer to Mottahari Digestive Clinic of Gastroenterohepatology Research Center affiliated to Shiraz University of Medical Sciences. The project was approved by the Ethics Committee of the university and a written consent was obtained from each patient participating in the study. The study was undertaken for a period of five months from April to September 2004 while 1978 subjects completed the questionnaire. The included subjects were aged > 35 years, of both genders, and from both urban and rural areas. A team of interviewers who had received an intense training completed the questionnaire consisting of 27 questions categorized into three sections of demographic, lifestyle and symptoms of GERD (Appendix 1). A gastroenterologist completed the clinical questions of the questionnaire in the clinic. The reliability and validity of the questionnaire were determined by requesting 100 subjects to be interviewed at our clinic by the same trained interviewers and a gastroenterologist for completion of the questionnaire, respectively. Heartburn was defined as a burning feeling in epigastric area that rises through the chest in substernal area and acid regurgitation as liquid coming back into the mouth leaving a bitter or sour taste. A subject was defined to suffer from GERD when he/she reported heartburn and/or acid regurgitation in the preceding year with a frequency of at least three times a week irrespective of its severity or duration. Sociodemographic variables included age, gender, habitat, marital status, educational level, biological characteristics, such as BMI [weight in kg in the fasting state divided by the square of the height in meters, resulting in five categories of thin (< 18 kg/m^2), normal (18-24.9 kg/m^2), overweight (25-29.9 kg/m^2), obese (30-40 kg/m^2) and very obese (> 40 kg/m^2)], lifestyle such as physical activity (at least 30 min/week or sufficient to produce adequate sweating), dietary habits, cigarette smoking, alcohol, coffee and tea consumption and the use of aspirin and NSAIDs. Rural and urban habitats were defined by the size of the residence area (under 30 000 inhabitants *vs* 30 000 inhabitants or more). Dyspepsia was defined as epigastric or upper abdominal symptoms (pain or discomfort) in the past year. Information was put directly into a computer database under supervision of a professional biostatician.

Statistical analysis

Statistical analysis was performed using the SPSS computer software package (Version 11.5, Chicago, Il). A *P* value of 0.05 or less was considered to be statistically significant and all reported *P* values were two sided using Chi-square tests.

RESULTS

Among 3600 visited households, the interview questionnaire was completed in 1978 subjects (response rate, 54.9%; mean age, 49.90 ± 11.14 years). Among the subjects, 29.4% were male, 56.6 % lived in urban and 43.4% in rural regions; 39.7%, 29.7%, 17.2% and 13.5% of the subjects were respectively in 35-44, 45-54, 55-64 and > 65 years age groups; 25.6%, 32.3%, 14.5% and 27.6% of the participants were illiterate, or with primary, high school and university educational levels, respectively. The reliability and validity of the questionnaire were 82% and 70%, respectively.

The prevalence rate of GERD was 15.4% (304 subjects, GERD occurring at least 3 times per week). Table 1 shows the prevalence rates of GERD in relation to demographic data, revealing that the prevalence was higher in females (17.3%, $P = 0.003$), in rural areas (19.8%, $P = 0.001$), and in illiterate subjects (21.5%, $P = 0.001$). In subjects with GERD, a higher prevalence of psychological distress (27.2%, $P = 0.003$) and headaches (22%, $P = 0.009$) was observed.

Table 2 demonstrates the frequency of GERD symptoms in relation to dietary, smoking and drinking habits and medication of the participants. The results indicated a lower prevalence in subjects having fried food (14.8%, $P = 0.005$), and a higher prevalence among those consuming pickles (22.1%, $P = 0.001$). There was no association between GERD symptoms and drinking spirits ($P = 0.095$) or water ($P = 0.063$) with meals, salt intake ($P = 0.458$) and physical activity ($P = 0.373$). The correlation between GERD symptoms and subjects being a current or former cigarette smoker (10.8%, $P = 0.055$) or water pipe smoker (18.7%, $P = 0.096$) was not significant either.

The prevalence of GERD was lower in subjects with more fruits and vegetables intake (14.6%, $P = 0.001$) and those drinking tea (14.9%, $P = 0.465$) and coffee (12.9%, $P = 0.701$), but was higher among those drinking alcohol (15.6%, $P = 0.205$) but the difference was significant from those with consumption of fruits and vegetables.

Table 2 Prevalence of GERD in relation to lifestyle of subjects in Shiraz, southern Iran (n = 1978)

Life style and dietary habits		GERD symptoms (%)		*P* value

GERD: Gastroesophageal reflux disease; NSAIDs: Non-steroidal anti-inflammatory drugs.

We noticed more symptoms in subjects taking NSAIDs (17.9%, $P = 0.067$), and aspirin (21%, $P = 0.020$) (Table 2), but the difference was only significant for aspirin. Subjects with GERD symptoms are restricting their diets (20%, $P = 0.001$), taking herbal medicine (19.0%, $P = 0.001$), using the over-the-counter (OTC) drugs (29.9%, $P = 0.001$) and consulting with physicians (24.8%, $P = 0.001$). In subjects consuming medication advised by their friends, the difference was not statistically significant (23.5%, $P = 0.058$). Subjects with GERD had a significantly higher accurrence of halitosis (18.3%; $P = 0.024$), dyspepsia (30.6%; $P = 0.001$), anxiety (19.5%; $P = 0.001$), nightmare (23.9%; $P = 0.001$) and restlessness (18.5%; $P = 0.001$) (Table 3). There was an association between GERD symptoms and a family history of the disease (22.3%; P=0.001) (Table 1).

Table 3 Health-seeking behavior of subjects with GERD Symptoms in Shiraz, Southern Iran (n = 1978)

Health-seeking behavior and associated symptoms		GERD Symptoms (%)		*P* value
		Present	Absent

	Yes	18.5	81.5	

DISCUSSION

It has been estimated that the digestive disease with the highest annual direct cost in the USA is GERD (about US$ 9.3 billion)[13]. Furthermore GERD patients have reported decrements in the health-related quality of life when compared with the general population[14,15]. Among western patients, heartburn and acid regurgitation are known to be specific for GERD[16].

In our population-based study, the prevalence of GERD was 15.4% defined as heartburn and/or acid regurgitation at least three times per week. In a population-based study, Khoshbaten[17] reported a prevalence of 2.7% for GERD as heartburn occurring at least thrice in recent two weeks in Tabriz, northwestern Iran. This difference may be due to his different case definition in the questionnaire. In a sample of general population in Germany, 18% of subjects suffered from GERD[18]. Wong *et al*[15] in a study by telephone contact reported a prevalence of 29.8% in a Chinese population. A study by telephone calls in a Spanish population showed a prevalence rate of 25.2%-34.7%[19]. A monthly prevalence of 1.6% was reported in Singapore[9]. Hu *et al*[20] demonstrated that only 5% of a Chinese population had GERD. In a large study of Taiwanese patients, 17% had at least one of three reflux symptoms daily[21]. Several factors that may influence the prevalence of GERD have been identified, including genetic factors and differences in body mass index and lifestyle[22-25]. Geographical differences in GERD prevalence are difficult to interpret due to the different case definitions and questionnaires used[4,26].

As shown in Table 1, the GERD prevalence was higher in females, rural areas, and illiterate subjects and those with a mean age of 50.25 years. Wong *et al*[11], Diaz-Rubio *et al*[12] and Mahadeva *et al*[19] also reported a higher prevalence of GERD in females. Some studies have not demonstrated a relationship between gender and GERD[10,27]. In relation to habitat, Diaz-Rubio *et al*[19] showed that GERD prevalence was higher in rural areas and in relation to educational level, a higher prevalence in illiterate subjects similar to our study. The relationship between a lower educational level and the frequency of GERD was described previously, which probably reflects the action of certain unhealthy lifestyle habits, or less ability to modify such habits[7,19].

In relation to life style, smoking and alcohol have often been cited as risk factors for GERD, although findings of

studies on this matter have been inconsistent[3,27,28,29]. According to Nocon *et al*[18], smoking was a risk factor for GERD, which was associated with reflux symptoms and was dose-dependent. Nilsson *et al*[3], reported that smoking and salt were risk factors for reflux symptoms. Our results showed no correlation between GERD and smoking.

In our study, we found no effect of alcohol, tea, coffee and spirits on GERD symptoms. In a population-based study, Nilsson *et al*[3] did not notice any effect for these risk factors. No relationship in Nocon *et al's* study[18] was found between the intake of alcohol and reflux symptoms. Wong *et al*[11] and Mahadeva *et al*[12] indicated the increase of GERD prevalence due to consumption of alcohol, which is not consistent with our results. Drinks such as tea and coffee have also been reported to be linked to GERD but this is controversial. Although tea has been shown to increase gastric acid secretion, it does not appear to contribute to GERD[22]. Wendle *et al*[30] showed that coffee increases GERD and the irritant effect of coffee was correlated to the caffeine content, but this has also been disputed. Chang *et al*[21] found no link between coffee or tea consumption and the incidence of GERD. Diaz-Rubio *et al*[19] also noticed that occurrence of GERD was inversely associated with coffee consumption. There was also no effect of tea or coffee on GERD symptoms in Nocon *et al's* study[18]. The inverse relationship with coffee, tea or alcohol consumption should not be interpreted as a protective role for these beverages. Restriction in drinking of tea, coffee and alcohol may arise from the suggestions of their friends, even in our country, where alcohol consumption is not legally allowed. The role of coffee as a promoter of gastroesophageal reflux disease[30] is also consistent, suggesting that the avoidance of coffee is a sound recommendation for GERD sufferers. In relation to fiber intake, El-Serag *et al*[5] and Nocon *et al*[18] reported that consumption of fruits were associated with GERD symptoms and found a protective effect of dietary fiber, which was similar to our results. In relation to dietary fat, El-Serag *et al*[5] found an increased risk of GERD in subjects with a high intake of dietary fat. The data of Nocon *et al*[18] also showed that subjects with reflux symptoms tend to have a diet richer in fat. It has been shown that dietary fat can increase the transient lower esophageal sphincter relaxation[31], possibly *via* release of cholecystokinin[32]. Therefore, the lower fat content in a population may explain, in part, the lower prevalence of GERD.

In relation to consumption of spirits, we found no association between reflux symptoms and consumption of spirits. These results were different from Nocon *et al*[18]. With regard to physical exercise, there are conflicting results[29]. According to Nocon *et al*[18], subjects with GERD were less active physically, but our data did not confirm these results. Some studies have observed an association between the use of aspirin or NSAIDs and the presence of GERD[19,33] and use of NSAIDs is a risk factor for erosive esophagitis[5,15,34], whereas others have not[27,35]. A higher consumption of NSAIDs and aspirin were visible in subjects of our study with GERD symptoms but was only statistically significant for aspirin. In relation to medical care utilization, the results vary among countries from 16% to 56%. A study from Singapore found that 40% of GERD sufferers used OTC drugs or visited a physician for GERD symptoms[9]. This is in contrast with a study in Minnesota, USA, in which only 5.4% of GERD sufferers visited physicians[27]. In the study of Wong *et al*[15], 48% of subjects with GERD had received treatment, 6% had taken OTC medication, and 35% had visited physicians. In our study, in relation to health seeking behavior, there were significant differences between GERD symptoms and restricting diets, consumption of herbal medicine, using OTC drugs and visiting a physician. Caution should be taken when applying the data to countries in which medical care is available on a fee-for-service basis. Patients usually associate certain nutritional habits with the occurrence of reflux symptoms, and the avoidance of certain food is often cited as a therapeutic measure[1,7,8]. Nevertheless, the causal role of particular food in the etiology of GERD is still unclear. A family history of reflux symptoms was reported as a risk factor for GERD[36]. GERD in the sufferer's spouse or a direct family member was reported to be associated with the presence of GERD[19]. These results were identical to our data. In relation to BMI, although most studies have confirmed the association between BMI and GERD symptoms, the results to date have remained inconsistent. Risk factors for GERD in the West have been shown to include a high BMI[27]. Similar to our study, a cohort study from New Zealand, also found no association between BMI and reflux symptoms[37]. In contrast, the large population-based HUNT 2 study reported an association between BMI and reflux symptoms. Nocon *et al*[18] reported similar results while being overweight or obese was significantly associated with GERD symptoms. Hampel *et al*[38] also found a significant association between obesity and GERD symptoms. The association between obesity and the prevalence and severity of GERD was confirmed by several other authors[5,39].

Our study showed that halitosis, headaches, psychological distress, anxiety, nightmares and restlessnes were common in GERD subjects. The importance of psychological distress was also suggested by others[8,19,40]. Some population surveys conducted in western countries have suggested that patients with GERD have a higher level of stress and anxiety[14,40,41]. Wong *et al*[15] showed that psychological morbidity may play an important role in health care-seeking behavior, and co-existing depression and anxiety may act as a catalyst for a patient to seek medical care, rather than as a cause of symptoms. Lower levels of psychological well-being were observed in subjects with GERD[42]. The important strength of our study was its large sample of subjects in a healthy population, which is representative of the adult population in our country between the ages of 35-75 years.

In conclusion, the prevalence of GERD (15.4%) was significantly higher in females, rural and illiterate subjects. An inverse correlation was seen between GERD and consumption of fat and fiber intake. A correlation was noticed between GERD and pickle consumption, occurrence of headache, psychological distress, dyspepsia, halitosis, anxiety, nightmare and restlessness and a pervious family history of GERD. The association between GERD and aspirin was also significant. Future longitudinal studies and follow-ups are needed to clarify other possible risk factors and associations with GERD.

COMMENTS

Background

Symptoms of gastroesophageal reflux disease (GERD) represent one of the most frequent health problems in the western world. When compared with the general population, GERD patients have reported decrements in the health-related quality of life. Based on the population studied, the prevalence of the primary GERD symptoms, heartburn or acid regurgitation varies between 9% and 42%. The relationship between GERD and lifestyle habits, e.g. cigarette smoking, alcohol and coffee consumption, ingestion of medications such as aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), and diet has not been firmly established, and inconsistent results have been obtained by population-based studies.

Research frontiers

The study was performed to determine the relationship between GERD and demographic factors, lifestyle habits, family history, health-seeking behaviors and other GI symptoms. How GERD might affect quality of life awaits further studies.

Innovations and breakthroughs

Many other studies on GERD were conducted by telephone surveys or in the form of questionnaires. In our study, however, subjects were interviewed face-to-face by a team of trained interviewers using a questionnaire for which validity and reliability had been determined. Both rural and urban inhabitants participated in this study, making possible a comparison of these two populations in regards to GERD. In our population-based study, the prevalence of GERD was 15.4%, which is higher than that reported by some other studies in Iran. Obesity, consumption of spirits and smoking have been suggested as the most important lifestyle risk factors for GERD symptoms, but we found no association between reflux symptoms and consumption of spirits, smoking or BMI.

Applications

The findings of this study are helpful to both the clinicians in handling GERD patients and patients in primary and secondary healthcare.

Terminology

Heartburn is defined as a burning pain or discomfort behind the breast bone. Acid regurgitation is referred to liquid coming back into the mouth leaving a bitter or sour taste.GERD, in this study, is considered as heartburn and/or acid regurgitation occurring at least three times per week.

Peer review

This is an extensive cross sectional study performed in Iran and gives attention to the contributing factors and demographics of GERD in the country of the authors.

Abstract

AIM: To compare the prevalence of *H pylori* infection, peptic ulcer, cytomegalovirus (CMV) infection and Candida esophagitis in human immunodeficiency virus (HIV)-positive and HIV-negative patients, and evaluate the impact of CD4 lymphocyte on *H pylori* and opportunistic infections.

METHODS: A total of 151 patients (122 HIV-positive and 29 HIV-negative) with gastrointestinal symptoms were examined by upper endoscopy and biopsy. Samples were assessed to determine the prevalence of *H pylori* infection, CMV, candida esophagitis and histologic chronic gastritis.

RESULTS: The prevalence of *H pylori* was less common in HIV-positive patients (22.1%) than in HIV-negative controls (44.8%; $P < 0.05$), and the prevalence of *H pylori* displayed a direct correlation with CD4 count stratification in HIV-positive patients. In comparison with HIV-negative group, HIV-positive patients had a lower incidence of peptic ulcer (20.7% *vs* 4.1%; $P < 0.01$), but a higher prevalence of chronic atrophy gastritis (6.9% *vs* 24.6%; $P < 0.05$), Candida esophagitis and CMV infection. Unlike HIV-negative group, *H pylori* infection had a close relationship to chronic active gastritis ($P < 0.05$). In HIV-positive patients, chronic active gastritis was not significantly different between those with *H pylori* infection and those without.

CONCLUSION: The lower prevalence of *H pylori* infection and peptic ulcer in HIV-positive patients with gastrointestinal symptoms suggests a different mechanism of peptic ulcerogenesis and a different role of *H pylori* infection in chronic active gastritis and peptic ulcer. The pathogen of chronic active gastritis in HIV-positive patients may be different from the general population that is closely related to *H pylori* infection.

Key words: Human immunodeficiency virus; Endoscopy; Cytomegalovirus; Candida esophagitis; *H pylori*; Peptic ulcer; Chronic gastritis

INTRODUCTION

H pylori has been extensively studied and proven to be the main cause of chronic gastritis and peptic ulcer in the HIV-negative population[1,2]. The reported prevalence of *H pylori* in unselected populations ranges from 32% to 65%[3-6]. Over 90% patients with chronic active gastritis showed an evidence of *H pylori* infection[3,4,7], and 70%-100% of those patients had peptic ulcer disease[1,5,7].

In contrast, the prevalence of *H pylori* infection in patients infected with HIV has been reported to be remarkably low[8-11]. Reasons for these lower rates of *H pylori* infection remain unclear. Other studies showed that *H pylori* infection is similar in both HIV-positive and HIV-negative patients[12,13]. Patients infected with HIV, with or without acquired immune deficiency syndrome (AIDS), have a high incidence (50%-90%) of upper gastrointestinal symptoms[14]. The immune deficiencies caused by HIV give rise to many different gastrointestinal opportunistic infections, such as cytomegalovirus (CMV) infection and fungal esophagitis[15,16].

The aims of our study are to assess the prevalence of *H pylori* infection and the association with histological chronic active gastritis in HIV-positive patients with gastrointestinal symptoms. The impact of $CD4^+$ count on the prevalence of *H pylori*, gastric CMV infection and Candida esophagitis was also evaluated.

MATERIALS AND METHODS

Patients

The study was carried out at Beijing You'an Hospital,

Capital Medical University, Beijing, the largest referral center for management of HIV infection and HIV-related complications in China, from January 2003 to March 2006. Endoscopy was performed in 151 patients for gastrointestinal symptoms such as abdominal pain, dyspepsia, diarrhea, nausea, vomiting, gastrointestinal bleeding, and odynophagia or dysphagia.

The study groups consisted of 122 HIV-positive patients (49 males and 73 females; mean age 40.8 ± 7.9, range 26-60 years) and 29 age-matched HIV-negative patients (15 males and 14 females; mean age 49.5 ± 12.7, range 28-77 years) as control groups. The absolute $CD4^+$ lymphocyte count of HIV-positive patients at the time of endoscopic examination was measured with FACS Count Reagents (BD Company, USA). Patients all gave their consent before undergoing endoscopy, and the symptoms, consumption of medications within one month, including antibiotics, proton pump inhibitors were also recorded.

Endoscopy, diagnosis and histology

Video-endoscopes (Olympus XQ240, Tokyo, Japan) were used for the procedure. All patients underwent three biopsies from the lesser and greater curvature of the gastric antrum and lesser curvature of lower body, one for Rapid Urease Test (RUT) and two for histology. Additional biopsies were obtained from endoscopic lesions such as ulceration. The biopsy specimens were placed in 10% formaldehyde at the time of endoscopy and stained with hematoxylin-eosin, Warthin-Starry stains for histologic chronic gastritis and *H pylori* infection, and immunocytochemical techniques were performed for CMV infection (Monoclonal Mouse Anti-Human Cytomegalovirus, Dako). The *H pylori* infection was diagnosed by positive identification of both the organism on histology (Warthin-Starry) and RUT. The histologic gastritis was diagnosed according to the Sydney criteria[17]. Specimens were reviewed by only one pathologist who was blind to the status of those patients in present study.

The Candida esophagitis was diagnosed by sheathed brush cytology from endoscopic lesions, and gross appearance of mucosal presented with white plaques. Specimens obtained by sheathed brush should be smeared onto slides for fungi.

Statistical analysis

Chi-square test or Fisher exact probability tests were used to compare the prevalence of *H pylori*, CMV infection, Candida esophagitis, and peptic ulcer between HIV-positive patients, control groups, and HIV-infected patients with higher and lower $CD4^+$ counts and the use of antibiotics and proton pump inhibitors. Independent sample *t* test was used to compare the age and sex between the HIV-positive and control groups. A value of $P < 0.05$ was regarded as statistically significant.

RESULTS

The patient data and the prevalence of *H pylori* and endoscopic findings in HIV-positive patients and HIV-negative patients are shown in Table 1. The gastrointestinal symptoms of HIV-positive patients were mostly nonspecific, such as diarrhea, dyspepsia, abdominal pain, nausea, vomiting, and odynophagia or dysphagia. Only the occurrence of symptoms of diarrhea, odynophagia, and dysphagia in HIV-positive patients was significantly higher than that of control group ($P < 0.05$). The prevalence of *H pylori* infection was significantly lower in the HIV-positive group than that of HIV-negative control group (27/122; 22.1% *vs* 13/29; 44.8%, $P < 0.05$). Endoscopic examination revealed more patients with peptic ulcer in HIV-negative group than in HIV-positive group (6/29; 20.7% *vs* 5/122; 4.1%, $P < 0.01$). More histologic chronic atrophy gastritis was found in HIV-positive patients than in HIV-negative group (30/122; 24.6% *vs* 2/29; 6.9%, $P < 0.05$). Opportunistic infection by CMV was noted in 4.9% (6/122) HIV-positive patients but none in the HIV-negative group ($P = 0.49$). The incidence of Candida esophagitis in HIV-positive patients (19/122; 15.6%) was significantly higher than that of HIV-negative patients ($P < 0.05$).

H pylori infection was less common in those with $CD4^+$ counts < 200/μL than those with $CD4^+$ counts > 200/μL in HIV-positive patients (8/57; 14.0% *vs* 19/65; 29.2%, $P < 0.05$). Interestingly, the prevalence of *H Pylori* infection displayed a direct correlation with the $CD4^+$ lymphocyte count stratification in HIV-positive patients (Table 2). The Candida esophagitis was significantly more common in

CMV infection	1 (1.5)	5 (8.8)	0.155

Table 4 Relationship of chronic active gastritis to *H pylori* infection

	HIV-positive group (*n* = 122)		HIV-negative group (*n* = 29)	
	H pylori $^+$ (*n* = 27)	*H pylori* $^-$ (*n* = 95)	*H pylori* $^+$ (*n* = 13)	*H pylori* $^-$ (*n* = 16)
Chronic active gastritis, *n* (%)	8 (29.6)	16 (16.8)	8 (61.5)	1 (6.3)
P	0.140		0.005	

HIV-positive patients with $CD4^+$ count < 200/μL than those with $CD4^+$ count > 200/μL (15/57; 26.3% *vs* 4/65; 6.2%, $P < 0.01$), and the average $CD4^+$ counts of patients with Candida esophagitis was 116.47 ± 133.08/μL. The CMV infection was more common in HIV-positive patients with $CD4^+$ count < 200/μL than those with $CD4^+$ count > 200/μL , but it was not statistically significant (5/57; 8.8% *vs* 1/65; 1.5%, $P = 0.155$) (Table 3).

Histological examination revealed less chronic active gastritis in HIV-positive patients than in HIV-negative control group (24/122; 19.7% *vs* 9/29; 31%, *P* = NS), but the difference was not statistically significant. The relationship of *H pylori* infection with chronic active gastritis was evaluated in HIV-positive and HIV-negative patients (Table 4). In HIV-negative group, the incidence of chronic active gastritis was significantly higher in those with *H pylori* infection (61.5%) than those without (6.3%; $P < 0.01$). In HIV-positive group, the rate of chronic active gastritis was not significantly different between those with *H pylori* infection (29.6%) and those without (16.8%; $P = 0.14$).

The relationship in *H pylori* and CMV infection and peptic ulcer was evaluated between the two groups of patients. Peptic ulcer was detected in five HIV-positive patients, one of whom (20%) was positive for *H pylori* infection and one (20%) for CMV infection. In HIV-negative group, six patients were diagnosed as having peptic ulcer, four (67%) as *H pylori* infection and none as CMV infection.

The previous use of antibiotics and proton pump inhibitor was also evaluated between HIV-positive and HIV-negative patients (47/122; 38.5% *vs* 3/29; 10.3%, $P < 0.01$ and 3/122; 2.5% *vs* 4/29; 13.8%, $P < 0.05$, respectively) (Table 1). If $CD4^+$ count was taken into consideration, the use of all kinds of antibiotics in HIV-positive patients with $CD4^+$ counts < 100/μL was not significantly different in those with $CD4^+$ counts > 100/μL (18/37; 48.6% *vs* 29/85; 34.1%, $P = 0.13$) (Table 3). Those antibiotics mainly included Sulfonamides, penicillins and quinolones. None of the patients took NSAIDs, aspirin or steroid before endoscopic examination.

The HIV-positive patients in this study were usually concomitant with HCV and/or HBV infection which was more significantly frequent than in HIV-negative patients (102/122; 83.6% *vs* 2/29; 6.9%, $P < 0.01$). Nine patients with esophagogastric varices (7.4%) and 3 patients with portal hypertensive gastropathy (2.5%) in HIV-positive group were also found by endoscopic examination.

DISCUSSION

In the present study, we found that the majority of gastrointestinal symptoms of HIV-positive patients at our hospital were similar to that of HIV-negative group. In comparison with HIV-negative group, the symptoms of diarrhea, odynophagia, and dysphagia were significantly more in HIV-positive patients ($P < 0.05$). Several previous studies[16,18-19] revealed that more than 71% of AIDS patients who present with dysphagia and odynophagia have endoscopic evidence of esophageal candidiasis. Our result showed a high infection rate of Candida esophagitis in HIV-positive patients (19/122; 15.6%), which may be a possible explanation. Studies showed that the incidence of Cryptosporidium infection has been estimated to be 16%-33% in the AIDS patients in north America with chronic diarrhea[20,21]. In developing countries, the infection of Cryptosporidium was 55% among AIDS patients[22]. The etiological factor of diarrhea in HIV-positive patients in our study was not evaluated.

The prevalence of *H pylori* infection in HIV-positive patients at our hospital was significantly lower than that in HIV-negative control group. Our results were in agreement with some previous reports[8-11]. The reason of lower prevalence of *H pylori* infection may be lack of $CD4^+$ cells, use of antibiotics and proton pump inhibitor, decreased acid secretion, or competitive inhibition by other pathogens in HIV-positive patients.

According to previous reports, $CD4^+$ lymphocytes were reported to be involved[23-25] in the pathogenesis of *H pylori*-related gastritis or ulcer. It is well known that $CD4^+$ cells play a role in inducing gastritis and this gastritis might be a mechanism by which *H pylori* colonization is enhanced[26]. Patients with HIV infection and a low $CD4^+$ count would then lose this mechanism by which *H pylori* colonization is sustained, and infection intensity would diminish. In addition, the T-cell response to the organism could serve to induce tissue and epithelial damage. In AIDS patients, the decreased T-cell would induce a decreased incidence of *H pylori* gastritis[27]. In our results, a stratification of cases on the basis of $CD4^+$ count has shown a decrease of *H pylori* infection with the progression of HIV-related disease, and histological examination revealed less chronic active gastritis in HIV-positive patients than in HIV-negative control group (19.7% *vs* 31%). *H pylori* infection was closely related to chronic active gastritis in HIV-negative group ($P < 0.05$), but not in HIV-positive patients, indicating that other pathogens might exist , such as CMV and Cryptosporidium infection.

An impairment of *H pylori* colonization environment

might result from a progressive atrophic involution of the gastric mucosa with secondary decreased acid secretion in HIV-positive patients, which represents an altered intragastric environment[28,29]. In our results, histologic chronic atrophy gastritis in HIV-positive patients was significantly higher than in HIV-negative group (30/122; 24.6% *vs* 2/29; 6.9%, $P < 0.05$), which might be result of gastric secretory failure in HIV infection patients. The impaired acid secretion may allow subsequent gastric bacterial overgrowth and provide a less suitable environment or competitive inhibition for *H pylori* colonization.

An altered intragastric environment might also result from frequent use of antibiotics against apportunistic infections in patients at an advanced stage of HIV infection[30]. In comparison with HIV-negative group, HIV-positive group had a more frequent use of antibiotics. In HIV-positive patients, previous use of antibiotics with $CD4^+$ counts < 100/μL was not significantly different from that of $CD4^+$ counts > 100/μL ($P = 0.13$), but the prevalence of *H pylori* infection showed significant difference. In our patients, the antibiotics most frequently used was trimetoprim-sulfa, usually for treatment or prophylaxis against pneumocystis in HIV-positive patients, and monotherapy of antibiotics has been proven to inhibit rather than eradicate *H pylori*[31]. Therefore, current prophylaxis has been excluded from evaluation of eradicating the microorganism. Previous use of proton pump inhibitors might alter intragastric environment and therefore influence the prevalence of *H pylori* infection. In the present study, the HIV-negative control group took proton pump inhibitors more frequently than HIV-positive group (13.8% *vs* 2.5%, $P < 0.05$), which further proved the lower prevalence of *H pylori* infection in HIV-positive patients.

In this study, all 122 HIV-positive patients with gastrointestinal symptoms, only 4.1% had peptic ulcer, but 20.7% in HIV-negative group. This might explain that the low prevalence of *H pylori* infection result in the lower incidence of ulcers among HIV-positive patients. On the other hand, decreased acid secretion in HIV-positive patients plays a role in the lower incidence of peptic ulcer. According to previous reports, CMV-associated peptic ulcer disease was highly prevalent and CMV was the only organism significantly associated with gastroduodenal ulcers in HIV-positive patients, and *H pylori* was an uncommon cause of peptic ulcer[11,32]. In our study, among the 5 patients with peptic ulcer in HIV-positive group, only one proved to have CMV infection, which was lower according to previous studies[11,32]. The inadequate biopsies in the present study may be a possible explanation. According to literature, histological changes of CMV infection are patchy in distribution, however, and the single biopsy sensitivity for ulcerative lesions has been reported to be as low as 13%. Therefore, at least 8-10 biopsies of suspicious lesions are recommended[33].

Candida esophagitis is one of the most common opportunistic infections in patients with AIDS[34]. Our study showed that the Candida esophagitis was significantly higher in HIV-positive patients with $CD4^+$ count below 200/μL, and the average $CD4^+$ counts with Candida esophagitis was 116.47 ± 133.08/μL. According to previous studies, the CMV infection is also a common opportunistic pathogen in HIV-positive patients with a low $CD4^+$ count and is one of the main causes of gastrointestinal ulcer in AIDS patients[11,33]. The incidence of CMV infection in HIV-positive patients (4.9%) in our study was lower than previous reports[32]. The incorrect location of biopsy may be another possible reason. According to literature review, gastric CMV infections are usually seen in the fundus with contiguous involvement of the esophagus and gastroesophageal junction, and the distal stomach and antrum are less commonly involved[35,36]. In the present study, the biopsy specimens were usually obtained from gastric antrum and lower body, therefore might lower the incidence of CMV infection in our patients.

The HIV-positive patients in the present study, mainly from Henan Province of China, infected through illegal blood plasma collection, and usually coinfected with HCV and/or HBV infection (83.6%). Endoscopic examination also revealed findings such as esophagogastric varices and portal hypertensive gastropathy, which were significantly different from previous reports.

In summary, we have found that a lower prevalence of *H pylori* infection and peptic ulcer in HIV-positive patients with gastrointestinal symptoms than that of HIV-negative patients with similar symptoms. The mechanism of chronic active gastritis in HIV-positive patients may be different from HIV-negative group that was closely related to *H pylori* infection. Various opportunistic infections (especially Candida esophagitis) of upper gastrointestinal tract likely occur in HIV-positive patients with a $CD4^+$ count less than 200/μL.

COMMENTS

Background

Helicobacter pylori has been proven to be the main cause of chronic gastritis and peptic ulcer in the HIV-negative population. The role and prevalence of *H pylori* infection might be different in the HIV infected patients.

Research frontiers

The immune deficiencies caused by HIV give rise to many different gastrointestinal opportunistic infections, and the prevalence of *H pylori* infection in patients infected with HIV is remarkably low.

Innovations and breakthroughs

It is the first report to characterize the prevalence and role of *H pylori* infection in chronic active gastritis and peptic ulcer in HIV-positive patients infected through illegal blood plasma collection in China, who are usually coinfected with HCV and/or HBV. The pathogen of chronic active gastritis in HIV-positive patients may be different from the general population that was closely related to *H pylori* infection.

Applications

This observation might be of potential value in HIV-positive patients with gastrointestinal symptoms.

Peer review

The authors compared the prevalence of *H pylori* infection, peptic ulcer, cytomegalovirus (CMV) infection and Candida esophagitis in human immunodeficiency virus(HIV)-positive and HIV-negative patients. The lower prevalence of *H pylori* infection and peptic ulcer in HIV-positive patients with gastrointestinal symptoms suggests a different mechanism of peptic ulcerogenesis and a different role of *H pylori* infection in chronic active gastritis and peptic ulcer.

Abstract

AIM: To explore the effects of *H pylori* infection on gap-junctional intercellular communication (GJIC) and proliferation of gastric epithelial cells *in vitro*.

METHODS: A human gastric epithelial cell line (SGC-7901) cultured on coverslips was exposed overnight to intact *H pylori* ($CagA^+$ or $CagA^-$ strains) and sonicated extracts, respectively. GJIC between the cells was detected by fluorescence redistribution after photobleaching (FRAP) technique. Proliferation of SGC cells was determined by methylthiazolyl tetrazolium (MTT) assay.

RESULTS: When compared with control in which cells were cultured with simple medium alone, both $CagA^+$ and $CagA^-$ *H pylori* isolates could inhibit GJIC ($CagA^+$: $F = 57.98$, $P < 0.01$; $CagA^-$: $F = 29.59$, $P < 0.01$) and proliferation ($CagA^+$: $F = 42.65$, $P < 0.01$; $CagA^-$: $F = 58.14$, $P < 0.01$) of SGC-7901 cells. Compared with $CagA^-$ strains, $CagA^+$ *H pylori* more significantly down-regulated GJIC of gastric cells (intact *H pylori*: $t = 13.86$, $P < 0.01$; sonicated extracts: $t = 11.87$, $P < 0.01$) and inhibited proliferation gastric cells to a lesser extent *in vitro* (intact *H pylori*: $t = 3.06$, $P < 0.05$; sonicated extracts: $t = 3.94$, $P < 0.01$).

CONCLUSION: Compared with $CagA^-$ *H pylori* strains, $CagA^+$ strains down-regulate GJIC of gastric epithelial cells more significantly and inhibit proliferation of gastric cells to a lesser extent *in vitro*. *H pylori*, especially $CagA^+$ strains, may play an important role in gastric carcinogenesis.

INTRODUCTION

Epidemiological and animal studies have demonstrated a strong causal relationship between gastric cancer and chronic infection with *H pylori,* especially cytotoxin-associated gene A (*cagA*)-positive strains[1,2]. The cagA gene product CagA is directly delivered into gastric epithelial cells *via* type Ⅳ secretion system. Following membrane localization and subsequent tyrosine phosphorylation, CagA interacts with a variety of host cell proteins that are involved in the regulation of cell growth and motility[3]. However, the exact mechanism responsible for the development of gastric cancer in *H pylori*-infected patients still remains unclear.

Gap-junctional intercellular communication (GJIC) is an important mechanism controlling cellular homeostasis, proliferation and differentiation. Inhibition of GJIC between adjacent cells has been postulated to be one of the important events occurring during the promotional stage of cancer[4]. The vast majority of neoplastic cells reduce GJIC compared to their nonneoplastic counterparts[5]. A number of tumor promoters, such as 12-O-tetradecanoylphorbol-13-acetate (TPA), have been known as potent inhibitors of GJIC[6].

So far, changes of GJIC in *H pylori*-associated gastric carcinoma have not been extensively exploited. In the present study, we attempted to explore the molecular mechanisms of *H pylori* infection in gastric carcinogenesis by studying its effects on GJIC of gastric epithelial cells *in vitro*.

MATERIALS AND METHODS

H pylori strains

H pylori strains 97002 and 97004 were identified by and stored in Department of Medical Microbiology and

[b]$P < 0.01$ one-way ANOVA *vs* negative control, [a]$P < 0.05$ ANOVA/Dunnett *vs* negative control, [d]$P < 0.01$ *vs* *t*-test of CagA$^+$ and CagA$^-$ *H pylori* strains.

Parasitology, Zhejiang University School of Medicine. The genotypes of vacuolating cytotoxin gene A (*vacA*) of the strains 97002 and 97004 were s1a/m1 and m2, respectively. The results of Western blot and cell vacuolation test demonstrated that the strain 97002 was CagA$^+$/VacA$^+$ and 97004 CagA$^-$/VacA$^-$.

H pylori culture

H pylori strains were cultured on ECY blood-free medium[7] at 37℃ for 5 d, under 100% humidity and microaerophilic conditions (50 mL/L O_2, 100 mL/L CO_2, and 850 mL/L N_2). The bacteria were harvested from the agar plates, washed twice with 0.01 mol/L PBS and stored at -20℃.

Preparation of intact H pylori and sonicated extract samples

The frozen bacteria were dissolved in RPMI1640 culture medium and adjusted to 1×10^{10} CFU/L in intact bacterial samples and 1×10^{12} CFU/L in sonicated extract samples, respectively. The preparation of sonicated extract samples additionally included *H pylori* pulverization with ultrasound, centrifugation at 10000 r/min for 20 min with the supernatant collected.

Cell culture

Human gastric epithelial cell line SGC-7901 was obtained from Department of Medical Microbiology and Parasitology, Zhejiang University School of Medicine and cultured in RPMI1640 medium (Gibco, USA) supplemented with 10% fetal bovine serum (FBS) (Sijiqing, China), 1×10^5 IU/L penicillin and 100 mg/L streptomycin. The cells were incubated at 37℃ in a humidified atmosphere containing 950 mL/L air and 50 mL/L CO_2. The cells were grown on 22 mm × 22 mm coverslips in tissue culture dishes (35 mm in diameter) and the culture medium was changed every other day. To determine cell proliferation, SGC-7901 cells were plated into 96-well microplates (0.5×10^5 cells/well) and cultured for 12 h.

Cell treatment with H pylori extracts

Twenty-four hours prior to GJIC measurement, cells of the test groups were treated overnight with intact *H pylori* or sonicated extracts. Negative and positive controls were treated with RPMI1640 with 2% NBS and 5 μg/L TPA was added to the positive control during the last 1 h.

Measurement of GJIC by FRAP technique

GJIC between SGC-7901 cells was measured by fluorescence redistribution after photobleaching (FRAP) technique first described in 1986[8]. 6-carboxyfluorescein diacetate (6-CFDA) was used as the dye that could be retained inside the cells due to its hydrolysis by cytoplamic esterases into 6-carboxyfluorescein (6-CF). 6-CF could permeate gap junction channels due to its low molecular weight. FRAP was achieved under a confocal laser scanning microscope (Leica TCS-SP, Germany) and the detailed protocol was performed as previously described[9].

Determination of cell proliferation by MTT assay

When SGC-7901 cells confluenced by 70% in the 96-well microplates, cell proliferation was assessed by methylthiazolyl tetrazolium (MTT) assay as previously described[10]. The absorbance value per well at 570 nm was read on an automatic multiwell spectrophotometer (Bio-Rad, USA).

Statistical analysis

All data were presented as mean ± SE. Statistical analysis was carried out by ANOVA followed by Dunnett's *t*-test. $P < 0.05$ was considered statistically significant.

RESULTS

H pylori down-regulated GJIC of SGC-7901 cells

The GJIC of SGC-7901 cells was measured by FRAP after treated with intact *H pylori* or sonicated extracts for 24 h and presented as fluorescence transfer rate (K, 10^{-3}/s) (Table 1). In the present study, both CagA$^+$ and CagA$^-$ *H pylori* isolates including intact *H pylori* and sonicated extracts down-regulated GJIC of SGC-7901 cells (CagA$^+$: $F = 57.98$, $P < 0.01$; CagA$^-$: $F = 29.59$, $P < 0.01$). Compared with CagA$^-$ strains, CagA$^+$ *H pylori* more significantly down-regulated GJIC of gastric cells (intact *H pylori*: $t = 13.86$, $P < 0.01$; sonicated extracts: $t = 11.87$, $P < 0.01$). In addition, our study demonstrated that TPA (5 μg/L for 1 h) had a significant inhibitory effect on GJIC of gastric cells.

Effect of H pylori on cell proliferation

The effects of intact *H pylori* and sonicated extracts on the proliferation of SGC-7901 cells were evaluated by MTT assay ($A_{570\ nm}$) (Table 2). The results suggest that both CagA$^+$ and CagA$^-$ *H pylori* isolates inhibited proliferation of SGC-7901 cells (CagA$^+$: $F = 42.65$, $P < 0.01$; CagA$^-$: $F = 58.14$, $P < 0.01$). However, CagA$^+$ *H pylori* strain inhibited proliferation of gastric cells to a lesser extent when compared with CagA$^-$ strain (intact *H pylori*: $t = 3.06$, $P < 0.05$; sonicated extracts: $t = 3.94$, $P < 0.01$).

DISCUSSION

Among various forms of intercellular communication systems in multicellular organisms, GJIC is the only form by which cells exchange signals directly from the inside of one cell to the neighboring cells. GJIC plays a crucial role in maintaining homeostasis by keeping growth control signals at equilibrium among GJIC-connected cells[11,12]. Most tumor cells have a reduced ability to communicate among themselves and/or with surrounding normal cells, confirming the importance of functional GJIC in growth control[13-15]. GJIC is mediated by gap junction channels composed of tetramembrane spanning proteins, known as connexins. At least 13 subtypes of connexin have been identified and four or five subtypes are detectable in the gastrointestinal tract[16].

It has been reported that connexin 32 in normal gastric mucosa is reduced significantly or absent in atrophic gastric mucosa and metaplastic epithelial cells, and no malignant cells from patients with gastric carcinoma contain detectable connexin 32[17,18]. These results suggest that loss of cell-cell communication through the gap junction may act as an early indicator of gastric carcinoma.

In this study, the effects of *H pylori* infection on GJIC of gastric epithelial cells were detected *in vitro*, suppressing interferences of various cytokines and immune factors *in vivo*, suggesting that both $CagA^+$ and $CagA^-$ *H pylori* isolates inhibit GJIC of SGC-7901 cells and the down-regulating effect of $CagA^+$ *H pylori* is more significant than that of $CagA^-$ strains. These findings emphasize the close relationship between *H pylori* especially $CagA^+$ strains and gastric carcinoma.

Increased cellular proliferation rates are characteristic in malignant tissue. Because of unstability of the genome of proliferating cells, hyperproliferation increases the possibility of DNA damage and aneupoidy. Dysplasia may evolve into carcinoma if damaged DNA cannot be repaired on time or fails in promoting the apoptosis system[19]. *H pylori* infection of the gastric mucosa is closely associated with changes in gastric epithelial cell proliferation. *In vivo* data show that gastric epithelial hyperproliferation is common in *H pylori*-infected persons and the degree of proliferation is directly associated with the severity of mucosal neutrophilic infiltration[20-22]. However, it was reported that an overall increase in gastric epithelial cell proliferation is not associated with *H pylori* gastritis[23]. It is not very clear whether the increased proliferation seen *in vivo* is a direct effect of *H pylori*, or a reflex increase in proliferation in response to increased cell damage, indirectly caused by *H pylori*. A recent report by Cabral *et al*[24] suggested that the increased cell proliferation rate in patients with *H pylori* infection might be related to the *H pylori*-induced inflammation rather than to a direct action of the pathogen.

Several *in vitro* studies reported that *H pylori* can inhibit cell proliferation[25,26] , which is consistent with the results of this study. The possible reason for the contradiction between the findings *in vivo* and *in vitro* is that *in vivo* studies are representative of the effect of persistent *H pylori* infection whereas *in vitro* experimental studies are representative of an acute *H pylori*-mediated effect. Also, the increased cell proliferation in patients with *H pylori* infection might be due to the increased production of gastrin *in vivo*[25]. Moreover, *in vivo* increased epithelial cell injury is associated with a reflex increase in proliferation of uninjured cells, which would not be seen *in vitro* as each cultured gastric cell is in contact with bacteria[27]. Cell proliferation is an essential process for the integrity of gastric mucosa. Deceasing cell turnover may increase the chances of ulcer formation and delay ulcer healing. Therefore, our findings seem to be relevant to the pathogenesis of *H pylori*-associated peptic ulcer diseases.

$CagA^+$ *H pylori* is frequently isolated from patients with gastric cancer in Western countries and may be more virulent in its pathogenesis[28,29]. *In vivo* studies reported that infection with $CagA^+$ *H pylori* strains is linked with higher acute inflammatory scores than $CagA^-$ strains[30,31], suggesting that these strains preferentially induce epithelial cell proliferation by stimulating inflammatory mediators. Our results show that $CagA^+$ strains could inhibit proliferation of gastric epithelial cells to a lesser extent than $CagA^-$ ones. Thus gastric cells injured by exposure to $CagA^+$ *H pylori* strains may be more likely to progress through the cell cycle, which possibly results in the risk of replication of cells with DNA damage[27].

In conclusion, *H pylori* can directly inhibit GJIC and proliferation of gastric epithelial cells *in vitro*. Compared with $CagA^-$ *H pylori* strains, $CagA^+$ strains more significantly down-regulate GJIC and inhibit proliferation to a of gastric epithelial cells lesser extent. Accelerated proliferation increases the risk of DNA damage and gene mutation. Inhibited GJIC makes cancer-initiated cells escape from the control of neighboring cells. *H pylori*, especially $CagA^+$ strains, may play an important role in gastric carcinogenesis.

COMMENTS

Background

It has been widely accepted that there is a strong association between *H pylori* infection and gastric cancer, but the exact molecular mechanism of the pathogen in gastric carcinogenesis has not clarified yet. Nearly 40 years ago, loss of functional gap junctions was described in cancer cells and led to the hypothesis that such a type of intercellular communication is involved in the carcinogenesis process. Since then, a lot of data have been accumulated confirming that gap junctions are frequently decreased or absent in cancer cells. Gap junction deficiency has been defined in the literature either as the lack of gap-junction plaques or as the lack of gap-junctional intercellular communication (GJIC). It has been reported that connexin 32 in normal gastric mucosa as a mediator of GJIC is reduced significantly or absent in atrophic gastric mucosa and metaplastic epithelial cells. However, these reports have not revealed the relationship between changed GJIC and *H pylori* infection of the gastric mucosa.

Research frontiers

There has been a considerable interest over recent years in factors that predispose individuals to develop gastric carcinoma. Complex interactions between several *H pylori*, host genetics and environmental factors determine this predisposition. Understanding the molecular mechanism of the interaction between *H pylori* and gastric epithelial cells will provide us with a new strategy for effective prevention of the development of gastric cancer induced by *H pylori* infection.

Innovations and breakthroughs

In this article, the molecular mechanism of *H pylori* infection in gastric carcinogenesis was explored by studying its effects on GJIC of gastric epithelial cells *in vitro*. The results suggest that *H pylori* could inhibit GJIC of cultured gastric epithelial cells and the down-regulation effect on GJIC of $CagA^+$ strains was more significant than $CagA^-$ ones.

Applications

This article emphasizes the close relationship between *H pylori* especially $CagA^+$ strains and gastric carcinoma. It provides a new direction to illuminate the molecular mechanism of *H pylori* in gastric carcinogenesis. It also implies that compounds able to restore GJIC in junctional deficient cells or prevent its disruption in junctional proficient cells may be used in making new strategies for the prevention and/or treatment of human gastric malignancies.

Terminology

Gap junctions: membrane structures made of intercellular channels which permit the diffusion of small hydrophilic molecules from cytoplasm to cytoplasm.

Peer review

The paper seems innovative. Altered expressions of connexins have been observed in various pathological processes of the digestive tract, including gastric cancer. To our knowledge, it is the first study to explore the molecular mechanism of *H pylori* infection in gastric carcinogenesis by studying its effects on GJIC of gastric epithelial cells *in vitro*.

Abstract

AIM: To investigate the regulation of activin receptor-interacting protein 2 (ARIP2) expression and its possible relationships with collagen type Ⅳ (collagen Ⅳ) in mouse hepatoma cell line Hepal-6 cells.

METHODS: The ARIP2 mRNA expression kinetics in Hepal-6 cells was detected by RT-PCR, and its regulation factors were analyzed by treatment with signal transduction activators such as phorbol 12-myristate 13-acetate (PMA), forskolin and A23187. After pcDNA3-ARIP2 was transfected into Hepal-6 cells, the effects of ARIP2 overexpression on activin type Ⅱ receptor (ActRⅡ) and collagen Ⅳ expression were evaluated.

RESULTS: The expression levels of ARIP2 mRNA in Hapel-6 cells were elevated in time-dependent manner 12 h after treatment with activin A and endotoxin LPS, but not changed evidently in the early stage of stimulation (2 or 4 h). The ARIP2 mRNA expression was increased after stimulated with signal transduction activators such as PMA and forskolin in Hepal-6 cells, whereas decreased after treatment with A23187 (25.3% ± 5.7% *vs* 48.1% ± 3.6%, $P < 0.01$). ARIP2 overexpression could remarkably suppress the expression of ActRIIA mRNA in dose-dependent manner, but has no effect on ActRⅡB in Hepal-6 cells induced by activin A. Furthermore, we have found that overexpression of ARIP2 could inhibit collagen Ⅳ mRNA and protein expressions induced by activin A in Hapel-6 cells.

CONCLUSION: These findings suggest that ARIP2 expression can be influenced by various factors. ARIP2 may participate in the negative feedback regulation of signal transduction in the late stage by affecting the expression of ActRIIA and play an important role in regulation of development of liver fibrosis induced by activin.

INTRODUCTION

Activin is a multifunctional growth and differentiation factor of transforming growth factor-beta (TGF-β) superfamily[1,2]. As an important regulator, activin is involved in the acute phase response of inflammatory diseases and tissue repair, and also play an important role in inducing liver fibrosis[3-5]. The actions of activin on target cells are tissue-specific, which associate with the difference of activin receptor signal transduction. It has been found that the tissue-specificity might depend on a new group of intracellular signal proteins, activin receptor-interacting proteins (ARIPs)[6-8]. ARIPs have four forms at least, all of which can specifically interact with activin type Ⅱ receptor (ActRII) and regulate intracellular signal transduction induced by activin[6-10]. It has been demonstrated that not only the expression and distribution but also the biological activities of ARIPs were obviously different in various tissues. ARIP2 can enhance ActRII endocytosis and reduce ActRIIA receptor expression on cell membranes *via* Ral/RalBP1-depending pathway, and has a capability of suppressing activin-induced signal transduction. There was high expression of ARIP2 mRNA in liver tissues tested by Northern blot[7]. Therefore, we reason out that ARIP2 may participate in the functional regulation of hepatocytes treated by activin.

Since ARIP2 has only been recently discovered, the mode of expression regulation and function of it have not been well characterized. In this study, we have explored

regulation of ARIP2 expression and its effects on the expression of collagen type Ⅳ (collagen Ⅳ) which is component of extracellular matrix (ECM), using mouse Hepal-6 cells, which were obtained from mouse hepatoma cell line and had functions of hepatic parenchymal cells[11].

MATERIALS AND METHODS

Materials

Lipopolysaccharide (LPS, from E.coli 0111:B4), A23187, phorbol 12-myristate 13-acetate (PMA) and forskolin were obtained from Sigma. AMV Reverse Transcriptase was purchased from Promega. ExTaq was obtained from Takara Biotechnology Co (Kyoto, Japan). Dulbecco's modified Eagle's medium (DMEM) was purchased from GIBCO. Trizol reagent was obtained from Invitrogen. Activin A was provided by Dr. Eto T (Ajinomoto Central Research Laboratories, Japan).

Cell culture

Hepa1-6 cells from mouse hepatoma cell line were provided by Shanghai Cell Bank of Chinese Academy of Sciences (Shanghai, China) and were maintained in DMEM medium supplemented with 10% fetal calf serum (FCS) at 37℃ in a 5% CO_2 humidified incubator.

Plasmid construction

The vector construction has been described previously[8]. The set of primers was designed as follows. The sense primer was 5'-GGAATTCATGAACGGACGGGTGGATTA-3', which introduced an *EcoR* I site, and the anti-sense primer 5'-GCTCGAGTCATTGTCTGCACAATAAACA-3', which introduced an *Xhol* I site. cDNA fragments encoding full-length ARIP2 (1-153 amino acid residues) were amplified by PCR. The amplified cDNA fragments were inserted into plasmid pMD18-T, and were then subcloned into eukaryotic expression vector pcDNA3. The reconstructed plasmid was named as pcDNA3-ARIP2.

Detection of ARIP2 mRNA expression in Hepal-6 cells stimulated by activin A and LPS

Hepal-6 cells were plated into 12-well tissue culture plates at a density of 2×10^5 cells/mL and incubated in 10% FCS-DMEM at 37℃, 5% CO_2 over night. The cells were cultured in 2% FCS-DMEM in the presence or absence of activin A (5 ng/mL) and LPS (2.5 μg/mL), respectively. After 2, 4, 8, 12 and 24 h, the cells were harvested respectively and total RNA was extracted by using the TRIzol reagent according to the manufacturer's protocol (Invitrogen). The mRNA expression of ARIP2 was examined by RT-PCR, and GAPDH was considered as inner control. PCR was performed for 30 cycles. Amplified PCR products were subjected to 1.5% agarose gel electrophoresis, and stained with ethidium bromide for detection. Specific bands were analyzed using ImageMaster VDS (Pharmacia Biotech Company, Sweden). The primer sequences were shown at Table 1.

Assay of the effects of signal transduction kinetins on the expression of ARIP2 mRNA

To further study the regulation elements of ARIP2 expression, the Hepal-6 cells plated into 12-well tissue culture plates were cultured in 2% FCS-DMEM in the presence or absence of activin A (5 ng/mL), A23187 (200 nmol/L), PMA (20 nmol/L), forskolin (50 μmol/L) and LPS (2.5 μg/mL), respectively. After 24 h, the cells were harvested respectively and total RNA was extracted by using the TRIzol reagent. The expression of ARIP2 mRNA was examined by RT-PCR.

Overexpression of ARIP2 in Hepa1-6 cells

To determine possible bioactivity of ARIP2, effects of ARIP2 on the mRNA expressions of ActRIIA, ActRIIB and collagen type Ⅳ were analyzed by RT-PCR. The Hepal-6 cells were washed once with serum-free DMEM, and were then transfected with pcDNA3-ARIP2 (0.1, 0.3 μg) and pcDNA3 (0.3 μg) by using Lipofectamine 2000 reagent according to the manufacturer's protocol (Invitrogen), respectively. The transfected cells were incubated in the presence or absence of activin A (5 ng/mL) overnight. The cultured cells were harvested and total RNA was extracted by using the TRIzol reagent. RT-PCR was performed for detecting ActRIIA, ActRIIB and type Ⅳ collagen mRNA expressions. The primer sequences were shown at Table 1.

Flow cytometry for type Ⅳ collagen protein expression

Hepal-6 cells were collected 24 h after transfected with pcDNA3-ARIP2. The expression of type Ⅳ collagen proteins were assessed by flow cytometry (FACSort Vantage; BD, Franklin Lakes, NJ) using anti-mouse type Ⅳ collagen antibodies. The data were collected and analyzed on computer (Cell Quest software; BD Biosciences), to assess the percentage of positive fluorescence cells. A representative experiment of the two performed was shown.

RESULTS

Kinetics of ARIP2 mRNA expression in Hepa1-6 cells stimulated by activin A and LPS

As a regulation protein of activin signal pathway, the expression of ARIP2 mRNA could be increased by stimulation with activin A. In this study, the levels of ARIP2 mRNA expression were time-dependently up-regulated 12 h after treatment with activin A in Hepal-6 cells, but not obviously changed at 2-4 h after being treated with activin A. Endotoxin LPS as inflammatory factor can bind with Toll-like receptor 4 on hepatocytes. We found that ARIP2 mRNA expression in Hepal-6 cells was remarkably promoted by LPS treatment, and the expression levels were time-dependently up-regulated 12 h after treatment with LPS in Hepal-6 cells (Figure 1). These data suggested that the expression of ARIP2 was increased in the late stage of activin A and LPS treatment, and ARIP2 might participate in the negative regulation of the late stage signal transduction in Hepal-6 cells.

The signal transduction kinetins regulated the expression of ARIP2 mRNA

PMA is the activator of protein kinase C (PKC)[12], A23187 is the calcium ion vector[13], forskolin is the kinetin of cAMP-dependent protein kinase A (PKA)[14]

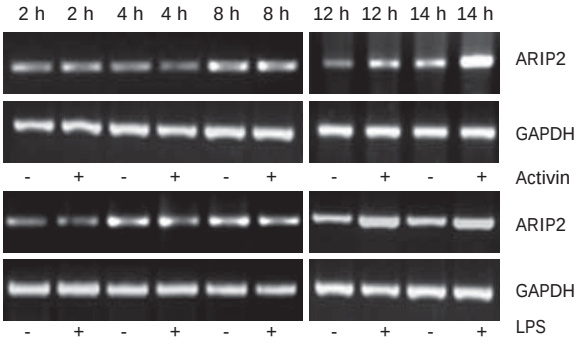

Figure 1 Expressions of ARIP2 mRNA in Hepal-6 cells stimulated by activin A and LPS.

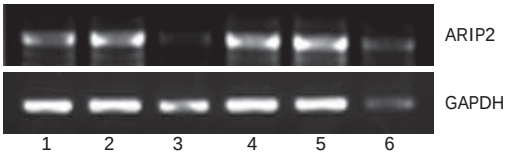

Figure 2 The effects of signal transduction activators on expressions of ARIP2 mRNA. Lane 1: Hepal-6 cells untreated; Lane 2: Treated with activin A (5 ng/mL); Lane 3: A23187 (200 nmol/L); Lane 4: LPS (2.5 μg /mL); Lane 5: PMA (20 nmol/L); Lane 6: forskolin (50 μmol/L).

and endotoxin LPS can bind with Toll-like receptor 4 on the surface of hepatocytes to stimulate cellular activities non-specifically[15]. To further study the regulation factors of ARIP2 expression, we used all of the above signal transduction activators to stimulate Hepal-6 cells and observed the expression of ARIP2 mRNA. The results showed that activin A (ARIP2 mRNA content relative to GAPDH, 66.2% ± 4.9%), LPS (76.5% ± 5.7%), PMA (72.3% ± 5.2%) and forskolin (79.8% ± 6.6%) could promote the expressions of ARIP2 mRNA (untreated control group, 48.1% ± 3.6%), whereas A23187 (25.3% ± 5.7%) could suppress it markedly (Figure 2), 25.3% ± 5.7% *vs* 48.1% ± 3.6%, $P < 0.01$. These data indicated that activators of the PKC, PKA signal transduction pathways and LPS *via* Toll-like receptor 4 could up-regulated the expression of ARIP2 mRNA.

Effects of ARIP2 overexpression on ActRII expression in Hepal-6 cells

To investigate the biological activities of ARIP2 expression in Hepal-6 cells, expression vectors pcDNA3-ARIP2 were

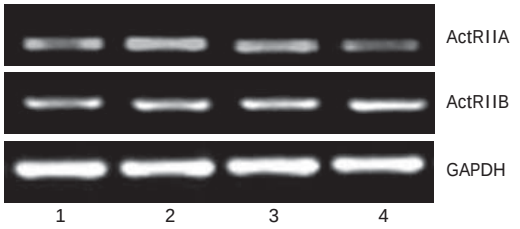

Figure 3 The mRNA expressions of ActRIIA and ActRIIB in ARIP2-overexpressed Hepal-6 cells. Lane 1 and 2: Hepal-6 cells were transfected with empty vector pcDNA3 (0.3 μg); lane 3: pcDNA3-ARIP2 (0.1 μg) + pcDNA3 (0.2 μg); lane 4: pcDNA3-ARIP2 (0.3 μg).

transfected into Hepal-6 cells and the effects of ARIP2 overexpression on ActRIIA and ActRIIB expression were observed in Hepal-6 cells. In this study, we found that ARIP2 overexpression could obviously suppress the expression of ActRIIA mRNA in Hepal-6 cells induced by activin A in dose-dependent manner, but has no effect on ActRIIB (Figure 3). These findings indicated that ARIP2 might down-regulated the expression of ActRIIA to suppress activin signal transduction in hepatocytes.

ARIP2 overexpression suppressed type Ⅳ collagen expression in Hepal-6 cells

The previous studies showed that activin A could induce liver fibrosis and stimulate excess secretion of ECM components, for example, collagen and fibronectin[3,16]. As an inhibitor of activin signal transduction, ARIP2 maybe influence the collagen production in hepatocytes induced by activin A. In this study, activin A could obviously stimulate the expression of type Ⅳ collagen mRNA in Hepal-6 cells. Whereas, after transfecting pcDNA3-ARIP2 into Hepa1-6 cells for 24 h, the ARIP2 overexpression could significantly suppress the expressions of type Ⅳ collagen mRNA induced by activin A in dose-dependent manner (Figure 4). To further determine the type Ⅳ collagen protein expression, the mature type Ⅳ collagen protein levels in Hepa1-6 cells were examined by flow cytometry. The results showed that ARIP2 overexpression could remarkably inhibit the expression levels of type Ⅳ collagen proteins in Hepa1-6 cells induced by activin A (the percent of positive fluorescence cells, 2% *vs* 16%) (Figure 5), which results were the same with that of type Ⅳ collagen mRNA by RT-PCR. These findings suggested that high level expression of ARIP2 might influence the expression of ECM components in hepatocytes and

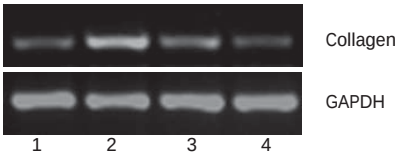

Figure 4 ARIP2-overexpression suppressed the expressions of collagen Ⅳ mRNA in Hepal-6 cells. lane 1 and 2: Hepal-6 cells were transfected with empty vector pcDNA3 (0.3 μg); lane 3: pcDNA3-ARIP2 (0.1 μg) + pcDNA3 (0.2 μg); lane 4: d pcDNA3-ARIP2 (0.3 μg). The cells were incubated in the absence (lane 1) or the presence of activin A (5 ng/mL) (lane 2, 3 and 4) for 24 h.

down-regulate the development of liver fibrosis induced by activin.

DISCUSSION

ARIPs have obvious expression and distribution diversity, which are key factors to the histological specificity of activin action[6-8]. It has been demonstrated that both ARIP1 and ARIP2 are inhibitors of activin signal transduction. However, ARIP1 mainly distributed in nerve tissues, ARIP2 widely existed in tissues. The high expression of ARIP2 mRNA could be detected in liver tissue by Northern blot[7]. In order to investigate the kinetic changes of ARIP2 expression, we used activin A and endotoxin LPS to stimulate Hepal-6 cells, and then examined the expression of ARIP2 mRNA. The results showed that the expression levels of ARIP2 mRNA were not changed obviously after being treated by activin in the early stage, but up-regulated depending on time 12 to 24 h after treatment (Figure 1). Stimulated by LPS, ARIP2 expression is also up-regulated evidently 12 h after treatment. In the present study, we further examined the effects of signal transduction activators PMA, A23187 and forskolin on the expression of ARIP2 in Hepal-6 cells (Figure 2). These data indicated that activin A, LPS, PMA and forskolin could promote the expression of ARIP2 mRNA in Hepal-6 cell, whereas calcium ion vector-A23187 could inhibit the expression of ARIP2 mRNA. These findings suggested that ARIP2 expression could be influenced by various factors and might participate in the regulation of signal transduction in the late stage in Hepal-6 cells.

Activin receptors are the members of serine/threonine kinase receptors[9,10]. Activin binds to receptor type Ⅱ to form a complex primarily. The complex interacts with the receptor type I and makes it phosphorylated, then activates endocellular Smad2/3 protein binding to receptor type I . Finally, it transduces signal into nucleus mediated by Smad4. Therefore, ActRIIs are the crucial receptors of activin signal transduction. In this study, we found that both ActR IIA and ActR IIB could be expressed in heapl-6 cells. To investigate the biological activities of ARIP2 expression in Hepal-6 cells, we transfected Hepal-6 cells with pcDNA3-ARIP2 and observed the effect of ARIP2 overexpression on ActRIIA and ActRIIB expressions in Hepal-6 cells. The results showed that ARIP2 overexpression could obviously suppress the expression of ActRIIA mRNA in Hepal-6 cells induced by activin A, but had no effect on ActRIIB (Figure 3). All the above data indicated that ARIP2 could down-regulated the expression of ActRIIA and participate in the process of negative feedback regulation of activin signal in hepatocytes.

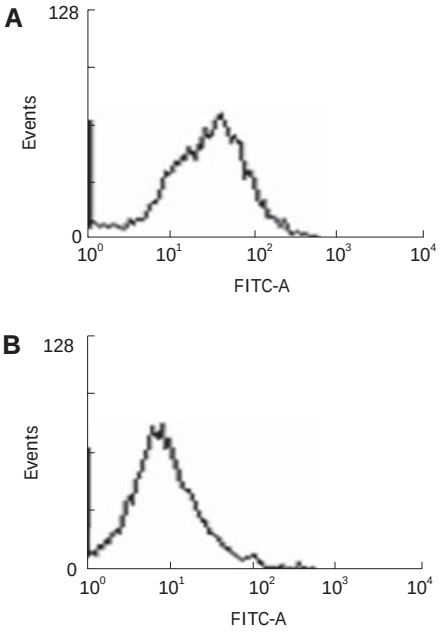

Figure 5 Flow cytometry analysis of collagen Ⅳ protein expressions in Hepal-6 cells. **A**: Hepal-6 cells were transfected with 0.3 μg pcDNA3; **B**: with 0.3 μg pcDNA3-ARIP2. 16% or 2% expressed the percent of positive fluorescence cells in **A** or **B**.

Activin not only play an important role in regulating secretion of hormone, but also serves as autocrine and paracrine factors to regulate the differentiation, proliferation, apoptosis of cells and embryonic development[17-21]. The latest studies have reported that as an important regulator, activin also has effects on inducing liver fibrosis, suppressing hepatocyte growth and so on[21-26]. It has been demonstrated that activin was produced by hepatocyte and hepatic stellate cell (HSC) and could promote HSC activation and stimulate excess production of ECM components, for example, collagen and fibronectin[3,16,25]. It has been reported that activin A could be expressed positively in fibrotic hepatocytes, and it also could take actions by autocrine[3,26]. In this study, we found that activin A could stimulate the expression of type Ⅳ collagen mRNA, whereas, the ARIP2 overexpression could remarkably suppress the mRNA expression of type Ⅳ collagen in Hepal-6 cells induced by activin A (Figure 4) and decrease the protein expression levels of type Ⅳ collagen. As a kind of collagen composed ECM, type Ⅳ collagen could co-deposited in Diss with fibronectin in the early stage of hepatic injury and take part in the formation of liver fibrosis. These findings suggested that ARIP2 overexpression might influence the synthesis of ECM in hepatocyte and negatively regulate the formation and development of liver fibrosis induced by activin A.

In conclusion, ARIP2 can be up-expressed in Hepal-6 cells by inducement with various factors and may participate in the regulation of signal transduction in the late stage. We may release or restraint liver diseases induced

by activin and achieve the goal of treatment if ARIP2 expression can be elevated in hepatocytes to inhibit the effects of activin.

ACKNOWLEDGMENTS

The authors thank Dr. Eto T (Ajinomoto Central Research Laboratories, Japan) for the kind gift of activin A, Dr. Tsuchida K (Institute for Comprehensive Medical Science, Fujita Health University, Toyoake, Japan) and Sugino H (Institute for Enzyme Research, The University of Tokushima, Tokushima 770-8503, Japan) for his help in field work.

COMMENTS

Background

Activin A is involved in hepatic fibrosis formation. However, the mechanism of fibrotic process is not well understood. In this study, effects of anti-fibrosis by ARIP2 are investigated in mouse Hepal-6 cells.

Research frontiers

ARIP2 is a regulator of activin signaling pathway, but studies about its regulation in production of component of extracellular matrix (ECM)s are not reported.

Innovations and breakthroughs

Since ARIP2 has only been recently discovered, the mode of expression regulation and function of it have not been well characterized. We designed this experiment to investigate ARIP2 expression and its effects on the expression of collagen type Ⅳ by using Hepal-6 cells.

Applications

No ideal drug is available so far for the therapy of hepatic fibrosis. ARIP2 may be play an important role in regulation of development of liver fibrosis induced by activin.

Terminology

Activin receptor-interacting protein2 (ARIP2) can specifically interact with activin type Ⅱ receptor (ActRⅡ) and down-regulate intracellular signal transduction induced by activin.

Peer review

The topic is of interest for that up to now no antifibrotic therapy is available in patients with hepatic fibrosis. The negative effect of ARIP2 on production of component of extracellular matrix described in this paper shows that ARIP2 might be a potential treatment option.

Abstract

AIM: To investigate the influence of high dose of dexamethasone on inflammatory mediators and apoptosis of rats with severe acute pancreatitis (SAP).

METHODS: SAP rats were randomly assigned to the model group and treatment group while the normal rats were assigned to the sham operation group. The mortality, ascite volumes, ascites/body weight ratio and pancreas pathological changes of all rats were observed at 3, 6 and 12 h after operation. Their contents of amylase and endotoxin in plasma and contents of tumor necrosis factor (TNF-α), phospholipase A_2 (PLA_2) and IL-6 in serum were also determined. The microarray sections of their pancreatic tissues were prepared, terminal transferase dUTP nick end labeling (TUNEL) staining was performed and apoptotic indexes were calculated.

RESULTS: There was no marked difference between treatment group and model group in survival. The contents of amylase and endotoxin in plasma and contents of TNF-α, PLA_2 and IL-6 in serum, ascite volumes, ascites/body weight ratio and pancreas pathological scores were all lower in treatment group than in model group to different extents at different time points [$P < 0.05$, 58.3 (26.4) ng/L *vs* 77.535 (42.157) ng/L in TNF-α content, 8.00 (2.00) points *vs* 9.00 (2.00) points in pathological score of pancreas respectively; $P < 0.01$, 0.042 (0.018) EU/mL *vs* 0.056 (0.0195) EU/mL in endotoxin content, 7791 (1863) U/L *vs* 9195 (1298) U/L in plasma amylase content, 1.53 (0.79) *vs* 2.38 (1.10) in ascites/body weight ratio, 8.00 (1.00) points *vs* 11.00 (1.50) points in pathological score of pancreas; $P < 0.001$, 3.36 (1.56) ng/L *vs* 5.65 (1.08) ng/L in IL-6 content, 4.50 (2.00) *vs* 7.20 (2.00), 4.20 (1.60) *vs* 6.40 (2.30), 3.40 (2.70) *vs* 7.90 (1.70) in ascite volumes, respectively]. The apoptotic indexes of pancreas head and pancreas tail were all higher in treatment group than in model group at 6 h [$P < 0.01$, 0.00 (2.00)% *vs* 0.00 (0.00)%, 0.20 (1.80) *vs* 0.00 (0.00) in apoptosis indexes, respectively].

CONCLUSION: The mechanism of dexamethasone treatment in acute pancreatitis is related to its inhibition of inflammatory mediator generation and induction of pancreatic acinar cell apoptosis.

Key words: Severe acute pancreatitis; Apoptosis; Inflammatory mediators; Dexamethasone; Tissue microarrays

INTRODUCTION

The pathogenesis of severe acute pancreatitis (SAP) is closely related to the factors such as activation of pancreatin, release of inflammatory mediators, microcirculation

disturbance and apoptosis. The sound therapeutic effects of large dose of dexamethasone on SAP have been demonstrated. In this experiment, the mechanism of large dose of dexamethasone in SAP was discussed and the changes of inflammatory mediator content and pancreatic acinar cell apoptosis after dexamethasone treatment for SAP rats were observed. The tissue microarray has also been applied to the pathohistological examination of pancreatitis to improve the study efficiency.

MATERIALS AND METHODS

Materials

Clean grade healthy male Sprague-Dawley (SD) rats with body weight of 250-300 g were purchased from the Experimental Animal Center of Medical School, Zhejiang University. Sodium taurocholate and pentobarbital were purchased from USA Sigma Company, and dexamethasone injection from Zhejiang Xinchang Pharmaceutical Company, China. The full automatic biochemical analyzer was used to determine the plasma amylase level (U/L). Plasma endotoxin tachypleus amebocyte lysate kit was purchased from Shanghai Yihua Medical Science and Technology Corporation (Institute of Medical Analysis, Shanghai, China), the calculation unit is EU/mL. The TNF-α ELISA kit was purchased from Jingmei Bioengineering Corporation, the calculation unit is pg/mL (ng/L). The serum secretory phospholipase A_2 enzyme assay ELA kit (PLA_2) was purchased from R&D System Institute and the calculation unit is U/mL. The above determinations were all operated according to the instructions of the kits.

Animal grouping and rat SAP model preparation

Ninety clean grade healthy male SD rats were prepared into SAP models by the improved Aho's method and randomly divided into the model group (45 rats) and treatment group (45 rats). Another 45 were assigned into the sham operation group. The above groups were then randomly divided into the 3, 6 and 12 h group with 15 rats in each. The treatment group was injected with dexamethasone via vena caudalis, 0.5 mg/100 g body weight, 15 min after successful preparation of SAP model. In the sham operation group, pancreas and duodenum were turned over before the abdomen was closed. The sham operation group and model group were injected with the saline of the same volume *via* vena caudalis 15 min after the operation[1]. SAP model was established according to the reference[1].

Observation indexes

The rat mortality was determined at 3, 6 and 12 h after operation and the survival rate was calculated at different time points.

After the rats were anesthetized by sodium pentobarbital and killed in batches, the pancreas samples were collected. Fix them according to the related requirements, observe the pathological changes of pancreas after HE staining and compare the pathological scores among groups. The standard of pancreas pathological score was in accordance with reference[2]. The content of amylase, endotoxin in plasma, and TNF-α, IL-6 and PLA_2 in serum of all groups were determined at different time points.

Table 1 Comparison of ascite volumes [M (Q_R)]

Group	3 h	6 h	12 h
Sham operation group	0.50 (0.00)	0.70 (0.50)	0.60 (0.30)
Model group	7.20 (2.00)	6.40 (2.30)	7.90 (1.70)
Dexamethasone treated group	4.50 (2.00)[b]	4.20 (1.60)[b]	3.40 (2.70)[b]

[b]$P < 0.001$, dexamethasone treated group *vs* model group.

Apoptotic indexes

The tissue microarray was applied to prepare the tissue microarray sections of pancreas, which were stained by DNA, and terminal transferase dUTP nick end labeling (TUNEL). The observation of pancreatic cells and calculation of apoptotic indexes were carried out respectively.

Statistical analysis

The statistical analysis was conducted with the SPSS11.5 software. The Kruskal-Wallis test or variance analysis (only applied to PLA_2) was performed for the comparison among the three groups. The Bonfferoni test was also applied to the comparison. There are statistical significances when $P < 0.05$.

RESULTS

Survival

The mortality of model group was 0% (0/15), 0% (0/15) and 13.33% (2/15) at 3, 6 and 12 h, respectively. The sham operation group and dexamethasone treated group survived at all time points while there was no marked difference between the model group and dexamethasone treated group ($P > 0.05$)[1].

Comparison of ascite volumes

The model group and treated group had significantly higher ascite columes than sham operation group ($P < 0.001$), while the treatment group had significantly lower ascite volume than the model group ($P < 0.001$) (Table 1).

Comparison of ascites/body weight ratio

The model group and treatment group had significantly higher ascites/body weight ratio than sham operation group ($P < 0.001$), while the treatment group had significantly lower ratio than the model group at 3 h ($P < 0.01$), and the treatment group had significantly lower ratio than the model group at 6 and 12 h ($P < 0.001$) (Table 2).

Comparison of plasma amylase content

The plasma amylase content in model group and dexamethasone treated group was significantly higher than in the sham operation group at all time points ($P < 0.001$). There was no marked difference between the dexamethasone treated group and model group at 3

Table 2 Comparison of ascites/body weight ratio [M (Q_R)]

Group	3 h	6 h	12 h
Sham operation group	0.20 (0.04)	0.30 (0 .30)	0.22 (0.10)
Model group	2.38 (1.10)	2.58 (0.70)	2.54 (0.71)
Dexamethasone treated group	1.53 (0.79)[b]	1.40 (0.63)[d]	1.36 (0.74)[d]

[b]$P < 0.01$, [d]$P < 0.001$, dexamethasone treated group *vs* model group.

and 6 h ($P > 0.05$). The plasma amylase content in the dexamethasone treated group was significantly less than in the model group at 12 h ($P < 0.01$) (Table 3).

Comparison of plasma endotoxin content

The plasma endotoxin content in the model group and dexamethasone treated group was significantly higher than in the sham operation group at all time points ($P < 0.001$). No marked difference was found between the dexamethasone treated group and model group at 3 h ($P > 0.05$). The content in dexamethasone treated group was significantly less than in the model group at 6 and 12 h ($P < 0.01$) (Table 3).

Comparison of serum TNF-α content

The model group and dexamethasone treated group had significantly higher serum TNF-α content than the sham operation group at all time points ($P < 0.001$). No marked difference was noticed between the dexamethasone treated group and model group at 3 h ($P > 0.05$). The dexamethasone treated group had significantly less serum TNF-α content than the model group at 6 and 12 h ($P < 0.05$)[1] (Table 3).

Comparison of serum IL-6 content

The serum IL-6 contents of model group and treatment group were significantly higher than those of sham operation group ($P < 0.001$); the content of treatment group was significantly lower than that of model group at 3 h ($P < 0.01$); and the contents of treatment group were significantly lower than those of model group at 6 and 12 h ($P < 0.001$) (Table 3).

Comparison of serum PLA_2 content

The model group and dexamethasone treated group significantly higher serum PLA_2 content than the sham operation group at all time points ($P < 0.001$). The content in the dexamethasone treated group was significantly less than in the model group ($P < 0.001$) (Table 4).

Pathological score of pancreatic tissue

HE staining was performed and the pathohistological score standard was referred to the improved Schmidt score. Two chief pathologists used the blind method for scoring[2].

Gross pathological changes of pancreas. (1) Sham operation group: No apparent abnormality of pancreas and peripancreatic epiploon at all time points. (2) Model group: The gross pathological change of pancreas tail was more apparent than that of pancreas head. The severity of overall pathological change increased with time after modeling. At 3 h, a small amount of hemorrhagic ascites was observed by naked eyes with relatively apparent changes of pancreas hyperemia and edema, hemorrhage and necrosis; at 6 and 12 h, hemorrhagic ascites increased more apparently with edema, hemorrhage and necrosis, and more saponified spots could be seen on peripancreatic epiploon and peritoneum. (3) Treatment group: At 3 h, the degree of pancreas hyperemia and edema, hemorrhage and necrosis was milder than that of model group with decrease of ascitic fluid; at 6 and 12 h, the pancreatic hemorrhage and necrosis area and degree were milder than those of model group with apparent decrease of ascitic fluid.

The pancreas pathological changes under light microscope. (1) Sham operation group: Mild interstitial edema occurred in a few cases, and neutrophil infiltration was occasional. No acinar cell, fat necrosis and hemorrhage were observed. (2) Model group: The pathological change severity increased with time after modeling. At 3 h, pancreas interstitial hyperemia, edema, a small amount of inflammatory cell infiltration, focal necrosis and interstitial hemorrhage occurred, among which some were lamellar hemorrhage and necrosis. At 6 h, interstitial edema, hemorrhage, inflammatory cell infiltration, focal and lamellar hemorrhage and necrosis occurred. At 12 h, large area of hemorrhage and necrosis, lobule outline damage and a large amount of inflammatory cell infiltration were found. (3) Treatment group: The pathological change scope and degree of most cases were milder than those of model group at corresponding time points. Only a few had lamellar hemorrhage and necrosis, but the scope of hemorrhage and necrosis decreased and inflammatory cell infiltration apparently alleviated.

Comparison of pathological score of pancreas

Both model group and dexamethasone group had significantly higher pathological score of pancreas than the sham operation group at different time points ($P < 0.01$) while that in dexamethasone group was significantly less than in the model group at 3 and 6 h ($P < 0.05$), and it was also significantly less in the dexamethasone group than in the model group at 12 h ($P < 0.01$) (Table 5).

Comparison of apoptosis indexes

The apoptosis index of pancreas head and tail at 3 and 12 h was not significantly different among all groups ($P > 0.05$). No marked difference was found between the model group and sham operation group at different time points ($P > 0.05$). At 6 h, the apoptosis index of pancreas in the treatment group was significantly higher in the model group and sham operation group ($P < 0.01$) (Table 6, Figure 1A and B).

Correlation analysis

There was a positive correlation between amylase and PLA_2 of model group at 3 h ($P < 0.05$); the TNF-α content of treatment group was positively correlated with PLA_2 at 6 h ($P < 0.05$). There was a positive correlation between pancreas pathological score and TNF-α ($P < 0.05$).

Table 3 Comparison of different indexes level in blood [M (Q_R)]

Index	Sham operation group			Model group			Dexamethasone treated group		
	3 h	6 h	12 h	3 h	6 h	12 h	3 h	6 h	12 h

DISCUSSION

Under normal circumstances, the inflammatory mediators are at low level of dynamic balance to maintain the stability of the internal environment. Excessive inflammatory reaction plays a vital role in SAP pathogenesis[3-6]. In this experiment, the influence of dexamethasone on inflammatory mediators in treatment of SAP rats was studied and its relationship with the apoptosis of pancreatic acinar cells was discussed.

TNF-α can increase the local tissue damage and capillary permeability, eventually aggravating pancreatic necrosis, which is important in AP[7,8]. Norman *et al*[7] found in SAP rats a positive correlation between the TNF-α concentrations in pancreatic tissue and plasma and the level of pancreatic injury and inflammation, which is consistent to the fact that in this experiment, the pancreas pathological score was positively correlated with TNF-α at 12 h in model group ($P < 0.05$). It was found in this experiment that the serum TNF-α contents were lower

in treatment group than in model group at 6 and 12 h ($P < 0.05$), demonstrating that dexamethasone plays a certain role in inhibiting serum TNF-α content. Since PLA_2 plays an important role in SAP onset[8-10], PLA_2 antagonist can significantly improve the pathological injury of pancreas of the animal model with pancreatic injury[11,12]. In this study, the serum PLA_2 content was lower in treatment group than in model group ($P < 0.001$), demonstrating a significant inhibiting effect of dexamethasone on PLA_2 or its generation. IL-6, mainly generated by monocyte/macrophage, T cell, B cell, *etc*, participates in many acute body reactions such as burn, sepsis and major operation. The positive correlation between serum IL-6 level and AP severity has been proved by many studies[13]. And the histological score of pancreas can be significantly improved by lowering IL-6. The serum IL-6 contents were all lower in treatment group than in model group to different extents ($P < 0.01$ or $P < 0.001$), demonstrating that dexamethasone can inhibit serum IL-6 content.

In recent years, it was found that both inflammatory mediators and pancreatic acinar cell apoptosis are related to AP[14,15]. Apoptosis participates in AP onset[16]. The apoptosis of pancreatic acinar cell might be a reaction beneficial to the body after the occurrence of pancreatitis[17,18]. Both necrosis and apoptosis are death modes of injured cells[19]. However, substantially different from necrosis, apoptosis will not release the harmful substance in lysosome or cause intense inflammatory reaction[20]. Necrosis prevails in SAP. The illness can be alleviated by apoptosis induction and aggravated by apoptosis inhibition[14]. In this experiment, according to the result of TUNEL staining, the apoptotic index was higher in treatment group than in model group ($P < 0.01$), and the pathological score was lower in treatment group than in model group ($P < 0.05$) at 6 h, demonstrating that dexamethasone can promote the apoptosis of pancreatic cells and protect pancreatic tissue.

The effect of glucocorticoid (represented by dexamethasone) on AP/SAP has been an issue in dispute. In 1952, Stephensen *et al*[21] for the first time reported the effect of glucocorticoid in AP treatment. Many empirical studies show glucocorticoid can improve the survival of AP animals[22,23] Its mechanisms mainly are: inhibiting the generation of inflammatory mediators and (or) inhibiting the effects of inflammatory mediators, enhancing body stress, improving microcirculation, alleviating endotoxemia, cleaning free radicals, inhibiting nitric oxide (NO) and expression of NF-κB, *etc*[24-26]. In terms of administration and dose, Dong *et al*[27,28] found a large dose of dexamethasone was obviously superior to the small dose dexamethasone in therapeutic effect and early use of dexamethasone was superior to dexamethasone of the same dose 5 h later. We used large doses of dexamethasone and achieved relatively sound therapeutic effects, obviously alleviating pathological changes of pancreas.

This empirical study used the improved Aho's method[29] to prepare SAP model, the rat survival of the dexamethasone treated group was significantly higher than that of the model group, but there was no marked difference between the two groups ($P > 0.05$). However, no matter gross or under light microscope, the treatment group has milder pancreatic tissue cell inflammatory pathological changes, less ascitic fluid and hemorrhage, and lower necrosis scope than the model group at all time points.

The contents of amylase and endotoxin in plasma and TNF-α, PLA_2 and IL-6 in serum were all lower in dexamethasone treated group than in model group. The apoptotic index was higher in treatment group than in model group while the inflammation, hemorrhage and necrosis of pancreas were all milder in treatment group than in model group, indicating that dexamethasone can improve the pancreatic injury of SAP rats by directly inducing pancreatic cell apoptosis, or indirectly inducing apoptosis through inhibition of excessive rise of TNF-α, IL-6, PLA_2, *etc*. In this experiment, no relation has been found between inflammatory mediators and pancreas apoptotic index. However, it has been found in many studies that the inflammatory mediators released by injured cells in AP can influence apoptosis. The role of inflammatory mediators that indirectly regulate apoptotic gene is significant and non-neglectable during its participation in apoptosis. It is worth mentioning that there are various but one influential factors act together to result in apoptosis during AP, presenting a network relation structure[30].

We used the tissue microarray section maker (Beecher Instruments, USA) to drill a hole 2.0 mm in diameter on recipient block and combined TUNEL staining method to examine the apoptotic index. The results indicate that the tissue chip 2.0 mm in diameter can achieve reliable experimental result, which is representative, time, energy and reagent saving, and convenient for control.

COMMENTS

Background

The severe acute pancreatitis (SAP) is one of the common acute abdomens in clinical practice. The pathogenesis of SAP is closely related to factors such as activation of pancreatin, release of inflammatory mediators, microcirculation disturbance and apoptosis. The recent studies prove the apoptosis could be a beneficial reaction to AP. The apoptosis of acinar cell in pancreas inducing injury can alleviate the inflammatory reaction. In this experiment, the mechanism of dexamethasone treatment in SAP was discussed and the changes of inflammatory mediator content and pancreatic acinar cell apoptosis were observed.

Research frontiers

To discuss the influence of dexamethasone on inflammatory mediators and apoptosis of rats with SAP, the authors established the rat SAP models and combined the tissue microarrays to observe the influence of dexamethasone on apoptosis of acinar cell in pancreas, providing a new theoretical basis for dexamethasone treatment of SAP and application of tissue microarrays in pancreatitis pathological examinations.

Innovations and breakthroughs

The tissue microarray has been applied to the pathohistological examination of pancreatitis to improve the study efficiency.

Applications

The sound therapeutic effects of a large dose of dexamethasone on SAP have been demonstrated. It is of some value to apply tissue microarrays to pathological examination and analysis of non-tumor diseases like pancreatitis.

Terminology

The apoptosis is a kind of self-protecting fashion namely the body starts the autogene program under certain pathological and physiological conditions and removes the irreparable cells, which is substantially different from necrosis. Tissue microarray (TMA), or tissue chip, is a method of harvesting small disks (diameter 0.6-2.0 mm) of tissue from a range of standard histologic sections and placing in an array on a recipient paraffin block by which hundreds of cases can be analyzed simultaneously. This technique allows maximization of tissue resources by analysis of small-core biopsies of blocks, rather than complete sections.

Peer review

Through animal studies, the authors investigated the influence of dexamethasone on inflammatory mediators and apoptosis of rats with severe acute pancreatitis. They concluded that the mechanism of dexamethasone treatment in acute pancreatitis is related to its inhibition of inflammatory mediator generation and induction of pancreatic acinar cell apoptosis.

Abstract

Endosonography-guided biliary drainage (ESBD) is a new method enabling internal drainage of an obstructed bile duct. However, the histological conditions associated with fistula development *via* the duodenum to the bile duct have not been reported. We performed ESBD 14 d preoperatively in a patient with an ampullary carcinoma and histologically confirmed changes in and around the fistula. The female patient developed no complications relevant to ESBD. Levels of serum bilirubin and hepatobiliary enzymes declined quickly, and pancreatoduodenectomy was carried out uneventfully. The resected specimen was sliced and stained with hematoxylin-eosin. Histological evaluation of the puncture site in the duodenum and bile-duct wall, and the sinus tract revealed no hematoma, bile leakage, or abscess in or around the sinus tract. Little sign of granulation, fibrosis, and inflammatory cell infiltration was observed. Although further large-scale confirmatory studies are needed, the findings here may encourage more active use of ESBD as a substitute for percutaneous transhepatic drainage in cases with failed/difficult endoscopic biliary stenting.

INTRODUCTION

The role of endosonography (ES) in digestive diseases is gradually expanding from diagnostic to therapeutic applications. In the mid 1990s, the feasibility of ES-guided cholangiopancreatography was first reported by Harada *et al*[1] (pancreatography) and Wiersema *et al*[2] (cholangiography). Several reports on the application of this technique for therapeutic purposes, such as ES as a guide for biliary drainage, have been published.

We have recently applied ES-guided biliary drainage (ESBD) for preoperative decompression of the biliary tree in a patient with cancer of the papilla of Vater. The results of histological evaluation of and around the sinus tract are reported herein.

CASE REPORT

A 76-year-old Japanese woman was admitted to our department, complaining of jaundice and itching. Laboratory data on admission showed the following abnormalities: serum total bilirubin, 11.7 mg/dL; glutamic oxaloacetic transaminase (GOT), 389 IU/L; glutamic pyruvic transaminase (GPT), 285 IU/L; and alkaline phosphatase (ALP), 1487 IU/L. Transabdominal ultrasonography and abdominal computed tomography revealed a mass in the ampullary region, along with dilatation of the bile and pancreatic ducts (Figure 1). To resolve her complaints, endoscopic retrograde cholangiopancreatography (ERCP) with biliary stenting was attempted. However, cannulation of the bile duct was unsuccessful because stenosis of the descending portion of the duodenum, and the presence of a tumor at the papilla of Vater that bled easily when contacted, made it impossible to manipulate the endoscope to identify the orifice. After obtaining written informed consent, ESBD was undertaken. Following visualization of the extrahepatic bile duct with a curved linear array echoendoscope (GF-UC240P; Olympus, Tokyo, Japan), the dilated bile duct was punctured *via* the upper part of the descending portion of the duodenum with a 19G needle (Olympus) (Figure 2A). Following removal of the core needle, white bile was aspirated. A small amount of contrast agent was then injected *via* the sheath catheter into the bile duct, to guide stent placement and to confirm the absence of bile leakage or extravasation. A guidewire 0.889 mm in diameter (Jagwire; Boston Scientific, Natik, MA, USA) was introduced into the sheath catheter and inserted into the intrahepatic bile duct. Subsequent to

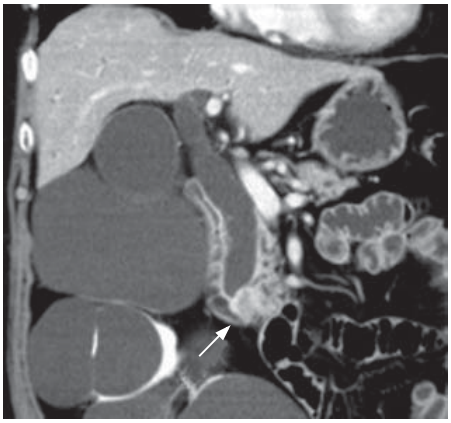

Figure 1 CT reveals a mass in the ampullary region (arrow) with a dilated extrahepatic bile duct. The patient also had multiple renal cysts.

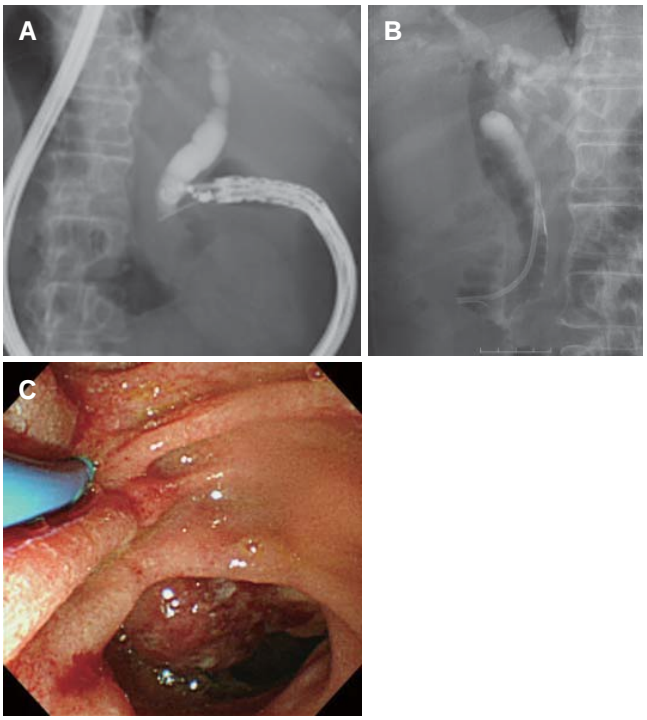

Figure 2 A, B: Puncture of the bile duct via the duodenum under endosonographic guidance, followed by deployment of a plastic stent. **C:** Endoscopic view after stent placement.

removing the sheath catheter and leaving the guidewire *in situ*, we dilated the puncture tract with a dilator catheter 7F in diameter, and placed a 7F plastic stent (Figure 2B and C). The patient developed no symptoms related to the procedure and her initial complaints also soon disappeared. One week after the procedure, levels of serum total bilirubin, GOT, GPT, and ALP had declined to 3.2 mg/dL, 33 IU/L, 47 IU/L, and 780 IU/L, respectively. She underwent pancreaticoduodenectomy 14 d after ESBD. Macroscopically, the sites of the puncture in the bile duct and duodenum were clear without infection, hemorrhage or hematoma (Figure 3).Histological examination revealed mild inflammatory cell infiltrate adjacent to the sinus tract in the duodenal and bile duct walls, without hemorrhage (Figure 4). A fistula was formed

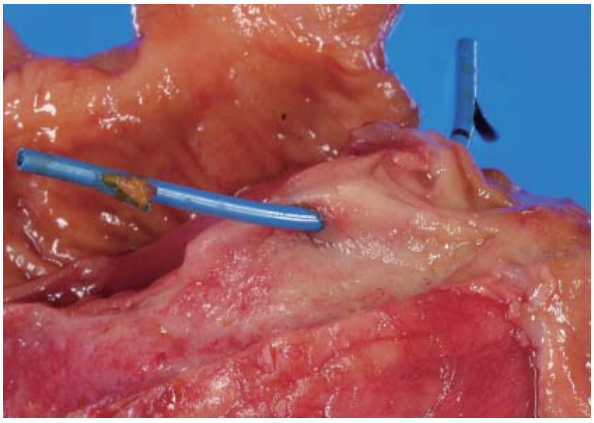

Figure 3 Fresh resected specimen. No hematoma or abscess is seen at the site of the puncture in the bile duct.

along the tract of the puncture without significant reactive changes. No evidence of severe inflammation, such as bile peritonitis, was found on the extraluminal side of either the duodenum or the bile duct.

DISCUSSION

The role of ES in the management of gastrointestinal diseases has evolved from imaging of the gut wall and organs adjacent to the alimentary tract, to its use as a guide for tissue sampling with a fine-needle, as well as in therapeutic applications such as injection of agents into tumors and drainage of pancreatic pseudocysts. Endosonographic approaches to an inaccessible bile duct and pancreatic duct by ERCP were first reported in the mid 1990s. In 1996, Wiersema *et al*[2] reported the feasibility of ES-guided cholangiopancreatography. Subsequently, several case series have been published on the feasibility and effectiveness of ESBD, the first being by Giovannini *et al*[3] in 2001, in a pancreatic cancer patient with a history of failed cannulation of the bile duct, even after precutting, who underwent preoperative chemoradiotherapy. They succeeded in the deployment of a 10F stent in a two-step procedure by changing endoscopes. In 2003, Burmester *et al*[4] reported three cases of successful stent placement among four attempts at ESBD. They achieved biliary drainage by a one-step technique, a modification of the Seifert technique[9] for drainage of pancreatic pseudocysts. They approached the bile duct via the duodenum, stomach and even the jejunum. Mallery *et al*[5] performed endoscopic ultrasound-guided rendezvous drainage of the bile duct and pancreatic duct after unsuccessful ERCP. They succeeded in stent placement following antegrade traverse of the stenosis with a guidewire in three (two biliary and one pancreatic) of six cases. Puspok *et al*[6] applied this technique to cases of bile duct stones with difficult cannulation of the bile duct, and reported excellent results. Kahaleh *et al*[7] recently published their experience of ESBD in 23 patients. They carried out puncture of the bile duct *via* the stomach, duodenum and jejunum, and concluded that intrahepatic access to the biliary system appears safer than the extrahepatic approach.

As described here, acceptable success rates and inci-

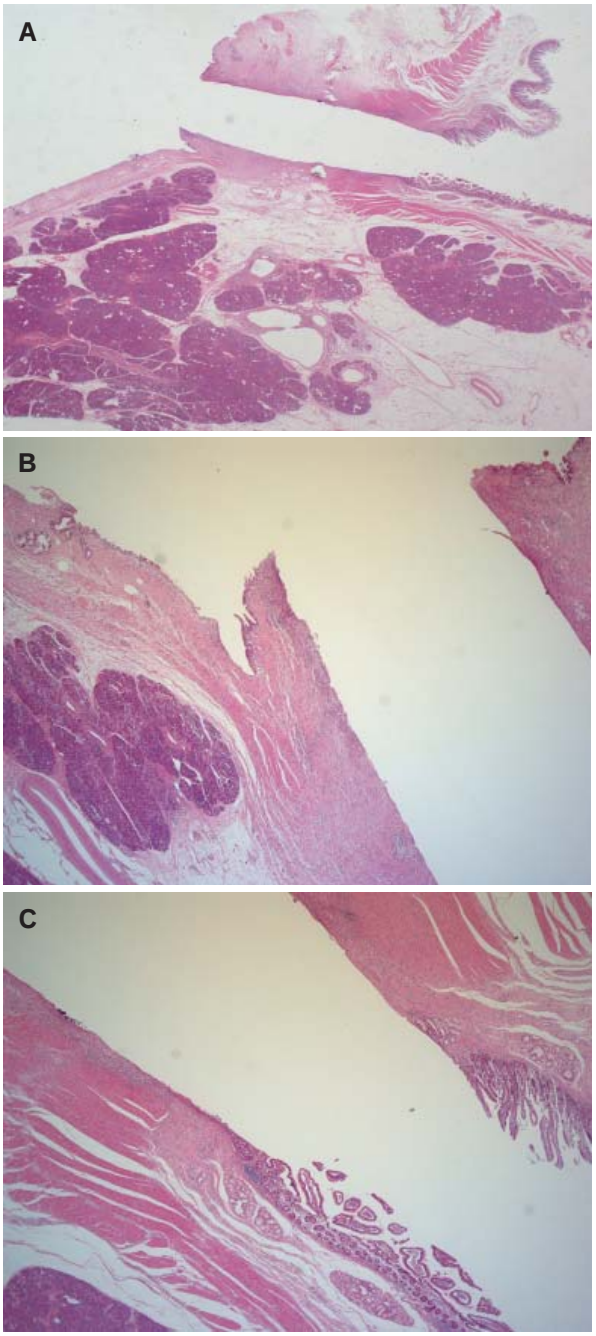

Figure 4 Microscopic views of the sinus tract. Mild inflammatory cell infiltrate adjacent to the sinus tract in the duodenal wall and the bile duct wall is seen, without hemorrhage or abscess formation. A fistula is formed along the tract of the puncture but without significant reactive changes. **A:** Low-power view of the sinus tract (× 1.25); **B:** End of the sinus tract on the bile duct side (× 5); **C:** End of the sinus tract on the duodenal side (× 5).

dence of complications were reported for puncture and stent placement under sonographic guidance. However, there have been no reports of the influence of this technique on the gut wall, bile duct, or intervening tissues between them. This is believed to be the first report describing the preoperative performance of ESBD and the histological condition of the sinus tract established by this method. The duodenum, bile duct and sinus tract showed no adverse histological changes. These results are attributable to the use of endosonography as a guide. This technique has a low potential risk of major bleeding as color Doppler evaluation is utilized for determining the route of the puncture. Injury to adjacent organs is also minimized due to clear visualization of the structures in the area of interest, with the use of high-frequency ultrasound. Some authors[4,6,8] have applied a fistulotome with electrocautery for puncture. However, it seems theoretically safer to apply a simple puncture needle to avoid damage to the tissues in and around the pathway of the puncture.

The present study elucidated histological changes at and around the sinus tract, following ESBD. The results that no severe inflammation or hemorrhage occurred should encourage the wider use of this technique, although further large-scale studies will be needed.

In general, the method of choice for biliary obstruction is endoscopic biliary stenting. Percutaneous transhepatic cholangio-drainage (PTCD) is considered a substitute. However, PTCD can result in pain after placement of the drainage tube, and can restrict activities of daily living. In contrast, ESBD is a safe and effective method for biliary drainage and does not cause pain or restriction of daily living, as is the case with endoscopic biliary stenting. It should therefore replace PTCD in a large proportion of those patients with an obstructed biliary tree and with difficult cannulation of the bile duct, duodenal stenosis, or deformity of the papilla of Vater caused by cancer, which hinders detection of the orifice, regardless of the likelihood of successful PTCD.

As is the case with plastic stents in endoscopic biliary stenting, the diameter of the stent available in ESBD is restricted by the diameter of the working channel of the endoscope employed. The endoscope we used had a 2.8-mm diameter working channel, allowing the use of only 7F stents, or smaller.

Dilation of the sinus tract can be achieved with a dilator balloon, following insertion of the guidewire into the bile duct *via* the lumen of the placed stent and removal of the sent alone. Therefore, once access to the bile duct has been established, it is possible to place a stent with a larger caliber, even a metallic stent, without difficulty in either a one- or two-step procedure. In the long term, it is inevitable that plastic stents will become occluded. Deployment of a metallic stent will prolong patency, as shown in endoscopic transpapillary biliary stenting[10]. Covered metallic stents are deemed to be advantageous in avoiding bile leakage.

Further development of accessory devices specialized for ESBD will help expand its indications.

Abstract

This study aimed to describe a case in which an isolated splenic metastasis was synchronous with the colonic primary and a concomitant splenic abscess was associated. A wide review of the literature was also performed. A 54-year-old woman with abdominal pain and fever was admitted to our department. Abdominal CT revealed two low-density areas in the spleen and wall-thickening of the left colonic flexure, which was indistinguishable from the spleen parenchyma. The patient underwent emergency celiotomy, with the presumptive diagnosis of obstructing colon carcinoma of the splenic flexure, and concomitant splenic abscess. Subtotal colectomy and splenectomy were performed. Pathological findings were consistent with mucinous colonic carcinoma, synchronous isolated splenic metastasis and concomitant splenic abscess. This paper is also a review of the existing literature on the association between colorectal cancer and splenic metastasis. Only 41 cases of isolated splenic metastasis from colon carcinoma have been reported in the literature. This report is the third described case of synchronous isolated splenic metastasis from colon carcinoma. Only one case with concomitant splenic abscess has been previously reported. When obstructing left-sided colorectal cancer is suspected, careful CT examination can allow early diagnosis of splenic involvement by the tumor. The literature review suggests that there might be a significant improvement in survival following splenectomy for a metachronous isolated splenic metastasis from colon carcinoma. Prognosis for synchronous splenic metastasis seems to be related to the advanced stage of the disease. Nevertheless, no definitive conclusions can be drawn because of the small number of cases.

INTRODUCTION

Primary and metastatic tumors of the spleen are described as unusual[1], excluding secondary involvement by lymphoma[2]. Since metastatic carcinoma involving the spleen is usually a manifestation of widely disseminated disease, isolated splenic metastasis from colorectal carcinoma is not a common occurrence[1,3]. Its rareness has been hypothetically explained by several characteristics of the spleen, such as anatomical, histological and immunological features[4]. Most cases are asymptomatic and the diagnosis is usually made by imaging studies during the diagnostic work up for colon cancer[5]. However, a few patients become exceptionally symptomatic following spontaneous rupture of the spleen, or the presence of an associated splenic abscess[6,7].

We report the case of a synchronous isolated splenic metastasis from colonic carcinoma, with a concomitant splenic abscess, and we also review all cases of isolated splenic metastasis from colorectal cancer reported in the literature. To the best of our knowledge, only one case of splenic metastasis from colonic carcinoma associated with concomitant splenic abscess has been reported in the literature[7], which is an extremely rare clinical entity.

CASE REPORT

In June 2006, a 54-year-old Caucasian woman was referred to our emergency department because of abdominal pain associated with intermittent fever over 40℃, shaking and chills. She also complained of general fatigue and loss of appetite. Otherwise, her previous medical history was unremarkable. On clinical examination, the patient was pale and shocked. Blood pressure and pulse rate were 90/60 mmHg and 98/min, respectively. The abdomen was distended, with tenderness in the left hypochondrium. There

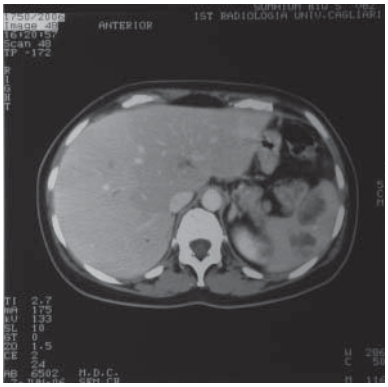

Figure 1 Two low density areas in the spleen (Axial CT-scan).

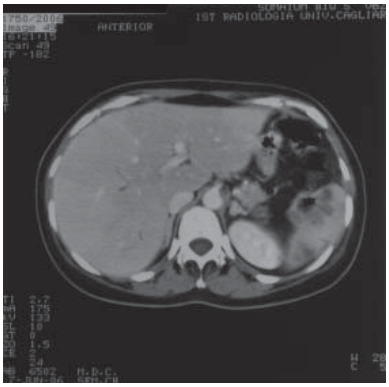

Figure 2 Wall thickening of the left flexure of the colon indistinguishable from the spleen parenchyma (Axial CT-scan).

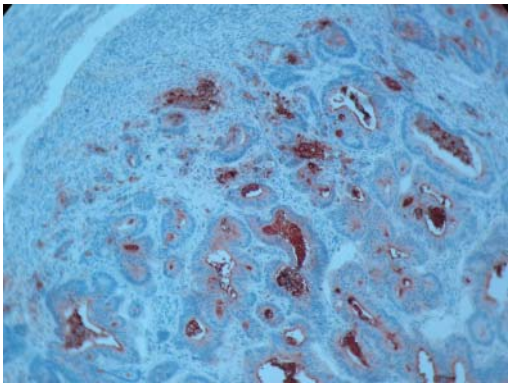

Figure 4 CEA along the luminal border of tumor cells infiltrating splenic pulp (anti-CEA monoclonal antibody staining, x 100).

was neither hepatosplenomegaly nor lymphadenopathy. Sepsis was identified both by a clear clinical picture which showed high fever and hemodynamic instability, and by positive blood culture which grew *Escherichia coli* and *Bacteroides fragilis*. Laboratory data on hospital admission were as follows: white blood cell count, 148 × 10^9/L; red blood cell count, 280 × 10^{12}/μL; hemoglobin, 67 g/L; thrombocyte count 383× 10^9/L; fibrinogen, 5.17 g/L; albumin 23 ug/L; and carcinoembryonic antigen (CEA), 31.1 ug/L (normal range < 2.50 ug/L).

Chest X-ray revealed a left pleural effusion. Abdominal plain radiography showed intestinal obstruction with typical air fluid levels in the bowel. Abdominal ultrasonography demonstrated a hypoechoic area with unclear margins in the lower pole of the spleen, with the features of a splenic abscess. Enhanced abdominal CT revealed two low-density areas in the spleen (Figure 1) and wall-thickening of the left colonic flexure, which was indistinguishable from the spleen parenchyma (Figure 2). Echocardiography was normal and detected no vegetations. The patient was treated with fluid, intensive antibiotics and blood transfusion as initial therapy, and then she underwent an emergency operation for a presumptive diagnosis of obstructing colonic carcinoma and septic shock from a concomitant splenic abscess. On explorative celiotomy, the splenic flexure of the colon presented a mass occluding the lumen, infiltrating the entire colonic wall, and invading the lower pole of the spleen. There were neither hepatic metastases nor peritoneal dissemination. Frozen section examination of the spleen was performed after splenectomy. Frozen section showed the presence of splenic metastasis from adenocarcinoma, with a concomitant splenic abscess. A subtotal colectomy with side-to-side ileo-sigmoid anastomosis was then performed. The spleen weighed 160 g and measured 12 cm × 7 cm × 4.5 cm. On gross examination, the tumor originated from the left colonic flexure and invaded the spleen, in which it formed a fistula and an abscess in the metastatic tissue. The splenic metastasis measured 4.5 cm at its largest diameter and had a central abscess with a cavity of 2 cm. Histopathological findings were consistent with mucinous adenocarcinoma of the colon, synchronous isolated splenic metastasis from the primary colonic tumor (Figure 3), and concomitant splenic abscess, without metastatic lymph-node involvement (T4N0M1). Immunohistochemistry of both colonic carcinoma and splenic metastasis was performed using anti-CEA monoclonal antibody (Clone Ⅱ-7, Dako Corporation, Carpinteria, CA, USA). Staining of CEA along the luminal border of tumor cells was demonstrated both in the colonic carcinoma and in the metastasis that infiltrated the splenic pulp (Figure 4). Left pleural effusion persisted for 10 d after the operation, and the patient was finally discharged on postoperative day 15.

After 1 mo, the CEA level dropped to 3.0 μg/L. The patient was treated with adjuvant chemotherapy. Six months after the operation, CEA level was 10.4 μg/L. Abdominal CT and positron emission tomography (PET) revealed a solitary liver metastasis of 2 cm, which was surgically removed. Exploration of the abdominal cavity revealed no further evidence of neoplastic disease. Afterward, the patient was once more subjected to adjuvant chemotherapy.

[1]This metastasis occurred 3 mo after colonic operation; [2]From the review of the Japanese literature.

DISCUSSION

Approximately 20% of colorectal carcinomas are metastatic at their clinical presentation[8]. Metastases to other sites in the absence of liver, lung or axial skeleton involvement are very rare[1,9]. Similar to the results of an autopsy study by Berge, microscopic splenic metastases were found in 7%-34% of cancer patients[2]. The same author reported the incidence of splenic micrometastases arising from colorectal carcinoma to be as high as 2% in 1019 colorectal tumors, but all of these involved other organs as well[2]. In 1969 Dunbar *et al*[10] published the first case report of isolated splenic metastasis from colorectal carcinoma and to date, only 41 such cases have been reported in the literature (Table 1). All but two of previously described cases of solitary splenic metastases from colon carcinoma had a metachronous metastasis (Table 1). We have described the third reported case in which an isolated splenic lesion was synchronous with colonic carcinoma[7,11]. The particularly interesting aspect of our case was also related to the simultaneous presence of a splenic abscess, because the only other reported case with similar clinical and pathological features is that by Paramelle *et al*[7].

The rareness of splenic metastasis arising from colonic carcinoma suggests the existence of some mechanism that prohibits tumor cell proliferation in the spleen. Anatomical and immunological characteristics may be reasons for the rarity of isolated splenic metastasis[4]. From an anatomical perspective, the sharp angle of the splenic artery with the celiac axis and rhythmic contraction by the sinusoidal splenic architecture are limiting factors for metastasis[4,12]. According to Indudhara *et al*[13], neoplastic cells can reach the splenic vein and parenchyma by retrograde diffusion through the inferior mesenteric vein. The spleen parenchyma contains no afferent lymphatic vessels, but they are present in the capsular, subcapsular and trabecular regions[12]. Tumor cells might also reach the spleen *via* the lymphatic system, which explains the typical subcapsular localization of isolated splenic metastases[12]. As the spleen is the second largest organ of the reticuloendothelial system, immune surveillance appears to potently inhibit tumor cell proliferation[14]. Moreover, experimental studies have shown that the growth rate of adenocarcinoma cells injected into the spleen is significantly lower than that of the same cells injected into the liver[15].

Histopathological findings in our case were consistent with mucinous adenocarcinoma of the colon, as in three other cases of isolated splenic metastasis[3,16,17]. Mucinous gastrointestinal malignancies are thought to cause perforation and infiltration of the full thickness of the bowel wall, which lead to extensive invasion of the pericolic fat[3,16]. A new mechanism has been proposed in the case of contiguous splenic metastasis from mucinous colonic tumors. Cabanas *et al*[16] have suggested that mucus-producing epithelial cells become trapped within the trabecula of the splenic capsule, in congenital clefts of the spleen, or in microfissures caused by trauma. The resistance of the splenic capsule or fibrous tissue surrounding the spleen causes the mucinous tumor to expand into the soft splenic parenchyma, rather than

the peritoneal cavity[16]. Following the more aggressive behavior of mucinous colonic tumors, this mechanism may have explained the presence of the synchronous splenic metastasis in our case. Furthermore, since CEA appears as an immunosuppressant, and acts as an adhesion molecule between tumor cells and visceral macrophages, colonic tumor cells with positive CEA staining should display more aggressive behavior[4,18]. In regard to these biological functions, CEA expression might be associated with the occurrence of isolated splenic metastasis[4] (Figure 4).

The diagnosis of isolated splenic metastasis is generally made by imaging studies during the diagnostic work up for colonic cancer[5]. Only a few patients with splenic metastasis become symptomatic because of the presence of an associated splenic abscess[8] or spontaneous rupture of the spleen[6,19], as in our case. Okuyama *et al*[20] have pointed out that only six of 28 reported patients were symptomatic at the time of diagnosis. Our patient became symptomatic as a result of abdominal occlusion and sepsis originating from the splenic abscess, in which *E. coli* and *B. fragilis* grew, as in most cases of colonic abscess associated with colonic cancer[21]. The association between splenic abscess and colonic cancer is a very rare clinical entity[22], as is isolated splenic metastasis. Only a few cases have been reported in the literature, and sometimes the splenic abscess resulted from a direct fistula of descending colon carcinoma, without spleen metastasis[23]. The most frequent complication of splenic abscess is its rupture into the peritoneal cavity, and untreated splenic abscesses have a high mortality rate[23].

Most previously described patients with solitary splenic metastasis from colon carcinoma had a disease-free survival of 3-144 mo after the primary tumor[11,17,24]. Long-term survival after splenectomy in patients with isolated metachronous splenic metastasis from colon carcinoma varied from 0.5 to 7 years[11,20,24]. As a result, prognosis of isolated splenic metastasis after splenectomy appears to be rather optimistic, despite the fact that splenic metastasis is one form of distant metastasis[20]. In our case of synchronous metastasis, intensive follow-up revealed a solitary liver metastasis 6 mo after operation, without further evidence of neoplastic disease in the abdominal cavity. However, the disease-free interval after splenectomy in the case of synchronous splenic metastasis reported by Avesani *et al*[11] was 10 mo, and the patients died of diffuse carcinomatosis after 1 year.

The spleen is considered unfavorable to the development of metastases but the reason for this is not clearly understood. An isolated splenic metastasis from colon carcinoma is a rare clinical finding. On the basis of the present case, when an obstructing left-sided colorectal cancer is suspected in emergency setting, careful examination of the abdominal CT-scan can allow early diagnosis of a splenic involvement by the tumor. Clinicians must pay close attention to the spleen for the early diagnosis of isolated splenic metastasis when routinely evaluating abdominal CT-scan and abdominal ultrasonography following curative resection of primary colorectal cancer. Splenectomy is necessary in the presence of isolated metastases from colon carcinoma both synchronous and methacronous. The occurrence of a splenic abscess makes emergency splenectomy mandatory as the most frequent complication is its rupture into the peritoneal cavity.

Splenectomy followed by chemotherapy seems to be the preferred treatment of isolated splenic metastases from colorectal carcinoma. There are few data available about recurrence after splenectomy for metastases of this type. Literature review suggests that there might be a significant improvement of long-term survival following splenectomy for methacronous splenic metastasis arising from colon carcinoma. Prognosis for synchronous splenic metastasis seems to be related to the advanced stage of the disease. Nevertheless, following the small number of cases reported in the literature, no definitive conclusions can be drawn.

Abstract

We report a case of a patient presenting with clinical, radiological and endoscopic features of colitis due to a compressive left para-aortic mass. Total open surgical excision was performed, which resulted in complete resolution of colitis. Histopathology and immunohistochemistry revealed benign retroperitoneal schwannoma. These neural sheath tumors rarely occur in the retroperitoneum. They are usually asymptomatic but as they enlarge they may compress adjacent structures, which leads to a wide spectrum of non-specific symptoms, including lumbar pain, headache, secondary hypertension, abdominal pain and renal colicky pain. CT and MR findings show characteristic features, but none are specific. Schwannoma can be isolated sporadic lesions, or associated with schwannomatosis or neurofibromatosis type Ⅱ (NF2). Although they vary in biological and clinical behavior, their presence is, in nearly every case, due to alterations or absence of the *NF2* gene, which is involved in the growth regulation of Schwann cells. Both conditions were excluded by thorough mutation analysis. Diagnosis is based on histopathological examination and immunohistochemistry. Total excision is therapeutic and has a good prognosis. Schwannomatosis and NF2 should be excluded through clinical diagnostic criteria. Genetic testing of NF2 is probably not justified in the presence of a solitary retroperitoneal schwannoma.

Key words: Colitis; Neurofibromatosis; Retroperitoneum; Schwannoma

INTRODUCTION

Schwannomas or neurilemmomas are encapsulated tumors arising from the neural sheath of peripheral nerves. They are usually present in the head and neck or in the upper extremities, but may appear in the posterior mediastinum and more rarely in the retroperitoneum. The latter are often found incidentally or may present with vague, non-specific symptoms if the tumor is large enough to compress surrounding structures.

We report a case of a benign retroperitoneal schwannoma with an unusual clinical presentation, its radiological, histopathological and genetic features, and its subsequent management.

CASE REPORT

A 45-year-old woman was admitted to our emergency department for severe colicky abdominal pain with nausea and vomiting that started about 15 min after her last meal. She had no relevant medical history but mentioned having had back pain for the last 2 mo, which she thought was due to her increasing workload and stress at work. She denied having any abdominal problems until that day. On clinical examination, the patient was afebrile, pale and uncomfortable. Blood pressure and heart rate were normal. Abdominal examination showed a diffusely tender abdomen, more pronounced in the left lower quadrant. She had no guarding or rebound. Deep palpation of the abdomen revealed a non-tender, non-pulsatile mass left of the umbilicus. Rectal examination was unremarkable, except for the presence of a little blood. Within the first hour after admission, the patient suffered one episode of diarrhea stained with a moderate amount of fresh blood. Laboratory tests showed an increased white blood cell count

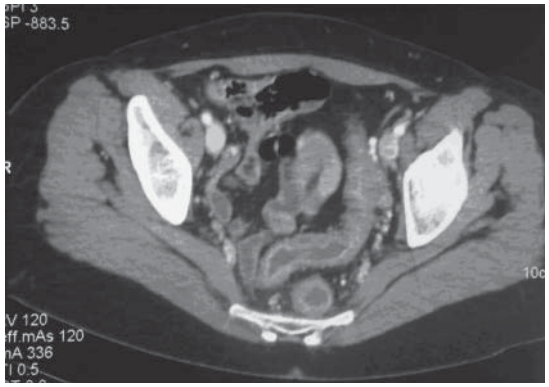

Figure 1 Contrast-enhanced CT scan of the abdomen showing a diffuse infiltration around the rectum and the sigmoid colon, and thickening of their walls.

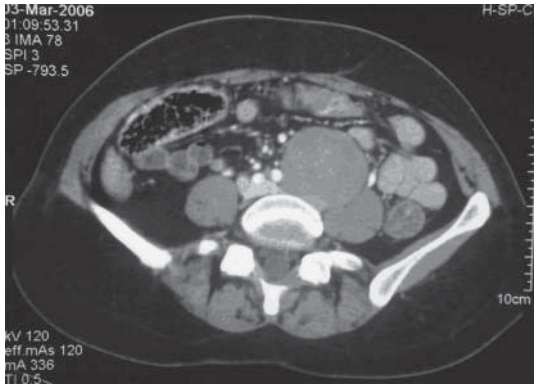

Figure 2 Well-demarcated, homogeneous mass measuring 60×50 mm in close proximity to the left iliac artery, lumbar vertebrae and psoas muscle, on contrast-enhanced CT scanning.

Figure 3 Coronal T_1-weighted MR image using gadolinium, showing a solid mass with the same features as seen with CT scanning.

Figure 4 Perioperative examination of the mass revealed a solid, greyish, ovoid tumor with a smooth capsule and a homogeneous yellow core.

(WBC) of 18 000 cells/mm³ and C-reactive protein (CRP) of 1.1 mg/dL. Other values were within the normal range. At this point our differential diagnosis included diverticulitis and a contrast-enhanced computed tomodensitometry (CT) of the abdomen was performed. It revealed a diffuse infiltration around the rectum and the sigmoid colon, and a thickening of their walls (Figure 1). No diverticula were found. It also showed a well-demarcated, homogeneous, left para-aortic mass lying between the lumbar vertebrae and the left psoas muscle, which measured 60 × 50 mm (Figure 2). With few specific findings, the scan was considered inconclusive.

She was hospitalized and received isotonic fluid resuscitation, and intravenous broad-spectrum antibiotics were commenced. Symptoms improved rapidly and disappeared almost completely 3 d after the initial complaints. During her hospital stay, several examinations were performed. First, the patient underwent colonoscopy to exclude inflammatory bowel disease (IBD). It revealed a diffusely edematous, slightly erythematous rectum and sigmoid colon, but no erosive or ulcerative lesions. Histopathological examination of biopsies taken during colonoscopy showed diffuse edema and signs of chronic inflammation, characterized by the presence of mostly lymphocytes and polynuclear granulocytes. Granulomas were absent. A few cryptic abscesses and zones of erosion were also found. The pathologist's diagnosis was chronic colitis, more pronounced in the sigmoid colon than the left colon, and excluded IBD. In laboratory tests, WBC had fallen to a normal value at 9780 cells/mm³ after a rise to 12 000. CRP level followed the same course to settle at 1.7 mg/dL, after it had risen to 10.8. Tumor markers CEA and CA 19.9 were within the normal range. Magnetic resonance imaging showed the same features as seen with CT scanning (Figure 3).

Since we believed that the mass caused the patient's signs and symptoms, we opted for open surgical excision. We approached the retroperitoneal space through a median laparotomy. During exploration and meticulous dissection of the mass, we noticed that it was in close proximity to the aorta and left iliac artery and vein, and seemed to arise from the left para-aortic sympathetic chain. It also adhered partially to the left psoas muscle and to the anterior aspect of the lumbar vertebrae. Complete excision was performed. Perioperative examination of the mass revealed a solid, greyish, spherical tumor with a smooth capsule and a heterogeneous core (Figure 4).

The postoperative course was uneventful. We noticed that the left leg was slightly warmer and dryer than the right, which suggested that we had performed a left lumbar sympathectomy, thus in favor of the excision of a tumor of neural origin. Microscopic histopathological examination revealed strings of spindle cells surrounded by a collagenous stroma that was partially hyalinized and showed cystic degeneration in some regions (Figure 5). There was some nuclear atypia with very limited mitotic activity, but

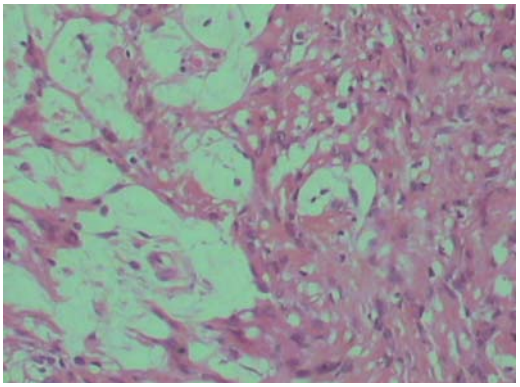

Figure 5 Antoni A area on the right (well-organised spindle cells in a palisade pattern) and Antoni B area (less cellular, loose pleomorphic cells) on the left (HE, × 200).

no signs of malignancy. The tumor tested intensely positive for S-100 protein, which confirmed the diagnosis of benign schwannoma. The integrity of the capsule was also noted, which confirmed total excision of the mass. The patient was discharged from the hospital on the fifth postoperative day.

Six weeks after surgery, she was still symptom free and signs of sympathectomy persisted. A CT scan and colonoscopy were performed to evaluate the evolution of colitis, which had completely resolved. Further investigations were performed to exclude neurofibromatosis type Ⅱ (NF2) or schwannomatosis. Thorough physical examination was performed on the patient but no superficial tumors were found. Family history for schwannoma or meningioma was negative. MRI did not show any tumor of the central nervous system. Furthermore, the presence of a germline *NF2* mutation was excluded by thorough mutation analysis on DNA extracted from the patient' s lymphocytes. We performed direct sequencing of all coding exons of the *NF2* gene. Deletion was excluded by multiplex ligation-dependent probe amplification (MLPA). We concluded that the schwannoma was most likely due to a somatic mutation in the *NF2* gene.

DISCUSSION

Schwannomas, or neurilemmomas, are tumors arising from the Schwann cells of peripheral nerves[1,2]. They are usually found in the head and neck or in the upper extremities. Only 1% is found in the retroperitoneum, which accounts for 0.5%-1.2% of all retroperioneal tumors[3,4]. They can be isolated as sporadic lesions or associated with schwannomatosis or NF2. Although they vary in biological and clinical behavior, their presence is in nearly every case due to alterations or absence of the *NF2* gene (located on chromosome 22q12), which codes for *merlin*, a tumor suppressor protein involved in the growth regulation of Schwann cells, but its exact mechanism has not yet been elucidated. Most schwannomas are benign but (although very rarely) malignant degeneration can occur, and is usually associated with NF2[5]. Patients with benign retroperitoneal schwannomas are predominantly in their second to fifth decade, and women are twice as often affected as men[4,6].

On gross appearance, schwannomas are well-demarcated, solid tumors with a smooth surface and have an ovoid or spherical shape[7]. Sometimes, secondary changes such as hemorrhage, cysts and calcification can be present[1]. They are usually solitary and slow-growing tumors[1]. The retroperitoneum is non-restrictive, so that benign tumors are often able to grow to a large size before causing symptoms. These are generally vague and non-specific[7], and range from lumbar pain and neurological symptoms in the lower extremities[8], to renal colicky pain, with or without hematuria, if it involves the urogenital tract[9]. Abdominal complaints can also occur but are mainly vague and poorly localized, with some digestive disturbances[3,10,11]. Our patient's presentation was peculiar, not only because of the abrupt onset of her symptoms, but also because she had colitis. We believe that the tumor was large enough to compromise venous return in the mesocolon, which led to stasis characterized by the infiltration and parietal thickening seen on CT, the edematous and erythematous aspect seen during colonoscopy, and the chronic inflammation with edema seen on histopathological examination. This idea has been strengthened by the fact that those signs disappeared completely after removal of the tumor.

Diagnosis is rarely made preoperatively. The mass seen on the CT scan showed characteristic features of benign schwannoma. It was a well-demarcated, spherical, solitary mass and in a paravertebral position[6]. Contrast enhancement homogeneity was seen because no gross cystic degeneration or calcification had yet occurred. Most authors agree that these features are not diagnostic. Other diagnoses such as paraganglioma, neurofibroma, ganglioneuroma, tumors of mesodermal origin and retroperitoneal malignancies, including malignant fibrous histiocytoma, lymphoma and liposarcoma, should be considered[12,13]. MRI was helpful because it has a better definition, multiplanar capabilities, and the possibility to differentiate the nature of the tumor, such as solid tissue, fibrous tissue, simple or atypical fluid, and blood[14]. It confirmed the presence of a solid, homogeneous mass, and showed its relation to adjacent structures in greater detail[6,15]. No invasive process was revealed and the margins were still regular, convincing us that the mass was benign in nature[16]. Definite diagnosis was made during histopathological examination and immunohistochemistry. Microscopically, the mass showed Antoni A (well-organised spindle cells in a palisade pattern) and B (less cellular, loose pleomorphic cells) areas[1,2], and tested intensely positive for S-100 protein, which is almost exclusively identified within benign nerve sheath tumors[17,18]. CT-guided fine needle aspiration biopsy can be helpful in determining the origin of a mass preoperatively, but is seldom accurate[7]. Since we believed the mass was causing colitis, open surgical excision was performed. Successful laparoscopic removal of retroperitoneal schwannomas has been reported[19], as well as with endoscopic minilaparotomy[20].

Recurrence is rare and probably due to incomplete excision[7,21]. Further investigations were performed to exclude schwannomatosis or NF2. Absence of other schwannomas and lack of family history of schwannoma theoretically excluded both conditions (see diagnostic criteria in Tables 1 and 2). The presence of a germline *NF2* mutation was excluded by a thorough genetic analysis. We performed direct

Table 1 Diagnostic criteria for NF2[22]

Definite NF2
1 Bilateral vestibular schwannomas or
2 Family history of NF2 (first-degree family relative) plus
   a Unilateral vestibular schwannoma at age < 30 yr, or
   b Any two of the following: meningioma, glioma, schwannoma or juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract

Presumptive or probable NF2
1 Unilateral vestibular schwannoma at age < 30 yr plus at least one of the following: meningioma, glioma, schwannoma or juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract
2 Multiple meningiomas (two or more) plus
   a Unilateral vestibular schwannoma at age < 30 yr, or
   b One of the following: glioma, schwannoma or juvenile posterior subcapsular lenticular opacities/juvenile cortical cataract

Table 2 Diagnostic criteria for schwannomatosis[23]

Definite schwannomatosis
1 Two or more pathologically proved schwannomas, plus
2 Lack of radiographic evidence of vestibular schwannoma at age > 18 yr

Presumptive or probable schwannomatosis
1 Two or more pathologically proved schwannomas without symptoms of eighth nerve dysfunction at age > 30 yr or
2 Two or more pathologically proved schwannomas in an anatomically limited distribution (single limb or segment of the spine), without symptoms of eighth nerve dysfunction, at any age

sequencing of all coding exons of the *NF2* gene. Deletion was excluded by MLPA. This mutation detection strategy, ideally performed on the original tumor specimen, allows the detection of a germline mutation in > 90% of NF2 patients with a family history of the disease, and in > 70% of sporadic cases. However, it is probably only justified in sporadic unilateral vestibular schwannoma in patients aged < 20 years, unless other features of NF2 are present[24].

In conclusion, benign retroperitoneal schwannomas are rare tumors arising from the neural sheath of peripheral nerves. They are usually incidental findings but may become symptomatic if sufficiently large. Symptoms are usually vague and non-specific and can mimic different diseases. CT and MR findings show characteristic features, but none are specific. Diagnosis is based on histopathological examination and immunohistochemistry. Total excision is therapeutic and has a good prognosis. Genetic testing for NF2 is probably not justified in the presence of a solitary retroperitoneal schwannoma.

Abstract

There are occasional incidences of gallstone spillage during laparoscopic cholecystectomy, and there have been frequent reports on such a topic in the literature. To the best of our knowledge, however, there have been no reports about spilled stones caused by spontaneously perforated hemorrhagic cholecystitis. Here, we report the radiologic findings of spilled stones caused by spontaneously perforated hemorrhagic cholecystitis in a 55-year-old man.

Key words: Gallbladder perforation; Gallstone spillage; Hemorrhagic cholecystitis

INTRODUCTION

With the increased use of laparoscopic surgery, the spillage of gallstones during laparoscopic cholecystectomy has been reported in 6%-40% of cases[1,2]. To the best of our knowledge, however, there have been no reports about spilled stones caused by spontaneously perforated hemorrhagic cholecystitis. Here, we present ultrasonography (US) and computed tomography (CT) images of this rare condition.

CASE REPORT

A 55-year-old man complained of abrupt upper abdominal pain during hospitalization for a brain abscess. A complete blood count taken 12 h after the attack showed that the level of hemoglobin dropped to 8.8 g/L (from 13.3 g/L, 36 h before the attack). Other blood analysis revealed mild thrombocytopenia (platelet count $106 \times 10^3/\mu L$), and mild hyperbilirubinemia (total bilirubin concentration 1.7 mg/dL); however, the white blood cell count was normal ($9.27 \times 10^6/\mu L$).

Immediately after the attack, the patient underwent US, which demonstrated echogenic material in the gallbladder lumen (Figure 1A), with a positive sonographic Murphy's sign. US was discontinued because the patient complained of severe abdominal pain. Contrast-enhanced CT was performed and its images revealed high-density fluid, both inside and outside the gallbladder. One impacted cystic duct stone was seen, as were several calcified objects (which looked like stones), within the high-density (46-61 HU) fluid surrounding the gallbladder (Figure 1B and C). A defect in the wall or mucosal disruption of the gallbladder was also noted (Figure 1D and E). In addition, underlying liver cirrhosis with splenomegaly was observed. Percutaneous transhepatic gallbladder drainage (PTGBD) and cholangiography were performed. Cholecystography demonstrated contrast leakage from the gallbladder (Figure 1F).

He had a medical history of several years of alcoholic liver cirrhosis with mild esophageal varices and multiple gallbladder stones. Two months before the current attack, he underwent an abdominal CT scan to evaluate liver cirrhosis. At that time, CT revealed multiple stones in the gallbladder, without complications (Figure 1G).

DISCUSSION

Laparoscopic cholecystectomy has become a popular alternative to open surgery for the treatment of gallstones. With the increase in laparoscopic cholecystectomy, the incidence of gallstone spillage has increased, with an incidence ranging from 6% to 40%[1,2]. The complications of peritoneal spilled gallstones are abscess, fistula formation within various intraperitoneal organs, or sinus tract formation[3-7]. To the best of our knowledge, however, gallstone spillage caused by spontaneously perforated hemorrhagic cholecystitis in a patient who did not undergo cholecystectomy has not been reported.

The proposed mechanism of gallbladder perforation is stone impaction in the cystic duct, which leads to retention of secretion from mucus glands and distention, with progressive distention leading to vascular compromise, followed by necrosis and perforation[8]. During this process, bleeding can occur, which results in hemorrhagic chole-

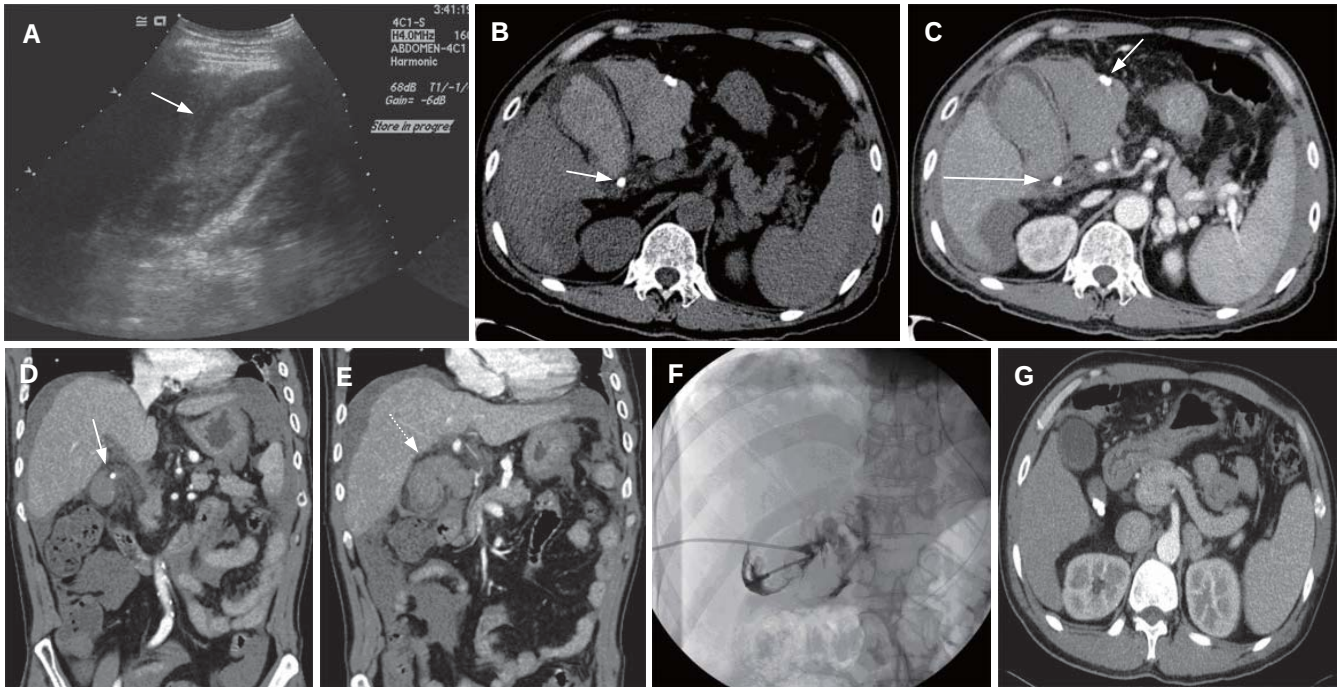

Figure 1 A 55-year-old man with right upper quadrant pain. US images (**A**) demonstrate heterogeneous, highly echogenic material, both within and outside the gallbladder lumen (arrows), with a positive sonographic Murphy's sign. Non-contrast (**B**) and contrast-enhanced (**C**) transverse CT images show high-attenuation (46-61HU) material, both in the gallbladder lumen and pericholecystic space. One stone is seen in the cystic duct (long arrow) and calcified material (with the same appearance as the cystic duct stone) is seen in the fluid collected (short arrow) around the gallbladder. Contrast-enhanced coronal CT images (**D**, **E**) show well the impacted cystic-duct stone (arrow), and the mucosal defect with continuation of hemorrhage (dotted arrow). PTGBD (**F**) with cholecystography demonstrates contrast leakage from the gallbladder. Contrast-enhanced transverse CT images (**G**) taken 2 mo before the current attack show multiple stones in the gallbladder neck without complications.

cystitis with hemoperitoneum. In our case, the patient had liver cirrhosis and therefore the risk of bleeding could have been increased.

In our study, US showed heterogeneous, highly echogenic material, both within and outside the gallbladder lumen, which may have been suggestive of gallbladder perforation with hemorrhage. However, we could not detect the exact perforation site nor spilled gallstones on US, and so we were not able to diagnose gallbladder perforation at that time. CT clearly demonstrated the perforation site at the gallbladder wall and spilled radiopaque stones that were missed on US. It has been reported that distended gallbladder, thickened and bulging gallbladder wall, pericholecystic fluid, cholelethiasis, and gallbladder wall defects are the US and CT findings of gallbladder perforation. The most specific of these findings is gallbladder wall defects, with a detection rate of 38.4% on US and 69.2% on CT[9]. The most common site of perforation is reported to be the fundus (70% of cases), due to poor vascular supply[10].

In conclusion, gallstone spillage due to spontaneous perforation is a very rare condition. However, US or CT visualization of mucosal disruption of the gallbladder wall, with gallstones within hemoperitoneum is suggestive of the condition.

Abstract

Mirizzi syndrome is a rare complication of gallstone disease, and results in partial obstruction of the common bile duct or a cholecystobiliary fistula. Moreover, congenital anatomical variants of the cystic duct are common, occurring in 18%-23% of cases, but Mirizzi syndrome underlying an anomalous cystic duct is an important clinical consideration. Here, we present an unusual case of type I Mirizzi syndrome with an uncommon anomalous cystic duct, namely, a low lateral insertion of the cystic duct with a common sheath of cystic duct and common bile duct.

INTRODUCTION

Mirizzi described a functional hepatic syndrome in 1948, which consists of obstruction of the common hepatic duct secondary to compression by an impacted gallstone in the cystic duct or in the infundibula of the gallbladder (GB) associated with an inflammatory response involving the cystic duct and the common bile duct (CBD), surrounding inflammation, recurrent cholangitis, and spasm of the circular muscular sphincter in the hepatic duct[1]. Mirizzi syndrome (MS) indicates a narrowing of the common bile duct by a gallstone impacted in the cystic duct or a cholecystobiliary fistula. Many cases have so far been reported, and various operations have been suggested depending on the types of MS. Laparoscopic cholecystectomy has become the standard operation for gallstones, and many authors have adopted this operation for type I MS. However, high rates of conversion and bile duct injury indicate that this is not a safe treatment modality for MS, especially when combined with a cystic duct anomaly[2-5]. In this report, we present a case of type I Mirizzi syndrome, complicated by a rare anomalous cystic duct, which was operated with an open procedure.

CASE REPORT

A 34-year-old Korean female presented at our hospital complaining of abdominal pain of 2-d duration. The finding of her physical examination was not remarkable except for tenderness at the right upper abdominal quadrant with a positive Murphy sign. Furthermore, her laboratory findings were not remarkable except for an abnormal liver function: 2.1/1.6 mg/dL bilirubin (total/direct), 126 IU/L alkaline phosphatase, 310 IU/L aspartate aminotransferase, 625 IU/L alanine aminotransferase, and 114 IU/L gamma glutamyl transpeptidase. Ultrasonography (US) revealed multiple gallstones with GB wall thickening and a suspicious 1 cm-sized distal CBD stone. The same findings were also noted on endoscopic ultrasonography (EUS). Endoscopic retrograde cholangiopancreatography (ERCP) was conducted for a closer examination and removal of the CBD stone. However, ERCP showed that the 1 cm-sized gallstone was impacted in an anomalous cystic duct joined with the distal CBD. In addition, a gallstone compressed the CBD at the level of union between the pancreatic and biliary ducts (Figure 1). Mirizzi syndrome with low medial insertion of the cystic duct was preoperatively diagnosed, and endoscopic nasobiliary drainage (ENBD) tube was placed to decompress the biliary obstruction after endoscopic sphincterotomy.

During laparotomy via a right subcostal incision, the GB was found to be shrunken, thickened, and inflamed. The long and dilated cystic duct seen on ERCP was not identified in the operative field, and the GB was strongly attached to the CBD because of chronic inflammation and also possible anomalous union to the CBD (i.e., possibly due to a common sheath cystic duct and CBD). After subtotal cholecystectomy, the remnant of cystic duct was thickened and dilated to about 1.5 cm in diameter. Intraoperative choledochoscopy was performed *via* the

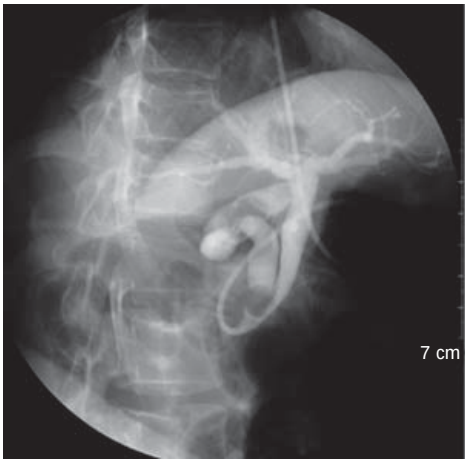

Figure 1 ENBD cholangiogam after endoscopic retrograde cholangiography showing a 1 cm-sized gall stone impacted in a cystic duct joining the extreme lower CBD portion and other stones in gall bladder. Mild CBD dilation was noted due to the presence of a cystic duct stone.

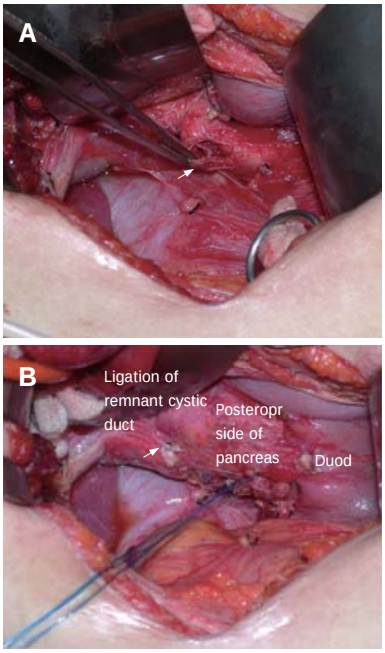

Figure 2 Torn pancreas and intrapancreatic portion of the cystic duct (**A**) and their primary repair (**B**) during lithotripsy of the impacted stone.

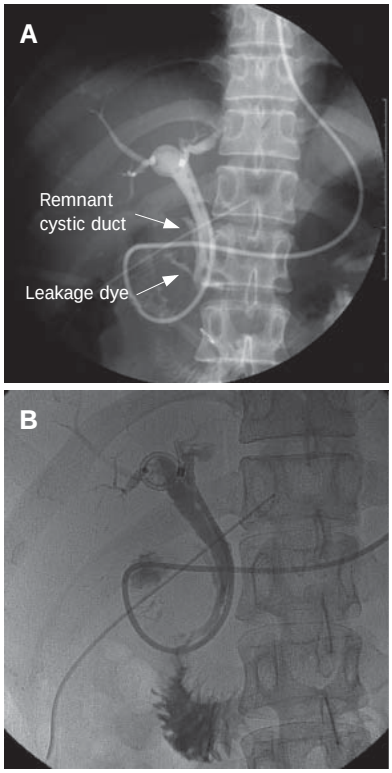

Figure 3 Follow-up ENBD cholangiogram showing minor leakage from the repaired cystic duct on the 7th postoperative day (**A**), but no visible leakage on the 21st postoperative day (**B**).

remnant of cystic duct and the impacted cystic duct stone was visualized. However, lithotripsy with choledochoscopy failed at this time. Another attempt was made to remove the cystic duct stone after duodenum mobilization through the remnant of cystic duct using a stone forceps made. Moreover, during this procedure, the pancreas and intrapancreatic portion of the cystic duct were torn, and the impacted cholesterol stone escaped retroperitoneally from the lacerated intrapancreatic cystic duct and pancreas (Figure 2A). After ligation of the stump of remaining cystic duct and primary repair of the torn cystic duct and pancreas (Figure 2B), intraoperative cholangiography *via* an ENBD tube showed neither leakage nor residual stone. A closed suction type drain was placed in the liver bed and retroduodenal space, and the abdominal wall was then closed. Because the ENBD catheter and endoscopic sphincterotomy were preoperatively performed, they could have played a role in biliary drainage in place of choledochotomy and T-tube insertion. The postoperative course was uneventful, except for minimal drainage from the closed suction drain and minor leakage from the repaired cystic duct, which was visible on the 7th postoperative day on ENBD cholangiography (Figure 3A). After conservative management, no visible leakage was observed from the repaired cystic duct on follow-up ENBD cholangiography on the 21st postoperative day (Figure 3B). After removal of the ENBD catheter, the patient was discharged on the postoperative 23rd d, and has now been doing well for over 3-years.

DISCUSSION

Congenital anatomical variants of the cystic duct are common, occurring in 18%-23% of cases. Among those cases, the cystic duct inserts into the middle third of the extrahepatic bile duct in 75% of cases and into the distal third in 10% of cases. Five types of cystic duct anomaly have been described: a long cystic duct with low fusion with the CHD, abnormally high fusion between a cystic duct and the CHD, accessory hepatic duct, cystic duct entering the right hepatic duct, and cholecystohepatic duct[6-8]. In particular, low medial insertion of the cystic duct deserves special attention, because this anatomical variant may lead to misdiagnosis by imaging studies, thus adversely affecting therapeutic intervention. In addition, anomalous cystic duct may also be a problem at cholecystectomy[9]. In the presently described case, ERCP demonstrated that the biliary obstruction was caused by a cystic duct gallstone in a low medially inserting cystic duct which joined the distal CBD near the ampulla of Vater, but not by a distal CBD stone as indicated by US and EUS.

Zhou[10] reported that 65 (5.9%) among 1100 cases had an abnormal cystic duct and common bile duct

confluence, as determined by ERCP, and he divided cystic duct anomalies into three types, and the very low-sited confluence was found in 9 (13.8%) cases among anomalous cystic ducts. Another study of 50 patients reported a single case (2%) of intrapancreatic confluence[11].

MS is a rare disease entity that accounts for about 0.1%-2.5% of all operations performed for gall bladder stones[12,13]. In 1982, McSherry *et al*[14] classified MS into two types, based on ERCP findings. Type I involves external compression of the common hepatic duct by a large stone impacted in the cystic duct, or the Hartmann's pouch, without any lesion in the gall bladder or common hepatic duct wall. In type Ⅱ, a cholecystocholedochal fistula is present, which is caused by a calculus that has eroded partly or completely into the common duct. In 1989, Csendes *et al*[12] classified MS into four types, and their classification categorized cholecystocholedochal fistula further depending on its extent of destruction. The McSherry classification or the Csendes classification has usually been used by clinicians, because these classifications more usefully guide surgical management.

MS has been highlighted because of its high incidence of iatrogenic biliary injuries and its demand for complex surgical procedures. Preoperative diagnosis of MS is difficult. However, it is important to prevent unexpected intraoperative morbidities, such as bile duct injury.

In the present case, a cystic duct stone was misdiagnosed as a CBD stone by US and EUS. However, in order to evaluate and remove the stone, ERCP was carried out and finally, a cystic duct stone with MS type I combined with a low lying anomalous cystic duct was diagnosed before surgery. Most MS cases have CBD obstruction symptoms such as jaundice (76.5%), which induce surgeons to attend to CBD problems[2]. However, cases not associated with CBD obstruction symptoms may be diagnosed as GB stone requiring only laparoscopic cholecystectomy. In a series reported by Tan *et al*[5], bile duct injuries were observed in 4 (16.7%) of 24 operatively treated patients, and all the 4 injuries occurred in patients without a preoperative diagnosis.

Surgical treatment of MS depends on its type. Although laparoscopic cholecystectomy has almost completely replaced open cholecystectomy for the treatment of symptomatic gallstone disease, laparoscopic cholecystectomy is relatively hazardous in patients with MS, because safe dissection of Calot's triangle is difficult due to severe local inflammations and adhesions[4]. Al-Akeely *et al*[2] reported that 2 of 6 type I MS patients successfully underwent laparoscopic partial cholecystectomy with an endo-GIA stapler. However, the procedure was converted to an open procedure in the remaining 4 patients. Schafer *et al*[4] reported that conversion to an open approach was needed in 24 of 34 patients (74%) with type I MS and in all 5 patients with type Ⅱ MS.

In the present case, open cholecystectomy was performed for MS combined with a cystic duct anomaly. However, bile duct injury occurred during removal of the impacted cystic duct stone. Thus, we would like to advise that, if MS combined with a cystic duct anomaly is diagnosed before surgery, the operator should not hesitate to perform open surgery and dissect carefully, while considering anatomical deformities associated with chronic inflammation. Moreover, intraoperative cholangiography should be performed to minimize the risk of biliary injury.

Abstract

The ingestion of a foreign body that penetrates the gastric wall and migrates to the liver, where it causes an abscess is uncommon. A case of an ingested rosemary twig perforating the gastric antrum, then migrating to the liver, complicated by hepatic abscess and Staphylococcus aureus sepsis is reported. A 59-year-old man without a history of foreign body ingestion was admitted to our hospital because of sepsis and epigastralgia, which had progressively worsened. No foreign body was identified at preoperative imaging, but a rosemary twig was discovered during laparotomy. The liver abscess and sepsis were controlled successfully with surgery and antibiotics. This unusual condition should be kept in mind when dealing with cases of hepatic abscess, or even sepsis of unknown origin. Despite the improvement of non-surgical techniques such as percutaneous drainage and interventional endoscopy, surgery still remains important in the treatment of hepatic abscess caused by an ingested foreign body.

Key words: Foreign Body; Gastrointestinal perforation; Hepatic Abscess; Ingestion; Migration

INTRODUCTION

The first case of hepatic abscess as a result of gastrointestinal tract (GIT) perforation caused by a foreign body was published by Lambert in 1898[1]. Most foreign bodies pass through the GIT without causing any damage once they pass the lower esophageal sphincter[2]. It is not unusual to come across patients in clinical practice with GIT perforation due to ingested foreign bodies, but the development of a secondary hepatic abscess due to foreign body perforation of the gastric wall is a rare condition[1-4]. In the majority of cases, an early diagnosis is difficult to make because of the non-specific clinical presentation[3].

CASE REPORT

A 59-year-old man presented with epigastric, right upper abdominal pain and intermittent high-grade fever, with chills and rigors for the past 2 mo. There was no history of foreign body ingestion. He had received treatment for his fever of unknown origin at a district hospital in the form of antibiotics (ceftriaxone, 2.0 g daily) and antipyretics. On admission, examination revealed a septic, high-grade febrile patient (38.9℃) with tachycardia (pulse 128 bpm) and tachypnoea (21 breaths/min). The white blood cell count was 28.8 × 10^9/L, alkaline phosphatase was 180 U/L, bilirubin was normal, and C-reactive protein (CRP) was 320 mg/L. The abdomen was tense with tenderness in the epigastrium and right hypochondrium, without any signs of peritoneal reaction. Chest X-ray revealed a right-sided pleural effusion, but X-ray of the abdomen was normal. Ultrasound (US) examination, contrast-enhanced computerized tomography (CT) (Figure 1) and magnetic resonance imaging (MRI) of the abdomen (Figure 2) revealed a hepatic abscess of 11.7 cm × 10.3 cm × 8.8 cm in the segments S4b-S5. The patient was started on meropenem and subjected to exploratory laparotomy, which revealed a huge abscess occupying the central segments of the liver, and concomitant acute calculous cholecystitis. There was no association between the inflammatory process in the gallbladder and abscess formation. After cholecystectomy, hepatotomy along the gallbladder bed was performed, and about 500 mL of pus

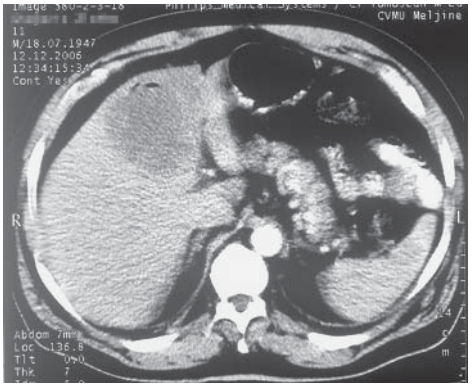

Figure 1 CT scan of the abdomen demonstrating a liver abscess containing a small amount of gas.

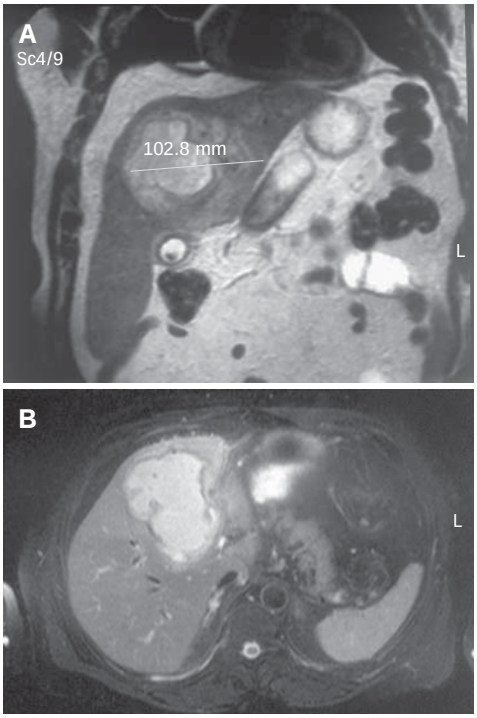

Figure 2 MRI of the abdomen showing the abscess in liver segments S4b-S5. (**A**) T2W coronal view; (**B**) T2W axial view.

was drained and a rosemary twig of 4.5 cm was retrieved from the abscess cavity (Figure 3). Since there was no obvious fistulous communication between the liver and stomach or duodenum, a careful examination of the upper GIT revealed a small covered perforation of the gastric antrum wall. The perforation was repaired by using single-layer interrupted sutures (Figure 4). The abscess was also drained with a triple-tube lavage system. Vancomycin was added postoperatively due to subsequent blood culture that showed Staphylococcus aureus. The patient recovered uneventfully and was discharged on postoperative d 10.

DISCUSSION

The reported incidence of foreign bodies penetrating the GIT is < 1%[1,2,5], with the objects being pointed or sharp in most cases, such as sewing needles, tooth picks, and

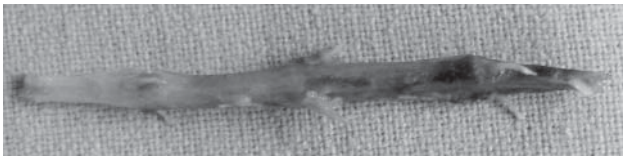

Figure 3 Rosemary twig after retrieval from the hepatic abscess.

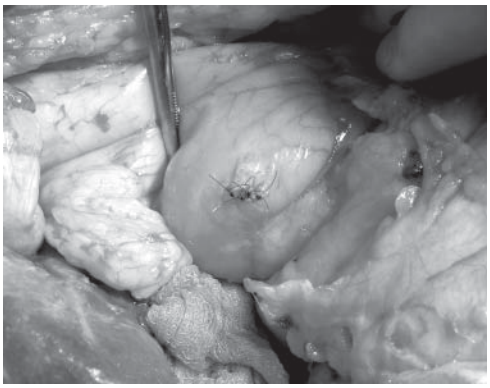

Figure 4 Repair of the perforation site in the gastric antrum.

chicken and fish bones[5-8], pens, toothbrushes and dental plates[9-11].

The most common sites of perforation of the GIT are the stomach and duodenum[1-3]. Abscess formation occurs more often on the left hemiliver[2,3]. The ingestion of a foreign body that penetrates the GIT wall and migrates to the liver, where it causes an abscess is indeed rare, with 46 cases being reported in the recent literature[3]. No report of hepatic abscess caused by ingestion of a rosemary twig (used for food flavoring), has been found so far in the medical literature.

The classical presenting features of hepatic abscess, such as fever with chills, abdominal pain and discomfort, and jaundice are present in only a small number of patients[1-4]. Most patients have non-specific symptoms such as anorexia, vomiting or weight loss with leucocytosis[6-9], or increased transaminases, bilirubin or alkaline phosphatase[10,11]. The migrating foreign body may remain silent for a long time and may only be discovered if there are features of infection or abscess formation[1]. The presentation of a penetrating foreign body (tooth pick) as a granulomatous liver abscess has been reported 1 mo after ingestion, requiring partial lateral resection of the liver[8]. The prolonged time course of the illness, the lack of history of foreign body ingestion, the relatively non-specific symptoms and signs, and the non-specific results obtained by using conventional radiography have resulted in delayed recognition of this possibly fatal diseas [4]. Deaths caused by missed or delayed diagnosis have been reported, one of which was discovered on autopsy[12-14]. Thus, both a high clinical suspicion index and prompt treatment are necessary for this rare condition[1-3,11-15]. An ingested foreign body may be identified with plain X-rays of the abdomen, if the body is radio-opaque. Other methods of foreign body identification include US, CT, MRI, upper GIT endoscopy, colonoscopy,

and laparotomy[8,15-16]. Endoscopy may be helpful when performed early, before the foreign body migration and mucosal healing[3,7].

The recommended treatment is exploratory laparotomy to evacuate the hepatic abscess, remove the foreign body, and repair the perforation site in the GIT[1-3,16]. Since the gastric perforation is small and is probably covered by the omentum or hepatic lobe, minimally invasive treatment such as percutaneous drainage of the pus collection, combined with endoscopic removal of the foreign body, can be employed to reduce open surgery[2,9]. Also, the successful treatment of hepatic abscess and foreign body removal by the percutaneous transhepatic approach has been reported[10].

In conclusion, we report a very rare case of the migration of an ingested rosemary twig into the liver through the stomach, which resulted in hepatic abscess and sepsis. Due to the lack of obvious fistulous communication between the liver and upper GIT, careful exploration of the abscess cavity is of great importance. This condition should be kept in mind when dealing with cases of hepatic abscess, or even sepsis of unknown origin. Therefore, an early diagnosis and prompt intervention are optimal for treatment and necessary to avoid death. Despite the improvement of non-surgical techniques such as percutaneous drainage and interventional endoscopy, surgery still remains important in the treatment of hepatic abscess caused by an ingested foreign body.

Abstract

Carcinosarcomas are rare, malignant, biphasic tumors. We report the case of a 62-year-old man with gastric carcinosarcoma, along with its clinical, macroscopic and histopathological features. Macroscopically, a specimen of deformed stomach was obtained that measured 200 mm × 150 mm × 100 mm. A 150 mm × 100 mm × 50 mm exophytic tumoral mass (Borrmann type Ⅰ) was found, which involved the posterior wall from the cardia to the antrum. Histopathologically, a mixed type of malignancy was revealed: an adenocarcinoma with intestinal metaplasia, with interposed fascicles of fusiform atypical cells and numerous large, rounded and oval cells. The tumor showed positive histochemistry for cytokeratin 18, epithelial membrane antigen, carcinoembryonic antigen, chromogranin A and vimentin. Liver metastases were diagnosed 8 mo postoperatively, and the patient died 4 mo later. A review of the available literature is also presented.

http://www.wjgnet.com/1007-9327/13/5533.asp

INTRODUCTION

Carcinosarcomas are rare, malignant, biphasic tumors. In the upper gastrointestinal tract, they are most frequently observed in the esophagus, while localization in the stomach has been less frequently reported[1-3]. We present the case of a 62-year-old man with gastric carcinosarcoma, along with its clinical, macroscopic and histopathological features.

CASE REPORT

The patient was a 62-year-old man admitted for surgery with a 2-mo history of blunt epigastric pain, nausea, loss of body weight and intermittent bleeding from the upper gastrointestinal tract. His and his family medical history was unremarkable.

Upon admission, the patient was in a forced position, bent anteriorly with a facial expression of pain. General examination revealed marked pallor, and tenderness in the epigastric region, radiating to the right side of the anterior abdominal wall. In the space of Labbé, an elastic, resistant, fixed mass was palpated. Routine laboratory parameters were found to be normal, except for markers of hypochromic anemia and inflammation: hemoglobin 100 g/L, hematocrit 26%, mean corpuscular volume (MCV) 78 fL, iron blood level 6.8 μmol/L, iron-binding capacity 84 μmol/L, saturation 8%, plasma fibrinogen 6.9 g/L, and erythrocyte sedimentation rate 85 mm at the end of the first hour (Wintrobe). The concentration of CA 72.4 was 110 U/mL.

Endoscopic examination revealed an exophytic, lobulated mass that infiltrated the entire posterior wall of the stomach, from the cardia to the antrum, obturating the gastric lumen throughout. An endoscopically taken biopsy revealed signs of carcinosarcoma, with strongly expressed adenomatous and fibromatous components. Barium-based contrast radiography revealed a satisfactorily passable pyloric canal, despite the initial antral obturation. Computerized abdominal tomography (Figure 1) detected an irregular inhomogeneous, prominent tumorous formation (120 mm × 80 mm × 50 mm) in the stomach, with enlarged solitary lymph nodes of up to 2 cm disseminated along the minor and major gastric curvatures. The patient subsequently underwent total gastrectomy with Roux-en-Y esophagojejunostomy and extirpation of the affected lymph nodes. Macroscopically, a specimen

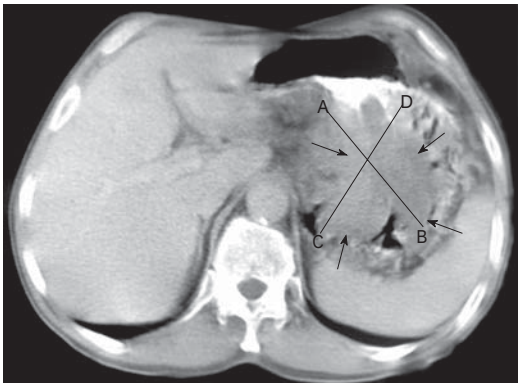

Figure 1 CT scan of the abdomen showing tumor (arrows). AB, CD: tumor diameters.

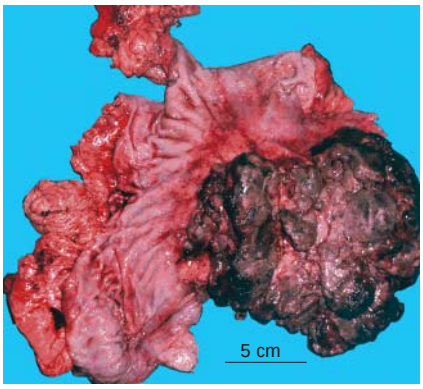

Figure 2 Macroscopic specimen obtained during surgery. Tumor underwent central necrosis, and a hemorrhagic zone is visible on the periphery.

of deformed stomach that measured 200 mm × 150 mm × 100 mm was obtained. A 150 mm × 100 mm × 50 mm exophytic tumoral mass (Borrmann type Ⅰ) was found, which involved the posterior wall from the cardia to the antrum. Areas of necrosis and haemorrhagia were observed in the tumor (Figure 2). The tumor did not invade the esophagus or duodenum, and metastases to other organs were not observed (TNM stage ⅢA).

Histopathologically, the tumor involved all the layers of the gastric wall. The malignancy had two components, epithelial and mesenchymal. The epithelial component consisted of irregular, dilated adenomatous structures, along with a low cylindrical epithelium, with atypical, pleomorphic hyperchromatotic or vesiculous nuclei and detectable nucleoli. Between the glandular formations spread the mesenchymal component, consisting of fascicles of fusiform atypical cells and numerous large, rounded and oval cells, with extremely pleomorphic, hyperchromatic nuclei. Among the aforementioned, multiple atypical, multinuclear giant cells with bizarre hyperchromatotic nuclei and spotted vacuolated cytoplasm were scattered (Figure 3A and B). The epithelial component showed positive histochemistry for cytokeratin 18 (Figure 4), epithelial membrane antigen (EMA) and carcinoembryonic antigen (CEA). Chromogranin-A-positive epithelial cells were also observed. The mesenchymal component showed intensive staining for vimentin (Figure 5), although neither muscular nor neural differentiation was found. No *H pylori* was seen.

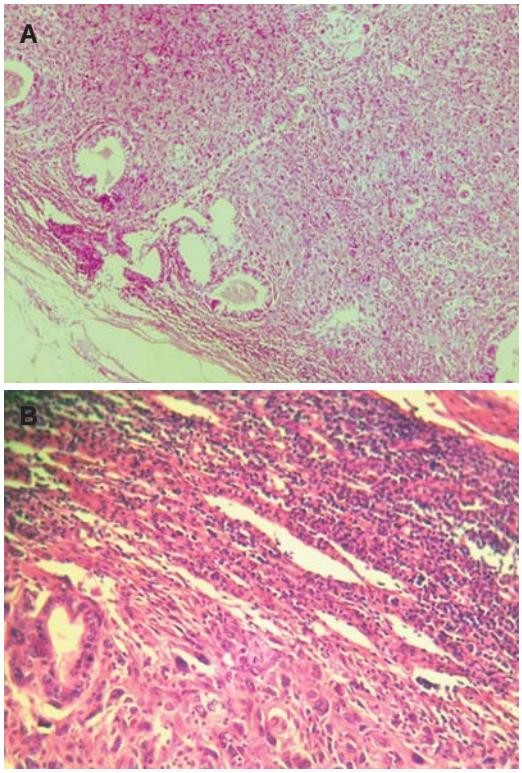

Figure 3 Massive lymph node infiltration with tumor cells. Only a few tubules can be seen on the lymph-node periphery. In between and all around, large polygonal cells are haphazardly arranged (sarcomatous component). This appearance resembles that of the main tumor mass. **A**: hematoxylin-eosin (HE), × 50; **B**: HE, × 100.

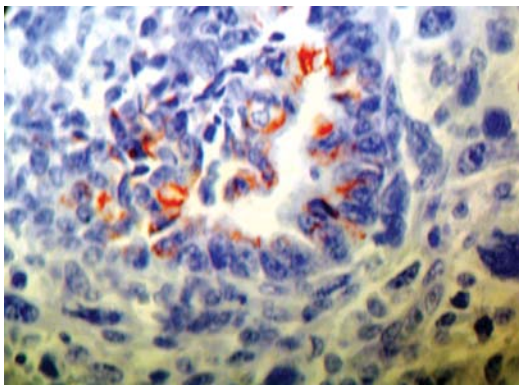

Figure 4 Cytokeratin-18-positive epithelial cells arranged in tubules (× 400).

The patient was discharged on the fifteenth postoperative day in a very well condition. Eight months after operation, liver metastases were observed on CT scanning, but his Karnofsky performance status (50) and Eastern Cooperative Oncology Group performance status (3) did not allow the administration of chemotherapy, and therefore he only received symptomatic medications. He died about 4 mo later.

DISCUSSION

In this paper, we presented the case of a patient with stomach carcinosarcoma, with simultaneous occurrence of moderately to well-differentiated adenocarcinoma

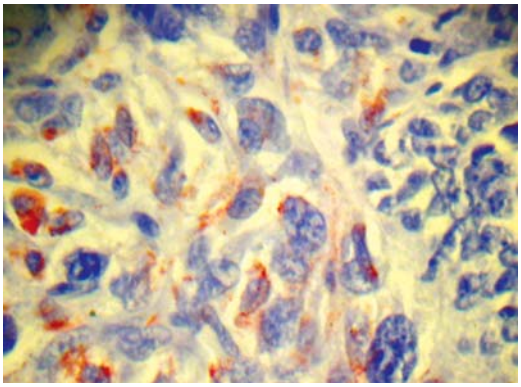

Figure 5 Vimentin-positive polygonal tumor cells (× 400).

and traces of neuroendocrinous, chromogranin-A-positive elements, combined with a vimentin-positive mesenchymal component. To the best of our knowledge, this is the first case of gastric carcinosarcoma seen in this part of the world. According to the available sources, about 50 cases of gastric carcinosarcoma have been reported so far, mostly in Japan and predominantly in the male population, mostly over the age of 60 years[4-6]. An Italian group has experienced five cases of synchronous occurrence of adenocarcinoma and stromal tumor during a 10-year period[7]. Carcinosarcomas in the stomach may be polypoid, exophytic or endophytic, with generally ulcerated surfaces, and they frequently infiltrate the gastric wall in the antral or pyloric region, and form large tumor masses[2,4,7]. Intestinal adenocarcinoma is predominant, but carcinoid and endocrinous or neuroendocrinous elements have been observed during the synchronous appearance of carcinoma and sarcoma in the stomach, while the sarcomatous component can vary between myoblastic, rhabdomyoblastic, chondroblastic and osteoblastic differ entiation[2,5,6,8-11]. Metastasis of carcinosarcoma, however, may be entirely carcinomatous, sarcomatous or biphasic in appearance[4].

Immunocytochemistry seems to be the gold standard for diagnosis of carcinosarcoma, because contrast-based radiography, computerized tomography (CT) and even endoscopy appear to be less efficient, and occasionally, even standard light microscopy is not adequate. Therefore, CEA, EMA, pancreatin, chromogranin A, CD56 and synaptophysin staining are highly specific markers for the carcinomatous components, while desmin, vimentin and α-smooth muscle/sarcomeric actin show affinity for the sarcomatous elements[5,12].

Therapy of carcinosarcoma is always radical and comprises partial or total gastrectomy with Roux-en-Y deviation of one of the jejunal loops, although some complications might appear in the postoperative period[13,14]. Some experimental studies reported possible tumor reduction following treatment with methionine/valine-depleted enteral nutrition, although its efficacy in humans is ambiguous and remains to be established[15].

Prognosis of carcinosarcoma in the stomach is poor[6], and patients with gastric endocrine cell carcinoma have a poorer prognosis than those with other types of gastric carcinoma. The mean survival period is estimated to be 10-15 mo, and overall tumor recurrence in the first postoperative year is greater than 50%[5,9,12].

With respect to the histogenesis of carcinosarcoma, two hypotheses have been proposed. Some authors have suggested that carcinosarcoma is derived from a single totipotential stem cell that has the ability to pursue both epithelial and mesenchymal differentiation[14]. There is no strong evidence that *H pylori* infection influences the appearance of carcinosarcoma[7,14].

In conclusion, carcinosarcoma of the stomach is a rare tumor with high malignant potential, often of unclear etiology. At present, no clinical tests are available for early diagnosis (MRI, barium-based gastrography). The gold standard for definitive diagnosis is immunohistochemical staining of endoscopic biopsy. The possibilities for therapy are confined to radical Roux-en-Y esophagojejunostomy, and recurrence of the tumor can be expected within the first postoperative year.

Abstract

Perivascular epithelioid cell tumor (PEComa) is a rare tumor which arises from mesenchymal tissues. It is predominant in the uterus, but very rare in the liver. To the best of our knowledge, less than 5 cases of PEComa of the liver have been reported. Herein we present two pathologically proven cases of PEComa of the liver, retrospectively analyze their clinical and imaging features, and review the literature.

Key words: Liver; Neoplasm; Tomography, X-ray computed; Magnetic resonance imaging

INTRODUCTION

Perivascular epithelioid cell tumor (PEComa) is a rare tumor which arises from mesenchymal tissues. The uterus is the predominant site, but it is very rare in the liver[1-3]. To the best of our knowledge, less than 5 cases of PEComa of the liver have been reported[2,3]. Herein we present two pathologically proven cases of PEComa of the liver, retrospectively analyze their clinical and imaging features, and review the literature.

CASE REPORT

Case 1

A 56-year-old woman complained of abdominal distention for a week. The laboratory examinations were normal. Ultrasonography found a mass in the superior segment of left lateral lobe of the liver. Non-enhancement CT showed a round isodense mass in the Ⅳ segment of the left liver with ill-demarcated margin. There was no evidence of fatty density, calcification and necrosis in the mass. On contrast enhancement CT, a well demarcated mass, sized 5.1 cm × 4.2 cm, was found with significant and heterogeneous enhancement (Figure 1A). It was more strikingly enhanced on portal venous phase than on arterial phase. Focal nodular hyperplasia (FNH) or adenoma of the left liver was considered before operation. After operation, pathological diagnosis was established as PEComa of the left liver (Figure 1B). Neither primary recurrence nor metastasis was found during the 2-year follow-up.

Case 2

A 63-year-old woman was found to have a mass of liver incidentally in physical examination. Blood, stool and urine routines were normal. Pre-contrast CT scan revealed a lower density mass in the lobus caudatus with a well demarcated margin and homogeneous density. Contrast-enhanced CT showed significantly and heterogeneously patchy enhancement of the lesion on arterial phase (Figure 2A), being slightly hypodense on delayed CT scan. On T1-weighted images, a round homogeneous hypointense mass in the lobus caudatus was found. On T2-weighted images (Figure 2B), the mass had mildly heterogeneous high-signal intensity with a well-demarcated margin. After contrast enhancement, the mass had striking and homogenous enhancement on arterial phase and venous phase. The diagnosis was FNH or HCC of the liver before operation. The gross appearance of the tumor was a smooth, grey and brown lesion with a capsule. The tumor cells were polygonal with eosinophilic cytoplasm. The final diagnosis was PEComa of the liver. Neither primary recurrence nor metastasis could be found during the 1-year follow-up.

DISCUSSION

The term "PEComa" was introduced by Zamboni *et al* in 1996[4]. In 2002 and 2003, two monographs published under the auspices of the World Health Organization (WHO) recognized a family of neoplasm with perivascular epithelioid cell differentiation and accepted the designation "PEComa"[5]. In the WHO soft tissue volume, PEComas are defined as "mesenchymal tumors composed of histologically and immunohistochemically distinctive

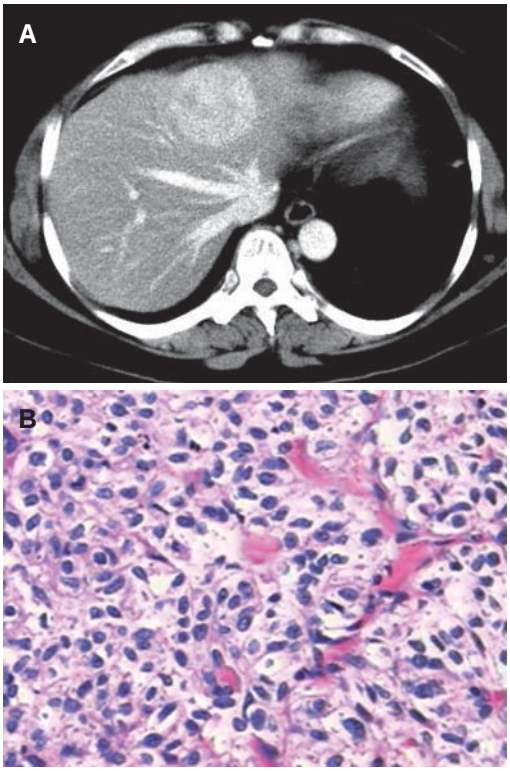

Figure 1 The PEComa of the liver in a 56-year-old woman. **A**: Contrast-enhanced CT scan shows significant and heterogeneous enhancement of the lesion; **B**: Photomicrograph shows polygonal or short spindle cells with oval nuclei and clear abundant cytoplasm (HE, × 200).

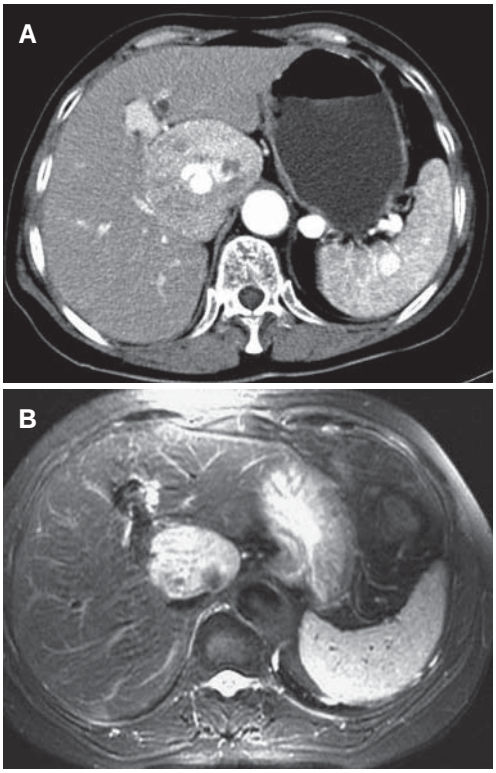

Figure 2 The PEComa in the lobus caudatus of the liver in a 63-year-old woman. **A**: Contrast-enhanced CT scan demonstrates a tumor in the lobus caudatus; **B**: Axial T2-weighted (7058/84) MR image shows a hyperintense mass with well-demarcated tumor margins.

perivascular epithelioid cells (PECs)"[5].

PECs are characterized by perivascular location, often with a radial arrangement of cells around the vascular lumen. Typically, PECs in an immediate perivascular location are most epithelioid and spindle cells resembling smooth muscle are seen away from vessels[5]. The PEC is characterized by positivity with melanocytic markers, such as HMB-45, Melan-A and microphthalmia transcription factor. Desmin is less often positive and cytokeratin and S100 protein are usually absent[5].

PEComas have been reported in the uterus, falciform ligament, gastrointestinal tract, kidney, pancreas, pelvic sidewall, skull, vulva, prostate, thigh, common bile duct and heart. It now appears that PEComas may potentially arise from any anatomic location, but the uterus is the predominant site. Of the 51 cases of PEComa that have been documented in the literature, 46% (21/51) were described in the uterine corpus and 90% developed in females[5]. The PEComas of the liver are extremely rare, and only 5 cases have been reported to date[6].

Clinical presentation of hepatic PEComa has no specificity. It is often found accidentally in physical examinations. But in other organs, the clinical presentation of PEComa might be significant, for example, uterine PEComa may induce uterine bleeding strikingly. Sometimes, a mass can be touched in the PEComa of the lower digestive system and soft tissues.

It is very difficult to make correct diagnosis of PEComa of the liver preoperatively. It is often misdiagnosed as hepatocellular carcinoma, hemangioma, FNH, adenoma and angiomyolipoma. Imaging modalities may be useful because they can help to differentiate PEComa from hepatocellular carcinoma. But the final diagnosis can only be made by pathology.

Clear criteria for malignancy in PEComas have not been elaborated, due to their rarity[5], but there have been a few reports about the tumor metastases[6,7]. On the basis of prior reports, it appears that PEComas displaying any combination of infiltrative growth, marked hypercellularity, nuclear enlargement and hyperchromasia, high mitotic activity, atypical mitotic figures, and coagulative necrosis should be regarded as malignant[5,8]. Malignant PEComas are aggressive sarcomas that frequently result in the death of affected patients, therefore, a close and long-term clinical follow-up is suggested.

Abstract

Infection with tapeworms is a major problem in many parts of the world. Patients may be asymptomatic or have a significant morbidity depending on the species. Infection with *Taenia* species is sometimes found by expulsion of eggs or proglottids in stool. Species specific diagnosis of *Taenia* is difficult, but possible. We present a case of *Taenia saginata* incidentally discovered, and risk factors for transmission, diagnosis, symptoms, and treatment.

Key words: *Taenia saginata*; colonoscopy; Tapeworm

TO THE EDITOR

A 63-year-old Lebanese male presented for routine surveillance colonoscopy of polyps. He denied abdominal pain, hematochezia, weight loss, or change in bowel habits. Physical examination and laboratory studies including a complete blood count were normal. While withdrawing the scope, the following item was seen (Figure 1).

The linear white object represented a parasite. On endoscopic examination, it was found to move within the colon. When retrieved and further analyzed, it was found to be a proglottid of *Taenia saginata*, the beef tapeworm. The scolex and majority of the worm are present in the small bowel, with the head usually residing in the jejunum or ileum. Each segment, known as a proglottid, has a complete set of reproductive organs. The adult worm may have hundreds to thousands of proglottids. The more distal the proglottids are, the more mature they are, containing an increasing number of eggs. *Taenia* species bud off distal segments from the rest of the body that are passed through the feces. The mature *T. saginata* tapeworm can reach 4-6 meters or more in length, and has 1000-2000 proglottids. The scolex has 4 suckers, but no hooks. In contrast, the mature T. solium, or pork tapeworm can reach 2-4 meters or more in length, and has 800-1000 proglottids. The scolex has 4 suckers and a small rostellum with a double crown of 25-30 small hooks[1].

Finding eggs or proglottids in the stool makes the diagnosis of *Taenia* infection. The eggs of *T. saginata* are indistinguishable from *T. solium*, and a species specific diagnosis requires examination of a proglottid segment. The microscopic differentiation of gravid *T. saginata* proglottids (usually more than 15 lateral uterine branches, vaginal sphincter muscle, and two ovarian lobes) and *T. solium* proglottids (usually 5-10 uterine branches on each side, vaginal sphincter muscle absent, one ovarian lobe) is possible. This is the only practical method that can be used in a basic laboratory if only gravid proglottids passed out in stool are present for diagnosis. The presence of a vaginal sphincter muscle in the proglottid can identify the organism as *T. saginata*. The presence of 2 ovarian lobes is also a specific trait of *T. saginata*. Following antihelminth therapy, the scolex is shed and in some cases may be retrieved. The absence of hooks on the scolex is a characteristic of *T. saginata*[2]. If findings are doubtful, the differentiation should be done in a specialized helminthological laboratory by enzyme electrophoresis, polymerase chain reaction (PCR), or various immunological assays[3].

The beef tapeworm is a common infection of both humans and cattle throughout the world, particularly in areas wherever beef is eaten. Areas of high prevalence are sub-Saharan African, southeast Asia, and the Middle East. Infection is associated with eating raw beef, poor sanitation, and allowing cattle on pastures fertilized by sewage sludge contaminated with human feces[4]. Lifecycles for *Taenia* involve two mammalian hosts, a carnivorous or omnivorous host, and a herbivorous intermediate host. In the tapeworm life cycle, humans are the final host and infections are acquired by ingesting raw or undercooked meat containing the cysticercus stage in a host capsule. When the cysticercus stage reaches the stomach, proteolytic enzymes start dissolving the capsule. In the small intestine, the cysticercus is stimulated to evaginate. The scolex attaches to the intestinal mucosa by means of 4 suckers and starts growing into a mature tapeworm.

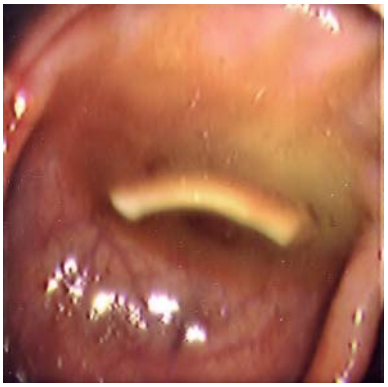

Figure 1 Endoscopic examination showing a parasite (a proglottid of *Taenia saginata*) moving in the colon.

Mature tapeworms have been known to live in the human gastrointestinal tract for up to 25 years[1]. Upon further questioning, our patient noted that he frequently ate raw beef in his native country.

Most patients who carry an adult *T. saginata* tapeworm are asymptomatic. The only symptom found in such a patient may be the spontaneous passage of proglottids. Nonspecific symptoms such as abdominal discomfort, epigastric pain, nausea, vomiting, diarrhea, and weight loss are known to occur[1], but these symptoms are rare. Obstruction of the appendix, pancreatic duct, or common bile duct by proglottid segments has been reported[1]. The occurrence of weight loss and malnutrition is extremely rare. B12 deficiency and megaloblastic anemia are not seen in *Taeniasis*, and associated with *Diphyllobothrium* species found in fish species. B12 deficiency is thought to occur as a result of the ability to compete with the human host for vitamin B12.

While the adult form of *T. saginata* generally does not lead to serious complications, juvenile forms of other tapeworm species may lead to such complications. Ingested ova from *T. solium*, the pork tapeworm, can form cysticercosi in the brain, subcutaneous tissue, skeletal muscle, eye, or other organs causing a significant morbidity. The life cycle of *T. solium* includes pigs that are the intermediate host because they develop the larval stage and transmit the parasite when human beings ingest insufficiently cooked pork[5]. It is endemic in Mexico, Latin America, tropical Africa, southeast Asia, the Philippines, and the Indian subcontinent[2]. Ova from *Echinococcus*, a tapeworm associated with canines, can also cause cysticercosi with a predominance for occurrence in the liver. There is no evidence that cysticerci can develop in humans as a result of T. saginata infection[6].

The treatment of choice in intestinal *Taeniasis* (*T. saginata* and *T. solium*) is praziquantel, a synthetic heterocyclic isoquinolone-pyrazine derivative. A single dose of 5 to 10 mg/kg has an efficacy of greater than 95%. Praziquantel induces ultrastructural changes in the teguments of parasites, resulting in increased permeability to calcium ions[7]. Calcium ions accumulate in parasite cytosol causing muscular contractions and ultimate paralysis of the worm. Additionally, this exposes parasite antigens to the host immune response. The ultimate response is dislodgement of worms from their intestinal sites and subsequent expulsion by peristalsis. For successful treatment, the scolex must be destroyed, and eliminated because residual scolex can result in regrowth. Albendazole or praziquantel can be used in the treatment of cysticercosis.

For people in high risk communities, primary prevention of *Taeniasis* is the removal of intermediate hosts such as cattle and pigs from the parasite's life cycle by eliminating exposure to raw sewage[1] and adequately cooking meats before consumption.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^1F, ^2F, ^3F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Final check list for authors

The format is at: http://www.wjgnet.com/wjg/help/13.doc

Responses to reviewers

Please revise your article according to the comments/suggestions of reviewers. The format for responses to the reviewers' comments is at: http://www.wjgnet.com/wjg/help/10.doc

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Publication fee

Authors of accepted articles must pay publication fee.
EDITORIAL and LETTERS TO THE EDITOR are free of change.

Abstract

Colonization of stomach by *H pylori* is followed by a marked infiltration of the mucosa with polymorphonuclear leukocytes, macrophages, and lymphocytes that very often remains asymptomatic, but in some circumstances can lead to the development of gastroduodenal ulceration, gastric carcinoma, and mucosa-associated lymphoid tissue lymphoma. The molecular mechanisms by which *H pylori* triggers and maintains the local immune response are complex, but there is evidence that cytokines produced by both immune and non-immune cells contribute to amplify the ongoing inflammation. *H pylori* infection is associated with a marked mucosal induction of T helper (Th) type 1 and Th17-type cytokines that is governed by specific antigen-presenting cell-derived molecules, such as interleukin (IL)-12 and IL-23. In this paper, we will review the available data on the expression and role of IL-23 and IL-17 in *H pylori*-related gastritis.

Key words: IL-23; IL-17; *H pylori*

INTRODUCTION

H pylori is a spiral-shaped Gram-negative flagellate bacterium that colonizes the human gastric mucosa and chronically infects more than half of the human population. Infection is inversely correlated with socioeconomic conditions. Most new *H pylori* infections occur in children, but the lack of specific *H pylori*-related clinical signs makes difficult to define the mode of transmission[1]. *H pylori* survives within the gastric mucus layer despite the acidic microenvironment, that limits the growth of most bacteria. This primarily relies upon the ability of *H pylori* to secrete a large amount of urease that breaks down urea into carbon dioxide and ammonia, the latter buffering its environment. Most *H pylori* organisms remain in the mucus layer, even though a small proportion adheres to the mucosal epithelial cells and rarely invades the mucosa[2]. Moreover, *H pylori* can inject into the epithelial cells bacterial products that modify epithelial cell functions[3].

IL-17 IS OVER-PRODUCED IN *H pylori*-COLONIZED GASTRIC MUCOSA

H pylori infection causes a marked infiltration of the gastric mucosa with neutrophils, macrophages, and lymphocytes. Most *H pylori*-infected patients are asymptomatic, but *H pylori*-driven gastritis can lead to the development of gastroduodenal ulcers, gastric carcinoma, and mucosa-associated lymphoid tissue lymphoma[4]. The level of inflammation increases the risk of disease, but it does not seem to influence which disease develops. In contrast, this is thought to be largely influenced by the pattern of gastric inflammation. In particular, antral gastritis is associated with increased stimulated acid production and predisposes to duodenal ulceration, while corpus-predominant or pangastritis is associated with reduced acid production and predisposes to gastric ulcer and gastric adenocarcinoma[5]. There is also evidence that the degree of gastric infiltration by neutrophils correlates with the development of gastroduodenal ulcerations, and this is in part dependent on the release of damaging inflammatory mediators such as reactive oxygen species[6,7]. Because neutrophils are short-lived, they must be constantly recruited into the infected mucosa from circulation. Antigens released by *H pylori* can stimulate endothelial cells, macrophages and epithelial cells to make huge amounts of chemokines, such as interleukin (IL)-8 and growth-regulated oncogene-alpha, that produce a chemotactic gradient for the migration of neutrophils into the gastric mucosa[8-11]. It is also known that infections with specific *H pylori* strains that possess the cag pathogenicity island (*cag*+) induce significantly higher levels of chemokines than do cag-strains[12]. Both macrophages and epithelial cells also synthesize neutrophil-recruiting chemokines in response to lamina propria mononuclear cell

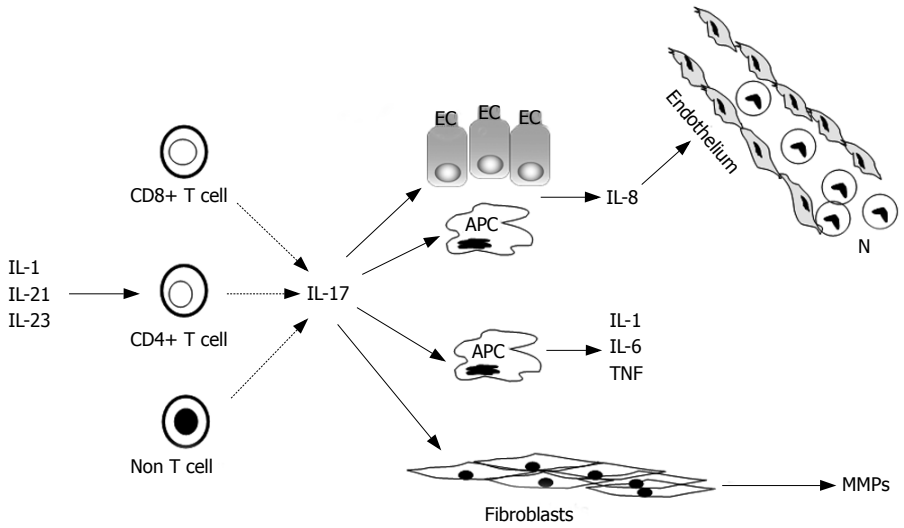

Figure 1 The figure illustrates some of the putative functions of IL-17 in the human gastric mucosa. During *H pylori* infection, IL-17 is produced by both lamina propria (LP) T (CD4+ and CD8+) and non-T cells, through a process that could be positively regulated by IL-1, IL-21, and IL-23. IL-17 stimulates both epithelial cells (EC) and LP antigen presenting cells (APC) to make IL-8, thereby enhancing the recruitment of blood neutrophils (N) into the mucosa. Additionally, IL-17 increases the production of inflammatory cytokines, such as IL-1, IL-6, and TNF by LP APC, as well as it stimulates fibroblasts to secrete matrix metalloproteinases (MMPs), a family of proteases that can cause mucosal degradation.

(LPMC)-derived molecules. In this context, we and others have recently shown that IL-17, a key regulator of neutrophil chemotaxis, is produced in excess in *H pylori*-infected stomach[13-15]. By real-time PCR and Western blotting it was shown that IL-17 up-regulation occurs at both RNA and protein levels in *H pylori*-infected biopsies in comparison to uninfected biopsies either with or without gastritis[13,14]. Notably, among *H pylori*-positive patients, the gastric mucosa at the site of ulcers contains more IL-17 than the non-ulcerated mucosa of the antrum[15]. Several observations suggest that IL-17 plays a decisive role in the neutrophil recruitment to the *H pylori*-infected gastric mucosa. First, IL-17 levels correlate with the number of neutrophils infiltrating the Hp-infected mucosa[15]. Second, both gastric LPMC and epithelial cells express IL-17 receptors and are functionally capable of responding to IL-17 by secreting IL-8[14-16]. Consistently, conditioned media of gastric epithelial cells stimulated with IL-17 enhance the migration of peripheral blood neutrophils, and this effect is inhibitable by a blocking anti-IL-8, but not anti-IL-17 antibody (Figure 1)[14]. Functional analysis of intracellular pathways involved in the induction of IL-8 synthesis by IL-17 revealed that IL-17 activates ERK1/2 MAP kinases in gastric epithelial cells, and that pharmacologic blockade of this pathway significantly inhibits IL-8 secretion[16]. These findings are in line with the demonstration that activated ERK1/2 and IL-8 are more pronounced in gastric epithelial cells isolated from *H pylori*-infected biopsies in comparison to uninfected controls, and that neutralization of endogenous IL-17 in *ex vivo* cultures of *H pylori*-infected gastric biopsies down-regulates the expression of activated ERK1/2 and IL-8[16]. Finally, IL-17 expression positively correlates with IL-8 content in *H pylori*-colonized biopsies[15].

Besides its effects on IL-8 synthesis, IL-17 exerts additional immune-regulatory functions which could influence the magnitude and/or severity of *H pylori*-related gastritis. For example, IL-17 stimulates the production of IL-1, IL-6, and TNF-α by both immune and non-immune cells[17], and induces fibroblasts to make matrix metalloproteinases (MMPs)[18]. MMPs are a family of proteases that can cleave multiple components of the extracellular matrix, thereby contributing to the mucosal damage[19] (Figure 1).

IL-23 CONTROLS IL-17 PRODUCTION IN THE HUMAN GASTRIC MUCOSA

IL-17 was originally named cytotoxic T lymphocyte-associated-8 (CTLA-8), subsequently IL-17, and more recently IL-17A, since it is one of six related members belonging to the IL-17 family (IL-17A-F)[20]. IL-17 was initially described at the message level as a product of human blood activated CD4+ memory T cells. Subsequent studies have shown that IL-17 can be also made by activated CD8+ T cells, TCR$\gamma\delta$+ T cells, and neutrophils[20]. More recently, it was shown that IL-17 is produced by a specific subset of CD4+ T cells, termed T helper (Th) 17-cells, that are distinct from, and antagonized by the classical Th1 or Th2 cells[21]. Th17-cells produce also, but to a lesser extent, TNF-α, IL-6, IL-17F, IL-22, and granulocyte macrophage-colony stimulating factor[22,23]. Flow-cytometry analysis of IL-17 production in gastric LPMC isolated from biopsies of *H pylori*-infected patients showed that CD4+ T cells are a major source of IL-17, even though CD8+ T cells and CD3-negative cells were also positive for IL-17 (Figure 1)[13]. The molecular pathways governing the development of Th17-cells in humans have not been yet elucidated, but studies in murine systems indicate that Th-17 cell differentiation is driven by IL-6 and TGF-β1[24,25]. There is also evidence that expansion and survival of Th17-cells require additional factors, such as IL-23[25]. IL-23 is a heterodimeric protein that is composed by the p40 subunit of IL-12 and a specific subunit, termed IL-23/p19. The functional IL-23 heterodimer is produced by activated dendritic cells (DC), monocytes and macrophages[26]. We have recently shown that IL-23 protein is produced in excess in *H pylori*-colonized mucosa. RNA transcripts for both p40 and p19 subunits were also up-regulated in biopsies from *H pylori*-infected patients, indicating that IL-23 is regulated at the transcriptional level in this condition[13]. These results confirm and expand on data of previous studies showing that *H pylori* enhances IL-23 secretion by monocyte-derived DC[27], and that *H pylori* neutrophil-activating protein (*H pylori*-NAP), a member of a broad super-family of ferritin-like proteins, induces IL-23 production by neutrophils and monocytes[28,29]. Functional studies also revealed that

IL-23 enhances IL-17 synthesis by normal gastric LPMC, and that blockade of endogenous IL-23 activity in cultures of LPMC isolated from *H pylori*-infected biopsies down-regulates IL-17 production[13]. The exact molecular mechanism by which IL-23 regulates IL-17 in *H pylori*-infected mucosa remains to be ascertained. Notably, neutralization of endogenous IL-23 by a blocking anti-IL-23/p19 antibody in cultures of LPMC isolated from *H pylori*-infected biopsies attenuates the expression of active Stat3. Moreover, in normal gastric LPMC, exogenous IL-23 enhances the activation of Stat3, and pharmacologic inhibition of Stat3 suppresses IL-17 production induced by IL-23[13]. Taken together, these results suggest that Stat3 plays a key role in the IL-23-driven IL-17 production during *H pylori* infection. This well fits with the demonstration that Stat3 is essential for the induction and expansion of IL-17-producing cells in response to cytokine stimulation both in vitro and *in vivo*[30]. Such an effect could rely on the ability of Stat3 to bind the promoter of IL-17 gene and enhance its transcriptional activity[31], and/or favor the induction of RORγt, a master regulator of Th17-cell differentiation[32], and the expression of IL-23R.

IL-17 synthesis may be regulated by additional cytokines other than IL-23. IL-1R1-deficient mice fail to mount a robust Th17 response, and IL-1R1-deficient cells do not produce IL-17 in response to IL-23[33]. Since *H pylori* infection enhances the production of IL-1 at the gastric level[34], it is tempting to speculate that this cytokine may act in concert with IL-23 in enhancing IL-17. IL-17 synthesis is also increased by IL-15 in cultures of human and murine CD4+ T cells[35]. However, the fact that IL-15 expression is down-regulated in *H pylori*-infected biopsies argues against a role for IL-15 in the control of IL-17 production during *H pylori*-related gastritis[36]. Th17 cell differentiation is also enhanced by IL-21[37,38], a T-cell derived cytokine that is produced in excess in *H pylori*-colonized stomach[39].

THE ROLE OF IL-23 IN AMPLIFYING *H pylori*-DRIVEN TH1-IMMUNE RESPONSE

During *H pylori* infection, there is a pronounced specific acquired immune response, characterized by generation of antibodies, and differentiation and activation of effector T cells. Although this later includes both a Th1 and a Th2 component, mucosal cytokine profiles imply Th1 predominance[40], and the number of cells producing interferon (IFN)-γ, the key Th1 cytokine, in the *H pylori*-infected human gastric mucosa correlates with the severity of gastritis[41]. Animal models also suggest that the extent of Th1 differentiation is important in pathogenesis. Mice with a predominant Th1 response develop more gastric inflammation during *H pylori* colonization than those with a Th2 response[42-43]. Gastric inflammation and atrophic changes are abrogated in the absence of IFN-γ[44], while IFN-γ infusion into mice, even in the absence of *H pylori* infection, induces pre-cancerous gastric atrophy, metaplasia and dysplasia[45]. IL-12-deficient mice have also reduced gastric inflammatory infiltration and are unable to clear *H pylori* infection[46].

Several virulence factors are reported to promote Th1 responses, including the plasticity region locus jhp0947-jhp0949 which is associated with duodenal ulcer disease[47] and the *H pylori*-NAP[29]. The Th1/Th2 balance is also influenced by phase-variable expression of Lewis blood-group antigens and genomic DNA recombination[48,49].

IL-12 is supposed to be one of the major Th1-inducing factors in *H pylori*-colonized gastric mucosa[50], even though IL-23 may contribute to expand the ongoing Th1 cell response[26]. Indeed, blockade of endogenous IL-23 by anti-IL23/p19 in cultures of LPMC isolated from *H pylori*-colonized biopsies reduces IFN-γ secretion, and stimulation of normal gastric LPMC with IL-23 enhances IFN-γ production. These data are in accordance with the demonstration that IL-23 activates Stat4 and enhances IFN-γ production in cultures of human and murine memory T cells[26], and that in two models of *H. hepaticus*-triggered T cell-dependent colitis, IL-23 enhances both IFN-γ and IL-17 responses that together synergize to trigger severe intestinal inflammation[51,52].

IL-23 and gastric cancer

As pointed out above, *H pylori* is a major factor in the induction of gastritis and its progression to pre-neoplastic lesions and non-cardia gastric cancer. Despite the high prevalence of *H pylori* infection, the risk of gastric cancer in *H pylori*-infected patients is, however, estimated to be approximately 1%-3%. This indicates that infection per se is not sufficient to induce the progression to gastric neoplasia and that additional bacterial and host factors are required[2]. A detailed description of such factors is beyond the scope of this review. In this context it is, however, noteworthy that accumulating evidence would seem to suggest that IL-12 and IL-23 are important mediators in the process that links *H pylori* infection to gastric cancer. Indeed, polymorphisms of IL-12p40 and p35 genes enhance the risk of non-cardia gastric cancers in *H pylori*-infected patients[53]. Moreover, high levels of IL-23 have been documented in human gastric cancers[53]. Nonetheless, no functional study has so far mechanistically linked the activity of IL-12 and IL-23 to gastric cancer. Additionally, studies in murine models of epithelial cancers have shown that IL-23, but not IL-12, is essential for sustaining the tumor-promoting inflammatory process and counteracting the ability of cytotoxic CD8+ T cells to infiltrate tumors[54].

CONCLUSIONS

Although bacterial virulence factors are important in conditioning the outcome of the *H pylori*-driven infection, it is the host attempt to clear the bacterium that causes an exaggerated and inappropriately counter-regulated immune response that may eventually cause tissue damage. Emerging experimental evidence suggests that IL-23/IL-17 pathway is an important driving force the ongoing gastric inflammation in *H pylori*-infected patients. However, further studies will be required to establish the exact contribution of each of these cytokines in the *H pylori*-associated gastric pathology. The availability of strains of mice deficient either for IL-23 subunits or IL-17 should provide valuable models to specifically address these issues.

Abstract

Renal dysfunction is common in liver diseases, either as part of multiorgan involvement in acute illness or secondary to advanced liver disease. The presence of renal impairment in both groups is a poor prognostic indicator. Renal failure is often multifactorial and can present as pre-renal or intrinsic renal dysfunction. Obstructive or post renal dysfunction only rarely complicates liver disease. Hepatorenal syndrome (HRS) is a unique form of renal failure associated with advanced liver disease or cirrhosis, and is characterized by functional renal impairment without significant changes in renal histology. Irrespective of the type of renal failure, renal hypoperfusion is the central pathogenetic mechanism, due either to reduced perfusion pressure or increased renal vascular resistance. Volume expansion, avoidance of precipitating factors and treatment of underlying liver disease constitute the mainstay of therapy to prevent and reverse renal impairment. Splanchnic vasoconstrictor agents, such as terlipressin, along with volume expansion, and early placement of transjugular intrahepatic portosystemic shunt (TIPS) may be effective in improving renal function in HRS. Continuous renal replacement therapy (CRRT) and molecular absorbent recirculating system (MARS) in selected patients may be life saving while awaiting liver transplantation.

Key words: Hepatorenal syndrome; Transjugular intrahepatic portosystemic shunt; Continuous renal replacement therapy; Molecular absorbent recirculating system; Acute liver failure; Systemic vascular resistance; Renal blood flow

INTRODUCTION

Renal and liver dysfunction often present together, either as part of multiorgan failure in a critically ill patient, or as a result of failure of each organ independently. Three major clinical scenarios can be identified in which liver and renal dysfunction coexist; diseases simultaneously involving the liver and the kidney, or a primary hepatic disorder with secondary renal dysfunction, or vice versa[1]. Concomitant renal and liver dysfunction may share common pathogenetic mechanisms. Renal dysfunction in this setting usually develops gradually, with the exception of certain infections such as leptospirosis, some viral hemorrhagic fevers and toxin-mediated injuries such as acetaminophen poisoning, which cause acute insufficiency of both organs[2]. Renal failure secondary to liver dysfunction is generally functional in nature and occurs in the absence of significant alterations in renal histology (pre-renal). However, intrinsic renal abnormalities can also complicate acute or chronic liver disease (intrinsic renal failure)[3]. Obstructive uropathy that leads to postrenal acute renal failure only rarely develops in chronic liver disease (papillary necrosis in alcoholic liver disease, bleeding in the urinary tract due to severe coagulopathy)[4]. Hepatorenal syndrome (HRS) is a unique form of functional renal failure (pre-renal) that often complicates advanced liver disease, hepatic failure or portal hypertension[5].

EPIDEMIOLOGY

The incidence of renal failure in acute liver failure (ALF) varies from 40% to 85%, depending on the etiology; paracetamol poisoning leads to renal failure in up to 75% of patients[6]. Renal failure following paracetamol overdose may also occur in the absence of ALF, and has a good prognosis[7]. In non-paracetamol cases the incidence of renal failure is usually accompanied by worsening encephalopathy and is associated with a poor outcome[5,6].

Acute renal failure (ARF) in patients with cirrhosis, particularly with advanced liver disease, seems to be common; however, the exact incidence is unknown and is probably underestimated[3]. This may be explained by the fact that patients with cirrhosis tend to have falsely low serum creatinine levels due to decreased hepatic creatinine synthesis and decreased skeletal muscle mass[8]. ARF in patients with cirrhosis frequently accompanies complications such as bacterial peritonitis or other

sepsis, hypovolemia from gastrointestinal bleeding or excessive diuretic therapy, administration of nephrotoxic drugs/contrast agents, or development of HRS[2,3]. The probability of the occurrence of HRS in patients with cirrhosis and ascites at 1 and 5 years is 18% and 39%, respectively, with mortality approaching 100% in type I HRS without specific therapy. The median survival time in these patients without liver transplantation was only 12 d after diagnosis in one study[9]. However, this seems to have improved with terlipressin and albumin therapy[10]. The development of ARF in patients with cirrhosis has significant prognostic importance. In patients with cirrhosis admitted to hospital with acute upper gastrointestinal hemorrhage, development of ARF forms an independent predictive factor for death[11,12].

PATHOPHYSIOLOGY OF RENAL FAILURE IN LIVER DISEASE

The mechanism underlying the development of ARF in advanced liver disease and cirrhosis is complex and includes interactions between changes in the systemic arterial circulation, portal hypertension, activation of vasoconstrictors and suppression of vasodilatory factors acting on the renal circulation[1,3,13]. The pathophysiology of functional renal failure in ALF is similar to that in cirrhosis[6,14], and patients with ALF may develop portal hypertension, but to a lesser degree than in those with cirrhosis[6]. The common pathway of renal dysfunction is the development of intense systemic arterial vasodilation, which follows increased release of endogenous vasodilators, especially nitric oxide, which escapes from the splanchnic to the systemic circulation through portosystemic shunts[1,13-15]. The systemic vasodilation leads to a reduction in systemic vascular resistance (SVR) and consequent high cardiac output and hyperdynamic circulation. However, the increase in cardiac output may be inadequate to compensate for the drop in SVR, especially in ALF, which results in hypotension with mean arterial pressure (MAP) commonly falling to 60-70 mmHg, which is on the pressure-dependent part of the autoregulatory curve of renal blood flow (RBF)[6,16]. In healthy individuals, autoregulation of RBF occurs until the renal perfusion pressure falls below 60-70 mmHg. Altered renal vascular autoregulation, as seen in sepsis, may also be present in the hyperdynamic circulatory failure of ALF, making RBF directly dependent on blood pressure[17]. In some patients with cirrhosis, especially alcoholics, the presence of cardiomyopathy and heart failure may further render them susceptible to renal compromise secondary to hypoperfusion[18].

The normal homeostatic response to vasodilation is activation of several neurohumoral mechanisms, such as the renin-angiotensin-aldosterone system (RAAS), the sympathetic nervous system (SNS), and arginine-vasopressin (AVP) which leads to intense vasoconstriction and salt and water retention, in an attempt to maintain blood pressure and perfusion of vital organs[2,5,14,17]. Other vasoconstrictors, such as eicosanoids, endothelins, thromboxane A2 and leukotrienes may further exacerbate this[6,13,14,19].

RBF is kept within normal limits in the early stage of the liver disease, due to the release of certain local vasodilators such as prostaglandins. However, in situations in which circulatory volume is acutely diminished, as in gastrointestinal hemorrhage, renal hypoperfusion and subsequent pre-renal azotemia may occur. As the liver disease progresses, there is extreme vasoconstriction of the renal vascular bed that predisposes the kidneys to development of HRS[2,20]. The presence of tense ascites may further impair renal perfusion. The continuing vasoconstriction and raised vascular resistance results in contraction of the mesangium, with a reduction in glomerular surface area, which leads to acute tubular necrosis (ATN)[21].

CAUSES OF ACUTE RENAL FAILURE IN LIVER DISEASE

Pre-renal

Patients with advanced liver disease are susceptible to pre-renal azotemia, secondary to the development of relative hypovolemia and reduced effective central blood volume. The initial event is development of portal hypertension, which then leads to splanchnic and systemic vasodilatation mediated by NO and other vasodilators. Vasodilatation seems to be the main mechanism, however, underfilling has also been suggested, which is explained by fluid sequestration in the peritoneal cavity[22-24]. True hypovolemia can further exacerbate renal dysfunction in these patients. It can be induced by gastrointestinal tract hemorrhage from varices, peptic ulcers, gastropathy or other sources, excessive diuresis, vomiting and diarrhea, or can be aggravated by large volume paracentesis without intravascular volume replacement[3,11,13]. Bacterial infections and the use of nonsteroidal anti-inflammatory drugs can also precipitate pre-renal azotemia in these patients[3,25]. Patients with ALF and cirrhosis are abnormally susceptible to infection. Hemodynamic abnormalities induced by cytokines and vasodilating substances, such as NO in spontaneous bacterial peritonitis, play an important role in the pathogenesis of renal dysfunction. Additionally, development of septic shock further impairs renal function[25,26].

Intrinsic renal

Intrinsic renal disease can either complicate acute liver diseases as a result of exposure to certain drugs, toxins and infections, or be a part of chronic liver disease. The former usually is tubular interstitial in nature and presents as ARF, while the latter predominantly leads to glomerulopathy and is characterized by stable kidney disease. The causes of intrinsic renal involvement in liver diseases are numerous and are beyond the scope of this review. This review will mainly concentrate on acute tubular necrosis (ATN) and HRS, with other causes listed in the Table 1.

ATN

Direct cellular toxicity with ATN and hepatocyte necrosis have been observed in paracetamol intoxication[16]. Despite the nephrotoxic potential of this drug, functional renal failure is also seen secondary to ALF. Renal failure rarely

occurs in the absence of liver failure[7]. Depletion of glutathione is believed to be the cause of both ARF and ALF[36]. Aspirin is another analgesic drug that can cause dose-related liver damage and renal failure in susceptible patients. Of special interest is the association of aspirin, used to treat symptoms of influenza or varicella, with Reye's syndrome[27,37]. The mechanism of renal damage is due to cyclooxygenase inhibition thereby preventing the production of vasodilatory prostaglandins.

ATN with acute renal insufficiency in patients with stable liver disease often follows insults such as hypovolemic shock, major surgical procedures and use of nephrotoxic drugs or contrast agents, infection or sepsis. The functional renal abnormalities associated with advanced liver disease and cirrhosis increase the susceptibility of the kidneys to the development of ATN. These renal abnormalities may either be ischemic or toxic in origin. The mechanism of renal failure is similar in both, and results from a reduction in glomerular filtration rate (GFR) due to impaired glomerular capillary pressure, disrupted integrity of tubular epithelium, and tubular obstruction from casts composed of detached epithelial cells, cellular debris and pigments (hemoglobin and myoglobin)[38]. It should be noted that all causes of pre-renal azotemia might lead to ischemic tubular injury if left untreated[21,39].

The association of obstructive jaundice and ARF is well-established. Susceptibility to renal failure in obstructive jaundice is a combination of cardiovascular instability due to defective vascular reactivity and blunted myocardial contractile response as a result of the deleterious effects of bile constituents. Furthermore, the natriuretic effects of bile acids can cause volume depletion and exaggerate the effective arterial underfilling. However, there is a direct nephrotoxicity of biliary products at very high levels of bilirubin (> 30 mg/dL) in both children and adults[40,41].

Contrast medium is a well-known precipitant of renal failure in hospitalized patients, particularly in the presence of predisposing conditions such as reduced effective blood volume, dehydration and diabetes mellitus. Cirrhosis has been considered a potential predisposing factor. However, a prospective study in euvolemic patients with cirrhosis has shown that administration of contrast medium is not associated with adverse effects on renal function, which suggests that cirrhosis per se should not be considered a risk factor for contrast media nephrotoxicity[42,43]. However, it may play a role in septic cirrhosis, or in patients who have bleeding or who have undergone transarterial embolization for hepatocellular carcinoma.

Table 1 Intrinsic kidney involvement in liver diseases

Tubulo-interstitial involvement
1 Drugs[7] (paracetamol, aspirin, carbon tetrachloride, halogenated hydrocarbons, immunosuppressant agents)
2 Toxins[28-35] (Galerina family of mushrooms, hemoglobin, myoglobin, bilirubin, contrast agents)
3 Infections (leptospirosis, malaria, hepatitis)
4 Hypersensitivity reactions (sulphonamides, salicylates, *etc.*)
Glomerular involvement
1 Drugs[7] (carbon tetrachloride)
2 Hepatitis[28-35] A, B, C
3 Type Ⅱ mixed cryoglobulinemia[28-35]
4 IgA nephropathy[28-35] (alcoholic cirrhosis, HCV cirrhosis)
5 Others (sickle cell disease, hemochromatosis, acute fatty liver and toxemia of pregnancy)
Vascular
1 Vasculitis
2 Toxemia of pregnancy and HELLP syndrome

HRS

HRS is a unique form of functional renal failure that often complicates advanced liver disease, hepatic failure or portal hypertension[3,9,20]. The incidence of HRS in patients with cirrhosis hospitalized for ascites is about 10%. The syndrome is characterized by intense intrarenal vasoconstriction in the presence of vasodilation of systemic and splanchnic circulation, which triggers a reduction in peripheral vascular resistance and a decrease in effective systemic circulatory volume, despite an overall expanded total extracellular fluid volume. The majority of patients have clinical evidence of advanced cirrhosis[20]. However, HRS may occur in patients with fulminant viral and alcoholic hepatitis[36]. Two patterns of HRS can be identified.

Type 1 HRS is characterized by a rapidly progressive reduction of renal function, defined as either doubling of the initial serum creatinine to > 2.5 mg/dL or a 50% reduction in GFR to < 20 mL/min over a 2-wk period. Precipitating factors include spontaneous bacterial peritonitis (SBP), major surgical procedures, and acute alcoholic hepatitis. It follows a fulminant course with development of oliguria, encephalopathy, and marked hyperbilirubinemia, and is associated with very poor prognosis, with death occurring within 1 mo after presentation[27,36].

Type 2 HRS is characterized by a more benign course, with a stable reduction in GFR over weeks to months, accompanying diuretic-resistant ascites and avid sodium retention[36]. The pathogenesis of HRS is incompletely understood. It may be the result of an imbalance between renal vasodilators and vasoconstrictors, with the latter predominating. This interplay between the intrarenal mechanisms is triggered by one of the above-mentioned precipitating factors, which exacerbate the previously diminished cardiac and renal function[14,20].

The diagnostic criteria of HRS as proposed by the International Ascites Club are listed in Table 2[44]. Only the major criteria are necessary for the diagnosis of HRS, while the minor criteria are supportive. The diagnosis of HRS is one of exclusion and depends mainly on the level of serum creatinine, despite the fact it does not provide an accurate reflection of GFR in patients with cirrhosis[8]. Patients with cirrhosis with serum creatinine > 1.5 mg/dL have a GFR (estimated by inulin clearance) of < 30 mL/min, which represents one quarter of the normal GFR for healthy subjects of the same age[45]. HRS is a form of functional renal failure, therefore, the

Table 2 Diagnostic criteria of HRS

Major criteria
1 Chronic or acute liver disease with advanced liver failure and portal hypertension
2 Low GFR, as indicated by a serum creatinine of > 1.5 mg/dL or a 24-h creatinine clearance < 40 mL/min
3 Exclusion of shock, ongoing bacterial infection, volume depletion, and the use of nephrotoxic drugs
4 No improvement in renal function despite stopping diuretics and volume repletion with 1.5 L of saline
5 No proteinuria or ultrasonographic evidence of obstructive uropathy or parenchymal renal disease

Minor criteria[1]
1 Urine volume lower than 500 mg/day
2. Urine sodium lower than 10 mEq/L
3 Urine osmolality > plasma osmolality
4 Urine blood cells < 50 per high-power field
5 Serum sodium concentration lower than 130 mEq/L

[1]Only major criteria are necessary for the diagnosis of hepatorenal syndrome.

characteristics of urine are those of pre-renal azotemia with oliguria, low sodium concentration, and increased osmolality and urine to plasma ratio. These parameters are not considered essential for the diagnosis of HRS because they may overlap with different types of renal failure[44,45].

DIFFERENTIAL DIAGNOSIS OF ARF IN LIVER DISEASE

The differential diagnosis of ARF in advanced liver disease includes pre-renal failure, intrinsic renal failure and HRS (Table 3). The diagnostic evaluation relies upon clinical and laboratory data, including examination of urinary sediment and urinary chemistry, as well as appropriate ultrasonographic and radiological investigations[3,14,20]. Renal biopsy generally is not necessary for the diagnosis of ARF in liver disease, but is useful in excluding an intrinsic renal disorder[3]. A history of gastrointestinal hemorrhage, vomiting or diarrhea, exposure to nephrotoxic medication, or features suggestive of sepsis may provide important diagnostic information. Arterial hypertension, which is an unexpected finding in patients with cirrhosis, suggests glomerulonephritis[46]. The course of renal response to fluid challenge or vasoconstrictor therapy can also help differentiate causes of acute azotemia in liver disease. Rapid improvement in renal function denotes pre-renal failure, whereas mild or no improvement represents ATN or HRS[39,44]. Vasoconstrictor agents such as terlipressin or noradrenalin can sometimes be used to differentiate HRS and ATN, with improvement of GFR in favor of HRS[47,48]. Urine indices such as osmolality, sodium concentration, urine:plasma osmolality ratio (U/Posm) and urine:plasma creatinine ratio (U/Pcreat), are useful theoretical tools for differential diagnosis of the three principal causes of ARF in liver disease. However, in reality apart from urinary sediments these are often not clear cut.

Duplex Doppler ultrasonography, is a sensitive method of assessing intrarenal hemodynamics in patients with stable cirrhosis and ascites, in whom the renal artery resistive index is significantly increased and correlated with GFR and plasma renin activity[49]. However, this method is only useful in stable cirrhosis and may not be applied to acute situations.

Table 3 Differential diagnosis of ARF in advanced liver disease

	Prerenal failure	Intrinsic renal failure	HRS
Urine sodium	< 10	> 30	< 10
U/Pcreat	> 30:1	< 20:1	> 30:1
U/Posm	UO > PO	UO = PO	UO > PO
Urine sediment	Normal	Casts, cellular debris	Unremarkable
History disease	Profound volume	Volume contraction	Advanced liver disease
Clinical course (renal response)	Contraction	Nephrotoxic agent sepsis	Tence ascites
Fluid challenge	+	-	-
Vasoconstriction	±	-	+
Ultrasound	Elevated resitive index	Elevated resitive index	Elevated resitive index

MANAGEMENT OF ARF IN LIVER DISEASE

Management of ARF in liver disease should follow the same general principles as for the management of renal failure of any etiology, as well as specific measures for the liver disease. Combined ARF and ALF should ideally be managed in an intensive care or high-dependency setting. Initial management comprises correction of life-threatening abnormalities such as hyperkalemia, hypoglycemia, severe blood gas abnormalities, gross fluid overload and coagulation disorders, which may lead to bleeding and worsening renal function[50]. Although bleeding problems in patients with chronic liver failure are much less than previously thought, as a result of normal thrombin generation, renal failure superimposed on liver failure may have a negative impact on bleeding diathesis and worsening of hemorrhage[51].

Potential nephrotoxic drugs should be discontinued if possible, diuretic therapy interrupted, and infusion of crystalloid or colloid solutions commenced, based on clinical assessment and hemodynamic monitoring. In ALF complicated by intracranial hypertension, in addition to general measures to treat cerebral edema, early continuous renal replacement therapy (CRRT) may be considered, especially when patients are oligo-anuric and are taking mannitol[5,6].

In patients with chronic liver disease, management of ARF must focus on pre-renal failure, HRS and ATN. Upper gastrointestinal hemorrhage needs transfusion of plasma expanders and packed red blood cells, while measures are being taken to identify and treat the bleeding focus[12]. Intestinal and renal fluid losses should be replaced with appropriate fluid. Evidence of sepsis should be meticulously sought and a non-nephrotoxic broad-spectrum antibiotic regimen commenced, regardless of the etiology of sepsis. Current literature does not support the role of low-dose dopamine in the prevention and treatment of sepsis-induced renal vasoconstriction and

failure[52]. Vasopressin and terlipressin provide adequate splanchnic vasoconstriction and have been used not only in patients with cirrhosis and HRS, but also in sepsis in resistant cases[53].

Many different therapeutic approaches have been proposed for the management of HRS[2,13,27,38]. Unfortunately, most treatment measures result in only transient beneficial effects on renal function, and are not consistently associated with improvement in patient survival. Liver transplantation remains the definitive treatment for HRS, but is associated with higher hospital mortality compared to those without HRS who are treated with transplantation[54]. Thus, every attempt should be made to prevent this severe complication or reverse it when managing patients with cirrhosis and ascites. In recent years, new treatment strategies such as the use of vasoconstrictor drugs, along with plasma volume expansion, or insertion of TIPS, have shown some promise[20]. These treatments may prolong survival time and, therefore, act as a bridge to liver transplantation in these patients. Vasoconstrictors used for HRS include vasopressin analogues (ornipressin and terlipressin), somatostatin analogues (octreotide), and alpha-adrenergic agonists (midodrine and noradrenalin)[20]. In type 1 HRS terlipressin in combination with albumin has shown to result in greater improvement in renal function compared to terlipressin alone[10,53]. Pharmacological treatment, when combined with interventional techniques, such as transjugular intrahepatic portosystemic shunt (TIPS), may further improve renal function in HRS[27,55]. However, TIPS is frequently associated with significant side effects, particularly hepatic encephalopathy and impairment of liver function, and its role in the management of HRS needs to be established by prospective, controlled investigations[56].

The molecular adsorbent recirculating system (MARS) has been used in the treatment of acute decompensation of chronic liver disease (ADCLF), ALF and HRS[57]. This liver support system utilizes either intermittent (6-8 h daily) or continuous hemodialysis with dialysate enriched with 20% human serum albumin as a means to remove albumin-bound toxins (bilirubin, bile acids, fatty acids, tryptophan, aromatic amino acids, and copper). The first randomized trial of MARS evaluated 13 ADCLF patients with type 1 HRS. Five patients treated with hemodiafiltration alone died within 7 d, whereas three of eight patients treated with MARS were alive at 7 d, and two of eight were alive at 30 d[58]. Another recent randomized control trial, which included 24 patients with ADCLF, showed improvement in hyperbilirubinemia and hepatic encephalopathy and 30-d survival in patients treated with MARS. There was also improvement in renal function in the MARS group[59]. Until now, MARS has shown no benefit in improving survival in acute exacerbations of chronic liver failure. Likewise, MARS in the context of ALF has not been studied in control trials.

CRRT

Theoretically, the indications for CRRT in advanced liver disease and renal failure should be similar to those for general population. However, in view of the underlying disease, renal support should only be provided to those with a clear goal of hepatic management and a potential positive outcome i.e., the possibility of hepatic recovery or liver transplantation[60,61]. Measures such as volume expansion with albumin and the use of terlipressin should be tried before considering RRT. In fulminant hepatic failure (FHF), CRRT has become a major part of the routine management. Although there are no randomized trials to prove its efficacy, it can be assumed that it has contributed in part to the improvement in mortality. The continuous form provides greater hemodynamic, and more importantly, greater intracranial pressure ICP stability than the intermittent forms[62]. Continuous techniques (hemofiltration/hemodiafiltration) are preferred since they are associated with greater cardiovascular stability and allow gradual fluid removal, which can be adapted to actual needs and the infusion volume required for drug therapy and nutritional support[61].

PREVENTION OF RENAL FAILURE IN ADVANCED LIVER DISEASE

Two different strategies can be used to prevent HRS. The first is to perform liver transplantation in patients with cirrhosis and ascites before HRS develops. The identification of factors associated with a high risk of developing HRS and the use of duplex Doppler ultrasonography to assess the renal artery resistive index in the follow-up of these patients may be useful for this purpose[9,24,49]. The second strategy is to prevent the development of renal impairment in patients by avoiding the precipitating factors i.e., prompt management of bleeding and infection. A recent study has indicated that the development of HRS in patients with SBP can be effectively prevented by the addition of albumin to antibiotic (cefotaxime) therapy (1.5 g/kg human albumin intravenously at the time of diagnosis of the infection and 1 g/kg intravenously 48 h later). The proportion of patients who developed HRS and the in-hospital mortality was significantly lower in the cefotaxime-plus-albumin group that in the cefotaxime alone[63]. The beneficial effect of albumin is probably related to its ability to prevent circulatory dysfunction and subsequent activation of vasoconstrictor systems that occur during infection[63].

ARF POST LIVER RESECTION AND LIVER TRANSPLANTATION

Liver transplantation is the optimal treatment for patients with end-stage liver disease and ALF. The immediate outcome of orthotopic liver transplantation (OLT) is dependent on several factors, including pretransplant renal function and hemodynamic conditions in the operative and postoperative periods[63]. The prevalence of renal insufficiency in patients before transplantation varies from 10% to 20%, although many of these patients may have HRS, which is potentially a reversible condition.

Pretransplant renal dysfunction is a poor prognostic marker[64]. The reason for the poorer prognosis of these patients may be related to the persistence of the hyperdynamic circulation after liver transplantation, and to the fact that these patients seem to be more susceptible to damage from immunotherapy with cyclosporine or tacrolimus[65]. Additionally, pretransplant renal failure increases the incidence of postoperative sepsis, the need for pre- and postoperative dialysis, the number of days spend in the intensive care unit, and short-term graft and patient survival rates[64,66]. Renal failure is a frequent complication after OLT. It is usually acute, appears early after transplantation, and has an unfavorable effect on prognosis of liver transplant patients. The reported incidence ranges from 12% to 61%, according to the criteria used for defining ARF (serum creatinine ranging from 1.5 to 3 mg/dL or higher)[66,67]. Post-transplant ARF is usually caused by ATN due to perioperative complications (circulatory instability, duration), sepsis, repeated rejection, calcineurin-mediated renal vasoconstriction or nephrotoxic drugs (e.g., aminoglycosides and amphotericin B).

Prevention of renal failure after liver transplantation is not easy. The benefit of RRT with continuous venovenous hemodialysis before and after liver transplantation has been established[68]. Administration of aprotinin, an antifibrinolytic agent may be of benefit in the prevention of renal failure in adult patients undergoing OLT, by reducing intraoperative blood loss. Despite its potential nephrotoxic side effects, the administration of regular doses of aprotinin does not lead to a higher incidence of renal failure in these patients[69].

Treatment of HRS prior to OLT could also be beneficial for the prevention of ARF[63,66]. Finally, a delay in the introduction of nephrotoxic immunosuppresive drugs could be helpful in the prevention of post-transplant ARF, especially in high-risk patients.

CONCLUSION

Acute renal dysfunction is common in patients with acute and chronic liver disease. The presence of renal failure in this group of patients significantly affects mortality. Several advances have occurred in the management of this complication in the last decade. Improvement in the management of ARF in ALF is reflected in our better understanding of the disease process and better hemodynamic and renal replacement support. In advanced liver disease complicated by liver failure, terlipressin and early formation of TIPS have shown some promise. The role of MARS, bioartificial liver support, high-volume hemofiltration, and therapeutic plasma exchange, are still unclear and need further evaluation. Finally, as liver transplant is the definitive treatment, further education to increase the organ donation pool may be the best way forward.

Abstract

Genetic factors play a significant role in determining inflammatory bowel disease (IBD) susceptibility. Epidemiologic data support genetic contribution to the pathogenesis of IBD, which include familial aggregation, twin studies, racial and ethnic differences in disease prevalence. Linkage studies have identified several susceptibility genes contained in different genomic regions named IBD1 to IBD9. Nucleotide oligomerization domain (NOD2) and human leukocyte antigen (HLA) genes are the most extensively studied genetic regions (IBD1 and IBD3 respectively) in IBD. Mutations of the NOD2 gene are associated with Crohn's disease (CD) and several HLA genes are associated with ulcerative colitis (UC) and CD. Toll like receptors (TLRs) have an important role in the innate immune response against infections by mediating recognition of pathogen-associated microbial patterns. Studying single-nucleotide polymorphisms (SNPs) in molecules involved in bacterial recognition seems to be essential to define genetic backgrounds at risk of IBD. Recently, numerous new genes have been identified to be involved in the genetic susceptibility to IBD: NOD1/Caspase-activation recruitment domains 4 (CARD4), Chemokine ligand 20 (CCL20), IL-11, and IL-18 among others. The characterization of these novel genes potentially will lead to the identification of therapeutic agents and clinical assessment of phenotype and prognosis in patients with IBD.

INTRODUCTION

Inflammatory bowel disease (IBD) includes ulcerative colitis (UC) and Crohn's disease (CD) which are characterized by chronic illness of unknown etiology; however, its development is influenced by genetic, environmental and immunological factors[1].

Epidemiological studies suggest that genetic susceptibility is a major contributing factor to IBD. Molecular data from total genome scans and from candidate gene studies have led to the identification of genetic determinants of susceptibility and disease phenotype of UC and CD. The primary goal of genetic research is to identify genetic variants within specific genes which could modify homeostasis and increase disease susceptibility. There is growing attention to the innate immune response and the interaction between genetic factors and bacterial flora, or pathogen-associated molecular patterns in order to understand the contribution of environmental factors to disease susceptibility, as well as the phenotype based on a more precise molecular basis of disease pathogenesis. Clinical impact of the genetic findings has helped in understanding the heterogeneity of IBD in location, age at onset, clinical course and predicting response to conventional treatment.

GENETIC MODEL

Clinical and epidemiological data do not support a simple Mendelian model of inheritance for IBD. In its place CD and UC are considered to be complex polygenic diseases. Two major methods for identification of genes in complex multifactorial diseases are used, the positional cloning method based on association studies and the candidate gene analysis. Linkage analysis allows scanning of the whole genome studying the co-segregation of the disease with a marker within families, constituting an important method where allele sharing between affected sibling pairs is used. An alteration of the observed ratio of sharing contrasting the expected is interpreted as evidence for linkage with a particular marker. On the other hand, the candidate gene analysis attempts to determine the

Table 1 Major regions and genes in IBD

Region	Localization	Involved genes
IBD1	Chromosome 16	NOD2/CARD15, IL-4R, CD11B
IBD2	Chromosome 12	Vitamin D receptor (VDR), STAT6, Interferon γ, β7 integrine.
IBD3	Chromosome 6	Major histocompatibility complex (MHC): Class Ⅰ, Ⅱ, Ⅲ.
IBD4	Chromosome 14	T- Lymphocyte receptor (TCR) and Leukotriene B4
IBD5	Chromosome 5	Organic cations transporter (OCTN), *Drosophila long disc homologue gene 5* (DLG5), *Multidrug resistant gene* (MDR1), IL-6, CD14
IBD6	Chromosome 19	Thromboxane A2, Leukotriene B4, ICAM-1
IBD7	Chromosome 1	Transforming growth factor Beta (TGFβ), TNFα receptors.
IBD8	Chromosome 16	Under research
IBD9	Chromosome 9	CCR-5, CCR9, IL-12

NOD2/CARD15: Nucleotide oligomerization domain 2/Caspase-activation recruitment domains 15; STAT6: signal transducer and activator of transcription-6; ICAM-1: intracellular adhesion molecule 1; CCR5: CC-chemokine receptor5.

importance of specific genes in disease pathogenesis, using case-control cohorts or trios of affected progeny with both parents. The allelic frequencies or the transmission of a single-nucleotide polymorphism (SNP) towards affected progeny is studied and the differences between patients and controls might point towards the implication of a particular gene in the pathogenesis of the disease under investigation. It also includes positional candidate genes which are found in areas of linkage defined by genome screening. As CD and UC are likely to share some susceptibility genes, it has been proposed a genetic model of UC and CD where the two are polygenic disorders, sharing some susceptibility *loci*, but differing in others[2]. Linkage studies support this concept because some *loci* appear to interfere with susceptibility to IBD, which have also been implicated in the abnormal immune response and those susceptibility genes could interfere with the disease phenotype such as extension, need for procto-colectomy, extraintestinal manifestations, as well as the response to different treatments. From most of the genome-wide scans performed in IBD, a number of susceptibility regions on several chromosomes have been found[3-6] and according to their initial date of reporting and independent confirmations, the regions on such chromosomes have been renamed as IBD1-9 (Table 1).

IBD1

Accurate mapping of the IBD1 locus has led to identification of the underlying gene called the NOD2/Caspase-activation recruitment domains 15 (CARD15) gene located on the pericentromeric region on the long arm of chromosome 16 (16p12.3) extending to 16q13[7-10]. Several studies have demonstrated the identification of NOD2/CARD15 gene within the IBD1 locus as a susceptibility gene in CD, suggesting that approximately 25%-30% of the genetic susceptibility in CD can be explained by mutations in NOD2/CARD5 though most of these studies have shown no association between NOD2 mutations and susceptibility to UC[11,12]. Thirty non-conservative polymorphisms have been identified within the gene that are associated with CD and only three are common (Arg702Trp, Gly908Arg and Leu1007insC). The three common variants, however, account for approximately 82% of the mutated alleles[13]. Nevertheless, these mutations seem to have different effects on the risk of developing CD: Arg702Trp, Gly908Arg and a deletion in the last 33 aminoacids Leu1007finsC, which are present in 43% of the patients with CD (10%-30% is heterozygous and 2%-15% is homozygous for these mutations)[8-10]. These variants in NOD2 have been associated with certain clinical features of CD[14]. The NOD2 contribution seems to be stronger in Ashkenazi Jewish population who has a higher frequency of the Gly908Arg NOD2 variant. In relation to phenotypic expression and translation into the clinic, some associations between NOD2 mutations and earlier-onset disease in adult populations, fistulizing disease, fibrostenosing disease behavior and increased risk of need for surgery in children have been described[15-18].

CARD gene codes for a protein expressed in several cells of innate immunity, epithelial cells and Paneth cells[11,12]. This protein consists of two N-terminal CARD, a central nucleotide-binding domain and a C-terminal leucin-rich-repeat region (LRR). It has been reported that CARD15 is implicated in the recognition of a bacterial product peptidoglycan-derived muramyl dipeptide (MDP) that enters into the cytosol via a transporter protein hPepT1 and interacts with the LRR of NOD2. Mutations within the leucine-rich region are associated with CD, as mutations within the nucleotide-binding domain are associated with granulomatous diseases[19]. Through the recognition of MDP, secretion of alpha-defensins is stimulated for protection against microbial invasion. In CD patients, a diminished expression of alpha-defensins has been found in those carriers with NOD2 mutation[20,21]. It is known that through this recognition of bacterial products the nuclear factor kappa B (NFκB) activation is regulated[10,22].

Evidence show that NOD2 protein acts as an important regulator of NFκB activation in response to the Toll-like receptor (TLR) 2 activation system leading to its down regulation[23,24]. However in carriers of mutant protein, this process does not occur and proinflammatory cytokines are produced with a Th1 profile[25,26].

IBD2

This region is located on chromosome 12 showing greater linkage evidence in UC compared with CD. A number of possible candidate genes have been investigated including signal transducer and activator of transcription-6 (STAT6), INFγ, metalloproteinase (MMP18), Vitamin D receptor (VDR) and β7 integrin family that could be associated with the susceptibility to IBD. Parkes *et al*[27] found that IBD2 appears to make a major contribution to UC susceptibility but has only a relatively minor effect on CD.

Vitamin D receptor

The Vitamin D receptor (VDR) is a member of a steroid receptor family and mediates the effects of the active metabolite 1.25 $(OH)_2$ vitamin D_3 by regulating

transcription of a number of different genes. It is synthesized by activated macrophages. It is expressed by monocytes and activated B and T lymphocytes. It activates monocytes and macrophages but suppresses lymphocyte proliferation and immunoglobulin production, and also inhibits transcription factor NFκB, and the production of IL-2, IL-12 and interferon γ. 1.25 $(OH)_2D_3$ is the form of vitamin D that binds to the VDR and inhibits experimental autoimmunity[28,29]. Vitamin D deficiency and VDR deficiency have been shown to exacerbate chronic IBD in IL-10 knock out mice[29,30]. Absence of the VDR results in mice that are extremely susceptible to chemical injury in the gut[30]. The linked SNPs found at the 3' end of VDR are: *Bsm*I, *Apa*I, *Taq*I, and the exon 2 splice site *Fok*I polymorphism[31,32]. *Fok*I polymorphism has been associated with osteoporosis, *Taq*I polymorphism with the risk of prostate cancer[33] and recently homozygotes for the *Taq*I allele have been shown to have altered susceptibility to a variety of infectious diseases[34]. Simmons *et al*[35] studied 403 European Caucasian patients with IBD, and found significantly more homozygotes for the *Taq*I polymorphism among patients with CD than in patients with UC or controls, providing evidence for a genetic association between CD susceptibility and a gene that lies within one of the candidate regions determined by linkage analysis. Dressner-Pollak *et al*[36] found that *Bsm*I VDR gene polymorphism is associated with increased susceptibility to UC in Israeli Ashkenazi patients with UC contrasting with *Taq*I polymorphisms that favor susceptibility to CD. It seems that in the absence of the VDR, inflammation in the gut is increased, colonic epithelial cell proliferation is dysregulated, and the host tissue fails to satisfactorily maintain gastrointestinal integrity following chemical insult. These data identify vitamin D as a key regulator of gastrointestinal homeostasis and an important player in regulation of the innate immune response.

IFN-γ

IFN-γ seems to be specifically important in CD pathogenesis as suggested by case control studies that showed elevated levels of IFN-γ production in the mucosa in patients with CD, but not in UC[37]. Data indicate that patients with relapsing perianal fistulizing disease have an increased production of IFN-γ measured by *in vitro* cell cultures[38]. Cytokine genotyping study showed that IFN-γ (+874T/A) polymorphism is found in an increased proportion of patients with fistulizing CD[39] probably related to the reduction of tissue repair and migratory potential in fibroblasts apparently influenced by IFN-γ in CD patients[40].

IBD3

Major histocompatibility complex (MHC) genes are located in this region, specifically on the short arm of the human chromosome 6.

With a candidate gene approach the MHC is the most extensively studied region. Two meta-analyses have been carried out to scan for IBD regions that are common for all populations[5,41] in which the highest evidence for linkage to IBD was achieved at the IBD3 locus. There are 3 classes of MHC genes: I, II and III. The antigenic recognizing process in T-lymphocytes from the antigen presenting cells is achieved through the antigenic recognition associated with the MHC gene product[42].

HLA class I

Some not classical genes related to the class I genes such as MHC class I chain-related gene A (MICA) and MHC class I-related chain B (MICB), are expressed in the basolateral cells in the gastric epithelium, fibroblasts, endothelial and dendritic cells. It is known that its expression rises during viral and bacterial infections[43]. Some genetic studies in patients with IBD have found associations with MICA-A6 and HLA-B52 in Japanese patients with UC[44], MICA*010 and HLA-B*1501 in English patients with fistulous CD[23]. MICA and MICB bind to an activating receptor natural killer group 2D (NKG2D) which is expressed on NK cells, T cells and macrophages and the interactions between these receptors may directly stimulate cell cytotoxicity as well as providing costimulation for NK and T cell activation. Several MICA alleles have been shown to alter the binding affinity with NKG2D suggesting they may exert a functional effect on immune activation. In contrast to HLA class II, HLA class I genes show a weak and inconsistent role in IBD. The functional significance of these polymorphisms and the nature of selective forces maintaining them are still being elucidated.

HLA class II

Class II genes are located on the centromeric pole of the short arm of the human chromosome 6 and include HLA-DR, DP and DQ *loci* expressed in a dimeric glycoprotein only in macrophages, activated T-lymphocytes, B-lymphocytes, dendritic, epithelial and endothelial cells, playing a central role in the immune response. Polymorphisms in these molecules are concentrated around specific pockets of the binding groove that interact with critical side-chains or anchor residues of peptides. The different HLA molecules may bind preferentially to different peptides, or bind the same peptide with varying affinities. In IBD the molecular mimicry may exist between the peptides derived from bacterial luminal flora and from self antigens present in the gut, leading to the generation of auto reactive T cells and contributing to disease pathogenesis. The mechanism of cross reactivity is supported by the identification of murine MHC-restricted CD4+ T cells reactive to enteric bacterial antigens that are able to induce colitis by adoptive transfer[45].

In a meta-analysis made by Stokkers *et al*[46], positive associations between UC and HLA-DR2, HLA-DRB1*1502, HLA-DR9 and HLA-DRB1*0103 were found. A study from Mexican population found that HLA-DRB1*0103 allele was associated with UC and its severe manifestations such as colectomy and pancolitis, while HLA-DRB1*15 allele was only associated with pancolitis in Mexican patients with UC.

HLA class III

These genes are located on the 1100 kb section between class I and II genes inside the MHC, and contain about 70

genes. The complement gene block is inherited as a genetic unit known as complotype. Each complotype codifies for the synthesis of complement classic pathway C2, C4A, C4b factors, and alternative pathway B factor, which may suggest that alterations within the region might affect the host's defense system and introduce a complement deficiency. This raises attention when TNFα is thought to play an important role in the pathogenesis of IBD, acting as a potent proinflammatory cytokine with elevated serum and tissue levels in patients with IBD[47-49], and evidence show that there are specific genetic polymorphisms involving TNFα that influence the amount of cytokine produced. Bouma *et al*[50] and Louis *et al*[51] studied the allelic frequency of TNFα gene polymorphisms at -308 position finding that polymorphism in allele 2 was decreased in UC patients as compared to normal controls. It was also found that patients with pancolitis had increased frequency in the TNF-C haplotype[52]. In a Mexican population with UC, the presence of TNF*2 allele was associated with the presence of this disease as compared with healthy subjects (23.7% *vs* 3%, $P = 0.00002$; OR = 10.1; 95% CI = 2.69-26.8)[53]. In Mexican patients with UC, an association was found between complotype SC30 (Bf*S-C2*C-C4A*3-C4B*0) and UC[54], which might suggest that activation of complement system could interfere with the disease pathogenesis.

IBD4

This locus is located on chromosome 14. Evidence for linkage to the adjacent D14S261 and D14S283 *loci* on chromosome 14q11-12 satisfied criteria for confirmed linkage and this region was designated IBD4 locus[55]. Vermeire *et al*[56] in a genome wide scan in a 149 Belgian IBD affected families cohort, demonstrated the existence of IBD4 on 14q11 as a susceptibility *loci*. The IL-25 gene is located within this susceptibility region at 14q11.2. The IL-25 gene is located within this susceptibility region at 14q11.2.

IL-25

Interleukin-25 (IL-25) is a newly identified proinflammatory cytokine that has been shown to promote Th2 responses by inducing cytokines such as IL-4, IL-5 and IL-13, implicated in the initiation of type 2 cytokine-dependent immunity to gastrointestinal infection and limiting proinflammatory cytokine production and chronic intestinal inflammation. IL-25-deficient knockout mice failed to develop a type 2 immune response or eradicate infection. Moreover, chronically infected IL-25 (-/-) mice developed severe infection-induced intestinal inflammation identifying a role for IL-25 in limiting pathologic inflammation at mucosal sites in the gastrointestinal tract[57]. Still more evidence is needed to conclude a precise role of this gene in the IBD susceptibility.

IBD5

The IBD5 locus on chromosome 5q31-33[58] contains the cytokine cluster and is a candidate region for IBD. The IBD5 risk haplotype has been associated with CD, although there have been some suggestions of a weak association with UC as well. Phenotypically this locus has been associated with earlier onset of disease as well as perianal disease[59-62].

Carnitine/Organic cation transporter genes

The organic cation transporter genes OCTN1 and OCTN2 are within a single haplotype block (block 7) of the IBD5 locus and some mutations have been reported within these: L503F (rs1050152) and G-207C (rs2631367) in the *SLC22A4 (OCTN1)* and *SLC22A5 (OCTN2)* genes, respectively, which are associated with the development of CD and also an association with susceptibility to UC has been reported[63]. The presence or combination of these mutations constitutes the TC haplotype, which is associated with ileal, colonic and perianal disease[64,65]. Associations between TC haplotype variants and CD affected sites have been shown in genotype-phenotype studies[66,67]. According to some studies, 1672C→T missense substitution in SLC22A4 and the -207G→C transversion in the SLC22A5 promoter contribute to disease susceptibility by impairing OCTN activity or expression respectively[68]. The risk associated with the OCTN-TC haplotype seems to be only observed in homozygotes and not in heterozygotes[60,63,69], so the carriage of the homozygous OCTN-TC haplotype is likely to be associated with a higher relative risk for colonic disease. The association of the OCTN polymorphisms with CD phenotypes shows a higher frequency of the OCTN-TC haplotype in patients with colonic involvement compared with exclusive ileal disease[60]. It has been reported a moderate increase in the frequency of the TC haplotype among patients without fistulas or stenosis and this is compatible with the negative association with ileal involvement, showing a tendency towards a lower-frequency of ileocecal resection in the presence of at least one OCTN-TC haplotype and might explain the absence of colonic involvement[64]. The impaired eradication of luminal pathogens results in a persistent infection which may constitute a possible mechanism causing IBD.

Drosophila long disc homologue 5 gene

Drosophila long disc homologue 5 gene (DLG5) on chromosome 10q22-23 is a member of the membrane associated guanylate kinase gene family which encodes cell scaffolding proteins and seems to play a role in the maintenance of intestinal epithelial cells, and its mutations have been involved in a rise in intestinal permeability[70]. DLG5 is a widely expressed protein found in many tissues such as the placenta, small bowel, colon, heart, skeletal muscle, liver and pancreas and it is important in signal transduction and epithelial cell integrity. Four haplotypes have been identified associated with IBD in a European cohort[71]. Haplotype A is characterized by the presence of an insertion of thirteen pairs in exon 26. It has been shown to be protective in some case control studies[72], however it is substantially undertransmitted in people with IBD[62]. The haplotype characterized by the haplotype-tagging SNP G113A called Haplotype D, was found substantially overtransmitted in patients with IBD controversially contradictory with another[73] Belgian study where the D haplotype involving the 113A variant was shown to be undertransmitted in flamish patients with

IBD. These apparently contradictory results might yet be compatible with the possibility that DLG5 has a small effect in IBD with heterogeneity in its effect.

ATP-binding cassette or multidrug resistant gene

The multidrug-resistance (MDR1) gene is located on the long arm of chromosome 7 and consists of 29 exons. The total length is 209 kb and 6326 bp. Its product, the P-glycoprotein (Pgp), a member of the ATP binding cassette family, is an integral membrane protein which functions as an energy-dependent efflux pump and reduces the intracellular concentrations of toxins and xenobiotics[74]. Studies show evidence for natural single nucleotide polymorphisms (SNPs) of MDR1 gene and their effects on drug efficiency, toxicity, distribution, absorption and elimination. Two main polymorphisms or variants of this gene have been described, C3435T and G2677T which are associated with IBD in some populations[75,76] and have also been related with the expression of glycoprotein P-170. Variant C3435T was related with the presence of pancolitis in patients with UC in Scotland[77]. However, the frequency of SNPs is low and is different among populations, with the exception of three SNPs in exon 12 (C1236T), exon 20 (G2677T/A) and exon 26 (C3435T), and some of them are correlated with different diseases and clinical characteristics[78]. Glucocorticoid is a potent inhibitor of the T cell activation and a highly effective treatment for IBD[79]. Over-expression produces three molecular mechanisms of glucocorticoid resistance: increase of P-gp and decrease of cytoplasmatic glucocorticoid, dysfunction at the level of glucocorticoid receptor and activation of NFκB, resulting in inhibition of glucocorticoid receptor transcriptional activity. Cucchiara *et al*[80] investigated the predisposition and response to medical therapy of TNFα and MDR1 genes in 200 pediatric patients with CD and 186 UC patients and 347 adults as a control. The 308A allele of the TNF-α gene was increased in both patients with CD and UC, strongly suggesting this polymorphism carries a significant reduction in response to steroid therapy.

IL-6 (-174G/C) polymorphism

IL-6 is a well-studied IBD candidate gene and its polymorphism has been associated with the site of disease in CD. IL-6 levels are higher in patients with active CD as compared to patients with active UC and normal controls[81,82]. A study from Cantor *et al*[39] demonstrated a relationship between IL-6 genotype and the site of CD, showing that patients with the high producer of IL-6 genotype were more likely to have colonic CD. In CD patients IL-6 concentrations also correlate with the disease activity, response to treatment and rate of relapse.

IBD6

In a Canadian linkage scan, a linkage peak of genome-wide scan on chromosome 19p was identified and appeared to confer susceptibility to both CD and UC[61]. Two independent genome-wide linkage studies also determined evidence for linkage to this region and two other meta-analyses of all published genome-wide scans[5,41,83] identified evidence that supports the existence of a locus conferring susceptibility to IBD in chromosomal region 19p, currently known as the IBD6 locus. In order to identify IBD susceptibility alleles in the 19p region two candidate genes DDXL and intracellular adhesion molecule 1 (ICAM-1) were examined in a case-control study with CD and UC patients but no association with either UC or CD was found in 3 single nucleotide polymorphisms in DDXL gene, however a significant association was found between ICAM-1 K469 homozygosity and CD as well as E469 and fistulating disease[84].

IBD7

Located on the short arm of chromosome 1, IBD7 is thought susceptibility genes are residing in this locus. One of these codifies for the transforming growth factor beta 2 (TGF-beta 2) which is a cytokine present in human and bovine milk and plays a critical role in the development of tolerance, prevention of autoimmunity, and in anti-inflammatory responses and is also a potent inhibitor of intestinal epithelial cell (IEC) growth and stimulates IEC differentiation[85-87]. McKaig and colleagues[88] studied the expression of TGF-beta isoforms in isolated and cultured primary human intestinal myofibroblasts from normal controls as well as from UC and CD patients, and determined the responsiveness of these cells to TGF-beta isoforms. Proliferation of myofibroblasts in CD patients was significantly greater than that of myofibroblasts derived from normal and ulcerative colitis tissue, suggesting that it may be related to the development of intestinal strictures, seen frequently as a major feature in CD. The anti-inflammatory attributes of TGF-β3 may be evidenced in a study of children with active intestinal Crohn's disease, who were treated with an oral polymeric diet rich in TGF-β2 as the sole source of nutrition for eight weeks and it was associated with mucosal healing and a down-regulation of mucosal pro-inflammatory cytokines mRNA in both the terminal ileum and colon[89]. However, further investigation on this locus is needed to determine the level of significance related to the pathogenesis of IBD.

IBD8

This gene is located on the short arm of human chromosome 16. There has been evidence of a second chromosome 16 locus (IBD8) independent of NOD2 that overlaps IBD1 on the pericentromeric short arm[90], but yet no studies have been performed for the identification on this locus.

IBD9

The CC-chemokine receptor 5 *(CCR5)* gene located on chromosome 3p21 coincides with this IBD susceptibility locus identified by genome-wide scanning[91]. The CCR5 is the receptor for regulated and normal T-cell expressed and secreted (RANTES), a natural pro-inflammatory cytokine. A 32-bp deletion (A32) in the CCR5 gene results in a nonfunctional receptor found with a high

frequency in Caucasians. They found an association between CCR5delta32 homozygosity and the presence of anal lesions in CD patients with statistical significance[92]. Several genes located in these regions are still under research (Table 1).

GENES INVOLVED IN THE INNATE IMMUNE RESPONSE

Toll like receptors

Rising evidence suggests an essential role of the enteric bacterial flora in the pathogenesis of IBD. Rather than a passive barrier, the intestinal epithelium is an active participant in the mucosal immune response through its expression of proinflammatory genes, secretion of inflammatory cytokines, and recruitment of inflammatory cells in response to pathogenic bacteria and their products[93]. IBD has been increasingly thought to result from an aberrant interaction between the environment and the genetically susceptible host. Specifically, several lines of evidence point to a deregulation of the immune response to a commensal or uncharacterized pathogenic bacterium in the gut[94]. Animal models have demonstrated that genes involved in the regulation of the immune response are likely to play a crucial role in the genetic predisposition to IBD[95]. The family of Toll-like receptors *(TLR)* recognizes pathogen-associated molecular patterns and activates signal transduction pathways of the innate immune response genes including NFκB[95]. The SNPs involved in bacterial recognition are becoming essential in understanding individual responses to bacterial components and defining genetic backgrounds at risk of IBD.

Toll-like receptor 4: The toll-like receptor 4 (TLR4) gene is located on the long arm of human chromosome 9 and it identifies lipopolysaccharides (LPS) on gram-negative bacteria. It has been found strongly upregulated in IBD, and it binds to LPS together with CD14 and by internalization prevents inappropriate NFκB activation[96]. The TLR4 Asp299Gly polymorphism has been associated with CD and UC in a Belgian study[97]. On the other hand this SNP was exclusively related to CD in other series[97-102] and TLR4 polymorphism Thr399Ile was exclusively associated with UC in others[99]. A lipid A-mimetic CRX-526 with antagonistic activity for TLR4, is known to block the interaction of LPS with the immune system, therefore, CRX-526 can prevent the expression of proinflammatory genes stimulated by LPS *in vitro*. This disturbed activation of the innate immune system by bacterial antigens may be crucial in some patients with IBD.

TLR1, TLR2, and TLR6: Pierik *et al*[100] studied the nonsynonymous polymorphisms in other TLR genes in IBD. They found no SNP was involved in disease susceptibility, and a number of variants influenced the disease phenotype, however, they found a positive association between TLR1 R80T and TLR2 R753G and pancolitis in UC. TLR2 and its cofactors TLR1 and TLR6 are involved in the initial immune response to bacteria and recognition of peptidoglycan. This TLR2 is required for recognition of Gram-positive and mycobacterial pathogen-associated molecular patterns (PAMPs) including bacterial lipopeptide lipoteichoic acid (LTA), peptidoglycan (PGN) and the mutations associated are involved in severe mycobacterial infections[103-109]. Further studies have shown that combinations of TLR molecules are required for recognition of certain PAMPs and that specifically, combined expression of TLR2 and TLR6 is required for recognition of PGN[110-114].

It is suggested that TLR1 may be regulated diversely in inflammation to down-regulate or enhance the response to certain TLR2 ligands and that a relative absence of TLR2 protein expression may be important in preventing chronic proinflammatory cytokine secretion in response to commensal Gram-positive bacteria in the gut[95].

TLR5: *TLR5* gene is located on the short arm of human chromosome 1 and is responsible for recognizing a protein named flagellin which is found in intestinal bacteria[113]. Lodes *et al*[113] observed through serological studies a strong response to flagellin in multiple animal models of colitis and synergism has been identified between NOD2 and TLR5 signaling[114]. The dominant negative variant of TLR5 (TLR5-stop) seems to protect against the development of CD and results in significant reduction of IgA and IgE circulating antibodies against flagellin[115], suggesting that pharmacological blockade of TLR5 has potential in the treatment of CD.

NOD1/CARD4 gene

Located on chromosome 7p14, *NOD1/CARD4* gene is one of the three human NOD-LLR proteins that has similar structure to NOD2/CARD15, having only one CARD domain, a central NOD domain and a leucine rich repeat region (LLR). Its function is the recognition of gram negative bacterial products such as γ-glutamine diaminopimelic acid and plays a role in colonic epithelial defense against the intracellular pathogens *E.coli* and *Shigella flexeneri*. Its effector domain is associated with Ripk2 (a CARD-containing interleukin-1 beta converting enzyme-associated kinase) mediating NFκB activation. In a recent study of 556 patients with IBD (294 CD and 252 UC), an association between the variant rs695857 in nucleotides 30, 258 and 950 of NOD1 and the development of IBD was found. Another variant known as rs2907748 in nucleotides 30, 246 and 263 was also associated with the presence of UC and CD and even with the early onset of the disease (< 25 years)[116]. These genetic variants of NOD1 have shown to be associated with disease susceptibility supporting that impaired local immunity might influence bacterial proliferation and aberrant immune responses in the host.

CCL20

CC-chemokine ligand 20 (CCL20) gene is located on the short arm of human chromosome 2 and codifies for the CCL20 cytokine ligand, which is responsible for the chemoattraction of immature dendritic cells that express CCR6 receptor on the intestinal epithelium and on Peyer's plaques[117], and also attracts memory T lymphocytes.

Microarray analysis and PCR-RT quantification have shown a rise in the expression of mRNA from IBD biopsies with inflammation compared to normal biopsies[118]. A study made in Korean UC patients showed that the expression of CCL20 was significantly up-regulated in the peripheral blood mononuclear cells compared with those of normal healthy controls. Interestingly, untreated UC groups expressed higher levels of CCL20 mRNA than treated UC and normal control groups, therefore suggesting that CCL20 could be modulated by anti-inflammatory drugs[119].

Interleukin 11

IL-11 mediates anti-inflammatory effects and is able to downregulate LPS-induced NFκB activation. The IL-11 gene is therefore a good candidate involved in genetic predisposition to IBD. Klein *et al*[120] evaluated the role of IL-11 in IBD, finding decreased expression and a failure to downregulate NFκB expression that could play an important role in the pathogenesis of UC.

Interleukin 18

IL-18 is a pleiotropic cytokine that induces the production of IFNγ and also regulates Th2 cytokines. It seems to be an important cytokine involved in the pathogenesis of IBD, apparently because SNPs at the 5'-end of IL-18 gene might be closely related to the etiology of IBD. Takagawa *et al*[121] found that IL-18 gene promoter polymorphisms may be related to the extent of disease in UC patients.

Interleukin 23

IL-23 is a heterodimeric cytokine composed of a p19 subunit and the p40 subunit of IL-12. It is produced by macrophages and dendritic cells, and activates memory T cells. Interleukin-12 (IL-12) is composed of p35 and p40 subunits and acts as an important factor for the differentiation of naive T cells into T-helper type 1 CD4+ lymphocytes secreting interferon-gamma. Therefore it has been reported that IL-12 is crucial for T-cell-dependent immune and inflammatory responses through the use of IL-12 p40 gene-targeted mice and neutralizing antibodies against p40[122-127]. Apparently IL-12 is a key factor driving Th1 responses and IFN production in the initial phases of an immune response, but conversely IL-12 may play a subsequent immunoregulatory role in late-stage inflammation at a point when IL-23 strongly supports the inflammatory process. IL-23 induces the production of IL-17 by a unique subset of memory T cells. IL-17 is known to stimulate fibroblasts, endothelial cells, macrophages and epithelial cells to secrete multiple pro-inflammatory mediators[128] and the local production of IL-17 causes site-specific activation of inflammatory cells[129-132]. Dendritic cells found in the lamina propria of the small intestine were described as constitutively expressing IL-23[131], whereas IL-23 regulates a highly potent T cell-derived cytokine that has major actions on the immune system. IL-23 specifically stimulates memory CD4+T cells contrasting the IL-12 which is a stimulant for naive CD4+ T cells[129,130]. Studies with IL-23 deficient mice show that IL-23 is essential for the manifestation of intestinal inflammation and a dominant role for IL-23 over IL-12 in central nervous system and joint autoimmune inflammation has been described. These findings point to IL-23, but not IL-12, as the necessary mediator for organ specific autoimmune diseases development. Furthermore, the absence of IL-12 results in more severe disease, reflected in elevated and prolonged expression of proinflammatory cytokines. Yen and colleagues[132] reported that the activation of tissue-homing memory T cells by IL-23 is responsible for chronic inflammatory disease.

CONCLUSION

Genetic research in IBD has provided knowledge about the complexity and heterogeneity of the disease and started to correlate the interactions between genetic and environmental risk factors in IBD; however, the complex genetic background that allows the development of IBD is not fully understood.

Understanding the pathways in which genetic factors influence IBD will uncover pathogenesis of the disease, offer more accurate diagnosis and ultimately lead to the breakthrough of better new drugs and therapies. Most of the important advances toward understanding this process have been identification of specific genetic associations with IBD, which will shed new light on future research of IBD.

Abstract

Increased numbers of mucosa-associated *Escherichia coli* are observed in both of the major inflammatory bowel diseases, Crohn's disease (CD) and ulcerative colitis (UC). A potential pathophysiological link between the presence of pathogenic invasive bacteria and genetic host susceptibility of patients with ileal CD is suspected. In CD patients, with increased ileal expression of the CEACAM6 molecule acting as a receptor recognized by type 1 pilus bacterial adhesin, and with the identification of mutations in the NOD2-encoding gene, the presence of pathogenic invasive bacteria could be the link between abnormal ileal bacterial colonization and innate immune responses to invasive bacteria. In a susceptible host, the sequential etiological steps of the disease induced by adherent-invasive *E. coli* (AIEC) are: (1) abnormal colonization *via* binding to the CEACAM6 receptor, which is overexpressed in the ileal mucosa of CD patients; (2) ability to adhere to and to invade intestinal epithelial cells, which allows bacteria to cross the mucosal barrier; (3) survival and replication within infected macrophages in the lamina propria; and (4) induction of tumor necrosis factor-α secretion and granuloma formation.

Key words: Adherent-invasive *Escherichia coli*; Crohn's disease; Inflammatory bowel disease; Ulcerative colitis

INTRODUCTION

Idiopathic inflammatory bowel diseases (IBDs), which include Crohn's disease (CD) and ulcerative colitis (UC), are chronic disorders of the gastrointestinal tract that have a combined prevalence of approximate 150-200 cases per 100 000 population in Western countries[1]. Several lines of evidence suggest that bacteria play a role in the onset and perpetuation of IBD[2-6]. Intestinal bacteria are essential for the development of intestinal inflammation, and are required for the onset of inflammation in numerous knockout models of IBD[7-9]. The pathogenesis of CD is complex and consists of three interacting elements: genetic susceptibility factors such as NOD2/CARD15 and ileal CEACAM6 expression; priming by enteric microflora; and immune-mediated tissue injury[4,6,10-13]. The role of luminal bacteria in the pathogenesis of CD is strongly supported by observations showing that clinical symptoms of CD improve when luminal bacterial levels decrease following intestinal washes and antibacterial drug administration[14-16]. In addition, postoperative exposure of the terminal ileum to luminal contents is associated with increased inflammation in CD, and diversion of the fecal stream is associated with improvement[17].

Studies of luminal bacterial composition in patients with IBD, using culture and molecular biology techniques, have shown a decrease in the number of beneficial bacteria such as *Bifidobacterium* and *Lactobacillus* spp. and an increase in pathogenic bacteria such as Bacteroides and *Escherichia coli* (*E. coli*)[18-20]. Such dysbiosis induces a breakdown in the balance between putative species of protective *vs* harmful intestinal bacteria, and may promote inflammation[21,22]. Patients with IBD have higher numbers of mucosa-associated bacteria than control patients[18], and the generalized or localized dysbiosis observed is due to the presence of low numbers of normal bacteria, high numbers of unusual bacteria, and sometimes, a reduction in biodiversity. CD has features that might be the result of a microbial process in the gut. These include onset of infection in Peyer's patches and lymphoid aggregates, and the presence of ulceration, micro-abscesses, fissures, fistulas, granulomas and lymphangitis. Interestingly, the earliest lesions are aphthous ulcers in the intestine, which also occur in some viral and bacterial infections.

Although a number of organisms have been implicated in CD, only two agents, *Mycobacterium paratuberculosis* and *E. coli*, are presently being actively investigated. The theory that *M. paratuberculosis* has a role in CD has some attractive features[23]. Indeed, there are clinical similarities between Johne's disease, a spontaneous *M. paratuberculosis* infection in ruminants, and CD. *M. paratuberculosis* is detected at a greater frequency in CD than in control patients (UC patients and healthy subjects), by culture and polymerase chain reaction (PCR). This organism has been detected in blood and breast milk of patients with CD[24]. The high levels of *E. coli* colonizing the intestinal mucosa in CD patients strongly suggest that it plays a role in the etiopathogenesis of CD.

E. COLI ABNORMALLY COLONIZES ILEAL MUCOSA OF GENETICALLY PREDISPOSED IBD PATIENTS

Bacterial adhesion to intestinal epithelial cells is the first step in the pathogenicity of many organisms involved in infectious diseases of the gut. Adhesion enables the bacteria to colonize the mucosa and to resist mechanical removal from the intestine. Studies on the adherence properties of *E. coli* in CD have yielded the general conclusion that *E. coli* strains are able to adhere to various human cells or cell lines. Fifty-three to 62% of *E. coli* strains isolated from feces of CD patients were able to adhere to buccal cells, compared to only 5%-6% of those isolated from control subjects[25,26]. The comparison of the adhesive properties of *E. coli* strains isolated from the ileum of CD patients and controls has revealed that 80% of *E. coli* strains associated with the ileal mucosa of CD patients preferentially adhered to differentiated Caco-2 cells, which mimic a mature intestinal cell model[20]. This is consistent with the finding that in patients with CD, crypt epithelial cells, which correspond to immature cells, are rarely involved in early lesions[27]. In addition, a correlation between bacterial adhesion to intestinal cells and intestinal colonization has been observed[20]. The presence of high levels of bacteria creates a biofilm on the surface of the gut mucosa in patients with CD and UC[18]. When bacteriologic samples were taken during surgery for CD, *E. coli* was isolated more frequently from the intestinal serosa and mesenteric nodes of CD patients (27% and 33%, respectively) than from those of control subjects[28,29]. Increased numbers of mucosa-associated *E. coli* are observed in CD and UC[18-20,30-33]. Rectal mucosa-associated *E. coli* counts were also higher in active than in inactive UC and CD and controls, and clusters of *E. coli* were observed in the lamina propria in UC and CD specimens, but not in controls[34]. In a study to assess the predominance of *E. coli* strains associated with the ileal mucosa of CD patients, *E. coli* was recovered from 65% of chronic lesions (resected ileum) and from 100% of the biopsies of early lesions (postoperative endoscopic recurrence)[20]. *E. coli* was abnormally predominant (between 50 and 100% of the total number of aerobes and anaerobes) in early and chronic ileal lesions of CD patients[20]. Moreover, in any given patient, healthy and ulcerated mucosa are colonized by *E. coli* strains having the same ribotype profile, which is indicative of uniform colonization, regardless of the inflammatory state of the mucosa[35].

Abnormal colonization of the ileal mucosa is due to increased expression of CEACAM6, a receptor for adherent–invasive *E. coli* (AIEC)[13]. These bacteria have been isolated from ileal lesions of CD patients, and express the type 1 pilus variant, as opposed to the type 1 pilus expressed by *E. coli* MG1655[36]. CD-associated AIEC strains adhere to the brush border of primary ileal enterocytes isolated from CD patients, but not from control patients without IBD. AIEC adhesion is dependent on type 1 pilus variant expression on the bacterial surface[36] and on abnormal CEACAM6 expression on ileal epithelial cells in CD patients[13]. The significantly increased ileal CEACAM6 expression in the uninvolved ileal mucosa of CD patients compared to that in controls without IBD, suggests that patients expressing a basal level of CEACAM6 are genetically predisposed to express that molecule. Additionally, CEACAM6 expression in cultured intestinal epithelial cells is increased after interferon (IFN)-γ or tumor necrosis factor (TNF)-α stimulation, and after infection with AIEC bacteria, which indicates that AIEC can promote its own colonization in CD patients[13]. Accordingly, in patients expressing a basal level of CEACAM6, the presence of AIEC bacteria and the secretion of IFN-γ and TNF-α lead to amplification of colonization and inflammation.

INVASIVES PROPERTIES OF *E. COLI* STRAINS ASSOCIATED WITH CD

Analysis of *E. coli* strains isolated from early or chronic ileal lesions of patients with CD has revealed the presence of true invasive pathogens, since CD-associated bacteria efficiently invade a wide range of human epithelial cell lines, including Hep-2 cells and the intestinal cell lines Intestine-407, Caco-2 and HCT-8[37]. Their uptake is dependent on functioning host-cell actin microfilaments and microtubules[37]. Electron microscopy of epithelial cells infected with CD-associated bacteria has revealed a macropinocytosis-like process of entry, characterized by elongation of the membrane extensions, which surround bacteria at the sites of contact between entering bacteria and epithelial cells. Inside the host cells, CD-associated bacteria survive and replicate in the cytoplasm after lysis of the endocytic vacuole. The invasive process of CD-associated bacteria is unique since it does not possess any of the known genetic invasive determinants described for enteroinvasive, enteropathogenic, and enterotoxigenic *E. coli*, and *Shigella* strains. The major virulence factors of CD-associated AIEC that play a role in their invasive ability are type 1 pili that induce membrane extensions[36], flagella that confer bacterial mobility and down-regulate the expression of type 1 pili[38], outer membrane vesicles that deliver bacterial effector molecules to host cells[39], and outer membrane protein C (OmpC), which regulates the expression of several virulence factors *via* the sigma(E) regulatory pathway[40]. Interestingly, among these virulence

factors, the outer membrane vesicles of *H pylori* and *Pseudomonas aeruginosa* have been reported to induce pro-inflammatory responses[41,42], and bacterial flagellin can interact with Toll-like receptor (TLR) 5 to activate an innate immune response.

The invasive ability of AIEC strains can allow bacteria to translocate across the human intestinal barrier and move into the deep tissues. Consequently, AIEC can interact with resident macrophages and continuously activate immune cells. In addition, patients with CD are more likely to be sensitive to AIEC infection. Indeed, the *NOD2* gene, located on chromosome 16q12, has been identified as the first susceptibility gene for CD[11,12]. NOD2-deficient mice show loss of protective immunity in response to bacterial muramyl dipeptide, and mice are susceptible to *Listeria* infection *via* the oral route[43]. The 3020insC mutant of NOD2 associated with CD has impaired function as a defensive factor against intracellular bacteria in intestinal epithelial cells[44]. Thus, patients carrying NOD2 mutations are unable to control bacterial infections. The mutated NOD2 receptor does not contribute to pro-inflammatory gene transcription in response to bacteria, which results in an inadequate innate response to bacterial invasion and enables bacteria to accumulate. Such a poor innate response can lead to the formation of granulomas and thus, to the activation and perpetuation of a deregulated secondary adaptive response.

AIEC SURVIVAL AND REPLICATION WITHIN MACROPHAGES AND GRANULOMA FORMATION

The search for infectious agents likely to cause CD has focused mainly on intracellular pathogens that have evolved to resist phagocytosis and to persist within macrophages, and which may be involved in chronic antigenic stimulation leading to T-cell and macrophage activation. AIEC strains isolated from CD patients are able to survive and replicate extensively within murine macrophages[45]. At 48 h post-infection, the number of intracellular AIEC bacteria can increase up to 74-fold compared to the initial infection. In contrast to its behavior within intestinal epithelial cells[37], CD-associated bacterial replication does not require bacterial escape into the cytoplasmic compartment[45]. Within J774-A1 macrophages, AIEC bacteria induce the formation of a single spacious vacuole by fusion of initial phagosomes. The behavior of the AIEC strains within macrophages is different from that of other invasive bacteria. In contrast to most invasive bacteria that induce death of infected macrophages[46], no necrosis or apoptosis of AIEC-infected J774-A1 macrophages is observed even after 24 h post-infection[45]. Moreover, in contrast to many pathogens that escape from the normal endocytic pathway, AIEC bacteria are taken up by macrophages within phagosomes, which mature without diverting from the classical endocytic pathway, and share features with phagolysosomes[47]. To survive and replicate in the harsh environment encountered inside these compartments, including acid pH and proteolytic activity of cathepsin D, AIEC have elaborate adaptation mechanisms, for which acidity constitutes a crucial signal, to activate the expression of virulence genes[48]. The major virulence factors of CD-associated AIEC that have a role in their ability to survive and replicate within macrophages are the *htrA* gene that encodes the stress protein HtrA, essential for intracellular replication within macrophages[48], and the *dsbA* gene that encodes the periplasmic oxidoreductase DsbA, essential for AIEC LF82 to survive within macrophages, irrespective of the loss of flagellum and type 1 pilus expression[49]. LF82-infected macrophages release large amounts of TNF-α[45]. This result is in accordance with the fact that several studies have shown that T helper (Th)1 cytokines, such as IFN-γ, TNF-α, and interleukin (IL)-12, are secreted in excess in CD whereas in UC, an atypical Th2 immune response with secretion of IL-4 or transforming growth factor (TGF)-β was observed[50]. Continuous macrophage activation and TNF-α release in CD patients may be due to the sustained multiplication of intracellular AIEC bacteria within phagosomes, and may be involved in the formation of granulomas. Granulomatous inflammation is a histological hallmark of CD and infection with some intracellular bacteria. *E. coli* DNA is present in 80% of microdissected granulomas in CD patients[51]. Granulomatous responses to *E. coli* have been reported in animals, such as granulomatous colitis of boxer dogs or Hjarre's disease in chickens and turkeys. *E. coli* strains were isolated from 100% of granulomas in boxer dogs with colitis[52], and these bacteria resembled CD-associated AIEC in phylogeny and virulence gene profile[53]. In Hjarre's disease, mucoid *E. coli* has been isolated from tuberculoid lesions of the cecum and liver of chickens and turkeys, while intramuscular inoculation of pure bacterial cultures or triturated diseased tissues reproduced the disease[54-56]. Using an *in vitro* model of human granuloma[57], CD-associated AIEC LF82 were reported to induce aggregation of infected macrophages, some of which fused to form multinucleated giant cells and subsequent recruitment of lymphocytes. Analysis of the cell aggregates indicated that they are very similar to the early stages of epithelioid granulomas[58].

PREVALENCE OF AIEC IN IBD

AIEC strains have been found to be highly associated with ileal mucosa in CD patients[56]. Such pathogenic strains were isolated from ileal specimens of 36.4% of CD patients *vs* 6% of controls. In colonic specimens, AIEC strains were found in 3.7% of CD patients, 0% of UC patients, and 1.9% of controls. These strains are preferentially found in early recurrent lesions after surgery, thus indicating their role in the initiation of inflammation, and not just as secondary invaders. Another study has shown that mucosa-associated *E. coli*, which accounted for 53% of isolates, were more common in CD (43%) than in non-inflamed control patients (17%), while intramucosal *E. coli* were found in 29% of CD patients *vs* 9% of controls[30]. These studies support a central role for mucosa-associated AIEC in the pathogenesis of CD[30,56], since the translocation of these pathogenic bacteria through the intestinal mucosa may be a crucial step in the propagation of the inflammatory process.

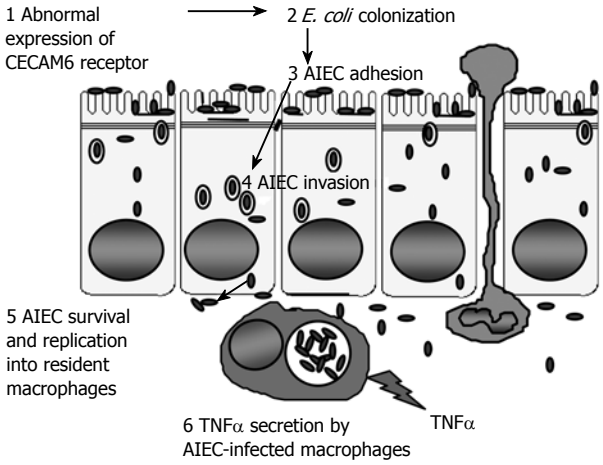

Figure 1 Sequential steps of the mechanisms of disease induced by AIEC bacteria: (1) abnormal expression of CEACAM6 in ileal mucosa of CD, inducing (2) AIEC colonization, (3) adhesion and (4) invasion, which allow the bacteria to cross the mucosal barrier. AIEC bacteria can (5) survive and replicate within infected macrophages in the lamina propria, and (6) induce TNF-α secretion.

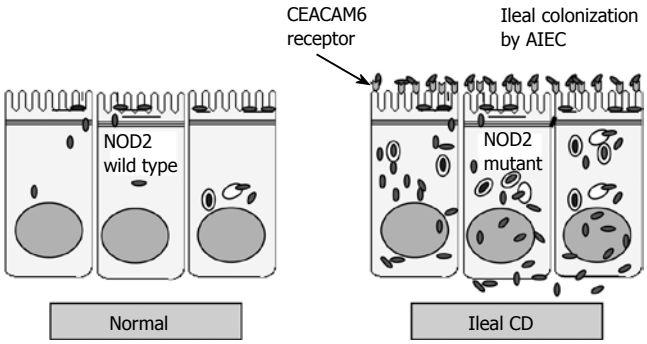

Figure 2 The infection cycle of AIEC may depend upon the ability of these pathogenic bacteria to colonize the gastrointestinal tract of genetically predisposed patients. Patients at high risk for developing severe ileal CD are those who overexpress CEACAM6 in the ileal mucosa, which allows AIEC colonization, and express the NOD2 3020insC mutant which has an impaired function as a defensive factor against intracellular bacteria in intestinal epithelial cells.

CONCLUSION

Various factors lend credence to the theory that AIEC is intimately linked to the etiopathogenesis of ileal CD. The high prevalence of AIEC in patients with ileal CD may be the first step in the establishment of a modified Koch's postulate that takes into account the genetic susceptibility of the host[30,56]. A possible role for AIEC in the etiopathogenesis of CD in susceptible hosts is summarized in Figure 1. The sequential steps involved in the induction of disease by the bacteria are: (1) abnormal colonization *via* binding to the CEACAM6 receptor, which is overexpressed in the ileal mucosa of CD patients[13]; (2) ability to adhere to and to invade intestinal epithelial cells, which allows bacteria to cross the mucosal barrier[37]; (3) survival and replication within infected macrophages in the lamina propria; and (4) induction of TNF-α secretion[45] and granuloma formation[58].

AIEC strains could colonize the ileal mucosa of CD patients by binding to CEACAM6, translocate across the human intestinal barrier to move into deep tissues, and once there, continuously activate immune cells. Patients having a high risk for developing severe ileal CD may be those who, in addition to expressing a variant of the NOD2 intracytoplasmic receptor[11,12], overexpress CEACAM6 at the surface of the ileal mucosa[13] (Figure 2). Host innate immune receptors that can be activated by AIEC components are mainly the transmembrane receptor TLR2 and the intracellular receptor NOD2. NOD2 is a negative regulator of the TLR2-mediated Th1 response, while the NOD2 3020insC mutation associated with CD is unable to inhibit TLR2 signaling, which skews the system toward an overactive Th1-mediated response[59]. This result provides a compelling explanation for why people carrying the NOD2 mutation might develop CD in response to abnormal colonization by AIEC[60]. The treatment of severe ileal CD could evolve from being almost exclusively surgical to management that places much greater emphasis on medical therapy, such as immunomodulators and anti-TNF-α agents, and also on antibiotic or probiotic treatments.

Abstract

The human intestinal tract is home to an enormous bacterial flora. The host defense against microorganisms can be divided into innate and adaptive immunity. The former is the most immediate line of response to immunologic challenges presented by bacteria, viruses, and fungi. The mucosal immune system has evolved to balance the need to respond to pathogens while co-existing with commensal bacteria and food antigens. In inflammatory bowel disease (IBD), this hyporesponsiveness or tolerance breaks down and inflammation supervenes driven by the intestinal microbial flora. Bacteria contain compounds and are recognized by a variety of receptors, including Toll-like receptors (TLRs) and NODs (a family of intracellular bacterial sensors) and are potent stimuli of innate immune responses. Several mutations in these receptors have been associated with development of IBD.

Key words: Innate; Immunity; Toll-like receptors; Inflammatory bowel disease

INTRODUCTION

Inflammatory bowel disease (IBD) comprises two major forms of chronic inflammation of the intestine, Crohn's disease (CD) and ulcerative colitis (UC).

IBD is currently presumed to result from the complex effect of diverse genes conferring risk of disease and environmental factors, which when combined lead to an aberrant inflammation response. Recent evidence suggests that innate immune responses play an important role in initiating the inflammatory cascade and subsequent characteristic pathological adaptive immune responses[1]. The innate immune response is the first line of defense for microbial infections. In addition to genetic factors in IBD, numerous studies have implicated a key role of the intestinal microbiota in patients with IBD[2-4]. The contribution of luminal microbes to the pathogenesis of IBD is highlighted by reports that surgical diversion of the fecal stream effectively resolves CD inflammation distal to the surgical site[2].

The human intestinal tract mucosa is exposed to an enormous microbial flora. A single layer of epithelial cells separates the host tissues from luminal bacteria. Innate immune mechanisms are involved in this relationship, and likely contribute significantly to the protection of the host from invasion by luminal bacteria and provide a rapid response to pathogens. Immediate activation of innate immunity relies on the detection by the host of conserved microbial motifs known as pathogen-associated molecular patterns (PAMPs), comprising diverse molecules from bacteria and viruses such as lipopolysaccharide, peptidoglycan, flagellin and lipoproteins[5].

Understanding of innate immunity has accelerated enormously with the discovery of many microbial sensors called "pattern recognition receptors" (PRRs). The toll-like receptor (TLR) and NOD receptor families of PRRs appear to play essential roles in mucosal homeostasis and alterations contribute to the pathogenesis of IBD.

THE TLR FAMILY

The mammalian TLR family consists of 13 mammalian members: each TLR having its intrinsic signaling pathway and inducing specific biological responses against microorganisms. Recognition of microbial components by TLRs triggers activation of signal transduction pathways, which then induce dendritic cell maturation and cytokine production, resulting in development of adaptive immunity[5].

Table 1 summarizes TLRs and the different molecular patterns associated with a broad range of microbes that they recognize. The activation of TLR signaling pathways originates from the cytoplasmic TIR domains. Four TIR domain-containing adaptors (MyD88, TIRAP/MAL, TRIF, and TRAM) play an important role in TLR signaling

Table 1 Molecular pattern recognition of NODs and TLRs

Receptor	Microbial motifs
NLR family	
NOD1	Lanthionine meso-diaminopimelic acid (meso-DAP) γ-D-Glu-meso-diaminopimelic acid (iE-DAP)
NOD2	Muramyldipeptide (MDP)
TLR family	
TLR1	Triacyl lipopeptides
TLR2	Lipoprotein, lipopeptides ($Pam_3CysSerLys_4$)
TLR3	dsRNA
TLR4	LPS
TLR5	Flagellin
TLR6	Diacyl lipopeptides
TLR7/TLR8	ssRNA
TLR9	Non-methylated CpG DNA
TLR11	Component of uropathogenic bacteria

pathway. These adaptors are associated with TLRs through homophilic interaction of TIR domains. Each TLR mediates distinctive responses in association with a different combination of these adapters[6].

THE NLR FAMILY

The mammalian NLR family comprises more than 20 members whose defining molecular characteristic is a C-terminal leucine-rich repeat (LRR) domain, a central nucleotide-binding NACHT domain and an N-terminal protein-protein interaction domain composed of a CARD (caspase activation and recruitment domain). Several studies have shown that several NLRs are necessary sensors of specific PAMPs.

The first NLRs reported to have a direct function as intracellular PRRs were NOD1 (CARD4) and NOD2 (CARD15). NOD2 detects muramyl dipeptide, the largest molecular motif common to Gram-negative and Gram-positive bacteria[7,8]. In contrast, NOD1 senses peptidoglycan containing meso-diaminopimelic acid (meso-DAP), which is more commonly found in Gram-negative bacteria[9,10].

NALP3 is a pyrin domain-containing NLR that activates the caspase-1 leading to interleukin 1β (IL-1β) and IL-18 processing, this protein is involved in sensing microbial components. In addition to NODs and NALP3 proteins, Ipaf (CARD12) and Nalp1 are intracellular sensors that detect intracellular flagellin, leading to inflammasome activation through a TLR5-independent pathway[11].

The signaling pathways downstream of NLRs include the NF-κB pathway, for NOD1 and NOD2, and activation of the caspase 1 inflammasome, for NAPLPs, Ipaf and Naip. NOD1 and NOD2 rapidly form oligomers and then transiently recruit receptor-interacting protein 2 (RIP2) through CARD-CARD interactions. The complex NOD-RIP2 then recruits the inhibitor of NF-κB kinase complex, which leads to activation of NF-κB. Several studies have shown that Ipaf and Naip can participate in the formation of inflammasomes (NALP1, NALP3 and Ipaf) that form in response to the detection of specific molecular motifs. It has been speculated that the formation of large protein complexes in a given inflammasome is sufficient to trigger caspase-1 activation[12].

NLRs are important in macrophage-mediated detection and control of bacterial infection *in vitro*. Ipaf is required for caspase-1 activation and IL-1β secretion in macrophages exposed to Gram-negative pathogen *Salmonella typhimurium*[13]. Cytosolic recognition of *Salmonella typhimurium* and *Legionella pneumophila* flagellins by Ipaf results in the induction of macrophage cell death and IL-1β secretion.

CONNECTION OF NOD AND TLR PATHWAYS

Intersection between TLR and NOD2 pathways is suggested by reports of synergistic induction of proinflammatory cytokines such as TNFα and IL-1β upon costimulation with MDP and specific TLR ligands[14,15]. MDP also substantially upregulated secretion of TNFα and IL-1β induced by ligands to five different TLRs ligands, TLRs 2, 4, 5, 7 and 9: ($Pam_3CysSerLys_4$, LPS, Flagellin, MALP-2 and R-848, respectively). Of note, these effects were observed in the presence of the most common NOD2 mutants associated with CD. In studies using mice lacking NOD2, Watanabe *et al* observed reduced responses to MDP, but enhanced responses to the TLR2 ligand peptidoglycan e.g., increases in IL-12. They interpreted these findings to suggest that the NOD2 signaling pathways normally down-regulate the TLR2 pathways. In their model, loss of function mutation of NOD2 together with TLR2 signals delivered by other bacterial products could result in enhanced cytokine responses to commensal bacteria by macrophages[16]. These findings suggest that interaction between NOD2 and specific TLR pathways may represent an important modulatory mechanism of innate immune responses, which is altered in some patients with CD.

TLRS IN IBD

TLRs are abundantly expressed on the surface of monocytes, macrophages, dendritic and epithelial cells. Alterations of TLR3 and TLR4 expression by intestinal epithelial cells have been described in IBD[17], suggesting that there is differential expression of TLR family members. Thus, primary intestinal epithelial cells of normal, non-diseased mucosa constitutively express TLR3 and TLR5, whereas TLR2 and TLR4 are present in much lower amounts. In active IBD, the expression of TLR3 and TLR4 was differentially modulated in the intestinal epithelium. TLR3 was significantly down-regulated in active CD but not in UC. In contrast, TLR4 was strongly up-regulated in both UC and CD. TLR2 and TLR5 expression remained unchanged in IBD.

Two common polymorphisms of TLR4 (Asp299Gly and Thr399Ile) have been described in humans. Asp299Gly has been associated with reduced responsiveness following lipopolysaccharide stimulation[18]. These polymorphisms have been associated with the development of CD and UC in Caucasian populations[19-21].

Recently, Pierik *et al*[22] showed that TLR1 R80T and TLR2 R753G polymorphisms were associated with pancolitis in UC patients, while a negative association

was observed between TLR6 S249P and proctitis in patients with UC. These results suggest that TLR2 and its co-receptors TLR1 and TLR6 are involved in the initial immune response to bacteria in the pathogenesis of IBD.

An important immune stimulatory effect mediated by the TLR family (TLR9) is induced by non-methylated CpG motifs found in bacterial DNA. In animal models of colitis, administration of CpG was able to ameliorate disease activity[23].

NODS IN IBD

Specific mutations of the NOD2 gene have been definitively associated with increased susceptibility to ileal Crohn's disease in Western (but not Asian) populations: Arg702Trp, Gly908Arg, and leu1007fsinsC (a frameshift mutation that truncates the carboxy terminal 33 amino acids)[24,25]. Heterozygous carriage of the risk alleles confers a 2-4 fold increased risk, and homozygotes or compound heterozygotes have a 20-40 fold increased risk[26]. More than 90% of all CD associated mutations are located in the LRR domain, suggesting that these may affect the function of NOD2 with respect to bacterial recognition and signaling. Transient transfection experiments indicate that CD-associated NOD2 mutants no longer activate NF-κB in response to MDP[27,28], which suggests that defective NF-κB activation facilitates infection of the lamina propria by enteric bacteria.

NOD2 mutants produce selective functional defects in leukocytes of patients with CD as shown by van Heel *et al*[8] who analyzed cytokine expression of peripheral blood mononuclear cells after exposure to MDP. In PBMC from CD patients the NOD2 ligand induced little TNFα and IL-1β, but strong IL-8 secretion. Furthermore, monocytes isolated from CD patients carrying the 1007fs (3020insC) mutation were reported to exhibit defects in the production of the proinflammatory cytokines, TNFα, IL-6 and IL-8, as well as the anti-inflammatory cytokine IL-10[29]. Dendritic cells derived from CD patients homozygous for leu1007fsinsC also fail to up-regulate the costimulatory molecules CD80 and CD86 in response to MDP and lack production of cytokines such as TNF-α, IL-12 and IL-10[30].

Evidence that NOD2 functions as an antibacterial factor in intestinal epithelial cells was demonstrated in Caco-2 cells stably expressing wild type NOD2 when infected with *Salmonella typhimurium*. This protective effect was absent in cells expressing a most common mutant NOD2 associated with CD (3020insC)[31].

NOD2 mutations in CD patients are also associated with diminished mucosal α-defensin expression[32]. Decreased β-defensin 1 and the lack of induction of both inducible antimicrobial peptides β-defensins 2 and 3 in CD could result in enhanced bacterial invasion and perhaps survival[33].

A study of 556 patients with IBD (294 CD and 252 UC) reported an association between the variant (rs695857) in nucleotides 30, 258 and 950 of the *NOD1* gene and the development of IBD. Another variant known as rs2907748 in nucleotides 30, 246 and 263 was also associated with the presence of UC and CD, particularly early onset of the disease (< 25 years)[34].

CROHN´S DISEASE

Marks *et al*[35] have provided provocative evidence that CD patients possess a generalized impaired innate immune response as reflected by diminished response to intradermal injection of killed bacteria as well as trauma of the skin or the intestine. When killed bacteria were injected into the forearms of CD patients, there was less blood flow to the injection site than non-CD patients. They also found that CD patients had reduced neutrophil accumulation and interleukin-8 (IL-8) production at sites of tissue trauma in the intestine and skin, although these findings need corroboration. This study supports the idea that CD may in some way be associated with relative inability to mount an acute inflammatory response compared to normal individuals.

Recent studies have suggested that the CD-associated NOD2 mutants might confer a milder defect in innate immune response than well-described innate immune deficiencies such as chronic granulomatous disease[8]. Rather than suppressing the secondary T-cell response, a different approach aims to normalize innate immune function through qualitative augmentation of neutrophil, macrophage and dendritic cell function. Clinical trials of granulocyte colony stimulating factor (G-CSF, specifically filgrastim) and GM-CSF (sargramostim) have suggested a benefit, although definitive evidence is not yet available[36,37]. However, G-CSF has a more limited effect on the innate immune system, acting primarily on neutrophils. GM-CSF is more widely and potently active, targeting a variety of cell types including not only neutrophils and monocytes as effector cells, but also intestinal epithelial cells that have receptors for GM-CSF.

CONCLUSION

The innate immune system is the first line of defense and provides a rapid response to pathogens. Elicitation of an innate immune response to bacterial products is mediated through families of pattern recognition receptors including the cell surface TLRs and cytosolic NODs that mediate the activation of NF-κB. Some mutations, TLRs, and NODs produce defects in sensing of pathogens and predispose the host to recurrent infections as well as perpetuation of chronic intestinal inflammation.

Abstract

Inflammatory bowel disease (IBD), the most important being Crohn's disease and ulcerative colitis, results from chronic dysregulation of the mucosal immune system in the gastrointestinal tract. Although the pathogenesis of IBD remains unclear, it is widely accepted that genetic, environmental, and immunological factors are involved. Recent studies suggest that intestinal epithelial defenses are important to prevent inflammation by protecting against microbial pathogens and oxidative stresses. To investigate the etiology of IBD, animal models of experimental colitis have been developed and are frequently used to evaluate new anti-inflammatory treatments for IBD. Several models of experimental colitis that demonstrate various pathophysiological aspects of the human disease have been described. In this manuscript, we review the characteristic features of IBD through a discussion of the various chemically induced experimental models of colitis (e.g., dextran sodium sulfate-, 2,4,6-trinitrobenzene sulfonic acid-, oxazolone-, acetic acid-, and indomethacin-induced models). We also summarize some regulatory and pathogenic factors demonstrated by these models that can, hopefully, be exploited to develop future therapeutic strategies against IBD.

Key words: Inflammatory bowel disease; Experimental colitis; Dextran sodium sulfate; Trinitrobenzene sulfonic acid; Oxazolone; Pathogenesis

INTRODUCTION

Inflammatory bowel disease (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), represents a chronic, relapsing and remitting inflammatory condition that affects individuals throughout life[1]. No completely effective therapeutic strategy has been established because the etiology of IBD remains largely unknown, although there has been extensive research on its pathogenesis. However, recent advances in the understanding of the pathophysiology of IBD have provided some clues for developing potentially helpful therapeutic tools.

Within the past two decades, several models of experimental colitis have been reported that demonstrate various pathophysiological aspects of human IBD. While no model serves as a complete surrogate for the human disease, some characteristically pathological features are open for investigation, depending on the method used to induce the experimental colitis. Experimental models of colitis enable us to dissect the pathogenic components during different phases of colitis, including acute, recovery and chronic phases. They also enable us to identify some pivotal immunological processes, as well as novel genes that are intimately involved in disease susceptibility.

In this review, we mainly focus on the role of functionally distinct factors, including immune cells, cytokines/chemokines, receptors/ligands, transcriptional factors, and enzymes/hormones, which maintain the homeostatic balance in the colon during the development of acute and chronic inflammation.

DSS-INDUCED COLITIS

The dextran sodium sulfate (DSS) model, originally reported by Okayasu *et al*[2] has been used to investigate the role of leukocytes in the development of colitis. Oral administration of 5% DSS in drinking water can induce not only acute, but also chronic colitis. One cycle of 3%-5% DSS administration for 5-7 d, followed by

regular water, results in extensive injury with complete crypt depletion (mainly basal crypt) and relatively slow regeneration of colonic epithelium. This regeneration is much slower than in other acute injury models, which use toxic substances such as acetic acid and ethanol[3]. The clinical features of this model include weight loss, loose stools/diarrhea, and rectal bleeding. Histopathological analysis typically reveals extensive crypt and epithelial cell damage, significant infiltration of granulocytes and mononuclear immune cells, and tissue edema, often accompanied with severe ulceration. In fact, because of the massive edema and subsequent ulceration during the acute phase, some researchers have wrongly used the DSS-induced colitis model by interpreting it as a model for human UC; however, this colitis is a simple model of acute chemical injury rather than chronic inflammation. Pathological scoring is generally performed on the distal segment of the colon, which is the most severely affected portion[3]. Histopathology, by hematoxylin and eosin staining, is scored based on three parameters: severity of inflammation (none, mild, moderate, severe), extent of inflammation (none, mucosa, mucosa and submucosa, transmural), and crypt damage (none, basal one-third damaged, basal two-thirds damaged, crypt lost but surface epithelium present, crypt and surface epithelium lost). It is noteworthy that long-term DSS administration produces colorectal carcinoma, which is similar to the dysplasia-carcinoma sequence seen in the course of cancer development in human UC[4].

Acute mucosal damage can be observed in both wild-type and severely combined immunodeficiency (scid) mice, which indicates that acquired immune responses are not involved in the induction of DSS-induced colitis[5]. The lesions observed in scid mice have been associated with increased production of macrophage-derived proinflammatory cytokines, such as interleukin (IL)-1β, IL-6, and tumor necrosis factor (TNF)-α. While the role of luminal bacteria in the pathogenesis of DSS-induced colitis is unclear, this colitis can be ameliorated by treatment with antibiotics that are clinically effective in patients with IBD[1], which suggests the importance of commensal bacteria in the development of colitis[6]. Although the earliest change of acute DSS-induced colitis is a progressive disruption of colonic crypts during the chronic phase (14 d after stopping DSS), macrophages and $CD4^+$ T cells are more prominent in areas of wound healing in the basal portions of the lamina propria (LP). These $CD4^+$ T cells secrete increased levels of interferon (IFN)-γ and IL-4, which suggests that chronic immune activation mediated by both Th1 and Th2 cells play a pathogenic role in chronic DSS-induced colitis[7].

2,4,6-TRINITROBENZE SULFONIC ACID (TNBS)-INDUCED COLITIS

In 1995, Neurath *et al* described a novel murine model of intestinal inflammation induced by intrarectal administration of hapten reagent TNBS in ethanol solution. Simultaneous administration of TNBS and ethanol is required to induce TNBS colitis, because ethanol disrupts the epithelial layer and exposes the underlying LP to bacterial components. Intestinal inflammation induced by intrarectal administration of TNBS has many of the characteristic features of CD in humans, including severe transmural inflammation associated with diarrhea, rectal prolapse, weight loss, and induction of an IL-12-driven inflammation with a massive Th1-mediated response[8]. Interestingly, prior oral administration of TNBS in the form of trinitrophenol-haptenated colonic protein (TNP-CP) prevents colitis induced by intrarectal administration of TNBS[9,10]. The preventive effect is due to the induction in the LP of regulatory cells consisting of $CD4^+$ T cells that produce transforming growth factor (TGF)-β after oral administration of TNP-CP[10].

The susceptibility to TNBS colitis varies between different mouse strains; SJL and BALB/c are susceptible, whereas C57Bl/6 and 10 mice are resistant. The susceptibility has been shown to be related to a genetically determined high IL-12 response to the lipopolysaccharide (LPS) locus on chromosome 11 in SJL/J mice[11]. In a recent study, te Velde and colleagues compared gene expression profiles in the colons of three different models of colitis (DSS, TNBS and $CD45RB^{high}$ T-cell transfer models)[12]. As a result, a restricted number of genes were either up- or down-regulated in the TNBS colitis (21 genes) model compared to DSS-induced colitis (387 genes) and $CD45RB^{high}$ transfer model (582 genes)[12]. Of the 32 genes known to change transcriptional activity in IBD (*TNF, IFN-γ, Lt*β*, IL-6, IL-16, IL-18R1, IL-22, CCR2* and *7, CCL2, 3, 4, 5, 7, 11, 17* and *20, CXCR3, CXCL1, 5* and *10, Mmp3, 7, 9* and *14, Timp1, Reg3*γ*, Pap, S-100a8, S-100a9, Abcb1,* and *Ptgs2*), two (*Mmp14* and *Timp1*) are up-regulated in TNBS, 15 (*IL-6, IL-16, IL-22, CCL2, 3* and *11, CXCL1* and *5, Mmp3* and *14, Timp1, Reg3*γ*, Pap, S-100a9,* and *Ptgs2*) are up- or down-regulated in DSS, and 30 (except for *CCL11 and Timp1*) are up- or down-regulated in the CD45RB transfer colitis models. The study suggests that the pattern of gene expression in these colitis models closely reflects altered gene expression in human IBD[12].

OXAZOLONE COLITIS

In contrast to TNBS, which leads to colitis driven by a Th1-polarized type of T-cell response, administration of another haptenating agent, oxazolone, leads to a colitis associated with a Th2-polarized type of response. This model is induced by the rectal administration of oxazolone suspended in an ethanol vehicle. Although the SJL/J strain of mice was utilized in the original description[13], over half of the later studies have been performed using the C57Bl/6 strain. The induction of colitis in the C57 strain requires a presensitizing treatment, since this strain is resistant to haptenating agents[14]. For presensitization, 4.5 mg - 6 mg of oxazolone in 100% ethanol is injected into the abdominal wall of mice, followed by intrarectal administration of various doses of oxazolone in 50% ethanol after 5 d.

Oxazolone colitis is limited to the distal part of the colon, in contrast to TNBS colitis that is characterized as pan-colitic. Microscopically, the inflammation of oxazolone colitis manifests as relatively superficial ulceration[13]. An IL-4-driven Th2-type of response is predominant and is

characterized by increased IL-4/IL-5, but normal IFN-γ production. The inflammation is prevented by the systemic co-administration of intraperitoneal anti-IL-4 antibody. The proinflammatory Th2-dominant cytokine response is regulated by TGF-β, which limits both the extent and duration of the disease. The histological features and inflammatory distribution of oxazolone colitis resemble human UC[13].

OTHER CHEMICALLY-INDUCED COLITIS MODELS

In a search for novel experimental models of acute IBD, MacPherson and colleagues have found that intrarectal administration of 3%-5% acetic acid induces acute colitis in the distal part of the colon in rats[15]. The initial injury consists of epithelial necrosis and edema that variably extends into the LP, submucosa, or external muscle layers. Epithelial injury is mainly caused by organic acids specifically because hydroxyl chloride (pH 2.3) does not generally induce acute colitis[4]. In mice, administration of acetic acid within 4 h results in colonic epithelial destruction without inflammation, which is then followed by an influx of acute inflammatory cells, and reaches its maximum intensity at 12 h. The inflammatory response is caused by non-specific factors after disruption of the epithelial barrier. The chemical injury heals within days in mice or 2-3 wk in rats[16].

Whereas acetic acid produces acute inflammation restricted to the colon, another pro-inflammatory agent, indomethacin, has been used to induce acute ileitis. Fasted rats are treated subcutaneously with indomethacin 7.5 mg/kg in sterile sodium bicarbonate, which leads to an acute inflammatory response characterized by multiple deep, longitudinal ulcers in the distal jejunum and proximal ileum. This acute response reaches its maximum intensity at 24 h and is completely resolved within 7 d, whereas two daily subcutaneous injections of indomethacin produce a chronic inflammation that lasts at least 2 wk[17]. Luminal bacteria and their products significantly contribute to the exacerbation and perpetuation of the chronic phase of indomethacin-induced inflammation.

These models have the advantage of being easy to initiate and therefore would be useful in the initial screening of new drugs for acute epithelial injury. However, the injury in the first 24 h is nonimmunologic and thus is not suitable for drug therapy trials for human IBD.

FACTORS INVOLVED IN THE PATHOGENESIS OF THE MAIN CHEMICALLY INDUCED COLITIS MODELS

In the following section, we focus more on the factors involved in the fine balance between pathogenic and regulatory factors in the pathogenesis of DSS- (Table 1), TNBS- (Table 2), and oxazolone- (Table 3) induced colitis.

T cells

$CD4^+$ T cells play a key role in the development of most T-cell-mediated IBD models. For example, the increased production of IFN-γ, mainly produced by $CD4^+$ T cells, is detected in most models of Th1-mediated colitis[18]. By contrast, IL-4 and IL-13, produced by natural killer (NK) T cells, have been shown to play a key role in the pathogenesis of Th2-mediated colitis, including oxazolone-induced colitis[19]. NK1.1 positive lymphocytes are also essential for alleviation of TNBS-induced colitis in the presence of peripheral tolerance[20].

Although $CD8^+$ T cells represent a major T-cell subset, there is little information available regarding the role of $CD8^+$ T cells in the pathogenesis of colitis. $CD8^+$ T cell receptor (TCR)-positive $V\beta14^+$ T cells, which are increased in the LP and have a cytotoxic effect[21], have a pathogenic role in the development of TNBS-induced colitis.

By contrast, TCRγδ T cells are an evolutionarily

conserved minor T-cell subset with characteristic properties that help maintain the homeostasis of epithelial cells, by providing a barrier between the luminal bacterial contents and underlying immune cells[22]. A regulatory role has been shown for TCRγδ T cells in DSS-[23,24] and TNBS-induced colitis models[25,26].

In addition to these populations, carcinoembryonic antigen-related cellular adhesion molecule 1 (CEACAM1; also known as CD66a) is a cell surface molecule that has been proposed to negatively regulate T cell function, and is associated with the regulation of T-bet-mediated Th1 cytokine signaling in TNBS- and oxazolone-induced colitis models[27].

Finally, regulatory T cells express the antigen non-specific suppressor factors transforming growth factor-β (TGF-β) and IL-10. Boirivant *et al* have shown that TNP-CP feeding cross-protects mice from an inflammatory response to a different hapten, oxazolone. This protective effect is associated with the appearance of mononuclear cells that produce regulatory cytokines[28]. This phenomenon of cross-protection could be exploited in designing novel treatments for IBD, because it demonstrates that an orally-administered antigen can induce production of regulatory cells that are able to suppress inflammation induced by a different type of antigen.

Cytokines/chemokines/growth factors

TNBS injection results in a transmural infiltrative colitis associated with an IL-12-mediated Th1-immune response[8]. In most cases, a single dose of TNBS is administered at the starting point of the experiment. In subsequent studies of IL-12, it has been reported that mucosal TNF-α is necessary for the initiation and perpetuation of TNBS colitis, since TNF-α-deficient mice are resistant to TNBS, and the colitis is extremely severe in mice that over-express TNF-α[29]. This result suggests that TNFα acts as a proximal co-factor for IL-12 or IL-18 production. One possible mechanism of amelioration by anti-IL-12 antibody treatment is through the induction of Fas-mediated apoptosis of Th1 cells[30].

Watanabe and colleagues have shown that TNBS-induced colitis is mediated by macrophage-derived IL-18[31]. In fact, neutralization with anti-IL-18 antibody results in dramatic attenuation of mucosal inflammation, and the administration of TNBS fails to induce significant colitis in IL-18 knockout (KO) mice. These results have been confirmed by another group who have demonstrated that recombinant human IL-18 binding protein isoform (rhIL-18BPa) leads to a significant reduction in TNBS-induced colitis, by decreasing local TNF-α production[32]. Interestingly, IL-18 is also a primary mediator of the inflammation in DSS-induced colitis, while neutralization of IL-18 attenuates intestinal damage in that colitis model[33].

In Th1-mediated colitis, the use of agents that block IL-12 secretion or activity provides the most direct approach for attenuating inflammation because IL-12 is critical for regulation of differentiation and activation of Th1 cells[8,30]. It has been demonstrated that IL-12p40 KO mice develop severe TNBS-induced colitis. Moreover, administration of IL-12p40 neutralizing antibody increases pathology in IL-12p35 KO mice, which suggests that IL-12p40, in contrast

to IL-12p70, exerts the major regulatory function in TNBS-induced colitis[34]. However, IL-12p40 forms heterodimers, not only with IL-12p35 (IL12p35p40; IL-12p70), but also with IL-23p19 (IL-23p19p40); a finding that raises the possibility that activity previously ascribed to IL-12 may be attributable to IL-23. Recently, it has been revealed that IL-23 is a key effector cytokine in the immune system of the intestine[35]. IL-23 specifically expands a pathogenic population of $CD4^+$ T cells called Th-17 cells, which produce IL-17A, IL-17F, IL-6 and TNF-α[36,37]. Indeed, IL-17R KO mice are protected against TNBS-induced colitis[38]. By contrast, Becker *et al*[39] have reported that IL-23 cross-regulates IL-12 production in T-cell-mediated TNBS colitis, since mice lacking the p19 subunit of IL-23 are highly susceptible to TNBS-induced colitis, and inhibition of IL-12p40 rescues IL-23p19 KO mice from lethal disease. These discrepancies regarding the role of IL-23 may result from different experimental models; therefore, further characterization should help in developing new therapeutic treatments for patients.

As for the Th2-type responses, oxazolone colitis is associated with increased production of IL-4/IL-5, and is prevented by the systemic co-administration of anti-IL-4 antibody[13]. Heller *et al*[19] have shown that IL-13, mainly produced by NK T cells, is a significant pathogenic factor in this model, since its neutralization by the decoy receptor IL-13Rα2-Fc prevents disease. As well, IL-13 induces TGF-β1, generally considered to be an anti-inflammatory cytokine, through IL-13Rα2 in oxazolone-induced colitis, and prevention of IL-13Rα2 expression leads to the marked down-regulation of TGF-β1 production and collagen deposition in bleomycin-induced lung fibrosis, during prolonged inflammation[40].

As an IL-12p40-related protein, it has been reported that Epstein-Barr virus-induced gene 3 (EBI3) dimerizes with a novel p28 subunit (which has homology to IL-12p35) to form the cytokine IL-27[41]. IL-27 has been shown to function as a proliferation factor for naïve, but not memory, $CD4^+$ T cells, and to synergize with IL-12 to stimulate IFN-γ production[41]. That EBI3 KO mice have been found to be resistant to oxazolone-induced colitis suggests that this molecule plays a crucial role in the induction of Th2-type immune responses[42].

Several families of growth factors regulate a wide spectrum of processes integral to IBD; including protection of the intestinal mucosa and activation, as well as regulation of the intestinal immune system. These factors mediate mucosal repair, restitution, remodeling and resolution of inflammation following tissue damage[43]. It is now widely accepted that TGF-β has an important function in regulating inflammation and tissue repair. Fuss *et al*[44] have elegantly demonstrated the relationship between TGF-β and IL-10 in the regulation of Th1-mediated inflammation in TNBS-induced colitis, by performing a study in which mice were fed a haptenated colonic protein and then administered either anti-TGF-β or anti-IL-10 antibody, at the time of subsequent rectal administration of TNBS. Anti-TGF-β antibody administration prevents TGF-β secretion, but leaves IL-10 secretion intact, whereas anti-IL-10 antibody administration inhibits both TGF-β and IL-10 secretion. Their data suggest that TGF-β alone is the primary mediator of counter-regulatory Th1-type mucosal inflammation, and that IL-10 is necessary as a secondary factor that facilitates TGF-β production, but does not act as a suppressor cytokine by itself. Interestingly, Kitani *et al*[45] have shown that single intranasal administration of DNA encoding active TGF-β prevents the development of Th1-mediated TNBS colitis. This study shows that following treatment, TGF-β-producing T cells and macrophages are found in the LP and spleen, in which they hypothetically act to prevent induction of TNBS colitis. Therapeutic strategies involving TGF-β-encoding DNA may provide beneficial effects in treating intestinal inflammation.

The role of TGF-α in the small intestine and colon has not been studied as extensively as it has been in the gastric mucosa. In DSS colitis, TGF-α is a mediator of protection and/or healing in the colon, which is demonstrated by the absence of disease in TGF-α-KO mice[46].

Hepatocyte growth factor (HGF) may be a critical regulatory factor in IBD since HGF activator-KO mice are unable to survive after DSS or acetic acid-induced colitis[47]. HGF promotes migration of gastrointestinal epithelial cells and accelerates wound repair by mucosal cells. The importance of HGF has been confirmed by the intrarectal administration of HGF-expressing adenovirus in TNBS-treated mice, which leads to significant improvements in mucosal damage[48]. The same group has also demonstrated the therapeutic effects of naked gene therapy of HGF in the DSS-induced colitis model[49]. Taking these results together, HGF gene delivery may be very useful as a therapeutic strategy for human IBD.

As well as HGF, basic fibroblast growth factor (bFGF or FGF-2) also improves mucosal damage by enhancing epithelial cell restitution and proliferation in the gastrointestinal tract[50]. In fact, rectal administration of human recombinant bFGF (hrbFGF) ameliorates DSS-induced colitis by significantly reducing the gene expression level of TNF-α[51]. Not only DSS-, but also TNBS-induced colitis is improved by the administration of hrbFGF, which not only enhances survival rate, but also up-regulates levels of cyclooxygenase (COX)-2, TGF-β, intestinal trefoil factor (ITF), and vascular endothelial growth factor (VEGF) in the colon[51].

Lastly, the trefoil factor family is comprised of three peptides; trefoil factor family 1 (TFF1), spasmolytic polypeptide (SP also known TFF2), and ITF (also known as TFF3). TFF2 is a low-molecular-weight protein that is up-regulated in gastric tissues infected with *Helicobacter* or affected by other inflammatory conditions[52]. TFF2 KO mice are susceptible to DSS-induced colitis, with prolonged colonic hemorrhage and persistent weight loss[53]. The importance of ITF in the modulation of inflammation, wound healing, and protection of the intestinal mucosa is supported by experiments in ITF KO mice, which have shown increased susceptibility and delayed wound healing during DSS- and acetic acid-induced colitis[54].

Receptors

TNF-α plays a central role in the pathology of Th1-mediated colitis such as CD; however, the role of its receptors, TNF receptor-type I (TNFR1) and -type Ⅱ

(TNFR2) in mediating pathology has not been fully explored. TNFR2 expression and signal transducer and activator of transcription (STAT) 3 activation in colonic epithelial cells (CECs) are markedly up-regulated during the recovery phase of DSS-induced acute colitis[55]. Recently, it has been reported that TNFR1 KO mice lose more weight and have increased mortality compared with wild-type mice, while TNFR2 KO mice lose less weight and have an improved survival rate compared to wild-type mice in TNBS-induced colitis. These results suggest that TNF-α signaling through TNFR1, but not TNFR2, is protective in mouse models of IBD[56].

As for Th1-type responses, CD40L-CD40 interaction is crucial for the priming of Th1 cells *via* the stimulation of IL-12 secretion by antigen-presenting cells (APC) in TNBS-induced colitis. The administration of anti-CD40L antibody prevents IFN-γ production and TNBS-induced colitis, which suggests that the Th1 response may be mediated by CD40L-CD40 interactions[57,58].

Recent studies have demonstrated that the proteinase-activated receptors (PARs), a family of G protein-coupled receptors activated by serine proteinases, have an important anti-inflammatory role in the colon. PAR-1 and -2 are highly expressed in CECs and neuronal elements, and are involved in regulating secretion by the epithelial cells of salivary glands, stomach, pancreas and the intestine[59]. Intracolonic administration of PAR-1 agonist in oxazolone-treated mice efficiently inhibits colitis[59]. By contrast, the inflammatory responses in PAR1 KO or PAR-1 antagonist-treated mice are exacerbated in oxazolone-induced colitis[60]. As well, PAR-2 activation prevents the development of TNBS-induced colitis[61].

Finally, the glucocorticoid-induced TNFR (GITR)-related gene is a member of the TNFR superfamily that is constitutively expressed at high levels on $CD4^+$ $CD25^+$ regulatory T cells, and at low levels on unstimulated T cells, B cells and macrophages[62]. GITR signalling in $CD4^+$ T cells is involved in the development and progression of colitis[63], while deletion of GITR protects against TNBS-induced colitis by reducing innate immune responses and effector T-cell activity[64].

Transcription factors

Nuclear factor (NF)-κB is the key transcription factor for pro-inflammatory responses, and is thought to be important in the initiation and progression of both human IBD and animal models of colitis[65,66]. Disease activity in mice with TNBS-induced colitis is inhibited by antisense oligonucleotides that inhibit the p65 subunit of NF-κB, which suggests a critical role for NF-κB in mediating inflammatory responses[65]. Attempts to control mucosal inflammation by the use of agents that block the NF-κB pathway have had some success in murine models. For example, it has been shown that administration of NF-κB decoy oligodeoxynucleotides (decoy ODNs) encapsulated in a viral envelope prevents the development of TNBS- and oxazolone-induced colitis by inhibiting production of IL-23/IL-17[67]. De Vry *et al* have used a chemically modified, non-viral NF-κB decoy and have shown that the NF-κB decoy ameliorates disease severity in TNBS-, DSS- and oxazolone- induced colitis. These studies suggest that NF-κB decoy ODNs are effective in attenuating Th1- as well as Th2-mediated colitis, and this would be a potentially useful therapeutic strategy for human IBD[68]. In addition to NF-κB, mitogen-activated protein kinase (MAPK) p38 is also a crucial mediator of inflammation. Inhibition of NF-κB and MAPK p38 by SB203580 is able to attenuate the inflammatory response in TNBS-induced colitis models[69,70].

By contrast, TGF-β1 functions as a negative regulator of T-cell immune responses, signaling target cells through the Smad family of proteins. Smad7, an inhibitor of TGF-β1 signaling, is over-expressed in the intestinal mucosa and purified mucosal T cells isolated from patients with IBD[71]. Oral administration of antisense oligonucleotide of Smad7 also ameliorates inflammation in TNBS- and oxazolone-induced colitis, by restoring TGF-β1 signaling *via* Smad3[72].

It has been demonstrated that cytokines exert their biological functions through Janus tyrosine kinases and STAT transcription factors. An experiment blocking the IL-6 receptor has demonstrated that IL-6 plays an important role in the development of Th1-mediated TNBS-induced colitis by activating the STAT3 signaling pathway[73]. Indeed, STAT3 was most strongly tyrosine-phosphorylated in human UC and CD patients and in DSS-induced colitis in mice[74]. These results suggest that the IL-6/STAT3 pathway plays a crucial role in the development and perpetuation of DSS-induced colitis.

Lastly, peroxisome proliferator-activated receptor γ (PPARγ) is a lipid-activated transcription factor, and PPARγ heterozygous mice are highly susceptible to TNBS-[75] and DSS-induced colitis[76]. It has also been reported that mice with a targeted disruption of PPARγ in macrophages display an increased susceptibility to DSS-induced colitis[77]. Therefore, activation of PPARγ may potentially protect against human IBD.

Adhesion molecules

Trafficking, activation and retention of leukocytes within inflamed tissues are mediated by several classes of specialized adhesion glycoproteins[78]. Collagens represent the most abundant extracellular matrix protein, and the major cell surface receptors for collagens are integrins[78,79]. The collagen-binding integrin α1β1 mediates inflammation in TNBS-[80] and DSS-induced colitis[81], which suggests the importance of α1β1-mediated adhesive leukocyte/matrix interactions in regulating mucosal inflammatory responses. Leukocyte β2 integrins are heterodimeric adhesion molecules consisting of a common β subunit (CD18) and different α subunits (CD11a-d)[82]. In DSS-induced colitis, leukocyte function-associated antigen-1 (LFA-1, CD11a/CD18) seems to have a pathogenic role, whereas Integrin alpha M (Mac-1α, CD11b/CD18) serves in a regulatory capacity[83]. Much attention has been focused on the role of α4 integrin in IBD, but it has recently been reported that neutralization therapy may result in undesirable complications such as multifocal leukoencephalopathy[84].

Toll-like receptors (TLRs) and their ligands

It is widely suspected that IBD arises from a dysregulated mucosal immune response to luminal bacteria. TLRs,

which are pattern-recognition receptors expressed by both immune and non-immune cells, play a pivotal role in host/microbial interactions and have two distinct functions-protection from infection and control of tissue homeostasis, depending on the recognition of pathogens or commensals[85-88]. TLRs send intracellular signals in response to intestinal commensal or pathogenic microbes that contain or release conserved molecular patterns, such as LPS, bacterial lipoprotein, bacterial cytosine-guanosine dinucleotide (CpG) DNA, and bacterial flagellin. Activation of TLRs results in the activation of the innate and/or adaptive immune response[85]. In this context, TLRs play an important role in the maintenance of intestinal homeostasis. TLR4 recognizes LPS, and transduces a proinflammatory signal through the adapter molecule myeloid differentiation marker 88 (MyD88)[86]. DSS treatment of TLR4 KO and MyD88 KO mice has been shown to induce earlier and more severe colitis compared to that in wild-type mice, which suggests that TLR4 signaling through MyD88 is an important suppressor of the inflammatory response to chemical injury[87].

Bacterial flagellin specifically stimulates TLR5 and activates MAPK and NF-κB-related signaling pathways, which leads to the production of macrophage inflammatory protein 3α (MIP3α) and IL-8[89]. Flagellin exposure exacerbates inflammation in DSS-induced colitis, but not in the intact colon[88]. By contrast, a TLR2 specific agonist, peptidoglycan or lipoteichoic acid, does not cause any inflammatory response[90].

Lastly, TLR9 is critical for the recognition of the CpG motif of bacterial DNA[91]. DSS-induced colitis is less severe in TLR-9 KO mice[92], and treatment of mice with an adenovirus expressing CpG-ODN that is known to block CpG effects results in significant amelioration of DSS-induced colitis[92], which indicates that ODN inhibition of the immune-stimulating properties of bacterial DNA may offer a novel and specific tool for the treatment of IBD.

Enzymes

Although intestinal epithelial cells constitutively express COX-1, COX-2 is induced only during inflammatory conditions. Enzymatic activity of these COX isoforms produces prostaglandins (PGs) that have proinflammatory roles mediating fever, hyperalgesia, vascular permeability and edema. However, PGs also have a protective role against gastrointestinal injury[93]. The linkage between COX-2 and PGE2 for protection against colitis has been highlighted in various studies. For example, COX-2 KO mice are more susceptible to DSS-induced colitis, which correlates with their inability to produce PGE2[94]. Kabashima *et al*[95] have used mice deficient in prostaglandin receptor EP4 and examined the roles of prostanoids in DSS-induced colitis; their mice developed severe colitis, which suggests that EP4 maintains intestinal homeostasis by keeping mucosal integrity and down-regulating immune responses. It has also been shown that COX-2-derived PGE2 is important in TLR4-related mucosal repair[96], and that COX-2 has a protective effect against acetic-acid-induced colitis[97,98]. These results suggest that COX-2 has a pivotal role in the maintenance of mucosal homeostasis. However, there is controversy about whether COX-2 inhibitors worsen symptoms of human IBD[99].

Through the use of DNA microarray analysis, our group has demonstrated that several detoxification-associated molecules, which contribute to the prevention of inflammation by regulating physiological balance under normal conditions, are highly down-regulated in CECs in chronic colitis[100]. Among the up-regulated detoxification-associated molecules, carbonic anhydrase (CAR)-Ⅳ is an important enzyme involved in the suppression of acidification, by regulating mucosal bicarbonate concentration[101]. Unexpectedly, inhibition of CAR-Ⅳ suppresses the severity of DSS-induced colitis but enhances CEC proliferation, which raises the possibility that CAR-Ⅳ may have a pathogenic role under inflammatory conditions. Microarray analysis also identifies chitinase 3-like-1 (CHI3L1) as being specifically up-regulated in inflamed mucosa[102]. The expression of CHI3L1 protein is detectable in LP and CECs in several murine colitis models, and also in IBD patients, but is absent in normal controls. Anti-CHI3L1 antibody administration significantly ameliorates DSS-induced colitis, which suggests that inhibition of CHI3L1 activity may be a novel therapeutic approach for IBD. Our group is currently investigating this possibility by utilizing murine models of chronic colitis.

As well, IL-1β-converting enzyme (ICE), also known as caspase-1, is an intracellular protease that cleaves the precursors of IL-1β and IL-18 into active cytokines[103,104]. ICE deficiency results in protection from DSS-induced colitis, accompanied by the reduced release of the proinflammatory cytokines IL-18, IL-1β and IFN-γ[105].

Lastly, recent studies have identified Vanin-1 as being involved in the regulation of innate immunity. Vanin-1 is an epithelial ectoenzyme with pantetheinase activity, which is involved in the metabolic pathway of pantothenate (vitamin B5), and provides cysteamine to tissues[106]. Vanin-1 deficiency protects from TNBS-induced colitis. Additionally, by antagonizing PPARγ, Vanin-1 promotes the production of inflammatory mediators by intestinal epithelial cells[107]. This study suggests that Vanin-1 is an epithelial sensor of stress that exerts control over innate immune responses in tissues. As such, it has been proposed as a potential new therapeutic target for IBD.

Hormones

It has been demonstrated that adipose tissue secretes a variety of biologically active molecules[108]. Adiponectin (APN) is an adipose tissue-derived hormone and is considered to be a member of the expanding family of adipokines[109]. APN has a protective role against DSS-induced murine colitis, but not TNBS-induced disease[110], by inhibiting the production of chemokines such as monocyte chemoattractant protein-1 and MIP-2 in CECs, and the subsequent inflammatory response. However, a proinflammatory role for APN in synovial fibroblasts[111] and CECs[112] has recently been suggested. APN exerts proinflammatory activity in the colon by producing proinflammatory cytokines and inhibiting the bioactivity of protective growth factors such as bFGF and heparin-

binding epidermal growth factor. It is interesting to note that APN KO mice are highly protected from both DSS- and TNBS-induced colitis[112].

Finally, leptin, a regulator of food intake and energy expenditure, can also modulate immune and inflammatory responses. Leptin-deficient (ob/ob) mice exhibit less severe colitis compared to wild-type mice in DSS and TNBS models, while replacement of leptin in ob/ob mice converts disease resistance to susceptibility, which indicates that leptin deficiency accounts for the resistance to acute DSS- and TNBS-induced colitis[113]. It has also been shown that phosphorylation of STAT3 and induction of COX-2 are absent in the colon of ob/ob mice[113]. Therefore, leptin represents a functional link between the endocrine and immune systems.

CONCLUSION

Dysregulated immune responses initiated by microbial-host interactions contribute to the development and perpetuation of both murine colitis and, most likely, to human IBD. In this process, intestinal epithelial cells play important roles linking innate and acquired immune responses. In this review, we have focused primarily on the role of functionally distinct factors in the pathogenesis of chemically-induced models of intestinal inflammation during acute, recovery and chronic phases. The increasing clinical use of biological therapy in human IBD illustrates the potential benefits that may be derived from molecular analysis of immunopathogenesis. However, the long-term effects of such therapy have still not been determined, and concerns regarding potentially increased risks of infection or tumor development have been raised, given the essential roles of innate and acquired immunity in host defense. In this respect, topical treatment would have the advantage of selectively targeting local immune responses while sparing systemic immune protective mechanisms. Therefore, we need to find agents that have more targeted effects or take advantage of local delivery systems that target diseased lesions, such as is seen with oligonucleotide-based therapeutics. The different animal models provide an easy means to study factors involved in pathogenesis and to test new therapeutic agents for human IBD.

Abstract

Crohn's disease (CD) and ulcerative colitis (UC) are complex polygenic disorders, characterized by several genes together with environmental factors contributing to the development of inflammatory bowel disease (IBD). Recent advances in research on genetic susceptibility have allowed the identification of diverse genes at different levels: (1) Innate immunity; (2) Antigen presentation molecules; (3) Epithelial integrity; (4) Drug transporter; (5) Cell adhesion. The application of genetic testing into clinical practice is close and all genetic markers may have several clinical implications: prediction of disease phenotype, molecular classification, prevention of complications, and prognosis.

Key words: Genetic; Susceptibility; Inflammatory bowel disease; Ulcerative colitis; Crohn's disease

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis (UC) are chronic relapsing inflammatory bowel diseases (IBD) of unknown etiology. CD and UC are complex polygenic disorders, characterized by several genes together with environmental factors contributing to the development of IBD.

A variety of epidemiological and clinical data suggest that genetic factors are intimately involved in the pathogenesis of IBD including familial aggregation pattern of disease with a much higher disease frequency in first degree relatives of affected individuals compared with the general population. Twin studies provide the argument for a genetic basis for IBD, with a much higher rate of disease concordance observed in monozygotic than in dizygotic twins and wide variations in the incidence and prevalence of IBD among different populations[1].

IBD is now considered a non-Mendelian polygenic disorder with important environmental interactions (e.g., microbial factors, smoking).

There are two main approaches to identifying genes in complex multifactorial diseases: the positional cloning approach based on linkage studies, and the candidate gene approach based on association studies. Linkage analysis studies the cosegregation of the disease with a marker within the families. Linkage analysis allows scanning of the whole genome. Eleven of these total genome scans have been undertaken in IBD, resulting in a number of susceptibility regions on chromosomes 1, 3, 4, 5, 6, 7, 10, 12, 14, 16, 19 and X[2]. According to their initial date of reporting and independent confirmations, the regions on chromosomes 16q, 12, 6, 14, 5, 19, 1, 16p and 10 have been renamed IBD 1 to IBD 9, respectively. However, new genes have been reported recently. All susceptibility genes discovered can be categorized into different levels of susceptibility: (1) Innate immunity; (2) Human leucocyte antigen (HLA) molecules; (3) Epithelial integrity (4); Drug transporter; and (5) Cell adhesion.

INNATE IMMUNITY

Understanding of innate immunity has progressed enormously with the discovery of many microbial sensors called pattern recognition receptors (PRRs). The toll-like receptor (TLR) and nucleotide oligomerization domain (NOD) receptor families of PRRs appear to play essential roles in mucosal homeostasis and their alterations contribute to the pathogenesis of IBD.

NOD2 is expressed constitutively in macrophages, neutrophils and dendritic cells[3], as well as in Paneth cells and is induced in epithelial cells[4]. NOD2 is a cytoplasmic protein that serves as a microbial sensor, and its leucine-rich repeat (LRR) domain is required for recognition of muramyl dipeptide (MDP), a fragment of peptidoglycan

present in bacterial cell walls. The ligand MDP ultimately leads to activation of the transcription factor nuclear factor kappa B (NF-κB), and induction of proinflammatory cytokines[5,6]. Specific mutations of the NOD2 gene have been definitively associated with increased susceptibility to ileal Crohn's disease in Western (but not Asian) populations: Arg702Trp, Gly908Arg, and leu1007fsinsC (a frame shift mutation that truncates the carboxy terminal 33 aminoacids)[7,8]. Heterozygous carriage of the risk alleles confers a 2-4 fold increased risk, and homozygotes or compound heterozygotes have a 20-40 fold increased risk[9]. More than 90% of all CD- associated mutations are located in the LRR domain, suggesting that these may affect the function of NOD2 with respect to bacterial recognition and signaling.

NOD1/ CARD4 (Caspase Recruitment Domain 4) plays a role in colonic epithelial defense against *E. coli* and *S. flexeneri* and mediates NF-κB activation[3,10]. Recently, genetic variants of NOD1 have been shown to be associated with disease susceptibility. In a recent study of 556 patients with IBD (294 CD and 252 UC), an association between the variant (rs695857) in nucleotides 30, 258 and 950 of NOD1 and the development of IBD was found. Another variant known as rs2907748 in nucleotides 30, 246 and 263 was also associated with the presence of UC and CD and even with the early onset of the disease (< 25 years of age)[11].

TLRs are abundantly expressed on the surface of monocytes, macrophages, dendritic and epithelial cells. Alterations of TLR3 and TLR4 expression by intestinal epithelial cells have been described in IBD[12], suggesting that there is differential expression of TLR family members. Two common polymorphisms of TLR4 (Asp299Gly and Thr399Ile) have been described in humans. Asp299Gly has been associated with reduced responsiveness following lipopolysaccharide stimulation[13]. These polymorphisms have been associated with the development of CD and UC in Caucasian populations[14-16]. Pierik *et al*[17] showed that TLR1 R80T and TLR2 R753G polymorphisms were associated with pancolitis in UC patients, while a negative association was observed between TLR6 S249P and proctitis in patients with UC. These results suggest that TLR2 and its co-receptors TLR1 and TLR6 are involved in the initial immune response to bacteria in the pathogenesis of IBD.

ANTIGEN PRESENTATION MOLECULES

The major histocompatibility complex (MHC) region is the region studied most extensively. Human leucocyte antigen (HLA) class Ⅱ molecules present partially digested antigen to the T-cell receptor and play a central role in the immune response. The mechanism by which classical HLA class Ⅱ genes exert their influence in IBD is unknown. Different HLA molecules may bind preferentially to different peptides, or bind the same peptide with varying affinity. In IBD, cross reactivity (known as molecular mimicry) may exist between the peptides derived from bacterial luminal flora and from self antigens present in the gut. This may lead to the generation of auto reactive T cells which contribute to disease pathogenesis. HLA-DRB1 is the most extensively studied gene in IBD. In a meta-analysis made by Stokkers *et al*[18], positive associations between UC and HLA-DR2, HLA-DRB1*1502 (OR = 3.74, CI: 2.2-6.38), HLA-DR9 (OR = 1.54, CI: 1.06-2.24) and HLA-DRB1*0103 (OR = 3.42, CI: 1.52-3.69) were found; a negative association was found with HLA-DR4 (OR = 0.54, CI: 0.43-0.68). Another study found that HLA-DRB1*0103 allele was associated with UC and its severe manifestations such as colectomy and pancolitis (P = 0.003, OR = 3.6, CI 95%: 1.46-8.9), while HLA-DRB1*15 allele was only associated with pancolitis in patients with UC (P = 0.001, OR = 8.5)[19].

On the other hand, HLA class Ⅲ genes have been associated with IBD. Several studies have shown the role of tumor necrosis factor α (TNF α) polymorphisms in IBD. There are specific genetic polymorphisms involving TNFα that influence the amount of cytokine produced. Bouma *et al*[20] reported an association between the polymorphism of *TNF*α gene promoter region at -308 position and UC, and this finding was confirmed by other studies[21, 22].

EPITHELIAL INTEGRITY

The organic cation transporter (OCTN) is a family of transporter proteins for organic cations, and may also transport carnitine, an essential cofactor of the metabolism of lipids. Carnitine is involved in the transport of long-chain fatty acids into the mitochondria. There is evidence that inhibition of fatty acid oxidation in the epithelium of the colonic mucosa is associated with the development of UC. There are two subtypes of this gene, OCTN1 and OCTN2, and some mutations have been reported in them: SLC22A4 1672C/T for OCTN1 and SLC22A5-207G/C for OCTN2, which are associated with the development of CD. The presence or combination of these mutations constitutes TC haplotype, which is associated with ileal, colonic and perianal affection and onset and the need of surgical treatment in CD[23, 24].

DLG5 (Drosophila long disc homologue 5) gene is a member of the membrane associated guanylate kinase gene family which encodes cell scaffolding proteins and seems to play a role in the maintenance of intestinal epithelial cells, and its mutations have been involved in a rise in intestinal permeability[25]. DLG5 is a widely expressed protein found in many tissues such as the placenta, small bowel, colon, heart, skeletal muscle, liver and pancreas. It is important in signal transduction and epithelial cell integrity. Four haplotypes have been identified, but only D haplotypes were associated with UC and CD in a European cohort[26]. Another variant of this gene (rs37462) was found in Japanese people with CD[27]. The haplotype characterized by the haplotype-tagging single nucleotide polymorphisms (SNP) G113A called haplotype D, was found substantially over-transmitted in patients with IBD.

DRUG TRANSPORTER

The multidrug-resistance (MDR-1) gene encodes the drug efflux pump P-glycoprotein 170 (Pgp-170). Various polymorphisms have been identified within MDR-1: a

mutation C3435T in exon 26 and a mutation G2677T in exon 21 have been correlated with altered Pgp expression and function in humans. Overexpression of MDR-1 leads to an increased efflux of drugs and decreased cytoplasmic drug concentrations. Several drugs, including glucocorticoids, are known Pgp-170 substrates. Farrell *et al*[28] showed that MDR was significantly elevated in CD and UC patients who required bowel resection and proctocolectomy after failed medical therapy. Variant C3435T was related to the presence of pancolitis in patients with UC in Scotland[29]. However, the frequency of SNPs is low and is different among populations, with the exception of three SNPs in exon 12 (C1236T), exon 20 (G2677T/A) and exon 26 (C3435T), and some of them are correlated with different diseases and clinical characteristics[30].

CELL ADHESION

Cell surface adhesion molecules conveying leukocyte-endothelial interactions, govern homing of activated inflammatory cells into gut. Extravasation and migration into the site of inflammation are mediated by integrins and selectins, and these molecules are increased in IBD patients. There are targeting therapies against adhesion molecules in clinical trials to date including natalizumab (integrin α4 subunit) and MLN-02 (selective adhesion molecule blocker for integrin $\alpha 4\beta 7$). In Japanese patients with IBD, the intercellular adhesion molecule-1 (ICAM-1) K469 allele is associated with CD and UC[31].

CONCLUSION

There are increasing numbers of genetic markers associated with the development of IBD at different levels: innate immunity, antigen presentation, epithelial integrity, drug transporter and cell adhesion that contribute, in genetic susceptibility, to the development of IBD in conjunction with environmental and immunological factors.

Abstract

While restorative proctocolectomy with ileal pouch-anal anastomosis has significantly improved the quality of life in patients with underlying ulcerative colitis who require surgery, complications can occur. Pouchitis as the most common long-term complication represents a spectrum of disease processes ranging from acute, antibiotic-responsive type to chronic antibiotic-refractory entity. Accurate diagnosis using a combined assessment of symptoms, endoscopy and histology and the stratification of clinical phenotypes is important for treatment and prognosis the disease. The majority of patients respond favorably to antibiotic therapy. However, management of chronic antibiotic-refractory pouchitis remains a challenge.

Key words: Classification; Complication; Ileal pouch; Inflammatory bowel disease; Restorative proctocolectomy

INTRODUCTION

Restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA) has become a part of standard surgical treatment for patients with ulcerative colitis (UC) or familial adenomatous polyposis (FAP). Despite advances in medical therapy, approximately 30% of patients with UC eventually require total proctocolectomy[1]. Restorative proctocolectomy with IPAA has the following advantages: (1) gastrointestinal continuity is reestablished with IPAA, (2) the procedure helps improve symptoms of patients and health-related quality of life, (3) the majority of patients with IPAA can avoid UC-related medications, particularly immunomodulators and biological agents and their associated potential adverse effects, and (4) IPAA with proctocolectomy substantially reduces the risk for dysplasia or cancer. However, adverse outcomes or complications often occur after surgery. Common long-term inflammatory and functional complications of restorative proctocolectomy are pouchitis, Crohn's disease (CD) of the pouch, cuffitis (inflammation in the rectal muscular cuff), and irritable pouch syndrome (IPS). Pouchitis likely represents a spectrum of disease processes ranging from acute antibiotic-responsive entity to chronic antibiotic-refractory type. Accurate diagnosis and classification of pouchitis are important for its proper management and prognosis.

INCIDENCE AND PREVALENCE

Pouchitis, a nonspecific inflammatory condition at the ileal pouch reservoir, is the most common long-term complication in patients with IPAA which significantly affects patients' quality of life[2]. Reported cumulative frequency rates of pouchitis 10-11 years after IPAA surgery range from 23% to 46%[3,4]. It is estimated that approximately 50% of patients who have undergone IPAA surgery for UC will develop at least one episode of pouchitis[5]. The estimated incidence within 12 mo after ileostomy was as high as 40% in a European study[6]. The discrepancy in the reported cumulative frequencies from different institutions likely results from diagnostic criteria used (e.g., diagnosis made based on symptom assessment alone or on a combined assessment of symptoms, endoscopy, with or without histology), intensity of follow-up with pouch endoscopy, and inclusion or exclusion of other inflammatory or functional disorders of the pouch and surgery related conditions (such as abscess, fistula, and sinus of the pouch).

ETIOLOGY AND PATHOGENESIS

Pouchitis almost exclusively occurs in patients with underlying UC and is rarely seen in patients with FAP[7,8]. Although the etiology and pathogenesis of pouchitis are

not entirely clear, bulk of evidence points towards an abnormal mucosal immune response (innate and adaptive) to altered microflora in the pouch leading to acute and/or chronic inflammation[6,9,10,11,12,13]. The prevailing theory holds that pouchitis results from an overgrowth of certain commensal bacteria[9,13,14,15]. Pouchitis only develops after ileostomy, i.e., the pouch mucosa starts to expose fecal stream. Manipulation of microflora with antibiotic or probiotic therapy resulting in improvement in patients with pouchitis provides additional evidence of involvement of microflora in the pathogenesis of pouchitis.

Immune mechanisms for pouchitis have been extensively studied in a similar fashion to that for inflammatory bowel disease. There are overlaps in tissue cytokine profiles between pouchitis and UC. However, pouchitis is not simply a duplication of the disease process seen in UC. The role of T-cell-mediated intestinal immunity in the pathogenesis of pouchitis is not entirely clear and is likely secondary to alterations in pouch microflora. Alterations in the macrophage and T cell subpopulations have been postulated in the process of pouchitis[16,17,18]. Increased T-cell activation and proliferation have been demonstrated in pouchitis, as evidenced by an increased expression in activation markers, such as CD25, CD30, and CD27[18]. As a result of activation of T cells and other immune cells, production of cytokines is up-regulated. Abnormal cytokine profiles have been reported in pouchitis including a deregulated production of proinflammatory and immunoregulatory cytokines[19]. Proinflammatory cytokines, such as TNF-α, are released at a great extent in the inflamed mucosa by macrophages and monocytes, leading to tissue injury, and are considered to be involved in pouchitis as a secondary pathophysiologic mechanism[19]. As in UC, the production of other inflammatory mediators including cytokines (such as IL-1β, IL-6, and IL-8)[20,21,22,30], cell adhesion molecules (such as E selectin and intercellular adhesion molecule-1)[23], platelet-activating factor[24], lipoxygenase products of arachidonic acids (such as leukotriene B4 and prostaglandin E2)[25], proinflammatory neuropeptides[26], macrophage inflammatory protein (MIP) 2α, matrix metalloproteinase (MMP)-1[21,27], MMP-2[21,27,28], MMP-9[28], MRP-14[21], and inducible nitric oxide[28], is also increased. Abnormalities in immunoregulatory cytokines such as IL-2, and interferon-γ[18,29], IL-4[29], and IL-10 are also seen in pouchitis. Imbalance between proinflammatory and immunoregulatory cytokines has been described in patients with pouchitis[30]. Abnormalities of T cells and other immune cells may not explain the whole mechanism of pouchitis. It is likely that such abnormalities are nonspecific and secondary in nature. Inconsistent results in the studies of immune cells and inflammatory mediators in pouchitis reflect the complexity in pathogenesis of the disease.

There are few published studies addressing the interplay between microflora and mucosal immune system in pouchitis. Exposure of peripheral blood and lamina propria lymphocytes *ex vivo* to sonicated flora from pouchitis induces more intense proliferation as compared with sonicates from healthy pouches. *In vitro* pretreatment of the sonicate preparation of pouch flora with metronidazole abolishes the stimulating ability[31]. Bacterial sonicates from a heterologous but healthy pouch do not stimulate lymphocyte proliferation[31]. The greater stimulatory effect of sonicates from pouchitis suggests that certain microflora may predominantly present in inflamed pouch mucosa and these microflora may be potentially pathogenic in activation of local mononuclear cells[31].

One of the most intriguing aspects of pouchitis is that it occurs almost exclusively in patients with underlying UC. Interestingly, there are similarities in terms of clinical presentations and immunological abnormalities between pouchitis and UC, suggesting that a subset of pouchitis may actually represent the recurrence of a UC-like disease in the ileal pouch. The theory of recurrent UC is supported by several lines of evidence. With the presence of stasis in the pouch, exposure to fecal contents and an increased microbial load could cause inflammatory changes leading to morphological alterations in the ileal pouch mucosa mimicking colon epithelia in UC[24]. Colonic metaplasia of the pouch mucosa seems to be a nonspecific adaptive response to the new luminal environment[24]. Colonic metaplasia characterized by villous blunting, crypt cell hyperplasia, and colon epithelium-specific antigens such as human tropomyosin 5, may increase the risk for pouchitis[32]. A similar alteration in mucin glycoproteins occurs in pouchitis as seen in UC[33]. It is possible that the altered glycoproteins are more susceptible to enzymatic degradation by bacteria, making the mucus barrier less resistant[34]. Additionally, some patients with pouchitis have the same extra-intestinal manifestations (such as arthralgia and primary sclerosing cholangitis or PSC) as those seen in patients with UC[35]. Smoking tends to have a protective effect against the development of pouchitis as it does against UC[36].

RISK FACTORS

Risk factors and potential predictors for pouchitis have been extensively studied. The implications of these studies include identification of etiopathogenetic factors, provision of strategies for modification of certain risk factors, and prediction of pouch outcome. Genetic polymorphisms such as those of IL-1 receptor antagonist[38,39,40] and NOD2/CARD15[40] may increase the risk for pouchitis. The reported risk factors for pouchitis also include non-carrier status of TNF allele 2[39], extensive UC[4,41,42], backwash ileitis[41], pre-proctocolectomy thrombocytosis[43], extra-intestinal manifestations, especially PSC[3,35,44,45], the presence of serum perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA)[46,47], being a non-smoker[36,42,48], and use of non-steroidal anti-inflammatory drugs (NSAID)[42,48]. In addition to p-ANCA, the presence of serologic markers, anti-*Saccharomyces cervesiae* antibodies to CD-related antigen from *Pseudomonas fluorescens* or outer membrane porin C of *Escherichia coli* in patients with pre-operative indeterminate colitis appears to be associated with persistent inflammation of the pouch after restorative proctocolectomy[49]. Acute and chronic pouchitis may have different risk factors[42].

It appears that few studies came up with the same risk factors. This inherent discrepancy among the studies may be contributed to the following factors: (1) small *vs* large

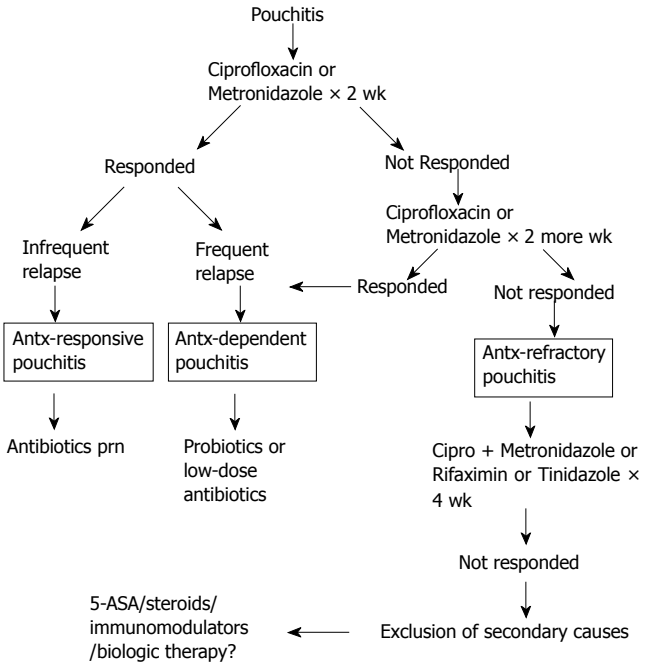

Figure 1 Classification and treatment algorithm.

sample sizes were analyzed, (2) the number of variables and outcomes was studied, (3) univariable analyses *vs* multivariable analyses were used, (4) diagnostic criteria for pouchitis were used, (5) pouchitis was stratified into acute *vs* chronic entities, and (6) type of controls was compared.

CLINICAL PRESENTATIONS

Patients with pouchitis have a wide range of clinical presentations, including increased stool frequency, urgency, tenesmus, incontinence, nocturnal seepage, abdominal cramping, and pelvic discomfort. While bloody bowel movements are uncommon in typical pouchitis, patients with IPAA with or without pouchitis can have iron deficiency anemia[50,51]. Patients with severe pouchitis occasionally present with fever, dehydration, malnutrition which may require hospitalization. Patients may have predominant extra-intestinal symptoms such as arthralgia and uveitis. These symptoms, however, are not specific and can present in disorders of the pouch other than pouchitis, such as cuffitis, CD of the pouch, proximal small bowel bacterial overgrowth, and IPS.

DIAGNOSTIC EVALUATIONS

Making diagnosis of pouchitis should not solely rely on presenting symptoms. The severity of symptoms does not necessarily correlate with the degree of endoscopic or histologic inflammation of the pouch[52,53]. A combined assessment of symptoms, endoscopic and histologic features is the key to making an accurate diagnosis and it is necessary to differentiate pouchitis from other inflammatory and non-inflammatory disorders of the pouch such as cuffitis, pouch stricture, pouch sinus, and IPS. There are no universally accepted diagnostic criteria for pouchitis. For clinical trials, the 18-point pouchitis disease activity index (PDAI) is most commonly used in the diagnosis of pouchitis and measurement of disease activity[54].

Pouch endoscopy yields valuable information on severity and extent of mucosal inflammation, presence or absence of concurrent ileitis or cuffitis, and structural abnormalities such as strictures, sinuses, and fistula openings. In addition, pouch endoscopy with segmental biopsy is the tool for dysplasia surveillance and can deliver effective therapy, including stricture dilation. Histopathology is invaluable for the detection of dysplasia, viral inclusion bodies of cytomegalovirus infection, granulomas, pyloric gland metaplasia, mucosal prolapse, and ischemic changes. It should be pointed out that villous blunting and an increased number of mononuclear cells in the lamina propria can be a part of "normal" adaptive changes of pouch mucosa to fecal stasis in the pouch which does not necessarily indicate pouchitis.

In cases of suspected complicated pouchitis, imaging studies such as contrasted pouchography, CT and MRI are typically used to assess the presence of mucosal and transmural disease activity within and around the pouch[55]. Wireless capsule endoscopy appears safe in patients with IPAA, which has been used for diagnostic evaluation in patients with chronic pouchitis[56] or anemia[57]. For patients with symptoms of dyschezia and feeling of incomplete evacuation, anal pouch manometry may be used to identify functional abnormalities such as paradoxical contractions.

CLINICAL CLASSIFICATION

Pouchitis likely represents a disease spectrum from acute, antibiotic-responsive type to chronic, antibiotic-refractory entity. From various perspectives, pouchitis can be categorized into: (1) idiopathic vs secondary based on etiology, (2) remission *vs* active based on disease status, (3) acute *vs* chronic based on disease duration, (4) infrequent episodes *vs* relapsing or continuous based on disease course, and (5) responsive *vs* refractory based on response to antibiotic therapy[58]. A subpopulation of patients has pouchitis associated with identifiable and modifiable causes (namely secondary pouchitis), such as *Clostridium difficile*[59,60] or cytomegalovirus[61,62] infection, and regular use of NSAID[63].

While the majority of patients with pouchitis respond favorably to antibiotic therapy particularly at initial stages of the disease, some patients develop pouchitis refractory to regular antibiotic treatment. This leads to another useful clinical classification based on the response to antibiotic therapy[64]. Analogous to the classification of UC according to the response to or dependency on corticosteroids, pouchitis can be classified as antibiotic-responsive, antibiotic-dependent, and antibiotic-refractory pouchitis[48,64] based on the manner of the patients' response to antibiotics (Figure 1).

TREATMENT

As the majority of patients develop acute pouchitis within the first year after IPAA[65], VSL#3® containing 4 strains of *Lactobacillus*, 3 *Bifidobacterium* species, and *Streptococcus*

salivarius subsp. *Thermophillus* was evaluated for the primary prophylaxis for the initial episode of pouchitis. Two of 20 patients (10%) treated with VSL#3® developed pouchitis within 12 mo after IPAA, while 8 of 20 patients (40%) experienced pouchitis in the placebo group during the same period of time[6].

The management and prognosis vary in different types of pouchitis (Figure 1). For antibiotic-responsive pouchitis, the first-line therapy includes a 14-d course of oral metronidazole (15-20 mg/kg per day) or ciprofloxacin (1000 mg/d)[66,67]. A randomized trial of ciprofloxacin and metronidazole showed that patients treated with ciprofloxacin experience significantly greater reductions in the PDAI scores and fewer adverse effects than those treated with metronidazole[67]. Other agents have been reported in open-labeled trials including tetracycline, clarithromycin, amoxicillin/clavulanic acid, doxycycline, rifaximin, and budesonide enemas[68], alicaforsen enemas, an anti-sense inhibitor of intercellular adhesion molecule-1[69], and AST-120, a highly adsorptive, porous, carbon microspheres[70].

Patients with antibiotic-dependent pouchitis often require long-term maintenance therapy with either antibiotics or probiotics to keep disease in remission. A randomized trial of VSL#3® at a dose of 6 g/d was conducted for the secondary prophylaxis for relapse of pouchitis, after remission was induced by oral ciprofloxacin (1000 mg/d) and rifaximin (2000 mg/d). During the 9-mo trial in 40 patients with relapsing pouchitis, only 15% in the probiotic group relapsed while 100% in the placebo group relapsed[11]. A separate randomized trial of VSL#3® in patients with antibiotic-dependent pouchitis showed that 17 of 20 patients (85%) in the VSL#3® group maintained clinical remission, compared to remission in 1 of 16 patients (6%) in the placebo group[12]. However, in a recent post-market open-labeled trial of VSL#3® in 31 patients with antibiotic-dependent pouchitis, patients received 2 wk of treatment with ciprofloxacin followed by VSL#3®[71]. After 8 mo, 6 of the 31 patients (19%) were still taking VSL#3® and the remaining 25 patients (81%) stopped the agent mainly because of lack of efficacy or development of adverse effects[71].

Antibiotic-refractory pouchitis which is often difficult to treat, is a common cause of pouch failure. Since the patients typically do not respond to full-dose, single-agent antibiotic therapy, it is important to investigate contributing causes (in secondary pouchitis) related to failure to antibiotic therapy. Secondary causes of refractory disease include use of NSAID, concurrent *Clostridium difficile* or cytomegalovirus infection, celiac disease and other autoimmune disorders, cuffitis, CD of the pouch, pouch ischemia, and inflammatory polyps of the pouch[72]. There are no randomized trials in the literature for this category of pouchitis. For patients without obvious causes, treatment options include a prolonged course of combined antibiotic therapy, 5-aminosalicylates, corticosteroids, immunosuppressive agents or even biological therapy. Regimens reported in open-labeled trials include combined ciprofloxacin (1000 mg/d) with rifaximin (2000 mg/d)[73] or metronidazole (1000 mg/d)[74] or tinidazole (1000-1500 mg/d) for 4 wk[75]. However, maintenance of remission in this group of patients after the induction therapy with dual antibiotics remains a challenge[76]. Anti-inflammatory agents, immunomodulators, and biological therapy have been used to treat pouchitis. These agents include bismuth carbomer enemas, short-chain fatty acid enemas, and glutamine enemas, mesalamine enemas, oral budesonide[77], 6-mercaptopurine, and infliximab.

NATURAL HISTORY AND PROGNOSIS

The natural history of pouchitis is not entirely clear. In a study consisting of 100 consecutive UC patients who had restorative proctocolectomy with IPAA, 32 patients developed pouchitis, 5 had chronic refractory pouchitis, 2 of them had pouch failure after pouch resection[58]. Few studies were performed to identify the natural history of pouch and pouchitis. Patients with initial pouchitis almost uniformly respond to antibiotic therapy. However, relapse of pouchitis is common. Of the patients with acute pouchitis, 39% have a single acute episode that responds to antibiotic therapy whereas the remaining 61% of patients develop at least one recurrence[35]. Approximately 5% to 19% patients with acute pouchitis develop refractory or rapidly relapsing symptoms[78-80]. Here is a common scenario: the more frequent the episodes of pouchitis a patient has, the more often the antibiotic therapy is administered, the less likely the patient maintains favorable response to the treatment. The course of antibiotic-responsive pouchitis could evolve into antibiotic-dependent pouchitis followed by antibiotic-refractory pouchitis. Chronic refractory pouchitis is one of the most common causes for pouch failure. Although PSC is a risk factor for pouchitis[3,44,45], liver transplantation with post-transplant use of immunosuppressive agents does not appear to have adverse effects on the course of pouchitis[81,82]. In addition, chronic inflammation of the pouch and cuff may pose an increased risk of developing dysplasia or cancer[83,84].

In summary, pouchitis is the most common long-term adverse sequela of IPAA after restorative proctocolectomy. The natural history of pouchitis is yet to be defined. Patients with pouchitis can have a wide range of clinical presentations, disease courses, and prognoses. Accurate diagnosis and classification of pouchitis are the keys to appropriate management. Treatment of pouchitis is largely antibiotic-based. Maintenance of remission in antibiotic-dependent pouchitis and management of antibiotic-refractory pouchitis are a challenge. Secondary causes for refractory pouchitis should be excluded.

Abstract

AIM: To investigate the effect of *Scutellariae Radix* extract (SRE) on ulcerative colitis (UC) in rats induced by dextran-sulfate sodium (DSS).

METHODS: Colitis was induced in male Sprague-Dawley (SD) rats (170-180 g) by 4% dextran sulfate sodium (DSS, wt/v; MW 54000) in drinking water for 8 d. The treated rats received 4% DSS and SRE orally (100 mg/kg per day). Control rats received either tap water or SRE only. Macroscopic assessment which included body weight changes, fecal occult blood and stool consistency were determined daily. At the appointed time, the rats were sacrificed and the entire colons were removed. The colon length and the myeloperoxidase (MPO) activity were measured. The severity of colitis was graded by morphological and histological assessments. The ion transport activity of the colonic mucosa was assessed by electrophysiological technique.

RESULTS: Rats treated with oral administration of 4% DSS regularly developed clinical and macroscopic signs of colitis. Treatment with SRE relieved the symptoms, including the reduction in body weight, shortening and ulceration of the colon. Administration of SRE also significantly reduced the histological damage induced by DSS. Moreover, the *Isc* responses of the colonic mucosa to forskolin were suppressed after the induction of colitis. The stimulated ion transport activity of DSS-rats treated with SRE displayed significant improvement in the secretory responsiveness.

CONCLUSION: SRE was effective in treating acute DSS-induced ulcerative colitis, as gauged by reduced clinical disease, improved macroscopic and histological damage scores, and enhanced recovery of normal colonic secretory function.

Key words: Ulcerative colitis; *Scutellariae Radix*; Inflammatory bowel disease; Colonic ion transport; Traditional Chinese medicine

INTRODUCTION

Ulcerative colitis is a worldwide, chronic, idiopathic, inflammatory bowel disease (IBD) of the rectal and colonic mucosa. In the past, this disease was thought to occur infrequently in the Asia Pacific region. However, new evidence is showing that IBD is on the rise in the region, including in Hong Kong and mainland China[1-3]. Although glucocorticoid and salicylazosulfapyridine have been mainly used for the treatment of this disease, their side effects remain a major clinical problem. Therefore, there is an increasing interest in using traditional Chinese medicines (TCM) as alternative therapy in addition to the conventional therapies that are used to treat UC[4].

The dried root of *Scutellaria baicalensis* Georgi (*Scutellaria Radix*, common name Huangqin) is widely used in TCM. It is officially listed in the Chinese Pharmacopoeia and is one of the most widely used Chinese herbal medicines for the treatment of bacterial infection of the respiratory and gastrointestinal tract. In Japan and China, *Scutellariae Radix* has been employed for centuries as an important medicine to treat chronic inflammatory and ulcerative disease. The main components of *Scutellariae Radix* (and of all *Scutellaria* species) are baicalein, baicalin and wogonin.

Scutellariae Radix and its major flavonoids possess multiple biological and pharmacological effects, including anti-inflammation[5], anti-viral[6], anti-tumor[7], anti-proliferative[8] and anti-bacterial[9], *etc*. Recent studies also suggest that *Scutellariae Radix*-containing TCM formula, such as Orengedoku-to (Huang Lian Jie Du Tang) may have therapeutic potential against murine colitis[10-12].

In this study, an experimental model of UC was established in SD rats using DSS. The effect of the total extract of *Scutellariae Radix* on DSS-rats was evaluated using macroscopic, histological, biochemical and electrophysiological assessments.

MATERIALS AND METHODS

Materials

Male SD rats, initially weighing 170-180 g, were housed five per cage and maintained in an animal holding room controlled at a constant temperature of 24℃ ± 2℃ with a relative humidity of 70% ± 5% and a 12 h light-dark cycle. Animals were fed on a standard pellet chow with free access to fresh tap water. The study was approved by the Animal Research Ethics Committee of our university. DSS was obtained from MP Biochemicals Inc. Hexadecyltrimethylammonium bromide, forskolin were obtained from Sigma. SRE was purified from the ground roots of *S. baicalensis* Georgi with hexane, acetone, and finally, with methanol as described previously[13,14].

Experimental design

The induction of colitis was modified from a previously described work[15]. The experiment lasted for 8 d. The rats were randomly divided into four groups. In the DSS Group, 4% DSS in drinking water *ad libitum* was given from d 0 to d 7. In DSS + SRE group, SRE (100 mg/kg per day) was orally administrated with exposure to 4% DSS drinking water. In the normal control group (Ctr), the rats had free access to a water bottle containing tap water. In Ctr + SRE group, SRE alone (100 mg/kg per day) was administered orally to the rats. In this model, the colonic damage was evaluated using macroscopic, histological, electrophysiological and biochemical assessments (see below). From d 3 to d 7, rats were sacrificed by CO_2 asphyxiation on each day. Postmortem, the entire colon was removed from the cecum to the anus and placed on an ice cold plate and cleaned of fat and mesentery. The length of each specimen was measured, which is an indirect marker of inflammation. The colon was divided into three parts (proximal, middle and distal) based on total length: 10% regions from three parts were fixed for histological examination; the distal portion was used for electrophysiological studies; and the adjacent distal 10% was snap-frozen in liquid nitrogen for later quantification of MPO activity.

Macroscopic assessment

Animals were checked daily for the three main clinical symptoms-body weight changes, stool consistency and fecal occult blood. Weight loss is usually observed in animals with colitis, thus body weight changes recorded could be an indicator for the severity of colitis. The colonic damage was quantified by a clinical scoring system assessing stool consistency and rectal bleeding[16]. For stool consistency, 0 points were given for well formed pellets, 2 points for pasty and semiformed stools that did not stick to the anus, and 4 points for liquid stools that did stick to the anus. Bleeding was scored 0 for no blood in hemoccult, 2 points for positive hemoccult, and 4 points for gross bleeding. These scores were added, forming a total clinical score that ranged from 0.0 (healthy) to 8.0 (maximal activity of colitis).

Histological assessment

For light microscopy, we used tissue samples from three parts (distal, middle and proximal) of colon of each animal fixed in 4% (40 g/L) buffered paraformaldehyde, dehydrated in increasing concentrations of ethanol, and embedded in paraffin. Thereafter, sections of tissue were cut at 5 μm on a rotary microtome, mounted on clean glass slides and dried overnight at 37℃. The sections were cleaned, hydrated, and stained with hematoxylin and eosin (HE) for histological evaluation of inflammatory infiltrate and tissue damage, according to standard protocols, and the slides were coded to prevent observer bias during evaluation. All tissue sections were examined in a blinded fashion by two investigators. Histological damage was scored using the criteria of Siegmund B *et al*[17] which considers the inflammatory infiltrate (maximum score = 3) and tissue damage (maximum score = 3). Photographs of colon samples were digitized using a ZEISS Axioskop 2 plus camera. Analysis of the figures was carried out with Axio Vision 3.1 image analysis program.

Electrophysiological assessment

Mucosal ion transport was examined in colonic segments (approximately distal colon) mounted in Ussing chambers according to a well established protocol in our laboratory[18]. In brief, tissues (surface area = 0.45 cm^2) were bathed in 20 mL of warm (37℃), oxygenated Krebs buffer. The spontaneous potential differences were maintained at 0 mV by a voltage clamp amplifier (Physiologic Instruments), and the short-circuit current (I_{SC} in μAcm^{-2}) was continuously measured as an index of electrogenic ion transport. A transepithelial potential difference of 1 mV was applied periodically, and the resultant change in current was used to calculate the transepithelial resistance (R_t) using Ohm's law. Stimulated ion transport was evoked by the addition of an adenylate cyclase-activating agent, forskolin (1 μmol/L), to the mucosal bathing solution. In all instances, the effect of the treatment was recorded as the maximum change in I_{SC} (ΔI_{SC}) to occur within 5 min.

Biochemical assessment

The MPO activity was determined following a published protocol[19]. Briefly, frozen tissue samples were weighed and suspended in potassium phosphate buffer (20 mmol/L, pH 7.4) at a ratio of 50 mg tissue to 1 mL of buffer. Tissue was homogenized by a polytron tissue homogenizer three times for 20 s, and homogenate was decanted into sterile

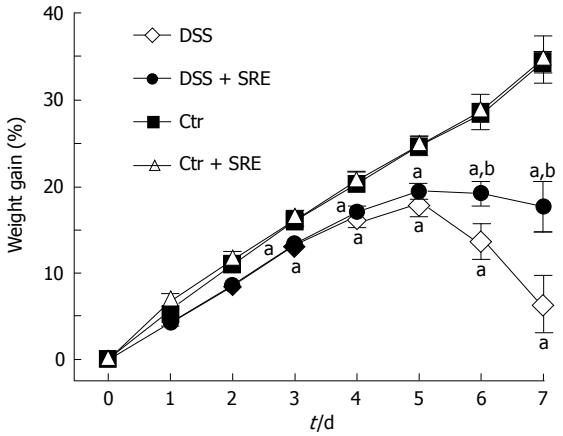

Figure 1 Figure showing the weight gain percentage (%) in different groups of rat from d 0 to d 7. Body weight was assessed daily and expressed as percentage increase of basal body weight. Values are expressed as the means ± SE, (n = 8), $^{a}P < 0.05$ *vs* Ctr group, $^{b}P < 0.05$ *vs* DSS group, one-way ANOVA followed by Tukey multiple comparison test.

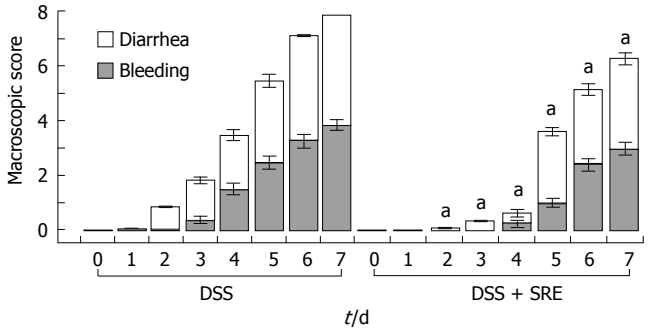

Figure 2 Ameliorative effect of SRE treatment on the time-course changes in the macroscopic score over the 8-d experimental period. The macroscopic score of Ctr and Ctr + SRE groups is 0 (data not shown). $^{a}P < 0.05$ *vs* DSS group. Non-parametric data are expressed as the means ± SE, Kruskal-Wallis One Way Analysis using Student-Newman-Keuls method (n = 6-8).

Eppendorf tubes and centrifuged at 10000 × g for 10 min at 4℃. The pellet was then resuspended in 1 mL potassium phosphate buffer (50 mmol/L, pH 6.0) containing 5 mg/mL hexadecyltrimethylammonium bromide (TMB) at a tissue concentration of 50 mg/mL. Samples were sonicated three times for 10 s, freeze-thawed three times, and centrifuged at 10000 × g for 5 min at 4℃. The reaction was started by mixing 20 μL of the supernatant at 25℃ with 30 μL TMB. After 110 s, the reaction was terminated by addition of 50 μL of 0.18 mol/L H_2SO_4. The change in absorbance was read at 450 nm. MPO activity (1 unit) was expressed as the amount of enzyme necessary for the degradation of 1 μmol H_2O_2/min per 100 mg tissue at 25℃.

Statistical analysis

All data are presented as means ± SE. One way ANOVA followed by post hoc statistics with Tukey test was used for statistical evaluation of the parametric data. Non-parametric data was analyzed by Kruskal-Wallis One Way Analysis using Student-Newman-Keuls method. $P < 0.05$ was considered as statistically significant. The values of n refer to the number of experiments undertaken using different rats. Non-parametric data are expressed as the means ± SE.

Figure 3 Macroscopic view of the colon showing the changes in colon length in different groups of rat on d 7. Not much difference was observed between the colon of the Ctr (**A**) and Ctr + SRE group (**B**), but significant difference could be found in the DSS group (**C**) which displayed extensive hyperemia and edema. In the DSS + SRE group, the shortening of colon was less severe (**D**) when compared with the control (**A**).

RESULTS

Macroscopic assessment

The weight gain % over the entire study period is shown in Figure 1. The weight gain % of rats in DSS group and DSS + SRE group were significantly lower than the Ctr group and Ctr + SRE group from d 3 until the end of experiment. The body weight of rats in DSS group then dramatically decreased from d 5 onwards. However, in the case of DSS + SRE group, the weight gain % became stabilized and the weight loss was found to be less severe than DSS group from d 6 to d 7. Figure 2 shows the macroscopic score recorded throughout the experimental period in DSS and DSS + SRE groups. Oral administration of SRE resulted in a significant reduction in the clinical activity of colitis compared with DSS-treated rats. Moreover, the occurrences of those clinical signs were found to be delayed in DSS + SRE group.

The colon length is a useful indication of colitis and is, therefore, measured as a marker of inflammation (Figure 3). After 8 d treatment with DSS in drinking water, there was a significant shortening of the colon length (Figure 3C) compared with the Ctr group (Figure 3A) and the Ctr + SRE group (Figure 3B). The oral administration of SRE significantly improved this inflammatory marker (Figure 3D). On d 7, the colon length of DSS group (11.2 cm ± 0.4 cm, n = 10) was significantly shorter than the control group (16.8 cm ± 0.6 cm, n = 8). The colon length of DSS-rats treated with SRE (13.5 cm ± 0.4 cm, n = 9), however, was significantly longer than that of untreated rats.

Histological assessment

Histological damage was evaluated by the grading method described above in Materials and Methods. The occurrence of UC was confirmed on the basis of histological damage and inflammatory infiltrate as shown in Figure 4. Figure 5 summarized the damage scores from DSS rats and DSS rats treated with SRE. The microscopic score of samples

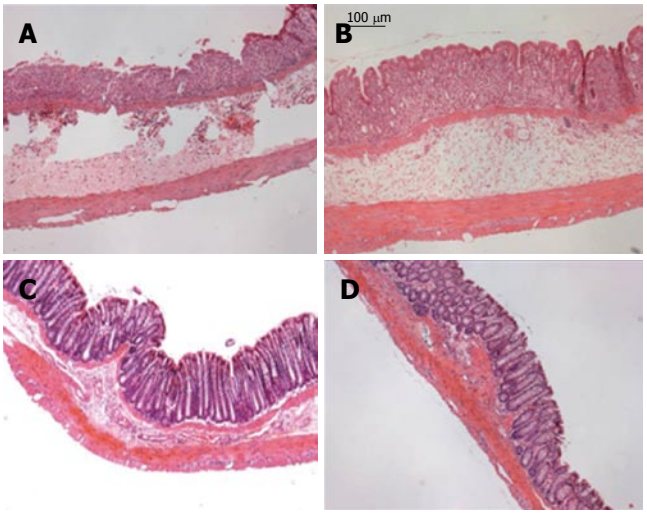

Figure 4 Histological sections from different groups of rats on d 7. **A**: DSS group showing extensive ulceration with a severe inflammatory cell infiltrate; **B**: DSS + SRE group showing recovery in the inflammatory cell infiltration with less severe ulceration; **C**: Non-colitic Ctr group showing the normal histology of the colon; **D**: Ctr + SRE group showing the normal morphology of the colon. (HE staining; original magnifications, x 100).

from different regions (distal, middle and proximal) of colon were not significantly different from each other (data not shown). The histological index began to increase on d 3 in both groups. However, the rats with SRE administration showed a significantly lower value than the untreated animals on d 6 and d 7.

Electrophysiological assessment

Electrogenic ion transport function was assessed by stimulating the colon with an adenylate cyclase activator, forskolin (1 μmol/L), using short-circuit current measurement technique (Figure 6). Under the experimental conditions, the increase in I_{SC} is mainly due to the cAMP-mediated Cl^- secretion *via* the cystic fibrosis transmembrane conductance regulator (CFTR)[18]. The basal I_{SC} and R_t in the tissues were recorded and these parameters were not significantly different (data not shown) when tissues from different groups were compared. On d 7, the secretory response to the cAMP-elevating agent was significantly diminished in tissues from rats treated with DSS (ΔI_{SC} = 4.94 ± 1.65 μAcm^{-2}, n = 6) when compared with Ctr (ΔI_{SC} = 60.97 ± 7.62 μAcm^{-2}, n = 8) and Ctr + SRE (ΔI_{SC} = 61.48 ± 6.78 μAcm^{-2}, n = 7). On the other hand, the reduced responsiveness was ameliorated in the colitic rats with SRE administration (ΔI_{SC} = 20.67 ± 3.30 μAcm^{-2}, n = 9).

Biochemical assessment

The MPO activity in the groups without DSS treatment remained at a low value throughout the entire experiment and there was no effect of SRE on the control (d 7: Ctr 0.09 ± 0.01 mU/mg, n = 6; Ctr + SRE 0.06 ± 0.0003 mU/mg, n = 5). In comparison, rats with colitis were accompanied by a significant increase in MPO activity (d 7: 0.52 ± 0.07 mU/mg, n = 8). On d 7, the increase in MPO activity (0.34 ± 0.05 mU/mg, n = 8) was significantly reduced in rats treated with SRE.

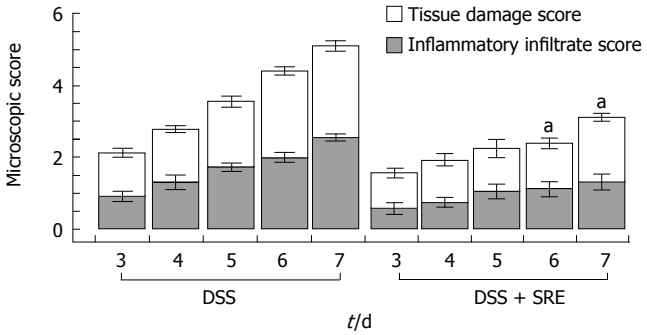

Figure 5 Ameliorative effect of SRE treatment on the time-course changes in the microscopic score from d 3 to d 7. The microscopic score of Ctr and Ctr + SRE groups is 0 (data not shown). $^aP < 0.05$ *vs* DSS group. Non-parametric data are expressed as the means ± SE, Kruskal-Wallis One Way Analysis using Student-Newman-Keuls method (n = 4-5).

DISCUSSION

Ulcerative colitis is an inflammatory disease that causes ulcerations of the mucosa in the colon. The incidence of UC is around 1 in 1000 people with a higher prevalence among Caucasians[20]. In the past, this disease has been considered to occur rarely in the Asia Pacific region, but recent evidence indicates that both UC and Crohn's disease (CD) are becoming increasingly prevalent in local populations[3]. For example, from 1991 to 2000, there has been a three-fold increase in the number of cases of UC in China[1]. In Hong Kong, from 1986-1989 to 1999-2001, there was also a three-fold increase in the incidence of CD in the Chinese population[2]. Although the etiology of IBD remains essentially unknown[21], results from many studies in human patients and animal models suggest that it may be related to an abnormal immune response in the gastrointestinal tract, possibly associated with genetic and environmental factors[22,23]. Although progress has been made in the overall management of UC, the pharmacological treatments that are available are still unsatisfactory. Glucocorticoids, sulfasalazine and immunosuppressive drugs have been mainly used for the treatment and maintenance of UC, but the side effects or toxicity of these drugs remain a major clinical problem[24]. As a result, there is an increasing interest in using TCM as alternative therapy in addition to the conventional therapies that are used to treat UC[25]. In Japan and China, the most commonly used alternative remedies are herbal and these have been widely used in patients with mild to moderate disease, as well as an adjunct to therapy in patients with moderate to severe disease[1]. Interestingly, a recent survey showed that one-third of both Chinese and Caucasian IBD patients had used complementary and alternative medicines and therapies[4]. Several TCM formulae have been shown to possess an anti-colitic effect in rats[26-28]. Recent studies suggest that *Scutellariae Radix* may have a pharmacological effect against murine colitis[10-12] and therefore in this study we aim to further evaluate the therapeutic effect of SRE on DSS-induced rat colitis.

In the present study, 4% DSS in drinking water was administrated for 8 d to induce acute colitis in rats. All DSS-treated rats showed numerous clinical symptoms such as body weight loss, diarrhea, bloody stools and shortening

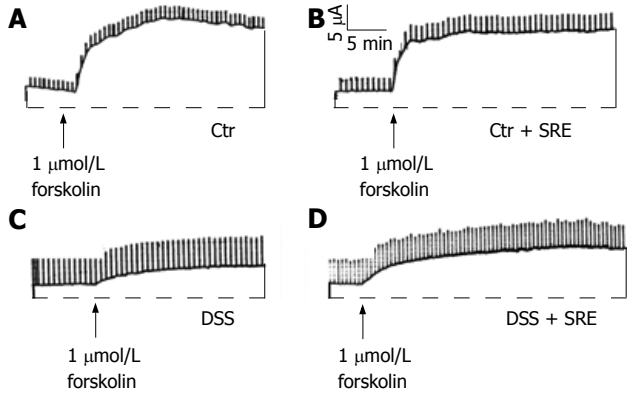

Figure 6 Representative tracings showing the change in I_{SC} evoked by forskolin in different groups of rat on d 7. All four groups showed an increase in ISC but with different magnitudes (**A-D**). The I_{SC} response was greatly reduced in the DSS group (**C**) when compared with the control (**A**). On the other hand, the reduction in secretory response appears to be ameliorated in the DSS + SRE group (**D**). The transient current pulses were the results of intermittently clamping the potential at 1 mV. The horizontal lines represent zero I_{SC}. The record is representative of at least six experiments.

of colon length. Body weight loss is a common symptom of UC because of the loss of body fluid and damage to the digestive system. In Ctr and Ctr + SRE groups, rats showed a steady increase in body weight throughout the experiment. In comparison, rats exposed to DSS had a lower rate of body weight increase followed by a dramatic decrease from d 5 onwards. Treatment with SRE to the colitic rats showed a less severe weight loss from d 6 to d 7. In DSS group, diarrhea and rectal bleeding occurred in d 1 and d 2, respectively. The SRE administration delayed the occurrence of both symptoms and with less severity. Colon shortening is always found in UC patients, which can act as an indirect marker of colonic inflammation. Although the colitic rats with SRE treatment also showed a decrease in colon length on d 7 when compared with the control, the shortening was much less severe than that of DSS rats. Taken together, the data suggested that SRE treatment could induce a decrease in the extent of colitis accompanied by reducing the severity and delaying the occurrence of the associated clinical symptoms.

Colitis induced by DSS was histologically characterized by severe disruption of tissue architecture, edema, a massive mixed immune cell infiltrate, ulceration and muscle thickening. To quantify the histological damage, we used a scoring system modified from a previous study[17]. We found that the overall histological damage of colitis was significantly reduced by the SRE treatment on d 6 and d 7 of the experiment. Together with the reduced MPO activity, our results showed that SRE treatment ameliorated the DSS-induced colitis possibly *via* its anti-inflammatory and protective effect against the colonic tissue damage.

The colonic epithelium, in addition to its absorptive and secretory properties, presents an efficient barrier to commensal flora and pathogens[29,30]. In fact, the secretion of water and electrolytes is one of the most important responses of the mucosa, purging the gut of offending agents and delivering anti-microbial mediators (e.g., antibodies) to the luminal surface[31]. In addition, mucus forms a gel layer covering the mucosal surface, and it has been hypothesized that changes in mucin structure and/or quantity may influence the protective functions of the mucosal surface, and affect the pathogenesis of IBD[32]. However, published data on the electrolyte transport mechanisms in an inflamed colon are inconsistent[33,34]. Some studies have documented the acute effects of immune and inflammatory agents in directly or indirectly stimulating intestinal anion secretion, while others do not support such a notion[35,36]. In most cases, however, disease models of colonic mucosa exhibit reduced ion transport responses to secretory agonists, especially in the setting of chronic inflammation[37-45].

The mechanism underlying the typical hyporesponsiveness of tissues from animal models of colitis has yet to be satisfactorily explained. For example, it has been reported that responsiveness to both Ca^{2+}- and cAMP-dependent secretagogues is reduced in mouse and rat colitis models when compared to normal tissue[37-45]. Similar reduction in secretory responsiveness, as measured by changes in I_{SC} has also been observed in tissue resections from patients with IBD[46,47]. It has been proposed that prolonged hyporesponsiveness to secretagogues is due to the upregulation of inducible nitric oxide synthase (iNOS), resulting in an ongoing synthesis of NO and chronic suppression of epithelial secretory function[41,42]. However, another recent study suggests that it may be related to a disturbance of the enteric nervous system resulting in defective mucosal cAMP production and inhibition of ionic secretion, although the epithelial secretory machinery (e.g., CFTR) appears to be normal[43]. Others suggested that prolonged hyporesponsiveness to secretagogues is due to the disruption of normal cholinergic control of ion secretion[40,48]. Nonetheless, intestinal secretion is an important component of mucosal defense. Reduced secretory responses will compromise the ability of the mucosal defense mechanism to clear bacteria, bacterial products, or antigens away from the epithelium, which may then predispose the colon to inflammation[49]. In this study, the I_{SC} responses of the colonic mucosa to forskolin were suppressed after the induction of colitis. Although the stimulated ion transport activity of DSS-rats treated with SRE was still reduced, they displayed improvement in the secretory responsiveness which may at least partly contribute to the therapeutic effect of SRE.

In summary, our findings indicated that SRE was effective in treating acute DSS-induced ulcerative colitis, as gauged by reduced clinical disease, improved macroscopic and histological damage scores, and enhanced recovery of normal colonic secretory function. The results support further evaluation of the therapeutic potential of SRE for the treatment of IBD.

ACKNOWLEDGMENTS

We thank Professor Woody WY Chan and Professor CH Cho for their technical advice in the performance of histological staining and MPO assay, respectively. We also thank Mr. Wallace CY Yip for his excellent technical help.

COMMENTS

Background

Scutellariae Radix, also known as Huangqin, is the dried root of *Scutellaria*

baicalensis Georgi (Lamiaceae). It is officially listed in the Chinese Pharmacopoeia and is one of the most widely used Chinese herbal medicines for the treatment of bacterial infection of the respiratory and gastrointestinal tract. In Japan and China, *Scutellariae Radix* has been employed for centuries as an important medicine. Although scientific evidence confirming the traditional use of *Scutellariae Radix* as an inflammatory modulator in experimental colitis is now accumulating, the physiological basis and the precise mechanism of action of *Scutellariae Radix* or its individual constituents remain largely unknown.

Research frontiers

Cytokine dysregulation is currently an important focus of both basic and clinical research in IBD, with recent immunologically based therapeutic interventions using highly specific agents demonstrating a promising clinical efficacy. The treatment of steroid-refractory Crohn's Disease with anti-TNF-α (infliximab) is an example of this kind of therapeutic approach. In addition, there is an increasing interest in using TCM as alternative therapy in addition to the conventional therapies that are used to treat IBD. However, there is still a paucity of scientific and clinical data so far to support the use of TCM in colitis patients. Therefore, there are unmet needs for further mechanistic, pharmacological and pharmacokinetic studies to delineate the biological basis underlying the therapeutic effects of TCM. More controlled clinical trials of the potential efficacy and safety of herbal TCM therapies are also required.

Innovations and breakthroughs

The authors showed for the first time that the therapeutic potential of *Scutellariae Radix* extract on experimental colitis may be related to the restoration of ion transport function of the colonic mucosa.

Applications

The results support further evaluation of the therapeutic potential of this herbal extract and its active component(s) for the treatment of IBD.

Terminology

Colonic ion transport: Intestinal fluid secretion is a passive process driven by osmotic forces generated by ion transport. In the colon, the main determinant of a luminally-directed osmotic gradient is the mucosal transport of chloride ions into the lumen. Intestinal secretion is an important component of mucosal defense. Reduced secretory responses will compromise the ability of the mucosal defense mechanism to clear bacteria, bacterial products, or antigens away from the epithelium, which may then predispose the colon to inflammation.

Peer review

This is an interesting paper which shows the anti-inflammatory effect of *Scutellariae Radix* on experimental colitis. It also demonstrates that TCM has a scientific and biological basis for its effectiveness.

Abstract

AIM: To observe the apoptosis and oncosis of pancreatic acinar cells and secondary inflammatory reaction in pancreatic tissue from rats with acute pancreatitis (AP), and the influences of artemisinin on them.

METHODS: AP was induced by 4 intraperitoneal injections of caerulein at 1 h intervals. To induce apoptosis, solution of artemisinin (50 mg/kg) was given intraperitoneally 1, 12, 24 and 36 h after the last caerulein injection. Histological examination of impairment of pancreatic tissue and detection of serum amylase were performed to evaluate the severity of acute pancreatitis. Apoptosis and oncosis were detected with acridine orange (AO) and ethylene dibromide (EB) staining. Caspase-3 and myeloperoxidase (MPO) activity were measured by colorimetric assay. Nuclear factor-kappa B (NF-κB) activation was detected by flow cytometry. Macrophage inflammatory protein-1α (MIP-1α) protein was measured by Western blot. Interleukin-1β (IL-1β) mRNA was detected by RT-PCR.

RESULTS: Addition of artemisinin increased the number of apoptotic cells (11.7% ± 1.4% *vs* 6.3% ± 0.7%, $P < 0.05$), while reduced the number of oncotic cells (13.0% ± 2.4% *vs* 17.5% ± 2.2%, $P < 0.05$). The activity of caspase-3 speeded up (1.52 ± 0.21 *vs* 1.03 ± 0.08, $P < 0.05$), the pancreas pathological impairment was relieved (3.0 ± 0.5 *vs* 4.0 ± 0.5, $P < 0.05$) and the level of serum amylase decreased (5642 ± 721 U/dL *vs* 7821 ± 653 U/dL, $P < 0.05$). The activation of NF-κB (29% ± 4.1% *vs* 42% ± 5.8%), MIP-1α protein (3.7 ± 0.5 *vs* 5.8 ± 0.7), MPO (0.52 ± 0.06 U/g *vs* 0.68 ± 0.09 U/g), IL-1β mRNA (1.7 ± 0.3 *vs* 2.4 ± 0.4) in the apoptosis inducing group was obviously decreased ($P < 0.05$).

CONCLUSION: Inducing apoptosis can relieve pathological impairment and inflammatory reaction in AP rats.

INTRODUCTION

Many factors lead to acute pancreatitis (AP). A series of cascade reactions of inflammatory mediators and over-activation of leukocytes are the important causes for systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS)[1]. Although anti-cytokine therapy is able to relieve the severity of AP, it is difficult to block each pathway due to the complicated network of cytokines[2]. Therefore, knowing how to inhibit the initial inflammatory reaction is the key to the treatment of AP. It was reported that inflammatory reaction is correlated to the death modes of pancreatic acinar cells[3]. If death of pancreatic acinar cells occurs in the mode of apoptosis, the cell membrane is intact and there is no release of inflammatory mediators and pancreatin, the inflammatory reaction may be mild[4]. However, if death of pancreatic acinar cells occurs in the mode of oncosis, various pancreatin and inflammatory mediators may release, thus causing a variety of inflammatory cell aggregations and inducing intense inflammatory reactions[5]. If we can induce apoptosis and reduce oncosis, intense inflammatory reactions may be inhibited.

In this study, apoptosis of pancreatic acinar cells was induced by the apoptosis inductor-artemisinin. Changes in apoptosis, oncosis and secondary inflammatory reaction were observed.

MATERIALS AND METHODS

Experimental protocol

Twenty-four male Wistar rats (200 g ± 20 g) were provided by the Animal Research Center of the First Clinical College of Harbin Medical University (Harbin, China), and divided into 3 groups (8 rats in each group): control group, AP group, and artemisinin-treated group (apoptosis inducing group). AP was induced by 4 intraperitoneal injections of caerulein (20 μg/kg, Sigma, USA) at 1 h intervals. To induce apoptosis, solution of artemisinin (2 mg/kg, Huaxin, Sichuan, China) was given intraperitoneally 1, 12, 24 and 36 h after the last caerulein injection. The control rats were only given saline solution. Forty-eight hours after the final injection of caerulein, rats were anaesthetized with sodium pentobarbital (40 mg/kg), and then a laparotomy was performed with the pancreas rapidly removed for further analyses.

Histological examination of pancreatic tissue

Samples of pancreatic tissue were fixed in 20% formaldehyde and processed for paraffin histology. After staining with hematoxylin and eosin (HE), histological grading of interlobular edema, inflammatory infiltration, parenchyma hemorrhage, parenchyma necrosis and vacuolization was valued as previously described[6], then a pathologic score was calculated based on these light microscopic examinations.

Measurement of serum amylase

Serum was collected from the rats for amylase measurement. Amylase level was determined using a commercial chromatometric kit (Jiancheng, Nanjing, China).

Detection of apoptosis and oncosis with acridine orange (AO) and ethylene dibromide (EB) staining

Pancreatic acinar cells were isolated from Wistar rats by two-step collagenase digestion[7] and loaded onto slides with AO (10 μg/mL, Sigma, USA) and EB (10 μg/mL, Sigma, USA) for 10 min. The slides were scanned under confocal laser microscope (Zeiss, Germany) and 500 cells were counted under fluorescent microscope (Nikon, Japan).

Measurement of caspase-3 activity by colorimetric assay

Caspase-3 activity was measured using a colorimetric assay kit (KeyGEN, Nanjing, China) according to the manufacturer's instructions. After isolation by two-step collagenase digestion, pancreatic acinar cells were mixed with 50 μL lysis buffer, the supernatant was mixed with 5 μL caspase substrate and 50 μL reaction buffer, and incubated at 37℃ for 4 h in the dark. Fluorescence intensity of the caspase substrate was measured photometrically at 405 nm.

Detection of NF-κB by flow cytometry

Fresh pancreatic tissues were sheared into pieces of 1.0 mm^3 with scissors, and centrifuged at 200 × *g* for 5 min. Then 10 mL detergent solution containing 1% TritonX-100 (Sigma,USA) was added, and stored in a refrigerator at 4℃ for 18 h, then filtered through 50 μm nylon meshes. For fluorescent labeling, 1 μL RNAase was added into 50 μL nucleus suspension and water-bath at 37℃ for 30 min, then 40 μL NF-κB p65 monoclonal antibody (Santa Cruz, USA) was added and incubated at room temperature for 20 min. The samples were treated with 1 μL FITC-labeled second antibody (Jackson Immuno Research, USA) and incubated at room temperature for another 20 min. After treated with 20 μL propidium iodide (PI, Sigma, USA) for 30 min in a dark room, the samples were analyzed using a FACScan flow cytometer (Becton Dicknson, USA).

Measurement of macrophage inflammatory protein-1α (MIP-1α) by Western blot

MIP-1α was detected by Western blot analysis, total protein extract was separated by 10% SDS/PAGE before it was transferred electrophoretically (100 V, 1 h) to hybond C membrane. The membranes were probed with 10 μL anti-MIP-1α monoclonal antibody (Santa Cruz, USA) in TBS-T (1:500), and the immunocomplexed membranes were re-probed at room temperature for 1 h with horseradish peroxidase-conjugated anti-rabbit secondary antibody (Jackson Immuno Research, USA) in TBS-T (1:500), with 5% blocking reagent. At last, the immunoreactive proteins were visualized using the ECL Western blot analysis system (Amersham, UK).

Chromatometric detection of myeloperoxidase (MPO) activity

The pancreatic tissue was frozen in liquid nitrogen and homogenated. MPO activity was detected with a chromatometric kit (Jianchen, Nanjing, China) following the manufacturer's instructions, and data were expressed as the change in absorbance at 460 nm.

Detection of interleukin-1β (IL-1β) mRNA by semi-quantitive RT-PCR

Total RNA was extracted from pancreatic tissue using Trizol reagent (Invitrogen, USA) and reversely transcriped into cDNA according to the instructions of the kit (Promega, USA). The resulting cDNA was used as a template for subsequent polymerase chain reaction (PCR). The sequences of rat-specific primers for IL-1β (519 bp) are as follows: 5'CCAGGATGAGGACCCAAGCA3' (sense), 5'TCCCGACCATTGCTGTTTCC3' (antisense). Housekeeping gene β-actin (348 bp) was used as a controller, 5'CATCACCATTGGCAATGAGCG3' (sense), 5'CTAGAAGCATTTGCGGTCGGAC3' (antisense). The PCR products were resolved in 1.0% agarose gel for electrophoresis and photographed under ultraviolet transillumination and the intensity of PCR products was measured using a video image analysis system.

Statistical analysis

Data were expressed as mean ± SD. Differences between the groups were tested for significance by one-way analysis of variance (ANOVA), and intergroup comparison was made by Student-Newman-Keuls test. $P < 0.05$ was considered statistically significant.

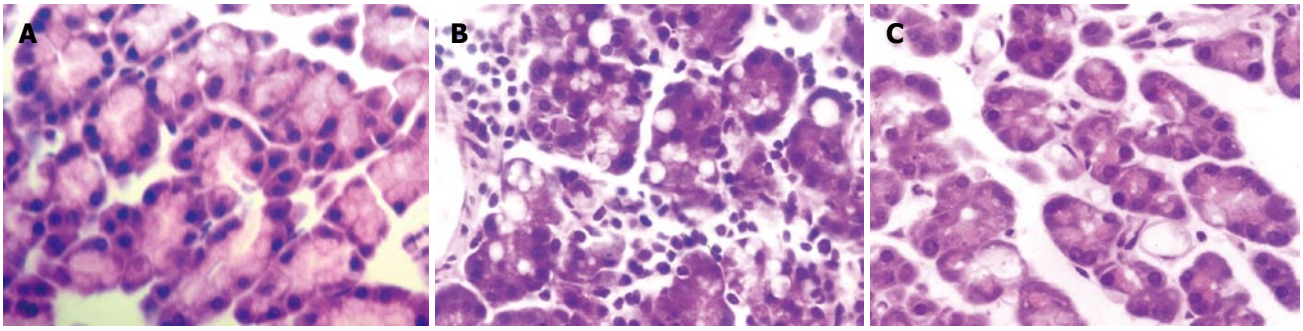

Figure 1 Representative HE-stained pancreatic tissue from the rats (original magnification × 40) in the control group (**A**), AP group (**B**) and artemisinin-treated group (**C**).

Table 1 Detection of cell death pathway and pathologic changes in different groups (mean ± SD, n = 8)

	Pathological score	Amylase (U/dL)	Apoptosis index (%)	Oncosis index (%)	Caspase-3 activity
Control	0.25 ± 0.03	2887 ± 298	1.5 ± 0.3	2.1 ± 0.3	0.35 ± 0.04
AP	4.0 ± 0.5[a]	7821 ± 653[a]	6.3 ± 0.7[a]	1.03 ± 0.08[a]	17.5 ± 2.2[a]
Artemisinin	3.0 ± 0.5[c]	5642 ± 721[c]	11.7 ± 1.4[c]	13.0 ± 2.4[c]	1.52 ± 0.21[c]

AP: Acute pancreatitis. [a]$P < 0.05$ *vs* control group; [c]$P < 0.05$ *vs* AP group.

RESULTS

Histological changes after induction of apoptosis

Pancreatic tissue was normal in the control group with a low pathological score. In the AP group, pancreatic tissue displayed lobular mesenchymal rarefaction, edema and inflammatory cell infiltration. In contrast, in the artemisinin-treated group, edema and inflammatory cell infiltration were significantly relieved compared with the AP group (Figure 1). The pathological score showed alleviated pathological impairment in pancreatic tissue after treated with artemisinin ($P < 0.05$ *vs* the AP group) (Table 1).

Effect of artemisinin on induction of apoptosis and avoidance of oncosis

As shown in Figure 2, the nuclei of normal cells showed normal morphology of green fluorescence, while apoptotic cells showed shrunk, condensed or splitted nuclei (green). EB could be resisted by the intact cytoplasmic membrane of normal and apoptotic cells. EB could penetrate the cytoplasmic membrane of oncotic cells, and stain the nuclei of orange-stained cells. So, the apoptotic index or oncotic index, i.e., the number of apoptotic cells or oncotic cells per 100 cells, could be calculated (Figure 3). The results indicate that only sporadic apoptotic or oncotic cells were observed in the control group, but more in the AP and artemisinin-treated groups. In the AP group, there were less apoptotic cells and more oncotic cells. The number of apoptotic cells increased and the number of oncotic cells decreased significantly in the artemisinin-treated group ($P < 0.05$) (Table 1).

Effect of artemisinin on caspase-3 activity

The activity of caspase-3 in isolated pancreatic acinar cells was low in the control group, and high in the AP group, which was significantly elevated after apoptosis was induced by artemisinin ($P < 0.05$) (Table 1).

Influence of apoptosis on NF-κB activation

Activation of NF-κB in normal pancreatic nuclei was significantly higher in the AP group than in the control group ($P < 0.05$) (Figure 4, Table 2).

Influence of apoptosis on MIP-1α

MIP-1α level was low in the control group and high in the AP group. It was obviously lower in the artemisinin-treated group than in the AP group ($P < 0.05$) (Figure 5, Table 2).

Influence of apoptosis on IL-1β mRNA expression

The expression of IL-1β mRNA was low in the control group and high in the AP group. It was lower in the artemisinin-treated group than in the AP group ($P < 0.05$) (Figure 5, Table 2).

Changes in MPO contents after induction of apoptosis

Since each neutrophil granulocyte contains a certain quantity of MPO, detection of MPO in pancreatic tissue reflects the degree of neutrophil infiltration of the tissue. In our study, the MPO concentration was low in the control group and high in the AP group. However, it was down-regulated after induction of apoptosis ($P < 0.05$) (Table 2).

DISCUSSION

AP characterized not only by pancreas impairment, but also by inflammatory cell infiltration and release of various kinds of inflammatory mediators, can develop into SIRS and MODS in some cases and endanger their life[8,9]. Initiation of inflammatory reaction is related to the death pathway of impaired pancreatic acinar cells[10]. Since the conception of apoptosis was proposed by Kerr in 1972[11], apoptosis has been extensively studied. In recent years, attention has been paid to another cell death pathway-oncosis, and it was gradually realized that oncosis makes no less sense than apoptosis[12]. Oncosis has a feature of cell swelling, and cell membrane integrity is destroyed and DNA is split into non-specific fragments. Finally the cells are dissolved accompanying inflammatory reaction. In some physiological and pathological processes, these two kinds of death pathways exist simultaneously, and may

interconvert to each other under certain conditions[13]. Oncotic cells may release much more entocytes (including digestive enzyme and inflammatory active medium). It not only destroys the local tissue, but also activates mononuclear cells, leading to SIRS. However, apoptosis may not cause secondary inflammation. During AP, the patient has his or her own self-regulating mechanism. Under certain conditions, the apoptotic signal conduction pathway can be initiated, and more apoptosis will be induced and harmful effects of oncosis may be relieved. However, if AP develops quickly or the patients' self-regulation is in disorder, the apoptosis signal conduction pathway cannot be initiated in time, causing predominant oncosis, leading to aggravation of the disease. This has been proved by Kaiser *et al*[14], who found that when apoptosis is inhibited by cycloheximide, AP obviously aggravates. However, Bhatia *et al*[15] induced apoptosis during their experiment, resulting in the relief of AP. It was reported that one of the therapeutic mechanisms of somatostatin analogue, the most effective drug for AP, is to induce apoptosis of impaired pancreatic acinar cells[16]. Whether AP can be controlled by inducing apoptosis of pancreatic acinar cells has been extensively studied.

Artemisinin is an important active component of traditional Chinese medicine which can induce apoptosis[17,18]. Hahm *et al*[19] found that apoptotic index is elevated but pathological changes in AP rats treated with DA-9610 (an extract from Artemisia Asiatica). In this study, artemisinin was used as an apoptosis inductor. After artemisinin was added into pancreatic acinar cells stimulated by caerulein, apoptosis and oncosis were detected with AO and EB staining, the number of apoptotic cells increased, but the number of oncotic cells decreased. Caspase-3 is a key molecule in the process of apoptosis. Generally, the precursor of caspase-3 in cells is incompetent. However, if it is activated, it can cleave important structural and functional proteins inside the cells and cause chromosome condensation, DNA fragmentation, nuclear membrane rupture, *etc*, finally resulting in apoptosis. The presence of activated caspase-3 indicates that apoptosis is at the irreversible stage[20]. Nam *et al*[21] found that artemisinin can induce apoptosis by up-regulating caspase-3. Our study also showed that the activity of caspase-3 in pancreatic acinar cells was obviously elevated after artemisinin was added, indicating that artemisinin may promote apoptosis. We examined the pancreatic tissue with HE staining and found that after induction of apoptosis, infiltration of inflammatory cells decreased and the pancreas impairment was relieved. Based on this understanding, we observed the degree of inflammatory reaction after induction of apoptosis.

We detected transcription factor-NF-κB which regulates synthesis of many inflammatory mediators and cytokines[22]. NF-κB is a protein that regulates gene transcription, participates in regulating many inflammatory factors, and evokes immune and inflammatory reactions[23]. NF-κB plays a key role in the development of AP[24]. In our study, activation of NF-κB in the apoptosis inducing group was obviously decreased, compared with the AP group, indicating that activation of NF-κB can be decreased by inducing apoptosis and reducing oncosis. The conserved sequence of MIP-1α combined with NF-κB exists in its promoter region[25], suggests that MIP-1α may be one of the downstream targets regulated by NF-κB. MIP-1α was detected by Western blot assay in this study, proving that if apoptosis is induced, MIP-1α can be inhibited. MIP-1α is a CC-type chemotatic factor and plays an important role in recruiting mononuclear cells and lymphocytes[26]. Just as the "over-activation of leucocyte theory" proposed by Rindernech *et al*[27], AP aggravates because inflammatory cells are over-activated, and these activated cells such as granulocytes and macrophages, play a great role in the development of AP. Therefore, MPO (the marker of neutrophils) and IL-1β (the inflammatory factors generated mainly by mononuclear macrophages)[28] were detected in this study, indicating that MPO is obviously decreased in pancreas tissue after induction of apoptosis, reducing neutrophil recruition and infiltration to pancreas tissue. IL-1β is a kind of proinflammatory cytokines mainly generated by macrophages in pancreas when AP occurs. IL-1β can activate neutrophils, up-regulate the expression of surface adhesion molecules of lymphocyte and endotheliocytes[29]. Fink *et al*[30] reported that release of pancreatic amylase and necrosis of pancreas tissue are obviously decreased by blocking IL-1 receptor, demonstrating that IL-1 is essential to inflammation and development of AP. Our study proved that after induction of apoptosis, the level of IL-1β mRNA in pancreas tissue was low, indicating that infiltration and activation of macrophages are decreased and inflammatory reaction is inhibited after induction of apoptosis.

In conclusion, infiltration of inflammatory cells and generation of inflammatory cytokines can be decreased by inducing apoptosis and reducing oncosis of pancreatic acinar cells.

COMMENTS

Background

One of the greatest findings in AP is the initiation of cytokine network in AP patients that promotes occurrence of SIRS and MODS. Efforts have been made to alleviate pathological changes in AP by inhibiting the cytokine network. Since cytokine network is so complex that it is impossible to block all the pathways, it may pave a new way for the treatment of AP to obstruct the cytokine chain reactions. It was reported that the cytokine network can be obstructed by inducing apoptosis, decreasing oncosis and release of endocellular enzyme, suggesting that any drugs regulating apoptosis may be used in the treatment of AP.

Research frontiers

It has been verified that AP worsens when apoptosis of pancreatic acinar cells is

inhibited by cycloheximide, and that AP is alleviated when apoptosis is induced. It was reported that the severity of AP is associated with the degree of oncosis. Hahm *et al* found that there is an elevated apoptotic index but extenuated pathological changes in AP rats after treated with DA-9610 (an extract from Artemisia Asiatica), suggesting that artemisinin can regulate cell death and can be used in the treatment of AP.

Innovations and breakthroughs

When the concept of apoptosis was first put forward by Kerr in 1972, a lot of studies have been performed with it. In recent years, more and more attention has been paid to oncosis, showing that the importance of oncosis is no less than that of apoptosis. In traditional Chinese medicine, some important prescriptions have been successfully applied in AP treatment, and one of the mechanisms is to suppress inflammatory response and induce apoptosis. Artemisinin is an important active component of traditional Chinese medicine which can induce apoptosis. In this study, we observed the regulatory effect of artemisinin on apoptosis and oncosis of pancreatic acinar cells and its therapeutic effect on AP.

Applications

Artemisinin can induce apoptosis and reduce oncosis of pancreatic acinar cells at the onset of AP, thus repressing the intense inflammatory reactions, such as SIRS and MODS. Therefore, there is a bright prospect for artemisinin in the treatment of AP.

Terminology

Oncosis, or cellular swelling, is a pathological process of cell death, in which the completeness of cell membrane is destructed and DNA is split to non-specific fragments, ultimately leading to cell lysis complicated by inflammatory reactions.

Peer review

The effect of artemisinin on acute pancreatitis was analyzed. The data presented are interesting.

Abstract

AIM: To review and summarize drug metabolism and its related interactions in prescribing drugs within the similar therapeutic or structural class for gastrointestinal disease treatment so as to promote rational use of medicines in clinical practice.

METHODS: Relevant literature was identified by performing MEDLINE/Pubmed searches covering the period from 1988 to 2006.

RESULTS: Seven classes of drugs were chosen, including gastric proton pump inhibitors, histamine H_2-receptor antagonists, benzamide-type gastroprokinetic agents, selective 5-HT_3 receptor antagonists, fluoroquinolones, macrolide antibiotics and azole antifungals. They showed significant differences in metabolic profile (i.e., the fraction of drug metabolized by cytochrome P450 (CYP), CYP reaction phenotype, impact of CYP genotype on interindividual pharmacokinetics variability and CYP-mediated drug-drug interaction potential). Many events of severe adverse drug reactions and treatment failures were closely related to the ignorance of the above issues.

CONCLUSION: Clinicians should acquaint themselves with what kind of drug has less interpatient variability in clearance and whether to perform CYP genotyping prior to initiation of therapy. The relevant CYP knowledge helps clinicians to enhance the management of patients with gastrointestinal disease who may require treatment with polytherapeutic regimens.

INTRODUCTION

More and more drugs within the similar therapeutic or structural class are emerging and it is essential to compare the alternative drug choices according to their efficacy, safety, suitability and cost. However, irrational prescription is common in many countries. Drug metabolism and its related interactions are most prone to be ignored in clinical practice. Actually, metabolism by cytochrome P450 (CYP) represents an important clearance mechanism for the majority of drugs, thus affecting their oral bioavailability, duration and intensity of pharmacological action[1]. The metabolic profile of a drug depicts its amount metabolized by CYP, CYP reaction phenotype, impact of CYP genotype on interindividual pharmacokinetics (PK) variability and CYP-mediated drug-drug interaction potential. It is closely related to the three-dimensional chemical structure of drug and may exhibit significant differences among drugs within the similar therapeutic or structural class, although the efficacy of these similar drugs do not show sharp differences at the dose used clinically[2,3]. The voluntary market withdrawal of cerivastatin by Bayer and withdrawal of medications such as terfenadine, astemizole, cisapride, and mibefradil from the market by the Food and Drug Administration (FDA) further demonstrate the relevance of metabolic drug-drug interaction profile. Although the FDA has published guidance for *in vitro* and *in vivo* drug metabolism/drug interaction

studies in the drug development process[4,5], systematic summary is not yet available on metabolic differences in market products within the similar therapeutic or structural class. This review focuses on seven classes of drugs for gastrointestinal diseases treatment and aims to help clinicians realize what kind of drug has less interpatient variability in clearance, whether to perform CYP genotyping prior to the initiation of therapy, and how to enhance the management of patients on polytherapy regimens.

MATERIALS AND METHODS

Seven classes of drugs for gastrointestinal diseases treatment were chosen, including gastric proton pump inhibitors, histamine H_2-receptor antagonists, benzamide-type gastroprokinetic agents, selective 5-HT_3 receptor antagonists, fluoroquinolones, macrolide antibiotics and azole antifungals. Relevant literature, focusing on drug metabolism, metabolic interaction potentials and clinical events of adverse drug reactions and treatment failures caused by drug-drug interaction, was identified by performing MEDLINE/Pubmed searches covering the period from 1988 to 2006.

RESULTS

Gastric proton pump inhibitors

Proton pump inhibitors (or "PPI"s) are a group of drugs widely prescribed for the treatment of acid-related diseases such as peptic ulcer, gastroesophageal reflux disease (GERD), nonsteroidal anti-inflammatory drug induced gastropathy and Zollinger-Ellison syndrome. Currently used PPIs in clinical practice are as follows: omeprazole, lansoprazole, pantoprazole, rabeprazole and esomeprazole. All are benzimidazole derivatives (Figure 1). Schematic depiction of metabolic differences among four PPIs is described in Figure 2.

Lansoprazole, omeprazole and pantoprazole are all primarily metabolized by CYP2C19, an isoenzyme that exhibits genetic polymorphism with 15%-20% of Asian populations being poor/slow metabolizers, whereas the prevalence is much lower (3%-5%) among Caucasians and Blacks[6]. Their PK behaviors are all dependent on CYP2C19 genotype. $AUC_{po(PM)}/AUC_{po(EM)}$, the ratio of parent drug area-under-the concentration *vs* time curve after oral dosing (AUC_{po}) derived from poor metabolizers (PM) and extensive metabolizers (EM), is 7.4, 3.7 and 6.0 for omeprazole, lansoprazole and pantoprazole, respectively[7]. CYP2C19 polymorphism is also a major predictor of treatment failures in patients receiving lansoprazole-, omeprazole- or pantoprazole based polytherapy for eradication of *H pylori*[8].

Omeprazole has also been known as a potent inhibitor of CYP2C19, and may cause pharmacokinetic interactions with other CYP2C19 substrates such as diazepam, phenytoin and moclobemide[9-11]. Both lansoprazole and omeprazole also induce CYP1A2 *in vitro*[12]. Omeprazole can reduce clozapine plasma concentrations by 40%[13]. However, concomitant intake of omeprazole or lansoprazole at high therapeutic doses does not affect the PK behavior of theophylline and caffeine[14,15]. The underlying explanation of the discrepancy may be that inducibility of CYP1A2 by

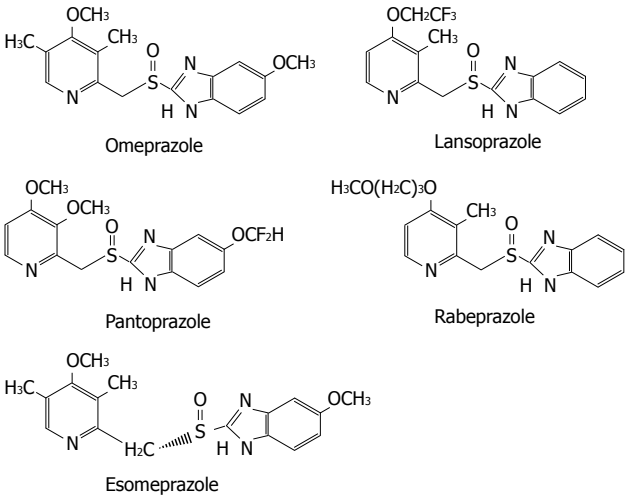

Figure 1 Chemical structures of five PPIs.

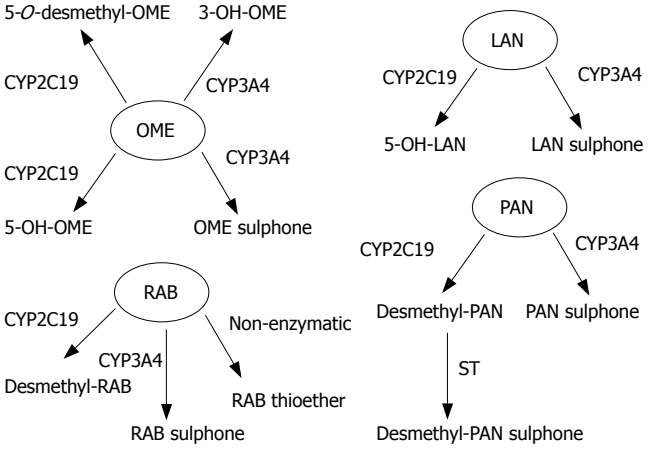

Figure 2 Metabolic differences between four PPIs (OME: omeprazole; LAN: lansoprazole; RAB: rabeprazole; PAN: Pantoprazole). Arrow thickness represents relative contribution to metabolism.

omeprazole *in vivo* is related to the genetic polymorphism of CYP1A2, dose and course of treatment[16-18]. Potential interactions between omeprazole or lansoprazole and CYP1A2 substrates with narrow therapeutic windows should be kept in mind in long-term concurrent therapy. Among these three old PPIs, pantoprazole has by far the lowest potential for interactions[19].

Rabeprazole, although metabolized partially by CYP2C19, is primarily metabolized by nonenzymatic reduction and hence genotype and modifiers of CYP2C19 have less impacts on its PK ($AUC_{po(PM)}/AUC_{po(EM)} \leqslant 1.8$) and clinical efficacy[20].

Esomeprazole is the S-enantiomer of omeprazole. Its metabolism involves CYP2C19, but to a lesser extent than omeprazole (Figure 3). Its PK is less dependent on CYP2C19 genotype ($AUC_{po(PM)}/AUC_{po(EM)}$ approximate 3.0) and hence, it has less interpatient variability in clearance than omeprazole. Moreover, esomeprazole is cleared more slowly *in vivo* and has an improved oral bioavailability, leading to the greater inhibition of gastric acid secretion compared to omeprazole[21,22].

The enantiomers of pantoprazole are differentially

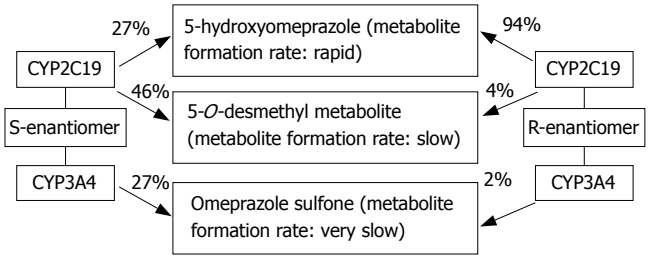

Figure 3 Stereoselective metabolism of omprazole in human.

affected by CYP2C19 genotype, such that the $AUC_{po(PM)}$/$AUC_{po(EM)}$ ratio is 11 and 2.5 for the R-(+)- and S-(−)-enantiomers, respectively[23]. Comparative clinical trial of S-(−)-pantoprazole *vs* racemic pantoprazole in the treatment of GERD has been carried out by Pai *et al*[24]. S-(−)-pantoprazole (20 mg) was found to be more effective than racemic pantoprazole (40 mg) in improving symptoms. Consequently, the use of S-(−)-pantoprazole offers both pharmacokinetic and pharmacodynamic advantages.

Many recent cost-effectiveness analyses have provided an economic basis to employ CYP2C19 genotyping prior to initiating omeprazole-, lansoprazole- or pantoprazole-based polytherapy. However, pharmacogenetic tests may be unnecessary if rabeprazole or esomeprazole based therapy are considered.

Histamine H_2-receptor antagonists

Histamine H_2-receptor antagonists are clinically applied for the treatment of gastritis, gastric and duodenal ulcers[25]. Six H_2-receptor antagonists are currently on the market: cimetidine, ranitidine, famotidine, nizatidine, ebrotidine and roxatidine acetate. Their chemical structures are depicted in Figure 4.

Martinez *et al*[26] compared the inhibitory effect of the H_2-receptor antagonists on the enzymes activities in human liver microsomes. The results were as follows: CYP1A2: cimetidine > ranitidine = ebrotidine; CYP2D6: cimetidine > ranitidine = ebrotidine; CYP3A4: ebrotidine > cimetidine > ranitidine. However, it should be cautiously considered when these *in vitro* data were extrapolated to *in vivo* situations. Firstly, cimetidine only selectively inhibits *in vivo* activities of CYP3A4 and CYP2D6[27]. For example, coadministered cimetidine increased the degree of beta-blockade of timolol (CYP2D6 substrate) ophthalmic solution and the maximum plasma concentrations of CYP3A4 substrates (e.g., midazolam and saquinavir) and disopyramide (CYP3A4 and CYP2D6 substrate)[26,28-30]. Coadministration of cimetidine 400 mg twice a day with saquinavir soft gel 1200 mg twice a day resulted in a significant increase in saquinavir $AUC_{0\text{-}24}$ (120%) and C_{max} (179%). From this view, coadministered cimetidine may be employed as a new pharmacoenhancer for boosting saquinavir for HIV infections. Beneficial effects of the inhibitory activity of cimetidine toward CYP are also used for the prevention of hepatotoxicity induced by overdoses with paracetamol, a substrate of several CYP isoenzymes which activate the drug by oxidation to the hepatotoxic metabolite N-acetyl-p-benzoquinone imine.

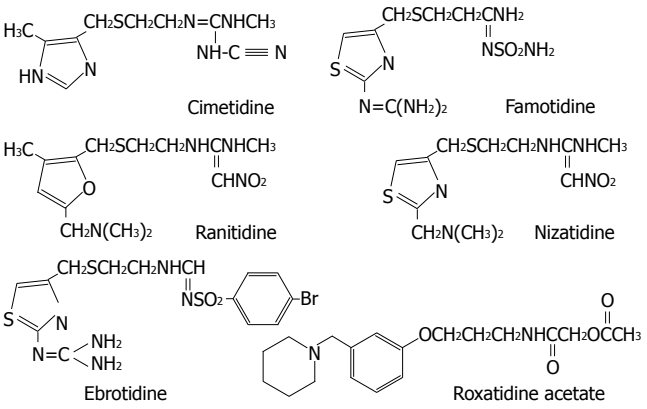

Figure 4 Chemical structures of six H_2-receptor antagonists.

Secondly, inhibition of CYP1A2 activity in humans by cimetidine has not been observed with clinical significance. In concurrent therapy of warfarin, disposition of the less potent R-warfarin (CYP1A2 substrate) was impaired. However, this interaction is likely to be of minimal clinical significance in most patients[31]. The interaction between cimetidine and theophylline was reported inconsistently. Degree of inhibition (absolute change in theophylline clearance) was closely related to route of administration, dosage, the basal theophylline clearance and smoking history[32-35]. Significant pharmacokinetic interaction between cimetidine and theophylline was not observed with low-dose cimetidine (200 mg twice daily), but with 800 mg cimetidine given once daily. Smokers or individuals with higher basal theophylline clearances had greater degree and percent of inhibition than non-smokers or individuals with lower basal theophylline clearances. It suggests that disposition of CYP1A2 substrates may still be impaired in smokers or other individuals with high CYP1A2 activities when coadministered with cimetidine. Thirdly, ebrotidine has no inhibitory effect on CYP3A4 *in vivo*, which is confirmed by lack of metabolic interaction with midazolam[26]. Overall, in contrast to cimetidine, the effects of the other H_2-receptor antagonists on CYP *in vivo* seem to have little clinical significance.

Benzamide-type gastroprokinetic agents

Benzamide-type gastroprokinetic agents (e.g., metoclopramide, cisapride, mosapride, itopride, renzapride and domperidone) are the mainstay of therapy in disorders of gastric motility such as non-ulcer dyspepsia (NUD), GERD, gastritis, diabetic gastroparesis and functional dyspepsia. Their chemical structures are depicted in Figure 5.

Among these gastroprokinetic agents, metoclopramide is predominantly metabolized by CYP2D6, thus its elimination being slow in PMs of CYP2D6 or in patients taking inhibitors of this isoform. Metoclopramide-induced acute dystonic reactions were more frequently observed in patients carrying homozygous CYP2D6 polymorphisms[36]. Meanwhile, it is also a potent inhibitor of CYP2D6 at therapeutically relevant concentrations and markedly inhibits *in vitro* codeine bioactivation[37,38]. Human pharmacokinetic interactions between metoclopramide and CYP2D6 substrates have not yet been documented.

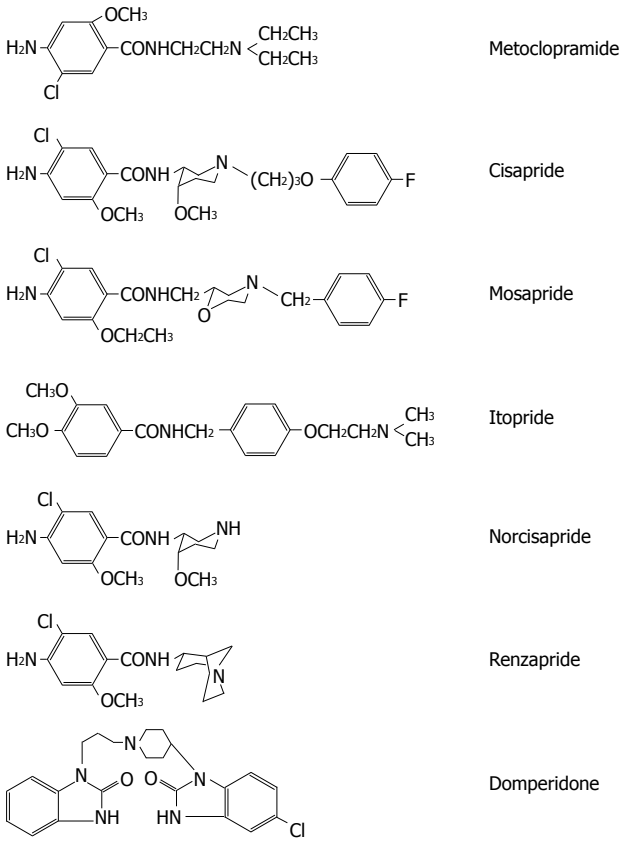

Figure 5 Chemical structures of seven benzamide-type gastroprokinetic agents.

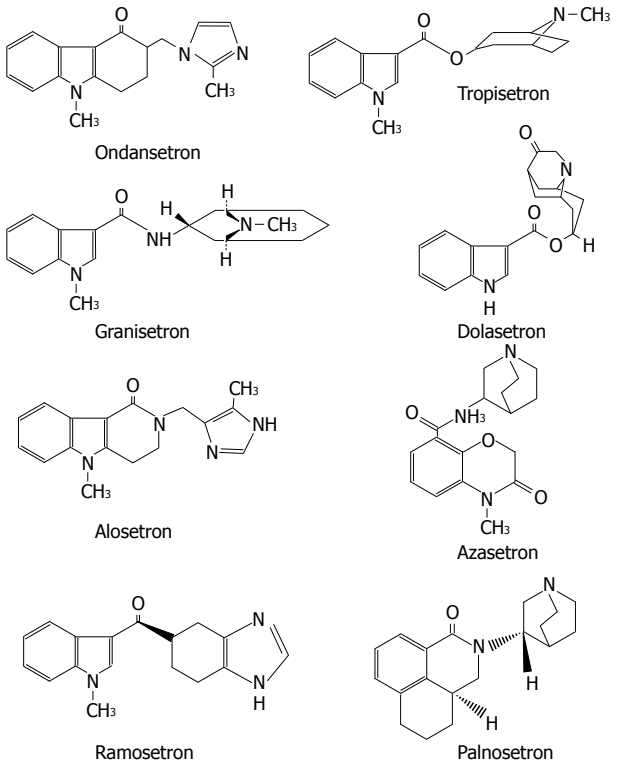

Figure 6 Chemical structures of eight setrons.

Cisapride, mosapride and domperidone, are all predominantly metabolized by CYP3A4. Their dispositions could be strongly impaired by CYP3A4 inhibitors, causing greatly elevated plasma concentrations of parent drugs[39-41]. Among these prokinetic agents, only interactions of cisapride and CYP3A4 inhibitors induce severe clinical adverse events like QT interval prolongation and/or torsades de pointe, which is responsible for the withdrawal of cisapride by FDA. However, cisapride is still on the market in some countries following restriction imposed on its usage. The most important step that can be taken to minimize the risk of cisapride-associated arrhythmias is to avoid the concomitant administration of contraindicated drugs, particularly the macrolide antibiotics (e.g., erythromycin, clarithromycin) and the azole antifungals, (e.g., itraconazole and ketoconazole).

Itopride is primarily metabolized by flavin-containing monooxygenase and its PK is unlikely influenced by CYP3A4 inhibitors[39]. Norcisapride is a major active meta-bolite of cisapride *via* CYP3A4-mediated N-dealkylation. It possesses approximately 15% of the prokinetic activity of cisapride, but has no apparent effect on myocardial conduction[42]. Compared with cisapride, norcisapride elimination does not depend on CYP, and so norcisapride does not interact with azoles or macrolides. Janssen Pharmaceutica has licensed Sepracor's patent on (+) -norcisapride, and its clinical trials are undergoing. This new compound along with mosapride, domperidone and itopride are potentially safer alternatives to cisapride in the concurrent therapy of gastroprokinetic agents with potent CYP3A4 inhibitors.

Renzapride is not metabolized by CYP. It is excreted *via* the renal route primarily unchanged. Thus, its disposition is unsusceptible to CYP modulators and it does not interfere with CYP-mediated metabolism of other drugs[43]. It is currently in clinical development for constipation-predominant irritable bowel syndrome.

Selective 5-HT$_3$ receptor antagonists

The selective 5-HT$_3$-receptor antagonists or "setrons", including ondansetron, dolasetron, tropisetron, granisetron, alosetron, azasetron, palonosetron and ramosetron (Figure 6) represent a class of antiemetics that are currently used for chemotherapy- and radiotherapy-induced, or postoperative nausea and vomiting. However, these setrons have different metabolic profiles.

Ondansetron is cleared by multiple CYP forms in humans, with no single CYP form dominating the overall metabolism. Therefore, its PK lacks bimodality and seems unchanged when ondansetron is used concomitantly with specific CYP isoenzyme inhibitors[44].

Dolasetron is rapidly reduced by carbonyl reductase to its major active metabolite hydrodolasetron, which is eliminated by multiple routes, including renal excretion and metabolism mainly by glucuronidation and hydroxylation[45]. Hence, dolasetron appears to be insusceptible to clinically significant metabolic interactions posed by drugs commonly used in chemotherapy or surgery.

Tropisetron metabolism is almost exclusively CYP2D6-dependent and the metabolites are not pharmacologically active, thus the efficacy of antiemetic treatment with tropisetron largely depends on CYP2D6 genotype. The dose of tropisetron has to be patient-tailored according to CYP2D6 genotype[46,47].

Granisetron is unique because it is not metabolized *via*

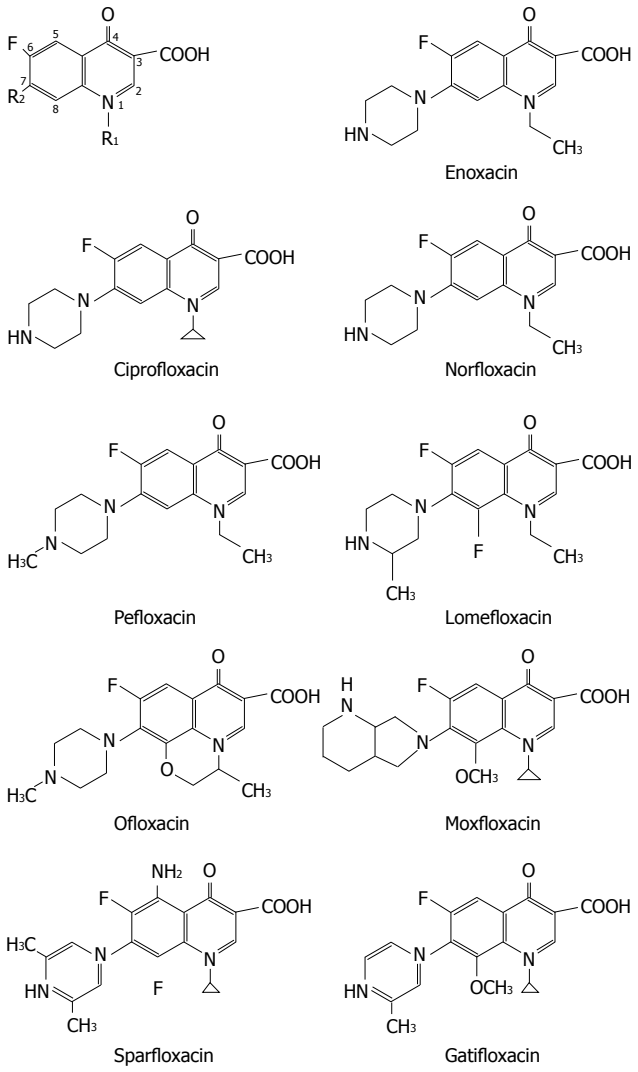

Figure 7 Chemical structures of nine fluoroquinolones.

CYP2D6. Instead, it is metabolized *via* CYP3A4, which is not subject to significant genetic polymorphism and variation in patient response. Moreover, carriers of the duplication of the CYP2D6 allele predicting ultrarapid metabolizer status had less frequent vomiting episodes in subjects receiving granisetron than patients receiving tropisetron. Use of granisetron would obviate the need for CYP2D6 genotyping and may lead to improved prophylaxis of postoperative nausea and vomiting[48-50].

Alosetron is extensively metabolized in humans. *In vivo* data suggest that CYP1A2 plays a prominent role in alosetron metabolism[51,52]. In a pharmacokinetic study, 40 healthy female subjects received fluvoxamine (a known strong inhibitor of CYP1A2) in escalating doses from 50 to 200 mg per day for 16 d, with coadministration of alosetron 1 mg on the last day. Fluvoxamine increased mean alosetron AUC by approximately 6-fold and prolonged the half-life by approximately 3-fold. Thus, concomitant administration of alosetron and strong inhibitor of CYP1A2 is contraindicated. Otherwise, dose-related side effects of alosetron such as constipation may occur more frequently[53].

Azasetron is mainly excreted in urine as the unmetabolized form (approximately 60%-70%), which is different from the fact that other setrons undergo extensive metabolism[54]. *In vitro* data suggest that azasetron does not cause clinically significant CYP-mediated drug interactions.

Palonosetron is metabolized in the liver (approximately 50%). The two primary metabolites, N-oxide-palonosetron and 6-(S)-hydroxy-palonosetron, are essentially inactive. CYP2D6 is the major enzyme of palonosetron metabolism. Clinical pharmacokinetic parameters were not significantly different between PMs and EMs of CYP2D6[55-57]. As for ramosetron, *in vitro* data with human liver microsomes showed its minimal potential to cause clinically important CYP-mediated drug interactions[58].

Fluoroquinolones

Fluoroquinolones are good choices in treatment of intestinal infections caused by sensitive bacterias. Meanwhile, fluoroquinolones-based polytherapy regimens are also used for *H pylori* infection in some occasions, especially after treatment failure in initial *H pylori* eradication[59-63].

The chemical structures of nine fluoroquinolones are listed in Figure 7. They have different CYP-mediated interaction potentials. Enoxacin, ciprofloxacin, norfloxacin and to a lesser extent pefloxacin all have inhibitory effects on metabolism of CYP1A2 substrates such as warfarin, tacrine, clozapine, tizanidine and theophylline. Ofloxacin, levofloxacin, sparfloxacin, lomexacin, gatifloxacin, sparfloxacin, lomefloxacin and moxifloxacin, are less prone to inhibit CYP1A2 and thus are alternative fluoroquinolones to patients receiving concurrent therapy of CYP1A2 substrate with narrow therapeutic window.

Moreover, ciprofloxacin and norfloxacin significantly depressed CYP3A4 in human microsomes[64]. Many case reports indicated their inhibitory effects on CYP3A4 in humans[65-69]. Clinicians should be wary of coadministration of norfloxacin or ciprofloxacin with CYP3A4 substrates with narrow therapeutic window. Table 1 lists the metabolic drug interactions related to fluoroquinolones with clinical relevance.

Macrolide antibiotics

Macrolide antibiotics are usually included in polytherapy regimen for treatment of *H pylori* gastritis[76-80]. In addition, erythromycin, clarithromycin and azithromycin all exhibit prokinetic effects and may be used in the management of gastroparesis[81-84]. For example, erythromycin therapy is effective in the treatment of patients with gastroparesis, in whom metoclopramide or domperidone was ineffective.

Macrolides can be classified into 3 groups based on the propensity of these compounds to interfere with CYP3A4[85-87]. The first group (e.g., troleandomycin, erythromycin and clarithromycin) are potent mechanism-based CYP3A4 inhibitors. Because mechanism based inhibition is an irreversible inhibition where a covalent bond is formed between a metabolite and the active site of the enzyme, destroying the enzyme's activity, so the first group of macrolides could produce drug interactions with clinical relevance. The second group (e.g., flurithromycin, midecamycin, josamycin and roxithromycin) form complexes to a lesser extent and rarely produce drug interactions. The

Table 1 Metabolic drug interactions of fluoroquinolones with clinical relevance

Polytherapy regimen	Clinical consequence	Ref
Ciprofloxacin + tizanidine	Oral ciprofloxacin (500 mg twice daily for 3 d) increased AUC (0-infinity) of tizanidine by 10-fold and Cmax by 7-fold and dangerously potentiates its hypotensive and sedative effects, mainly by inhibiting CYP1A2. Care should be exercised when tizanidine is used concomitantly with ciprofloxacin.	70
Ciprofloxacin + clozapine	Ciprofloxacin (250 mg twice daily for 7 d) can moderately increase serum concentrations of clozapine and N-desmethylclozapine in patients with schizophrenia. A probable mechanism of interaction is an inhibition of CYP1A2 by ciprofloxacin.	71
Ciprofloxacin + theophylline	The interaction between oral ciprofloxacin (500 mg twice daily for 60 h) and theophylline can be clinically significant. Inter-individual variability in the magnitude of interaction can be attributed to inter-individual differences in the level of CYP1A2 expression.	72
Ciprofloxacin + olanzapine	Ciprofloxacin treatment (250 mg twice daily for 3 d) doubled olanzapine concentrations in one patient through the inhibition of CYP1A2.	73
Ciprofloxacin + sildenafil	Ciprofloxacin significantly increased sildenafil bioavailability (above 2-fold) in healthy volunteers, mainly by CYP3A4 inhibition. Dose adjustment of sildenafil is thus necessary.	65
Ciprofloxacin + methadone	Ciprofloxacin inhibited metabolism of methadone *via* CYP1A2 and CYP3A4, and caused profound sedation, confusion, and respiratory depression	66
Ciprofloxacin + cyclosporine	Ciprofloxacin and cyclosporine may be used together safely at the recommended dosage. However, case reports have suggested a possible pharmacokinetic interaction, e.g., ciprofloxacin substantially increased cyclosporine blood levels in a patient with pure red blood cell aplasia. However, levofloxacin therapy (500 mg/d Ⅳ) did not interfere with cyclosporine blood levels and thus it could be a therapeutic alternative.	67, 68
Enoxacin + fluvoxamine	Enoxacin (200 mg/d for 11 d) significantly increased the plasma concentrations at 2, 3 h and the Cmax of fluvoxamine in healthy volunteers. Sleepiness produced by fluvoxamine increased when coadministered with enoxacin.	74
Enoxacin + theophylline	A multidose regimen of enoxacin significantly slowed the clearance of theophylline and elevated theophylline concentrations in serum. The careful monitoring of serum theophylline level and modification of theophylline dosage in patients receiving enoxacin and theophylline were recommended.	75
Norfloxacin + cyclosporine	In pediatric patients undergoing renal transplantation norfloxacin impaired cyclosporine disposition by inhibition of CYP3A4, resulting in cyclosporine dose reduction from 7.4 mg/kg per day to 4.5 mg/kg per day.	69

last group (e.g., azithromycin, dirithromycin and spiramycin) does not inhibit CYP3A4 and are unable to modify the PK behaviors of other compounds.

Metz *et al*[88] reported a potentially significant pharmacokinetic drug interaction between clarithromycin and carbamazepine in two patients with long-standing epilepsy who received omeprazole-clarithromycin therapy for *H pylori* gastritis. In both cases, clarithromycin therapy was temporally related to an increase in serum carbamazepine levels, which returned to the therapeutic range following cessation of clarithromycin therapy. If possible, erythromycin and clarithromycin should be avoided in patients taking CYP3A4 substrates such as atorvastatin, simvastatin, rifabutin, midazolam, cyclosporin, cisapride, pimozide, disopyramide, astemizole, nifedipine and carbamazepine. Azithromycin may be an alternative[89-92]. If clinical judgment suggests erythromycin and clarithromycin should be used, it is necessary to adjust dosage of CYP3A4 substrates with narrow therapeutic window (e.g., decrease the dosage of carbamazepine by 30%-50%), monitor the serum drug levels closely, and warn the patient about the signs and symptoms of toxicity.

Moreover, both erythromycin and clarithromycin are also potent inhibitors of P-glycoprotein and can significantly interfere with the PK behaviors of P-glycoprotein substrate such as digoxin. For example, a case of a clarithromycin-associated digoxin toxicity in a patient with chronic atrial fibrillation and *H pylori* infection was reported by Gooderham *et al*[93].

Azole antifungals

Azole antifungals (i.e., ketoconazole, itraconazole, fluconazole and voriconazole) may be used in treatment for fungus infections in digestive tracts. Their chemical structures are illustrated in Figure 8.

Ketoconazole is extensively metabolized into several inactive metabolites in the liver and the metabolites primarily excreted in bile[94]. Itraconazole is metabolized predominately by CYP3A4. Renal excretion of the parent drug is less than 0.03% of the dose[95]. Fluconazole is mainly excreted in urine as the unmetabolized form (approximately 80%). Accordingly, renal function is the major determinant of fluconazole PK[96]. The concurrent therapy of CYP3A4 inducers (e.g., rifampin and rifabutin) with itraconazole or ketoconazole results in poor antifungal response, thus their coadministrations are not recommended. However, fluconazole PK is less affected by CYP3A4 inducers[97], so fluconazole may be as an alternative for patients receiving comedicated CYP3A4 inducers.

Voriconazole is extensively metabolized by CYP2C19, CYP2C9 and CYP3A4. The major metabolite of voriconazole is the N-oxide, which has negligible antifungal activity. Inducers or inhibitors of these isoenzymes may increase or decrease voriconazole plasma concentrations. Coadministration of voriconazole with rifampicin, carbamazepine and phenobarbital is contraindicated. Allelic polymorphisms of CYP2C19 have been shown to be the most important determinants of the clearance of voriconazole, resulting in two phenotypes: PMs and EMs (both homozygous and heterozygous). Homozygous EMs have a two-fold lower exposure than heterozygous EMs and four-fold lower drug exposure than PMs[98-100]. Coadministration of a potent CYP3A4 inhibitor leads to a higher and prolonged exposure with voriconazole that might increase the risk of ADRs on a short-term

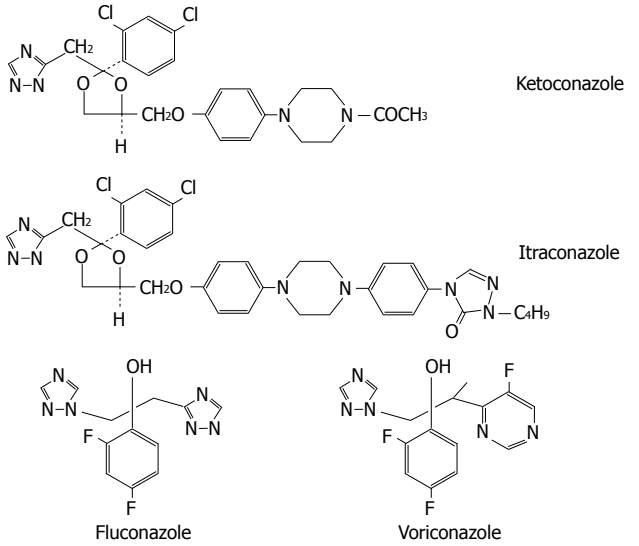

Figure 8 Chemical structures of four azole antifungals.

basis, particularly in CYP2C19 PM patients[101]. Thus, it is necessary to implement CYP2C19 genotyping prior to initiation of voriconazole therapy or therapeutic drug monitoring in the course of treatment.

Ketoconazole and itraconazole are potent inhibitors of CYP3A4. Coadministration with CYP3A4 substrates can cause clinically significant drug interactions, some of which can be life-threatening. Cisapride, oral midazolam, pimozide, quinidine, triazolam, levacetylmethadol, statins metabolized by CYP3A4 (i.e., lovastatin, simvastatin and atorvastatin), ergot alkaloids metabolized by CYP3A4 (i.e., dihydroergotamine, ergometrine, ergotamine and methylergometrine) are contraindicated with ketoconazole and itraconazole.

The potency of fluconazole as a CYP3A4 inhibitor is much lower and thus its clinical interactions with CYP3A4 substrates are of less magnitude. Doses of less than 200 mg/d are not associated with significant CYP3A4-mediated interactions. So fluconazole ($\leqslant$ 200 mg/d) is a relatively safe alternative azole antifungal when coadministered with statins metabolised by CYP3A4[102]. However, it is a potent inhibitor of CYP2C9. Coadministration of fluconazole with CYP2C9 substrates such as phenytoin, warfarin, fluvastatin and losartan leads to clinically significant drug interactions, whereas concurrent therapy of itraconazole or ketoconazole has minimal effect on PK of CYP2C9 substrates[103,104].

Voriconazole inhibits the activities of CYP2C19, CYP2C9 and CYP3A4. Thus, there is a potential for voriconazole to increase the plasma levels of substances metabolized by these CYPs. Coadministration of voriconazole with CYP3A4 substrates (e.g., terfenadine, astemizole, cisapride, quinidine and sirolimus) is contraindicated. When initiating voriconazole in patients already receiving cyclosporine or tacrolimus, it is recommended that the maintenance dosage of two immunosuppressive agents should be adjusted and that their level be carefully monitored. If patients receiving CYP2C9 substrates (e.g., warfarin, phenytoin or sulphonylureas) are treated simultaneously with voriconazole, pharmacotherapy monitoring and dosage adjustment for these drugs should be implemented accordingly.

DISCUSSION

The relationship between chemical structure and metabolic profile has been described in the above summary on seven classes of drugs for gastrointestinal diseases treatment. The underlying molecular mechanism of interactions between drug and metabolizing enzymes is complex and it determines whether the drug is a substrate or inhibitor of the specific enzyme and how far it influences the enzyme activity.

Comparative molecular field analysis (CoMFA) modelling can reveal the key molecular characteristics of CYP inhibitors. For example, both electrostatic and steric interactions were found to account for the differences in the potencies of drugs to inhibit CYP2B6. The differences in inhibitory effects of H_2-receptor antagonists on CYP enzymes may be attributed to the different ability of substituent to bind to the heme iron in CYP[105]. Cimetidine carries both the imidazole and the cyano groups which strongly bind to the heme iron and are responsible for its prominent interaction potential. In comparison to cimetidine, ranitidine has the following structural characteristics: (1) the imidazole ring is substituted with a furane ring, and (2) the side chain cyano group is substituted with a nitro group. Famotidine, nizatidine and ebrotidine all possess a thiazole nucleus instead of the imidazole ring, and the cyano-group in the side chain is substituted by aminosulfonyl- or nitro group. The affinity of binding with CYP isoenzymes is in the following order: imidazole ring (cimetidine), furane ring (ranitidine), thiazole ring (famotidine, nizatidine and ebrotidine). Roxatidine carries no imidazole group in its chemical structure, so it also has a weak inhibitory effect on CYPs.

The relationship between chemical structure of fluoroquinolone and its interaction magnitude has been determined[106, 107]. Molecular modeling studies showed that it is possible to explain the potency of the quinolones to inhibit CYP1A2 on a molecular level. The keto group, the carboxylate group, and the core nitrogen at position 1 are likely to be the most important groups for binding to the active site of CYP1A2, because of the molecular electrostatic potential in these regions. Fluoroquinolones carrying an alkylated piperazinyl moiety at the position 7 (e.g., ofloxacin, levofloxacin, sparfloxacin, lomexacin and gatifloxacin) or a bulky substituent at the position 8 (e.g., sparfloxacin, lomefloxacin, gatifloxacin and moxifloxacin), are less prone to inhibit CYP1A2 than those without corresponding substituents.

The type of CYP metabolism and degree to which an azole antifungal is metabolized are governed by a number of factors including the physiochemical properties of the drug (lipophilicity) and its PK characteristics. Because ketoconazole and itraconazole are highly lipophilic, their clearance is heavily dependent upon CYP-mediated metabolism[108]. Fluconazole, on the other hand, is relatively less lipophilic and requires less CYP-mediated

metabolism at low dosages (< 200 mg/day). Ketoconazole carries an imidazole ring, whereas itraconazole, fluconazole and voriconazole contain triazole rings. The four azole antifungals are strongly binding to hepatic microsome CYP enzymes in a Type Ⅱ manner (i.e., involving the direct ligation of an azole nitrogen with the iron atom of the haem group in the CYP enzyme), which resulted in the broad-spectrum inhibition of multiple CYP isoforms, although the relative potencies towards the various isoforms vary from drug to drug[109].

Generally, if some type of CYP isoenzyme is the most important determinants of the clearance of a drug, metabolic drug interactions can be anticipated when the drug is coadministered with inducers or inhibitors of this isoenzyme. If this drug has a relative narrow therapeutic window, drug-drug interaction may be of clinical relevance. Morever, obvious inter-individual clinical outcome may be observed in patients if a CYP isoenzyme (the determinant of the clearance of a drug) exhibts polymorphism. Under all these situations in clinical practice, clinicians and pharmcists should show abilities in medication therapy management. Careful observations are needed in using new drugs in view of few clinical experiences.

In conclusions, the metabolic profile includes the fraction of drug metabolized by CYP, CYP reaction phenotype, impact of CYP genotype on interindividual PK variability and CYP-mediated drug-drug interaction potential. Significant differences may be observed with the metabolic profiles of medications for gastrointestinal disease treatment even if they belong to the same therapeutic or structural class. Many events of severe ADRs and treatment failures were closely related to the ignorance of this respect. Clinicians should acquaint themselves with what kind of drug has less interpatient variability in clearance and whether to perform CYP genotyping prior to initiation of therapy. The relevant CYP knowledge also helps clinicians enhance the management of patients on polytherapy regimens, i.e., better anticipate or avoid a drug interaction, choose an alternative agent with lower interaction potential, and perform pharmacotherapy monitoring (e.g., monitoring clinical symptoms and alterations in laboratory values) and dosage adjustment accordingly when concurrent therapy can not be avoided.

CONMENTS

Background

Metabolism by cytochrome P450 (CYP) represents an important clearance mechanism for the majority of drugs, thus affecting their oral bioavailability, duration and intensity of pharmacological action. The metabolic profile of a drug depicts its amount metabolized by CYP, the CYP reaction phenotype, impact of the CYP genotype on interindividual pharmacokinetics variability and CYP-mediated drug-drug interaction potential. It is closely related to the three-dimensional chemical structure of drug and may exhibit significant differences among drugs within the similar therapeutic or structural class, although the efficacy of these similar drugs do not show sharp differences at the dose used clinically. Many events of severe adverse drug reactions and treatment failures are attributed to the ignorance of above issues. In order to promote rational drug use in clinical practice, it is essential to let clinicians know what kind of drug has less interpatient variability in clearance, whether to perform CYP genotyping prior to therapy and how to enhance the management of patients on polytherapy regimens from the perspective of drug metabolism.

Research frontiers

Food and Drug Administration (FDA) published guidance for *in vitro* and *in vivo* drug metabolism/drug interaction studies in the drug development process in 1999. Withdrawals of medications such as terfenadine, astemizole, cisapride, and mibefradil from the market by FDA demonstrate the relevance of metabolic drug-drug interaction profile. Some scientists tried to describe the three-dimensional quantitative structure activity relationships (QSARs) within substrates, inducers and inhibitors of CYP in recent years. There are also sporadic reports on metabolic differences in market products within the similar structural class.

Innovations and breakthroughs

This article is the first systematic summary on metabolic differences in market drug products within the similar therapeutic or structural class for gastrointestinal disease treatment.

Applications

The significance of this article is: (1) it helps doctors realize what kind of drug for gastrointestinal disease treatment has less interpatient variability in clearance and whether to perform CYP genotyping prior to therapy; (2) help doctors enhance management of patients on polytherapy regimens. Doctors will learn to better anticipate or avoid a drug interaction, choose an alternative agent with lower interaction potential, perform pharmacotherapy monitoring and adjust dosage accordingly when concurrent therapy cannot be avoided; and (3) help doctors attach equal importance to medicines for other disease treatment, and finally promote rational drug use in clinical practice.

Terminology

Drug metabolism: the process by which the drug is chemically converted in the body to a metabolite, usually through specialized enzymatic systems. Its rate is an important determinant of the duration and intensity of the pharmacological action of drugs. Cytochrome P450: the most important element of oxidative metabolism of a large number of endogenous compounds (e.g., steroids) and xenobiotics (e.g., drugs). CYP is the standard abbreviation for mammalian cytochrome P450. CYP reaction phenotype: the relative contribution of the CYP isoforms to the metabolic pathways. CYP genotyping: the process of determining the CYP genotype of an individual by molecular biology techniques. It can be used to prospectively identify individuals at risk for adverse drug reactions or therapeutic failure due to altered drug metabolism. $AUC_{po(PM)}/AUC_{po(EM)}$: the ratio of parent drug area-under-the concentration *vs*. time curve after oral dosing (AUC_{po}) derived from poor metabolizers (PM) and extensive metabolizers (EM).

Peer reviews

The review by Zhou *et al* summarizes current literature on seven classes of drugs used in the treatment of gastrointestinal diseases with respect to the clearance of these substances. It is highly interesting and may help physicians to choose an equivalent drug or drug combination in clinical practice.

Abstract

AIM: To investigate the anatomic variations in the cystic artery by laparoscopy, and to provide a new classification system for the guidance of laparoscopic surgeons.

METHODS: Six hundred patients treated with laparoscopic cholecystectomy from June 2005 to May 2006 were studied retrospectively. The laparoscope of 30° (Stryker, American) was applied. Anatomic structures of cystic artery and conditions of Calot's triangle under laparoscope were recorded respectively.

RESULTS: Laparoscopy has revealed there are many anatomic variations of the cystic artery that occur frequently. Based on our experience with 600 laparoscopic cholecystectomies, we present a new classification of anatomic variations of the cystic artery, which can be divided into three groups: (1) Calot's triangle type, found in 513 patients (85.5%); (2) outside Calot's triangle, found in 78 patients (13%); (3) compound type, observed in 9 patients (1.5%).

CONCLUSION: Our classification of the anatomic variations of the cystic artery will be useful for decreasing uncontrollable cystic artery hemorrhage, and avoiding extrahepatic bile duct injury.

Key words: Cystic artery; Laparoscopic cholecystectomy; Bile duct injury; Calot's triangle

INTRODUCTION

Since the advent of laparoscopic cholecystectomy in the last two decades, minimally invasive surgery has evolved through advances in videoscopic technology, instrumentation, and surgical techniques[1-14]. Currently, laparoscopic cholecystectomy is widely accepted as the gold standard in the treatment of cholelithiasis[15-18]. This new technique was initially associated with a significant increase in morbidity, and in particular, in iatrogenic biliary injury and arterial hemorrhage[19-30], perhaps due to a lack of knowledge of the laparoscopic anatomy of the gallbladder pedicle. Therefore, the laparoscopic surgeon has to deal with the new anatomical views and must be aware of the possible arterial and biliary variants.

A good knowledge of Calot's triangle is important for conventional and laparoscopic cholecystectomy. Calot's triangle is an important imaginary referent area for biliary surgery. In 1981, Rocko drew attention to possible variations in the region of Calot's triangle bordered by the cystic duct, common hepatic duct, and lower edge of the liver[31]. In 1992, Hugh suggested Calot's triangle should be renamed the hepatobiliary triangle, with the small cystic artery branches supplying the cystic duct being called Calot's arteries[32].

Cystic artery bleeding is a troublesome complication during laparoscopic cholecystectomy, which increases the rate of conversion to open surgery. If surgery is performed incorrectly, injury to the extrahepatic bile duct or intra-abdominal organs is inevitable. The reported incidence of conversion to open surgery because of blood vessel injuries is approximately 0%-1.9% during laparoscopic cholecystectomy[33], and its mortality is about 0.02%[34]. Safe laparoscopic cholecystectomy demands a good knowledge of the anatomy of the cystic artery and its variations.

The cystic artery has many possible origins, with the right hepatic artery being the most common[35]. The anatomy with respect to the cystic artery between laparoscopic cholecystectomy and open cholecystectomy is different. We investigated the appearance of the cystic artery during laparoscopic cholecystectomy, and proposed a new classification system for the cystic artery during laparoscopic cholecystectomy, according to our practical experience.

MATERIALS AND METHODS

Between June 2005 and May 2006, we undertook a retrospective evaluation of 600 non-emergency patients, 232 men and 368 women, who underwent laparoscopic

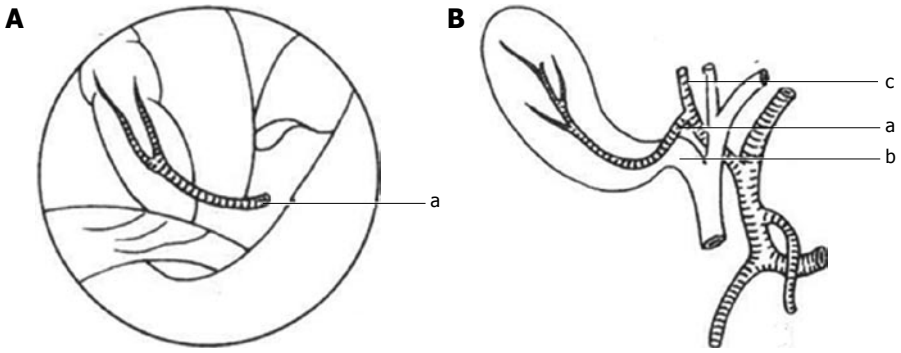

Figure 1 Classical single cystic artery. **A**: Laparoscopic visualization; **B**: Conventional visualization. a: Cystic artery; b: Cystic duct; c: Right hepatic artery.

cholecystectomy for different gallbladder diseases, including 530 with cholecystitis and gallstones, and 70 with gallbladder polyps. All of the patients were examined with ultrasound before surgery.

Laparoscopic cholecystectomy was carried out under general anesthesia using the four ports technique. The information of Calot's triangle and distribution of cystic artery on endoscopic visualization was recorded respectively. A laparoscope (Stryker, USA) at 30° tilt angle was used. The anatomical structures were viewed on a three-dimensional video monitor.

RESULTS

Based on our laparoscopic observations, we classified cystic artery anatomy into three groups.

Group I

Group I represents the Calot's triangle type, in which the cystic artery passes through Calot's triangle. The anatomic location of the cystic artery can be found ahead or behind of the cystic duct, and in hepatoduodenal ligament, under laparoscopic observation. This is the most common type and has been reported in about 80%-96% of cases in previous studies[35,36]. We observed this type in 513 of the 600 patients (85.5%). Group I is further subdivided into two subtypes, as follows.

Classical single cystic artery: The cystic artery originates from the right hepatic artery within Calot's triangle. When approaching the gallbladder, the artery is divided into deep and superficial branches at the neck of the gallbladder. The superficial branch proceeds along the left side of the gallbladder. The deep branch runs through the connective tissues between the gallbladder and liver parenchyma. The deep branch gives rise to tiny branches to supply the gallbladder, which anastomose with the superficial branches. This type of cystic artery is laterally positioned from the cystic duct within Calot's triangle during open cholecystectomy, whereas during laparoscopic cholecystectomy it is just behind and slightly deeper than the cystic duct. According to the literature, this type is found in 70%-80% of cases[32,35]. In our study it was recorded in 440 of 600 patients (73.3%) (Figure 1).

Suzuki *et al* has reported a special example of this type. A single cystic artery originates from the right hepatic artery and then hooks around the cystic duct from behind and reappears at the peritoneal surface near the neck of the gallbladder. They named this the cystic artery syndrome[37]. We did not find any examples of this type in our study.

Double cystic artery: The cystic artery also originates from the right hepatic artery, while it divides into the anterior and posterior branches at their cystic artery origin. Congenital absence of the deep branch signifies the existence of another cystic artery, which is occasionally detected by subsequent bleeding control. The posterior cystic artery is very delicate in some cases and is often cut by electrocoagulation during dissection. A double cystic artery has previously been found in 15%-25% of patients[32]. During our laparoscopic cholecystectomy we recorded 73 patients (12.2%) with double cystic artery (Figure 2).

Group II

Cystic artery approaches the gallbladder outside Calot's triangle and cannot be observed within the triangle by

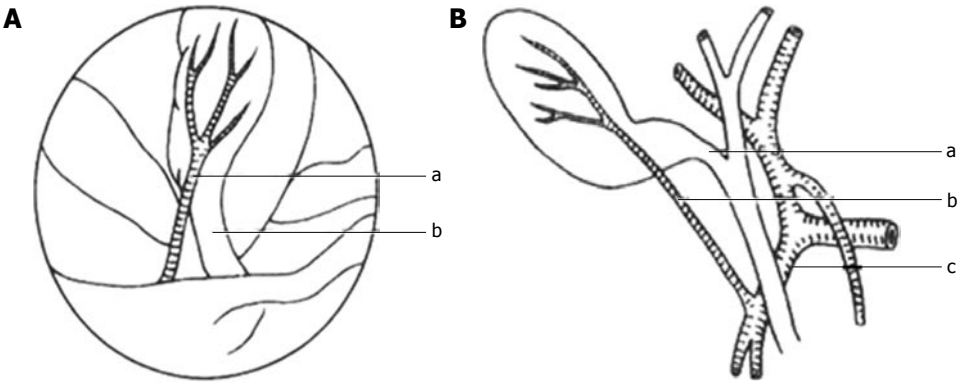

Figure 3 Cystic artery originating from gastroduodenal artery. **A**: Laparoscopic visualization; **B**: Conventional visualization. a: Cystic artery; b: Cystic duct; c: Gastroduodenal artery.

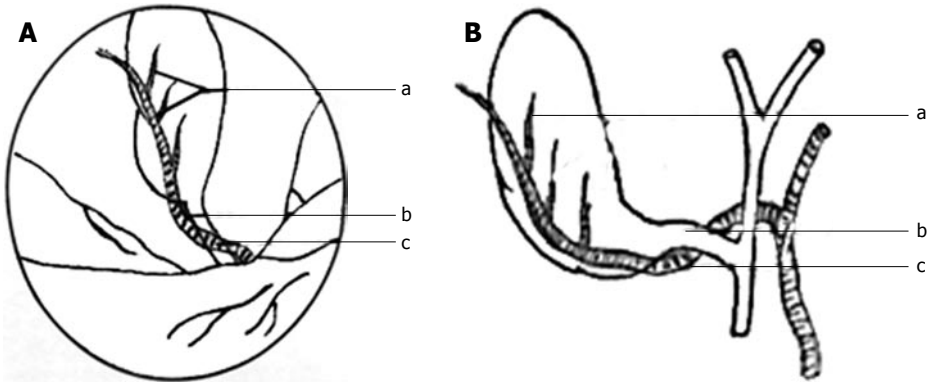

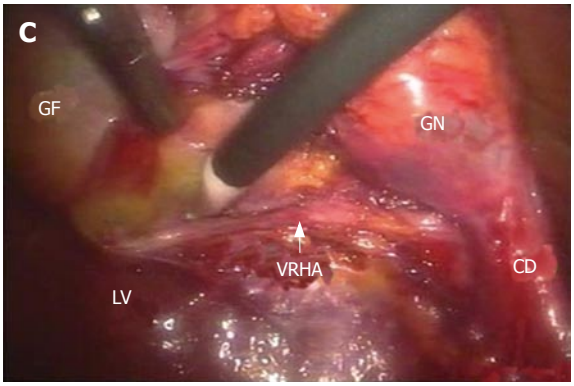

Figure 4 Cystic artery originating from variant right hepatic artery. **A**: Laparoscopic visualization; **B**: Conventional visualization; **C**: Video in operation. a: Cystic artery; b: Cystic duct; c: Variant right hepatic artery; GF: Fundus of gallbladder; CD: Cystic duct; GN: Neck of gallbladder; LV: Liver; VRHA: Variant right hepatic artery.

laparoscopy during dissection. We found 78 patients (13%) in group II during laparoscopic cholecystectomy. This group includes the following four subgroups.

Cystic artery originating from gastroduodenal artery: This type of cystic artery is also called low-lying cystic artery, which does not pass through Calot's triangle but approaches the gallbladder beyond it. In conventional open cholecystectomy it is seen as inferior to the cystic duct, while it usually localizes superficially and anterior to the cystic duct from a laparoscopic viewpoint. Its terminal segment as it approaches the gallbladder is important for laparoscopic surgeons. Because it not only must be manipulated at first, but it is also susceptible to injury and hemorrhage during dissection of the peritoneal folds that connect the hepatoduodenal ligament to Hartman's pouch of the gallbladder or to the cystic duct. This anatomic variation was found in 45 patients (7.5%) in our study (Figure 3).

Cystic artery originating from the variant right hepatic artery: Anatomic variation of the right hepatic artery usually originates from the superior mesenteric artery or aorta[32,38]. It enters Calot's triangle behind the portal vein, and runs parallel to the cystic duct on its passage through the triangle. It can be completely covered by the cystic duct of the gallbladder[32]. We found a very interesting type of right hepatic artery variant. This artery has a long course, approaching the gallbladder deep at its neck, and then passing between the gallbladder and liver parenchyma, extending along the deep right side of the gallbladder, and finally entering the liver parenchyma near the right-lateral side of the gallbladder fundus. It yields multiple small branches to supply the gallbladder at its body, and it is often completely covered by the gallbladder. We should be cautious of this right hepatic artery variation. From the laparoscopic viewpoint it looks like a single large artery. This anatomic variation was found in 18 patients (3%) in our study (Figure 4).

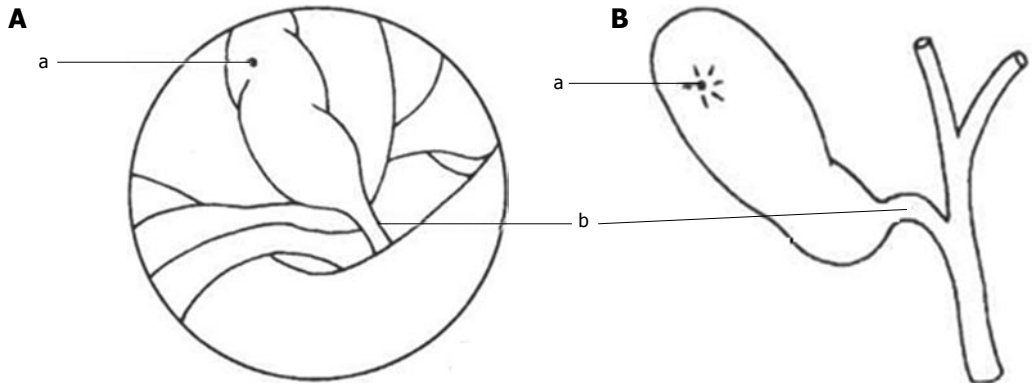

Figure 5 Cystic artery arising from hepatic parenchyma. **A**: Laparoscopic visualization; **B**: Conventional visualization. a: Cystic artery; b: Cystic duct.

Variant right hepatic artery has been shown to have a prevalence of approximate 4%-15%[37,39].

Cystic artery originating directly from the liver parenchyma: This cystic artery pierces the hepatic parenchyma approaching the bladder from the gallbladder bed. It usually situates in the right lateral of the border of gallbladder body and bottom. However, a few are situated in the center of the gallbladder bed or situated left lateral of gallbladder bottom. No other arteries are found within Calot's triangle. This anatomic variation of the cystic artery is not observed until bleeding and is caused by dissection of the gallbladder fundus. It is difficult to explore and requires careful dissection. We found it in 15 patients (2.5%) (Figure 5).

Cystic artery originating from the left hepatic artery: The cystic artery occasionally originates from the left hepatic artery, passes through the liver parenchyma, and reaches the middle of the gallbladder body, at which point it bifurcates into ascending and descending branches. This has a prevalence of 1%[39]. However, we did not find this type of variant cystic artery.

Group Ⅲ

This group has more than one blood supply. We named it the compound cystic artery type. The cystic arteries exist not only in Calot's triangle, but also outside it. We found that nine patients (1.5%) belonged to this group. Five of these patients (0.8%) had a normal single cystic artery in Calot's triangle, and an artery extending along the cystic duct but posterior to it, and some small arteries that passed immediately from the liver parenchyma to the gallbladder. Three of the nine patients (0.5%) had another cystic artery superficial to the cystic duct in addition to the normal cystic artery. Finally, one patient (0.17%) had multiple cystic arteries, including the double cystic artery in Calot's triangle, and one of the arteries crossed anterior to the common bile duct, while another was situated on the right side of the border of the gallbladder body and fundus.

DISCUSSION

Anatomic variations in and around Calot's triangle are frequent (biliary tree, cystic artery)[40,41], and we found them in 20%-50% of patients. Therefore, careful blunt dissection of Calot's triangle is necessary for both conventional and laparoscopic cholecystectomy.

Since the introduction of laparoscopic gallbladder surgery, surgeons have been very interested in gallbladder vascularization. A great number of papers on this issue have been published[36,42-44], although some vagueness still exists, because of the diversity of data and classification. There have been relatively few reports on the laparoscopic anatomy of the hepatobiliary triangle, especially of the cystic artery.

It is important for every laparoscopic surgeon to be familiar with the anatomic variations in the extrahepatic biliary tree and those of the arterial supply of the gallbladder. The possible anatomic position and variations of the cystic artery are difficult to establish before surgery. They were only identified during disconnection of Calot's triangle and the gallbladder. The laparoscopic anatomy of the cystic artery can be considered as a precondition for performing safe laparoscopic procedures. The variations of cystic artery often make surgeons recognize an error, causing them to abscise incorrectly and, subsequently, leading to a hemorrhage. When hemorrhage cannot be controlled, conversion to open cholecystectomy is inevitable.

The position of the cystic artery appears differently during laparoscopic and conventional cholecystectomy for the following reasons. (1) Under laparoscopy, as the gallbladder fundus is pulled, the liver is moved upward, thereby opening the subhepatic space. (2) By pulling Hartman's pouch downward, the anterior aspect of Calot's triangle is presented. On the contrary, by pulling Hartman's pouch upward, the posterior aspect of Calot's triangle is clearly exposed. (3) Better transparency and visualization under laparoscopy facilitates recognition of cystic artery variation by the surgeon.

Previous studies have contained fewer reports on the laparoscopic classification of the cystic artery. Some have divided the cystic artery into low-lying cystic artery and cystic artery originating from variant right hepatic artery. Balija classified cystic artery variations into two groups. Group I comprises five variations of the cystic artery within the hepatobiliary triangle: (a) normal position; (b) frontal cystic artery; (c) backside; (d) multiple; and (e) short cystic artery that arises from an aberrant right hepatic artery. Group Ⅱ consists of variations of the cystic artery that approaches the gallbladder beyond the hepatobiliary

triangle: (a) low-lying; (b) transhepatic; and (c) recurrent cystic artery[36]. Ignjatovic has divided the cystic artery into three types in minimally invasive surgical procedures: type 1 shows normal anatomy; type 2 more than one artery in Calot's triangle; and type 3 no artery in Calot's triangle[45]. However, none of the above classifications satisfies the practical needs of laparoscopic surgery. Based on our experience, the anatomic variations of the cystic artery can be classified into three groups. Group I showed the cystic artery passing within Calot's triangle. It included two types: (1) single cystic artery, found in 440 patients (73.3%); and (2) double cystic artery, observed in 73 patients (12.2%). Group Ⅱ showed the cystic artery situated outside Calot's triangle. This group included four variations: (1) cystic artery originating from the gastroduodenal artery, found in 45 patients (7.5%); (2) cystic artery originating from the variant right hepatic artery, found in 18 patients (3%); (3) cystic artery directly arising from the liver parenchyma, observed in 15 patients (2.5%); and (4) cystic artery originating from the left hepatic artery. Group Ⅲ had a compound appearance, with the variant cystic artery situated not only within Calot's triangle, but also outside it. This classification of cystic artery can help surgeons understand the cystic artery more thoroughly, and may be more practical to use in real operations.

Variations in the cystic artery are miscellaneous, and we must be cautious during the performance of laparoscopic cholecystectomy. Our laparoscopic classification of the cystic artery is very useful for dissection of Calot's triangle, reduces uncontrollable cystic artery hemorrhage, and may be advantageous for avoiding extrahepatic bile duct injury.

COMMENTS

Background

Uncontrolled bleeding from the cystic artery and its branches is a serious problem that may increase the risk of intraoperative injury to vital vascular and biliary structures. Anatomic variations of the cystic artery are frequent and can differ in origin, position and number. We investigated 600 cases treated with laparoscopic cholecystectomy and analyzed the anatomic structure of the cystic arteries under laparoscopic observation. The cystic artery variations were classified into three groups: (1) Calot's triangle, (2) outside Calot's triangle, and (3) compound type. These will be helpful to laparoscopic surgeons.

Research frontiers

Laparoscopic cholecystectomy is widely accepted as the gold standard in the treatment of gallstone disease. However, the incidence of bile duct injury caused by this procedure is more than that caused by conventional cholecystectomy. The main areas of research in laparoscopic cholecystectomy are as follows: (1) biliary injury during laparoscopic cholecystectomy; (2) anatomic characteristics of the cystic artery; (3) intraoperative bleeding during laparoscopic cholecystectomy; (4) cholecystectomy techniques.

Innovations and breakthroughs

There are few reports concerning classification of the cystic artery during laparoscopic cholecystectomy. Some authors have classified it into two groups: Group Ⅰ comprises variations of the cystic artery within the hepatobiliary triangle; and Group Ⅱ comprises variations of the cystic artery that approach the gallbladder beyond the hepatobiliary triangle. Other authors have divided cystic artery variations into three types: type 1, normal anatomy; type 2, more than one artery in Calot's triangle; and type 3, no artery in Calot's triangle. We present a new classification of cystic artery variations based on three groups. Group I shows the cystic artery passing within the Calot's triangle. This includes two types: (1) single cystic artery, and (2) double cystic artery. Group Ⅱ shows the cystic artery situated outside Calot's triangle. This group includes four variations: (1) cystic artery originating from the gastroduodenal artery; (2) cystic artery originating from the variant right hepatic artery; (3) cystic artery arising directly from the liver parenchyma; (4) cystic artery originating from the left hepatic artery. Group Ⅲ shows the cystic artery is compound in nature; the variant cystic artery was situated not only within Calot's triangle, but also outside it. Furthermore, we found a new variant right hepatic artery (Figure 4), which has not been reported before.

Peer review

The authors introduce a new classification of cystic artery variations during laparoscopic cholecystectomy. Their system is different from those reported previously. The new system divides the anatomic variations of the cystic artery into three groups according to the position of the cystic artery relative to Calot's triangle, as seen by laparoscopy. The classification system should be useful to laparoscopic surgeons, and help reduce incidences of bile duct injury and intraoperative bleeding during laparoscopic cholecystectomy.

Abstract

AIM: To ascertain whether constitutive androstane receptor (CAR) activation by 1,4-bis-[2-(3,5,-dichloropyridyloxy)] benzene (TCPOBOP) modulates steatohepatitis in the methionine choline-deficient (MCD) diet-fed animal.

METHODS: C57/BL6 wild-type mice were fed the MCD or standard diet for 2 wk and were treated with either the CAR agonist, TCPOBOP, or the CAR inverse agonist, androstanol.

RESULTS: Expression of CYP2B10 and CYP3A11, known CAR target genes, increased 30-fold and 45-fold, respectively, in TCPOBOP-treated mice fed the MCD diet. TCPOBOP treatment reduced hepatic steatosis (44.6 ± 5.4% *vs* 30.4 ± 4.5%, $P < 0.05$) and serum triglyceride levels (48 ± 8 *vs* 20 ± 1 mg/dL, $P < 0.05$) in MCD diet-fed mice as compared with the standard diet-fed mice. This reduction in hepatic steatosis was accompanied by an increase in enzymes involved in fatty acid microsomal ω-oxidation and peroxisomal β-oxidation, namely CYP4A10, LPBE, and 3-ketoacyl-CoA thiolase. The reduction in steatosis was also accompanied by a reduction in liver cell apoptosis and inflammation. In contrast, androstanol was without effect on any of the above parameters.

CONCLUSION: CAR activation stimulates induction of genes involved in fatty acid oxidation, and ameliorates hepatic steatosis, apoptosis and inflammation.

Key words: Apoptosis; CYP4A; Fatty acid oxidation; Inflammation

INTRODUCTION

Hepatic steatosis or fatty infiltration of the liver has reached epidemic proportions in Western Society. Approximately 30 million adults in the United States have hepatic steatosis, and a subset of these individuals will develop accompanying hepatic inflammation referred to as steatohepatitis[1]. If the steatohepatitis is not associated with significant alcohol intake, it is commonly referred to as nonalcoholic steatohepatitis (NASH). Unfortunately, NASH can progress to cirrhosis and chronic liver failure with considerable morbidity and mortality[2]. Treatment options for NASH are limited and, therefore, there is an unmet need for the pharmacologic treatment of this liver disease.

Although the precise etiopathogenesis of NASH remains to be defined, it is a disease due to perturbations of intermediary fat metabolism. In hepatic steatosis, an excess of non-esterified fatty acids are released from peripheral tissues into the serum[3]. These excess serum-free fatty acids are cleared by the liver where they are esterified and accumulate as neutral fat. The formation of neutral fat is presumably due to a limited capacity to oxidize excess fatty acids. Mechanisms to enhance hepatic fatty acid oxidation are, therefore, a potential strategy to protect the liver from hepatic steatosis. Hepatic fatty acid oxidation occurs by three pathways[4]. β-oxidation is a predominant pathway, which occurs in the mitochondria, and is rate-regulated by carnitine palmitoyltransferase (CPT1) and the mitochondrial trifunctional protein (MPT) complex. Peroxisomal β-oxidation oxidation occurs within peroxisomes and is rate-limited by the peroxisomal L-bifunctional enzyme (L-PBE), acetyl-COA oxidase (ACO), and urate oxidase (UO). The third

pathway is ω-oxidation which occurs in the endoplasmic reticulum. This pathway is dependent upon expression of the cytochrome enzymes CYP4A10 and CYP4A14. Stimulation of these pathways either individually or collectively could help remove excess free fatty acids from the liver and attenuate NASH.

Nuclear receptors are a family of transcription factors, which regulate metabolism of endo- and xenobiotic compounds[5]. In particular, the constitutive androstane receptor (CAR), which is highly expressed in the liver, is a biosensor for endo- and xenobiotic compounds, such as toxic bile acids[6-8] and steroids[9]. CAR mediates the induction of detoxifying enzymes by the widely used antiepileptic drug phenobarbital in humans and by the potent synthetic inducer, 1,4-bis-[2-(3,5,-dichloropyridyloxy)] benzene (TCPOBOP) in mice. Once stimulated, CAR increases expression of *CYP2B* genes in the mouse[7,8,10] and human[11]. From a teleological perspective, this nuclear receptor can be viewed as a general hepatoprotective response system, as it detoxifies potentially injurious endo- and xenobiotics. In addition, it serves as a hepatic mitogen and as an anti-apoptotic agent by increasing transcriptional expression of the anti-apoptotic protein, Mcl-1[12,13]. These composite effects eliminate toxins, enlarge the liver[14], and render it resistant to liver injury-all hepatoprotective responses. Whether CAR also protects the liver from injurious endobiotics, such as free fatty acids, is less clear but a viable concept.

Based on the above concepts, we postulated that CAR would protect the liver from the development of steatohepatitis by enhancing processes involved in fatty acid oxidation. Thus, the overall objective of the current study was to ascertain whether CAR activation by TCPOBOP modulates steatohepatitis induced by the methionine choline-deficient diet, a well known murine model of NASH[15]. Two fundamental questions were formulated. In TCPOBOP-treated MCD diet-fed mice: (1) Does CAR activation modify steatosis, and if so, does it alter expression of genes involved in fatty acid oxidation? and (2) does CAR alter apoptosis and inflammation in this model of NASH? The results indicate that CAR activation can stimulate an induction of genes involved in fatty acid oxidation, ameliorating hepatic steatosis, apoptosis and inflammation. These observations suggest CAR stimulation renders the liver resistant to MCD diet-mediated steatohepatitis. An understanding of these mechanisms may allow the development of CAR agonists as therapeutic strategies for NASH.

MATERIALS AND METHODS

Animal models

The care and use of the animals for this study were reviewed and approved by the Institutional Animal Care and Use Committee (IACUC). C57/BL wild-type mice (Jackson laboratories, Bar Harbor, ME), weighing 20-25 g, were fed a methionine choline-deficient (MCD) diet (Harland Tech Lad, Madison, WI) for 2, 3 or 4 wk. This diet rapidly induces steatosis and steatohepatitis in rodents[16]. The mice were maintained in a temperature-controlled, pathogen-free environment and fed a standard rodent chow diet and water ad libitum. To assess the effect of CAR modulation, mice were intraperitoneally (ip) injected with either vehicle (corn oil), 1,4-bis [2-(3,5-dichloropyridyloxy)] benzene (TCPOBOP) (Sigma-Aldrich, St Louis, MO) (3 g/kg) daily for the first 3 d[7] at the starting of the MCD diet, or 5β-androstan-3β-ol (androstanol) (a CAR inverse agonist) (Steraloids, Newport, RI) (100 mg/kg) daily for 3 d at the starting of weeks one and two of the MCD diet (total of 6 injections). Androstanol was used as negative control for CAR target genes. At selected times, the animals were anesthetized with ether, and a hepatectomy was performed prior to euthanasia *via* exsanguination. Blood was drawn *via* the portal vein to examine triglyceride levels. Liver tissue sections were placed in fixative for subsequent microscopic analyses. Liver sections were also subjected to RNA extraction using the Trizol Reagent (Invitrogen, Carlsbad, CA).

Oil red O staining and fat quantification

Liver sections were cut into a thickness of 20 μm in a cryostat, air dried, and then stained with oil red O as per standard techniques[17]. Slides were then viewed under microscopy (Axioplan 2, Carl Zeiss, Inc. Oberkochen, Germany). Digital pictures were captured to quantitate percent fat (red color in area/field area × 100) of digital photomicrographs as described previously[18].

Histology, TUNEL assay and immunohistochemical identification of activated caspases 3/7

Histology, TUNEL assay, and immunohistochemical analysis for activated caspases 3/7 was performed as previously described by us[18]. To accurately quantitate TUNEL-positive and caspase 3/7-positive cells, slides were examined by digital image analysis to quantitate the percent fluorescence/field area of digital photomicrographs as described previously[13].

Measurement of Leukotriene B4

LTB4 was quantitated using a specific ELISA kit (R&D systems) according to the manufacturer's instructions[19].

Immunohistochemistry for CD68

Unstained slides of liver tissue specimens were deparaffinized and hydrated. Antigen retrieval was performed using EDTA (1 mmol/L, pH 8.0). Slides were placed in a vegetable steamer for 40 min at 97℃, followed by a cooling for 2 min. Thereafter, the catalyzed signal amplification system (DAKO, Carpinteria, CA) was used according to manufacturer's instructions. CD68 immunostaining was performed as previously described by us[20].

Real time-polymerase chain reaction (RT-PCR)

Total RNA was obtained from whole liver as previously described by us[21]. After the reverse transcription reaction, the cDNA template was amplified by PCR with Taq polymerase (Invitrogen) and mRNA was quantitated for acetyl-CoA oxidase (ACO), carnitine palmitoyltransferase (CPT1); peroxisomal 3-ketoacyl-CoA thiolase (ketoacyl thiolase), L-peroxisomal bifunctional enzyme (L-PBE), mitochondrial trifunctional protein (MTP) subunits alpha

ACO: Acetyl-CoA oxidase; CPT1: Carnitine palmitoyltransferase; Ketoacyl thiolase: Peroxisomal 3-ketoacyl-CoA thiolase; L-PBE: L-peroxisomal bifunctional enzyme; MTP: Mitochondrial trifunctional protein subunits alpha and beta; PPAR-α: Peroxisome proliferators-activated receptor-alpha.

and bet, peroxisome proliferators-activated receptor-alpha (PPAR-α) as previously described[22]. Primers used are listed in Table 1. 18S primers (Ambion, Austin TX) were used as a control for RNA isolation and integrity. All PCR products were confirmed by gel electrophoresis. Real-time PCR was performed using the LightCycler (Roche Diagnostics, Mannheim, Germany) and SYBR green as the fluorophore (Molecular probes). The results were expressed as a ratio of product copies per milliliter to copies per milliliter of housekeeping gene 18S from the same RNA (respective cDNA) sample and PCR run.

Statistical analysis

All data represent at least three independent experiments and are expressed as mean ± SE of the mean. Differences between groups were compared using Student *t*-tests and one-way analysis of variance with post hoc Dunnett test was used for multiple comparisons. $P < 0.05$ was considered statistically significant.

RESULTS

Stimulating CAR target genes in the MCD diet-fed mouse by TCPOBOP

CYP2B10 and CYP3A11 have been identified as CAR target genes[10,23,24]. Therefore, to determine if TCPOBOP activates CAR in the MCD diet-fed mouse, expression of these genes was examined. When TCPOBOP treatment was administered to the MCD diet-fed mice, expressions of both CYP2B10 and CYP3A11 increased (Figure 1A and B). We also observed 45-fold and 30-fold elevations in CYP2B10 mRNA level in TCPOBOP-treated standard

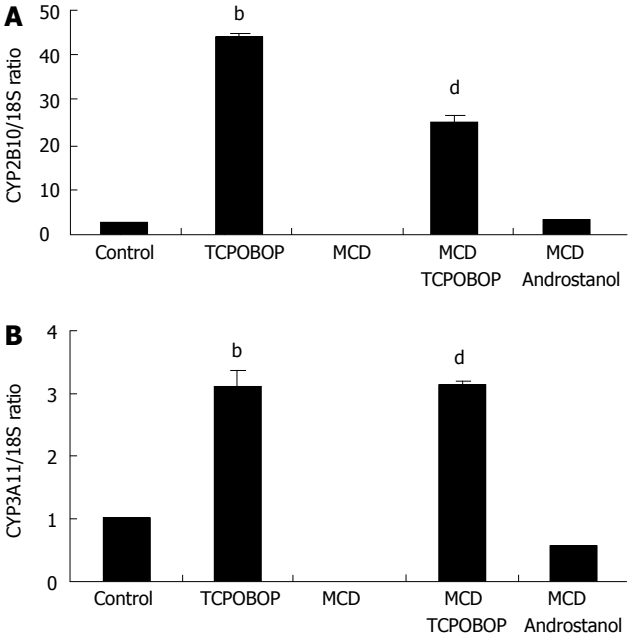

Figure 1 Over-expression of CAR target genes in MCD diet-fed mice treated with TCPOBOP. CAR activation was assessed by measuring CYP2B10 and CYP3A11 (CAR target genes) expression in whole liver from vehicle-treated and TCPOBOP-treated chow-fed and MCD diet-fed mice. Expression was measured by real-time PCR and normalized as a ratio using 18S mRNA as housekeeping genes. A value of 1 for this ratio was arbitrarily assigned to the data obtained from vehicle-treated $CAR^{+/+}$ mice. (**A**) CYP2B10 and (**B**) CYP3A11 mRNA expressions were increased in TCPOBOP-treated (3 mg/kg ip for 3 d) chow-fed mice ($^bP < 0.01$ for CYP2B10 and CYP3A11 compared to control) and MCD diet-fed mice ($^dP < 0.01$ for CYP2B10 and CYP3A11 compared to untreated). This phenomenon was abated by treatment with a CAR inhibitor androstanol (100 mg/kg ip) daily for 3 d at the starting of weeks one and two of the MCD diet (total of 6 injections), ($n = 5$ in each group).

diet-fed mice and MCD diet-fed mice, respectively. CYP3A11 mRNA levels were also similarly increased in TCPOBOP-treated animals. Administration of the CAR inverse agonist, androstanol[10,25], did not alter expression of these gene products (Figure 1A and B). Androstanol was, therefore, used as a negative control for CAR target genes in this model, as it blocks basal activity of CAR[26]. Unexpectedly, CYP2B10 and CYP3A11 mRNA levels remained elevated for 2 wk after initial TCPOBOP administration, mRNA expression of these target enzymes began to decrease by week three (down to 7-fold elevation) and further decreased by week four (down to 6-fold elevation) (data not shown). This data illustrates that TCPOBOP is a potent CAR agonist in the fatty liver and its effects are long-lasting after initial treatment.

Effects of TCPOBOP on hepatic and serum lipid content in MCD diet-fed mice

Animals treated with TCPOBOP and fed the MCD diet for 2 wk had 25% less hepatic steatosis than animals fed the MCD diet alone (Figure 2A). Interestingly, MCD diet-fed animals treated with androstanol had 15% more hepatic steatosis per surface area than untreated MCD diet-fed littermates. Of note, the fat pattern observed in the androstanol-MCD group was homogenously macrovesicular, where in untreated MCD diet-fed animals, the steatosis pattern was heterogeneous with both

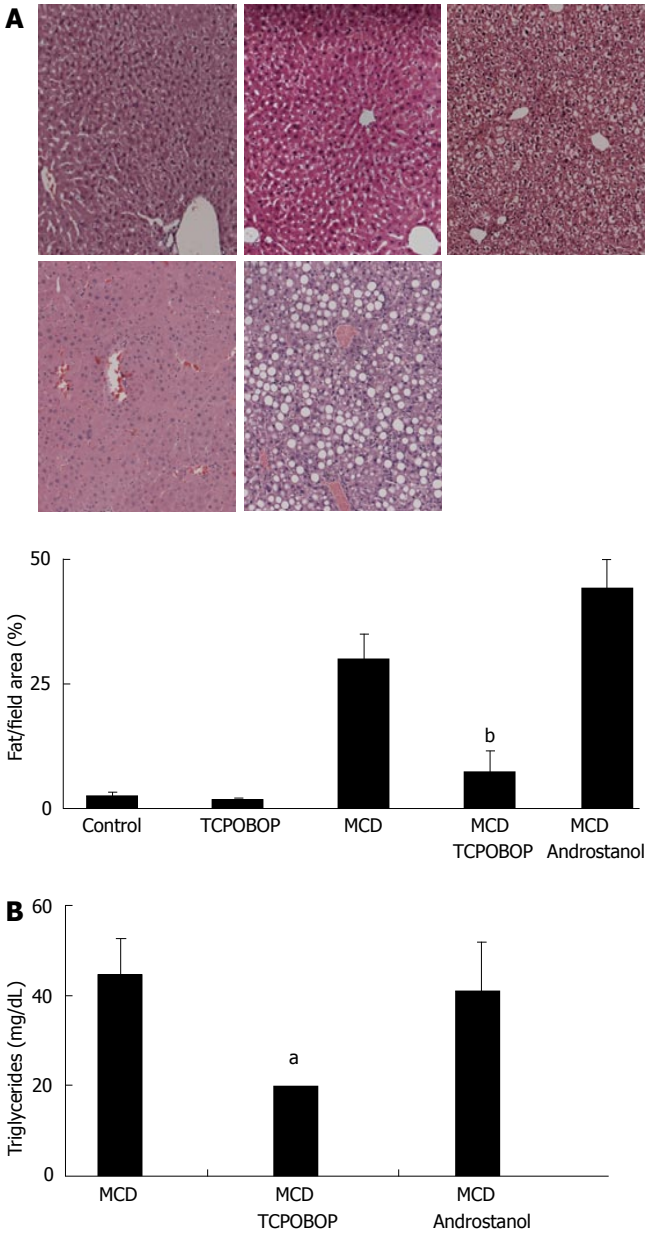

Figure 2 Hepatic and serum fat content reduced by TCPOBOP treatment in the MCD diet-fed mice. (**A**) Top panel, from left to right: Fixed liver specimens from vehicle-treated chow-fed mice, TCPOBOP-treated (3 mg/kg ip for 3 d) chow-fed mice, vehicle-treated (corn oil) MCD diet-fed diet mice for 2 wk, TCPOBOP-treated MCD diet-fed mice for 2 wk; CAR inhibitor, androstanol-treated MCD diet-fed mice for 2 wk were stained by conventional H&E. Lower panel: Quantitation of hepatic fat content by Oil red O staining. Note the marked reduction of hepatic fat in the TCPOBOP-treated MCD diet-fed mice (^{b}P = 0.001); (**B**) Serum triglyceride levels from mice fed the MCD diet for 2 wk with either TCPOBOP or androstanol treatment. Treatment with TCPOBOP reduced serum triglyceride levels by half (^{a}P = 0.03).

microvesicular and macrovesicular steatosis. Administration of TCPOBOP to the MCD diet-fed animals also markedly lowered serum triglyceride levels by 2-fold (Figure 2B). As expected, treatment with androstanol did not alter serum triglyceride levels. Collectively, these data demonstrate that TCPOBOP treatment decreased hepatic fat accumulation and improved serum triglyceride levels.

Modulation of hepatic expression of genes involved in fatty acid oxidation by TCPOBOP

The reduction in hepatic steatosis was consistent with stimulation of fatty acid oxidation by TCPOBOP. Therefore, we evaluated the effect of TCPOBOP on expression of several target genes involved in fatty acid oxidation (Table 2). In the liver, microsomal, mitochondrial and peroxisomal fatty acid oxidation systems are regulated by PPAR-α. PPAR-α mRNA expression levels were not altered by treatment with TCPOBOP in the MCD diet-fed animal (data not shown). However, CYP4A10 and CYP4A14, target enzymes for PPAR-α involved in the microsomal ω-oxidation system, were altered by TCPOBOP administration (Table 2). CYP4a10 mRNA expression was increased 4-fold ($P < 0.001$), while, CYP4A14 mRNA expression was actually decreased by TCPOBOP treatment ($P < 0.01$). L-PBE and peroxisomal 3-ketoacyl-CoA thiolase (ketoacyl thiolase), genes involved in peroxisomal β-oxidation were also significantly modified by TCPOBOP. mRNA expression was increased 6-fold for L-PBE, ($P < 0.001$) and 2-fold for ketoacyl thiolase ($P < 0.05$), when compared to MCD diet-fed untreated animals (Table 2). Two key genes involved in mitochondrial β-oxidation, carnitine palmitoyltransferase (CPT1) and mitochondrial trifunctional protein (MTP), showed no significant difference between TCPOBOP-treated and -untreated MCD diet-fed mice. These data demonstrated a PPAR-α-like effect on microsomal ω-oxidation and peroxisomal β-oxidation by TCPOBOP, which may confer protection against steatosis in the MCD diet-fed animal.

Table 2 Effect of TCPOBOP on genes involved in fatty acid oxidation

Type of fatty acid oxidation	Gene	MCD	MCD-TCPOBOP[a]	Fold-change	*P* value
ω-oxidation	CYP4A10	1.40 ± 1.69	6.07 ± 1.73	4.3	0.001
(ER)	CYP4A14	0.81 ± 0.04	0.07 ± 0.02	-11.6	0.008
β-oxidation	L-PBE	0.07 ± 0.01	0.39 ± 0.01	5.6	0.0004
(peroxisome)	Ketoacyl thiolase	0.12 ± 0.03	0.28 ± 0.06	2.3	0.04
	ACO	0.25 ± 0.14	0.32 ± 0.08	1.3	NS
	Urate oxidase	0.29 ± 0.02	0.16 ± 0.02	-1.8	NS
β-oxidation	CPT1	0.79 ± 0.21	0.77 ± 0.19	-1.0	NS
(mitochondria)	MTP-α	0.60 ± 0.30	0.88 ± 0.71	1.5	NS
	MTP-β	0.50 ± 0.40	0.59 ± 0.07	1.2	NS

Values are expressed as mRNA expression/18S ratio ± SD. [a]Animals fed methionine choline-deficient (MCD) diet for 2 wk and pre-treated with the CAR agonist, TCPOBOP (3 mg/kg ip for 3 d at starting of diet). NS: Not significant; ER: Endoplasmic reticulum; L-PBE: L-peroxisomal bifunctional enzyme; ACO; Acetyl-CoA oxidase; Ketoacyl thiolase: Peroxisomal 3-ketoacyl-CoA thiolase; CPT1: Carnitine palmitoyltransferase; MTP: Mitochondrial trifunctional protein subunits alpha and beta.

Alteration of apoptosis and inflammation in the MCD diet-fed animals by TCPOBOP treatment

Although TCPOBOP reduced hepatic steatosis, this reduction may or may not be sufficient to attenuate liver inflammation. Therefore, we assessed the effect of TCPOBOP on hepatocyte apoptosis and its effect on inflammation by quantitating macrophage/Kupffer cell numbers. Apoptosis was assessed by quantitating TUNEL- and caspase 3/7-positive cells. TUNEL- and caspase 3/7-positive cells were reduced in TCPOBOP-treated MCD diet-fed mice; this reduction of apoptosis was not observed with androstanol treatment (Figure 3A and B). Hepatic inflammation was assessed by

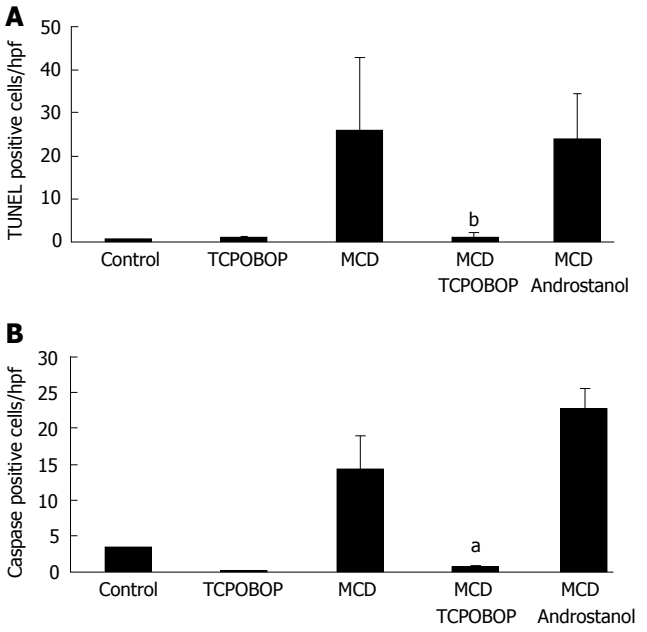

Figure 3 Hepatocyte apoptosis is attenuated by TCPOBOP in the MCD-diet fed animal. (**A** and **B**) Fixed liver specimens were analyzed by TUNEL and immunofluorescence for active caspase 3/7 to identify apoptotic liver cells. The percent/field area of TUNEL- (^bP = 0.01) and active caspase 3/7-positive cells (^aP = 0.03) were significantly higher in vehicle-treated MCD diet-fed mice than TCPOBOP-treated (3 mg/kg ip for 3d) MCD diet-fed mice (n = 5 in each group).

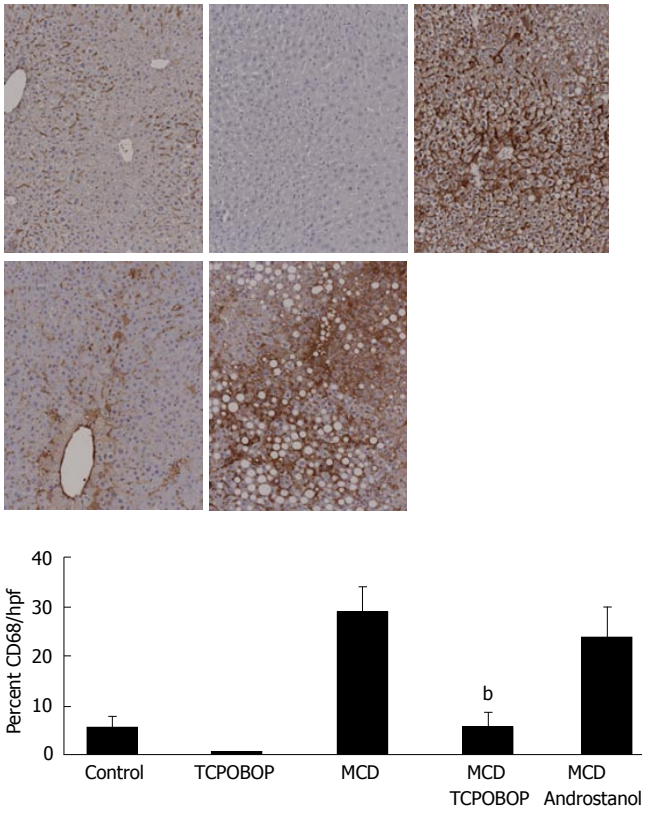

Figure 4 Hepatic inflammation attenuated by TCPOBOP treatment in the MCD diet-fed mice. Top panel: Representative photomicrographs of immunohistochemistry for CD68, a marker of Kupffer cells; Lower panel: The percentage of CD68-positive areas in the liver sections was quantitated using digital image analysis. Immunoreactivity for CD68 was significantly reduced in TCPOBOP-treated MCD diet-fed mice as compared with vehicle- and androstanol-treated mice (^bP = 0.002) (n = 5 in each group).

immunohistochemical staining for CD68, a marker for macrophage/Kupffer cells[27] (Figure 4). CD68-positive cells were less abundant in the MCD diet-fed mice treated with TCPOBOP as compared with the untreated mice on MCD diet; androstanol treatment did not reduce the number of CD68 immunoreactive cells. Consistent with these findings, leukotriene B4 (LTB4), a potent chemotactic agent that initiates, sustains and amplifies the inflammatory response, was also reduced in TCPOBOP-treated MCD diet-fed animals (55.6 ± 2.8 pg/mL) as compared to untreated MCD diet-fed mice (266.9 ± 12.1 pg/mL) (P = 0.001). These results suggest that TCPOBOP pre-treatment abrogates apoptosis and inflammation induced by the MCD diet.

DISCUSSION

The principle findings of this study relate to the effect of CAR modulation of steatohepatitis. The observations suggest TCPOBOP stimulation of CAR in the MCD diet-fed mice model of NASH: (1) reduces hepatic steatosis; (2) increases expression of genes involved in microsomal ω-oxidation and peroxisomal β-oxidation pathways; (3) and reduces hepatic inflammation.

We utilized the MCD animal model of steatosis for this study. The MCD diet stimulates steatosis by inhibition of fatty acid oxidation[15]. This animal model of hepatic steatosis is unique in that mice fed the MCD diet develop inflammation, thereby mimicking human NASH. Recently, peroxisome proliferator-activated receptor α (PPAR-α) agonists have been shown to be useful in ameliorating steatohepatitis induced by the MCD diet in mice by increasing genes involved in fatty acid oxidation[28,29]. PPAR-α is a transcription factor belonging to the nuclear receptor superfamily (NRSF) that increases hepatic uptake and breakdown of fatty acids by up-regulating genes involved in peroxisomal and mitochondrial β-oxidation and microsomal ω-oxidation[5]. In our current study, TCPOBOP administration demonstrated a PPAR-α-like effect on fatty acid microsomal ω-oxidation and peroxisomal β-oxidation enzymes, by increasing expression of CYP4A10, L-PBE and 3-ketoacyl-CoA thiolase. Our observations are consistent with findings from other studies in which protection from hepatic steatosis was afforded by changes in fatty acid microsomal ω-oxidation and peroxisomal β-oxidation without alteration of genes involved in the mitochondrial β-oxidation pathway[30]. These results indicate that upregulation of peroxisomal and microsomal enzymes was primarily responsible for the CAR-dependent reduction in hepatic steatosis.

Our data indicated that CAR activation by TCPOBOP had a PPAR-α-like effect on enhancing expression of genes involved in fatty acid oxidation. How CAR activation mimics PPAR-α activation is unclear, but suggests a potential interaction between the two nuclear receptors. CAR binds to its cognate DNA motif as a heterodimer with the retinoid X receptor (RXR), which serves as a common heterodimerization partner for other nuclear receptors in the superfamily, such as PPAR-α, pregnane X receptor (PXR), liver X receptor (LXR), and farnesol

X receptor (FXR)[31]. Although evidence exists for cross-talk between nuclear receptors of this superfamily[32,33], it is unknown if there is a direct link between CAR and PPAR-α activation. CAR could potentially bind to PPAR-α/RXR heterodimer, as LXR has been shown to bind directly to the PPAR-α/RXR complex[34]. This may afford CAR's ability to enhance expression of PPAR-α target genes involved in fatty acid oxidation. CAR has been shown to increase expression of gene targets otherwise thought to be regulated by other nuclear receptors. Recent experiments have illustrated CAR's ability to activate CYP3A, normally thought as the target of PXR[35]. Further studies are necessary to define the nature of the potential cross-talk between CAR and PPAR-α.

Apoptosis of markedly steatotic hepatocytes may incite the inflammatory response in NASH[36]. Apoptotic markers were reduced in TCPOBOP-treated MCD diet-fed animals in the present study. Indeed, previous work by us[13] has demonstrated CAR to have anti-apoptotic properties. In these studies, CAR activation by TCPOBOP depleted hepatocytes of the pro-apoptotic proteins Bak and Bax and increased expression of the potent anti-apoptotic protein Mcl-1 by directly promoting Mcl-1 transcription. These CAR-dependent processes rendered the liver resistant to death receptor-induced liver injury by Fas. The steatotic liver is highly susceptible to Fas-mediated apoptosis[37]. Perhaps, the CAR-induced resistance to Fas or other death ligands, such as tumor necrosis factor-alpha (TNF-α), accounts for its cytoprotective effects on the MCD diet-fed mouse. Finally, we noted that CAR can modify bile acid metabolism, and the role of bile acids in lipotoxicity remains unexplored[38].

The accumulation of fat in hepatocytes (steatosis) and the onset of steatohepatitis may reflect successive stages in fatty liver disease. The "two-hit" hypothesis postulates that the steatotic liver is susceptible to secondary insults including vulnerability to reactive oxygen species, tumor necrosis factor-α and other cytokines, which ultimately culminates in a sustained inflammatory response[39]. TCPOBOP treatment of MCD diet-fed mice resulted in a marked reduction in steatosis as well as inflammation. CAR-stimulated MCD diet-fed animals had decreased hepatic macrophage/Kupffer cell numbers and less circulating serum leukotriene B4 (LTB4). LTB4 is a potent chemotactic agent that initiates, sustains and amplifies the inflammatory response. Catabolism of LTB4 occurs in hepatocytes, as the liver is the principle organ for clearance of LTB4 from circulating blood[40]. In the liver, degradation of the fatty acid-like derivative LTB4 is modulated by PPAR-α regulation of microsomal ω-oxidation and peroxisomal β-oxidation pathways. Upregulation of PPAR-α-regulated genes involved in fatty acid oxidation by CAR activation may have attributed to a reduction in the inflammatory response, in part by enhancing LTB4 hepatic clearance.

In summary, our findings suggest that CAR activation is sufficient to attenuate hepatic steatosis, apoptosis and inflammation in the MCD diet-fed mice. The CAR-dependent PPAR-α-like stimulation of genes involved in microsomal ω-oxidation and peroxisomal β-oxidation pathways may, in part, be responsible for the hepatic cytoprotective effects observed in this model. These data also implicate a mechanistic link between fatty acid oxidation, hepatocyte apoptosis and Kupffer cell infiltration or inflammation. These preclinical studies suggest the employment of CAR agonists in the treatment of fatty liver diseases merits further attention.

COMMENTS

Background

Nonalcoholic steatohepatitis (NASH) is a progressive spectrum of fatty liver disease for which there are limited therapeutic options. Apoptosis or programmed cellular death is a prominent histopathologic feature of NASH and correlates with disease severity. Recently, the constitutive androstane receptor (CAR), a nuclear receptor, has been reported to promote hepatic cytoprotection against apoptosis. Therefore, we hypothesized that CAR may ameliorate apoptosis induced by NASH.

Research frontiers

The incidence of nonalcoholic steatohepatitis is increasing with the rise in obesity over the last decade. New therapeutic regimens to slow down the process of fibrosis and cirrhosis in these patients will be important.

Innovations and breakthroughs

There is a prominent role for CAR cytoprotection against Fas-mediated hepatocyte injury *via* a mechanism involving upregulation of Mcl-1 (anti-apoptotic proteins) and, likely, downregulation of Bax and Bak (pro-apoptotic proteins).

Applications

At this time the use of CAR agonists to reduce the liver injury caused by NASH-induced hepatocyte apoptosis is still in its early phase of development. We need more data to fully evaluate its role in NASH.

Terminology

CAR is highly expressed in the liver and the small intestine, two key tissues expressing xenobiotic metabolizing enzymes, and mediates the induction of their expression by the widely used antiepileptic drug, phenobarbital (PB) and the potent synthetic inducer 1,4-bis-[2-(3,5,-dichloropyridyloxy)] benzene (TCPOBOP). TCPOBOP is an agonist ligand for CAR. PB induces its nuclear translocation, which results in increased expression of CAR target genes. The nuclear receptor, peroxisome proliferator-activated receptor alpha (PPAR-α), mediates many, if not all, of the adaptive consequences of peroxisome proliferator exposure in the liver, including alteration in lipid metabolism genes, hepatomegaly, and increases in liver tumors. Apoptosis is executed by caspases, a family of proteases that sequentially disassemble a cell. The pathways leading to caspase activation are dependent on the cytotoxic stimulus. Cytotoxic stress activates caspases by initiating signaling pathways that converge on the Bcl-2 family of proteins. After apoptotic stimulation, changes in the balance between pro- and anti-apoptotic members of this family lead to alteration of mitochondrial pore structure or integrity and permeabilization and release of proteins that promote cell death.

Peer review

This paper describes a series of experiments investigating the modulation of the CAR of steatotohepatitis in experimental rat model of NASH. The paper is well written and the methodology seems adequate. There are some issues that have to be addressed.

Abstract

AIM: To evaluate safety and effect on hepatitis B virus (HBV) suppression of a long-term treatment with lamivudine (LAM) at standard (100 mg/d) or double (200 mg/d) dose in chronic hepatitis B.

METHODS: This was a case study with matched controls (1:3) in patients with chronic hepatitis B with anti-HBe antibodies.

RESULTS: Twelve patients received LAM 200 mg/d and 35 LAM 100 mg/d, for a median of 28 mo. A primary response (PR; i.e., negative HBV-DNA with Amplicor assay) was achieved in 100% of LAM-200 patients and 83% of LAM-100 patients. A virological breakthrough occurred in 16.7 and 24.7%, respectively, of the PR-patients, with the appearance of typical LAM resistance mutations in all but one patient. Viremia blips (i.e., transient HBV-DNA below 80 IU/mL in patients who tested negative at Amplicor assay) were detected using a real time polymerase chain reaction (PCR) and occurred in seven out of nine patients with subsequent BT and in four out of 32 patients with end-of-study response (77.7% *vs* 12.5%; $P = 0.001$) at chi-square test). At the end of the study, 51.4% of LAM-100 patients and 83.3% of LAM-200 patients had remained stably HBV-DNA negative. Double-dose LAM was well tolerated.

CONCLUSION: Long-term treatment of anti-HBe positive chronic hepatitis B with double dose lamivudine causes a more profound and stable viral suppression as compared to conventional treatment.

Key words: Lamivudine; Hepatitis B; Chronic; Hepatitis; Polymerase chain reaction

INTRODUCTION

Lamivudine (LAM) treatment has changed the therapeutic approach to chronic hepatitis B (CHB), since it has a potent antiviral effect and an excellent tolerability profile[1-4]. In chronic hepatitis B with anti-HBe antibodies, lamivudine must be administered indefinitely, since drug discontinuation causes an immediate rebound in the vast majority of patients[5,6]. Unfortunately, the drug has a low genetic barrier which causes the emergence of resistant mutants and disease resurgence at a rate of approximately 15% a year[7-10]. In addition, a percentage of patients ranging from 11% to 32% are primary non-responders to treatment[11-14], which limits further the efficacy of lamivudine in this setting.

At present, about 80% of patients with CHB in the Mediterranean area lack HBeAg in serum and present anti-HBe antibodies with the presence of HBV-DNA in serum[15]. This percentage is expanding in other parts of the world[16], due to the control measures against HBV and the subsequent decline in the proportion of hepatitis B virus (HBV) infections in young patients.

Lamivudine is registered for the treatment of chronic hepatitis B at a standard daily dose of 100 mg. This dosage derives from studies which compared the efficacy of 25, 100 and 300 mg/d given for 12-24 wk and found that viral suppression was similar at 100 and 300 mg[17,18]. As a consequence, 100 mg was adopted as the standard of therapy and the potential of higher doses in improving long-term outcomes has never been investigated.

In this pilot study we investigated the feasibility and the effects on viral suppression of a long-term treatment with a daily dose of 200 mg lamivudine in patients with HBeAg-negative chronic hepatitis B compared with matched patients treated with the standard dose.

MATERIALS AND METHODS

The study enrolled consecutive patients with HBeAg-negative, anti-HBe positive CHB between June 1999 and December 2002. The patients had to be negative for anti-HDV, anti-HCV and anti-HIV antibodies and present HBV-DNA in serum at levels $> 2 \times 10^4$ IU/mL. Basal evaluation comprised routine liver function tests, abdominal ultrasound (US) and liver biopsy. Histological specimens were evaluated using the Ishak's scores for necroinflammation and fibrosis[19]; minimal requirements for a specimen to be evaluated were a length of at least 2 cm and the presence of $\geqslant$ 10 portal tracts.

Twelve consecutive patients received lamivudine at the daily dose of 200 mg (LAM 200; 100 mg b.i.d.). As a reference group, we selected three age matched patients for each case, with anti-HBe positive CHB treated in the same period with the standard dose of 100 mg according to an open label, long-term study. In both cases and controls, the therapy was continued indefinitely; the therapy was stopped in patients who did not clear HBV-DNA after 12 mo of treatment. The study was closed on June 30, 2005.

The patients were followed-up monthly, including medical examination and alanine aminotransaminase (ALT) determination; at each visit a serum sample was stored at -40℃ for HBV-DNA testing. An abdominal US was performed every six months. Lamivudine tablets were dispensed directly monthly.

HBV-DNA analysis

Routine quantitative testing for HBV-DNA in serum was performed using Amplicor HBV Monitor (Roche, Branchburg, NJ, USA; detection limit 80 IU/mL).

In addition, analysis of HBV-DNA in serum was performed by the use of a Real Time PCR (RT-PCR) and Sybr Green as a fluorescent intercalating agent of the double strand DNA. The reference standards used for the external calibration were the WHO hepatitis B virus DNA International Standards No. 97/746 and the working reagent HBV No. 98/780, both provided by the National Institute of Biological Standards and Controls. HBV-DNA was extracted from serum by a slightly modified guanidinium thiocyanate method. Briefly, 100 μL of serum or plasma were added to 400 μL of the extraction solution and 0.5 mL of 2-propanol were added to the tube. The mixture was centrifuged for 10 min, then supernatant was removed and pellets washed twice with 70% ethanol. Each sample was dissolved in 50 μL sterile water and 10 μL were used for PCR (sensitivity = 10 IU/mL).

Processed specimens were added to 40 μL of an amplification buffered (pH = 8.0) mixture containing 0.5 μmol/L each of the reverse and forward primers directed toward the highly conserved HBV pre-core/core region and Sybr Green (BMA Molecular Probe), 2.5 IU of Taq Gold (Applied Biosystem) and 0.5 IU of Uracil DNA Glycosylase (Amersham Life Science - USB). The PCR process was carried out with the following amplification cycles: 50℃ for 2 min; 94℃ for 10 min; two cycles, each of 1 min duration, at 94℃, 60℃ and 72℃; 38 cycles at 94℃, 60℃ and 72℃, of 20 s each. Real time detection was performed using a ABI PRISM 7000 Sequence Detection System (Applied Biosystem).

HBV polymerase mutant and HBV genotype assay

Polymerase mutants conferring LAM resistance were detected using a commercial assay (InnoLipa HBV-DR, Innogenetics, Gent, Belgium) in all patients who presented serum HBV-DNA reappearance while on therapy and in those who remained viremic from the beginning of the therapy. HBV genotypes were identified using the INNOLIPA HBV-Genotyping test (Innogenetics, Gent, Belgium).

Therapy outcome definitions

Virological response (VR) to treatment was a fall in HBV-DNA below 80 IU/mL with or without a biochemical response (BR). Patients who remained constantly serum HBV-DNA positive over a 12 mo therapy period were defined as primary non-responders (PNR). A virological breakthrough (VBT) was defined as an increase $\geqslant$ 1 log in serum HBV-DNA in a previous responder patient while continuing LAM therapy; a biochemical breakthrough (BBT) was an ALT elevation above 2 × in a virological BT. An ALT flare was an ALT elevation > 500 U/L. A viral blip was a transient HBV-DNA below 80 IU/mL detected by RT-PCR in patients who tested negative at Amplicor assay. Complete viral suppression was a stably undetectable HBV-DNA in serum using RT-PCR.

Safety

A clinical examination was performed monthly. At the same time, differential blood count and serum biochemistry were performed, including serum amylase, lipase and creatinine phosphokinase (CPK) determination. Any adverse event was registered.

Statistical analysis

The data were analyzed according to an intention to treat procedure. Patients who were lost at follow-up were considered as non-responders. Chi-square and Fisher's exact test were used to analyze categorical variables and Student's *t* test for continuous data. The data were analyzed using SPSS software, version 12. The study was approved by the local Ethics Committee.

RESULTS

Twelve patients received LAM 200 mg/d and 35 patients LAM 100 mg/d (one patient receiving 200 mg LAM was matched with two controls only). The basal characteristics of the patients are reported in Table 1. There was no difference between the groups relating to demographic data and ALT values, serum HBV-DNA values and liver histology. Overall, a liver biopsy taken within 18

[a]*P* = 0.051; 51.4% *vs* 83.3%.

mo before therapy was available in 34 patients; 50% of whom had cirrhosis. In both groups median treatment duration was 28 mo. Based on Roche Monitor assay, a primary VR was observed in all the patients treated with 200 mg lamivudine and in 83% of those treated with the standard regimen (Table 2). In both groups, median HBV-DNA disappearance time was 3 mo and in no patients did HBV-DNA become undetectable at Monitor test later than the sixth months of therapy. Primary non-response was observed in six patients, all belonging to the 100 mg group. In PNRs LAM therapy was discontinued after 12 mo; during treatment, HBV-DNA levels remained above 2×10^4 IU/mL.

During treatment, a VBT was detected in nine patients, of whom two belonged to the 200 mg group (2/12; 16.6%) and seven to the 100 mg group (7/29; 24.1%). A BBT followed in all patients with VBT; in these patients, the ALT values were below 2 × the basal value in eight out of nine patients and in the range of a hepatitis flare in one patient (belonging to 100 mg group). At the end of the study, 63% of the patients in LAM-100 group and 83% in LAM-200 group were still VR (Table 2). None of the basal variables considered in Table 1 was associated with the outcome of the treatments.

In 11 patients who were constantly negative at the HBV-Monitor test, the RT-PCR revealed transient viremia blips below 80 IU/mL. This feature was recorded in seven out of the nine patients who subsequently presented a BT and in four out of the 32 patients with end of study response, the latter belonging to the 100 mg group (Table 3; $P = 0.001$).The negative predictive value and positive predictive value for BT were 0.93 and 0.63, respectively. Viremia blips occurred in 10 out of 29 (34.4%) patients who were initially responders to LAM 100 mg and in one out of 12 (8.4%) of those responding to LAM 200 mg. On the whole, the patients who showed absent or partial viral suppression (i.e., a PNR or a VBT or viral blips) were 17 out of 35 treated with LAM 100 mg and two out of 12 treated with LAM 200 mg ($P = 0.051$).

Lamivudine resistance mutations were researched in 13 cases, five of whom were PNRs and eight BTs (Table 4). None of the primary non responders had detectable mutations at baseline; however, all of them developed rtM204V/I mutant (none with concomitant rtL180M) while continuing LAM therapy, two with an ALT increase after the appearance of the mutation and one with a hepatitis-like flare. Among BT patients, seven presented rtM204V/I (four with concomitant rtL180M) and one patient presented an ALT flare with no detectable mutations. Mutations preceded the clinical BT by one to

eight months. HBV genotypes were detected in 24 patients, all but one were genotype D.

Lamivudine was well tolerated; one patient belonging to the 100 mg group discontinued the treatment due to an increase in serum amylase to eight times the UNL. No serious adverse events were recorded in either treatment group.

DISCUSSION

This study was designed to check whether a long-term, double dose lamivudine treatment is feasible in patients with chronic hepatitis B and has the potential for a more profound and stable suppression of viral replication.

Basically, lamivudine pharmacokinetic is subjected to significant individual variability[20-22]. Plasma concentrations of lamivudine do not reflect its antiviral activity, since it depends on the 5-triphosphate anabolite of the drug, which is formed through an intracellular, saturable enzymatic process. Higher dosage of lamivudine produced higher intracellular lamivudine triphosphate concentrations. The intracellular half-life of active compound varies from 17 to 19 h in hepatic cell lines and from 10.5 to 15.5 h in peripheral blood mononuclear cells (PBMCs)[23,24] which suggested a dose interval of 12 h in HIV patients. In our study giving daily LAM 200 mg in two refracted doses may have enhanced intracellular active drug availability and even reached adequate anti-viral concentrations in extrahepatic sites of HBV replication.

In chronic hepatitis B, lamivudine doses ranging from 25 to 300 mg/d were used obtaining a steady viral inhibition at 100 mg[17,18] as measured by a hybridization assay. Looking at long term efficacy, Yuen *et al*[25] found no difference in the cumulative incidence of resistance mutations between patients treated with lamivudine 100 mg/d and those who received 25 mg/d for one to three years, though viral suppression was less effective at lamivudine 25 mg than at lamivudine 100 mg. This suggests that viral suppression may be sub-optimal even at the dose of 100 mg and is in keeping with our results at 100 and 200 mg.

In our study, the use of a sensitive PCR method highlighted that viral suppression was less efficient at 100 mg/d and this was the background for mutant selection and viral breakthroughs. Indeed, some patients classified as VR by Monitor assay had viremia blips below 80 IU/mL. This phenomenon was significantly associated with subsequent stable resurgence of viral replication and was mostly observed in patients receiving 100 mg lamivudine. At the end of the study a stable viral suppression was achieved in 83% of the patients receiving 200 mg LAM and in 51% of those treated at 100 mg/d.

There are some practical consequences from these observations, which are summarized in Figure 1. First of all, patients under treatment with lamivudine require strict follow-up with a high-sensitivity PCR assay, in order to detect, as soon as possible, even low level viremia. Secondly, an early change in therapeutic strategy is advisable for patients with viremia blips, by switching to adefovir or to entecavir[26-28], in order to prevent virological and biochemical BTs. Finally, patients with undetectable HBV-DNA and no viremia blips are candidates for continuing long-term lamivudine monotherapy, since the absence of viremia blips is predictive of long-term response.

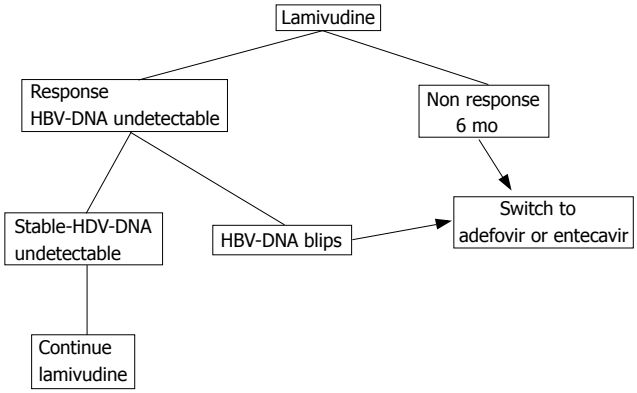

Figure 1 Flow-chart for patients under lamivudine treatment.

Genotype D of HBV was largely prevalent in our series and this raises the question as to whether the results are applicable to different HBV genotypes. There is evidence that response rates to Peg-interferon depend on HBV genotypes while less clear-cut results were obtained with anti-HBV analogs[1,29-31].

None of the primary non-response was associated with a pre-existing mutation, supporting the concept that the pharmacokinetic of the drug may play an important role in primary non-response and that higher drug doses may force this pharmacokinetic defect. Alternatively, PNR patients might harbour viral variants not detected by our method. Lamivudine resistance mutations were detected in all but one patient with virological BT.

In all primary non-responders continuing the treatment caused the appearance of resistance mutations, with further ALT elevation. From a practical point of view, patients who do not respond to a standard lamivudine dose should stop the treatment within the first six months (Figure 1), since a response after this period is unlikely. There is no data on early shifting to a higher lamivudine dose after an initial non-response to a standard dose.

In conclusion, our results indicate that the patients under lamivudine should be monitored using a high sensitivity PCR assay. An extended treatment with a double dose of lamivudine is feasible in chronic hepatitis B, and has the potential for a more pronounced viral suppression than a standard dose. Since lamivudine is a well-used, non-toxic and non-expensive anti-viral agent, these data should stimulate more powered studies aimed at optimizing treatment strategies.

COMMENTS

Background

Sustained viral suppression is the main goal of antiviral therapy in chronic hepatitis B. Lamivudine was the first antiviral drug approved for HBV treatment, at the standard daily dose of 100 mg. Although it was safe and potent, it caused the emergence of drug-resistant viral strains, at a rate of about 15% a year. At present, other antiviral drugs against HBV are available (adefovir, entecavir, telbivudine) that show a higher genetic barrier than lamivudine. Recent guidelines do not recommend the use of lamivudine as first line therapy in chronic hepatitis B.

Research frontiers

Thousands of patients with chronic hepatitis B are under lamivudine treatment.

Furthermore, lamivudine is the cheapest anti-HBV drug. After five years of continued treatment approximately 25% of the patients have an undetectable HBV-DNA. Can we improve the efficacy of lamivudine and predict the long-term response to treatment? There is a lack of studies with a higher than standard dosage of lamivudine in immunocompetent patients. This article examines the possibility of prolonged treatment with double daily dose of lamivudine (200 mg) and the predictive value of close monitoring of serum HBV-DNA using a highly sensitive real-time PCR.

Innovations and breakthroughs

Patients treated with lamivudine 200 mg/d achieved a more rapid primary response and a more profound and long-lasting viral suppression. In fact, the use of a sensitive PCR for HBV-DNA detection showed that transient low viremia levels ("viral blips") were more frequently detected in patients receiving lamivudine 100 mg and predicted a virological breakthrough and the emergence of lamivudine resistance mutations.

Applications

Patients under lamivudine treatment require a strict follow-up using a highly sensitive PCR. Real time PCR has a lower detection limit of 10 IU/mL and seems the best method for this purpose. Detecting even low level viremia during treatment may predict the emergence of resistance mutations. In this case, an early change in therapeutic strategy is advisable as indicated in Figure 1 of the paper. The paper suggests that therapy with double dose lamivudine is feasible and may achieve better results than the standard dose.

Terminology

Virological breakthrough is the increase of at least one log of the plasma viral concentration during anti-viral therapy. In most of the cases it is due to the emergence of viral resistant strains. Biochemical breakthrough is the increase of ALT value that follows the virological breakthrough. Genetic barrier may be defined as the probability of not reaching any resistant escape strains.

Peer review

The aim and content of the study were considered innovative. However, some limits come from the low number of patients enrolled in the 200 mg lamivudine group. As the authors stated, these results should encourage further trials.

Abstract

AIM: To assess the long-term clinical benefit of sustained virological response (SVR) in patients with hepatitis C virus (HCV) cirrhosis treated by antiviral therapy using mostly ribavirin plus interferon either standard or pegylated.

METHODS: One hundred and thirteen patients with uncomplicated HCV biopsy-proven cirrhosis, treated by at least one course of antiviral treatment ⩾ 3 mo and followed ⩾ 30 mo were included. The occurrence of clinical events [hepatocellular carcinoma (HCC), decompensation and death] was compared in SVR and non SVR patients.

RESULTS: Seventy eight patients received bitherapy and 63 had repeat treatments. SVR was achieved in 37 patients (33%). During a mean follow-up of 7.7 years, clinical events occurred more frequently in non SVR than in SVR patients, with a significant difference for HCC (24/76 *vs* 1/37, $P = 0.01$). No SVR patient died while 20/76 non-SVR did ($P = 0.002$), mainly in relation to HCC (45%).

CONCLUSION: In patients with HCV-related cirrhosis, SVR is associated with a significant decrease in the incidence of HCC and mortality during a follow-up period of 7.7 years. This result is a strong argument to perform and repeat antiviral treatments in patients with compensated cirrhosis.

Key words: Hepatitis C; Cirrhosis; Interferon alpha

INTRODUCTION

In patients with chronic liver diseases, the prognosis strongly depends on the extent of liver fibrosis, as life-threatening complications mainly occur in patients with cirrhosis. In chronic hepatitis C in particular, hepatocellular carcinoma (HCC) is observed only in case of cirrhosis or severe fibrosis (some of them presumably with under diagnosed cirrhosis due to sampling error of liver biopsy). In patients with compensated hepatitis C virus (HCV)-related cirrhosis, the annual incidence of HCC, decompensation and death reach around 3%, 4% and 3%, respectively[1-4] and the main cause of death is HCC[1].

Interferon-α was approved for use in chronic hepatitis C in 1991. During the past 15 years, subsequent improvements have included extension of therapy to 48 wk, the combination of interferon-α with ribavirin, and the use of pegylated interferon. These progresses have resulted in improvement in the sustained virological response (SVR) rate in patients included in randomized trials from less than 10% with the initially recommended 24-wk course of interferon-α monotherapy to as high as 50%-60% with the combination of peg interferon and ribavirin for 48 wk. In unselected patients, the percentage of SVR is expected to be lower particularly in patients with cirrhosis.

Most studies of antiviral therapy of HCV have been limited to 6 mo of follow-up after the end of treatment and have not included HCC, liver decompensation or death as end points. Therefore, studies of the effect of antiviral therapy on clinical outcome of HCV-cirrhosis have largely been retrospective analyses of therapeutic trials using interferon-α alone, focusing on patients with cirrhosis[4-11]. Only three randomized trials have assessed

this effect, giving conflicting results[12-15]. Recent meta-analysis suggested a slight, but significant preventive effect of standard interferon-α monotherapy on HCC occurrence in patients with HCV-cirrhosis, especially in those who achieve SVR, who intrinsically represent a small proportion of patients in these trials[16,17]. The influence of interferon-α on the incidence of decompensation or death in patients with HCV-cirrhosis was less studied and more controversial[4,8,10,12,14,18].

At present, bitherapy with standard then pegylated interferon plus ribavirin has created a new perspective for patients with HCV because of the higher rate of SVR reported[19,20]. The clinical long-term benefit of bitherapy with standard interferon-α has been recently assessed in Chinese patients with HCV-cirrhosis[21]. Such data are still not available in Western patients. Therefore, to assess the impact of achievement of a SVR on clinical long-term outcome of cirrhosis, we conducted a long-term, retrospective, bi-centre analysis of prospective collected data from a cohort of 113 French patients with histological proven HCV cirrhosis treated at least 3 mo by different regimens including ribavirin plus standard or pegylated interferon, and periodically followed and screened for HCC according to standardized criteria.

MATERIALS AND METHODS

Patients

We retrospectively selected all the consecutive patients followed-up in two French liver centres between 1989 and 2006 fulfilling the following criteria: (1) HCV-related cirrhosis defined by association of positive serum anti-HCV antibodies and RNA, with typical liver histology; (2) absence of complication before or at inclusion (Child-Pugh class A); (3) absence of HBV or HIV co infection (negative serum HBsAg and HIV antibodies); (4) daily alcohol consumption < 50 g; (5) absence of contra-indication to antiviral treatment, particularly platelet and polymorphonuclear counts ⩾ 80 000/mm^3 and 1500/mm^3, respectively; (6) at least a 3 mo course of antiviral treatment using standard or pegylated interferon with or without ribavirin, according to therapeutic advance over time and international guidelines; (7) a regular follow-up ⩾ 30 mo after the starting of the first treatment; (8) absence of HCC or even suspicious findings such as liver nodule or serum level of alpha-fetoprotein (AFP) above 50 ng/mL; (9) residence in France allowing regular follow up.

Assessment of Response to antiviral treatment

SVR was defined as undetectable serum HCV RNA 6-mo after discontinuation of the last treatment. Non responder patients to a first line treatment were retreated once or more each time it was possible with the same or a different regimen according to therapeutic advance over time. Serum HCV RNA was measured annually during follow-up and at the time of the last visit. According to final virological response, patients were separated into SVR and non SVR groups. Patients not fulfilling SVR criteria, including all patients who relapsed after the achievement of the end of treatment response, were classified as non-SVR.

Follow-up

All patients were prospectively followed-up according to the same schedule in both centres. Complete physical examination, standard biochemical tests, serum AFP determination and abdominal ultrasonography (US) were repeated every 6 mo, whatever the virological response. Baseline then annual endoscopy of the upper gastrointestinal tract allows assessment of the presence of gastrooesophageal varices. In case of significant endoscopic portal hypertension, prophylactic treatment (propranolol and/or endoscopic treatment) was started. The length of the study was calculated from the starting date of antiviral therapy and ended at death or at the last follow-up visit.

Endpoints

When a focal liver lesion or increased AFP levels were detected, tomodensitometry and, whenever possible, fine needle guided liver biopsy were performed. Diagnostic criteria for HCC were: (1) histological and (2) clinical, in patients with AFP value greater than 400 ng/mL and evidence of focal liver lesion at imaging techniques. After 2002, the HCC diagnosis was based on the guidelines of the European Association for the Study of the Liver[22].

Liver-related complications (ascites, upper gastro-intestinal bleeding, and hepatic encephalopathy) were considered an endpoint in all patients with or without the occurrence of HCC. In the subjects who developed HCC, liver complications were recorded only when they occurred before tumour development. Ascites was diagnosed by clinical examination and/or US detection. Porto-systemic encephalopathy was defined by clinical parameters. The source of gastro oesophageal bleeding was confirmed by endoscopy whenever possible.

Dates and causes of deaths were recorded. Liver transplantation was considered as liver-related death endpoint. Reference date was February 2006.

Statistical analysis

Continuous variables are reported as mean and standard deviation, and categorical variables as absolute and relative frequencies. The Mann-Whitney rank-sum test (M-W) and the Kruskal-Wallis nonparametric analysis of variance (K-W) were applied to compare the means. The associations between Non-SVR or SVR status and events in 2 × 2 cross tabulations were tested using Fisher's exact test. In case of larger cross tabulations, we tested the correlation by computing Pearson's Chi-square, or by computing either the exact probability value, or the Monte Carlo estimate of the exact probability value. Cumulative incidence curves of liver-related complications, HCC and mortality according to response to interferon treatment were plotted using the Kaplan-Meier method. The differences between groups were assessed using log-rank tests. Data was censored when individuals died, received a liver transplantation or were lost during follow-up. The variables which proved to be significant at univariate analysis were tested by the multivariate Cox proportional hazards regression model to assess their independent effect on the development of events during the follow-up. The

SVR: Sustained virological response. [1]*P* values were obtained between SVR and non SVR groups.

results were expressed as hazard ratio (HR) and their 95% confidence interval (CI). Data handling and analysis were performed with the Statistical Package for Social Sciences (SPSS 13.0; SPSS Inc., Chicago, IL) and STATXACT. All tests were 2-sided and $P < 0.05$ was considered to be statistically significant.

RESULTS

Patients and treatment regimens

One hundred thirteen patients fulfilled inclusion criteria (mean age: 54 ± 11 years, males: 61%, HCV genotype 1: 51%) (Table 1). As a whole, the mean (± SD) cumulated duration of treatment was 15.3 ± 9 (range: 3-42, median 12) mo. Treatment courses were performed 1, 2, 3 and 4 times in 50 (44.2%), 42 (37.2%), 19 (16.8%) and 2 (1.8%) patients respectively (Table 2). Interferon-ribavirin bitherapy was administered in 78 patients (69%), using pegylated interferon in 38 cases. SVR was obtained in 37 patients (33%). Nineteen out of 113 treated patients (16.8%) became SVR after the first treatment, 15/113 (13.3%) after the second, 3/113 (2.7%) after the third and 0/113 (0%) after the fourth treatment. Among the 37 SVR patients, 11 (29.7%) received only a monotherapy versus 24 (31.6%) in the 76 non SVR group ($P = 1.00$). Cumulated duration of antiviral treatment (14 mo ± 6 mo *vs* 16 mo ± 10 mo) did not significantly differ between SVR and non SVR patients ($P = 0.99$). There was no significant difference between the 2 groups regarding the number and the patterns of treatment (Table 2). Furthermore, there was no heterogeneity among the 2 centres in terms of duration and patterns of treatment.

The main patients' baseline characteristics according to final response are reported in Table 1. Compared to non SVR, SVR patients were more often males (84% *vs* 50%, $P = 0.0005$), younger (51 ± 11 *vs* 56 ± 11 years, $P = 0.02$), leaner (25 *vs* 26.5 kg/m^2, $P = 0.015$), less frequently infected with HCV genotype 1 (35.5% *vs* 73.4%, $P = 0.0001$), and had higher serum albumin levels (45 *vs* 42 g/L, $P = 0.001$) and lower AFP serum level (8.7 *vs* 17.3 ng/ mL, $P = 0.008$).

Follow-up and clinical events occurrence

The mean duration of follow-up was 7.7 ± 3.0 years from the beginning of the first treatment in the whole population. SVR and non SVR patients did not differ in term of follow-up (7.7 ± 2.6 *vs* 7.6 ± 3.1 years, $P = 0.6$) (Table 2).

During the follow-up, at least one severe clinical event (HCC or ascites or hepatic encephalopathy or gastrointestinal bleeding or death) occurred in 37 patients with a significant higher frequency in non-SVR (44.7% versus 8.1%, Hazard Ratio 6.3 (95% Confidence Interval 1.9-20.4), $P = 0.002$). Ascites, hepatic encephalopathy or gastrointestinal bleeding occurred in 11/76 non-SVR and in 3/37 SVR (Figure 1); HCC occurred in 24/76 non-SVR and in 1/37 SVR (Figure 2). The difference between the two groups was significant only for HCC [$P = 0.01$, Hazard Ratio 13.6 (95% Confidence Interval 1.8-100.5)], while there was no significant difference for the occurrence of other clinical events [ascites, hepatic encephalopathy or gastrointestinal bleeding: $P = 0.44$, Hazard Ratio 1.65 (95% Confidence Interval 0.46-5.9)] (Table 3). The diagnosis of HCC was assessed by histology in 9 patients (before June 2002) and according to guidelines of European Association for the Study of the Liver[22] in 16 patients (after July 2002). The median number of nodules was 1.5 (range, 1-8) and the median size 30 (range, 10-65) mm. The median times from the beginning of the first treatment until complications were not different in SVR and non-SVR: 6.99 years in SVR and 6.36 years in non-SVR for the occurrence of HCC ($P = 0.150$); 6.91 years in SVR and

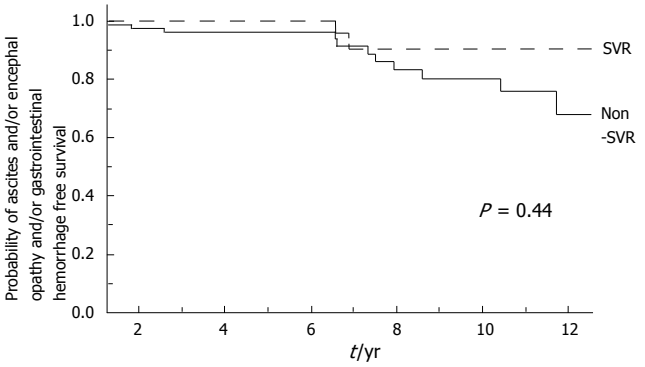

Figure 1 Incidence of ascites or encephalopathy or gastrointestinal haemorrhage from the beginning of the first treatment according to the response to antiviral treatment (SVR: Sustained virological response in dotted line; non-SVR in full line; Log-Rank, $P = 0.44$).

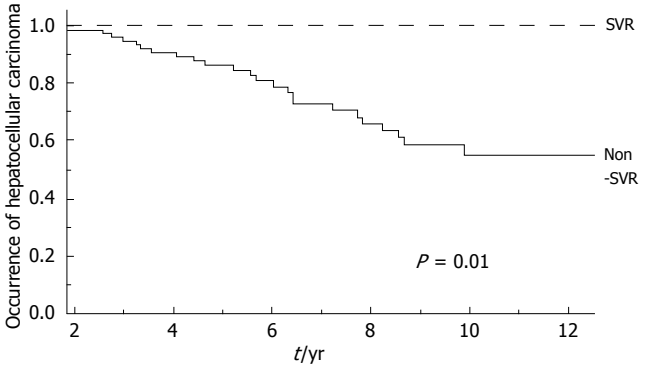

Figure 2 Incidence of hepatocellular carcinoma from the beginning of the first treatment according to response to antiviral treatment. SVR: Sustained virological response in dotted line; Non-SVR in full line; Log-Rank, $P = 0.01$.

6.78 years in non-SVR for the onset of decompensation or upper GI bleeding ($P = 0.531$). For the 37 patients who achieved a SVR, the median time from SVR (i.e., 6 mo after the end of the successful antiviral treatment) to the occurrence of complication was 4.79 years for HCC and 4.66 for decompensation. Death rate was significantly higher in case of non-SVR patients (20/76 *vs* 0/37; $P = 0.002$, Figure 3). Deaths were mainly related to liver disease and HCC was causative of 45% of the deaths. There was no heterogeneity among the 2 centres in terms of patterns of the duration of follow-up and of the number of events observed.

The multivariate analysis (Cox model) found two independent predictive factors for clinical events: SVR [$P = 0.001$, HR 7.1 (95% CI 2.2; 23.2)] and duration of treatment [$P = 0.001$, HR 0.93 (95% CI 0.89; 0.97)]. In other words, the Hazard for HCC was 7% lower for each additional year of treatment.

There was no significant difference with age, gender, or viral genotype for HCC occurrence.

DISCUSSION

Our study demonstrates a significant difference in long-term outcome between initially uncomplicated HCV cirrhotic patients with and without SVR after antiviral treatment. Over a mean follow-up period of 7.7 years, there were no deaths and virtually no severe clinical events in patients with SVR. At the opposite, HCC and liver decompensation occurred in patients without SVR with incidence rates similar to those previously reported in untreated cirrhotic patients[23]. We should emphasize that HCC was carefully screened before treatment, which eliminates HCC of small size appearing a few months after antiviral treatment.

Several studies performed in patients with chronic hepatitis C have suggested that successful antiviral treatment could result in a dramatic decrease in severe clinical events and mortality, life expectancy of patients with SVR being close to general population[6,9,10,24,25]. However, those studies used only interferon-α. In the past, interferon-α monotherapy resulted in a small rate of SVR in patients with cirrhosis due to low virological efficacy and poor tolerance resulting in a high rate of premature interruption of treatment. Accordingly, in the studies including a subset of cirrhotic patients, SVR rates in those populations did not usually exceed 15%.

Table 3 Severe liver-related events and deaths occurring from the beginning of first treatment according to final virological response

	SVR *n* = 37	Non SVR *n* = 76	*P*

[1]1 patient had 2 complications; [2]4 patients had 2 complications. SVR: Sustained virological response; GI: Gastrointestinal.

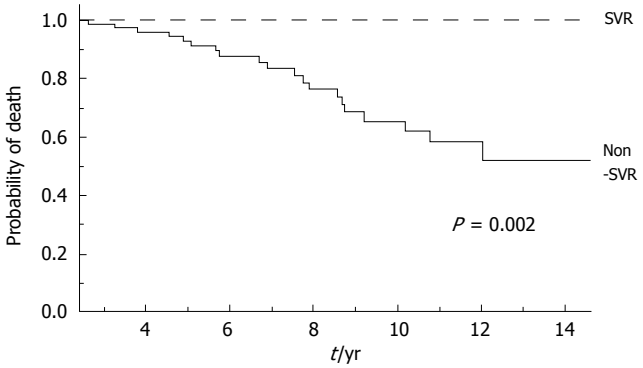

Figure 3 Incidence of death from the beginning of the first treatment according to response to antiviral treatment. SVR: Sustained virological response in dotted line; Non-SVR in full line; Log-Rank, $P = 0.002$.

Our study has several differences. Firstly, it was strictly restricted to patients with histological proven cirrhosis. This population is clearly at high risk of severe short-term complications occurrence as demonstrated by previous studies[1,26]. Secondly bitherapy using interferon-α and ribavirin was used in about 70% of cases in our study, with pegylated interferon in 38 cases. Thirdly antiviral treatment was repeated each time it was possible due to the absence of a priori contra-indication to treatment in those patients. Overall, after one (51.4%) or repeated (48.6%) antiviral treatments, 33% of our patients achieved HCV eradication, which is a rate twice higher than those obtained in previous studies.

Due to the lack of randomization, patients with SVR were obviously different from non SVR. Particularly, they were younger, more often men and significantly more frequently infected with HCV genotypes 2 or 3 than non SVR patients, as observed by Bruno *et al*[10]. Excepted male gender, these factors had been previously identified as predictive factors of SVR and it is not surprising to identify them in our study. The reduced rate of serious events in patients with SVR could result more from the presence of protective factors than from antiviral treatment. Patients with SVR were younger and this could result in a lower risk to develop complications as demonstrated for HCC occurrence. The role of genotype in spontaneous outcome of HCV-related cirrhosis although still debated does not seem to be a determinant factor in this setting and the male sex is a favouring factor of fibrosis progression and HCC occurrence. Subsequently the absence of serious event seems related to the complete response to treatment.

Several successive treatment courses have been performed in most of the patients, representing a cumulated time of treatment of 15.3 ± 9 mo. It could explain why clinical event incidence was decreased with a linear fashion from the start of treatment even if viral eradication was obtained later with further treatment. About half of SVR patients had no HCV eradication after the first course of treatment. It could seem questionable that severe events incidence have been reduced even before eradication was achieved in those patients. We postulate that it could reflect a more complete blockade of HCV replication in those patients occurring from the first course of treatment and due to higher sensitivity of virus. The fact that patients received similar duration of treatment in both groups is in favour of this hypothesis and against a non specific effect of treatment such as antifibrotic and/or antiproliferative effects of interferon.

The association between SVR and a significantly reduced number of clinical events has been previously reported[10,16,17,25]. However, this result cannot be applied to the whole population of patients with HCV-cirrhosis. In this study as in others, patients were selected and those with initial major contra-indication to treatment were excluded. These patients are probably the most severe with the higher risk of developing complications such as HCC. In addition, due to the selection of patients, the risk of death related to co morbidity was very low in our study.

Even in case of SVR, the periodic follow-up of cirrhotic patients should be recommended, particularly HCC screening as it is worth noting that the only HCC observed in SVR occurred 4.8 years after the achievement of viral clearance. In spite of a significant decrease in the incidence of HCC in case of SVR, several isolated cases of HCC were reported 4.5 to 6.6 years after the achievement of a SVR[27-30].

In conclusion, repeated antiviral therapy actually results in SVR in 33% of patients with HCV-cirrhosis. Virological cure seems to be associated with a strong decrease in the incidence of complications particularly HCC. These results are a strong argument to perform and repeat antiviral treatments in patients with compensated cirrhosis.

COMMENTS

Background

HCV cirrhosis is a life threatening disease with annual incidences of hepatocellular carcinoma (HCC), decompensation and death reaching around 3%, 4% and 3% respectively. The achievement of a sustained viral eradication (SVR) with the initially recommended 24-wk course of interferon-α monotherapy is associated with a slight preventive effect on HCC occurrence but its influence on the incidence of decompensation or death was less studied and more controversial.

Reasearch frontiers

Subsequent progresses in the field of HCV treatment (including extension of therapy to 48 wk, the combination of interferon-α with ribavirin, and the use of pegylated interferon) have created a new perspective for patients with HCV-cirrhosis because of the higher rate of SVR. Thus, the clinical long-term benefit of antiviral treatment in patients with HCV cirrhosis needed to be re-assessed.

Innovation and breakthroughs

Long-term effect of standard interferon-α plus ribavirin therapy on incidence of HCC in patients with HCV cirrhosis was recently studied in Chinese patients. Our results are the first in Western patients. In addition, death was a clinical end-point and we showed a significant reduced mortality in patients who achieved SVR.

Applications

While firm recommandations on antiviral treatment for patients with compensated HCV-cirrhosis was not made by international conferences, this is a strong argument to perform and repeat antiviral bitherapy in these patients to achieve SVR.

Terminology

Sustained virological response (SVR) is defined by the absence of detectable serum HCV RNA six months after the end of antiviral treatment and is associated with a durable viral eradication in most patients. Hepatocellular carcinoma (HCC) is the most frequent primary liver cancer and the first cause of death in patients with HCV-cirrhosis.

Peer review

The manuscript by El Barks *et al* demonstrates that antiviral treatment in patients with HCV-related cirrhosis decreases the incidence of HCC. The data provided argue for an antiviral treatment in HCV patients. The study was well performed and the data are clearly presented.

Received: June 29, 2007 Revised: August 6, 2007

Abstract

AIM: To determine the impact of cirrhosis on trauma patients and define the factors predicting death.

METHODS: The data on patients admitted to the trauma center from January 2000-2005 were studied retrospectively. The clinical variables were recorded and compared to identify the factors differentiating cirrhotic trauma survivors from non survivors. Child's classification criteria were derived from the reviewed charts of cirrhotic trauma patients to evaluate their predictive value in cirrhotic trauma. Trauma registry was also used to generate a trauma control group by matching for age, sex, abbreviated injury score (AIS) over the same period of time. The outcome variables compared were mortality rate, time of ICU and hospital stay. Results were expressed as mean ± SD. These data were analyzed by SPSS.11.0 statistical software. Univariate analysis was performed to identify significant medical factors for survivor and non survivors subjected to chi-square test. Fisher's exact test and Student's *t* test were performed to determine the statistical difference between cirrhotic and control groups. $P < 0.05$ was considered statistically significant.

RESULTS: Poor prognosis of traum patients was associated with one or more of the following findings: ascitcs, hyperbilirubinemia (more than 2 mg/dL), hypoalbuminemia (less than 3.5 mg/dL), and prolonged prothrombin time (more than 12.5 seconds). Although Child's classification was used to predict the outcome in cirrhotic patients undergoing portacaval shunt procedures, no significant difference was found in mortality rate as a function of Child's classification.

CONCLUSION: Cirrhosis is associated with a higher mortality, a longer time of ICU and hospital stay of trauma patients. It seems that treatment of trauma patients with pre-existing severe liver disease is a challenge to surgeons.

Key words: Pre-existing cirrhosis; Trauma; Mortality rate

INTRODUCTION

Liver cirrhosis is the tenth leading cause of death[1]. Although cirrhosis-related deaths have decreased over the years, the impact of cirrhosis remains with approximately 30 000 deaths annually, mostly in Asian countries[2]. Cirrhotic patients often suffer from complications[3]. Cirrhosis impairs nutrition, alters response to stress, and affects the functions of other organ systems.

Trauma continues to be a major public health problem in the world. Due to the rapid economic development in China, the number of motor vehicles has increased tremendously in the past decade[4], leading to more deaths and injuries resulting from trauma. WHO predicts that trauma injuries will result in about 2.3 million deaths globally by 2020, becoming the third contributor to the global death[5]. Trauma not only causes a significant loss of life, but also results in loss of economic, medical, educational, and legal resources.

Trauma, in combination with cirrhosis in patients, brings about a unique challenge. Surgeons in trauma centers treat a variety of patients every day, but treatment of traumatized cirrhotic patients remains a challenge[6]. It has been shown that the mortality and morbidity rates increase in patients with cirrhosis undergoing elective or emergency surgery[7]. Also the degree of hepatic insufficiency is a prime factor for determining the outcome in these patients[8]. Despite the interest in the surgical outcome of cirrhotic patients, few reports are available on the outcome of cirrhotic patients after traumatic

injury. This study reviews and analyzes the data on trauma patients with pre-existing cirrhosis who were admitted to a trauma center in East China from 2000 to 2005.

MATERIALS AND METHODS

Data on more than 11 000 trauma patients (64 trauma patents with pre-existing liver cirrhosis) admitted to the Trauma Center of the First Affiliated Hospital, College of Medicine, Zhejiang University, China, from January 2000 to January 2005 were contained in their respective trauma registries. The data on patients under the ICDM-3 index for cirrhosis patients with chronic liver disease were analyzed. The trauma registry abstracts and medical records of all patients diagnosed as hepatic cirrhosis were reviewed. Diagnosis of hepatic cirrhosis was confirmed by the past medical history, clinical examination, operation findings, biopsy, and/or imaging.

The clinical variables were recorded and compared to identify the factors affecting prognosis of the patients and prolonging survival of the patients. In addition, evidence of hepatic insufficiency was evaluated by ascites, hyperbilirubinemia (more than 2 mg/dL), hypoalbuminemia (less than 3.5 mg/dL), elevated alkaline phosphatase (more than 125 st/L), serum glutamic oxaloacetic transaminase (SGOT more than 40 st/L), and/or prothrombin time (more than 12.5 s) detected at admission.

The trauma registry was also used to generate a trauma control group consisting of 86 patients by matching for age, sex, abbreviated injury score (AIS) over the same period of time. The AIS-85 scores were used because they permitted us to match patients with similar injuries. No cirrhosis or chronic liver failure was found in patients within the control group. The outcome variables compared were mortality rate, time of ICU and hospital stay.

Results were expressed as mean ± SD. The data were analyzed by SPSS.11.0 statistical software. As our sample size was too small to perform multivariate analysis, a univariate analysis was performed to identify the significant predictive factors. The data were subjected to chi-square test. To determine the statistical difference between the cirrhotic and control groups, we compared the mortality rates by Fisher's exact test. Parametric values of AIS, and time of hospital and ICU stay were compared by Student's *t* test. $P < 0.05$ was considered statistically significant.

RESULTS

Sixty-four cirrhotic trauma patients (5.9 per 1000 trauma patients) admitted to the Trauma Center of the First Affiliated Hospital, College of Medicine, Zhejiang University were include in this study. These patients were diagnosed as cirrhosis before admission and during laparotomy for traumatic injury, respectively. The etiology of cirrhosis was related to HBV infection and alcohol in 62 and 1 patients, respectively and unidentified in 1 patient. The demographic and outcome data are listed in Table 1. Although the major causes for injury were motor vehicle accidents (MVA) (Table 2), 30.77% (4 of 13) of deaths were due to accidental fall. Other causes for injury included superficial abdominal stab wound, criminal assault. Seven patients had sustained blunt thoracic traumas including rib fracture, pulmonary contusion. Blunt abdominal trauma as evidenced by hemoperitoneum, splenic rupture, and/or liver laceration was the predominant injury in 9 patients. Pelvic fracture or limbic long-bone fracture occurred in 36 patients. Twenty-seven patients had injuries involving multiple sites. The remaining 37 patients had injuries involving a single site and two of them died (Table 3).

Table 1 Demographic and survival data on patients studied (48 males, 16 females)

(*n* = 40)	Range
Mean age = 52	31-84
Mean TS = 12	6-16
Mean ISS = 12	5-34
Surv = 87.5%	

Table 2 Mechanism of injury

Mechanism of injury	Total	Non survivors *n* (%)
Fall	13	4 (30.77)
MVA	48	3 (6.25)
Other	3	1 (33.33)

Table 3 Injury characteristics

Site	Total	Non survivors *n* (%)
Head	22	2 (9.09)
Thorax	7	2 (28.57)
Abdomen	9	3 (33.3)
Pelvis/Ext	26	1 (3.85)
Multiple	27	6 (22.22)
Single	37	2 (5.41)

The clinical or laboratory findings associated with hepatic insufficiency in this group of patients are outlined in Table 4. Ascites was confirmed during operation or radiological examination in 16 patients (6 of them died). An elevated prothrombin time of over 12.5 s was found in 15 patients (including 7 non survivors). Serum bilirubin exceeding 2 mg/dL was found in 15 patients at admission (6 of them died). The presence of any of these parameters was associated with a significant increase in mortality rate ($P < 0.05$). SGOT, alkaline phosphatase and hypoalbuminemia were elevated in many patients, but did not significantly affect their outcome.

Child's classification could predict the outcome of cirrhotic patients undergoing portacaval shunt procedures. In order to identify the predictive value of Child's classification, we retrospectively derived Child's classification criteria from the reviewed charts of cirrhotic trauma patients. The mortality of cirrhotic trauma patients according to the (retrospective) Child's classification is listed in Table 5, showing that 92.2% of our cirrhotic trauma patients corresponded to Child's class A or B. No

Table 4 Presence of HEPATIC insufficiency

Parameters of hepatic insufficiency	Total	Non survivors *n* (%)
Ascites	16	6 (37.50)[a]
SGOT > 40 μ/L	36	3 (8.33)
Alk phos. > 125 μ/L	32	3 (9.37)
Ser bili. > 2.0 md/dL	15	6 (40)[a]
Ser alb. 6 ≤ 3.0 md/dL	16	6 (37.5)[a]
PT > Control	15	7 (46.67)[a]

[a]$P < 0.05$ *vs* survivors.

Table 5 Effect of Child's classification on mortality in cirrhotic trauma patients *n* (%)

Child's classification	No. of patients (% total)	Mortality
Class A	44 (68.75)	5 (11.38)
Class B	15 (23.44)	2 (13.33)
Class C	5 (7.81)	1 (20)
Total	64 (100)	8

significant difference in mortality as a function of Child's classification was found ($P > 0.05$).

The second part of our study focused on comparing the trauma registry data between the cirrhotic trauma and control groups (Table 6). The cirrhotic trauma patients had a statistical ISS score similar to the control trauma patients. The time of ICU and hospital stay, and the mortality rate in the cirrhotic trauma group were greater than those in the control group ($P < 0.05$).

Table 6 Comparison of outcomes of trauma patients and cirrhotic trauma patients

	Cirrhosis	Control
Age (yr)	51.80 ± 13.01	48.70 ± 15.4
Percentage male	75%	76.11%
AIS	14.25 ± 8.31	13.67 ± 6.56
hospital stay	21.26 ± 5.61	8.21 ± 4.25[a]
length of ICU stay	11.24 ± 4.21	4.23 ± 1.36[a]
Mortality rate	12.53%	1.26%[a]

[a]$P < 0.05$ *vs* cirrhotic patients.

DISCUSSION

Hepatitis B is one of the most common infectious diseases in Asian countries[9], and about 10% of Chinese people have been infected with hepatitis B virus (HBV)[10]. It is estimated that about 350 million people worldwide are chronically infected with HBV, approximately 15%-40% of them are expected to develop cirrhosis and end-stage liver disease[11], which is frequently followed by hepatocellular necrosis. Cirrhosis, regardless of its etiology, inhibits the liver's response to injury. The predominant histological features are wide-spread fibrosis and nodule formation with loss of normal hepatic architecture. These changes are manifested clinically as hepatic failure and portal hypertension, the magnitude of which determines the course and prognosis of individual patients[12].

Although great progress in traumatology has been made, the number of traumatic casualties still increases[13]. In China, trauma and intoxication were the 9th, 7th and 4th leading cause of deaths in 1975, 1985 and 2000, respectively. More than 100 000 people die of traumatic injury and millions of people are injured each year in China. Furthermore, experts predict that the number of traumatic casualties will double in the 22nd century[14]. All these suggest that trauma in combination with cirrhosis is a challenge to Chinese doctors.

Adequate hepatic function is necessary in physiological response to surgery or traumatic injury[15]. The liver plays a vital role in protein synthesis, detoxification, and immune responses. In a patient subjected to surgical intervention for traumatic injury, any degree of hepatic insufficiency would diminish the liver's ability to carry out these vital metabolic functions[16]. Because of impaired cirrhotic reserves, a surgical or trauma cirrhotic patient would be at a great risk of developing complications and death may occur during the recovery period[17].

The increased risk of cirrhotic patients undergoing surgery has been well documented[18]. The Child's classification system has been used to define the surgical mortality in cirrhosis patients[19] and is moderately accurate in predicting mortality and complications of portacaval shunt surgery, but less predictive when it is applied to other types of surgery[20]. The Child's classification is mainly to classify the risk of cirrhotic patients undergoing portosystemic shunt surgery[21], showing that the degree of hepatic decompensation correlates with the rate of operative mortality in these patients. Furthermore, if therapeutic measures are taken to improve the clinical status and Child's class of cirrhotic patients before operation, the outcome of portosystemic shunting can be improved.

Child's classification criteria could not be used to classify these patients because nutritional status and response to therapy are unavailable[22]. Furthermore, changes in mental status at admission cannot be solely attributed to the etiology of cirrhosis[23]. However, hepatic insufficiency, as determined by the presence of ascites and/or elevated prothrombin time, is correlated with the outcome of these patients undergoing surgical intervention. Multivariate analysis revealed that cirrhotic trauma victims presenting with ascites, hyperbilirubinemia, or elevated prothrombin time exhibit a uniformly lower rate of survival independent of injury characteristics[24].

The impact of cirrhosis on trauma patients has recently been addressed[25]. Thirty percent of trauma patients with pre-existing liver disease have an increased risk of death and an increased time of hospital stay[26]. Tinkoff *et al*[27] have also tried to define the variables predicting the outcome of survivors and non survivors. The results of these studies suggest that trauma cirrhotic patients behave as cirrhotic patients requiring emergency surgery with similar stress and compensatory responses and that the mortality is directly related to the extent of injury.

In addition, hepatic insufficiency further diminishes survival, regardless of the injury sustained[28]. In the present study, cirrhosis was associated with a higher mortality, a longer time of ICU and hospital stay of trauma patients.

Factors predicting death are APACHE Ⅱ. ISS. RTS2,

the number of packed red blood cells transfused and organs injured, which are associated with the severity of injury[29]. Our study showed that liver insufficiency was positively associated with a poorer outcome. The lower survival and increased complication rates of cirrhotic trauma patients suggest that there is no "margin for error" in managing these patients. Thus, several management suggestions can be proposed for the improvement in cirrhotic patients with abdominal trauma[30]. It is critical to promptly diagnose and treat injuries in cirrhotic trauma patients. Since bleeding complications are frequent in cirrhotic patients, early and aggressive correction of coagulation parameters and hypothermia is crucial[31]. Poor nutrition is common in these patients and low albumin is different in survivors and non survivors. Therefore, early appropriate nutritional support should be provided. Solutions rich in branched-chain amino acids and low in aromatic amino acids can reduce hepatic encephalopathy and improve the outcome[32,33].

In conclusion, cirrhotic patients constitute a small subset of trauma patients admitted to our institution. Cirrhosis has a significantly independent adverse impact on survival of these patients. Treatment of trauma patients with severe pre-existing liver diseases remains a challenge to the surgeon.

COMMENTS

Background

Liver cirrhosis is the tenth leading cause of death. Although cirrhosis-related deaths have decreased, it leads to approximately 30 000 deaths annually, mostly in Asian countries. Trauma is a major public health problem in the world. Trauma in combination with cirrhosis brings about unique challenges and problems in patients. Surgeons in a trauma center treat a variety of patients every day, but treatment of trauma cirrhotic patients remains a challenge.

Research frontiers

Many reports have shown that mortality and morbidity rates are increased in patients with cirrhosis undergoing elective or emergency surgery. Also the degree of hepatic insufficiency is a prime factor for determining the outcome of these patients. Despite the interest in the outcome of surgical cirrhotic patients, few reports are available on their outcome.

Innovations and breakthroughs

The authors reviewed and analyzed the data on trauma patients with pre-existing cirrhosis admitted to a trauma center in East China from 2000 to 2005. This study showed that liver insufficiency was positively associated with a poorer outcome, suggesting that cirrhosis has a significantly independent adverse impact on survival of these patients.

Applications

Several management suggestions are proposed for the improvement in cirrhotic patients with abdominal trauma. It is critical to promptly diagnose and treat injuries for cirrhotic trauma patient. Since bleeding complications are frequent in cirrhotic patients, early and aggressive correction of coagulation parameters and hypothermia is crucial. Early appropriate nutritional support should be provided.

Terminology

Hepatic cirrhosis: a kind of pathological changes in liver. Hepatic cirrhosis is frequently followed by hepatocellular necrosis. Cirrhosis, regardless of its etiology, inhibits the liver's response to injury. The predominant histological features are wide-spread fibrosis and nodule formation with loss of normal hepatic architecture. These changes are manifested clinically as hepatic failure and portal hypertension, the magnitude of which determines the course and prognosis of individual patients.

Peer review

This is an interesting manuscript, showing that cirrhosis is associated with a higher mortality, a longer time of ICU and hospital stay in trauma patients. Treatment of trauma patients with severe pre-existing liver disease remains a challenge to the surgeon.

Abstract

A 54-year-old man presented with rectal pain and bleeding secondary to ulcerated, necrotic rectal and cecal masses that resembled colorectal carcinoma upon colonoscopy. These masses were later determined to be benign amebomas caused by invasive *Entamoeba histolytica*, which regressed completely with medical therapy. In Western countries, the occurrence of invasive protozoan infection with formation of amebomas is very rare and can mistakenly masquerade as a neoplasm. Not surprisingly, there have been very few cases reported of this clinical entity within the United States. Moreover, we report a patient that had an extremely rare occurrence of two synchronous lesions, one involving the rectum and the other situated in the cecum. We review the current literature on the pathogenesis of invasive *E. histolytica* infection and ameboma formation, as well as management of this rare disease entity at a western medical center.

INTRODUCTION

Amebiasis is an infectious disease caused by the protozoan *Entamoeba histolytica*. Infection rarely, but potentially may evolve into invasive colitis and formation of ameboma, which can closely resemble colorectal carcinoma. In general, the clinical spectrum of colorectal amebiasis ranges from asymptomatic carrier to severe fulminant necrotizing colitis with bleeding and perforation[1]. As previously reported, focal ileocolonic intussusceptions from ameboma formation serving as the lead point, although rare, can occur[2].

The experience with invasive amebiasis is largely from endemic countries. From documentation dating back to 1933, to date 2970 cases of invasive amebiasis have been reported in the United States, mostly comprising recent immigrants from Mexico, Central and South America, plus Asians and Pacific Islanders[3]. With increasing patterns of immigration and travel in and out of the US, continued recognition of this disease is required. Therefore, the roles of the gastroenterologist and surgeon are to maintain a high index of clinical suspicion in patients at increased risk for this disease entity, and to distinguish this from other more common causes of gastrointestinal masses, as well as instituting appropriate therapy. In this report, diagnosis, pathogenesis and treatment of this rare clinical entity from a western medical center are reviewed.

CASE REPORT

A 54-year-old man of Middle Eastern decent, without significant medical history, presented to a community hospital complaining of rectal pain and bleeding for about 2 d. The patient described the pain as constant, without aggravating or alleviating factors. In addition, the patient complained of constipation that led to mild, crampy abdominal pain. He denied nausea, vomiting, diarrhea or fever. The patient also denied any history of weight loss. Pertinent to the patients' presentation was that he had no history of recent travel abroad, anoreceptive intercourse, or family history of carcinoma.

Physical examination revealed a healthy, well-nourished man who was normothermic with normal hemodynamic parameters. His abdominal examination was unremarkable: soft and non-tender, without any appreciable organomegaly.

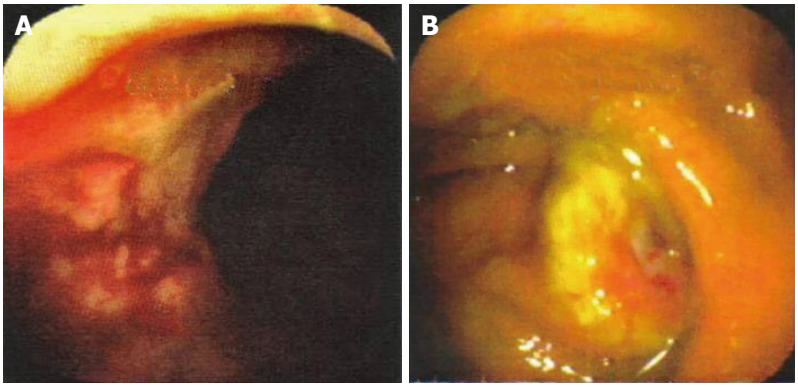

Figure 1 Endoscopy demonstrating ulcerated rectal (**A**) and cecal (**B**) lesions suggestive of carcinoma.

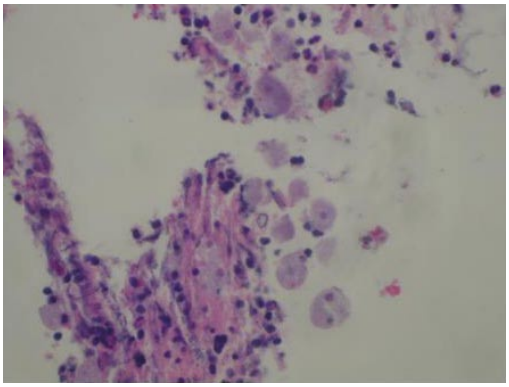

Figure 2 High-powered magnification of a hematoxylin-eosin preparation of a colonic biopsy that demonstrates trophozoites of *E. histolytica*.

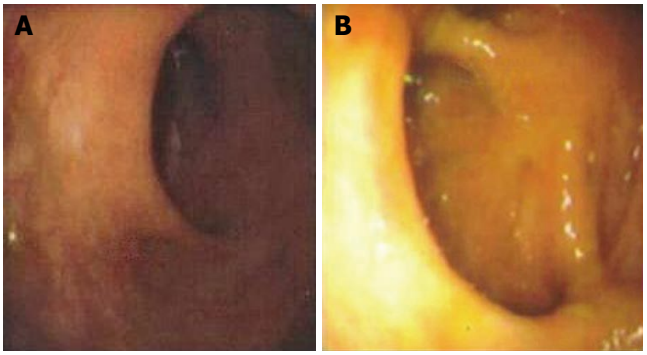

Figure 3 Follow-up colonoscopy subsequent to a completed course of antibiotic therapy, which demonstrates complete resolution of rectal and cecal lesions, with normal appearing colonic mucosa.

External anal inspection was normal. Rectal examination revealed a large, firm mass in the left lateral position, about 3 cm from the anal verge, with gross blood. Rigid proctosigmoidoscopy was performed, which revealed an ulcerated mass starting at the dentate line (Figure 1A). The surface of the lesion appeared necrotic and highly suggestive of carcinoma, which was the preliminary diagnosis. CT scan of the abdomen and pelvis revealed diffuse, non-specific thickening of the rectal wall without intra-abdominal pathology. A colonoscopy was performed that demonstrated an additional ulcerated lesion involving the cecum (Figure 1B). Both lesions were biopsied and were consistent with lymphocytic colitis. Importantly, protozoan organisms, consistent with amebiasis were identified (Figure 2). Serology for *Entamoeba histolytica* infection was also confirmed. The rectal and cecal lesions were determined to be amebomas as a result of invasive amebiasis. The patient was given a course of oral antibiotic therapy with metronidazole for 4 wk, with complete resolution of his symptoms. A follow-up surveillance colonoscopy and CT scan of the abdomen and pelvis demonstrated complete regression of both the rectal and cecal lesions (Figure 3A and B).

DISCUSSION

The intestinal protozoan parasite *E. histolytica* is the causative organism responsible for human amebiasis and amebic dysentery. Of epidemic proportions, it afflicts millions of people worldwide in developing countries, and about 40 000-100 000 people die annually from this disease[4]. Transmission is mostly by ingestion of contaminated food and water; however, venereal transmission *via* the fecal-oral route can occur[5].

Trophozoites are responsible for invasive disease and may lead to colonic mucosal ulceration. The gastrointestinal tract and liver are the two main organ systems affected by the parasite. Rarely, patients with long-standing infection develop ulcerative, exophytic, inflammatory masses that are indistinguishable from carcinomas and can become a considerable size, reportedly up to 15 cm in diameter[5]. Such lesions are referred to as amebomas. Moreover, colonic amebomas may present with synchronous amebic liver abscesses, which can also masquerade as advanced carcinoma of the gastrointestinal tract.

Amebomas result from the formation of annular colonic granulation tissue at single or multiple sites, usually within the cecum or ascending colon (Figure 4). Formation of an ameboma is an uncommon complication of invasive amebiasis. It occurs in 1.5% of all cases with invasive amebiasis[6]. Amebomas usually develop in the untreated or inadequately treated patients with amebiasis years after the attack of dysentery[5]. The current report is atypical, as our patient denied any history of antecedent symptoms suggestive of dysentery or foreign travel. Clinically, amebomas can also cause obstructive symptoms. Patients may also present with diarrhea or constipation and associated systemic symptoms, including weight loss

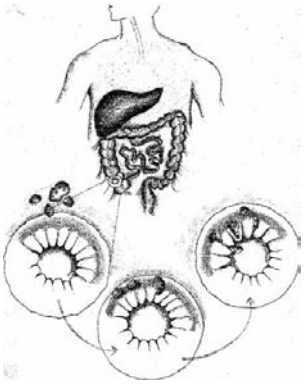

Figure 4 Pathogenesis of ameboma formation: infection is initiated by ingestion of fecally contaminated food or water containing *E. histolytica* cysts. Excystation occurs in the bowel lumen in which motile and potentially invasive trophozoites are formed. Invasion of the mucosa and submucosa may lead to colitis. Ameboma forms when severe inflammatory reaction occurs, with formation of granulation tissue that leads to a pseudotumor appearance.

and fever. In areas in which infection is prevalent, crampy abdominal pain plus a palpable mass usually suggests the diagnosis. In contrast, in western countries, a similar presentation alternatively raises suspicion of malignancy. The differential diagnosis for this clinical picture may also include inflammatory bowel disease (IBD), lymphoma, enterocolitis and intestinal tuberculosis[6]. In most cases in western countries, a diagnosis of colorectal carcinoma or IBD is considered more likely than a parasitic infection. Interestingly, there has been only a single *E. histolytica* outbreak in the United States, which occurred in Chicago in 1933 when sewage pipes contaminated tap water pipes in a hotel, which led to 800 cases of amebiasis[3].

The pathological range of amebic colitis extends from mucosal thickening with discrete ulcer formation, separated by regions of normal colonic mucosa, to diffusely inflamed and edematous mucosa. Severe forms of invasive amebiasis may progress to frank necrosis and perforation of the intestinal wall[3]. These findings are grossly similar to those found with IBD, in particular Crohn's colitis. Parasitic colitis results when the trophozoite penetrates the intestinal mucosal layer. Subsequent invasion occurs as a result of epithelial, neutrophil and lymphocyte cellular destruction by trophozoites[7].

The standard method for diagnosis of intestinal amebiasis is examination of stools by microscopy. However, the reported sensitivity of this method for identifying amebic organisms ranges from 25% to 60%[4]. False-positive results may also occur because *E. histolytica* is morphologically identical to non-pathological species, namely, *Entamoeba dispar* and *Entameba moshkovskii*[4]. Currently, more sensitive and specific methods, including antigen detection in stools and serum, and polymerase chain reaction techniques are now utilized[4].

The primary treatment for amoebic colitis is oral metronidazole therapy. Affected patients should be treated with metronidazole for 5-10 d. Longer intervals of therapy may be warranted in cases with ameboma formation, as in our patient. Treatment with metronidazole may be followed by a luminal agent such as paromomycin, iodoquinol or diloxanide furoate for 5-20 d to eradicate colonization[4]. Surgical intervention is rarely indicated except for rare instances of acute necrotizing colitis with bowel perforation, or if the patient fails to respond to anti-amebic therapy. Although amebiasis is a clinical entity rarely encountered in developed western countries, it should be included in the differential diagnosis of patients presenting with bloody diarrhea and a colon mass, with a history of dysentery along with travel to endemic areas. A high index of suspicion is required for appropriate diagnosis and treatment.

Unfortunately, there are no pathognomonic radiographic or endoscopic features suggestive of invasive ameboma formation; therefore, pathologic confirmation is crucial, as well as appropriate serology. Multiple biopsies may often be required to confirm the diagnosis. Two important caveats are essential to consider when managing patients with invasive amebomas: (1) follow up sigmoidoscopy or colonoscopy after completion of medical therapy to assure complete resolution of disease; and (2) persistent disease or incomplete regression should raise the suspicion for an underlying malignancy as the two entities may coexist[1].

In summary, the equivocal clinical symptoms (i.e., pain, bleeding and obstruction) that differentiate invasive amebiasis presenting as an ameboma from carcinoma may prove problematic. Notwithstanding, in a high-risk patient, clinical suspicion is warranted to assure appropriate diagnostic evaluation. Differentiating amebiasis from colorectal carcinoma by endoscopy with biopsy, serology, and other novel modes of antigen detection provides essential information. Therapeutic intervention with oral anti-parasitic medications rather than surgical management should then occur.

Abstract

Black esophagus is a very rare disease and its pathogenesis has been unclear. Black esophagus developed concomitantly with candidiasis after diabetic ketoacidosis has not been reported yet. We report a case who developed esophageal stricture after the treatment of black esophagus and thus balloon dilatation was performed several times but failed, hence, surgical treatment was performed.

INTRODUCTION

Black esophagus was reported in 1990 by Goldenberg *et al*[1]. Black esophagus is a rare disease and defined as a dark, pigmented esophagus at endoscopy together with histologic mucosal necrosis. The etiology remains unknown, but is most likely multifactorial, even though most reports have suggested an ischemic pathogenesis[2-5]. It caused by diabetic ketoacidosis or candidiasis, but it is very rare etiology. Here, we present a case of a patient with black esophagus developed concomitantly with candidiasis after diabetic ketoacidosis.

CASE REPORT

A 34 year old male patient with the past history of type Ⅱ diabetes transferred to the emergency room with drowsy mentality. His general condition was poor. He presented with arterial hypotension (60/30 mmHg), hyperglycemia (819 mg/dL), electrolyte imbalance (sodium 118 mEq/L and potassium 6.5 mEq/L), impaired renal function (BUN 194 mg/dL and creatinine 2.90 mg/dL), and an acid-base disorder known as metabolic acidosis (pH = 7.241 with low bicarbonate levels). Urine ketones were elevated (+++). The clinical picture suggested that patient had diabetic ketoacidosis.

Two days after admission, hematemesis was detected, Esophago-gastro-duodenoscopy (EGD) showed black and friable mucosa from 3 to 4 cm below the cricopharyngeus to the cardia (Figure 1). Biopsies of the esophagus were not obtained at this time due to concern about possible perforation.

The patient gradually recovered after the conservative treatments such as intravenous proton pump inhibitor, total parenteral nutrition, oral intake restriction and antibiotics. Six days after admission, biopsies of the esophagus were obtained with EGD and revealed submucosal necrosis and candidiasis. After conservative treatments including antifungal agents (fluconazol 200 mg for seven days), the patient was discharged on the thirtieth day of admission. Subsequently, after 2 months, esophagus stricture was developed. Balloon dilation was performed 3 times during 6 months, but it was not improved (Figure 2A), and thus subtotal esophagectomy and esophagogastrostomy were performed (Figure 2B), and on the eighteenth day of surgery, he was discharged without complication.

DISCUSSION

Black esophagus was reported in 1990 by Goldenberg *et al*[1]. Black esophagus is a rare disease, and the incidence detected by EGD has been reported to be 0.01%-0.2%[2-5]. It is developed preferentially in the male (81%), and it has been reported to occur predominantly in the elderly[4].

The pathogenesis of black esophagus remains undefined and is probably a combination of an low systemic perfusion, gastric outlet obstruction, and malnutrition[2-5].

Several etiologies have been suggested including ischemia, lye ingestion, microbial infection related to a nasogastric tube, anticardiolipin antibody syndrome, herpes simplex esophagitis, diabetic ketoacidosis, severe vomiting, acute gastric outlet obstruction with massive gastroesophageal reflux, *Lactobacillus acidophilus* infection, acute caustic injury from detergent in the endoscope, antibiotics, Stevens-Johnson syndrome, and hypothermia[2,3,5]. Among 88 cases of black esophagus reported until now,

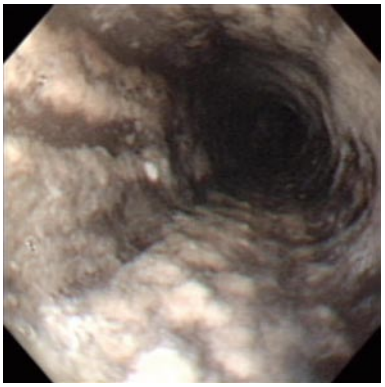

Figure 1 Endoscopy shows that esophagus is circumferentially black and friable.

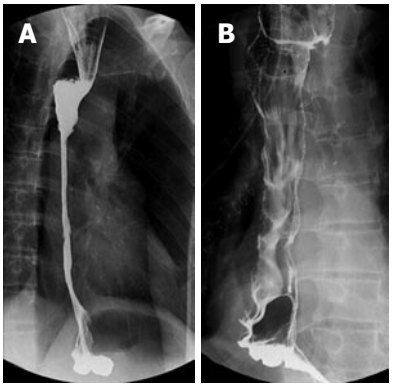

Figure 2 Barium swallow study. **A**: Stricture formation at middle esophagus; **B**: Improvement of the stricture was seen after surgical treatment.

cases whose etiology was diabetic ketoacidosis were 3 cases[4], cases whose etiology was fungal infection were 2 cases[5,6]; however, reports showing diabetic ketoacidosis and candidiasis concomitantly have not been reported.

Most patients are symptomatic, and the most common symptoms are upper gastrointestinal bleeding such as hematemesis, coffee-ground vomiting and melena[2-4].

The diagnosis is based on typical endoscopic appearance and on histopathological findings after the exclusion of true necrosis and ulceration. It shows the finding of the diffusely black esophageal mucosa, and in most cases it disappears suddenly in the Z-line. Histological findings of esophagus biopsy show necrotic debris, and it may show the finding of the necrotic mucosa without the viable epithelium, and occasionally, the submucosa and up to the muscularis propria, although rare, may be involved[2,4]. This case showed that submucosal involvement.

The prognosis of black esophagus is very poor, and its mortality reaches up to 31.8%-50%, although most of the deaths were caused by underlying illnesses[2-4]. Death secondary to esophageal necrosis occurs in less than 6% of cases[4]. Therapeutic modalities are not standardized, but most authors support a conservative approach by correcting the underlying disease, intravenous proton pump inhibitor, total parenteral nutrition, and oral intake restriction[2-5].

The major complications of black esophagus are esophageal stenosis and stricture formation, and they occur in 10.2%-15% of patients. Repeated dilation is required in most patients[2,4,5]. In our case, repeated dilation was not effective, and thus surgical treatment was performed. Other complications are esophageal perforation, mediastinitis and abscess formation, which occurs in approximately 6% patients[4].

Surgical treatments for black esophagus have been reported in 5 cases[4], nevertheless, all 5 cases were performed surgery for early complications such as esophageal perforation and our case is the first case of black esophagus performed surgical treatment for the late complication esophageal stricture.

Abstract

Colonic lipoma is an uncommon tumor of the gastrointestinal tract. Most cases are asymptomatic, with a small tumor size, and do not need any special treatment. However, we encountered one patient with a giant submucosal lipoma, with a maximum diameter of 8.5 cm, which exhibited symptoms such as intermittent lower abdominal pain, changes in bowel habits with passage of fresh blood and mucus per rectum, abdominal distension, anorexia and weight loss. Unfortunately, the possibility of colonic malignancy could not be precluded and left hemicolectomy was planned. The exact diagnosis of this special case was accomplished by intraoperative pathology. In the end, local resection was performed instead of left hemicolectomy. To the best of our knowledge, colonic lipoma exceeding 8 cm in diameter has not been previously reported. We, therefore, present this case and discuss age and sex factors, clinical and histopathological findings, diagnostic methods and treatment by reviewing the available literature, to serve as a reminder that colonic lipoma can also exist in patients with significant symptoms. In addition, intraoperative pathology should be investigated in those doubtful cases, so as to guide the exact diagnosis and treatment plan.

INTRODUCTION

Lipoma of the colon is a rare condition which may be detected incidentally at colonoscopy, surgery or autopsy[1-3]. Most colonic lipomas are asymptomatic and need no treatment, whereas lesions exceeding 2 cm in diameter do produce symptoms[1,3-5]. Large colonic lipomas are usually mistaken for more serious pathology as a result of their rarity and variable presentation. Although the nosopoietic location of colonic lipoma usually varies with different cases, the commonest site is the ascending colon[2,4]. To the best of our knowledge, colonic lipoma exceeding 8 cm in diameter has not been reported previously. We report here, a patient with a giant lipoma, whose maximum diameter reached 8.5 cm, located in the submucosa of the descending colon, and review the literature regarding colonic lipoma.

CASE REPORT

A 42-year-old man presented to us in February 2007 with a 3-wk history of intermittent lower abdominal pain. One month previously, he experienced changes in bowel habits (7-10 times daily), with passing fresh blood and mucus per rectum, abdominal distension, anorexia and weight loss. A routine colonoscopy had been performed in another hospital 15 d previously, which revealed a yellowish, 7.5-cm diameter, spherical polypoid lesion arising from the lateral wall of the descending colon (Figure 1). The related biopsy revealed a lot of inflammatory necrotic tissue and a glandular cell with mildly atypical hyperplasia. Physical examination revealed mild tenderness in the left lower quadrant. Routine blood tests were normal except for mild anemia. Abdominal ultrasonography indicated a space-occupying mass of the lower abdomen. Considering the uncertain diagnosis, we suggested that colonoscopy or computed tomography (CT) should be performed again in our hospital, but this was refused by the patient. In view of his age, symptoms and related examinations, the possibility of colonic malignancy could not be precluded, and left hemicolectomy was subsequently planned.

At laparotomy, an 8.5 cm × 7 cm × 6.5 cm yellowish polypoid lesion, associated with numerous areas of ulceration on its surface, was seen arising from the descending colon. The lesion almost obstructed the whole lumen, and resulted in dilatation of the proximal colon. However, to our surprise, such a large lesion was only located on the submucosa, without invasion of the serosa. Subsequently, microscopical examination confirmed that this lesion was

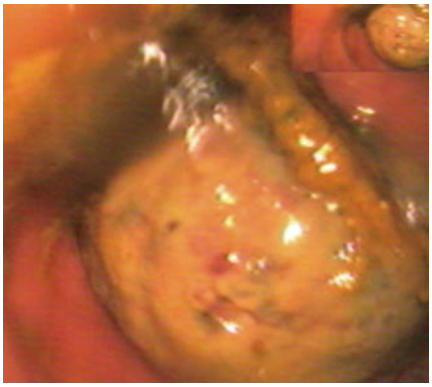

Figure 1 Colonoscopy showed a yellowish, spherical, polypoid lesion, with a lot of inflammatory necrotic tissue and numerous areas of ulceration on its surface, which arose from the lateral wall of the colon. The lesion almost obstructed the whole lumen.

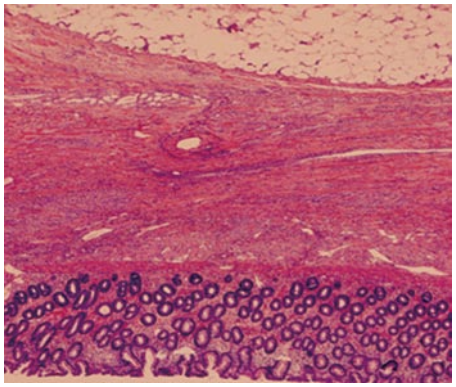

Figure 2 Histopathology showed that the lesion was located in the submucosa, of adipose origin, and was complicated with necrotic tissue and granulation on its surface (HE, × 100).

only located in the submucosa, and originated from adipose tissue, but it had necrotic tissue and ulcerations on its surface (Figure 2). Finally, the diagnosis was confirmed to be one of submucosal lipoma of the descending colon, and local resection was performed. The patient recovered and was discharged 12 d postoperatively.

DISCUSSION

Lipoma of the colon is an uncommon tumor of the gastrointestinal tract, and belongs to the group of benign non-epithelial tumors. As reported at autopsy, the incidence of colonic lipoma ranges from 0.035 to 4.4%[4]. In general, colonic lipomas do not cause symptoms and, therefore, are usually detected incidentally during colonoscopy, surgery and autopsy. However, a minority of lipomas can cause symptoms when the lesion is large, especially for those with a diameter > 2 cm[1,3-5]. To the best of our knowledge, colonic lipoma with a maximum diameter of 8.5 cm, associated with significant symptoms, has not been previously reported.

The clinicopathologic features of symptomatic lipomas are reviewed in the literature[1-4,6-9] and are summarized in Table 1. Thus, we can conclude that the most common signs and symptoms include abdominal pain (42.4%), bleeding per rectum (54.5%) and alteration in bowel habits (24.2%). With respect to sex distribution, there is a female predominance (66.7%), while other authors have found a nearly equal sex distribution[10]. The most common age is the fifth or sixth decades of life. As for its location, the most typical site for solitary colonic lipoma is the ascending colon (45.5%), whereas the lesion in our report was located in the descending colon. From Table 1, we can see that a solitary lesion is usually found in most cases; by contrast, multiple lesions occur in 6.1% of cases.

Microscopically, colonic lipomas are usually located in the submucosa, and numerous fibra intervals (Figure 3) can be observed in adipose tissue, resulting in the lobulated appearance of lipoma. Furthermore, varying degrees of fat necrosis, granulation and ulceration may be found on the surface of relatively large lipomas.

With the widespread application of colonoscopy, small lesions are found incidentally, and their diagnosis and treatment are mainly dependent on endoscopy[1-3]. However, large colonic lipomas are often mistaken for more serious pathology, as a result of their rarity and variable presentation. Therefore, more attention should be paid to how to increase the rate of preoperative diagnosis. Clinical fea-

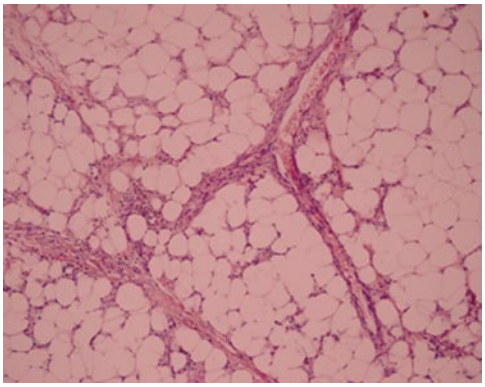

Figure 3 Histopathology showed the numerous fibra intervals in the adipose tissue (HE, × 200).

tures are still important, especially for those large lesions. Our patient with an 8.5 cm × 7 cm × 6.5 cm lesion should have presented with the appearance of complete intestinal obstruction. However, to our surprise, he did not present as an emergency with significant symptoms. Several factors may have contributed to this phenomenon. One potential explanation is the slow growth rate of colonic lipoma. Another, and perhaps more likely explanation is the long-standing obstruction caused by the lesion, which results in proximal colonic dilatation.

Although imaging findings may be less specific, they have still contributed to the preoperative diagnosis. Barium enema may demonstrate a filling defect, and the lesion may exhibit a lobulated appearance[4,6], but this phenomenon is non-specific and the lesion can be mistaken for another type of neoplasm, although water enemas are thought to improve the contrast with radiolucent fat[11]. For large colonic lipomas and acutely ill patients, CT and magnetic resonance imaging are the preferred methods because their imaging characteristics are relatively typical for adipose tissue, and they provide a rapid diagnosis[2,6].

Since most lipomas are submucosal, colonoscopy can provide direct visualization and pathologic examination via biopsy forceps. Thus, preoperative diagnosis mainly depends on colonoscopy. Typical lipomas appear as smooth, spheroidal, slightly yellowish polyps of variable size, with or without a pedicle[3]. In addition, three signs may contribute to the diagnosis, including "cushion sign"[12] (probing the polyp with a closed biopsy forceps will often yield a pillow-like indentation), "tenting effect"[12] (grasping the overlying mucosa with the biopsy forceps presents a tent-like appearance), and the "naked fat sign"[13] (biopsies may result in an extrusion of yellowish fat). Although colonoscopy is reliable for the diagnosis of the usual type of lipoma, it is more difficult for diagnosis of those lesions with an atypical, callous or ulcerated shape. In our case, the necrotic mucosa and numerous areas of ulceration that existed on the tumor surface, together with a relatively hard texture, may have confused the above-mentioned signs, therefore leading to the subsequent misdiagnosis. In addition, biopsy by colonoscopy may provide limited help for the diagnosis of some large lesions, because it cannot obtain adequate tissue. If the adipose tissue lies beneath the normal or ulcerated mucosa, it is not likely to be diagnostic; furthermore, if biopsy yields benign tissue, it is not possible to completely exclude the possibility of malignancy. The exact diagnosis still mainly relies on an intra- or postoperative pathology examination.

Many therapeutic interventions have been tried for the treatment of colonic lipoma, which have varied from hemicolectomy to segmental resection and local excision, according to the correct preoperative diagnosis and intraoperative findings. With the advancement of colonoscopy, endoscopic cautery snare resection of colonic lipomas has become popular and has been proven to be a safe therapeutic method, especially for small lesions[1,3,4,6,7,14]. However, various views with regard to endoscopic removal of large lipomas have been reported. Some studies have demonstrated that removal of lipomas $\geqslant$ 2 cm in diameter is associated with a greater risk of perforation[3,15,16]. On the contrary, some authors have reported that large pedunculated and large sessile lesions can be removed without perforation[6,7]. Kim *et al*[1] have performed endoscopic removal of lipoma with a maximum diameter of 3.8 cm, assisted by injection of saline solution with or without epinephrine into the submucosa beneath the lesion, with no complications. Bar-Meir *et al*[7] have described the safe endoscopic removal of a very large 5-cm lipoma. In addition, the feasibility of slow mechanical transection of a large colonic lipoma (4 cm) with an endoloop ligation technique has been demonstrated by Raju *et al*[15], whereas this novel technique may require application of additional loops several weeks later. The removal of colonic lipoma with the assistance of laparoscopy has also been reported[17].

However, on the basis of our case and the published literature, we think that surgical removal should be the preferred choice for the following indications: (1) lipoma with a diameter of > 4 cm, with a sessile appearance or limited pedicle; (2) unclear preoperative diagnosis; (3) lesions with significant symptoms, especially the appearance of intussusception; (4) involvement of the muscular layer or serosa; and (5) lesion cannot be resected radically under colonoscopy. Although colonic lipoma is a benign tumor, intraoperative frozen sections are required to ensure negative surgical margins, which can guide the choice of surgical approach. As far as our patient was concerned, left hemicolectomy would have been performed instead of local resection, if we had not taken a frozen section intraoperatively. Overall, intraoperative pathology is the most important examination for doubtful cases of colonic lipoma, which can also assist in guiding the exact diagnosis and treatment planning.

Instructions to authors

GENERAL INFORMATION

World Journal of Gastroenterology (*WJG, World J Gastroenterol* ISSN 1007-9327 CN 14-1219/R) is a weekly journal of more than 48 000 circulation, published on the 7th, 14th, 21st and 28th of every month.

Original Research, Clinical Trials, Reviews, Comments, and Case Reports in esophageal cancer, gastric cancer, colon cancer, liver cancer, viral liver diseases, *etc*., from all over the world are welcome on the condition that they have not been published previously and have not been submitted simultaneously elsewhere.

Indexed and abstracted in

Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®) and Journal Citation Reports/Science Edition, *Index Medicus*, MEDLINE and PubMed, Chemical Abstracts, EMBASE/Excerpta Medica, Abstracts Journals, *Nature Clinical Practice Gastroenterology and Hepatology*, CAB Abstracts and Global Health. ISI JCR 2003-2000 IF: 3.318, 2.532, 1.445 and 0.993.

Published by

The WJG Press

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed double-spaced on A4 (297 mm × 210 mm) white paper with outer margins of 2.5 cm. Number all pages consecutively, and start each of the following sections on a new page: Title Page , Abstract, Introduction, Materials and Methods, Results, Discussion, acknowledgements, References, Tables, Figures and Figure Legends. Neither the editors nor the Publisher is responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of The WJG Press, and may not be reproduced by any means, in whole or in part without the written permission of both the authors and the Publisher. We reserve the right to put onto our website and copy-edit accepted manuscripts. Authors should also follow the guidelines for the care and use of laboratory animals of their institution or national animal welfare committee.

Authors should retain one copy of the text, tables, photographs and illustrations, as rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for the loss or damage to photographs and illustrations in mailing process.

Online submissions

Online submissions are strongly advised. Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/index.jsp. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/wjg/help/instructions.jsp) before attempting to submit online. Authors encountering problems with the Online Submission System may send an email you describing the problem to wjg@wjgnet.com for assistance. If you submit your manuscript online, do not make a postal contribution. A repeated online submission for the same manuscript is strictly prohibited.

Postal submission

Send 3 duplicate hard copies of the full-text manuscript typed double-spaced on A4 (297 mm × 210 mm) white paper together with any original photographs or illustrations and a 3.5 inch computer diskette or CD-ROM containing an electronic copy of the manuscript including all the figures, graphs and tables in native Microsoft Word format or *.rtf format to:

Editorial Office

World Journal of Gastroenterology
Editorial Department: Apartment 1066, Yishou Garden,
58 North Langxinzhuang Road,
PO Box 2345, Beijing 100023, China
E-mail: wjg@wjgnet.com
http: //www.wjgnet.com
Telephone: +86-10-85381892
Fax: +86-10-85381893

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using a word-processing software. All submissions must be typed in 1.5 line spacing and in word size 12 with ample margins. The letter font is Tahoma. For authors from China, one copy of the Chinese translation of the manuscript is also required (excluding references). Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Full manuscript title, running title, all author(s) name(s), affiliations, institution(s) and/or department(s) where the work was accomplished, disclosure of any financial support for the research, and the name, full address, telephone and fax numbers and email address of the corresponding author should be included. Titles should be concise and informative (removing all unnecessary words), emphasize what is new, and avoid abbreviations. A short running title of less than 40 letters should be provided. List the author(s)' name(s) as follows: initial and/or first name, middle name or initial(s) and full family name.

Abstract

An informative, structured abstract of no more than 350 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections: AIM: Only the purpose should be included. METHODS: The materials, techniques, instruments and equipments, and the experimental procedures should be included. RESULTS: The observatory and experimental results, including data, effects, outcome, *etc*. should be included. Authors should present *P* value where necessary, and the significant data should accompany. CONCLUSION: Accurate view and the value of the results should be included.

The format of structured abstracts is at: http://www.wjgnet.com/wjg/help/11.doc

Key words

Please list 5-10 key words that could reflect content of the study mainly from *Index Medicus*.

Text

For most article types, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include in appropriate Figures and Tables. Data should be presented in the body text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. No detailed legend should be involved under the figures. This part should be added into the text where the figures are applicable. Digital images: black and white photographs should be scanned and saved in TIFF format at a resolution of 300 dpi; color images should be saved as CMYK (print files) but not as RGB (screen-viewing files). Place each photograph in a separate file. Print images: supply images of size no smaller than 126 mm × 85 mm printed on smooth surface paper; label the image by writing the Figure number and orientation using an arrow. Photomicrographs: indicate the original magnification and stain in the legend. Digital Drawings: supply files in EPS if created by freehand and illustrator, or TIFF from photoshops. EPS files must be accompanied by a version in native file format for editing purposes. Existing line drawings should be scanned at a resolution of 1200 dpi and as close as possible to the size where they will appear when printed. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes of atrophic gastritis after treatment. A: ...; B: ...; C: ...; D: ...; E: ...; F: ...; G: ...

Tables

Three-line tables should be numbered as 1, 2, 3 and so on, and mentioned clearly in the main text. Provide a brief title for each table. No detailed legend should be included under the tables. This part should be added into the text where the tables are applicable. The information should complement but not duplicate that contained in the text. Use one horizontal line under the title, a second under the column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P<0.05$, $^{b}P<0.01$ should be noted ($P>0.05$ should not be noted). If there are other series of *P* values, $^{c}P<0.05$ and $^{d}P<0.01$ are used. Third series of *P* values can be expressed as $^{e}P<0.05$ and $^{f}P<0.01$. Other notes in tables or under

illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or some other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.* in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscripts and who endorse the data and conclusions are included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should code the references according the citation order in text in Arabic numerals, put references codes in square brackets, superscript it at the end of citation content or the author name of the citation. For those citation content as the narrate part, the coding number and square brackets should be typeset normally. For example, Crohn's disease (CD) is associated with increased intestinal permeability[1,2]. If references are directly cited in the text, they would be put together with the text, for example, from references [19,22-24], we know that...

When the authors code the references, please ensure that the order in text is the same as in reference part and also insure the spelling accuracy of the first author's name. Do not code the same citation twice.

PMID requirement

PMID roots in the abstract serial number indexed by PubMed (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=PubMed). The author should supply the PMID for journal citation. For those references that have not been indexed by PubMed, a printed copy of the first page of the full reference should be submitted.

The accuracy of the information of the journal citations is very important. Through reference testing system, the authors and editor could check the authors name, title, journal title, publication date, volume number, start page, and end page. We will interlink all references with PubMed in ASP file so that the readers can read the abstract of the citations online immediately.

Style for journal references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). Title of the cited article and italicized journal title (Journal title should be in its abbreviation form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634]

Note: The author should test the references through reference testing system (http://www.wjgnet.com/cgi-bin/index.pl)

Style for book references

Authors: the first author should be typed in bold-faced letter. The surname of all authors should be typed with the initial letter capitalized and followed by their name in abbreviation (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

16 **Pagedas AC**, inventor; Ancel Surgical R&D Inc., assignee. Flexible endoscopic grasping and cutting device and positioning tool assembly. United States patent US 20020103498. 2002 Aug 1

Inappropriate references

Authors should always cite references that are relevant to their article, and avoid any inappropriate references. Inappropriate references include those that are linked with a hyphen and the difference between the two numbers at two sides of the hyphen is more than 5. For example, [1-6], [2-14] and [1, 3, 4-10, 22] are all considered as inappropriate references. Authors should not cite their own unrelated published articles.

Statistical data

Present as mean ± SD or mean ± SE.

Statistical expression

Express t test as t (in italics), F test as F (in italics), chi square test as χ^2 (in Greek), related coefficient as r (in italics), degree of freedom as γ (in Greek), sample number as n (in italics), and probability as P (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p(B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6 24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2 not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format about how to accurately write common units and quantum is at: http://www.wjgnet.com/wjg/help/15.doc

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further mention.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyr*A, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H pylori, E coli, etc.*

SUBMISSION OF THE REVISED MANUSCRIPTS AFTER ACCEPTED

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be copied on a floppy or compact disk. Author should send the revised manuscript, along with printed high-resolution color or black and white photos, copyright transfer letter, the final check list for authors, and responses to reviewers by a courier (such as EMS) (submission of revised manuscript by e-mail or on the *WJG* Editorial Office Online System is NOT available at present).

Language evaluation

The language of a manuscript will be graded before sending for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing; (4) Grade D: rejected. The revised articles should be in grade B or grade A.

Copyright assignment form

Please downloaded CAF from http://www.wjgnet.com/wjg/help/9.doc.

We certify that the material contained in this manuscript:

Ms:

Title:

is original, except when appropriately referenced to other sources, and that written permission has been granted by any existing copyright holders. We agree to transfer to WJG all rights of our manuscript, including: (1) all copyright ownership in all print and electronic formats; (2) the right to grant permission to republish or reprint the stated material in whole or in part, with or without a fee; (3) the right to print copies for free distribution or sale; (4) the right to republish the stated material in a collection of articles or in any other format. We also agree that our article be put on the Internet.

Criteria for authorship: The WJG requests and publishes information about contributions of each author named to the submitted study. Authorship credit should be based on (1)direct participation in the study, including substantial contributions to conception and design of study, or acquisition of data, or analysis and interpretation of data; (2) manuscript writing, including drafting the article, or revising it critically for important intellectual content; (3)supportive work, including statistical analysis of data, or acquisition of funding, or administration, technology and materials support, or supervision, or supportive contributions. Authors should meet at least one of the three conditions. The WJG does not publish co-first authors and co-corresponding authors.

We hereby assign copyright transfer to WJG if this paper is accepted.

Author Name in full (Full names should be provided, with first name first, followed by middle names and family name at the last, eg, Eamonn MM Quigley). Handwritten names are not accepted.

Author Name in abbreviation (Family name is put first in full, followed by middle names and first name in abbreviation with first letter in capital, eg, Quigley EMM). Handwritten names are not accepted.

Abstract

Hepatitis C virus (HCV) infection affects 180 million people worldwide with the predominant prevalence being infection with genotype 1, followed by genotypes 2 and 3. Standard anti-HCV therapy currently aims to enhance natural immune responses to the virus, whereas new therapeutic concepts directly target HCV RNA and viral enzymes or influence host-virus interactions. Novel treatment options now in development are focused on inhibitors of HCV-specific enzymes, NS3 protease and NS5B polymerase. These agents acting in concert represent the concept of specifically targeted antiviral therapy for HCV (STAT-C). STAT-C is an attractive strategy in which the main goal is to increase the effectiveness of antiviral responses across all genotypes, with shorter treatment duration and better tolerability. However, the emergence of resistant mutations that limit the use of these compounds in monotherapy complicates the regimens. Thus, a predictable scenario for HCV treatment in the future will be combinations of drugs with distinct mechanisms of action. For now, it seems that interferon will remain a fundamental component of any new anti-HCV therapeutic regimens in the near future; therefore, there is pressure to develop forms of interferon that are more effective, less toxic, and more convenient than pegylated interferon.

Key words: Hepatitis C virus; Chronic hepatitis C; Polymerase inhibitors; Protease inhibitors; Cyclophilin B inhibitors

INTRODUCTION

Hepatitis C virus (HCV) infection affects 180 million people worldwide, about 3% of the world's population. Globally, 3-4 million persons are newly infected each year, with the predominant prevalence being infection with genotype 1, followed by genotypes 2 and 3. The other genotypes, 4, 5, and 6, have specific geographical distributions. The acute phase of infection is asymptomatic in the majority of cases, but leads to chronic infection in about 70%-80% of affected individuals[1,2]. This results in progressive liver disease and eventually liver cirrhosis, with increased risk of hepatocellular carcinoma[3].

HCV is an enveloped virus belonging to the Flaviviridae family. The virion consists of an outer envelope composed of E1 and E2 proteins covering the nucleocapsid, with a single-stranded RNA genome (Figure 1). The HCV genome encodes structural proteins that form the capsid and envelope, as well as non-structural proteins required for virus replication. The latter are potential targets for new drugs aimed at directly affecting HCV. The non-structural components include proteases and helicase (NS2, NS3 and NS4A), a protein responsible for anchoring the replication complex to intracytoplasmic membranes (NS4B), the RNA-binding protein (NS5A), and RNA-dependent RNA polymerase (NS5B). After entering the cell, HCV RNA is released into the cytoplasm. The genome is directly translated by host enzymes. The HCV polyprotein is subsequently processed by the host and viral proteases into structural and non-structural proteins, including NS5B, which is crucial for HCV replication. There are two viral proteases, NS2-3 and NS3. NS2-3 is responsible for cleavage at the NS2/3 site. NS3 catalyses cleavage at four sites: NS3/4A, NS4A/B, NS4B/5A and NS5A/B. The proteolytic activity of NS3 protease is significantly enhanced by heterodimerization with its cofactor NS4B[4].

CURRENT TREATMENT OPTIONS

The therapy currently regarded as the standard consists of pegylated interferon injections administered once weekly, along with daily oral ribavirin. This combination exerts synergistic antiviral effects, although it is efficient in only about 50% of treated individuals. The most important predicting factor appears to be the HCV genotype. Sustained viral response (SVR) expressed as an absence of detectable serum HCV RNA 24 wk after completion of therapy is achieved in only 33%-42% of patients with genotype 1, but in about 90% of those with genotypes 2 and 3[5]. There are patients who do not achieve an SVR due to unresponsiveness or relapse after treatment, as well as those who lack tolerance to adverse events that occur during treatment. Therefore, there is a need for new therapeutic strategies with higher efficacy, shorter

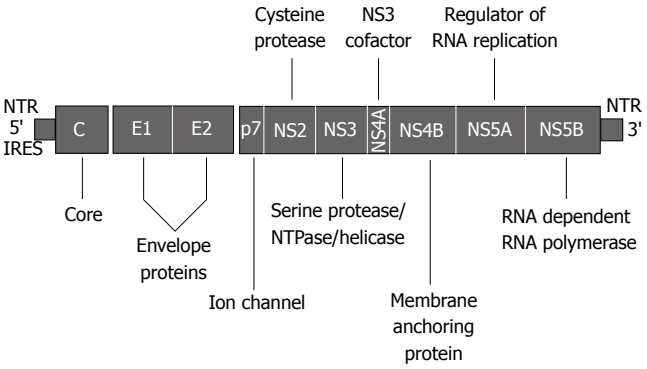

Figure 1 Organization of the HCV genome (adapted from Appel *et al*[4]).

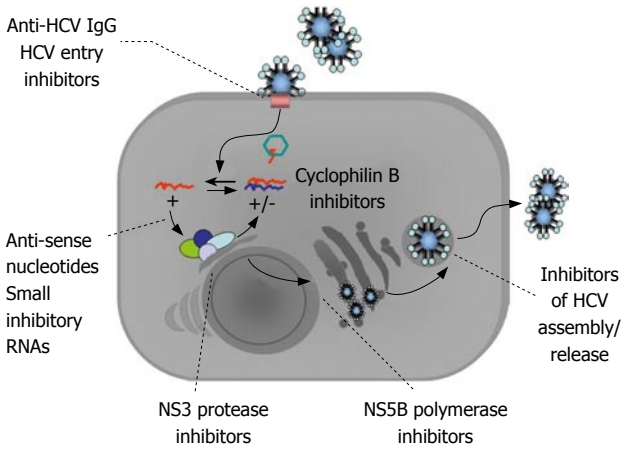

Figure 2 Potential targets for new anti-HCV agents.

treatment duration, convenient routes of administration and favorable side-effect profiles.

The standard anti-HCV therapy currently aims to enhance natural immune responses to the virus; whereas, new therapeutic concepts directly target HCV RNA (anti-sense nucleotides, small inhibitory RNA) and viral enzymes (protease and polymerase inhibitors), or influence host-virus interactions (cyclophilin inhibitors, bavituximab, inhibitors of viral entry) (Figure 2)[6-9]. These findings essentially came from attempts to create an experimental model for studies of the molecular details of the virus and HCV infection of cells. The development of the replicon system and pseudoviruses has greatly contributed to the current knowledge of HCV replication. However, a highlight in recent studies on HCV has been the establishment of a complete cell culture replication system that enables further research into the HCV lifecycle and novel antivirals.

NOVEL ANTIVIRAL AGENTS

Novel treatment options now under intensive development are focused on the inhibitors of HCV-specific enzymes, NS3 protease and NS5B polymerase. The actual protease inhibitors under clinical development are telaprevir and SCH 503034. Among the polymerase inhibitors, several drugs have reached the clinical stage. These include valopicitabine, R1479, HCV-796 and BILB1941. Such agents acting in concert represent the concept of specifically targeted antiviral therapy for HCV (STAT-C). The principle of this new therapeutic strategy is the achievement of higher rates of efficacy, shortened treatment duration, improved tolerability and adherence, oral administration and the possibility for use in special populations (e.g., those with contraindications to interferon). However, the emergence of resistance mutations that limit the use of these compounds in monotherapy complicates the regimens. Thus, a predictable scenario for treatment of HCV in the future will be combinations of drugs with distinct mechanisms of action. Interferon, however, appears pivotal for any new therapeutic regimens.

INTERFERONS IN DEVELOPMENT

Pegylated interferon underpins the current standard of care therapy for HCV. Its immunomodulatory activities with positive pharmacokinetics significantly improve the efficacy of anti-HCV regiments, although the effectiveness of antiviral treatment remains unsatisfactory, especially as regards genotype-1 infections. Another limitation is the frequent occurrence of adverse events, which greatly influence adherence to the treatment regimen. Therefore, there is pressure to develop forms of interferon that are more effective, less toxic, and more convenient than pegylated interferon. Phase 1 clinical trials are in progress with oral forms of interferon (Belerofon; oral interferon alpha). Another goal in the field of interferon development is to obtain forms with a longer half life, which will allow a reduction in the number of injections required and lengthen the period between injections. These agents [IL-29 (PEG-interferon lambda), Belerofon Interferon (long-acting), BLX-883 (Locteron), and Medusa Interferon (Multiferon)] are mostly in the first or second phase of their clinical development. Omega interferon, which is in phase Ⅱ development, is used in an implantable infusion pump that releases a steady amount of interferon for about 1 mo[10]. Albinterferon (IFN-α2b genetically fused to human albumin) and interferon β-1a (REBIF) have reached phase Ⅲ development. Albinterferon is a protein that combines the antiviral properties of IFN-α2b with the prolonged half-life of human serum albumin. Clinical trials have shown that albinterferon administered every 2 wk exerts an antiviral efficacy comparable to that of Peg-IFN-α2a, with a similar frequency of occurrence of adverse events and laboratory abnormalities[11]. Consensus interferon (Infergen) administered daily is currently in phase Ⅳ clinical trials, and research evaluating its usefulness in treatment of prior non-responders is ongoing, with promising interim results[12,13].

PROTEASE INHIBITORS

Telaprevir (VX-950), an investigational oral selective inhibitor of HCV NS3/4A protease[14], appears to be the one of most advanced therapeutic agents that specifically target the HCV lifecycle. Clinical phase Ⅱb studies utilizing VX-950 are ongoing. These include the PROVE

1 and PROVE 2 trials that have enrolled 260 and 320 treatment-naïve HCV genotype 1 patients, respectively, and the PROVE 3 study in patients with HCV genotype 1, previously treated by standard of care therapy (at least one prior course of peginterferon with ribavirin).

The phase Ⅰb studies showed that VX-950 had potent anti-HCV activity in monotherapy, which led to a rapid decline in HCV RNA of about 3 log within 3 d in all dosage groups (450 mg q8h, 750 mg q8h and 1250 mg q12h), both in genotype 1 treatment-naïve patients and non-responders to prior treatment. In the optimal dose group, 750mg q8h, the highest plasma concentration was achieved with a 4.4 log reduction in HCV RNA load at d 14. When sub-optimal doses were applied, maximal HCV RNA reduction was seen after 3-7 d treatment, with any following increase in viral load being related to the selection of HCV variants less sensitive to VX-950[15,16]. Moreover, other studies have reported that the abovementioned HCV RNA fluctuations, as well as alanine aminotransferase (ALT) levels during treatment correlated with the concentration of neopterin - a monocyte/macrophage-derived factor that can be considered an indicator of inflammatory activity during the course of chronic C hepatitis[17,18]. Furthermore, the ultrasound evaluation of perihepatic lymph nodes (PLNs) in HCV-infected individuals undergoing treatment with telaprevir alone showed a significant reduction in PLN volume after 14 d therapy. This suggests that VX-950 may have the ability to reduce inflammatory activity in liver tissue; however, this research is limited by a lack of objective parameters for inflammatory activity, such as histopathological evaluation[19].

The HCV NS3 protease diversity determined before administration of VX-950 appears to have no predictive impact for the effectiveness of antiviral responses[20]. Whereas, identification of HCV NS3 protease variants after 14 d treatment demonstrates the emergence of mutations that implicate varying decreases in sensitivity to VX-950, low-level resistance characterized by V36A/M, T54A, R155K/T, and A156S mutations, and high-level resistance determined by the emergence of A156V/T, V36A/M-R155K/T, and V36A/M-A156V/T variants. Each dosage group has a distinct mutation pattern that results from the different levels of drug pressure on the variants selected. It has been suggested that these drug-resistant variants pre-exist at a minimal frequency before the introduction of treatment, because of the low fidelity of HCV polymerase and the high rate of HCV replication. Resistant variants appear to be less fit and have lower replication rates compared to wild type; therefore, they may not be detected prior to treatment[21,22].

Further studies of VX-950 administered with peginterferon, with or without ribavirin, have confirmed the advantageous effect of combination therapy on virus selection. Data presented at the American Association for the Study of Liver Diseases (AASLD) Meeting in 2006 demonstrated a 5.5 log HCV RNA drop when VX-950 was combined with peginterferon α2a *vs* a 1 log drop in those receiving peginterferon alone, and a 4 log decrease in monotherapy with VX-950 at d 14 of the study[23]. With regard to selection of the resistant variant, this study provides evidence of the suppressing effect of peginterferon when it is included in a combination therapy regimen, or is applied as a follow-on after discontinuation of VX-950, thus indicating that VX-950-resistant variants remain sensitive to the standard care therapy. This observation is consistent with *in vitro* research confirming the decreased replication capacity of resistant variants while the sensitivity to interferon is fully retained[22]. Interestingly, in a few patients receiving VX-950 alone, the higher level resistant variant A156V/T emerged, but was subsequently suppressed by therapy with VX-950 followed by peginterferon and ribavirin. In this study, all patients receiving peginterferon and ribavirin subsequent to 14 d treatment with VX-950 had undetectable HCV RNA at the end of wk 24. However, the discontinuation of therapy at that point in individuals with undetectable HCV RNA at wk 12, resulted in relapses in two of the four patients from the VX-950 monotherapy group, and one of six from the VX-950 with peginterferon group, which showed the advantages of combination therapy over monotherapy[23,24]. The interim results after 12 wk of the PROVE 1 study, the first major phase Ⅱ clinical trial to evaluate VX-950, are now available. Analysis shows a definitely higher incidence of undetectable HCV RNA [limit of detection (LOD) 10 IU/mL] at wk 12 in patients receiving VX-950 in combination with peginterferon and ribavirin, in contrast to those receiving standard therapy (88% *vs* 52%). The frequency of adverse events was comparable in the telaprevir-treated and control groups. However, discontinuation due to adverse events was higher in the telaprevir than in the control groups, 9% *vs* 3%. The adverse events most frequently reported in the telaprevir group included rashes (3%), gastrointestinal disorders and anemia. The incidence of serious adverse events in the telaprevir groups was about 3% compared to 1% in the control[25]. Further research on telaprevir that aimed to assess its activity against the NS3/4A proteases of HCV genotypes 2, 3 and 4 was presented at the European Association for the Study of the Liver (EASL) Meeting in 2007. *In vitro* studies have demonstrated that the VX-950 activity against genotypes 2a, 2b, 3a and 4a is similar to that for genotypes 1a or 1b. Moreover, NS3/4A protease heterogeneity seems to have an unremarkable impact on VX-950 suppressive activity. Hence, it has been suggested that the majority of genotype-specific polymorphic sequences are located peripherally to the active sites of HCV protease, and do not affect binding of the agent molecule[26]. This investigation confirms the necessity for further research in this subject area. By contrast to the above are observations of telaprevir activity in a liver biopsy model of HCV infection. Cell cultures from liver biopsies of patients with genotype 1 and non-genotype 1 HCV were exposed to VX-950, which resulted in a significant decrease in HCV genotype 1 RNA, but only a minimal effect in non-genotype 1 HCV[27]. Thus further studies are required.

Another HCV protease inhibitor, SCH 503034, orally bioavailable with satisfactory pharmacokinetics and a good safety profile, is being tested in a phase Ⅱ clinical trial[28]. *In vitro* studies have determined its anti-viral activity on its

own, and an additive effect in combination with interferon α-2b[29,30]. Monotherapy with SCH 503034, at a dose of 400 mg q8h, in HCV-genotype-1-infected non-responders to prior standard therapy resulted in a 2.06 log reduction of the mean maximum viral load during the 14 d period of observation. Moreover, the HCV RNA decline correlated with ALT activity, and both of these parameters appeared to be dose-dependent. It is important to mention that the frequency of adverse events was comparable to the control group receiving a placebo[31]. Similar to telaprevir, further research into combination therapy with SCH 503034 and peginterferon has shown advantages over monotherapy with SCH 503034 or peginterferon. The mean maximum HCV RNA decline was dose-dependent, 2.4 log and 2.9 log for 200 mg q8h and 400 mg q8h, respectively, of SCH 503034 with peginterferon[32]. Another study designed to evaluate the antiviral effects of a combination of an NS3 protease inhibitor with a polymerase inhibitor strongly supports the concept of STAT-C. In this research, genotype 1b HCV replicon cells, wild-type, as well as replicons with reduced susceptibility to protease inhibitors or polymerase inhibitors, were exposed to a combination of SCH 503034 with the polymerase inhibitor HCV-796. The results were encouraging; the antiviral effect of these two agents was additive, with a favorable cross-resistance profile. Furthermore, the emergence of resistant viral variants was less frequent compared to that for monotherapy[33].

ITMN-191, a novel agent with a high genetic barrier to emergence of resistance mutations, is in preclinical development and has been shown to retain significant potency against variants with decreased sensitivity to other protease inhibitors[34]. Other *in vitro* studies have shown that ITMN-191 displays synergistic antiviral activity in combination with interferon[35,36], as well as HCV polymerase inhibitor R1479[37].

Recently, the clinical trials for BILB2061, another specific and potent inhibitor of HCV NS3 protease, were halted due to drug-induced cardiotoxicity[38].

ACH-806 is a novel anti-HCV agent, currently in phase Ⅰ/Ⅱ clinical studies, which has a distinct mechanism of action. Preclinical data have demonstrated that ACH-806 inhibits HCV genotype 1 replication *via* binding to NS4A and consequently blocks the formation of HCV replication complexes[39]. Resistance induction studies in replicon cells have shown a lack of cross resistance between ACH-806 and protease or polymerase inhibitors; thus confirming its different mode of action. Interestingly, viral quasispecies resistant to protease or polymerase inhibitors remain sensitive to ACH-806 and vice versa[40]. *In vitro* studies of a combination of ACH-806 with telaprevir or valopicitabine or interferon have demonstrated potent antiviral effects, which are synergistic when cells are exposed to ACH-806 with telaprevir or ACH-806 with valopicitabine. Hence the authors have concluded that ACH-806 could in the future become a potent component of STAT-C. Clinical studies preformed on genotype 1 HCV-infected subjects have shown an ~ 1 log reduction in HCV RNA at d 5. Further research on ACH-806 has been limited because of reversible nephrotoxicity reported in a clinical trial[41].

POLYMERASE INHIBITORS

The inhibitors of HCV NS5B polymerase influence different steps in RNA synthesis, from initiation to elongation through binding to the enzyme's active sites. Valopicitabine (NM283) appears the most advanced orally bioavailable pro-drug of a ribonucleoside analogue that displays an ability to sufficiently inhibit HCV NS5B polymerase. It is currently in phase Ⅱ clinical development. It has been shown that NM283 given as monotherapy exhibits significant, dose-related antiviral activity in both treatment-naïve and non-responders to prior interferon therapy. This effect was marked and synergistic, with a mean HCV RNA reduction of 2.7 log at d 28 when NM283 was administered in combination with peginterferon[42]. Studies in genotype 1 HCV-infected treatment-naïve patients showed an intense HCV RNA decline of about 4 log at wk 24 when NM283 was included in the regimen[43]. However evaluation of the side effects, mainly gastrointestinal and hematological disorders at higher doses, resulted in revision of the dosages. Interestingly, at higher doses, NM283 developed superior rapid response rates, although after 12, 24 and 36 wk of treatment the results were similar in all the different dose groups. Hence, low-dose NM283 in combination with peginterferon seems to display marked antiviral effects with fewer adverse events[43,44]. Moreover, there are promising results of *in vitro* research into the efficacy of NM283 against HCV variants resistant to protease inhibitors. All mutations tested conferring resistance to protease inhibitors were sensitive to NM283, thus supporting the advantages of combination therapy. As well, only a single mutation (S282T), described in the highly conserved B domain of NS5B, has so far been identified as determining moderate resistance to NM283[45]. In a separate study, a combination of two agents with distinct mechanisms of action, NM283 and SCH 503034, revealed enhanced anti-replicon activity, without observed cross-resistance[46]. These data support the initiative to develop combination regimens for treatment of HCV infections.

Other polymerase inhibitors currently in clinical development are nucleoside analogue R1479 (prodrug R1626) and non-nucleoside analogues HCV-796 and BILB1941. In phase I trials, R1626 has been shown to induce the greatest viral load reduction in genotype 1 HCV-infected patients, so far reported among this class of antiviral agents. It was a 3.7 log mean HCV RNA decline for 4500 mg q12h at d 14, and a 2.6 log decline for the lower dose of 3000 mg q12h, but with better tolerability[47]. *In vitro* analysis of the antiviral effects exerted by combinations of R1479 with interferon or ribavirin have demonstrated synergistic effects, whereas with other direct antivirals the effects were additive[48]. Another compound, HCV-796, when utilized in monotherapy exhibited dose-related anti-HCV activity across multiple genotypes, and with a good tolerability profile. Although, a selection of variants with reduced susceptibility was observed, they retained sensitivity to

interferon[49]. Associated studies of combined HCV-796 and peginterferon have confirmed the increased antiviral response to therapy, which was more intense in non-genotype 1 HCV[50]. In a clinical evaluation, polymerase inhibitor BILB 1941 showed anti-HCV activity; however, a high discontinuation rate due to adverse events within the group with appropriate pharmacokinetics was observed[51].

Several novel compounds are now being tested in preclinical trials; these include PSI-6130, GSK 625433, A-848837, A-837093 and AG-021541[52-56]. Additional studies should determine whether these polymerase inhibitors reach a clinical development stage in the future.

CYCLOPHILIN INHIBITORS

The favorable complementary elements of various prospective therapies seem to be the cyclophilin inhibitors, which exhibit peculiar mechanisms of action based on targeting of virus-host interactions. Cyclophilin B (Cyp B) has been shown to serve as a cellular cofactor of the NS5B RNA-dependent RNA polymerase that promotes HCV replication[57,58]. Thus the blocking of Cyp B appears to be an attractive target for the development of new anti-HCV agents[59-61]. The first compound shown to exhibit inhibitory properties with reference to cyclophilins was cyclosporin A (CsA)[60-62]. It was shown that its antiviral activity against HCV was distinct from its immunosuppressive function, which was dependent on anti-calcineurin activity[60-63]. Clinical studies on a regimen based on a combination of CsA with interferon-α demonstrated a high antiviral potency compared to that with interferon alone[63]. However, the immunosuppressive function of CsA limits its usefulness in anti-HCV therapy. Moreover, there are various opinions regarding the benefits of administering CsA *vs* tacrolimus in post-liver transplantation management of individuals with HCV infection[64,65]. The available data are limited, and the results are equivocal[66,67]. Thus, further studies are required in this area.

The first synthesized CsA derivate found to be devoid of immunosuppressive activity was NIM811. It has been investigated in regard to its anti-HIV inhibitory features[68,69]. Recent studies have confirmed its anti-HCV activity *in vitro*. The reduction of HCV RNA in replicon cells was more potent, even at low concentrations, compared to CsA. Moreover, NIM811 shows activity against HCV in replicons with high resistance to protease or polymerase inhibitors. Also, combinations of NIM811 with other groups of HCV inhibitors display at least additive effects[71]. Analogous results, with potentially synergistic effects, have been obtained when HCV replicon cells were exposed to a combination of NIM811 with interferon-α[72]. The anti-HCV activity of NIM-811 exerted at low drug concentrations infers reduced potential side effects from the therapy. Hence, *in vivo* evaluations of the safety profile, pharmacokinetics and anti-HCV activity need to be undertaken.

The first oral non-immunosuppressive cyclophilin B inhibitor, Debio 025, to enter into clinical trials displayed potent antiviral effects in chimeric mice, and the effect was enhanced in combination with pegylated interferon[72]. *In vitro* studies have demonstrated that Debio 025 has a unique potency for clearing HCV replicon cells of virus when used alone or in combination with other antivirals. The combination of Debio 025 with interferon α-2a results in additive to slightly synergistic antiviral effects. Resistant replicon cells, selected by passage in increasing concentrations of Debio 025, are sensitive to protease or polymerase inhibitors and interferon[73]. Moreover, Debio 025 exerts antiviral activity against wild-type HCV, as well as HCV replicons resistant to protease or polymerase inhibitors. The emergence of resistant variants to protease inhibitors (VX-950, BILB 2061) is restrained by the presence of Debio 025[74]. Clinical research shows that Debio 025 exerts both anti-HIV and anti-HCV activity in HIV/HCV co-infected subjects. The anti-HIV effect at d 15 was a 1 log decrease in viral load when the dose was 1200 mg q12h. HCV viremia decline was more profound, reaching 3.6 log at d 15. However, at this dose, transitional hyperbilirubinemia led to the discontinuation of treatment in some patients[6]. Debio 025 has been shown to exert anti-HCV activity in both genotype 1 and non-genotype 1 infections. Interestingly, no signals of emerging mutation appeared during the period of observation, which suggests a possible ability for this agent to suppress selection of resistant variants[75].

Recently the novel non-immunosuppressive CsA derivate, SCY-635, has been evaluated in preclinical studies that have demonstrated its favorable properties as an anti-HCV agent. Compared to CsA, this compound has good affinity with cyclophilin, and exerts potent antiviral activity with suitable pharmacokinetics and lower cytotoxicity. The combination of SCY-635 with interferon-α has antiviral effects on HCV replicon cells that range form additive to synergistic; thus supporting the need for more evaluations of this drug in anti-HCV treatment options[7].

CONCLUSION

Specifically targeted antiviral therapy, through interference in the replication cycle, leads to the selection of resistant variants[76-78]. This observation has been confirmed in several studies focusing on STAT-C agents as used in monotherapy. Combination therapy displays higher antiviral efficacy and has a fundamental impact on the selection of HCV strains with concomitantly reduced sensitivity and decreased viral fitness. It has also been shown that protease and polymerase inhibitors demonstrate advantageous cross-resistance profiles with improved anti-HCV activity, which supports the STAT-C development initiatives. Interestingly, the introduction of interferon to regimens based on novel compounds not only augments antiviral effects, but has a strong suppressive activity against the emergence of resistant mutations. Considering this, it is seems unlikely that interferon will be eliminated from antiviral regimens in the near future.

STAT-C presents an attractive strategy, one in which the main goal is to increase the effectiveness of antiviral responses across all genotypes, with shorter

Table 1 Anti-HCV agents currently under clinical development

Compound		Clinical advancement nt	Viral efficacy	Resistance (HCV resistant variants)	Remarks
Protease inhibitors	Telaprevir	Ⅱ	(dose-750 mg q8h; genotype-1)	Low level: V36A/M, T54A, R155K/T, A156S	Rash, GI and hematological adverse events (AE)
	(VX-950)	PROVE-1, 2, 3	VLR = 3 log d 3 VLR = 4.4 log: d 14 VLR = 5.5 log: d 14 when combined with PEG-IFNa2a	High level: A156V/T, V36A/M-R155K/T, V36A/M-A156V/T; After 14 d of treatment	
	SCH 503034	Ⅱ	(dose 400 mg q8h; genotype-1) VLR = 2.06 log d 14 VLR = 2.9 log: when combined with PEG-IFN	Low to moderate levels: V170A T54A A156S High level: A156T	Frequency of AE comparable to control group receiving placebo
Inhibitor of protease cofactor NS4A	ACH-806	Ⅰ / Ⅱ	VLR = 1 log: d 5	Single mutation at N-terminus of NS3; lack of cross resistance to any of the polymerase inhibitors or protease inhibitors now under development	Reversible nephrotoxicity
Polymerase inhibitors	Valopicitabine (NM283)	Ⅱ	VLR = 0.8 log: d 28 VLR = 2.7 log: d 28, when combined with PEG-IFN VLR = 4.24 log: wk 24, when combined with PEG-IFN	S282T	GI and hematological AE
	R1479 (R1626)	Ⅱ	VLR = 3.7 log for 4500 mg q12h at d 14, VLR = 2.6 log for 3000 mg q12h	no data	Mild to moderate hematological AE with increasing doses
	HCV-796	Ⅱ	VLR = 1.4-1.5 log: d 4 VLR = 3.3-3.5 log: d 14, when combined with PEG-IFN	C316Y	Mild to moderate headache-the most frequent AE; no treatment-emergent serious AE
	BILB 1941	Ⅰ	Data incomplete due to high discontinuation rate	No data	GI AE
Cyclophilin inhibitors	DEBIO 025	Ⅰ	VLR = 3.6 log: d 14 of monotherapy	No breakthrough during the treatment	Transitional hyperbilirubinemia

treatment duration and better tolerability. Recent studies have shown that these aims are within reach. Novel therapeutic agents are already in advanced clinical development; listed here in Table 1. Although there are many limitations pertaining to the STAT-C strategy; including variable bioavailability, and different effects exerted against various HCV genotypes and even quasispecies. A disadvantage of direct interference in the virus replication cycle is the increased rate of resistant mutations, but this could be ameliorated by the use of multiply agents with different mechanisms of actions. In combination with interferon, these drugs could augment antiviral effects and reduce some of the toxic side effects of this cytokine. On the other hand, the toxicity of new agents needs to be carefully evaluated, along with their pharmacokinetics, safety and effective doses. New regimens will also need to be worked out. Currently, it appears that interferon will remain as an element of anti-HCV therapy in the near future; indeed its effectiveness could be elevated by the introduction of new drugs.

Abstract

Hepatitis B virus (HBV) is a highly pathogenic virus that causes chronic liver diseases in millions of people globally. In addition to a symptomatic, serologically evident infection, occult persistent HBV carriage has been identified since nucleic acid amplification assays of enhanced sensitivity became introduced for detection of hepadnaviral genomes and their replicative intermediates. Current evidence indicates that occult HBV infection is a common and long-term consequence of resolution of acute hepatitis B. This form of residual infection is termed as secondary occult infection (SOI). The data from the woodchuck model of HBV infection indicate that exposure to small amounts of hepadnavirus can also cause primary occult infection (POI) where virus genome, but no serological makers of exposure to virus, are detectable, and the liver may not be involved. However, virus replicates at low levels in the lymphatic system in both these forms. We briefly summarize the current understanding of the nature and characteristics of occult hepadnaviral persistence as well as of its documented and expected pathological consequences.

Key words: Hepatitis B virus; Hepadnaviruses; Woodchuck hepatitis virus; Hepadnaviral hepatitis; Occult viral persistence; Hepadnavirus lymphotropism; Primary occult infection; Secondary occult infection; Virus reactivation

INTRODUCTION

Despite the availability of effective prophylactic vaccines, hepatitis caused by hepatitis B virus (HBV) remains one of the most troublesome infectious diseases responsible for significant morbidity and mortality in the world. HBV-induced chronic hepatitis B (CHB), defined as a prolonged liver inflammation accompanied by HBV surface antigen (HBsAg) in serum for longer than 6 mo, develops in up to 10% of individuals infected as adults and in about 85% of individuals exposed in the neonatal period and early childhood[1,2]. Consequently, up to 400 million people worldwide are afflicted with serum HBsAg-positive chronic infection, which in high endemic areas is mainly acquired by vertical virus transmission[3]. Furthermore, it is estimated that as much as one third of the world population have been exposed to HBV[4]. Many of these individuals may unknowingly carry the virus. It is assumed that, due to low virus loads in many of the cases, HBV may not be identifiable by commonly used serological assays based on detection of HBsAg and that the infection is often asymptomatic or has non-specific symptoms. This serologically and clinically unapparent infection makes the true global incidence of HBV hard to estimate. Consequently, the pathogenic significance of HBV might be much greater than that currently assumed.

OCCULT HBV INFECTION

The clinical data and the findings from animal models accumulated in the past ten years strongly argue that persistent, serologically silent, i.e., serum HBsAg-negative, HBV infection is a natural consequence of resolved acute hepatitis B, but it may also occur following an asymptomatic exposure to HBV, and may have serious pathological and epidemiological repercussions. Another important aspect of infections with HBV and other related viruses, that has been known for a long time but remained controversial and/or not fully realized, is the fact that the immune system, in addition to the liver, is the site of active hepadnaviral replication and long-term persistence.

Occult HBV infection is defined as the existence of HBV DNA in the serum, cells of the lymphatic (immune) system, and/or hepatic tissue in the absence of serum HBsAg. Most frequently, occult HBV infection follows

resolution of acute hepatitis and continues indefinitely after clearance of HBsAg and biochemical improvement in liver function[5-9]. For this reason, this form of infection is termed as residual or secondary occult infection or SOI, in opposite to primary occult infection or POI, which will be discussed later. Serological testing in SOI normally reveals the presence of antibodies to HBV core antigen (anti-HBc), which are now recognized not only as a valuable marker of prior exposure to HBV but also as an indicator suggesting actually progressing occult HBV infection. Nonetheless, recent estimates suggest that up to 20% of individuals with occult HBV carriage evidenced by HBV DNA detection could be nonreactive for anti-HBc or any other serological indicator of exposure to HBV[7]. It also is of note that the detection of naturally acquired antibodies to HBsAg (anti-HBs) does not exclude the existence of occult infection[5-7,9].

DETECTION OF OCCULT HEPADNAVIRAL PERSISTENCE

One of the main current challenges in diagnosis of occult HBV infection is the relatively low sensitivity of HBV DNA detection assays. The present assays are based on different approaches to amplification of HBV DNA by polymerase chain reaction (PCR) and their lowest detection limits range between 200 and 1000 virus genome copies, which are also referred to as virus genome equivalents (vge) per mL of plasma or serum. Although these assays are adequate to detect prodromal and symptomatic HBV infections and to monitor the progress of antiviral therapy, they are yet not sufficiently sensitive to identify occult infection in the majority of the individuals affected, where serum loads are usually below 100 vge per mL, as well as to determine whether virus was indeed completely eradicated following antiviral treatment[9]. In contrast to the clinical assays, the current research tests, which in our laboratory apply nested PCR and detection of resulting amplicons by nucleic acid hybridization (NAH), i.e., PCR/NAH, identify hepadnaviral DNA at loads below 10 vge/mL[10,11]. Furthermore, by testing of serial samples of serum and peripheral blood mononuclear cells (PBMC) and, when feasible, liver biopsies, and by amplifying different non-overlapping regions of the virus genome, detection of occult infection is greatly enhanced[9]. Application of these ultrasensitive assays to investigation of clinical materials and animal models, particularly the woodchuck model of hepatitis B, led to identification in the last decade of occult hepadnavirus infection as a new, distinctive entity and to delineation of its unique characteristics. However, due to yet limited population-based studies and relatively low sensitivity of the assays approved for clinical testing, the full impact of this infection remains to be determined. Nonetheless, with the recent introduction of clinical HBV nucleic acid testing (HBV NAT) in many parts of the world, significant progress in this area is expected.

EXPERIMENTAL OCCULT HBV INFECTION IN THE WOODCHUCK MODEL

Many of the characteristics of occult HBV infection have been originally identified in the woodchuck model of hepatitis B[5]. Woodchuck hepatitis virus (WHV) infecting the Eastern North American woodchuck (*Marmota monax*) is accepted as the most adequate, natural model of human HBV infection, hepatitis B and HBV-induced hepatocellular carcinoma (HCC). WHV closely resembles HBV in the structure, biology, and in the patterns and outcomes of the liver diseases induced. Much of the basic understanding of the natural course, requirements for transmission, molecular and immunological properties of occult hepadnaviral carriage, and its long-term pathological ramifications is owed to the woodchuck-WHV experimental system[10-15].

Occult WHV infection was first identified as a residual, life-long persistent infection in woodchucks who apparently completely resolved experimental acute hepatitis and developed anti-WHs (antibodies to WHV surface antigen, WHsAg)[10]. Analysis of sequential sera, PBMC and liver biopsies collected during the lifespan of these animals, as well as autopsy lymphatic and hepatic tissues, using sensitive PCR/NAH assays, identified WHV DNA in all three compartments, i.e., serum, lymphoid cells and the liver. In addition, the WHV replicating intermediates, covalently closed circular DNA (cccDNA), and virus mRNA were consistently found in the cells of the lymphatic system and the liver. Anti-WHc (equivalent of anti-HBc) persisted in all animals for life. This form of WHV infection become later termed as SOI[5,14]. In addition and unexpectedly, a low grade, intermittent liver inflammation was diagnosed throughout the remaining life in the majority of the woodchucks who apparently completely resolved acute hepatitis[10]. Not less importantly, one fifth of the animals developed HCC in 3-5 years after recovery and despite anti-WHs presence[10]. The same rate of HCC development was reported in woodchucks recovered from acute hepatitis which were examined by other investigators[16]. Most recently, it has also been shown that residual WHV in animals with SOI can be reactivated by treatment with an immunosuppressive agent, Cyclosporin A, leading to transiently serum WHsAg-positive infection[17]. Taken together, the data accumulated indicate that despite resolution of acute hepatitis, the replication of WHV continues for life, albeit at very low levels, both in the liver and the lymphatic system, that limited inflammatory process continues in hepatic tissue, and that the silently persisting virus may retain its oncogenic potency. This implies that although the immune system is able to resolve acute hepatitis and can keep persistently propagating hepadnavirus under relative control, it is unable to eradicate the virus completely[10,14]. The same conclusion was recently reached when bicistronic WHV core-gamma interferon (IFN) DNA vaccine was found to be able to prevent WHV hepatitis, but could not mount sterile immunity and prevent establishment of occult infection[18]. Furthermore, it became apparent that the detection of anti-WHc in the absence of other serological indicators of infection is a reliable indicator of occult WHV persistence[15]. This state, similarly as strong HBV-specific cytotoxic T cell (CTL) and T helper lymphocyte responses detectable years after resolution of acute hepatitis B[19,20], is likely a consequence of sustained restimulation of the immune system with a

viral protein produced during low-level virion assembly[15]. The high degree of compatibility between WHV and HBV infections and the data from studies on otherwise healthy anti-HBc-positive individuals[21,22] suggest that the occurrence of isolated anti-HBc could also be of value in identifying occult HBV persistence.

The virus recovered from woodchucks with SOI remains infectious. It was observed that WHV harvested from PBMC isolated during SOI and *ex vivo* stimulated with lipopolysaccharide (LPS) induced classical acute WHV hepatitis in virus-naive animals[10]. Furthermore, woodchuck dams with SOI were found to transmit virus to offspring, however, the infection induced frequently displays characteristics different than those of SOI[11]. Thus, WHV DNA and WHV cccDNA was harboured only in the lymphatic system, but not in the liver, and in the absence of serological markers of infection, including anti-WHc antibodies. This form of hepadnaviral infection was later named as primary occult infection or POI[14]. Interestingly, POI, in contrast to SOI, is not associated with protection from reinfection and hepatitis after challenge with liver pathogenic doses of WHV[11]. In subsequent studies, the same profile of occult infection was experimentally induced in adult animals by intravenous injections with WHV doses lower than 1000 virions[14]. At the same time, it was also established that WHV quantities higher than 1000 virions, in addition to infecting the lymphatic system, consistently cause classical acute hepatitis. This revealed that doses greater than 1000 virions are liver pathogenic in woodchucks[14]. From these data it was inferred that the threshold level of WHV required to infect lymphoid cells is 100 to 1000-fold lower than that to infect hepatocytes. WHV sequence variation was not responsible for the induction of these two contrasting forms of infection[14].

At the present time, POI is the entity which has not yet been convincingly identified in humans. However, the detection of occult HBV DNA-positive, anti-HBc-negative infection may suggest its existence. The persistence of trace amounts of replicating virus, especially at the extrahepatic locations, could have an impact in terms of unforeseen virus transmission and induction of disorders which are not yet considered to be related to hepadnaviral infection. Small quantities of the virus carried across the placenta may induce POI, similarly to CHB developing in neonates born to mothers with serum HBsAg-positive infection.

OCCULT HEPADNAVIRAL INFECTION AND THE HOST'S IMMUNE SYSTEM

Since the cells of the immune system are clearly the site of WHV propagation, independent of whether infection is symptomatic or occult, it became of interest to enumerate the cells carrying the virus in different forms of experimentally induced infection. By applying *in situ* PCR combined with flow cytometric quantification of cells containing amplified WHV core gene sequences, the proportion of WHV DNA-positive circulating lymphoid cells was found to range from 3.4% to 20.4% (mean 9.6%) in serum WHsAg-positive hepatitis, as compared to 1.1% to 14.6% (mean 4.8%) in occult WHV infection[13]. There was no difference between SOI and POI in the numbers of infected cells.

In terms of WHV-specific T cell responses, recent studies have shown that animals with POI display weak but evident, persistent and multispecific virus-specific T cell proliferative reactivity and that this cellular response does not provide protection against challenge with liver pathogenic doses of WHV[23] (Gujar *et al*, manuscript in preparation). The existence of active peripheral WHV-specific T cell response and innate immune cell activation in the livers of animals with SOI have also been established[12] (Gujar *et al*, manuscript in preparation). Overall, the findings in experimental SOI in woodchucks are closely compatible with those reported for humans convalescent from acute hepatitis B[19,20].

PRIMARY VERSUS SECONDARY OCCULT WHV INFECTION

In summary, experimental occult hepadnaviral infection occurs in two distinctive forms, as primary and secondary infection. POI is induced upon exposure to WHV doses at or below 1000 vge and engages the lymphatic system, although the infection with time may also spread to the liver[11,14]. Animals with POI carry virus in serum and lymphoid cells at levels which are comparable with those occurring in SOI and mount virus-specific T cell proliferative response, but they do not have serological (immunovirological) markers of infection and they are not protected from challenge with liver pathogenic doses of the virus. On the other hand, in SOI, a low-level replication of the virus progresses in both the liver and the lymphatic system, anti-WHc and frequently anti-WHs are detectable, and the animals are protected from hepatitis when re-exposed to liver pathogenic doses of WHV. Moreover, while SOI can be accompanied by low grade, protracted liver inflammation and HCC may finally develop, the liver is entirely normal in POI and a possible development of hepatoma has not yet been assessed.

IMPLICATIONS OF OCCULT HEPADNAVIRAL PERSISTENCE

Given the high degree of similarity between WHV and HBV and infections induced by these viruses, it is important to recognize the impact of silent HBV persistence in terms of its overall incidence, infectivity and pathogenic consequences. The previous clinical and research focus on the liver as essentially the only reservoir of HBV has somehow restricted characterization of extrahepatic sites of hepadnaviral replication and its potential pathological consequences. Recent studies are bringing occult HBV infection and the virus' lymphotropic nature to the forefront. Some of the cardinal works on occult HBV infection were accomplished by examining lymphoid cells of patients with resolved acute hepatitis B where HBV DNA sequences were found[19,24,25]. Furthermore, immunological studies showed that vigorous CTL and T cell proliferative

responses specific against HBV antigens persisted for years after recovery[19,20]. Many case reports also indicate that immunosuppression caused by chemotherapy[26,27], immunomodulatory agents[28], or immune deficiencies, such as HIV infection[29] or hematological malignancies[30], can reactivate occult infection. As in woodchucks with SOI, mild necroinflammation has been documented in liver samples obtained many years after recovery from acute hepatitis B[31,32]. Liver fibrosis and cirrhosis of unknown origin has now been explained by occult HBV infection in many retrospective studies[33,34]. There also is strong evidence for the risk of HCC development in patients with occult HBV[35-38] and this risk is further elevated in alcoholics[39] and in patients with other liver ailments, like hepatitis C[40]. Interestingly, convincing evidence points to the conservation of the HBV genome sequence in occult infection, negating the possibility that faulty HBsAg production accounts for all incidences of occult infection[32,41]. On the other hand, studies demonstrating the passage of HBV in non-liver cells, such as stem cells[42,43] and bone marrow[44], and by blood donations collected from individuals with occult HBV[45] are increasingly frequent in the literature. Recent estimates suggest that transient HBV DNA levels of up to 10^4 vge/mL can be found in sera from apparently healthy individuals with occult infection, which evade detection by current clinical assays, especially when testing is done on single serum or plasma samples[9,46].

CONCLUSION

The seriousness of the consequences of occult HBV infection is yet not fully recognized. Accumulated evidence indicate that occult HBV can be both a source of virus contamination in blood and organ donations, as well as the reservoir from which full blown hepatitis can arise. The oncogenic potency of occult HBV persistence becomes progressively evident. This silent infection can also affect the progression and outcomes of other viral diseases, particularly hepatitis C. It can be expected that while the burden of CHB will decrease with time due to introduction of more effective antiviral therapies, occult HBV infection could become a main concern. Understanding in its entirety of the nature and consequences of this form of HBV persistence should be of a high priority and this quest has already been initiated.

Abstract

Non-specific abdominal complaints are a considerable problem worldwide. Many patients are affected and many differential diagnoses have to be considered. Among these, carbohydrate malabsorption seems to play an important role. However, so far, only incomplete absorption of lactose is broadly accepted, while the malabsorption of fructose and sorbitol is still underestimated, although in many parts of the world it is much more frequent. Despite the success of dietary interventions in many patients, there are still a lot of unanswered questions that make further investigations necessary.

INTRODUCTION

The incomplete absorption of carbohydrates may cause serious problems for the affected patients, and is a frequent cause of so-called non-specific abdominal complaints. Non-specific abdominal complaints are characterized by a lack of morphological or biochemical abnormalities in the affected patients[1,2]. These complaints are a major problem throughout the world, with up to 30% of the population in Western countries being affected. Although only a minority seek medical attention, some 20%-50% of patients are referred to gastroenterologists so because of these non-specific complaints[2]. A study in Germany[3] has reported similar data, with 30% of the population being affected. A quarter of the patients required medical treatment, and no other diagnosis could be established in two-thirds of the cases. Similar findings have been described in Africa[4]; the rates appear to be lower in Asia, although they are still substantial, with a prevalence of up to 10% being reported[5].

There is a wide range of symptoms; the predominant ones are pain, flatulence, constipation and diarrhea. These symptoms should always be distinguished from those such as anemia, weight loss, bleeding and fever, which may indicate more dangerous conditions[6].

CARBOHYDRATE MALABSORPTION

Pathogenesis

Carbohydrates are a major source of calories in the diet. They may be ingested as monosaccharides, disaccharides, oligosaccharides or polysaccharides. During their passage from the mouth to the small intestine, they are broken down enzymatically until, in the small intestine, brush-border enzymes hydrolyze them into monosaccharides, which can be absorbed by various carrier systems[7].

The most important carbohydrates that routinely cause clinical abdominal complaints are lactose, fructose, and the sugar alcohol sorbitol. Lactose has long been recognized as one of the most important nutrients, and fructose and sorbitol have become increasingly important following recommendations to increase fruit and vegetable consumption, and also as a result of their use as sweeteners in dietary preparations and so-called sugar-free sweets. Further disorders such as sucrase-isomaltase deficiency or lack of trehalase are rare or only of regional importance, and are not discussed in this paper, although in affected patients, diets free from these sugars are very successful.

Malabsorption may result from congenital or acquired defects of single transport systems (primary malabsorption), or from impairment of the epithelial surface of the small intestine, due to general intestinal diseases such as celiac disease or Crohn's disease, which impede the absorption of all carbohydrates (secondary malabsorption). In secondary malabsorption, treatment is directed at the underlying disease, and successful therapy can lead to the normalization of carbohydrate absorption. In primary malabsorption, selective interventions are necessary.

Lactose is split by the enzyme lactase (β-d-

galactosidase), derived from the brush border of the enterocytes, into galactose and glucose, which can be absorbed by a special carrier system. The most frequently associated deficiency is primary lactase deficiency in adults. In these patients, lactase activity gradually declines during early life, and symptoms may occur as early as late childhood. Congenital lactase deficiency is rare and already affects neonates[8].

Several carriers, such as the GLUT family, are known to be involved in the transport of monosaccharides. GLUT-5 is the most important carrier currently known for the absorption of fructose. A deficiency in GLUT-5 leads to incomplete absorption or malabsorption of fructose[9,10]. Sorbitol is only sparsely absorbed, and is therefore used therapeutically as an osmotic laxative. Absorption is thought to take place through passive diffusion[11-13].

Congenital and acquired deficiencies are recognized. An important aspect is that the presence of glucose stimulates GLUT-5 activity, while sorbitol blocks it[9]. These data from animal intestinal perfusion tests (in most cases rat jejunum) confirm previous clinical and experimental data, which show that addition of glucose to fructose in patients known to have fructose malabsorption can prevent malabsorption, and suppress the occurrence of the accompanying symptoms. In contrast, the presence of sorbitol may aggravate malabsorption and the symptoms[13-17]. However, the mechanisms of carbohydrate absorption are still not completely understood.

There are also data that indicate an additional role for other factors in fructose metabolism, such as GLUT-2, which is capable of stimulating absorption[10].

Prevalence

Lactase deficiency is the most common enzymatic defect worldwide, although there are considerable regional differences in its prevalence. The majority of people in Asia and Africa, as well as the aboriginal populations of America and Australia, are affected, while in Europe, there are very low rates (under 10%) in the north, with a strong increase (up to 70%-100%) in regions further south, such as in Italy and Turkey.

There have been many studies reporting high malabsorption rates for fructose and sorbitol. Depending on the dosage and concentration, the reported data are closely comparable. After the ingestion of 50 g fructose dissolved in 250 mL water (corresponding to the traditional lactose test), there are malabsorption rates of about 60%-70%[15,18,19], while the rates are about 40% after a dosage of 25 g in 250 mL, the concentration now most commonly used[14,20]. Similar values have also been documented in children[21,22]. With regard to sorbitol, the test dosages used are less standardized, but even after an intake of 10 g, malabsorption rates can reach 100%[12,19,23].

For all of these sugars, it should be noted that the malabsorption rates are quite similar in patients and healthy controls. While some 50% of those with malabsorption of fructose and sorbitol have no concomitant symptoms, the symptomatic rates for lactose malabsorption are much more varied, with only a few people being symptomatic in some populations, despite high malabsorption rates.

Symptoms

The clinical symptoms of carbohydrate malabsorption include flatulence, abdominal cramps and pain, diarrhea, and sometimes even headache, usually after the ingestion of a product containing the incompletely absorbed sugar. There are no symptoms specific for a single sugar. However, there are data showing that, in patients (mainly females) with fructose and sorbitol malabsorption, diet can improve not only gastrointestinal disturbances, but also mood[24]. An association with reduced plasma levels of tryptophan has been discussed as a possible mechanism for this[25].

The gastrointestinal symptoms are thought to be provoked by the increased osmotic load of the sugar, with an augmented intraluminal volume (water) and a consequent acceleration of intestinal passage. Gas production and diarrhea occur in connection with the bacterial flora in the colon, the unabsorbed sugar presenting as a substrate for increased bacterial fermentation. Moreover, the capacity of the colon to absorb the surplus water plays a role in the pathogenesis of diarrhea.

In view of these etiologic factors, it is of particular interest that many patients report that initial symptoms develop after an infection (mostly gastrointestinal) or after antibiotic therapy, although it must be assumed that malabsorption has been present since childhood. Irritable bowel syndrome (which probably often includes patients with carbohydrate malabsorption) has also been reported to develop in connection with infections, both inside and outside the gastrointestinal tract[26,27]. In two small series, our own group has shown that the degradation of the malabsorbed sugar in stool cultures correlates with the occurrence of symptoms and a different pattern of short-chain free fatty acids[28,29].

It may therefore be speculated that the symptoms of carbohydrate malabsorption depend on the pattern of the colonic flora. A further argument in favor of this view is the observation that, in volunteers in whom more than one type of malabsorption is detected, the symptoms occur either after each malabsorption or after none[30].

Diagnosis

Carbohydrate malabsorption can be detected using direct or indirect methods. Using a cecal tube to measure the amount of unabsorbed sugar after oral ingestion is not practicable for routine purposes. Measurement of enzymatic activity in intestinal biopsies is a valuable tool for quantifying disaccharidase activity. It is therefore suitable for diagnosing lactase insufficiency, but is rarely used. Indirect methods are more widely used. Measurement of blood sugar after lactose ingestion was formerly a widespread method, but it declined in importance with the introduction of hydrogen exhalation tests. Direct measurement of ingested sugar in blood or urine is applicable for xylose.

By far the most frequently used method nowadays is the hydrogen exhalation test. After ingestion of the test sugar, the amount of hydrogen in the exhaled gas is measured. If there is incomplete absorption, part of

the ingested sugar passes into the colon, in which it is metabolized by bacteria into hydrogen, methane, carbon dioxide and free fatty acids. A small amount of hydrogen is absorbed and exhaled during the first passage through the lungs. An increase in hydrogen of more than 20 parts per million is considered to indicate malabsorption[31-33]. The extent of the hydrogen increase does not correlate either with the patients' symptoms or with the degree of malabsorption[34]. Hydrogen tests are only able to detect or exclude malabsorption. It should be pointed out that to avoid false-negative results, the presence of hydrogen-producing bacteria should be confirmed by carrying out a lactulose test (as lactulose is a disaccharide that cannot be absorbed by humans and therefore causes an increase in hydrogen). False-positive results due to bacterial overgrowth or accelerated orocecal transit can also be reduced with this test[35].

Concomitant measurement of blood glucose may improve the accuracy of lactose tests and should be mandatory in all fructose tests, in order to detect rare cases of fructose intolerance, which may mimic the symptoms of fructose malabsorption, but can cause severe hypoglycemia and even death after the ingestion of fructose. There is also some evidence that parallel methane assessment may improve the accuracy of the hydrogen test, but the data are sparse and require further evaluation[36]. The use of ^{13}C exhalation tests also requires further evaluation[37].

Therapy

Avoidance of the malabsorbed sugar is still the treatment of choice. In patients with lactose malabsorption, the addition of lactase (most conveniently in liquids) is an alternative, as well as the consumption of lactose-free milk products. Patients with fructose malabsorption can choose fruits and vegetables that have an equal ratio of fructose and glucose. In liquids, the addition of glucose can prevent malabsorption and its symptoms, but does not appear appropriate from the point of view of healthy nutrition. For sorbitol malabsorption, restricting sorbitol intake is the best method of preventing symptoms. In the same way that glucose can reduce malabsorption when administered along with fructose, adding sorbitol to fructose may aggravate the symptoms, and this should be taken into account when establishing the dietary regimen. For all sugars, small amounts are tolerated by most patients. Ingesting them along with or after other nutrients further improves tolerance.

The diet and its effects are often an important method of establishing a diagnosis of clinically relevant carbohydrate malabsorption. As mentioned above, many people are affected by malabsorption, but by no means are all symptomatic. Improvement after dietary adjustment and recurrence of symptoms when dietary errors occur is still the best way of confirming the diagnosis. There have been few studies that have documented the beneficial effects of dietary changes in patients with fructose and sorbitol malabsorption. In addition, there are methodological problems in all of these studies, including those by our own group. The diet itself is sometimes not clearly described; patient compliance with the diet is difficult to assess; there are no control groups, so that the role of a placebo effect is difficult to assess; and there are inadequacies in the way in which the patients' dietary behavior is recorded.

Nevertheless, the available data are fairly consistent. In our own study, which had both prospective and retrospective parts (in order to assess the placebo effect), symptomatic improvement of 60%-100%, depending on the degree of patient compliance, was observed to a similar degree in both arms of the study[38]. Fernandez-Banares et al[39] have reported similar results and were able to show that the treatment effect was long-lasting, with the positive effects of the diet being maintained at 12 mo. Shepherd and Gibson have confirmed these data in a group of 62 patients[40]. The largest study (so far available only as an abstract, so far as we are aware), including 1320 patients, documented an improvement after dietary changes in 87.5% of the patients[41]. In a more recent study including 90 selected patients with non-specific abdominal complaints, we observed a high rate of carbohydrate malabsorption (lactose 34%, fructose 61%, and sorbitol 91%)[42]. After dietary information had been provided, the patients reported significant improvement in 75% of cases, depending on the extent of compliance. The study by Ledochowski *et al*[24], which has shown that dietary changes in patients with fructose malabsorption have a beneficial effect on gastrointestinal complaints and also on mood, as documented by improvements in depression score, has already been mentioned above. However, there are also contradictory data that show that only avoiding one sugar (with proven malabsorption) may not be sufficient for patients with irritable bowel syndrome[43,44].

The phenomenon that patients with non-specific abdominal complaints frequently report improvement in their symptoms for several weeks after colonoscopy (thought to be due to bowel preparation with cleansing of the colon) underlines the possible role of bacteria in the colon. Treatments involving antibiotics[45,46], attempts to reduce colonic bacterial fermentation[47], and administration of probiotics[48] therefore require further investigation.

Open questions

Although carbohydrate malabsorption appears to play an important role in patients suffering from non-specific abdominal complaints, there are several problems with this diagnosis that should not be overlooked. In the first place, diagnosis using hydrogen tests is still problematic, particularly if the increase is borderline. The threshold value of 20 p.p.m. requires further evaluation, as there may be significant variations in methane production in the colon, among other factors. Moreover, hydrogen tests are not capable of quantifying the amount of malabsorption. Symptoms do not always occur during the test, even in patients who are considered to be symptomatic. Assessing the clinical relevance of the diagnosis may therefore sometimes be difficult.

The etiology of the symptoms is not fully understood. If the data published by our own group, which show that symptoms occur after each malabsorbed sugar or after none (see above), are reproducible, it would theoretically mean that no patient should become symptom-free, since

physiological malabsorption of carbohydrates is essential for the colonocytes. Moreover, if the data showing that there is a beneficial effect of carbohydrate malabsorption on the short-chain free fatty acid ratio, and especially on the increase in butyrate, are confirmed[29], this might also raise doubts about whether treatment is advantageous at all in the longer term.

CONCLUSION

Carbohydrate malabsorption is a common phenomenon not only in patients, but also in healthy individuals. In patients suffering from non-specific abdominal complaints, it is therefore very difficult sometimes to clarify whether the malabsorption that has been detected is definitely the cause of the symptoms. On the other hand, many patients with these symptoms and confirmed malabsorption appear to benefit considerably from dietary interventions, thus underlining the importance of diagnosing carbohydrate malabsorption. Another advantage of diagnostic work-up, including hydrogen exhalation tests, is that the results may provide evidence of other diseases that feature in the differential diagnosis of non-specific abdominal complaints, such as intestinal bacterial overgrowth or alterations in the orocecal transit times.

As pointed out above, however, there are still a considerable number of open questions in this field, so that further controlled studies are urgently necessary. The first step for the scientific community is to accept that, in addition to the widely accepted condition of lactose malabsorption, malabsorption of other sugars such as fructose and sorbitol also occurs and may be at least as important, or perhaps even more, than lactose malabsorption.

Abstract

AIM: To screen out the differentially methylated DNA sequences between gastric primary tumor and metastatic lymph nodes, test the methylation difference of gene *PTPRG* between primary gastric tumor and metastatic lymph nodes, and test the regulatory function of 5-aza-2-deoxycytidine which is an agent with suppression on methylation and the level of methylation in gastric cancer cell line.

METHODS: Methylated DNA sequences in genome were enriched with methylated CpG islands amplification (MCA) to undergo representational difference analysis (RDA), with MCA production of metastatic lymph nodes as tester and that of primary tumor as driver. The obtained differentially methylated fragments were cloned and sequenced to acquire the base sequence, which was analyzed with bioinformatics. With methylation-specific PCR (MSP) and RT-PCR, methylation difference of gene *PTPRG* was detected between primary tumor and metastatic lymph nodes in 36 cases of gastric cancer. Methylation of gene *PTPRG* and its regulated expression were observed in gastric cancer cell line before and after being treated with methylation-suppressive agent.

RESULTS: Nineteen differentially methylated sequences were obtained and located at 5′ end, exons, introns and 3′ end, in which KL59 was observed to be located at 9p21 as the first exon of gene *p16* and KL22 to be located at promoter region of *PRPRG*. KL22, as the probes, was hybridized with driver, tester and 3-round RDA products respectively with all positive signals except with the driver. Significant difference was observed in both methylation rate of gene *PTPRG* and PTPRG mRNA expression rate between primary tumor and metastatic lymph nodes. Demethylation of gene *PTPRG*, with recovered expression of PTPRG mRNA, was observed after gastric cancer cell line being treated with methylation-suppressive agent.

CONCLUSION: Difference exists in DNA methylation between primary tumor and metastatic lymph nodes of gastric cancer, with MCA-RDA as one of the good analytical methods. Significant difference exists in methylation of gene *PTPRG* between primary tumor and metastatic lymph nodes of gastric cancer. Methylation level in gastric cancer cell line can be decreased by 5-aza-2′-deoxycytidine, which is the methylation-suppressive agent, with PTPRG expression being recovered.

INTRODUCTION

Metastasis of gastric cancer, at the genetic level, is caused by mutations or loss of corresponding cancer suppressor genes, while at epigenetic level it is caused by low expression of metastasis-suppression genes due to multiple reasons, in which gene hypermethylation is an important mechanism[1-3]. A genome with methylation at CpG is usually accompanied by inactivation of genes in that region. If not, on the contrary, it is usually accompanied by active expression of genes in the region. The aberrant hypermethylation of CpG islands in transcription regulatory region of metastasis-inhibition genes relating to gastric cancer causes these genes to be in silence and this fact will induce the metastasis of gastric cancer[4-6]. Most of previous analytic methods on methylation can only analyze the methylation condition of a known gene,

but cannot analyze that of a whole genome. Methylated CpG islands amplification (MCA) methods, combined with representative difference analysis (RDA), can analyze effectively the condition of methylation in a whole genome, especially good at detecting unknown methylated fragments.

In this research, gene methylation difference was detected between primary tumor and metastatic lymph nodes of gastric cancer using MCA-RDA method, to screen out genes relating to metastasis of gastric cancer, which further underwent analysis on methylation difference with methods, including methylation-specific PCR, in order to define further the mechanism of metastasis of gastric cancer.

MATERIALS AND METHODS

Subjects

Pathological specimens, including tumor tissues and metastatic lymph nodes, taken from 36 gastric cancer patients hospitalized in Surgical Oncology Ward of the First Affiliated Hospital of China Medical University, were included in this study. The tumor tissues and suspected metastatic lymph nodes, after resecting from the patients, were promptly placed into a liquid nitrogen tank. Each tumor tissue and lymph node was cut into two pieces, one piece was kept in liquid nitrogen and the other underwent HE pathological staining to examine whether a true metastasis had occurred. In addition, gastric cancer line SGC7901 was also included in this study.

Extraction of DNA and total RNA

Hydroxybenzene-chloroform extraction method was adopted to extract DNA of the genome, and total RNA was extracted with TRIZOL reagent according to the manufacturer's instruction.

MCA

MCA was adopted to obtain CpG islands enriched with methylation. The CpG island region of DNA mixture extracted from tumor tissues and metastatic lymph nodes of 5 cases of gastric cancer were enriched with MCA, respectively. Firstly, 5 μg of DNA of genome was digested with 100U *Sma*I endonuclease (provided by NEB, not functional on methylated sites) for 6 h to cut the unmethylated -CCCGGG- sites to form the blunt ends, and also digested with 20U *Xma*I enzyme (provided by NEB) for 16 h to cut the methylated -CCCGGG- sites to form the sticky -CCCGGG- ends. Then T4DNA (Promega) was used to connect corresponding adaptor RXMA 24/12, with RXMA24 fragment as the primer to amplify the DNA fragments with adaptor, which were incubated for 5 min at 72℃, followed by pre-denaturalization for 3 min at 95℃, 30 amplification cycles for 1 min at 95℃ and 3 min at 72℃, and a final extension for 10 min at 72℃, to enrich methylated fragments of DNA from both tumor tissues and metastatic lymph nodes. The products were electrophoresed on 15 g/L agarose gel containing ethidium bromide[7].

Table 1 Adaptor used in MCA-RDA and their sequence

Adaptor	Sequence
RXMA24	5'-AGCACTCTCCAGCCTCTCACCGAC-3'
RXMA12	5'-CCGGGTCGGTGA-3'
JXMA24	5'-ACCGACGTCGACTATCCATGAACC-3'
JXMA12	5'-CCGGGGTTCATG -3'
NMCA24	5'-GTTAGCGGACACAGGGCGGGTCAC-3'
NMCA12	5'-CCGGGTGACCCG-3'

RDA

The methylated DNA fragments obtained from tumor and metastatic lymph nodes were underwent representative difference analysis. The adaptor of methylated CpG fragments taken from tumor and metastatic lymph nodes was cut-off with *Sma*I being used for tumor tissue to form blunt ends as the driver, and with *Xma*I being used for metastatic lymph nodes to form sticky ends to be connected with new ends as the tester. Tester and driver were underwent 3 cycles of hybridization RDA analysis in a ratio of 1:80, 1:400 and 1:800, respectively. After each analysis, the adaptor was cut off with *Xma*I, with new adaptor being added. The adaptors used in the 3 cycles of analysis were NMCA24/12, JXMA24/12 and NMCA24/12, with different extension temperature for different connectors. The sequence of each connector is listed in Table 1. The products were analyzed on 15 g/L agarose gel containing ethidium bromide[8].

Cloning, sequencing and analysis of similarity

Products of the 3rd cycle of RDA analysis as well as pCAT®3-Control carrier (Promega) were treated with *Xma*I to cut their ends into sticky ones, which were connected with T4 ligase and transformed into competent bacteria JM109 for incubation with matrix containing Ampicillin. Positive clones were selected and cultivated in matrix containing antibiotics at 37℃. Then plasmid DNA was extracted, and was underwent to cleavage with *Xma*I, and to electrophoresis; then the more than 100 bp and the clones of more than 100 bp cleavage products were selected and delivered to bio-company (Combined Gene Company) for sequencing. The obtained sequence were underwent repeated sequence analysis with Repeatmasker. BLAST system was used to carry out similarity analysis, with relationship between cloned sequence and corresponding genes being analyzed *via* GenBank.

Dot blot

The differentially methylated fragments of KL22 obtained from MCA-RDA analysis were labeled with digoxin, using random primer method to form the probe. With this latter hybridization analysis was carried out on the 1st, 2nd, 3rd round RDA. MCA products of tumor or metastatic lymph nodes, respectively, in a volume of 5 μL for each sample, were dotted onto nylon membrane with positive electricity.

Cell cultivation and methylation intervention

Gastric cancer cell line was subcultured according to

Table 2 MSP primers of gene *PTPRG*

Methylated primers	5'-GTTCGTTCGTTTTTTCGTTC-3' 5'-CATACTCCTAAAAATTATAACTCCGAC-3'
Unmethylated primers	5'-TTTTGTTTGTTTGTTTTTTTGTTTG-3' 5'-AATCCATACTCCTAAAAATTATAACTCCA-3'

standard methods and then randomized into two groups, one of them was treated with 5 μmol/L 5-Aza-2'-deoxycytidine and cultured for 5 d.

Methylation-specific PCR (MSP)

Sodium hydrogen sulfite was used for DNA modification, and then sodium hydrogen sulfite was eliminated from DNA with Wizard DNA Clean-up kit (Promega). The samples were amplified through 30 cycles, each amplification cycle consisting of denaturation at 95℃ for 40 s, primers annealing at 65℃ (unmethylation) or at 60℃ (methylation) for 40 s and extension at 72℃ for 60 s. Cycles were preceded by incubation at 95℃ for 3 min to ensure full denaturation of the target gene, and finally by an extra incubation at 72℃ for 10 min to ensure full extension of the products. PCR was carried out with methylated primer and unmethylated primer, respectively. The primers adopted are listed in Table 2. The PCR products were analyzed on 20 g/L agarose gel[9].

RT-PCR

RNA was reverse transcribed into cDNA as the template, which was amplified through 30 cycles, each amplification cycle consisting of denaturation at 94℃ for 40 s, primers annealing at 57℃ for 30 s and extension at 72℃ for 60 s. Cycles were preceded by incubation at 94℃ for 2 min to ensure full denaturation of the target gene, and finally by an extra incubation at 72℃ for 10 min to ensure full extension of the products.

Meanwhile, β-actin was adopted as internal control. The sequences of primers are listed in Table 3. The products were electrophoresed on 15 g/L agarose gel.

Statistical analysis

Chi-square test was adopted to verify the difference of PTPRG methylation rate and PTPRG mRNA expression between gastric tumor and metastatic lymph nodes, as well as the difference on absent expression of PTPRG mRNA between negative and positive group of methylated nodular PTPRG. Rectilinear regression was used to test the correlation between PTPRG methylation rate and metastatic lymph nodes number. SPSS11.0 software was used to process the data.

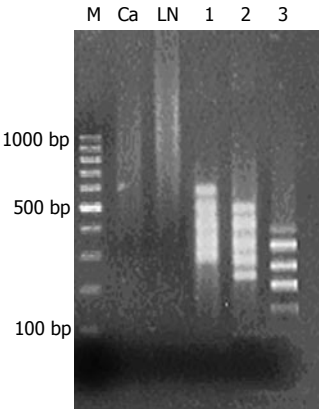

Figure 1 Methylated CpG islands amplification (MCA) and representational difference analysis (RDA). M: Marker; Ca: MCA products of gastric cancer tissues; LN: MCA products of metastatic lymph nodes; lanes 1-3: The 1st to the 3rd round RDA products. After methylated CpG islands amplification (MCA) of genome DNA of primary tumor and metastatic lymph nodes, bright smears were observed between 300 bp and 2000 bp, which were the concentrated methylated CpG islands. From the 1st to the 3rd cycle of analysis, fragments with methylation difference decreased gradually and the straps gradually became clear. In the 3rd RDA analysis, 5 straps of different methylation were observed.

RESULTS

MCA

After methylated CpG islands amplification (MCA) of genome DNA of primary tumor and metastatic lymph nodes, bright smear was observed between 300 and 2000 bp, which were the concentrated methylated CpG islands (Figure 1).

RDA

MCA products of metastatic lymph nodes were adopted as the tester and MCA products of primary tumor as the driver to carry out 3 cycles of RDA analysis, which resulted in 100-500-bp fragments with methylation difference. From the 1st to the 3rd cycle of analysis, fragments with methylation difference decreased gradually and the straps gradually became clear. In the 3rd RDA analysis, 5 straps of different methylation were observed (Figure 1).

Cloning, sequencing and analysis on homology

Ninety-six positive clones were selected to undergo sequencing analysis, 19 of them demonstrated the sequence longer than 100 bp. KL8 appeared for 21 times, while KL22 11 times, KL59 4 times, and both KL40 and KL71 for twice. No repeated sequence, such as ALU, was found after repeated sequencing analysis. Table 4 shows the 19 sequence characteristics. All sequences were of length between 100 bp and 400 bp, with GC content beyond 50%. Analysis showed these fragments to be distributed into various regions in the genome, including 5' ends, exons, introns and 3' ends, in which KL59 was situated at 9p21 as the first extron of gene *p16*, with 100% similarity rate, and KL22 was situated at 3p21, in the promoter region of gene *PTPRG*.

probe, with which the three rounds MCA-RDA products underwent hybridization analysis with testers and drivers. Positive results were observed in all products of the 3-round RDA as well as in testers, while negative one in drivers (Figure 2).

Gene PTPRG methylation rate of primary tumor and metastatic lymph nodes of gastric cancer

A positive band was observed at 158 bp of non-methylation PCR of primary tumor, with a positive rate of 77.78% (28/36), while that of metastatic lymph nodes was 63.89% (23/36) ($P > 0.05$). A positive strap was observed at 150 bp of methylation PCR of metastatic lymph nodes, with a positive rate of 52.78% (19/36), while that of primary tumor was 25.0% (9/36) ($P < 0.05$) (Figure 3 and Table 5). Linear correlation was observed between MSP positive rate of metastatic lymph nodes and the number of metastatic nodes ($r = 0.882$, $P < 0.001$, Figure 4).

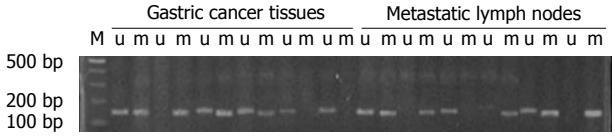

Figure 3 Methylation-specific PCR (MSP) of gene *PTPRG*. M: Marker; u: Unmethylated (158 bp); m: Methylated (150 bp). A positive band was observed at 158 bp of non-methylation PCR of primary tumor, with a positive rate of 77.78% (28/36), while that of metastatic lymph nodes was 63.89% (23/36). A positive strap was observed at 150 bp of methylation PCR of metastatic lymph nodes, with a positive rate of 52.78% (19/36), while that of primary tumor was 25.0% (9/36) ($P < 0.05$).

Table 5 Methylation and mRNA expression of gene *PTPRG n* (%)

Tissue	*PTPRG* gene methylation		PTPRG mRNA expression
	U	M	
Primary tumor	28 (77.78)	9 (25.0)	18 (50.0)
Metastatic lymph nodes	23 (63.89)	19 (52.78)[a]	9 (25.0)[a]
Before cell line treatment	+	+	-
After cell line treatment	+	-	+

[a]$P < 0.05$. U: Unmethylation; M: Methylation.

A positive strap was observed at 177 bp in RT-PCR of gene *PTPRG* of primary tumor, with a positive rate of 50.0% (18/36) and a 177-bp positive band was observed in metastatic lymph nodes, with a positive rate of 25.0% (9/36) ($P < 0.05$), (Figure 5, Table 5).

Relationship between methylation of PTPRG in metastatic lymph nodes and absent expression of mRNA

Among 19 cases of positive PTPRG methylation in metastatic lymph nodes, there was only one case of positive expression of PTPRG mRNA, with the positive rate of 5.26%, while 9 cases of positive expression existed among 17 cases of negative PTPRG methylation, with the positive rate of 52.9% ($P < 0.01$), (Table 6).

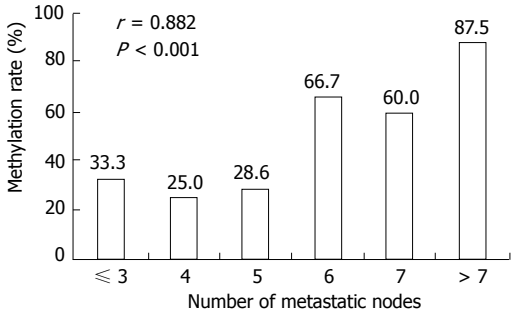

Figure 4 Relationship between number of metastatic lymph nodes and positive rate of PTPRG methylation.

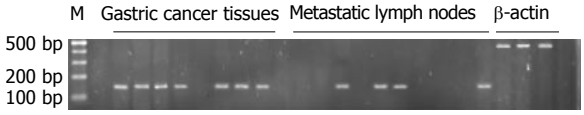

Figure 5 PTPRG mRNA expression of gastric cancer tissues and metastatic lymph nodes. M: Marker. Gastric cancer tissues: Products of *PTPRG* gene (177 bp) of gastric cancer tissues; Metastatic lymph nodes: Products of *PTPRG* gene (177 bp) of metastatic lymph nodes; β-actin: 483 bp. RT-PCR showed a positive strap at 177 bp in gene *PTPRG* of primary tumor, with a positive rate of 50.0% (18/36), while a 177-bp positive band was observed in metastatic lymph nodes, with a positive rate of 25.0% (9/36) ($P < 0.05$).

PTPRG methylation level and its mRNA expression in gastric cell line SGC7901 before and after the treatment with 5-aza-2'-deoxycytidine

Before the treatment, a positive band was observed at 158 bp in unmethylated PCR, while a positive band was seen at 150 bp in methylated PCR of gastric cancer cell line. After the treatment, a positive band was also observed at 158 bp in unmethylated PCR, but no positive band was seen in methylated PCR (Figure 6, Table 5). PTPRG mRNA expression of cell line was negative before treatment, while a weak positive band was seen at 177 bp after treatment (Figure 7, Table 5).

DISCUSSION

Based on previous researches, a group containing methyl exists in every 100 nucleotide acids in human DNA, which is usually combined onto 5'-C position. Almost all methylated cytosine residues appear on the 5'-GC-3' nucleotide acid in the symmetrical sequence. This kind of sequence is not randomly distributed, but concentrated to GC-enriched islands (CpG islands), which usually situates at the position in or near transcription regulatory region. Sensitivity of methylation on all CpG is not the same, and the methylation level at the site of CpG can be changed[10-12]. Prevalent hypomethylation and local hypermethylation exist in genome of cancer tissue, for example, hypermethylation on promoters of p16, E-cadherin, and genes encoding hormone receptors and genes of DNA repair, and genes inhibiting the genesis of blood vessels may induce the absent or low expression of these gene and improve the oncogenesis and metastasis. Therefore, research on methylation of genome provides a new route to study the oncogenesis and metastasis of cancer[13-17].

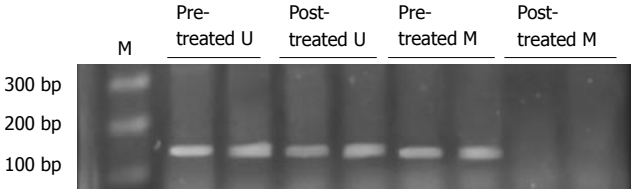

Figure 6 Methylation-specific PCR (MSP) of gene *PTPRG* in gastric cell line before and after the treatment with 5-aza-2'-deoxycytidine. M: Marker; U: Unmethylated; M: Methylated. Before the treatment, a positive band was observed at 158 bp in unmethylated PCR, while a positive band was seen at 150 bp in methylated PCR of gastric cancer cell line. After the treatment, a positive band was also observed at 158 bp in unmethylated PCR, but no positive band was seen in methylated PCR.

MCA technique is a new approach which has recently been adopted for research on gene methylation, which can be applied promptly and efficiently to the research on the whole genome methylation, with specific advantage especially for research on methylation condition of various unknown genes. Through the optimization of PCR condition, it is almost fit for every gene containing two adjacent *Sma*I restriction sites. The content of CpG is different in CpG islands, so different PCR primers and reaction conditions are needed, such as RXMA and RMCA. Thus RXMA seems to be more fit for this research. Through the optimization on the reaction condition, RXMA may yield MCA product steadily. It needs to point out that high quality sample of DNA is needed for MCA experiment, so generally wax-embedded sample is not considered in the case, in which only some sites can be detected, but not in total, among all sites in the CpG islands, which is only sensitive to partially digested products by *Sma*I, with distance shorter than 1000

bp between every two *Sma*I constriction sites. Generally speaking, GC content of MCA's products is high; in this case if only an optimized PCR reaction system is adopted with high GC content, a satisfactory result can be made. RDA is a relatively mature technique adopted to screen out accurately the different fragments between two groups of DNA. In this research, we combined MCA and RDA to screen out the differentially methylated fragments between primary tumor and metastatic lymph nodes of gastric cancer, to explore the gene with alteration in methylation involved within process of metastatic lymph nodes. It provides a relatively accurate method with high efficiency, and it is fit for the primary screening out large quantities of metastasis-suppressive genes. It may be considered a high flux analytical method.

Phosphorylation of tyrosine residue is the important characteristic of many cellular signals transmission, influencing a number of vital biological processes including growth and differentiation of cells, adjustment of cell cycle, cell apoptosis and transference. Phosphorylation and dephosphorylation of tyrosine are adjusted by tyrosine kinase (TK) and tyrosine phosphatase (TP), respectively. Despite several tyrosine kinases have been recognized to correlate to oncogenesis directly through activating the mutant of cells *in vivo*, only a small amount of tyrosine phosphatase is known to correlate oncogenesis[18,19]. Gene *PTPRG* is a member belonging to the classic tyrosine phosphatase gene family, which includes receptor genes and non-receptor genes. *PTPRG* is a member of receptor gene, and is situated at 3p14 chromosome[20-22]. Previous researches observed methylation extinguishments of other genes that belong to the same family of *PTPRG*, such as *PTPRN2*, *PTPRO*, *etc*, in hepatic cancer[23]. *PTPRG* mutation is often found in colon cancer, lung cancer and kidney cancer, with conclusive identification on the role of *PTPRG* as one of tumor-inhibition genes[18,24]. However, there is a little information in literature regarding the extinguishments of *PTPRG* on epigenetic level. Based on recent studies, its deactivation on epigenetic level occurs in skin T-cell lymphoma. A study has demonstrated that a significant difference exists on *PTPRG* methylation in metastatic lymph nodes compared to primary tumor[9]. The silencing of genomic induced by methylation mainly consists of the methylation in promoter and in the first exon[9].

Methylation-specific PCR (MSP) revealed a significant difference in the positive methylation rate of PRPGR in primary tumor of gastric cancer (25.0%) compared to in metastatic lymph nodes (52.78%) ($P < 0.05$)[25,26]; this fact which further proved that the differentially methylated fragments we screened out were accurate. The significant linear correlation existing between positive rates of methylated *PTPRG* and numbers of metastatic nodes suggests that there is certain relationship between *PTPRG* methylation and metastatic lymph nodes of gastric cancer. In addition, a significant difference in *PTPRG* mRNA expression was observed between primary gastric tumor and metastatic lymph nodes, suggesting that product of *PTPRG* gene exerts suppressive effect against metastatic lymph nodes of gastric cancer. It is because of the down-regulated PTPRG, that the metastatic lymph nodes of gastric cancer was promoted.

PTPRG methylation exists in gastric cancer cell line. RT-PCR analysis demonstrated that PTPRG is not expressed in the cell line. However, MSP result of the cell line was negative and RT-PCR result was weakly positive after treatment with 5-aza-2'-deoxycytidine as the methylation suppressor; this fact, suggested that methylation of this gene was suppressed after the treatment with 5-aza-2'-deoxycytidine, so the MSP result was negative and the expression of PTPRG was partially recovered[27,28].

Among all 19 cases of positive methylation of PTPRG in metastatic lymph nodes, there was only one case of positive expression of PTPRG mRNA (positive rate of 5.26%), while among 17 cases of negative methylation of PTPRG, there were 9 cases of positive expression of PTPRG mRNA (positive rate of 52.9%) ($P < 0.05$); this result further implies that methylation in promoter region of PTPRG might be the mechanism of its being distinguished. However, the concrete mechanism of this gene involved in metastatic lymph nodes of gastric cancer is not clear yet, and it is waiting for the further research.

COMMENTS

Background

Metastasis of gastric cancer, at the genetic level, is caused by mutation or loss of corresponding cancer suppressor genes, while at epigenetic level it is caused by low expression of metastasis-suppression genes due to multiple reasons, among which gene hypermethylation is an important mechanism.

Research frontiers

Methylated CpG islands amplification (MCA) methods, combined with representative difference analysis (RDA), can analyze wholly and effectively the condition of methylation in a whole genome, especially good at detecting unknown methylated fragments.

Innovations and breakthroughs

In this research, gene methylation difference was detected between primary tumor and metastatic lymph nodes of gastric cancer using MCA-RDA method, to screen out genes relating to metastasis of gastric cancer, which further underwent analysis on methylation difference by methylation specific PCR, in order to define further the mechanism of metastasis of gastric cancer.

Applications

This observation might be of potential value in gene therapy of gastric cancer.

Peer review

The manuscript looked at the potential role of the *PTPRG* gene as metastatic suppressor gene, by comparing methylation status and LOI between the primary tumor and lymph nodes metastasis in 36 cases. Additionally, gastric cancer cell line was treated with 5-aza-2'-deoxycytidine (inhibitor of methylation) and gene expression was investigated. This study proved the hypothesis by demonstrating a significant difference in the level of methylation between the primary tumor and metastasis.

Abstract

AIM: To investigate dynamic characteristics and pathological mechanism of signal in rabbit VX-2 tumor model on diffusion-weighted imaging (DWI) after chemoembolization.

METHODS: Forty New Zealand rabbits were included in the study and forty-seven rabbit VX-2 tumor models were raised by implanting directly and intrahepatically after abdominal cavity opened. Forty VX-2 tumor models from them were divided into four groups. DWI was performed periodically and respectively for each group after chemoembolization. All VX-2 tumor samples of each group were studied by pathology. The distinction of VX-2 tumors on DWI was assessed by their apparent diffusion coefficient (ADC) values. The statistical significance between different time groups, different area groups or different b-value groups was calculated by using SPSS12.0 software.

RESULTS: Under b-value of 100 s/mm^2, ADC values were lowest at 16 h after chemoembolization in area of VX-2 tumor periphery, central, and normal liver parenchyma around tumor, but turned to increase with further elongation of chemoembolization treatment. The distinction of ADC between different time groups was significant respectively (F = 7.325, P < 0.001; F = 2.496, P < 0.048; F = 6.856, P < 0.001). Cellular edema in the area of VX-2 tumor periphery or normal liver parenchyma around tumor, increased quickly in sixteen h after chemoembolization but, from the 16th h to the 48th h, cellular edema in the area of normal liver parenchyma around tumor decreased gradually and that in the area of VX-2 tumor periphery decreased lightly at, and then increased continually. After chemoembolization, Cellular necrosis in the area of VX-2 tumor periphery was more significantly high than that before chemoembolization. The areas of dead cells in VX-2 tumors manifested low signal and high ADC value, while the areas of viable cells manifested high signal and low ADC value.

CONCLUSION: DWI is able to detect and differentiate tumor necrotic areas from viable cellular areas before and after chemoembolization. ADC of normal liver parenchyma and VX-2 tumor are influenced by intracellular edema, tissue cellular death and microcirculation disturbance after chemoembolization.

INTRODUCTION

Transcatheter arterial chemoembolization (TACE) is a kind of classic interventional therapy and it is commonly performed to treat the unresectable hepatocellular carcinoma and secondary liver cancers. The major goal of chemoembolization is to destroy the tumor. It is very important to evaluate obviously progression of hepatic tumors and differentiate accurately the areas and degrees of necrotic tumor from that of viable tumor before and after chemoembolization.

As reported, ultrasound (US), digital subtraction

angiography (DSA), computed tomography (CT) and magnetic resonance imaging (MRI) are usually used to diagnose and evaluate the progression of hepatic tumor but they have their respective defects. US is able to comprehend the size, blood provision and liquefied or cystic areas of tumor but it can not differentiate necrotic tumor from viable tumor[1,2]. DSA can infer necrotic tumor and viable tumor from the degree of tumor stain. CT can manifest the areas of iodized oil and necrotic or viable tumor but, because density of iodized oil is very high on CT, some areas of necrotic or viable tumor are easily covered before and after chemoembolization[3-5]. MRI is not affected by high density of iodized oil and it is more valuable than US and CT in evaluating the progression of the tumor and in differentiating necrotic from viable tumor. The signals of coagulative necrotic areas of tumor are low on T1- and T2-weighted imaging after chemoembolization and there are no enhanced in MR enhancement scanning[6-11].

Diffusion-weighted imaging is a kind of new functional imaging technology having been developed in recent years and it is the only one method which is able to reflect non-woundingly water molecular diffusion *in vivo*. It has been generally accepted that it is valuable in diagnosing qualitatively and quantitatively cerebral ischemia in hyper-inchoate period[12-14] and, at the same time, many studies of hepatic pathological changes on DWI have been reported[15-17]. ADC values of benign lesions, such as hepatic cysts and hemangiomas, were higher than those of malignant lesions, such as hepatocellular carcinomas and metastases on DWI, as reported by Ichikawa *et al*[15,16], Yamashita *et al*[17], Taouli *et al*[18], Sun *et al*[19]. Colagrande *et al*[20], indicating that the signals of tumor coagulative necrotic areas were lower in comparison with those of tumor viable areas. Kamel *et al*[21] confirmed, in their clinical investigation of 8 case of hepatocellular carcinomas, by image-pathology, that ADC would become high directly with the degree of tumor cellular necrosis increasing and that the signals of 6 tumors were higher than those of normal parenchyma on DWI. Geschwind *et al*[22] demonstrated that the signals of VX-2 tumor necrotic areas were low and that ADC in the area of tumor necrosis were significantly greater than those in the area of viable tumor after chemoembolization.

As indicated by findings of above preliminary experiments, DWI, especially ADC, has potential values in reflecting characteristics of liver pathological changes and of differentiation to benign tumor from malignant one.

There has been no dynamically and image-pathologically investigated report on the characteristics of hepatocellular carcinomas on DWI after chemoembolization. The purpose of our experiment is to investigate dynamic characteristics and pathological mechanism of signal with DWI in rabbit VX-2 tumor model after chemoembolization, which is the most valuable animal model of hepatocellular carcinoma for imaging investigations. Moreover the aim is to evaluate the contribution of DWI in differentiating of tumor viable cells to necrotic ones.

MATERIALS AND METHODS

Animals and establishment of VX-2 tumor model

Animal studies were carried out under the supervision of a veterinarian according to the guidelines on the Use of Laboratory Animals of the Ministry of Public Health of China. All animals were provided by the Laboratory Animal Center of the Second Xiangya Hospital and all protocols were approved by the Animal Use and Care Committee of the Second Xiangya Hospital.

Forty New Zealand rabbits were included in the study. Twenty-two were male rabbits and eighteen were female, weighed 1.7 to 2.5 kg, aged 5 to 6 mo. All of them were healthy. Forty-seven rabbit VX-2 tumor models were raised by implanting the tumor directly and intrahepatically after the abdominal cavity was opened. The VX-2 tumor strain of rabbit was provided by the Fourth Military Medical University.

Forty VX-2 tumor models were layered and randomly chosen from forty-seven VX-2 tumor models and were divided into four groups, including control group (non-interventional group, namely group A) and investigation group (at the 16th h after chemoembolization, at the 32nd h after chemoembolization, at the 48th h after chemoembolization, namely group B, C, and D, respectively). Otherwise, ten cases were randomly chosen from all data were carried out by DWI for all rabbits of group B, C and D at 6th h after chemoembolization and the data was put into group of the 6th h after chemoembolization, as one of investigation groups, namely E group.

Chemoembolization protocol

After DWI at the 21st d after implantation, trans-hepaticartery catheterization chemoembolization was directly and respectively carried out for all rabbits of B, C and D group in the Animal Operating Room of the Second Xiangya Hospital.

First, once rabbits were anesthetized by injecting 3% soluble pentobarbitone and the skin of abdomen was disinfected, then we exposed organs of the hepatic hilar region by incising the skin and vagina musculi recti abdominis. Arteria coeliaca, arteria hepatica communis, arteria hepatica propria, arteria gastroduodenalis, portal vein *etc* were recognized. Second, we drew off arteria gastroduodenalis, we occluded its distalpart and dropped a little attenuated aethocaine on it. Third, we punctured the arteria gastroduodenalis and put plastic transfixion pins or scalp acupunctures into it; the top of transfixion pins were put in arteria hepatica propria. Fourth, we fixed the microtubular or transfixion pins and then infused iodized oil (0.3 mL/kg) and pharmorubicin (2 mg/kg) into arteria hepatica. At last, abdominal membrane, musculature and cutaneous were sutured layer by layer after the liver and other organs in abdominal cavity stopped bleeding.

Magnetic resonance imaging protocol

After animals were anesthetized by injecting 3% soluble pentobarbitone into auriborder vein at a dose of 1 mL/kg or at different doses based on different animal status to make sure that the breathing of animals was slow and stable, DWI(axial) was carried respectively and periodically out a 1.5-Tesla Signa Twinspeed MR scanner (General Electron Medical Systems, USA) using a small diameter cylindrical brain radiofrequency coil before chemoembolization and at the 6th h, the 16th h, the 32nd

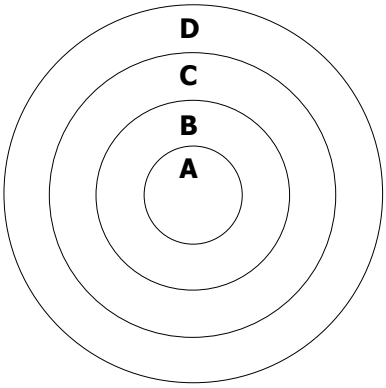

Figure 1 **A**: The area of VX-2 tumor center; **B**: The area of VX-2 tumor periphery; **C**: The area of VX-2 tumor outer layer; **D**: The normal liver parenchyma area around tumor when the values of ADC and signals were measured on DWI and samples were investigated pathologically.

h and the 48th h after chemoembolization. The scanning parameters of DWI included spin echo echoplanar imaging (SE-EPI) series, b-value 100 and 300 s/mm^2, repetition time (TR) 6000 ms, echo time (TE) 45 ms, 20 cm × 15 cm field of view (FOV), 8 number of excitations (NEX), 2 mm thickness layer, 0.5 mm Space, 128 × 128 matrix, *etc*.

ADC values and signal values in the area of VX-2 tumor periphery, in the VX-2 tumor center and in the normal liver parenchyma around tumor (Figure 1) were obtained by using Function Software in GE workstation. Three different regions of interest (ROIs) (50 mm^2 each area) were chosen in the area of normal liver parenchyma (area D in Figure 1) and we measured their ADC values and signal values. The average value of above was considered as the ADC value or the signal value of normal liver parenchyma around tumor. The thickness of area A and B in Figure 1 was respectively two fifth diameter of VX-2 tumor. By the same methods, the average value of three different ROIs ADC values or signal values in area B was considered as the ADC value or the signal value of VX-2 tumor periphery area; ADC value or signal value of area A was its ADC value or signal value of VX-2 tumor center area. All measurements were finished cooperatively by two senior attending physicians or associate professors.

Pathology protocol

All of the rabbits in each group were euthanized by injecting an overdose of 3% soluble pentobarbitone into auriborder vein when DWI was respectively carried out before chemoembolization, and after the 16 h, the 32 h and 48 from chemoembolization. We got layer by layer VX-2 samples under the condition of asepsis (Figure 1) and made them fixed in the formaldehyde solution for 24 h before being embedded in mineral wax. Each VX-2 tumor was divided into the outer layer area, the periphery area and the center area (Figure 1) so that samples included four parts: VX-2 tumor center area, VX-2 tumor periphery area, VX-2 tumor outer layer area and normal liver parenchyma around tumor.

All samples were investigated respectively under 100 × and 400 × microscope and the emphases were on investigating cellular edema in the VX-2 tumor and normal liver parenchyma around tumor.

Edema index was used to estimate the degree of cellular edema, which was the contrast of edema cell number to total cells under microscope. Manifestations of edema cells under microscope included cell body increasing, unclear cellular membrane and intracytoplasm vacuolar or ballooning degeneration; the latter was the most important manifestation of edema cell. Two campus visualises under 400 × microscope were obtained randomly in the zone of non-necrosis. The number of edema cells and total cell number were counted by two external doctors not from our study team with double blind method. Otherwise, we investigated specially the degree of tumor cellular necrosis and the abnormity of cell membrane. Statistical analysis based on apparent diffusion coefficient (ADC) value of ROIs and edema index, the distinction between different area groups, different time groups and different b-value groups was respectively estimated. The statistical significance was calculated by analysis of variance (ANOVA) or analysis of non-parameter by using SPSS software (version 12.0; SPSS, Tokyo, Japan)

RESULTS

Image manifestations of hepatic VX-2 tumor before and after chemoembolization

ADC values and signal values of VX-2 tumors were shown in Table 1 and Figures 2-5.

The distinction between ADC in the area of VX-2 tumor periphery, tumor center or normal parenchyma around tumor was respectively significant ($F = 14.366$, $P < 0.001$; $F = 4.674$, $P = 0.033$; $F = 23.054$, $P < 0.001$) with b-value 100 s/mm^2 and with b-value is 300 s/mm^2 was respectively significant ($F = 14.366$, $P < 0.001$; $F = 4.674$, $P = 0.033$; $F = 23.054$, $P < 0.001$). Signals in the area of VX-2 tumor periphery, tumor center and normal parenchyma around tumor b-value was 100 s/mm^2 were higher than with b-value was 300 s/mm^2 ($F = 112.874$, $P < 0.001$; $F = 83.455$, $P < 0.001$; $F = 135.455$, $P < 0.001$).

When b-value was 100 s/mm^2, the distinction of ADC in the area of VX-2 tumor periphery, tumor center and normal parenchyma around tumor among group A, B, C, D and E was respectively significant($F = 7.325$, $P < 0.001$; $F = 2.496$, $P = 0.048$; $F = 6.856$, $P < 0.001$). The distinction of signal in the area of VX-2 tumor periphery among group A, B, C, D and E was significant ($F = 3.005$, $P < 0.05$) but that in the area of VX-2 tumor center and normal parenchyma around tumor was not significant ($F = 1.399$, $P > 0.05$; $F = 2.146$, $P > 0.05$).

Manifestations of VX-2 tumor pathology

Observed by the naked eye, most surfaces of normal hepatic parenchyma around VX-2 tumor were paler in investigation group than those in control group and there was embolization of unequal areas but well-circumscribed. The tumors were hard and there was clear demarcation. The cavities of unequal size were found in the area of VX-2 tumors because kermesinus liquid had run off after the tumors werfae cut open.

Under microscope, some edema cells containing ballooning degeneration were observed in the area of normal parenchyma around VX-2 tumor. Inequality

Table 1 ADC values of tumor and normal parenchyma after Chemoembolization

Group	VX-2 tumor periphery areas		VX-2 tumor center areas		Hepatic normal parenchyma	
	b = 100	b = 300	b = 100	b = 300	b = 100	b = 300
Control	1.71 ± 0.27	1.48 ± 0.23	1.77 ± 0.36	1.55 ± 0.30	2.71 ± 0.42	2.30 ± 0.40
6 h	1.56 ± 0.40	1.36 ± 0.18	1.97 ± 0.49	1.79 ± 0.37	2.44 ± 0.53	1.87 ± 0.31
16 h	1.24 ± 0.22	1.12 ± 0.20	1.56 ± 0.40	1.69 ± 0.35	2.10 ± 0.54	1.65 ± 0.37
32 h	1.48 ± 0.37	1.23 ± 0.16	1.99 ± 0.32	1.66 ± 0.31	2.10 ± 0.49	1.97 ± 0.29
48 h	1.57 ± 0.23	1.40 ± 0.18	2.04 ± 0.54	1.82 ± 0.27	2.43 ± 0.33	2.06 ± 0.23
Total	1.51 ± 0.33	1.32 ± 0.23	1.87 ± 0.45	1.70 ± 0.32	2.36 ± 0.51	1.97 ± 0.38

Data are expressed as mean ± SD × 10^{-3} mm^2/s; ADC: Apparent diffusion coefficient.

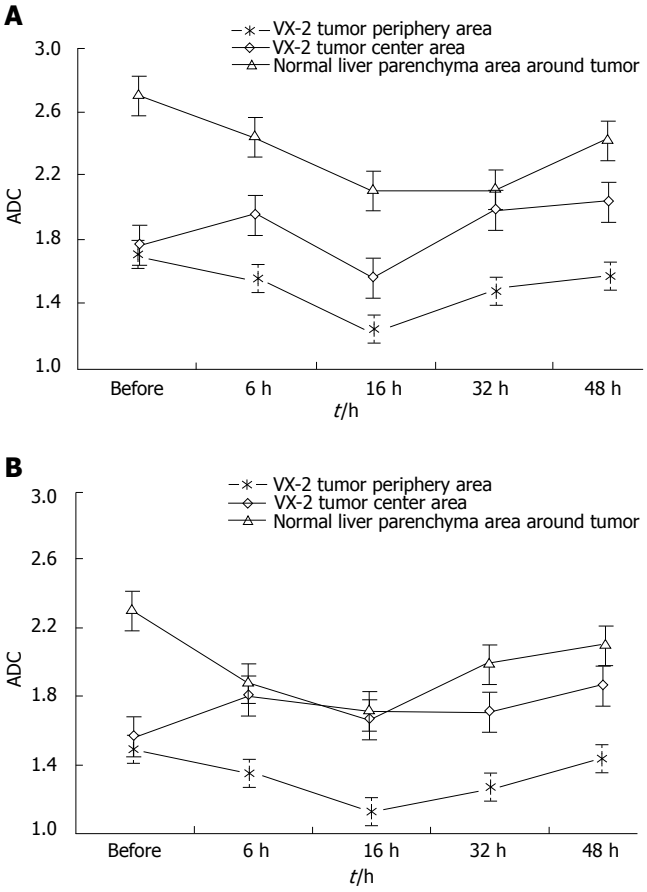

Figure 2 ADC values of different areas on DWI after chemoembolization. **A**: B-value was 100 s/mm^2; **B**: B-value was 300 s/mm^2.

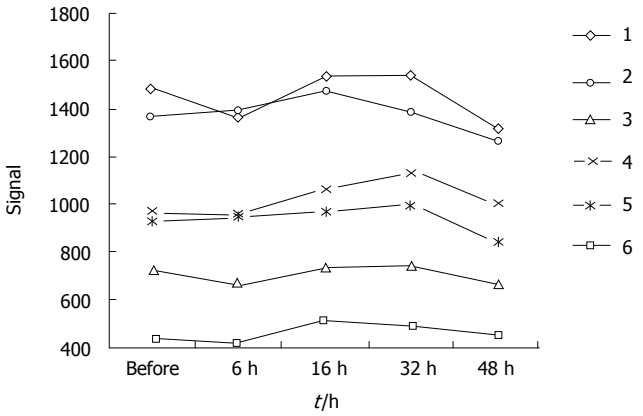

Figure 3 Signal values on DWI when area and b-value was different after chemoembolization. Areas: 1-signal of VX-2 tumor periphery area when b-value was 100 s/mm^2; 2-signal of VX-2 tumor center area when b-value was 100 s/mm^2; 3-signal of the normal liver parenchyma area around tumor when b-value was 100 s/mm^2; 4-signal of VX-2 tumor periphery area when b-value was 300 s/mm^2; 5-signal of VX-2 tumor center area when b-value was 300 s/mm^2; 6-signal of the normal liver parenchyma area around tumor when b-value was 300 s/mm^2.

of size, round or ellipse or strip tumor nests could be observed in different areas of VX-2 tumor. The degree of cell edema and necrosis were more obvious in group B,C and D (after chemoembolization) than group A (before chemoembolization), the necrotic areas were more in the area of VX-2 tumor center than those in the area of tumor periphery or tumor outer layer, and most areas of tumor center were necrotic in some VX-2 tumors.

Edema cells showed their volume increased obviously, kytoplasm dyeing thinly and obvious ballooning degeneration (Figure 6 and 7). Dynamical information of cellular edema and necrosis were counted in Tables 2 and 3.

DISCUSSION

The signal and ADC characteristics of many hepatic pathological changes on DWI have been reported in recent years[23-26]. DWI has significant and potential clinical application values in detecting, diagnosing and differentiating tumors earlier. From what has been determined when DWI was investigated by Yuan *et al* in rabbit liver VX-2 tumor model, VX-2 tumor is a solid tumor and its body mainly consists of tumor nests and other cells so that its water molecule diffusion motion is obviously restricted, the signal of them is significantly high and ADC is significantly low.

The signals in VX-2 tumors were higher than those in the area of normal parenchyma around tumor while ADC values were lower than those in the area of normal parenchyma after chemoembolization, and the tendency of the signal and ADC in VX-2 tumors and in the area of normal parenchyma was basically the same. The signals in VX-2 tumors were uneven, the signals in the area of tumor center were lower than that in the area of tumor periphery, while those in the 48 h after chemoembolization were lower than that before chemoembolization. The areas of low signal and high signal were observed in VX-2 tumor and ADC of them was higher than that in the equal signal area of VX-2 tumor or in the area of normal parenchyma. Accordingly with pathology, the areas of low signal in VX-2 tumor were coagulation necrosis, those of high signal were liquid or cystic tissue,

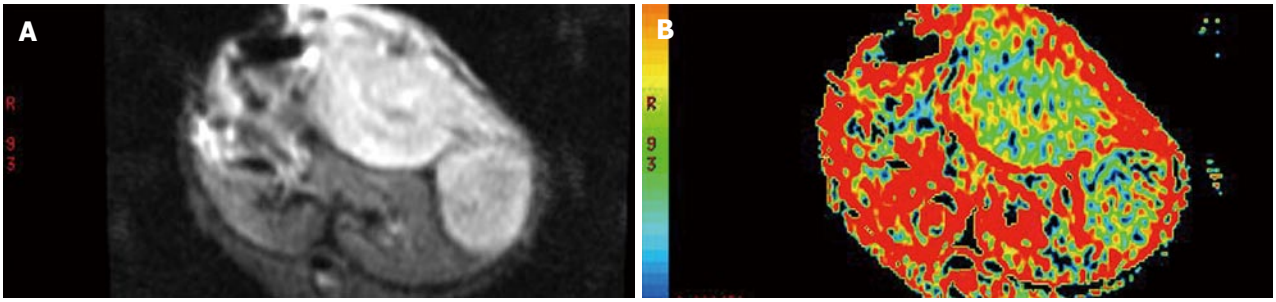

Figure 4 Image manifestations of hepatic VX-2 tumor on DWI and ADC map when b-value was 100 s/mm^2 at 6 h after chemoembolization **A**: High signal and distinct margin of VX-2 tumor on DWI; **B**: Low signal of it on the ADC map.

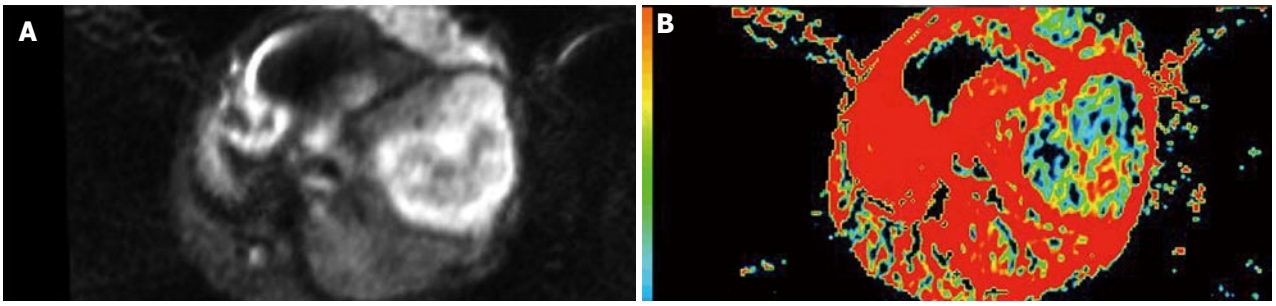

Figure 5 Image manifestations of hepatic VX-2 tumor on DWI and ADC map when b-value was 100 s/mm^2 at 48 h after chemoembolization **A**: High and uneven signal and distinct margin of VX-2 tumor on DWI; **B**: Low and uneven signal of it on the ADC map.

and other areas except low signal and high signal areas in the lump were viable tumor cells. Moreover, necrotic areas in VX-2 tumors after chemoembolization were more than those before chemoembolization. When coagulation necrosises/necroses takes place in the tumor because of insufficient blood provision, cellular membrane will break and the limitation of water molecular motion in the tumor decreases greatly so that the signals is reduced while ADC values are upgraded. After coagulation necroses have been liquefied or become cystic, cell lysis and leakier cell membranes can no longer compartmentalize water molecules and allow free diffusion to take place so that ADC values increase greatly. Nyway the signals of above mentioned liquefied or cystic areas are higher than those of coagulative necrosis areas, even viable tumor areas or normalparenchyma. It can be explained by the presence of greater amounts of extracellular water molecules within the necrotic region which is a kind of long T2-value contribution constitution and the b-value is 100 or 300 s/mm^2, a small b-value, in diffusion-weighted imaging scanning so that the signals of above are affected significantly by "shine-through".

At 6 h after chemoembolization, the signals in the area of tumor centers decreased slightly while ADC increased slightly, the signals in the area of tumor periphery and normal parenchyma increased significantly while ADC decreased at different degrees. However, pathology demonstrated that the degree of cellular necrosis in the area of normal parenchyma before chemoembolization was the same of that after chemoembolization while in the area of tumor periphery areas before chemoembolization was much more than after chemoembolization.

Accordingly with what discussed above, the signal increasing and ADC decreasing cannot completely be explained by tumor cellular necrosis after chemoembolization. The dynamic mechanisms of water molecular diffusion decreasing and the signal increasing while ADC values decreasing after cerebral infarction have been investigated by many investigators in recent years, and it is not completely comprehended yet, but most of them demonstrated it was connected with cytotoxic edema, microcirculation disturbance, temperature or abnormality of cellular membrane permeability, *etc*[27-31]. A series of clinical and animal experimental investigations by Xie *et al*[28], Han *et al*[29] and Marks *et al*[30] have demonstrated that the cytotoxic edema after embolization had significant influences on the change of water molecules diffusion. Because of dysfunctional Na-K pump due to early hypoxia after embolization, the density of intra-cellular electrolyte increases and then also water molecules of intra-cells increase significantly, while extra-cell water molecules decrease significantly, so that ADC starts decreasing while the signal starts increasing. When intracellular edema reaches to the biggest degree, ADC of constitution will decrease to the lowest and it will maintain at a low degree if intracellular edema maintains or if there are constitution edema originating from the blood vessel. ADC of constitution will start increasing after cellular membrane has been broken and cells have dissolved; it will reach the biggest when constitution has been liquefied and become cystic.

After chemoembolization, ADC in the area of VX-2 tumor periphery and normal parenchyma decreased quickly wuth ther bottom at biggest in the 16th h and

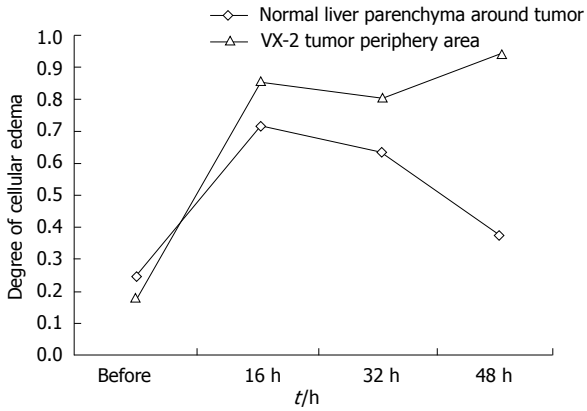

Figure 6 Cellular edema of different areas after chemoembolization.

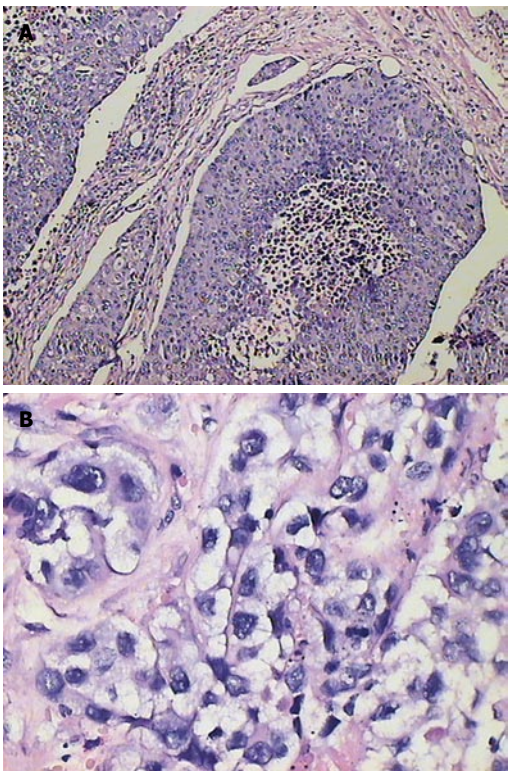

Figure 7 **A**: Cell nest of VX-2 tumor and wide zone of necrosis in the tumor(x 100) and **B**: cellular edema in the VX-2 tumor (x 400).

then increased gradually but they were significantly lower in the 48th h after chemoembolization than those before chemoembolization. Pathology demonstrated the degree of cellular edema in the area of VX-2 tumor and normal parenchyma were significant higher after chemoembolization than before chemoembolization and it reaching a peak at 16th h after chemoembolization and then decreased gradually. The signal and ADC changes in the area of VX-2 tumor and normal parenchyma were significantly relative to cellular edema. The function of Na-K pump decreases or misses because of ischemia and hypoxia from chemoembolization and toxic action from chemotherapeutic drug; the degree of intra-cell edema also increases significantly after chemoembolization so that ADC starts decreasing. With intracellular edema lessening

Table 2 Dynamic information of cellular edema after chemoembolization (%) (mean ± SD)

	Control	16 h	32 h	48 h
Normal parenchyma	24.90 ± 11.69	72.12 ± 34.48	63.89 ± 29.87	38.00 ± 24.57
Tumor periphery areas	18.16 ± 10.35	86.06 ± 16.01	81.18 ± 20.03	96.66 ± 4.76

Table 3 Manifestations of VX-2 tumor pathology after chemoembolization

	Cellular membrane		Cellular necrosis			
	0	1	0	1	2	3
Normal parenchyma (Control)	8	2	7	3		
Tumor periphery areas (Control)	10				9	1
Normal parenchyma (16 h)	7	3	7	1	2	
Tumor periphery areas (16 h)	10			2	4	4
Normal parenchyma (32 h)	7	3	7	1	2	
Tumor periphery areas (32 h)	10				3	7
Normal parenchyma (48 h)	6	4	8	2		
Tumor periphery areas (48 h)	10				4	6

or cell breaking, ADC values will increase gradually. The dynamic changes of ADC can reflect the degree of tumor cellular edema and cellular necrosis.

However, after chemoembolization, ADC in the area of VX-2 tumor periphery and normal parenchyma increased gradually but the signals decreased gradually from the 16th h to the 48th h after chemoembolization; the signals were lower in the 48th h than those before chemoembolization. Pathology demonstrated that the degree of cellular edema in the area of normal parenchyma reached a peak in the 16th h and then decreased gradually but that in the area of tumor periphery reached a peak in the 16th h and then increased continually after chemoembolization. The degree of cellular edema in the area of tumor periphery was significantly lower than that in the area of normal parenchyma. Double blood-provision from hepatic artery and portal system plus our protocols of transcatheter hepaticarterial chemoembolization can explain it. Selective catheterization was not carried out in our experiments so that ischemia and hypoxia took place in the VX-2 tumor and normal parenchyma at the same time and ADC decreased because of intracellular edema. The degree of cellular edema in VX-2 tumor was higher than that in the area of normal parenchyma after chemoembolization because 95%-99% blood provision of hepatocellular carcinoma comes from hepatic artery while 70%-75% blood provision of normal parenchyma comes from portal system and others comes from hepatic artery. Blood provision from portal system would recover step by step after chemoembolization so that the degree of cellular edema in the area of normal parenchyma decreased significantly but that in VX-2

tumor increased continually from the 16 h to the 48 h after chemoembolization. Otherwise, as reported by Yang *et al*[31], blood provision decreasing could lead to ADC decreasing and ADC reflected blood provision to a certain degree when b-value was small in diffusion-weighted imaging scanning. Since b-value was small in our scanning, ADC could be affected by blood provision after chemoembolization.

Necrotic tumor manifests low signal and high ADC value, while viable tumor manifests high signal and low ADC value after chemoembolization. DWI has potential ability in detecting and differentiating viable tumor from necrotic tumor and, besides water molecular diffusion, intracellular edema, microcirculation disturbance and tumor necrosis from chemoembolization are significantly relative to ADC changing dynamically.

COMMENTS

Background

Transcatheter arterial chemoembolization (TACE) is a kind of classic interventional therapy and it is commonly performed to treat the unresectable hepatocellular carcinoma and most secondary liver cancers. The major goal of chemoembolization is to destroy the tumor. Ultrasound (US), digital subtraction angiography (DSA), computed tomography (CT) and magnetic resonance imaging (MRI) are usually used to diagnose and to evaluate the progression of hepatic tumor but they have their respective defects. Diffusion-weighted imaging is a kind of new functional imaging technology having been developed in recent years and it is the only one method which is able to reflect non-woundingly water molecular diffusion *in vivo*. Geschwind *et al* demonstrated that the signals of VX-2 tumor necrotic areas were low and ADC of them were significantly greater in the area of tumor necrosis than those in the area of viable tumor after chemoembolization. Therefore, we believe that DWI, especially ADC, has potential values in reflecting characteristics of liver pathological changes and differentiating benign tumor from malignant one.

Research frontiers

Many studies of hepatic pathological changes on DWI have been reported. ADC values of benign lesions, such as hepatic cysts and hemangiomas, were higher than those of malignant lesions, such as hepatocellular carcinomas and metastases on DWI and many studies also indicated that the signals of tumor coagulative necrotic areas were lower in comparison with that of tumor viable areas. There has been no dynamically and image-pathologically investigated report on the characteristics of hepatocellular carcinomas on DWI after chemoem-bolization.

Innovations and breakthroughs

Our study clearly showed that necrotic tumor manifested low signal and high ADC value while viable tumor manifested high signal and low ADC value after chemoembolization. DWI would have potential ability in detecting and differentiating viable tumor from necrotic tumor and, besides water molecular diffusion, intracellular edema, microcirculation disturbance and tumor necrosis from chemoembolization were significantly relative to ADC changing dynamically.

Applications

Physicians can apply this knowledge to evaluate obviously progression of hepatic tumors and differentiate accurately the areas and degrees of necrotic tumor from that of viable tumor before and after chemoembolization.

Peer review

This is an interesting, well designed, and written study on a problem of real clinical significance.

Abstract

AIM: To understand the interactions between iron and zinc during absorption in iron- and zinc-deficient rats, and their consequences on intestinal oxidant-antioxidant balance.

METHODS: Twenty-four weanling Wistar-Kyoto rats fed an iron- and zinc-deficient diet (< 6.5 mg Fe and 4.0 mg Zn/kg diet) for 4 wk were randomly divided into three groups (n = 8, each) and orally gavaged with 4 mg iron, 3.3 mg zinc, or 4 mg iron + 3.3 mg zinc for 2 wk. On the last day of repletion, 3 h before the animals were sacrificed, they received either 37 mBq of ^{55}Fe or ^{65}Zn, to study their localization in the intestine, using microautoradiography. Hemoglobin, iron and zinc content in plasma and liver were measured as indicators of iron and zinc status. Duodenal sections were used for immunochemical staining of ferritin and metallothionein. Duodenal homogenates (mitochondrial and cytosolic fractions), were used to assess aconitase activity, oxidative stress, functional integrity and the response of antioxidant enzymes.

RESULTS: Concurrent repletion of iron- and zinc-deficient rats showed reduced localization of these minerals compared to rats that were teated with iron or zinc alone; these data provide evidence for antagonistic interactions. This resulted in reduced formation of lipid and protein oxidation products and better functional integrity of the intestinal mucosa. Further, combined repletion lowered iron-associated aconitase activity and ferritin expression, but significantly elevated metallothionein and glutathione levels in the intestinal mucosa. The mechanism of interactions during combined supplementation and its subsequent effects appeared to be due to modulation of cytosolic aconitase, which in turn influenced the labile iron pool and metallothionein levels, and hence reduced intestinal oxidative damage.

CONCLUSION: Concurrent administration of iron and zinc corrects iron and zinc deficiency, and also reduces the intestinal oxidative damage associated with iron supplementation.

Key words: Iron; Zinc; Absorption; Intestine; Aconitase; Ferritin; Metallothionein; Oxidative damage

INTRODUCTION

Iron-deficiency anemia is frequently the result of low intake of dietary iron, and high intake of phytate and tannins, which inhibit iron absorption. An iron-deficient population can generally have zinc deficiency, due to similar influences of various dietary factors on iron and zinc absorption[1]. There is strong evidence in humans that a blockage of zinc absorption is a consequence of daily intake of high amounts of iron[2]. Studies in pregnant women also provide evidence that the absorption of supplemental iron is lower from multimineral antenatal supplements, particularly in the presence of high calcium and magnesium than when it is administered alone[3,4]. It has therefore become evident during the past decade that deficiencies of iron and zinc co-exist, and those vulnerable groups may benefit from iron as well as zinc supplementation, rather than individual supplementation with these minerals. However, iron and zinc are known to interact, either at the site of absorption or post-absorptively, because of competition for similar transport pathways[5-8]. Moreover, these two minerals have opposing effects on oxidant-antioxidant balance in either iron- or zinc-deficient intestines[8,9]. As mineral supplementation programs are designed for populations at risk of both iron and zinc deficiencies, understanding of quantitative and qualitative aspects of the potential of the two metals is critical. Iron and zinc have been found to interact antagonistically at the site of absorption, and this interaction helps in reducing the iron-mediated generation of hydroxyl radicals and

subsequent intestinal oxidative damage during repletion in a single mineral deficiency[8,9]. Other cascading effects of such interactions are the reduction of iron and zinc uptake, aconitase activity, and ferritin expression in the intestinal mucosa. Besides, zinc induction of metallothionein in the intestinal mucosa helps to restore its functional integrity[8]. However, absorption of these two minerals is regulated at the intestinal level[10,11], and hence the nature and extent of interactions may differ when the deficiencies co-exist, because of molecular adaptations that modulate the absorption of these minerals. Therefore, in the present study, we depleted iron and zinc in weanling rats and studied the nature of the interactions between two metals, and their consequences on intestinal oxidant-antioxidant balance; finally we postulated a probable mechanism.

MATERIALS AND METHODS

Animals and diets

This study employed a typical depletion-repletion design for understanding the potential interactions of iron and zinc during supplementation in iron- and zinc-deficient rats. The Institutional Animal Ethical and Bio-safety Committee of the National Institute of Nutrition approved the study.

Twenty-four weanling female Wistar-Kyoto rats, (National Center for Laboratory Animal Science at the National Institute of Nutrition, Hyderabad, India) weighing 35-45 g, were fed an egg-albumin-based, semi-synthetic, purified iron- and zinc-deficient diet (< 6.5 mg Fe and 4.0 mg Zn/kg diet) for 4 wk (Table 1). Rats were housed individually in polypropylene cages with stainless steel wire floors (45 cm × 16 cm, 7.5 mm mesh, 1 mm wire diameter) to prevent coprophagy, in a room maintained at 23℃ and 60% humidity, with a 12-h light: dark cycle. Deionized distilled water, in plastic bottles with stainless steel sippers, was freely available to all rats. Body weight was recorded weekly and blood was collected by orbital sinus puncture for determination of iron and zinc status at the end of depletion and repletion.

Oral repletion of iron and/or zinc

At the end of depletion phase, rats were randomly divided into three groups and assigned to either Fe, Zn and Fe + Zn groups for repletion (n = 8, each). In order to achieve complete repletion of both the minerals, while minimizing the intestinal oxidative damage, we used a dose of 4 mg iron and 3.3 mg zinc for repletion. Force feeding was performed daily during the repletion period, either with a dose of 4.0 mg iron (Fe group), 3.3 mg zinc (Zn group) or a combination of 4.0 mg iron and 3.3 mg zinc (Fe + Zn group) in 1.0 mL 0.01 mol/L HCl, via an orogastric plastic tube, for 2 wk[12]. During this period, the rats were fed an iron- and zinc-deficient diet *ad libitum*. The doses were prepared by dissolving $FeSO_4$ and $ZnSO_4$ salts, either individually or in combination, in dilute HCl[8]. Administration of 0.01 mol/L HCl alone to the rats had no significant effect on the parameters studied[12]. Therefore, vehicle controls were not included in the present study. All the rats were fasted for 16 h before administering the last dose for uptake studies and for studying various other parameters.

Table 1 Composition of the iron and zinc-deficient diet

Ingredient	Concentration g/kg diet
Egg albumin powder	220
Cornstarch	293
Sucrose	300
Cellulose	40
Peanut oil	70
Mineral mixture[1]	35
Vitamin mixture[1]	10
DL-methionine	4

[1]Mineral and vitamin mixture were formulated according to AIN (1993), but mineral mixture was devoid of iron and zinc salts (4.0 mg Zn and 6.5 mg Fe/kg diet) during depletion and repletion.

Uptake of iron and zinc; immunolocalization of ferritin and metallothionein in the duodenum

Three rats, each from the Fe and Zn repleted groups, along with six rats from the Fe + Zn repleted group (three each for ^{55}Fe and ^{65}Zn) were randomly selected. Fe group rats received 4.0 mg Fe with 37 mBq of ^{55}Fe (specific activity, 46.9 mCi/g), Zn group rats received 3.3 mg Zn with 37 mBq of ^{65}Zn (specific activity, 1.14 Ci/g), and the Fe + Zn group rats received 4.0 mg Fe and 3.3 mg Zn with either 37 mBq of ^{55}Fe (n = 3) or 37 mBq of ^{65}Zn (n = 3) (BRIT, Mumbai, India). The rats were killed after collecting blood. Proximal 10-cm portion of the duodenum was excised for mucosa collection. Samples of liver were collected from the rats for iron and zinc determination by atomic absorption spectrophotometry.

The tissues were placed immediately on ice, trimmed of excess fat and mesentery, and weighed. The intestinal segments were flushed with ice-cold saline. Of the 10-cm portion, the first 2.0 cm was used for studying iron and zinc uptake, and localization of their responsive proteins, while the remaining portion was saved and processed for obtaining mucosal homogenates. The 2.0-cm portion was placed in 10% neutral-buffered formalin for 12 h, washed in PBS for 24 h, using a "Swiss roll" technique[13] to evaluate the entire longitudinal section on one slide and embedded in paraffin at 58℃. Multiple serial sections of 4-μm thickness were obtained from these blocks. These sections were dewaxed, defatted, mounted on chrome alum-gelatin coated slides, and dip-coated with Amersham LM1 photographic emulsion (Amersham, UK). These were then exposed for 30 d in a light-proof desiccator at 4℃, before developing and fixing in Kodak D-19 developer and Kodak Rapid fix (Kodak, Rochester NY), respectively. Sections were stained with Mayer's hematoxylin and eosin, and then examined using a Nikon Microfot-FX microscope (Nikon, Japan) at 100 × magnification, and photographed. In separate serial sections, localization of ferritin and metallothionein was probed using immunohistochemistry. Briefly, dewaxed and defatted sections were incubated overnight with a 1:500 dilution of rabbit anti-rat liver ferritin[12], or 1:50 dilution

of metallothionein antibody (Clone E9; Dako Corp, Carpinteria, CA), or with IgG from non-immune rabbit serum. The specific binding was detected by biotinylated goat anti-rabbit IgG and avidin-biotin peroxidase complex (Sigma, St. Louis, MO) using hydrogen peroxide and diaminobenzidine. The endogenous peroxidase was quenched with 0.3% hydrogen peroxide in 100% methanol for 15 min. The sections were counterstained with hematoxylin and eosin and observed by light microscopy at 250 × magnification, and photographed.

Preparation of intestinal mucosa

We used the remaining 7-cm intestinal segment from the radioisotope-treated animals and the whole segment from non radioisotope-treated animals, for preparation of intestinal homogenates. All the animals were sufficiently repleted for 2 wk. However, radioisotope-treated animals received an additional dose of iron and/or zinc at the end of repletion. This single additional dose is unlikely to contribute much to the nutrient status compared to animals that have not received radioisotope.

The duodenal segments collected from each rat in ice-cold 1.15% KCl were scraped and a 10% homogenate of the mucosal suspension was prepared in 1.15% KCl containing 0.5 mmol/L butylated hydroxy tolune (to prevent *ex vivo* peroxidation) as described previously[12]. The homogenate was subjected to differential centrifugation (Sorvall RC-5B, Du Pont Instruments, CT) at 800 *g* for 30 min, 12 000 *g* for 30 min, and 100 000 *g* for 1 h at 4℃, and the respective supernatants were collected and stored at -20℃ until further analysis. The protein content in these supernatants was determined using a modified Lowry method, with BSA as the standard.

Iron and zinc content in diet, plasma and liver

Iron and zinc concentrations in the diet, liver, mineral solutions and plasma were determined by atomic absorption spectrophotometry using a SpectrAA-400 atomic absorption spectrometer (Varian, Sunnyvale, Melbourne, Australia). The mineral deficient diet fed to the rats was digested with concentrated nitric acid and 70% perchloric acid by method (Ⅱ) A of the Analytical Methods Committee (1960)[14]. One g of liver tissue was ashed in a muffle furnace at 600℃ for 6 h and was used to prepare the mineral solution.

Markers of functional integrity

Activity of alkaline phosphatase and lys-ala-dipeptidyl aminopeptidase was measured in the 12 000 *g* supernatant to assess the functional integrity of the intestinal mucosa, because of the differential localization of these two enzymes within the mucosal cells: the maximum activity of the former towards the upper half of the villus, and that of the latter towards the lower half[8,12]. Alkaline phosphatase activity was determined using β-glycerophosphate and lys-ala-dipeptidyl aminopeptidase activity was measured using lys-ala-7-amido-4-methyl coumarin.

Markers of oxidative stress

The amount of thiobarbituric acid-reactive substance (TBARS) in the 12 000 *g* supernatant was measured using malondialdehyde as a standard, and was quantified, using a reverse-phase silica-based C18 column, according to Templar *et al*[15]. Elution was done for 10 min at a flow rate of 1.2 mL/min with 65% 50 mmol/L KH_2PO_4-KOH, pH 7.0, and 35% methanol buffer, while monitoring at 532 nm. Protein carbonyls were estimated by incubation of 1 mL of the 100 000 *g* supernatant with 10 mmol/L dinitrophenyl hydrazine (DNPH) for 1 h in the dark, followed by protein precipitation with trichloroacetic acid according to the method of Reznick & Packer[16]. The final DNPH and lipid-free precipitate was dissolved in 6 mol/L guanidine hydrochloride and the absorbance was read at 375 nm. The amount of protein in the final pellet was quantified at 280 nm using BSA in guanidine hydrochloride as a standard.

Antioxidant status

Activity of total superoxide dismutase (SOD), glutathione peroxidase (100 000 *g* supernatant), Mn-SOD and catalase (12 000 *g* supernatant) was determined as previously described[17-19]. Glutathione (reduced GSH and oxidized GSSH) levels were determined using HPLC equipped with a fluorimetric detector (excitation at 350 nm and emission at 420 nm), according to Pastore *et al*[20]. Briefly, thiols were extracted using sulfosalicylic acid and injected onto a 150 mm × 4.6 mm Hypersil ODS column, equilibrated with 30 mmol/L ammonium nitrate and 40 mmol/L ammonium formate buffer, pH 3.6. For GSH determinations, $NaBH_4$ was substituted with 2 mmol/L EDTA-DTT. The thiols were eluted from the column with a 6-min gradient of acetonitrile (0-4 min, 0%-30% acetonitrile; 4-5 min, 30%-100% acetonitrile; 5-6 min, 100% acetonitrile) at a flow rate of 1.5 mL/min.

Activity of duodenal mucosal aconitase

The activity of aconitase in cytosolic (100 000 *g* supernatant) and mitochondrial (12 000 *g* pellet) was measured by a coupled isocitrate dehydrogenase reaction, monitored at 37℃ (Cary 100 Bio UV-Vis spectrophotometer, Varian Inc., CA) at 340 nm for 1 h [21,22].

Statistical analysis

Statistical analysis was performed using SPSS/PC+, version 5.0 (SPSS, Chicago, IL, USA). Comparison among the three groups was tested by one-way ANOVA with post-hoc multiple comparison tests. For measurements of body weight and iron and zinc status, comparisons were made with littermates maintained in the animal colony. The values were considered significantly different at $P < 0.05$.

RESULTS

Body weight changes

Rats fed an iron- and zinc-deficient diet for 4 wk weighed 57% less than their littermates in the animal colony (62.0 ± 8.0 g and 108.2 ± 7.5 g, respectively). However, the final bodyweight of Fe-, Zn- and Fe + Zn-repleted rats was similar, but weighed 50% of their littermates (95.6 ± 10.2 g and 190.0 ± 14.8 g).

Iron and zinc status

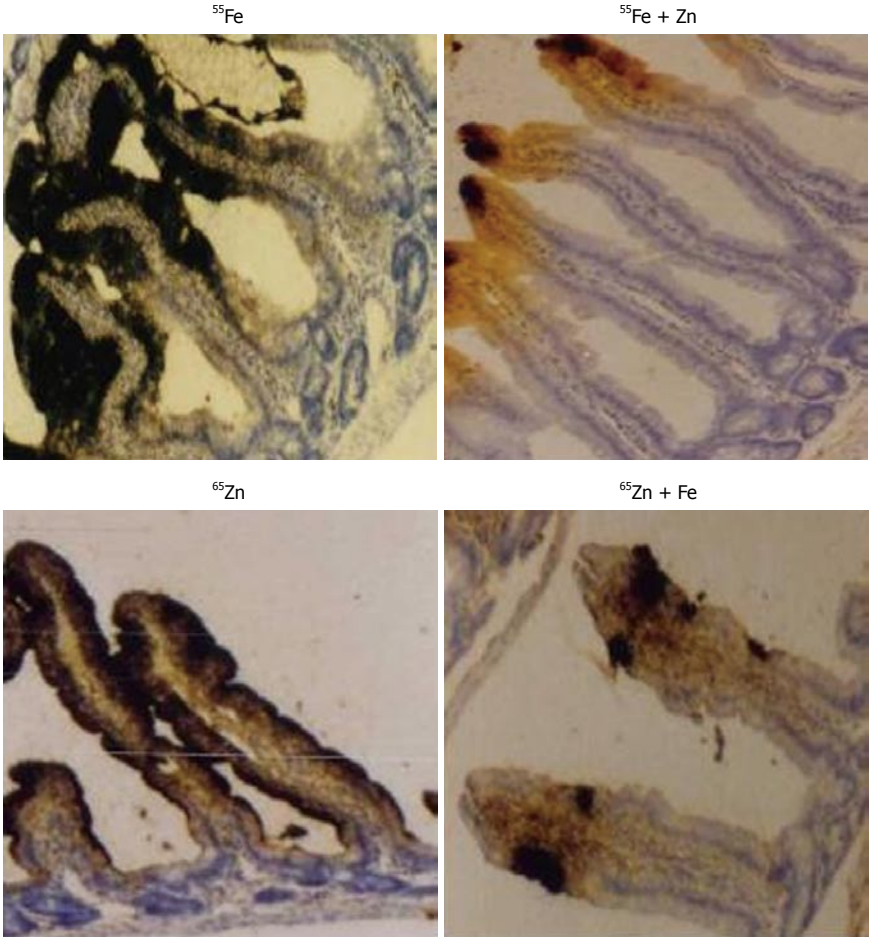

Figure 1 Zn reduces uptake of ^{55}Fe and Fe reduces uptake of ^{65}Zn during combined administration: A representative microautoradiogram of the duodenal mucosa of ^{55}Fe in Fe (top left), Fe + Zn (top right), ^{65}Zn in Zn (bottom left). and Fe + Zn (bottom right) groups. Iron and zinc deficient rats were orally administered 37mBq of ^{55}Fe and 4.0 mg Fe and/or 37mBq of ^{65}Zn and 3.3 mg Zn. Presence of black spots in the intestinal mucosa indicates the presence of the radioactivity (× 100).

Table 2 Iron and zinc status after concurrent depletion and repletion

Group	Hemoglobin (g/L)	Iron		Zinc	
		Plasma (μmol/L)	Liver (μg/g)	Plasma (μmol/L)	Liver (μg/g)
-Fe - Zn	82.0^{a} ± 3.2	65.0^{a} ± 4.6	-	12.3^{a} ± 2.0	-
Fe	126.9^{b} ± 3.0	94.8^{b} ± 7.2	192.8^{a} ± 12.5	13.0^{a} ± 1.8	22.8^{a} ± 4.5
Zn	80.0^{a} ± 2.8	64.0^{a} ± 5.5	43.7^{b} ± 6.6	29.6^{b} ± 3.0	48.6^{b} ± 4.6
Fe + Zn	106.8^{c} ± 3.0	82.4^{c} ± 3.8	157.5^{c} ± 7.7	20.5^{c} ± 3.2	37.1^{c} ± 4.2

Iron and zinc deficient (-Fe-Zn) rats were administered 4.0 mg Fe and/or 3.3 mg Zn/day for 2 wk; Fe: Iron administered group; Zn: Zinc administered group; Fe + Zn: Iron and zinc administered group; Number of animals was 8 in each group. Values are mean ± SD; means with different superscripts are significantly different with $P < 0.05$.

Iron and zinc depletion were confirmed by lowered hemoglobin and plasma zinc concentrations compared to their littermates in the animal colony, which were fed an iron- and zinc-adequate diet (35.0 mg Fe and 30.0 mg Zn/kg diet). Concurrent depletion of iron and zinc resulted in reduction of hemoglobin to 58%, plasma iron to 86% and plasma zinc to 38% compared to littermates. A significant lowering in all the above measured variables indicated the co-existence of iron and zinc deficiency in the experimental rats (Table 2). On repletion, hemoglobin and plasma and liver iron concentrations were significantly higher in the Fe and Fe + Zn groups compared to the Zn group (Table 2). Among the iron-repleted groups, iron status was significantly higher in the Fe than in the Fe + Zn group. Similarly, plasma and liver zinc concentrations were significantly higher in the Zn and Fe + Zn groups than in the Fe group. However, the Fe + Zn group showed significantly lower zinc status compared to the Zn group (Table 2).

Uptake of ^{55}Fe and ^{65}Zn; immunolocalization of ferritin and metallothionein in intestinal mucosa

To understand the effect of interactions following concurrent repletion of iron and zinc to depleted rats, we looked for their presence in the site of absorption. Uptake of ^{55}Fe and ^{65}Zn at the end of repletion in the intestinal mucosa was reduced in Fe + Zn-supplemented rats compared with Fe- or Zn-supplemented rats, respectively (Figure 1). Intestinal ferritin concentration was higher in the Fe than in the Fe + Zn group (Figure 2, upper panel). Identically, metallothionein concentration in the intestinal mucosa was high and appeared similar in the Zn and Fe + Zn groups, but relatively weak in the Fe group (Figure 2, Lower panel).

Intestinal oxidative stress and its functional integrity

Interactions between iron and zinc and their functional relevance to intestinal oxidative stress were assessed by as TBARS and protein carbonyls. TBARS and protein carbonyl concentrations were 1.5-fold higher in the Fe than in the Fe + Zn group. These indices did not differ in the Zn and Fe + Zn groups (Figure 3A and B). Activity

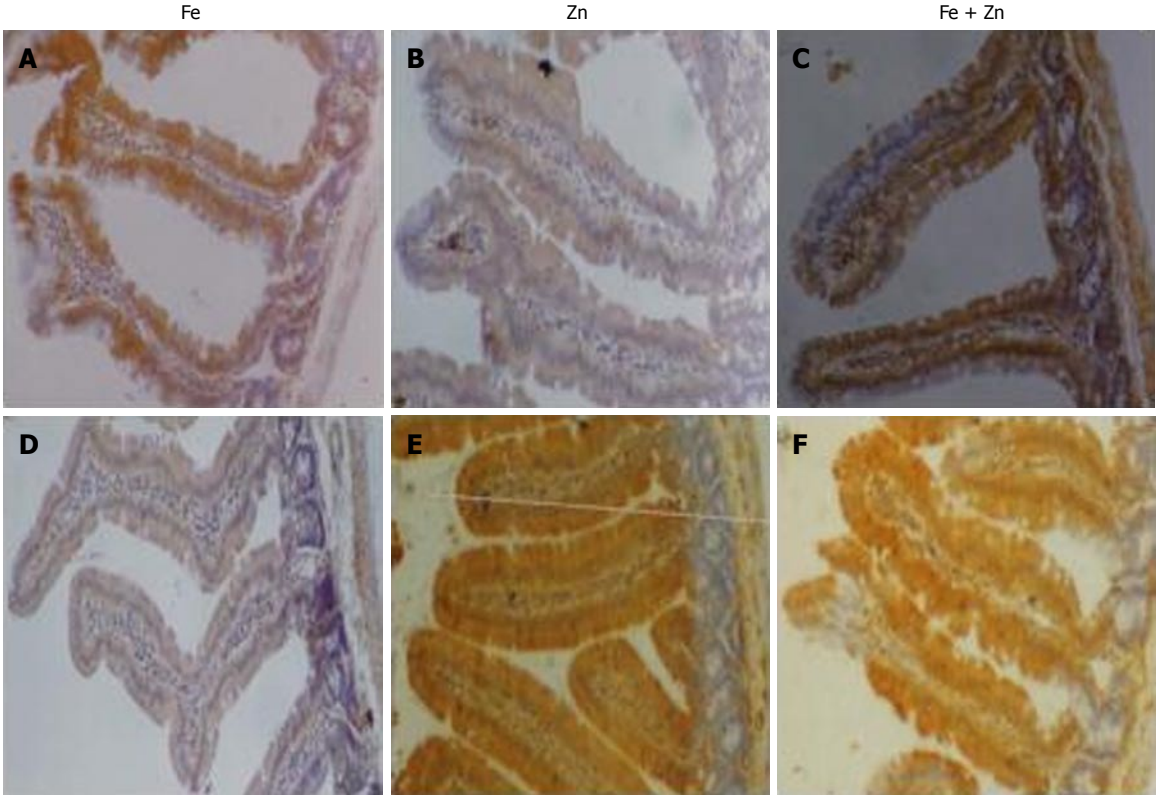

Figure 2 Zn reduces ferritin but enhances metallothionein abundance in the intestinal mucosa: A representative photomicrograph of the immunohistochemical localization of ferritin (top panel) and metallothionein (bottom panel) in the intestinal mucosa of Fe, Zn and Fe + Zn repleted groups. The staining intensity indicates the abundance of ferritin and metallothionein (× 250).

of the marker enzymes alkaline phosphatase and lys-ala-dipeptidyl aminopeptidase in the intestinal mucosa was about 20% lower in the Fe than in the Fe + Zn group. The activity did not differ between the Zn and Fe + Zn groups (Figure 3C and D).

Antioxidant status

Activity of intestinal SOD and glutathione peroxidase, except Mn-SOD, was significantly higher in the Fe than in the Zn and Fe + Zn groups. Catalase activity was significantly higher in the Fe and Fe + Zn groups compared to the Zn group. These enzyme activities did not differ between the Zn and Fe + Zn groups (Figure 4A-D), except for catalase activity. Glutathione concentration was significantly lower in the Fe than in the Zn and Fe + Zn groups. On the other hand, oxidized glutathione (GSSG) concentration was significantly higher in the Fe than in the Zn and Fe + Zn groups (Figure 5A and B).

Intestinal aconitase activity

Activity of cytosolic and mitochondrial aconitase was measured as an indicator of the cellular labile iron pool. Activity was higher in the Fe group, but lowered significantly in the Zn and Fe + Zn groups. Activity in the Fe + Zn group was higher than that in the Zn group (Figure 6A and B).

DISCUSSION

In the light of high prevalence of anemia, emerging incidence of zinc deficiency, and interactions during supplementation, we studied the interactive effects of iron and zinc repletion on oxidant/antioxidant status in combined deficient rats. Metabolic studies and supplementation trials suggest an antagonistic relationship between iron and zinc, in which zinc reduces the positive effects of iron supplementation and vice versa. For example, inorganic iron was found to compete for absorption with zinc when given to adults in solution in ratios > 2:1[2]. Zinc absorption in fasting pregnant Peruvian women treated with Fe or Fe + Zn was significantly reduced compared with non-metals supplemented women[23]; which indicates a post-absorptive effect of iron on zinc absorption. In women treated only with Fe, plasma zinc concentrations was also lower, compared with controls. Conversely, there were smaller improvements in hemoglobin and serum ferritin concentrations in Indonesian children treated both with Fe and Zn than in children treated with Fe alone[24]. Two recent studies on iron and zinc supplementation of Indonesian infants show that iron and zinc interactions occur when they are given as supplements[25,26]. In the study by Dijkhuizen *et al*, infants were treated with iron alone (10 mg/d), zinc alone (10 mg/d), both elements together (10 + 10 mg/d) and placebo from 4 to 10 mo of age. Supplementation significantly reduces the prevalence of iron deficiency anemia and zinc deficiency. Iron supplementation does not negatively affect plasma zinc concentration, and zinc supplementation does not increase the prevalence of anemia. However, combined iron and zinc supplementation is less efficacious than iron supplementation alone in reducing the prevalence

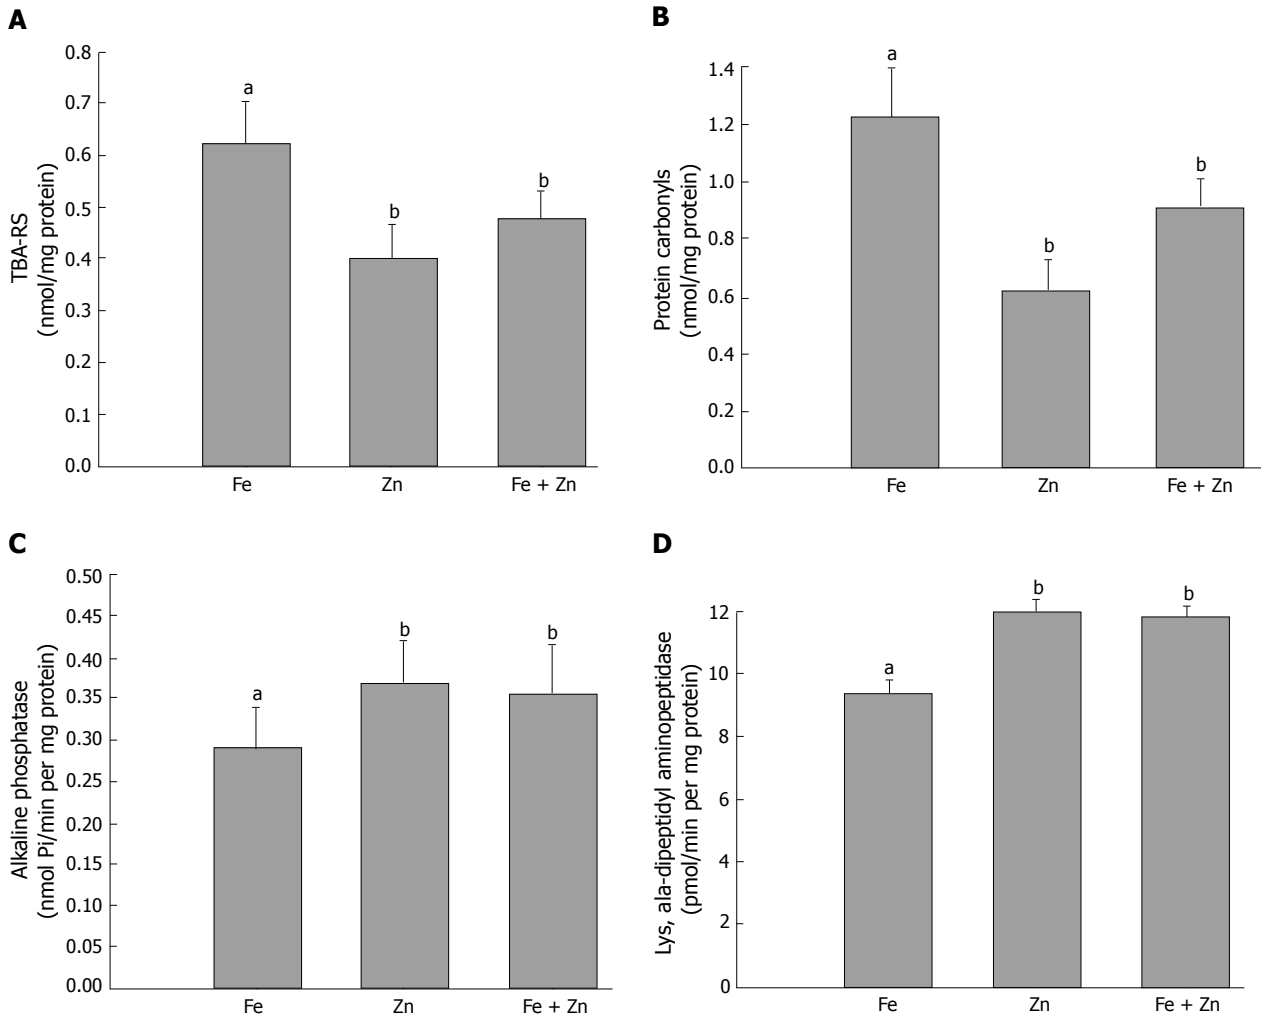

Figure 3 Iron increases intestinal oxidative stress and lowers functional integrity: Concentrations of thiobarbituric acid-reactive substances (TBA-RS) and protein carbonyls (**A** and **B**) as indicators of oxidative stress, and activities of alkaline phosphatase and lys-ala-dipeptidyl aminopeptidase (**C** and **D**), as markers of mucosal functional integrity, in the intestinal mucosa of iron and zinc deficient rats treated with iron and/or zinc. Fe: Iron administered group; Zn: Zinc administered group; Fe + Zn: Iron and zinc administered group; Number of animals: 7 in each group. Vertical columns and error bars represent mean and SD respectively; Bars with different superscripts are significantly different with $P < 0.05$ among groups.

of anemia (20% *vs* 38% reduction) and in increasing hemoglobin and plasma ferritin concentrations. In the study by Lind *et al*, infants received the same treatments, but from 6 to 12 mo of age. After supplementation, the Fe group had higher hemoglobin and serum ferritin than the Fe + Zn group; this fact indicates an effect of zinc on iron absorption. The Zn group had higher serum zinc than the placebo group, whereas this was not the case for the Fe and Fe + Zn groups, this fact suggests an effect of iron on zinc absorption. Thus, supplementation with Fe + Zn is less efficacious than single supplements alone in improving iron and zinc status, with evidence of negative interactions between iron and zinc when a combined supplement is given. However, the crucial question is whether such interactions between iron and zinc have any functional consequences for intestinal oxidative stress and functional integrity.

Both these nutrients are essential for growth, and in populations in which deficiencies of these minerals co-exist, stunting of growth has been reported[27]. Depletion of both iron and zinc in the diet has a significant impact on the growth of rats, and causes a marked reduction in iron and zinc status. Thus, the model developed in the present study had characteristic clinical and sub-clinical manifestations of iron and zinc deficiency, respectively. Although several studies have examined the effect of iron supplementation on zinc absorption, few have considered the effect of zinc supplementation on iron absorption. The molar ratio of iron and zinc seems to be critical in determining the interactive effects. One study has shown that zinc inhibited iron absorption when the zinc-iron ratio was 1.14:1 (1:1 molar ratio), but not when it was 0.36:1 (0.4:1 molar ratio)[28]. Another study has shown that a zinc-iron ratio of 5:1 significantly reduced iron absorption from an aqueous solution, but did not affect heme iron absorption from a hamburger meal in humans[29]. In the present study, we used a 1:1 molar ratio for repletion of iron- and zinc-deficient rats.

Several possible sites of interaction during transfer from the apical membrane into the intestinal cytosolic compartment, and from the basolateral membrane into plasma have been suggested by Fairweather-Tait[30].

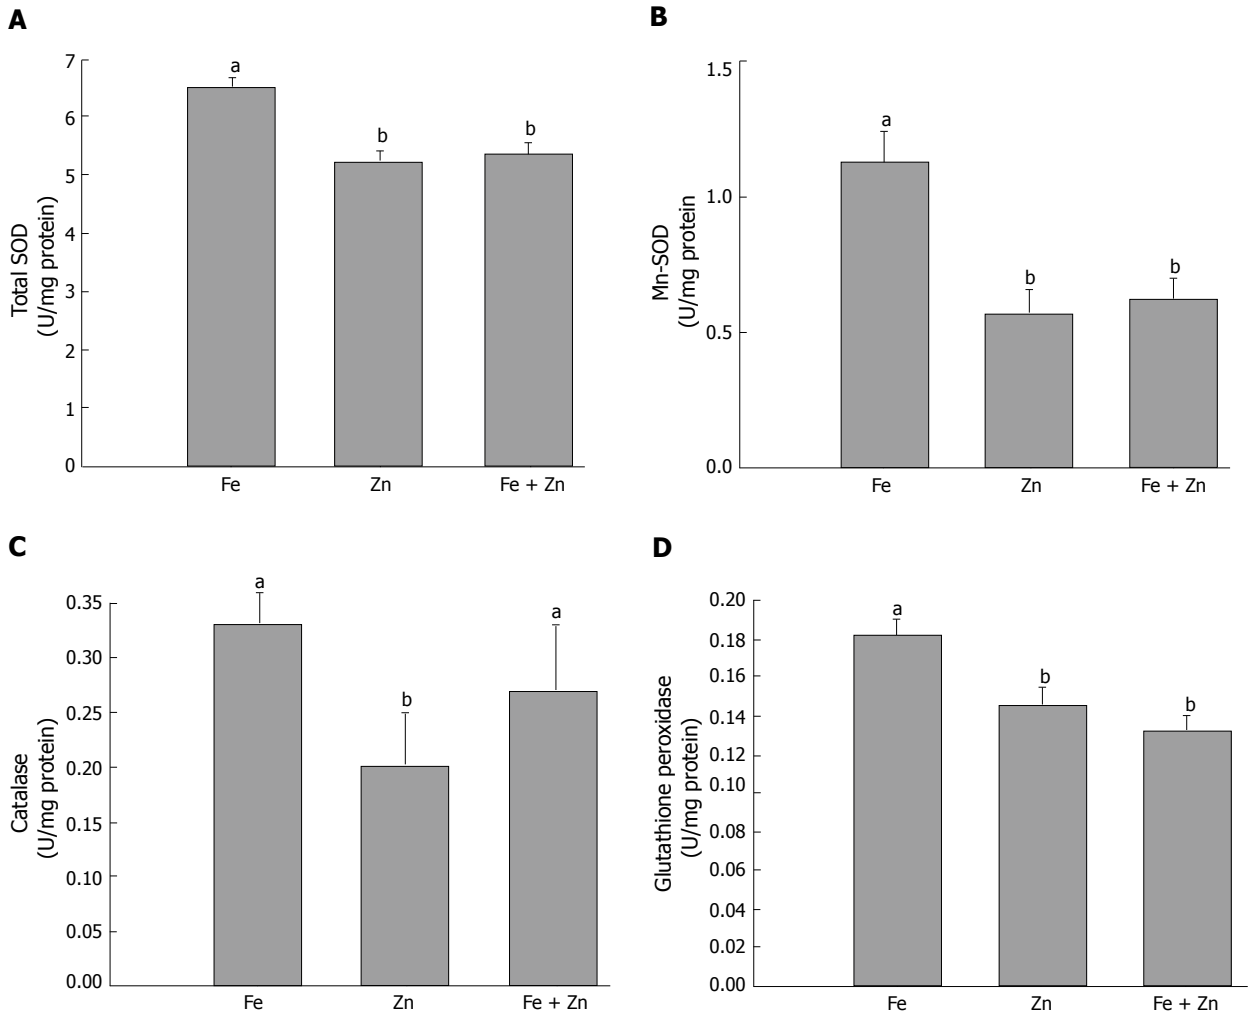

Figure 4 Changes in antioxidant enzyme activities due to iron and zinc repletion: Activity levels of superoxide dismutase (SOD, **A** and **B**), catalase (**C**) and glutathione peroxidase (Gpx, **D**) in the small intestinal mucosa of rats during repletion with iron and/or zinc. Total SOD activity indicates the activity of Cu, Zn-SOD and Mn-SOD. Fe: Iron administered group; Zn: Zinc administered group; Fe + Zn: Iron and zinc administered group; Number of animals: 8 in each group. Vertical columns and error bars represent mean and SD respectively; bars with different superscripts are significantly different with $P < 0.05$.

The possibility of iron and zinc inhibiting each other's intestinal uptake through competition for a common pathway, has been studied by measuring ferritin and metallothionein concentrations, and aconitase activity in the site of absorption. Intestinal uptake of iron and zinc was significantly reduced in the presence of the other metal during repletion in rats with combined deficiencies of iron and zinc. This may have been due to increased competition between iron and zinc for the ligands/transporters at the site of absorption. Reduced uptake of ^{55}Fe or ^{65}Zn in the Fe + Zn group compared to the Fe or Zn groups provides clear evidence for their antagonistic interaction during repletion. Reduced plasma and liver iron and zinc concentrations in the Fe + Zn group compared to individual supplementation groups suggests that iron and zinc interactions affect not only the uptake, but also retention of these minerals. Thus, this study clearly demonstrates that a combined supplement is less efficacious than a single supplement in improving iron or zinc status.

Another intriguing possible site of interaction between iron and zinc is the duodenal transport protein divalent cation transporter 1 (DCT-1). DCT-1 appears to be a key transporter that is involved in iron absorption, but can also transport many other metals, including zinc[31]. It is possible that iron and zinc can inhibit each other's absorption by competing for DCT-1, and their effects are expected to be most noticeable when one metal is in relative excess compared with the other, or when both deficiencies co-exist. Although we have not studied DCT-1 expression, the influence of iron and zinc on their responsive proteins clearly suggests that both interact at the site of absorption during concurrent repletion.

The intestine is vulnerable to oxidative damage during iron and/or zinc depletion and repletion. Incessant pulses of iron during repletion leave excess unabsorbed iron in the intestinal mucosa, which is a potential pro-oxidant. Moreover, electron paramagnetic resonance spectroscopy in rats has shown that oral iron therapy with ferrous sulfate results in iron-mediated oxidative stress, through hydroxyl radicals in the small intestine. This stress-stimuli results in a decrease in cell turnover, shortening of microvillus height, and partial or complete erosion of the microvilli in the duodenum[32-34]. On the

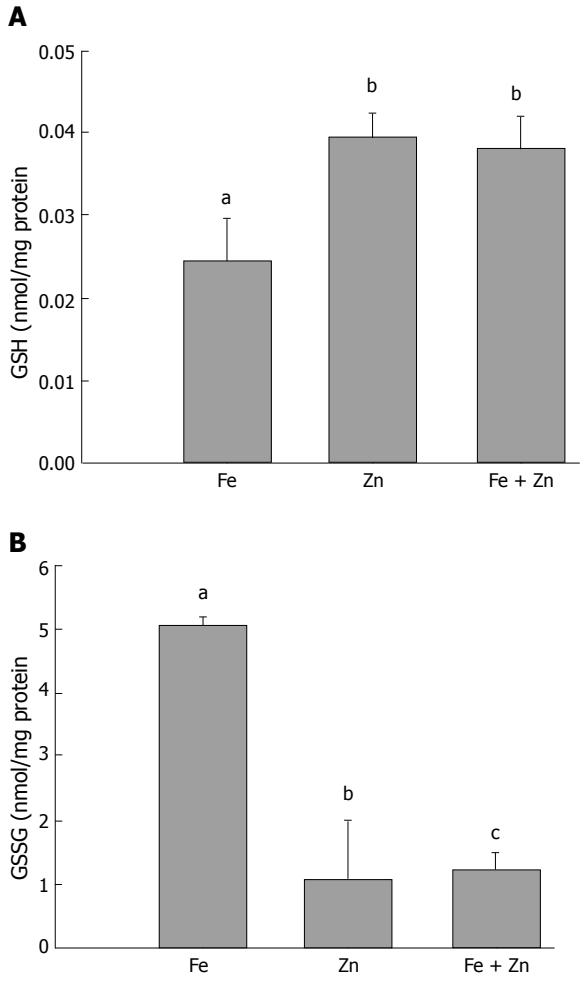

Figure 5 Altered intestinal mucosal redox status: Changes in the levels of GSH (Panel **A**) and GSSG (Panel **B**) in the intestinal mucosa at the end of repletion for 2 wk with iron and/or zinc. Vertical columns and error bars represent mean and SD respectively; bars with different superscripts are significantly different with $P < 0.05$.

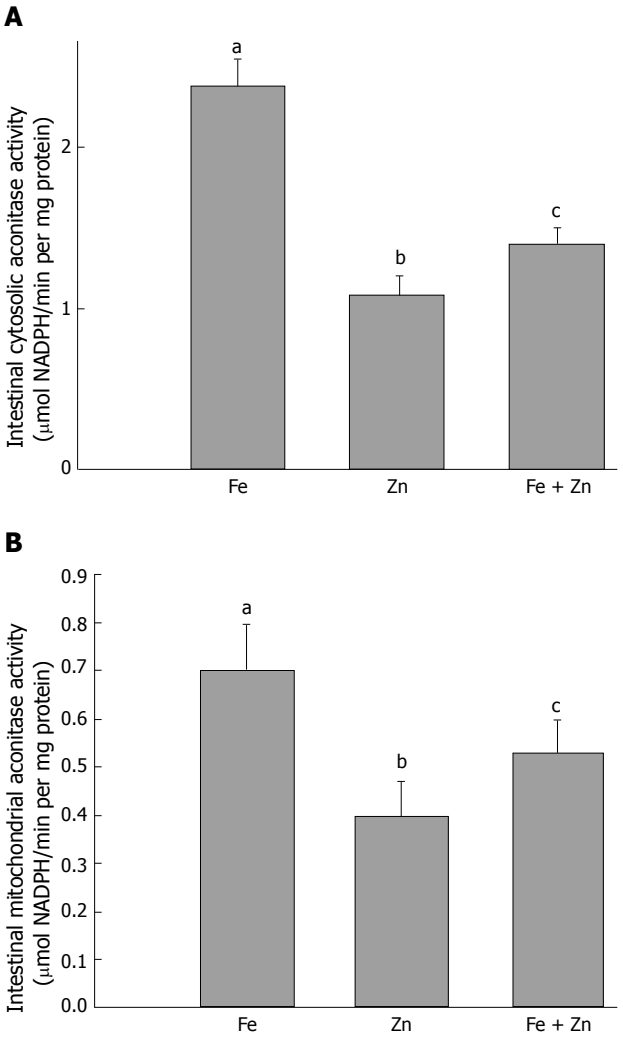

Figure 6 Intestinal aconitase activity in response to iron and/or zinc repletion: Response of intestinal cytosolic (Panel **A**) and mitochondrial (Panel **B**) aconitase to intestinal iron content and as a functional indicator of oxidative stress after 2 wk of oral iron and/or zinc administration. Fe: Iron administered group; Zn: Zinc administered group; Fe + Zn: Iron and zinc administered group. Number of animals :is 8 in each group. Vertical columns and error bars represent mean and SD respectively; bars with different superscripts are significantly different with $P < 0.05$.

other hand, zinc deficiency impairs intestinal antioxidant capacity by lowering the expression of metallothionein, an effective scavenger of hydroxyl radicals that can play a major role in the development of oxidative damage. In an earlier study, we have shown increased hydroxyl radical production, associated decrease in turnover of intestinal epithelial cells, and compromised functional integrity of the mucosa, when iron-deficient rats were repleted with 8.0 mg Fe[12]. This dose may be relatively high and could have produced structural and functional impairment at the site of absorption. To reduce these effects, we used 4.0 mg Fe for repletion and maintained a 1:1 molar ratio of iron and zinc in the present study. Iron repletion resulted in significantly higher levels of peroxidation products, i.e., TBARS and protein carbonyls in the intestinal mucosa, even with lower doses of iron. This also decreased the alkaline phosphatase and dipeptidase activity, which indicates compromised functional integrity. Although zinc negatively affected iron uptake, concurrent repletion of iron and zinc significantly reduced the oxidative damage and improved the functional integrity. The reason for the beneficial effects with co-administration of iron and zinc may be due to the changes in antioxidant balance. We have observed increased localization of metallothionein in the intestinal mucosa during zinc repletion. These findings support the view that zinc *per se* can act at various levels and exert its antioxidant effect. Incorporation of zinc along with iron in supplements seems to be efficacious in improving the antioxidant capacity.

To determine the role of antioxidant defense enzymes in reducing iron-induced oxidative damage, activity of SOD, catalase and glutathione peroxidase were determined. Cu, Zn-SOD was more active in the Fe group compared to that in the Zn and Fe + Zn groups. On the other hand, Mn-SOD activity was similar in all three groups. This indicates that the formation of superoxide anion and its conversion to hydrogen peroxide is greater in the cytosolic compartment than in the mitochondria. The other antioxidant enzyme that showed a difference in the Fe and Zn + Fe groups was glutathione peroxidase (Gpx), which implies that reduction of peroxides to water was more prevalent in the Fe than in the Fe + Zn group.

No increase was observed in the catalase activity of iron-treated animals, which suggests that hydrogen peroxide conversion to water was similar among all groups, but was compensated by an increase in Gpx in the Fe group. This increase in Gpx is indicative of excess formation of organic peroxides in the Fe group, which may have enhanced oxidative stress. In a recent study, we have shown that zinc *per se* can reduce iron-mediated production of hydroxyl radicals and thereby protect against oxidative stress[8]. Hence, concurrent administration of iron and zinc or zinc alone substantially enhances the intestinal non-enzymatic antioxidant capacity. In addition, we have observed in zinc-supplemented groups, increased intestinal metallothionein concentrations, which has been reported to be more effective than GSH on a molar basis for preventing oxidative damage of various cellular components[35]. Quenching of hydroxyl radicals by sulfhydryl groups in metallothionein, releasing zinc and its subsequent uptake by the membranes can protect both cellular components and membranes against oxidative damage[36,37]. Thus, zinc-induced metallothionein not only reduces the oxidative stress, but also improves the functional integrity of the mucosa.

Control of iron uptake and storage through regulation of transferrin receptor and ferritin proteins represents an important avenue through which cellular iron homeostasis is modulated and maintained[38,39]. The expression of ferritin and transferrin receptor is linked to iron status through the action of two iron-regulated RNA-binding proteins, iron regulatory proteins, IRP1 and IRP2. Iron regulates the RNA-binding function of IRP1 and IRP2 through fundamentally different mechanisms[40,41]. For IRP1, which is a bifunctional protein, iron inhibits RNA-binding activity by promoting assembly of an iron-sulfur cluster in the binding protein, thereby converting it to cytosolic aconitase[42]. Walter *et al*[43] has suggested that iron deficiency can induce the IRP-mediated cellular iron signaling pathway, which leads to enhanced intracellular iron levels. Therefore, we assessed the activity of cytosolic and mitochondrial aconitase. Cytosolic aconitase activity was found to be suppressed in the presence of zinc in the Fe + Zn group compared to that in the Fe group. A decrease in cytosolic aconitase activity implies a decrease in cellular iron availability in the presence of zinc, or inhibition of aconitase *per se* by zinc. It has been shown that zinc competitively inhibits duodenal cytosolic aconitase activity[22]. Reduced ferritin protein in the intestinal mucosa of the Fe + Zn group when compared to that of the Fe group supports the decrease in cytosolic aconitase activity in the Fe + Zn group. We also observed a decrease in mitochondrial aconitase activity in the Fe + Zn compared to the Fe group. This may have been due to a decrease in citrate availability or post-transcriptional regulation by IRP1, as reported by Chen *et al*[44]. Nevertheless, zinc seems to act as a buffer against free-radical damage invoked by the presence of free iron. The presence of zinc during supplementation had a significant effect on the levels of various antioxidants, including GSH and metallothionein.

Thus, this study clearly demonstrates that the interactions between iron and zinc during absorption in iron- and zinc-deficient rats are mutually antagonistic. Competition of iron and zinc for common transporters (DMT1) at the site of absorption results in reduced uptake of these minerals during concurrent administration. The presence of zinc during iron administration also influences aconitase activity, ferritin expression and thereby the labile iron pool. Furthermore, zinc induction of metallothionein and scavenging of hydroxyl radicals helps to control iron-mediated oxidative stress.

COMMENTS

Iron deficiency is the single most common nutritional disorder worldwide and the main cause of anemia in infancy, childhood and pregnancy. It is prevalent in most of the developing world, where it coexists with other micronutrient deficiencies such as zinc, vitamin A and folate. The exact prevalence of zinc deficiency is not known, but it is estimated that the magnitude might not be too different from that for iron deficiency. This is probably because the diet of populations in the developing world is based mainly on foodstuffs that have low iron and zinc concentrations, and with a poor bioavailability of these minerals. Combined supplementation with iron and zinc in target populations may be effective in preventing deficiencies of these micronutrients, but knowledge of their potential interactions when given together is inadequate.

Research frontiers

Combined supplementation with both micronutrients is one strategy that can be used to improve the iron and zinc status of a population. However, there is concern about the negative interactions between these two minerals. Studies performed in humans have shown an inhibitory effect of zinc on iron absorption, but it is not well established whether this interaction depends on the absolute amount of iron and zinc in the supplement and/or on the molar ratio between these two minerals, or on nutritional status. This information could help design rational guidelines for iron and zinc supplementation programs. A review of the randomized trials that have assessed the effects of iron and zinc supplementation on iron and zinc status shows that zinc supplementation alone does not appear to have a clinically important negative effect on iron status. However, when zinc is given with iron, iron indicators do not improve as greatly as when iron is given alone. In most of the studies, iron supplementation did not affect the biochemical status of zinc, but the data are not clear regarding morbidity outcomes. Although some trials have shown that joint iron and zinc supplementation has less effect on biochemical or functional outcomes than supplementation with either mineral alone, there is no strong evidence to discourage joint supplementation. Supplementation programs that provide iron and zinc together are an efficient way to provide both micronutrients, provided the benefits of individual supplementation are not lost. Further research is needed before health policies on joint supplementation programs can be established.

Innovations and breakthroughs

Oral iron supplementation is a widely used practice to correct iron-deficiency anemia. Exposure of iron-deficient intestine to large doses of iron is known to induce oxidative damage, which leads to loss of functional integrity and reduced mucosal cell turnover. Intestinal conditioning with anti-oxidants during iron administration has been shown to suppress iron-induced oxidative damage. Zinc is known to protect cells from peroxidative damage by inducing metallothionein and maintaining sulfhydryl group stability. Nevertheless, co-administration of iron and zinc may antagonize each other with respect to absorption. In the present study, we showed that although combined supplementation of iron and zinc marginally inhibits iron uptake, it significantly attenuates oxidative stress by induction of metallothionein and elevation of GSH level. Furthermore, the presence of zinc *in situ* reduced the iron-induced hydroxyl radical production in the intestinal mucosa, as assessed by electron paramagnetic resonance spectroscopy. These results strongly suggest a protective role for zinc on iron-induced oxidative stress, which might have implications in anemia control programs.

Applications

Supplementation with multiple micronutrients is an appealing strategy for the prevention and treatment of anemia and common morbidities that affect women and young children. However, drawing definitive conclusions regarding the

potential benefit or harm of joint supplementation, based on a variety of study designs, target populations and outcome measures, has proven challenging.

Terminology

Nutrient-nutrient interactions: Although the term interaction denotes a bidirectional effect, many interactions are unidirectional, i.e., one nutrient affects the biological disposition of another, which remains more or less passive. Bidirectional interactions are most common among nutrients with similar physicochemical properties and that share a common mechanism of absorption or metabolism. Some uni- or bidirectional interactions are affected by the presence of a third dietary constituent. Nutrient interactions are not usually additive. From the physiological standpoint, nutrient interactions can occur at several different levels: (1) In the diet. The mode of preparation of diets may be as important as their composition in determining nutrient interactions. For example, cooking in an alkaline medium may decrease the interaction between ascorbic acid and iron by destroying the vitamin; (2) In the intestinal lumen. Interactions at this level have received the most attention, because they determine the true availability of a nutrient for translocation through the enterocytes. Most luminal interactions consist of direct nutrient-nutrient interactions, but certain nutrients can indirectly affect the absorption of others by modifying gastrointestinal physiological activities. For example, certain dietary fibers can stimulate gastrointestinal hormone secretion or inhibit micellar formation, thus indirectly affecting nutrient absorption (Table 2); (3) In the post-absorptive phase. Many interactions take place after the process of absorption has been completed. These interactions may be in the form of physiological synergism, such as the effect of vitamin A and zinc on the visual process, or between vitamin A and iron mobilization. Conversely, negative interactions may affect circulating or storage levels of nutrients.

Peer review

In this study, the authors investigated the nature of interactions between iron and zinc, and their consequences on intestinal oxidant-antioxidant balance. They demonstrated that the interactions between iron and zinc during absorption in iron- and zinc-deficient rats were antagonistic. They demonstrated that the antioxidant status was significantly lower in the Fe than in the Zn and Fe + Zn groups, whereas the aconitase activity was higher in the Fe than in the Zn and Fe + Zn groups. In conclusion, they reported that the competition of iron and zinc for common transporters such as DCT-1, at the site of absorption, resulted in reduced uptake of Fe and Zn during concurrent administration. Moreover, they suggested that zinc induction of metallothionein and scavenging of hydroxyl radicals assisted in controlling iron-mediated oxidative stress.

Abstract

AIM: To investigate the role of SMYD3 in hepatocellular carcinoma (HCC) development and progression and to verify whether its regulation activity was through RIZ1 inactivation.

METHODS: Expression of SMYD3 in HCC cell lines and tissues were measured; silencing of SMYD3 by RNA interference (RNAi) was effectuated, hepatoma cell proliferation, migration and apoptosis were tested, with RIZ1 CpG promoter methylation, and corresponding mRNA expression were investigated.

RESULTS: SMYD3 over-expression in HCC was associated with RIZ1 hypermethylation and mRNA down-expression. Suppression of SMYD3 expression de-methylated RIZ1 CpG promoter ($P < 0.01$) and increased RIZ1 mRNA expression ($P < 0.01$). Consequently, SMYD3 down-expression with RIZ1 de-methylation strongly inhibited hepatoma cell growth (MTT inhibitory rates: Pgenesil-1-s1 60.95% ± 7.97%, Pgenesil-1-s2 72.14% ± 9.68% *vs* Pgenesil-1-hk 6.89% ± 4.12%, $P < 0.01$) and migration (Pgenesil-1-s1 4.24% ± 1.58%, Pgenesil-1-s1 4.87% ± 0.73% *vs* Pgenesil-1 19.03% ± 4.63%, Pgenesil-1-hk 19.95% ± 5.21%, $P < 0.01$) and induced apoptosis (FCM subG1 phase Pgenesil-1-s1 19.07% ± 1.78%, Pgenesil-1-s2 17.68% ± 2.36% *vs* Pgenesil-1 0.47% ± 0.12%, Pgenesil-1-hk 1.46% ± 0.28%, $P < 0.01$. TUNEL-positive cells: Pgenesil-1-s1 40.24% ± 5.18%, Pgenesil-1-s2 38.48% ± 4.65% *vs* Pgenesil-1 2.18% ± 1.34%, Pgenesil-1-hk 2.84% ± 1.22%, $P < 0.01$) in HepG2 cells.

CONCLUSION: These results demonstrate that SMYD3 plays a critical role in the carcinogenesis and progression of HCC. The proliferation, migration induction and apoptosis inhibition activities of SMYD3 may be mediated through RIZ1 CpG promoter hypermethylation.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignancies worldwide, generally long-term survival is disappointing. Epigenetics, defined as heritable changes in gene expression that are not coded in the DNA sequence itself, is increasingly linked with tumorigenesis[1,2]. It is well established that DNA methylation, nucleosomal histone post-translational modifications such as methylation, acetylation/deacetylation, phosphorylation ADP-ribosylation, and ubiquitination, and other epigenetic patterns are central to proper gene expression. Increasing evidence shows that disrupting epigenetic patterns can induce carcinogenesis or affect the outcome of cancer[3,4]. Among these, histone methylation is considered to be critical for transcriptional regulation and seems to play an important role in tumor epigenetic modification. Recently, SMYD3 was identified and characterized to specifically methylate histone H3 at lysine 4 (K4), and this activity is indeed dependent on an intact SET domain, an evolutionarily conserved protein module shown to facilitate histone methyltransferase activity[5]. Expression of SMYD3 was frequently enhanced in colorectal carcinoma (CRC), breast cancer tissue, as well as HCC, and elevated *SMYD3* expression was involved in the growth of CRC, breast cancer and HCC cells[5-7]. Although transcriptional activation of downstream genes including *Nkx2.8* and *WNT10B* gene has been reported[5,6], the effect of SMYD3 on HCC development and the underlining mechanism remains unclear.

Inactivation of tumor suppressive genes (TSGs) plays an important role in carcinogenesis. RIZ1, a typical

TSG with H3-K9 methyltransferase activity, was shown to lose its expression and tumor-suppressing activity in many types of human tumors including HCC[8], CRC[9], breast cancer[10], prostate cancer[11] and gastric cancer[12]. Adenovirus-mediated RIZ1 expression causes G2-M cell cycle arrest and/or apoptosis in breast cancer, liver cancer, and microsatellite instability-positive colon cancer cells. Adenovirus RIZ1 can also inhibit growth of colon cancer xenografts[13]. Previous data suggest that the RIZ locus is a target of frequent deletion in HCC, but a more common way of RIZ inactivation in HCC may not involve mutations that alter peptide sequences, but by CpG promoter hypermethylation[14].

Therefore, we sought to explore whether targeting of SMYD3 expression can inhibit the development of HCC, and determine whether the biological function of SMYD3 in HCC development and progression is mediated through RIZ1 inactivation. We found SMYD3 was significantly overexpressed in HCC cell lines, but not in normal hepatocellular cells and peri-cancerous tissues. Silencing of SMYD3 by RNAi remarkably inhibited HCC cell proliferation and migration, and induced apoptosis *in vitro*. Furthermore, RIZ1 was under-expressed in HCC cells with its promoter hypermethylated, while inhibition of SMYD3 demethylated RIZ1 and recovered its expression in HCC cells. Our results indicated that SMYD3 plays pro-oncological function in HCC development and progression; thus the activity of SMYD3 in HCC may be partly through its activity on RIZ1 promoter hypermethylation and RIZ1 inactivity.

MATERIALS AND METHODS

Cell lines

HCC cell lines HepG2 and Hep3B were purchased from the American Type Culture Collection (Rockville, MD). HCC cell line SMMC-7721 and liver cell line L-02 were generous gifts from Dr. Danhui Weng (HUST, China). The cells were cultured in Dulbecco's modified Eagle's medium (Gibco-BRL, Carlsbad, CA) supplemented with 10% fetal bovine serum (Gibco-BRL).

RT-PCR

Total RNA was extracted using Trizol reagent (Takara, Tokyo, Japan). RT-PCR was performed with the Advantage RT-PCR kit (Takara), according to the manufacturer's protocol. PCR setting: Initial denaturation at 94℃ for 3 min before 18 cycles (for *GAPDH*) or 30 cycles (for *SMYD3* and *RIZ1*) at 94℃ for 30 s, 50℃ for 45 s and 72℃ for 60 s. The sets of primers are listed in Supplementary Information Table S1.

shRNA construction and transfection

The Pgenesil-1 vector containing the U6 promoter region was purchased from Genesil Biotechnology Corporation (Wuhan, China). Plasmids expressing siRNAs were prepared by cloning double-stranded oligonucleotides into the Pgenesil-1 vector. The sets of primers are listed in Supplementary Information Table S1. Positive clones were identified by restriction digestion and confirmed by sequencing. The resulting plasmids were designated as Pgenesil-1-s1, Pgenesil-1-s2 and negative control Pgenesil-1-hk. Transfection was performed by Lipofectamine 2000 reagent (Invitrogen, Carlsbad, CA) in accordance with the manufacturer's protocol.

Western blot analysis

Proteins were prepared by homogenization of cells in lysis buffer (10 mmol/L Tris-HCl, pH 8.0; 140 mmol/L NaCl; 5 mmol/L EDTA; 0.25 g/L NaN_3; 10 g/L Triton X-100; 10 g/L deoxycholate; 1 g/L SDS; 0.5 mmol/L PMSF; 1 g/L leupeptin; 1 g/L aprotinin). Protein concentration was determined by the Lowry method (Bio-Rad, Hercules, CA). Proteins were resolved (30 μg per lane) in 120 g/L sodium dodecyl sulfate-polyacrylamide gel electrophoresis and was transblotted onto a PVDF membrane (Amersham, Arlington Heights, IL). Membranes were blocked in 50 mL/L non-fat milk overnight and subsequently incubated with 1:2000 rabbit polyclonal anti-SMYD3 antibody (a generous gift from Dr. Ryuji Hamamoto of the University of Tokyo, Tokyo, Japan), or anti-β-actin (1:5000 dilution, Sigma, St. Louis, MO) for 1 h and then with secondary anti-rabbit IgG-horseradish-peroxidase antibody for 1 h at room temperature. Immunoreactive proteins were visualized by means of enhanced chemiluminescence reagent (Pierce Biotechnology, Rockford, IL) and exposure to autoradiographic film.

Proliferation assay of HepG2 cell

MTT experiments were carried out using the cell proliferation kit (Roche Diagnostics, Indianapolis, IN), according to the manufacturer's manual. Briefly, stable transfected and parental HepG2 cells were seeded at a density of 5×10^3 cells/well in 96-well plates and allowed to grow for 48 h and then 20 μL 5 g/L MTT was added. After incubation for 4 h, DMSO 200 g/L was added to each well to dissolve crystals. After 5 min incubation at 37℃, absorbance was measured at 570 nm. Assays were performed in triplicate.

Migration assay of HepG2 cell

This assay for the invasiveness of cells was based on the principle of Boyden chamber (BD Biosciences, San Diego, CA) and performed according to the manufacturer's protocol. Briefly, the top compartment was prepared by coating the filter with diluted Matrigel and incubated for 30 min. A suspension of 1×10^4 cells in serum-free medium was inoculated in the upper chamber, and conditioned media obtained from NIH3T3 cells was placed in the lower compartment of the chamber, as a chemoattractant. After 24 h incubation, noninvasive cells were removed with a cotton swab. The cells which migrated through the filter and adhered to the lower surface of the filter were fixed with methanol, stained with hematoxylin, and counted manually in 5 randomly selected microscopic fields. Assays were performed in triplicate. The data were reported as the percentage of cells successfully passing through the Matrigel and filter relative to those migrating through the control filter.

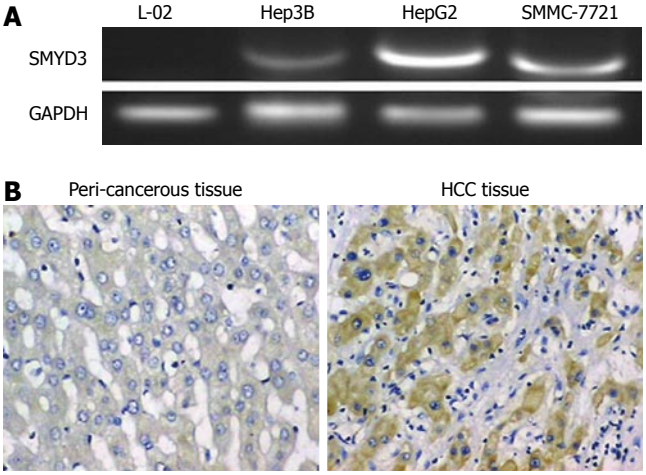

Figure 1 Enhanced expression of SMYD3 in HCC. **A**: The expression of SMYD3 genes was determined by RT-PCR and GAPDH served as an internal control; **B**: Representative images of immunohistochemical staining of accumulated SMYD3 protein in HCC tissue, but not in peri-cancerous tissue.

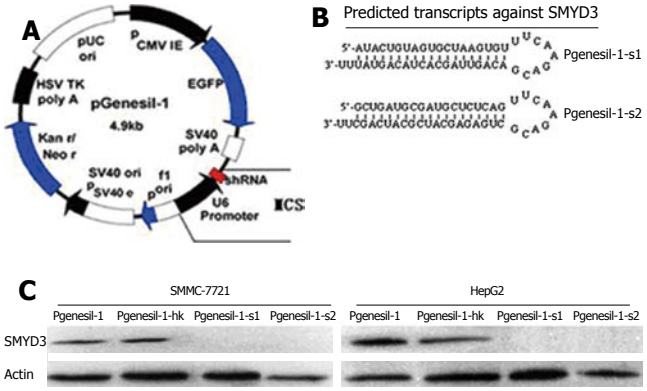

Figure 2 RNAi specifically inhibits SMYD3 expression in HCC cell lines. **A**: Schematic drawing of the Pgenesil-1 vector; **B**: The predicted secondary structures of the Pgenesil-1-s1 and Pgenesil-1-s2 transcripts target SMYD3 are shown; **C**: 48h after transfection, Western blot analysis showed the inhibitory effect of plasmids expressing SMYD3 shRNAs in HepG2 and SMMC-7721 cells.

FCM analysis

HepG2 cells, 1×10^6, were seeded in 60-mm dishes and transfected with SMYD3-RNAi-plasmids at 60%-80% confluence. Then, 48 h after transfection, cells were deprived of serum for 36 h. Afterwards, cells were harvested, fixed in 700 mL/L ethanol and washed with 1 × PBS and suspended in 50 mg/L propidium iodide. DNA content was determined by flow cytometry using a Becton-Dickinson FACSCalibur (Becton Dickinson, Bedford, MA). Results were analyzed by ModFit LT2.0 and Cellquest software. Assays were performed in triplicate.

TUNEL assay

Apoptotic cells were identified with the *In Situ* Cell Death Detection kit (Roche Applied Science, Shanghai, China) using the protocol recommended by the manufacturer. In brief, HepG2 cells were grown on coverslips. The next day, cells were transfected with SMYD3-RNAi-plasmids. At 48 h after transfection, cells were deprived of serum for 36 h. Coverslips with adherent cells were fixed in 40 g/L paraformaldehyde for 1 h at room temperature and permeabilized with 1 g/L Triton X-100 for 2 min on ice. DNA fragments were labeled with the TdT-mediated dUTP nick end labeling (TUNEL) reaction mixture for 60 min at 37℃ in a humidified atmosphere in the dark. Diaminobenzidine was used to mark the apoptotic cells (brown staining). Cells were counted manually in six randomly selected microscopic fields for each sample. The apoptosis index was defined by the percentage of apoptotic cells among the total cells of each sample.

RIZ1 promoter methylation specific PCR assay

Methylation Specific PCR (MSP) assay was performed according to the procedure described by Fang *et al*[15]. In brief, 1 μg of the genomic DNA was modified by sodium bisulfide using the CpGenome DNA Modification Kit (Intergen, Purchase, NY) in accordance with the manufacturer's instructions. Modified DNA was amplified by two different primer pairs specific to the unmethylated (U) and methylated (M) *RIZ1* sequences, respectively. The sets of primers are listed in Supplementary Information Table S1. The PCR amplification was performed for a total of 45 cycles with an annealing temperature of 68℃ and 60℃ for M-sequences and U-sequences, respectively. The PCR products were then analyzed using a 35 g/L agarose gel.

Statistical analysis

SPSS 13.0 was used to analyze the data. Statistical significance was assessed by comparing mean ± SD with Student's *t* test for independent groups. $P < 0.05$ was considered statistically significant.

RESULTS

Enhanced SMYD3 expression in HCC cell lines

To determine whether SMYD3 gene is overexpressed in HCC cell lines, we compared the level of SMYD3 gene expression in normal human hepatocellular cell line L-02 to that of three HCC cell lines. RT-PCR analysis revealed that SMYD3 was overexpressed in all HCC cells, but absent in L-02 cells (Figure 1). These data indicate that enhanced SMYD3 expression is involved in a majority of HCC.

RNAi specifically inhibits SMYD3 expression in HCC cell lines

To inhibit SMYD3 expression in HCC cells, we used a DNA-based siRNA method (Figure 2A). Two siRNAs targeting different 21 sequences of human SMYD3 were cloned into Pgensil-1 vector to express RNA, which is expected to fold back to form a hairpin loop structure after being transcribed. The hairpin dsRNA can then be further cleaved by Dicer to generate a 21-nucleotide siRNA, the active form for the RNAi effect (Figure 2B). We used HepG2 and SMMC-7721 cells, which overexpress SMYD3 abundantly. Forty eight hours after transfection, Pgenesil-1-s1 and Pgenesil-1-s2 markedly knocked down SMYD3 expression in these cells, as determined by Western blot analysis. The specificity of RNAi targeting SMYD3 was shown by transfection with Pgenesil-1-hk which had no effect on SMYD3 expression (Figure 2C).

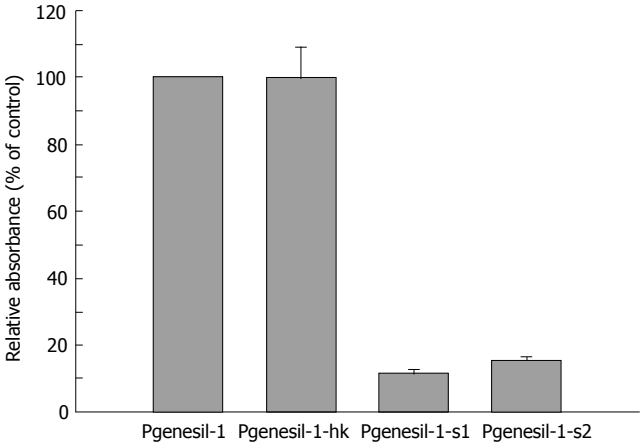

Figure 3 Inhibition of SMYD3 reduces hepatoma cell proliferation (MTT assays).

Inhibition of SMYD3 reduces hepatoma cell proliferation

MTT assay was used to examine the inhibitory effect of RNAi against SMYD3 on cell growth in HepG2 cells. Suppression of SMYD3 expression significantly inhibited cell growth compared to the cells transfected with control plasmid Pgenesil-1. Pgenesil-1-hk, which did not suppress expression of SMYD3, was shown to have little inhibitory effect on growth of HepG2 cells, compared to Pgenesil-1 (Figure 3). The growth inhibitory effect of the plasmids was consistent with their gene silencing effect. Therefore, SMYD3 RNAi significantly suppressed the growth of HeG2 cells *in vitro*, indicating that SMYD3 may be involved in the regulation of cell proliferation.

Inhibition of SMYD3 reduces hepatoma cell migration

The HepG2 cell line has been characterized as a highly invasive hepatocellular cancer cell line. To determine whether SMYD3 gene knockdown by RNAi could reduce its invasive potential, an *in vitro* invasion assay was performed. As shown in Figure 4, HepG2 cells were greatly deprived of invasiveness by depletion of SMYD3 gene expression. The percentage of invasive cells was decreased by 3-4 fold in Pgenesil-1-s1 and Pgenesil-1-s2 treated groups, compared to Pgenesil-1 treated groups. No significant decrease of invasive cells was observed in Pgenesil-1-hk treated cells. These results demonstrate that SMYD3 not only plays a pivotal role in the process of development, but it also is involved in tumor cell migration.

Inhibition of SMYD3 promotes apoptosis in hepatoma cells

Flow cytometry analysis showed that after 48 h of transfection and 36 h serum deprivation, the number of cells in the sub G1 phase was 19.07 ± 1.78% and 17.68 ± 2.36% in HepG2 cells transfected with Pgenesil-1-s1 and Pgenesil-1-s2, respectively, while only 0.47% ± 0.12% and 1.46% ± 0.28% cells were observed in HepG2 cells transfected with Pgenesil-1 and Pgenesil-1-hk, respectively (Figure 5A). These results possibly suggest the induction of apoptosis. To confirm whether silencing of SMYD3 can induce apoptosis in HCC cells following serum deprivation, TUNEL assay was performed. The number

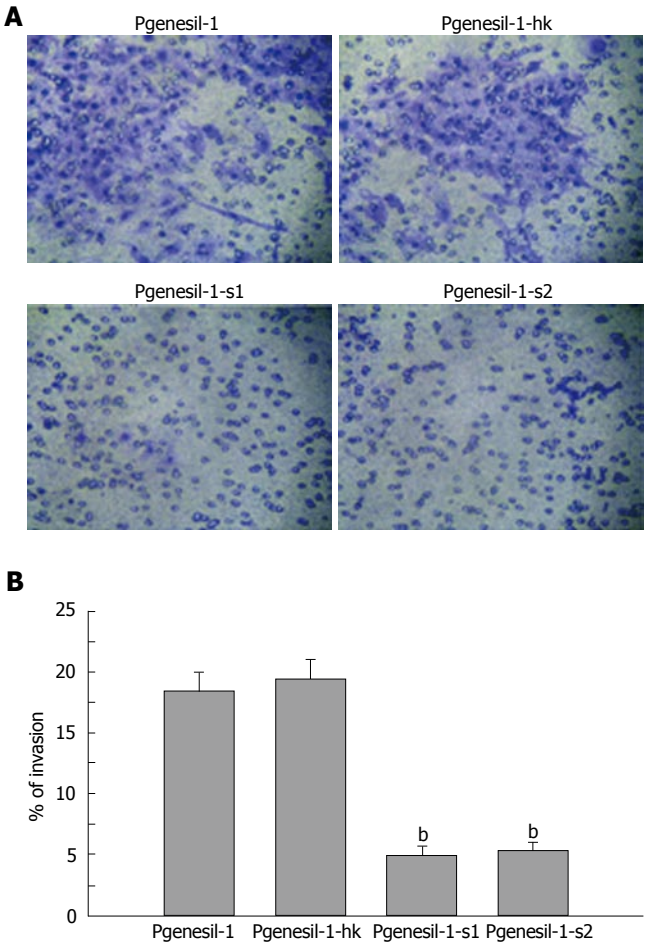

Figure 4 Inhibition of SMYD3 reduces hepatoma cell migration. **A**: Representative cells (blue) invade through Matrigel and membrane; **B**: The percentage of cells successfully passing through the matrigel and membrane ($P < 0.01$).

of TUNEL-positive cells was 40.24% ± 5.18% and 38.48% ± 4.65% in HepG2 cells transfected with Pgenesil-1-s1 and Pgenesil-1-s2, respectively. Only 2.18% ± 1.34% and 2.84% ± 1.22% were TUNEL positive in control cells transfected with Pgenesil-1 and Pgenesil-1-hk, $P < 0.01$, respectively (Figure 5B). These results indicate that inhibition of SMYD3 by RNAi significantly promoted apoptosis in HepG2 cells following serum deprivation.

Inhibition of SMYD3 de-methylates RIZ1 promoter CpG islands and re-expresses RIZ1 in hepatoma cells

Through MSP and RT-PCR, we observed that the RIZ1 promoter was totally methylated with the lack expression of RIZ1 mRNA in HepG2 cells. After inhibition of SMYD3 by Pgenesil-1-s1, the RIZ1 promoter was found partial methylated in HepG2 cells, consistent with the change of RIZ1 mRNA (Figure 6). These results suggest that the activity of SMYD3 may be regulated through RIZ1 CpG promoter hypermethylation and RIZ1 inactivation.

DISCUSSION

Among epigenetic regulatory ways, histone methylation, perhaps more than any other form of modification, has demonstrated the power of modifications over DNA-

based functions, regulating fundamental processes such as gene transcription and DNA repair[16]. SMYD3, a gene located in 1q44 chromosome, encodes a protein with HMTase activity specifically on histone H3 at K4, and is involved in carcinogenesis and tumor progression[5]. In the present study, we confirmed that SMYD3 is overexpressed in HCC cell lines. To further investigate the function of SMYD3 in HCC carcinogenesis and tumor progression, RNAi technology was applied to specifically knock down SMYD3 expression in HCC cell lines. We demonstrated that depletion of SMYD3 reduced hepatoma cell growth, migration and induced cell apoptosis upon serum deprivation. Our findings suggest that SMYD3 plays pro-oncologic role in HCC development and progression. Interestingly, our results show that the expression level of SMYD3 in Hep3B cells differs significantly from that in HepG2 and SMMC-7721 cells. We hypothesized that the difference is possibly due to the HBV infectious state of the cells that we used; HBV positive in Hep3B, but negative in HepG2 and SMMC-7721 cells. However, this hypothesis needs to be further clarified.

SMYD3 is considered to function through its H3-K4 histone metylation, regulating expression of Nkx2.8[17,18], Wnt10B[19,20] and other genes involved in hepatoma cell-cycle regulation, cell proliferation and apoptosis. SMYD3 also upregulates genes linked to cell adhesion and invasion, such as ITGA5[21], COLQ[22], SELL[23], NEURL[24], and PECAM1[25], which may be responsible for cell migration regulatory role of SMYD3 in our experiment. To investigate whether SMYD3 might act on HCC oncological activity through TSG inactivation, we examined if RIZ1 activity could be regulated by SMYD3 in different hepatoma cells. RIZ1 was found to be downregulated in HepG2 cells with its promoter CpG hypermethylated, which was in line with enhanced SMYD3 expression, while knockdown of SMYD3 demethylated RIZ1 promoter and upregulated RIZ1 expression in these cells. In addition, different SMYD3 expression levels in hepatoma cells was also consistent with RIZ1 promoter methylation and mRNA expression in hepatoma cells in our results (data not shown) and in other results. HepG2 cells have been shown to lack RIZ1 expression due to promoter hypermethylation; in contrast, Hep3B cells do not show *RIZ1* promoter hypermethylation and express RIZ1 mRNA[26,27]. These results strongly suggest that SMYD3 plays a role in HCC development and progression, partly through RIZ1 promoter hypermethylation and RIZ1 inactivation.

As a histone/protein methyltransferase, SMYD3 mainly acts on histones or proteins; therefore, the mechanism by which SMYD3 regulate RIZ1 promoter CpG islands needs to be further clarified. SMYD3 includes a putative 428-amino acid protein containing a SET domain (codons 148-239) which is HMT, and a zf-MYND domain (codons 49-87), a typical zinc finger domain. The presence of a MYND-type zinc-finger domain in SMYD3 suggests that SMYD3 can recognize and bind particular sequences present in the promoter region of downstream genes through its MYND zinc finger. The specific SMYD3

binding elements (SBE) in target DNA are 5'-CCCTCC-3' or 5'-GGAGGG-3', which are present in the promoter regions of SMYD3 downstream genes, such as Nkx2.8[5]. It is interesting to note that one SBE, 5'-GGAGGG-3', is present in the promoter region of RIZ1[27]. A typical zinc finger domain in SMYD3 and SBE sequence in RIZ1 promoter strongly suggests that SMYD3 may act on RIZ1 promoter through its zf-MYND domain recognizing and binding to the SBE within the RIZ1 promoter. However, SMYD3 may also recognize SBE in other genes, such as DNA methyltransferases (DNMT), which are crucial for DNA methylation[28], and sequentially regulates RIZ1 promoter hypermethylation. There is other evidence suggesting that histone modification may interact with DNA methylation or may regulate DNA methylation[29]. In mammals, H3K9 methylation and CpG methylation shows a complex interplay in which each mark can influence the activity of the other.

Our results imply that, besides their gene-transacting role, SMYD3 and other H3-K4 methyltransferases might influence carcinogenesis and tumor progression by silencing TSGs through DNA methylation. In mammals, DNA methylation must be catalyzed by DNA methyltransferases, whether SMYD3 directly regulates DNMT expression, or SMYD3 changes the local conformation of RIZ1 promoter to facilitate DNMT congregation needs to be further investigated. Moreover, SMYD3 can di- and tri-methylate H3-K4, if its DNA methylation activity is dependent on H3-K4 transactivation, the H3-K4 hypermethylation patterns also needs to be established.

COMMENTS

Background

SMYD3, a H3K4 methyltransferase, was shown to be enhanced expressed in HCC, and involved in the growth of hepatocellular carcinoma (HCC) cells. Although transcriptional activation of downstream genes including Nkx2.8 and WNT10B gene was reported, the effect of SMYD3 on HCC development and the underlining mechanism remain unclear. RIZ1, one typical TSG with H3-K9 methyltransferase activity, was shown to lose its expression and tumor-suppressing activity in HCC, RIZ inactivation in HCC was mainly through its CpG promoter hypermethylation. In this article, whether SMYD3 regulates HCC proliferation, apoptosis and migration through RIZ1 promoter hypermethylation was initially investigated.

Research frontiers

In previous studies, histone metylation were thought to be irreversible. However, in recent studies, histone demethylase was found, which means that histone can be hypermethylated or demethylated in regulating gene expression. Since histone modification play important epigenetic regulating roles in gene transcription, this may provide new target for carcinoma therapy through hypermethylating or demethylating histone.

Innovations and breakthroughs

This article suggests H3-T4 histone methyltransferase regulates HCC biology, not only through oncogene transcription, but through interacting with H3-K9 HMT which mainly plays inhibitory role in oncogene expression, and through inhibiting TSG expression by promoter hypermethylation. These findings deepen our understanding of the interaction of different histone modification ways in gene transcription modification.

Applications

Clarifying the regulating models of H3-K4 methyltransferase, such as SMYD3, represents a potentiality for understanding oncogene expression and tumor suppressive gene under-expression in carcinogenesis and progress. By deepened understanding the key role of SMYD3 in HCC development may also provide new target for carcinoma treatment.

Terminology

SMYD3 SET and MYND domain-containing protein 3; RIZ1 retinoblastoma protein-interacting zinc finger gene1; TSG tumor suppressive gene; HMT Histone methyltransferase; DNMT DNA methyltransferases.

Peer review

The manuscript describes studies showing that several HCC cell lines and one HCC tissue sample express SMYD3 and is well described.

Abstract

AIM: To investigate associations between the *Rsa* I polymorphism of *CYP2E1* and risk of colorectal cancer.

METHODS: A case-control study was conducted with 315 colorectal cancer cases (105 colon, 210 rectal) and 439 population-based controls in Jiangsu Province of China. Genomic DNA samples were assayed for restriction fragment length polymorphisms in *CYP2E1* by PCR amplification followed by digestion with *Rsa* I. Information on smoking and alcohol drinking was collected using a questionnaire. Odds ratios (ORs) were estimated with an unconditional logistic model.

RESULTS: The proportional distribution of the *CYP2E1 Rsa* I c1/c1, c1/c2 and c2/c2 genotypes were 61.4%, 35.6% and 3.0% in controls, 60.6%, 33.7% and 5.8% in colon cancer cases, and 58.4%, 34.0% and 7.7% in rectal cancer cases, respectively. A significant difference was noted between controls and rectal cancer cases (P = 0.029), the c2/c2 genotype being associated with elevated OR (adjusted age, sex and status of the smoking and alcohol drinking) for rectal cancer (1.64, 95% CI, 1.12-2.41, *vs* c1 allele carriers), but not for colon cancer. In interaction analysis between the *CYP2E1 Rsa* I genotype and smoking and drinking habits, we found a significant cooperative action between the c2/c2 genotype and alcohol drinking in the sex-, age-adjusted ORs for both colon (4.74, 95% CI, 1.10-20.40) and rectal (5.75, 95% CI, 1.65-20.05) cancers. Among non-smokers, the *CYP2E1 Rsa* I c2/c2 genotype was also associated with elevated ORs in the two sites (1.95, 95% CI, 0.99-3.86 and 2.30, 95% CI, 1.32-3.99).

CONCLUSION: The results of the present study suggest that the *CYP2E1* c2/c2 genotype increases susceptibility to rectal cancer and the gene-environmental interactions between the *CYP2E1* polymorphism and smoking or alcohol drinking exist for colorectal neoplasia in general.

INTRODUCTION

CYP2E1, a member of the cytochrome P450 superfamily, is involved in the metabolic activation of many low-molecular-weight compounds such as N-nitrosamines, aniline, vinyl chloride, urethane and alcohol[1]. N-nitrosamines present in tobacco and diet are well-recognized carcinogens involved in tumor development at various sites. Functional *CYP2E1* gene polymorphisms might therefore impact on susceptibility to cancer development.

A substitution polymorphism (G1259C) detected using the restriction enzymes *Pst* I or *Rsa* I has been associated

with decreased *CYP2E1* activity/inducibility[2-5]. The *Dra* I polymorphism is also associated with altered activity of *CYP2E1*, although *Dra* I is located in intron 6 and is not thought to affect gene transcription[6]. Activity of *CYP2E1* is also modulated by various physiological determinants, such as obesity[7], fasting[7] and liver dysfunction[8] and can be induced by ethanol[9]. In contrast, dietary isothiocyanates[10] and garlic[11,12], as well as some drugs, such as disulfiram[13] and chlormethiazole[14], inhibit its activity. A number of environmental factors may thus modify the cancer risk through altered *CYP2E1* enzyme activity.

Previous studies have shown inconsistent findings on *CYP2E1* polymorphism associations with cancer risk. Some studies demonstrated the common genotype or alleles to confer greater risk of oral[15], pharyngeal[15], esophageal[16,17] liver[18] and lung[19,20] cancers. On the other hand, increased risk of oral[21], nasopharyngeal[22], liver[23] and colorectal[24,25] cancers was observed with the rare genotype or allele carriers in other studies. Furthermore, some case-control studies failed to find a significant association between *CYP2E1* polymorphisms and risk of neoplasia of the oral cavity and pharynx[26], esophagus[27], stomach[28,29], lung[30-33], bladder[34] and colorectum[35]. The reasons for these inconsistent results are not clear, but one problem is a lack of sufficient investigation of gene-environmental interactions, including links with dietary and smoking habits. We hypothesized that environmental factors may alter the enzyme activity of *CYP2E1* and therefore modify cancer susceptibility due to *CYP2E1* polymorphisms. One earlier study in our laboratory showed that gene-environment interactions between the *CYP2E1* polymorphism and smoking have the potential to alter susceptibility to gastric cancer[36].

To investigate possible relations between *CYP2E1 Rsa* I polymorphisms and environmental factors (smoking and alcohol drinking) on the risk of colorectal cancers, we conducted a population-based case-control study in Jiangsu province, China.

MATERIALS AND METHODS

Subjects

We recruited colorectal cancer cases using data of Cancer Registries in Huian and Jintan Cities of Jiangsu Province of China, and also recruited cases who visited Jiangsu Province Cancer Hospital from these cities from August 2000 to September 2002. All were histopathologically diagnosed as having a primary colorectal cancer. Physicians at the hospital asked eligible cases to participate in our study, and doctors or nurses interviewed the subjects and collected blood samples from a peripheral vein after obtaining informed consent. Population-based controls were selected from healthy residents in eight villages or towns of Huian and Jintan Cities. Doctors of the public health center randomly selected one or two controls for each case, after matching for ethnicity, sex and age within 2 years using the records of residents at the local governmental office, and then asked eligible residents for their participation. Interviews and blood collection were performed as for the cancer cases. A few patients and residents refused to participate in our study, but the response rates were 97% for cases and 93% for controls. The ethics committee of Jiangsu Province Institute of Cancer Research approved this study.

Environmental factors

The items of our questionnaire covered smoking and drinking habits. Smokers were divided into never- and ever-smokers (current and former). Drinkers also were divided into two groups ($\geq$ 2 times/mo and < 2 times/mo) according to drinking frequency.

DNA extraction and genotyping of the CYP2E1

Whole blood was collected into EDTA-coated tubes and centrifuged for 15 min, and the buffy coat layer was isolated. Genomic DNA was extracted from 200 μL of buffy coat using a Qiagen QIAamp DNA Blood Mini Kit (QIAGEN Inc., Valencia, CA). The method for genotyping of the *CYP2E1* has been previously described[30]. In brief, PCR was used to amplify the transcription regulation region of *CYP2E1* that includes the *Rsa* I enzyme recognition site[3]. The primers were 5'-CCAGTCGAGTCTACATTGTCA and 5'-TTCATTCT GTCTTCTAACTGG. The PCR product was subjected to *Rsa* I restriction enzyme digestion and samples were then analyzed by electrophoresis in 5% polyacrylamide gels. There were three genotypes of *CYP2E1* resulting from digestion with the restriction enzyme *Rsa* I : the common homozygote c1/c1; the heterozygote c1/c2; and the rare homozygote c2/c2. Among 754 examined samples, PCR products could not be visualized for 2 cases and 6 controls.

Statistical analysis

Associations between the *Rsa* I polymorphism and colorectal cancer risk were estimated by OR, using the unconditional logistic regression model. We calculated adjusted ORs for age (continuous), sex, smoking and drinking habits. To investigate gene-environmental interactions, we also calculated (stratified analysis) ORs according to combinations of the *CYP2E1* genotypes and habits of the smoking and drinking, with *Rsa* I c1 allele carriers as the reference. The procedure LOGISTIC from the statistical package SAS was employed for the calculations. The probability of Hardy-Weinberg equilibrium was assessed by the χ^2 test.

RESULTS

Numbers of subjects were 190 male and 125 female with colorectal cancer, and 223 male and 216 female controls (Table 1). The proportion of females in controls was significant higher than in colorectal cases but the mean age did not differ between cases and controls. The proportional distributions of smokers and alcohol drinkers were significant higher in colorectal cancer cases than in controls.

The distributions of *CYP2E1 Rsa* I c1/c1, c1/c2 and c2/c2 genotypes were 61.4%, 35.6% and 3.0%, respectively, in controls, 59.1%, 33.9% and 7.0% in colorectal cases, 60.6%, 33.7% and 5.8% in colon cancer cases, and 58.4%, 34.0% and 7.7% in rectal cancer cases (Table 1). The proportional distribution significantly differed

Rectal cancer					
	c1/c1	122	266	1.00	1.00
	c1/c2	71	154	1.01 (0.71-1.44)	1.01 (0.71-1.44)
	c2/c2	16	13	1.61 (1.09-2.36)	1.64 (1.12-2.41)

[1]ORs were adjusted for age and sex in a logistic regression model. [2]ORs were adjusted for age, sex and status of smoking and alcohol drinking.

between control and colorectal (χ^2_{MH} = 6.58, P = 0.037) or rectal (χ^2_{MH} = 7.07, P = 0.029) cancer cases. The allelic distribution of the *Rsa* I polymorphism for controls was in Hardy-Weinberg equilibrium (χ^2 = 2.77, P > 0.05). It shows that the controls from general population are representative. The *CYP2E1 Rsa* I c2/c2 genotype was associated with significantly increased ORs for colorectal cancer (sex-, age- and habits of smoking and alcohol drinking adjusted OR = 1.55, 95% CI, 1.08-2.22) and rectal cancer (adjusted OR = 1.64, 95% CI, 1.12-2.41) (Table 2).

Table 3 shows the results of the multivariable analysis of smoking, alcohol drinking and *CYP2E1 Rsa* I c2/c2 genotypes and risk of colorectal cancer. The smoking habit was not associated with any increased OR for colon or rectal cancer, but alcohol drinking was linked with elevated ORs for colon (1.68, 95% CI, 0.97-2.89) and rectal (2.08,

[1]ORs were adjusted for age and sex.

95% CI, 1.36-3.19) cancers. The *CYP2E1 Rsa* I c2/c2 genotype significantly increased the OR for rectal cancer (1.58, 95% CI, 1.08-2.32).

Table 4 shows the results of interaction analysis of the *CYP2E1 Rsa* I polymorphism with smoking and alcohol drinking habits. Among nonsmokers, *Rsa* I c2/c2 was associated with elevated ORs for colon (1.95, 95% CI, 0.99-3.86) and rectal (2.30, 95% CI, 1.32-3.99) cancers. Among smokers with the *Rsa* I c2/c2 genotype, no increase in the OR for colon cancer was observed, and the slightly increased OR for rectal cancer also was not statistically significant.

Among carriers of the *Rsa* I c1 allele, alcohol drinking was significantly associated with an elevated OR for rectal cancer (2.07, 95% CI, 1.37-3.14). As compared with non-drinkers with the *Rsa* I c1 allele, drinkers with RsaI c2/c2 genotype had significant increased ORs for colon cancer (4.74, 95% CI, 1.10-20.40) and rectal cancer (5.75, 95% CI, 1.65-20.05).

DISCUSSION

The present study revealed a significant association between the *CYP2E1 Rsa* I c2/c2 genotype and risk of rectal cancer, as well as a notable interaction with smoking or alcohol drinking as environmental factors.

Previous investigations showed inconsistent findings. As regards colorectal cancer, Kiss *et al*[24] found the *CYP2E1* c2 allele to be significantly associated with colorectal cancer (OR: 1.91, 95% CI, 1.05-3.52) in a Hungarian population. Yu *et al*[25] found the *CYP2E1 Pst* I c2 allele to be a susceptibility factor for colorectal cancer, especially for colon cancer, and there is an apparent gene-environment interaction with salted food in a Chinese population. In a study from the Netherlands, although calculation of crude ORs revealed an increased risk for colorectal cancer associated with the variant *CYP2E1* genotype (OR: 2.2, 95% CI: 1.3-3.8), this was no longer evident after adjustment for age and gender[35].

The reason for the inconsistent findings for the *CYP2E1* polymorphism is unknown but clearly variation with ethnicity and gender could contribute to differences in influence on neoplasia. The rare *Rsa* I allele is considered to result in increased transcriptional activation of the *CYP2E1* gene[2,3], with elevated expression levels of *CYP2E1* mRNA and protein[3,37]. However, several studies demonstrated common genotype carriers to have the higher *CYP2E1* enzyme activity[4,5]. Differences in *CYP2E1* activity by ethnicity and gender have also been reported, females showing 25% lower activity than males[7,38]. Japanese appear to demonstrate 30%-40% lower activity of *CYP2E1* than Caucasians, even after taking account differences in body size[39].

In the present study, we found a gene-environmental interaction between the *CYP2E1* polymorphism and smoking. Thus, increased risk of colon or rectal cancer was associated with the *CYP2E1 Rsa* I c2/c2 genotype among smokers, but not non-smokers. A similar phenomenon was also found in another study[40]. It has been shown that among non-smokers, urinary styrene metabolites are significantly decreased in subjects with c1/c1 alleles of *CYP2E1* as compared with those with the c1/c2 genotype, whereas no significant differences in urinary metabolites were noted among smokers[41].

We found alcohol drinking to significantly increase risk of cancer development, especially in the rectum, and there was a significant interaction with the *CYP2E1 Rsa* I c2/c2 genotype in both the colon and rectum. Our results are consistent with previous investigations indicating that alcohol consumption is associated with an increased risk for cancers of many organs, such as oral cavity, pharynx, larynx, esophagus, breast, liver, ovary; colon, rectum, stomach and pancreas[42]. Chronic ethanol consumption may promote carcinogenesis by (1) production of acetaldehyde, which is a weak mutagen and carcinogen; (2) induction of *CYP2E1* and associated oxidative stress and conversion of pro-carcinogens to carcinogens; (3) depletion of S-adenosylmethionine and, consequently, induction of global DNA hypomethylation; (4) induction of increased production of inhibitory guanine nucleotide regulatory proteins and components of extracellular signal-regulated kinase-mitogen-activated protein kinase signaling; (5) accumulation of iron and associated oxidative stress; (6) inactivation of the tumor suppressor gene BRCA1 and increased estrogen responsiveness (primarily in breast); and (7) impairment of retinoic acid metabolism[43]. Alcohol also can affect the pharmacokinetics of drugs by altering gastric emptying

or liver metabolism by inducing *CYP2E1*[43]. *CYP2E1* is the key microsomal enzyme that metabolizes alcohol in the non-alcohol dehydrogenase pathway. Choi *et al*[44] also discovered that "ever"-drinking women with the *CYP2E1* c2 allele containing genotypes had an increased risk of developing breast cancer compared to non-drinkers with the *CYP2E1* c1/c1 genotype in the Korean population.

Finally, some limitations require discussion. Because the frequency of the *CYP2E1 Rsa* I c2/c2 genotype is lower in subjects, only relatively small numbers were available for subgroup analyses, with consequent reduction in the magnitude of statistical power and increase in the potential for random error. Another possible problem is selection bias for controls, these being recruited by local health staff, albeit from the general population with a high response rate. The proportional distribution of female in controls was higher than that in colorectal cases, which may have caused a lower prevalence of smokers and alcohol drinkers in the present controls, though we adjusted for sex and age in all statistical analyses.

In summary, the present study revealed a link between the *CYP2E1 Rsa* I polymorphism and increased risk of rectal cancer, with a significant interaction between the *Rsa* I polymorphism and smoking and alcohol drinking habits regarding development of both colon and rectal cancers. The data provide support for our hypothesis that cancer susceptibility with the *CYP2E1* polymorphisms may be altered by background environmental factors.

COMMENTS

Background

Colorectal cancer is the fifth most commonly occurring cancer in China. Cytochrome P450 (CYP) enzymes in epithelial cells lining the alimentary tract play an important role in both the elimination and activation of (pro-) carcinogens. To estimate the role of *CYP2E1* in colorectal cancer development, we conducted a population based case-control study of colorectal cancer in Jiangsu Province of China.

Research frontiers

A lot of carcinogens from environment must be metabolized for their elimination and activation. Genetic polymorphisms of metabolizing enzymes may affect the metabolism of carcinogens and the risk of cancer formation in humans. Susceptibility to cancer is generally thought to be the sum of complex interactions between environmental and genetic factors. Thereby, how interaction between environmental and genetic factors is a hotspot of cancer epidemiological study. We Regarding to the hotspot, we studied interactions between *CYP2E1* and habits of smoking and alcohol drinking in colorectal cancer development.

Innovations and breakthroughs

In present study, we demonstrate a correlation between *CYP2E1 Rsa* I polymorphism in c2/c2 genotype is associated with rectal and not colon cancer. This increased risk associated with this polymorphism was negated in smokers. Furthermore, a significant cooperative action was seen between the c2/c2 genotype and alcohol consumption in both colon and rectal cancers.

Applications

This research exposes a screenable genetic risk factor and the effects of gene-environment interactions in identifying individuals at risk for colon or rectal cancer. These results have some theoretical and application values in the etiology and prevention of colorectal cancer.

Terminology

CYP2E1: cytochrome P450 2E1. *CYP2E1 Rsa* I polymorphism: *Rsa* I enzyme recognized polymorphism in *CYP2E1* gene.

Peer review

Gao *et al* demonstrate a correlation between *CYP2E1 Rsa* I polymorphisms in c2/c2 genotypes are associated with rectal and not colon cancer. This increased risk associated with this polymorphism was negated in smokers. Furthermore, a significant cooperative action was seen between the c2/c2 genotype and alcohol consumption in both colon and rectal cancers. The experiments contain appropriate controls and weightings of the data taking into consideration age, sex, smoking status and alcohol consumption. This research exposes a screenable genetic risk factor and the effects of gene-environment interactions in identifying patients at risk for colon or rectal cancer.

Abstract

AIM: To establish the role of enteric glial cells during infection with *Mycobacterium avium* subspecies paratuberculosis (MAP) in Crohn's disease.

METHODS: In order to establish the role of enteric glial cells during infection with *M. avium* subspecies *paratuberculosis* (MAP) in Crohn's disease, Map adhesion experiments on enteric glial cells were performed as well as expression analysis of Map sigma factors during infection.

RESULTS: In this study, for the first time, we found a high affinity of MAP to enteric glial cells and we analyzed the expression of MAP sigma factors under different conditions of growth.

CONCLUSION: The fact that Map showed a high affinity to the glial cells raises concerns about the complicated etiology of the Crohn's disease. Elucidation of the mechanisms whereby inflammation alters enteric neural control of gut functions may lead to novel treatments for Crohn's disease.

Key words: *Mycobacterium avium* subspecies *Paratuberculosis*; Enteric glial cells; Inflammatory bowel diseases; Crohn's disease; Sigma factors expression

INTRODUCTION

Several cell lines of the gut have been extensively studied such as intestinal epithelial cells, immune cells, smooth muscle cells and enteric neurons[1-4]. However, very little is known about enteric glial cells which belong to the enteric nervous system (ENS) along with the neurons[5]. The ENS, comprised of several plexuses, is located alongside the intestinal wall. The enteric glia are localised within the mucosal plexuses and the glial processes make close contact with the epithelial cell layers. The epithelial crypt bases, in particular, are surrounded by a dense network of glial cells[6]. These glial cells are small, star shaped with different processes of various length and shape[6]; they are morphologically and immunohistochemically different from microglia of the central nervous system and from all other peripheral glia and appear more closely related to astrocytes although functionally different[6]. Evidence for functional heterogeneicity of enteric glia has recently been described[7]. The enteric glial cells (EGC) could participate in neurotransmitter synthesis/inactivaction or in synaptic transmission. Moreover, they may also interact with intestinal capillaries to modulate endothelial permeability[8].

It has been shown that the enteric nervous system regulates intestinal barrier functions by regulating the zonula occludens-tight junctions[9]. Regarding EGC, it has been shown in a mouse model that EGC ablation results in fulminant intestinal inflammation due to disregulation and rupture of the epithelial intestinal barrier[8,10]. It has been suggested that there is a direct interaction between EGC (releasing soluble factors) and epithelial cells to enhance the intestinal epithelial cells[5]. Moreover they could have a role in the prevention of epithelial barrier disorganization and hyperproliferation during bacterial infection, inflammatory processes and neoplasia[11-13]. All these findings indicate that glial cells may be an important component of the intestinal mucosal defense system.

On the other hand, *Mycobacterium avium* subspecies *paratuberculosis* is the causative agent of Johne's disease, a chronic and incurable disease affecting ruminants and other animals[14]. Moreover, there is increasing evidence of its involvement in the enteric granulomatous syndrome of

[1]longest sequence available (primary and TIGR annotation). ECF: Extracitoplasmatic function; TIGR: The Institute for Genomic Research.

humans called Crohn's disease[15-17]. For all these reasons we analyzed the interactions between EGC and M. paratuberculosis *in vitro*.

Sigma factors are part of the transcriptional regulators family and are responsible for binding to the RNA polymerase complex (composed of four distinct subunits); to recognize promoters and separate DNA strands[18]. In fact, every sigma factor has its own specificity, allowing the initiation of transcription of different subset of genes[18,19]. Some sigma factors (sigD, sigE, sigC, sigH and sigL) play a role in the virulence of *M. tuberculosis*[20,21]. The number and abundance of sigma factors reflect the ability of the bacterium to cope with various environmental conditions, stresses and insults[18,22].

In this study the expression of all 19 sigma factors of M. paratuberculosis were also tested during EGC infection.

MATERIALS AND METHODS

Bacterial strains and culture conditions

M. paratuberculosis ATCC 43015, of human source was obtained from The RIVM, Bilthoven, The Netherlands. *M. paratuberculosis* for DNA extraction was grown in Mycobacteria Growth Indicator Tube (MGITl) medium supplemented with Mycobactin J and egg yolk. Murine enteric glial cells were previously isolated and characterized by Dr. Anne Ruhel[23].

Identification of M. avium subsp. paratuberculosis putative sigma factors

Identification of individual sigma factors in *M. avium* subspecies. paratuberculosis was obtained by text annotation searches and by BlastP similarity searches using *M. smegmatis* and *M. tuberculosis* H37Rv Sigma ORF as queries. Primers used in real time PCR are described in Table 1.

DNA extraction

DNA extraction was performed using the Ribolyser system (HYBAID, USA) and purified as previously described[17].

PCR conditions

Oligonucleotide sequences and position are reported in

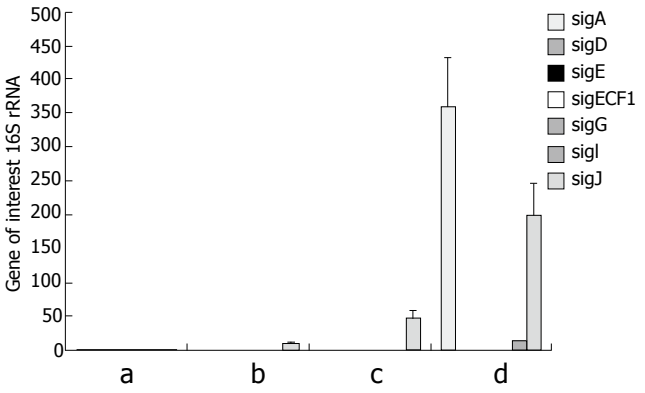

Figure 1 Relative quantification of expression of MAP sigma factors relative to the expression of the 16S rRNA MAP gene (calculated by the Biorad software) by Real Time PCR after different conditions of growth. a: After growth in 7H9 medium plus mycobactin J; b: Infection of EGC after 6 h of incubation; c: Infection of EGC after 48 h of incubation; d: Infection of EGC cells after 7 d of incubation.

Table 1. Specificity of primer pairs was ascertained with PCR with the following conditions: $MgCl_2$ 1.5 mmol/L, deossi Nucleotide Triphosphate (dNTPS) 150 μmol/L, primers 0.2 μmol/L each, Taq 0.025 U/μL reaction volume. After an initial denaturation of 3 min at 94℃, 30 cycles of 1 min at 94℃, 1 min at 58℃, 1 min at 72℃ and a final extension at 72℃ for 5 min were performed. Only the amplification products of the expected length were obtained.

RNA extraction

RNA was extracted using the Ribolyser instrument[17]. RNA was extracted from MAP cells after different conditions: (1) growth in 7H9 medium plus Mycobactin J, (2) after addition of lysozyme at 24 h and 7 d; (3) after infection of EGC line, after 6 h, 24 h, 48 h and 7 d. RNA was quantified for further experiments and samples were stored at -80℃ until further use. cDNA was prepared by an initial incubation at 65℃ for 10 min of the reaction mixture containing 100 μmol/L oligo-dT and 10 μL of extracted RNA; this first step was followed by a second incubation of 1 h at 42℃ of the mixture containing 50 U/reaction of reverse transcriptase (Mooloney-Murine Leukemia Virus M-MLV 200 U/μL), 0.1 mol/L buffer 5 × Tris HCl pH 8.3 (Life Technologies) with 150 mmol/L KCl, 7 mmol/L $MgCl_2$ and 20 mmol/L dithiothreitol (DTT); 0.1 mol/L DTT, 10 mmol/L dNTPs, 40 U/μL RNase inhibitor.

Real time PCR analyses

Real Time PCR was performed using the iCycler Detection System (Biorad) with the SyberGreen assay (Applied Biosystems). Gene expression of all the Sigma factors (except Extracytoplasmic function 3 ECF3) was determined using quantitative Real-Time PCR by comparing the fluorescence produced by test samples to that of the 16S rRNA gene expression (house-keeping gene). Five micro liters of cDNA was subjected to PCR (1 cycle at 94℃ for 1 min; 50 cycles at 94℃ for 30 s and at 60℃ for 40 s) with primers that amplified 16S rRNA, all 19 sigma factor genes. PCR was carried out with the following reaction-mixture in a total volume of 30 μL: 1 × of 10 × buffer, $MgCl_2$ 1.5 mmol/L, dNTPs 0.2 mmol/L, primers 0.5 μmol/L each, DNA polymerase 0.5 U/sample. PCR was performed in a 96 well plate, for each sample 2 wells were utilized to guarantee uniformity in results. The quantitative analysis of the data obtained was performed by Biorad's method of relative quantitation of gene expression (Bio-Rad Laboratories, USA).

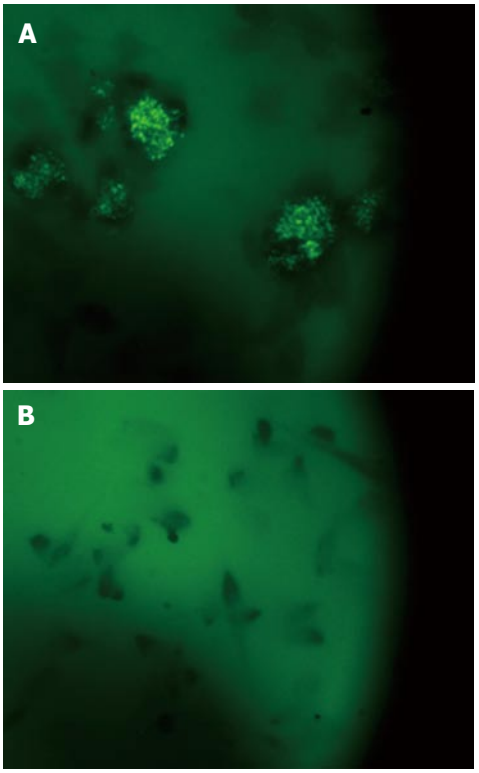

Figure 2 MAP cells stained with auramine rodhamine at 6 h after infection of EGC (**A**) and without infection (**B**) and visualized under a fluorescence microscope (× 100).

Infection experiments

Glial Enteric cell lines were cultivated in 24 well plastic dishes. The EGCs were cultivated in Dulbecco's modified Eagle medium supplemented with 15% fetal bovine serum and 4 mmol of L-glutamine per liter. All tissue culture reagents were obtained from Sigma (Sigma Chemical Co.). Cells were seeded at 2×10^4 cells per well and incubated at 37℃ in 5% CO_2. EGC cells were used when they were semiconfluent. MAP grown over night in 7H9 broth (with mycobactin J) was diluted in cell medium. One milliliter containing 10^6 bacteria was added to each well containing EGCs (cells were infected at a ratio of bacteria/cells of 10:1). After two hours infected EGCs were washed with cell medium containing Kanamycin 100 μg/mL and incubated with the same medium. Cells were stained with auramine rodhamine at the different incubation times (6 h, 48 h and 7 d at 37℃) to visualize MAP, and counted as previously described[17].

RESULTS

Expression of sigma factors in different conditions of Growth

7H9 broth plus mycobactin J: MAP during growth in

broth 7H9 supplemented with Mycobactine J, expressed several sigma factors as expected (Figure 1A). SigA, Sig D, SigE, Sig G and Sig I were among the most expressed ones as compared to the 16S rRNA expression taken as house keeping gene whereas ECF1 and sig J were expressed in lower quantity (Figure 1A).

Infection of EGC: The expression of the 19 sigma factors of MAP was observed and quantified after growth infection of EGC at 6 h, 48 h and 7 d (Figure 1 B-D). Soon after infection, expression of all sigma factors shut down, except for sig J which was expressed in high quantity (Figure 1B). The expression of sig J increased after 48 h (Figure 1C) and 7 d. SigA was overexpressed after seven days (Figure 1D), at the same time an expression of sig I was also detected. Figure 2 reveals an example of EGC infection by MAP where bacteria were visualized within the intestinal glial cells after staining with auramine rodamine as compared to control cells not infected.

DISCUSSION

Enteric glias are distinct from all other glial cell types[5,7]. No gastrointestinal disorder has been reported linked to glial defect yet, most probably because subtle changes in glial function might be involved in the etiopathogenesis of enteric disorders. Crohn's disease with neuroinflammation and neurodegeneration components may be associated with EGC alteration[23-25]. Indeed EGC interact with enteric neurons, endothelial cells, immune cells and the intestinal epithelium; all these factors can contribute to the pathogenesis of Crohn's disease. In our experiments, we found that MAP has a high affinity to EGCs. Experiments "*in vitro*" show a high adhesion and intracellular multiplication as confirmed by the active expression of sigA (the housekeeping sigma factor) after seven days of infection along with the expression of sigJ and sigI (expressed in different conditions of cellular stress).

The fact that this dangerous intestinal pathogen has a demonstrated affinity to the glial cells and that MAP has recently been reported in substantial percentages of Crohn's patients[15-17] raises concerns about the complicated etiology of the Crohn's disease.

MAP expression of sigma factors in EGC is very similar to sigma factor expression after infection of the Caco2 intestinal epithelial cell line (manuscript in preparation) and shows how there is a rapid change in gene expression after cell infection.

EGCs are an active part of an intestinal network system essential for a healthy and functional gut[23,26,27]. The role of EGC in Crohn's and other enteric diseases is not well studied and this is the first report that attempts to unravel interaction between an intestinal pathogen and EGC. Future work is certainly needed to elucidate this complex interaction.

COMMENTS

Background

Enteric glia might play a role in regulating barrier functions in mucosal epithelia. *Mycobacterium avium subspecies paratuberculosis* (MAP) is the causative agent of Johne's disease, a chronic and incurable disease affecting ruminants and other animals. Moreover, evidence of its involvement in Crohn's disease is accumulating. MAP enter the host through Peyer's patches and intestinal epithelium and are sampled by intestinal dendritic cells; they survives inside macrophages. Nothing is known about the role of enteric glial cells during MAP infection thus we performed this study to establish the role of enteric glial cells during infection with *Mycobacterium avium subspecies paratuberculosis* (MAP) in Crohn's disease.

Research frontiers

It is firmly established that intestinal inflammation is accompanied by functional and structural alterations of the Enteric Nervous System to which belong Enteric Glial Cells. In Crohn's disease patients, a compromised glial network that responds poorly to inflammatory stimuli has been suggested. Our report will open a new frontier on the interaction of MAP and enteric glia cells supporting the idea that Crohn's disease is associated with the invasion and persistence of a multi host pathogen as it is MAP.

Innovations and breakthroughs

This is the first research that highlights the interaction of a true enteric pathogen such as Map with Enteric glial cells. This study will open the research field in this matter.

Applications

Enteric glial cells may be the target of a series of cytokine modulators or drugs. Map will be recognized as a pathogen associated with intestinal disorders.

Terminology

EGCs: enteric glial cells; Map: Mycobacterium avium subs. Paratuberculosis; ENS: Enteric nervous system; Johne's disease: Enteric granulomatous infection of ruminants caused by Map; Crohn's disease: Enteric granulomatous chronic inflammation in humans with ulcerative colitis (UC) forms inflammatory bowel disease (IBD).

Peer review

The manuscript by Sechi *et al* describes the expression of MAP sigma factors during infection of enteric glial cells. The first findings that sigma factors are differentially expressed during infection are very promising.

Abstract

AIM: To study the predictive value of the vegetative-depressive symptoms of the Zung Depression Rating Scale for the occurrence of depression during treatment with peg-interferon α-2b of chronic hepatitis C (CHC) patients.

METHODS: The predictive value of vegetative-depressive symptoms at 4 wk of treatment for the occurrence of a subsequent diagnosis of major depressive disorder (MDD) was studied in CHC patients infected after substance use in a prospective, multicenter treatment trial in Belgium. The presence of vegetative-depressive symptoms was assessed using the Zung Scale before and 4 wk after the start of antiviral treatment.

RESULTS: Out of 49 eligible patients, 19 (39%) developed MDD. The area under the ROC curve of the vegetative Zung subscale was 0.73, $P = 0.004$. The sensitivity at a cut-point of > 15/35 was 95% (95% CI: 74-100). The positive predictive value equalled 44% (95% CI: 29-60).

CONCLUSION: In this group of Belgian CHC patients infected after substance use, antiviral treatment caused a considerable risk of depression. Seven vegetative-depressive symptoms of the Zung scale at wk 4 of treatment predicted 95% of all emerging depressions, at a price of 56% false positive test results.

Key words: Interferons; Hepatitis C; Chronic; Substance-related disorders; Depression; Zung self rating scale; Prognosis

INTRODUCTION

Following the recent expert consensus, patients with chronic hepatitis C (CHC) should now receive interferon (IFN) and ribavirin regardless of psychiatric status, except in uncontrolled psychiatric disease[1-3]. As 23%-44% of patients treated with IFN develop depressive symptoms during treatment[4,5] and since, more patients are treated, interferon-induced psychiatric illness is likely to become an increasingly important clinical problem[4,6-14].

IFN-induced depression appears to be a depressive disorder that is unusually responsive to antidepressant treatment. Approximately 80% of patients are responsive within 4 wk[15]. This high response rate may be related to the usually short duration of this illness when treatment is initiated, to the mild to moderate severity of illness in most cases[1], but also to the mainly interferon-induced influences on the central nervous system[16].

Based on the results of a small scale study ($n = 16$), it has been hypothesised that vegetative symptoms are

early predictors for the emergence of full depression[9]. We wanted to confirm or refute this finding in a larger patient group of CHC positive substance users, classically considered as predisposed for depression[17].

Therefore, the predictive value of an increase in the score of the seven vegetative-depressive symptoms from the 20-item Zung Depression Rating Scale[18] was studied in a new study in substance users, using the emergence of a DSM-IV based major depression during treatment as the outcome measure.

MATERIALS AND METHODS

Subjects

Previously untreated patients, 18 years or older, with compensated chronic HCV infection acquired after substance use, with a serum alanine aminotransferase level above the upper limit of normal, and positive serum HCV RNA were eligible for the study.

HCV patients infected after substance use were defined as patients who were HCV-positive and who had used cocaine, heroin or LSD at least once. All of them were currently or previously cared for in multidisciplinary and specialised programs, according to criteria defined in the Belgian guidelines for the treatment of CHC patients infected after substance use (Table 1)[1]. Patients, who had co-infections such as hepatitis B virus or human immunodeficiency virus, or patients with a diagnosis of uncontrolled neurological, cardiovascular, endocrine, haematological, hepatic or renal disease or patients with insufficient knowledge of the Dutch or French language were excluded.

The study was approved by the ethical review board of the Catholic University of Leuven Medical School and by the Medical Ethical Committees of each of the different centres, and carried out in accordance with the Declaration of Helsinki. Written informed consent was obtained from each subject prior to participation.

Methods

Patients were treated in a prospective, randomised, multi-center study in Belgium between November 2001 and February 2004 with pegylated interferon α-2b, 1.5 μg/kg weekly by subcutaneous injection in combination with ribavirin (administered orally, 1000-1200 mg/d, depending on body weight) or interferon α-2b PEN 3 MIU subcutaneously 3 times/wk in combination with ribavirin (administered orally, 1000-1200 mg/d, depending on body weight). The total duration of therapy for the two study medication arms was 48 wk if the patient was infected with genotype non-2-3 and 24 wk if the patient was infected with genotype 2-3. The patients were required to use effective birth control. A subgroup out of the study centers that collaborated to the study, also recorded the emergence of depression. In this group we systematically investigated the occurrence of depression during therapy in patients who were not already depressed at baseline.

A complete medical history, physical examination, laboratory blood test and liver biopsy were performed before study entry. A liver biopsy was performed before randomisation.

Table 1 Characteristics at baseline of chronic hepatitis C patients infected by substance use in a Belgian population eligible for treatment in a randomised trial

Characteristics at baseline	*n*	Thrice in wk 3 MIU interferon	Weekly pegylated interferon	Total	Wilcoxon rank sum test or fishers exact test

Risk determination

In total, 12 hepatologists in collaborating treatment centres (in whom 49 patients were treated) agreed to apply a 20-item Zung self-rating depression scale (SDS) at wk 0, 4 wk after start of treatment and after the treatment regimen was completed. Zung scale results could score between 25 (normal) and 100 points. A high score indicates a depressive attitude. A cut-off of equal to and higher than 60/100 was considered as indicative for diagnosable depression[18].

Cognitive-depressive and vegetative-depressive symptom dimensions were constructed as described earlier[19]. The vegetative-depressive symptoms (Diurnal variation, lack of sleep, loss of appetite, loss of sex drive, weight loss, constipation, fatigue) were scored from 1 to 4 (in the analysis multiplied with 5/4).

Outcome measures

Clinical diagnosis of depression was confirmed by a qualified psychiatrist on the basis of DSM-IV criteria for major depression[20].

Statistical analysis

Quantitative measures are expressed as mean or as median. Qualitative variables are presented as counts and percentages.

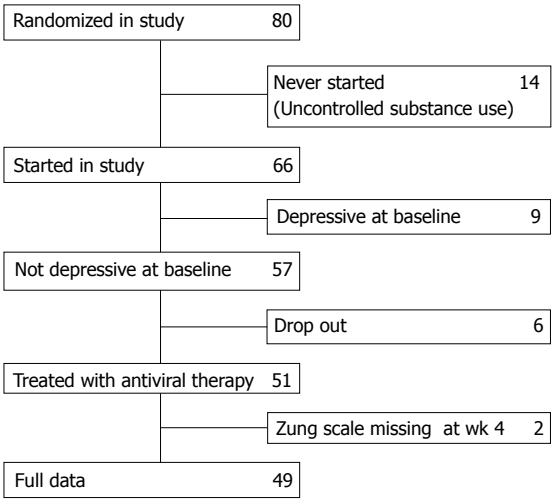

Figure 1 Flow chart of the patients included in the study.

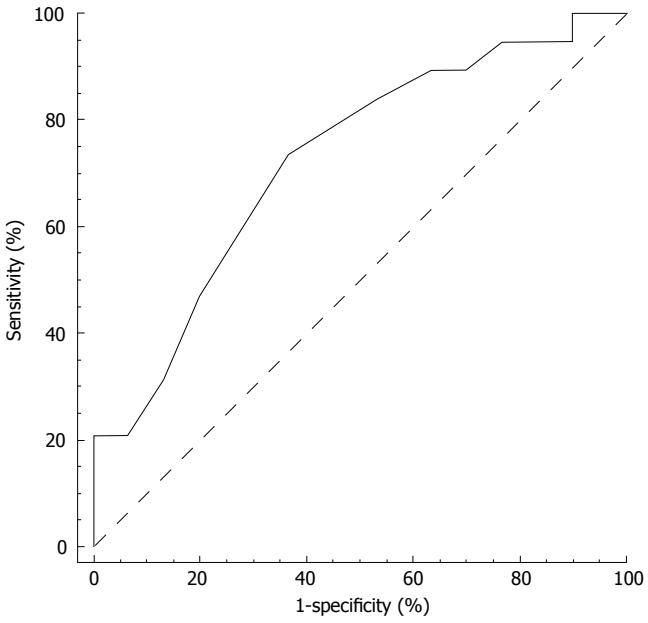

Figure 2 ROC prediction of depression based on vegetative Zung scale at wk 4.

The χ^2 test statistic and logistic regression methodology were used to compare two patient subgroups with respect to categorical outcome measures. *T*-tests for independent samples and linear regression methodology were applied to compare subgroups for differences in means of continuous variables. Non-parametric test statistics such as the Wilcoxon Rank Sum test were used if normality was absent.

In identifying an optimal cut-point for the Zung-vegetative symptoms score, we searched for a maximal sensitivity with a positive predictive value of at least around 50%. We report the full ROC curve, the AUC and its confidence interval for the four-week vegetative subscale of the Zung and the AUC and the *P*-values for possible alternative measures.

RESULTS

Participants

Eighty patients in whom chronic hepatitis C was diagnosed as acquired after substance use were randomised to treatment with either interferon α-2b or pegylated interferon α-2b combined with ribavirin and were followed by a hepatologist who accepted to apply the Zung rating scales. Fourteen patients never started the study because they were still consuming substances in an uncontrolled way. Nine had major depressive disorder (MDD) at baseline and were therefore excluded. For 8 patients data collection was incomplete. In total 49 eligible patients were included in this analysis (Figure 1).

Baseline characteristics

Demographic characteristics and clinical data for all eligible patients not having depression at baseline (n = 49) are summarized in Table 1. There were no baseline differences between the two treatment groups, with the exception of HCV genotype distribution (P = 0.02) and alanine aminotransaminase (ALT) level (P = 0.06).

Depression (DSM IV)

Nineteen patients became depressed during antiviral treatment. Median time to depression ranged from 4 to 26 wk and was distributed over this whole period with a mean of 10 wk.

Zung scale

At baseline there was no difference in total, vegetative or cognitive Zung score between patients who subsequently became depressed or not.

At wk 4 after treatment start the mean vegetative Zung scale was higher among the patients developing depression later on compared to other patients (P = 0.008). It decreased slightly from baseline to wk 4 (difference: -0.72; P = 0.49) for patients not getting depressed. Patients getting depressed increased on average 4.13 points on the vegetative Zung scale during the first four weeks of therapy (P = 0.03).

Diagnostic accuracy characteristics

The ROC curve for the prediction of depression emerging during treatment by the vegetative subscale at wk 4 is reported in Figure 2. The area under the curve (AUC) was 0.73 (95% CI 0.58-0.84; P = 0.004). At a cut-off point of > 17/35, the sensitivity and specificity of the vegetative subscale at wk 4 were 90% and 30%, respectively. The positive and negative predictive value equalled 45% and 82%. For a sensitivity of 95% (95% CI 74-100) the vegetative subscale criterion was > 15 and the corresponding specificity 23% (95% CI 10-42), the positive predictive value 44% (95% CI 39-60) and negative predictive value 88% (95% CI 47-100).

The increased vegetative Zung scale was not merely a measure of depression at that moment, but predicted the occurrence of depression scattered over the weeks and months afterwards. Results were not different according to gender, age and genotype.

The change in vegetative symptoms between wk 0 and 4 was marginally predictive (AUC = 0.68; P = 0.06).

The cognitive subscale at wk 4 was not able to predict a clinical diagnosis of depression (AUC = 0.62; $P = 0.15$). The total Zung at wk 4 did only have marginal predictive power (AUC = 0.67; $P = 0.05$).

DISCUSSION

The early presence of vegetative symptoms seems to be predictive for the occurrence of depression later on. In a small scale prospective study ($n = 16$)[9] it was found that the increase in the vegetative subscale score of the Montgomery Asberg Depression Rating Scale (MADRS) or the Hamilton Depression Rating Scale scales after one week of antiviral treatment following the start of antiviral treatment in CHC patients was predictive for MDD. We could confirm these findings in this prospective study during treatment with regular interferon or pegylated interferon in combination with ribavirin. Our study was larger and we had a more vulnerable population resulting in a higher number of patients becoming depressed during treatment. In this study, we found that a cut-off point of > 15/35 at the vegetative subscales at wk 4 resulted in a sensitivity of 95% at an acceptable positive predictive value of 44%.

This high sensitivity was found using a questionnaire of 7 items, part of the 20-item Zung scale. A similar sensitivity was found using the Minnesota Multiphasic Personality Inventory[21]. However, this rating scale includes 566 items and is more elaborate to perform in a routine outpatient clinic.

There was no relation between a higher score or a significant increase in the cognitive subscale at wk 4 and a higher risk of subsequent clinical depression. This is in agreement with the hypothesis formulated in reference[9].

Also, the Zung depression rating scale as a whole was not predictive for the development of depression in substance use patients, at least after exclusion of the patients that were already depressed at baseline. In other studies the baseline value was found to be predictive for patients with the Minnesota Multiphasic Personality Inventory[22], the Hamilton Depression Rating Scale score (HDRSS)[23] and the Centre for Epidemiological Studies-Depression Scale, CES-D[24] higher than a certain cut-off level[21,25,26]. However, in these studies people that were depressed at baseline were not always excluded[25,26].

In our study, an increased vegetative subscale score at 4 wk of treatment predicted diagnosis of major depression scattered over the weeks and months afterwards. This scatter is comparable to results found in other recent studies[4,7-10,25].

Although depressive symptomatology occurring in patients treated with interferon has usually been called 'depression' or 'major depressive episode', the more appropriate term according to new DSM-Ⅳ -TR should be 'substance induced mood disorder'. There are psychopathological (e.g., more irritability)[27], epidemiological (the gender difference in major depressive episode is different from the gender difference in interferon induced mood disorder)[28], genetic[29] and treatment (more patients than in major depressive episode respond well to SSRIs)[30] arguments to support this really to be a different disorder.

This study has some limitations. It was restricted to substance users with CHC infection and antiviral treatment. Therefore, it is not possible to extrapolate to other patient groups. However, from small studies there seems no difference in the development or the mechanism of depression in other patient groups[9,30]. Secondly, although larger than previous studies[9] our sample size is still relatively low resulting in large confidence intervals.

In conclusion, the development of depression can reliably be predicted at wk 4 after start of interferon treatment by an increase in vegetative symptoms of depression (subscale score) to at least 15/35. This results in a prediction with a sensitivity of 95%, at the price of 56% false-positive test results, which for a screening test is considered to be acceptable. Treatment with antidepressants may cure or prevent depression and so increase the treatment adherence. This may improve the SVR in patients evolving to depression and make the SVR comparable to SVR in non-depressed patients. To formally prove this, however, it should be the subject of another study.

COMMENTS

Background

Interferon derived treatment will remain the cornerstone for antiviral therapy in chronic hepatitis C patients in the near future. Interferon induced depression is a frequent side effect that may influence the outcome of the treatment. Since interferon-induced depression is unusually responsive to antidepressant treatment, it is important to detect the patients who are at risk for depression and who can benefit from antidepressive treatment.

Research frontiers

At this moment very few tools have been extensively studied to detect the patients at risk of depression during treatment with interferon. The Minnesota Multiphasic Personality Inventory is thoroughly studied but questioning 566 items makes it very elaborate to perform in a routine outpatient clinic.

Innovations and breakthroughs

Using only seven questions at week four of treatment from the vegetative-depressive symptoms of the Zung scale, it is possible to predict 95% of all emerging depressions, at a price of 56% false positive test results.

Applications

Treatment with antidepressants may cure or prevent depression and so increase the treatment adherence. This may improve the SVR in patients evolving to depression and make the SVR comparable to SVR in non-depressed patients. To formally prove the hypothesis that antidepressants may improve SVR in patients at risk for depression, should be the subject of further studies.

Abstract

AIM: To elucidate the frequency and characteristics of pancreatic involvement in the course of acute (nonfulminant) viral hepatitis.

METHODS: We prospectively assessed the pancreatic involvement in patients with acute viral hepatitis who presented with severe abdominal pain.

RESULTS: We studied 124 patients with acute viral hepatitis, of whom 24 presented with severe abdominal pain. Seven patients (5.65%) were diagnosed to have acute pancreatitis. All were young males. Five patients had pancreatitis in the first week and two in the fourth week after the onset of jaundice. The pancreatitis was mild and all had uneventful recovery from both pancreatitis and hepatitis on conservative treatment. The etiology of pancreatitis was hepatitis E virus in 4, hepatitis A virus in 2, and hepatitis B virus in 1 patient. One patient had biliary sludge along with HEV infection. The abdominal pain of remaining seventeen patients was attributed to stretching of Glisson's capsule.

CONCLUSION: Acute pancreatitis occurs in 5.65% of patients with acute viral hepatitis, it is mild and recovers with conservative management.

Key words: Acute hepatitis; Pancreatitis; Viruses; Pain; Abdomen

INTRODUCTION

Although hepatitis viruses have a strong tropism for hepatocytes, viral antigens have also been detected in other tissues such as the pancreas and gallbladder[1,2]. Several viral infections have been implicated as an aetiological factor of acute pancreatitis. The viruses most frequently responsible are mumps virus, Coxsackie B virus, Epstein-Barr virus and measles virus[3-6].

Acute pancreatitis is not uncommon in fulminant hepatic failure (FHF) and has been confirmed based on histology or serology[7-9]. Acute pancreatitis has been reported very rarely in acute (nonfulminant) viral hepatitis. It has been reported with hepatitis A (HAV), hepatitis B (HBV) and non-A-non-B (blood-borne) and hepatitis E virus (HEV) infection[10-20].

The aim of this study was to determine the frequency and characteristics of pancreatic involvement in the course of acute viral hepatitis.

MATERIALS AND METHODS

Materials

Patients seen at the gastroenterology clinic and ward of SMS hospital, Jaipur between January 2004 and December 2006 were included in this prospective study. Acute viral hepatitis was defined as patients with prodromal symptoms, deep jaundice, markedly raised transaminases, presence of markers of hepatitis B (positive for HBsAg, IgM anti-HBc, HBeAg, but negative for anti-HBe), hepatitis A (IgM anti-HAV), hepatitis C (anti-HCV), hepatitis E (IgM-anti-HEV) viruses in serum and ultrasound abdomen showing thick walled gallbladder and hypoechoic liver. Patients with other causes of acute hepatitis, chronic liver disease, history of alcohol intake and fulminant hepatic failure were excluded from the study.

The diagnosis of acute pancreatitis was based on pancreatic type abdominal pain, raised amylase and lipase levels to three times the upper limit of normal and ultrasound (US) or contrast enhanced computed tomography (CECT) of abdomen suggestive of acute pancreatitis.

Methods

The acute viral hepatitis group underwent hemogram, serum bilirubin, serum aspartate aminotransferase (AST), serum alanine aminotransferase (ALT), serum alkaline phosphatase, prothrombin time, HBsAg, IgM anti-HBc, HBe Ag, anti-HBe, IgM anti-HAV, anti-HCV, IgM anti-HEV and ultrasound abdomen. Serum amylase and lipase, US of the abdomen and/or CECT were done in patients who had severe abdominal pain. Informed consent was obtained from each patient.

Table 1 Clinical and laboratory characteristics of 124 patients of acute viral hepatitis

	Acute viral hepatitis A (n = 16)	Acute viral hepatitis B (n = 54)	Acute viral hepatitis E (n = 54)
Male: Female	13:3	42:12	39:15
Age (yr)[1]	18.3 (8-35)	36 (20-74)	33.6 (17-62)
Clinical features			
Jaundice	15 (93.8)	54 (100)	54 (100)
Prodromal symptoms	16 (100)	54 (100)	54 (100)
Pain abdomen	4 (25)	8 (14.8)	12 (22.2)
Pruritis	4 (25)	9 (16.6)	19 (35.2)
Hepatomegaly (%)	6 (37.5)	16 (29.6)	21 (38.9)
Splenomegaly (%)	2 (12.5)	6 (11.1)	5 (9.2)
Hemoglobin (gm/dL)[1]	12.3 (9.6-14.5)	12.4 (9-15.1)	12.6 (9-14.7)
Platelets ($\times 10^5/mm^3$)[1]	2.5 (1.8-3.2)	1.8 (1.2-2.5)	1.6 (1-3.4)
Total leucocyte count ($\times 1000/mm^3$)[1]	7.9 (6.4-10.5)	8.4 (5-10.1)	7.2 (6-10.6)
Bilirubin (mg/dL)[1]	9.4 (0.67-35.8)	12.4 (3-36.5)	10.7 (3.3-26.3)
AST (IU/L)[1]	1969 (60-7715)	824 (223-3600)	1621.1 (240-3684)
ALT (IU/L)[1]	2134.3 (56-5165)	1024 (489-4900)	1830.6 (240-5549)
Serum alkaline phosphatase (IU/L)[1]	521.9 (196-1426)	424.5 (110-860)	324 (114-647)
Protein/Albumin (gm/dL)[1]	7.2 (6.5-7.8)/4.0 (3.5-4.6)	7 (6-8)/3.9 (3.4-4.8)	6.5 (5.5-8)/3.8 (3.4-4.6)
Prothrombin time prolongation[1]	4 (2-14)	5.5 (1-11)	6 (3-18)
Ultrasonography of the abdomen			
Thickened gallbladder	14 (87.5)	38 (70.4)	44 (81.5)
Hypoechoic liver	8 (50)	24 (44.6)	26 (48.1)
Gallbladder sludge	2 (12.5)	2 (3.7)	3 (5.5)
Ascites	1 (6.25)	3 (5.5)	26 (48.1)
Bulky pancreas	2 (12.5)	1 (1.8)	4 (7.4)

[1]Mean (range).

RESULTS

We had 124 patients with acute viral hepatitis over the three-year period, consisting of 94 males and 30 females, with a mean age of 32.7 years (range 8-65). The viral serology assays showed HBsAg and IgM-anti-HBc in 54 patients, IgM anti-HEV in 54 and IgM anti-HAV in 16 (Table 1). Twenty-four patients (19.4%) presented with history of severe abdominal pain, and 7 of these (29.2%) had evidence of acute pancreatitis. So, 5.65% of patients with acute viral hepatitis presented with acute pancreatitis. In the remaining 17 patients, the amylase and lipase were less than three times the upper limit of the normal. They did not have evidence of acute (calculous or acalculous) cholecystitis. We attributed the abdominal pain to stretching of the Glisson's capsule.

The clinical, laboratory and radiological profile of the patients with acute pancreatitis is given in Tables 2 and 3. The mean age was 23.9 (range 11-32) years, all were males. Abdominal pain occurred 2-30 (mean 12) days after the onset of jaundice. The duration of abdominal pain ranged from 24 to 120 h. None of the patients had a past history of jaundice, abdominal pain, alcoholism, trauma, hyperparathyroidism or drug intake. All patients had jaundice at presentation, mild hepatomegaly and epigastric tenderness. Three patients also had features of ileus.

On investigation, mean bilirubin was 16.4 mg/dL (range 5.8-32.4 mg/dL), mean AST 519 (range 182-1313) U/L and mean ALT 1371.1 (range 702-2438) U/L. Amylase and lipase ranged from 275-596 (mean 364.6) U/L and 520-7258 (mean 2495.4) U/L respectively. Serum lipid profile and calcium levels were normal in all patients. IgM anti-HEV, IgM anti-HAV, IgM anti-HBc were positive in 4, 2 and 1 patient respectively. US could detect pancreatitis in three patients, minimal ascites and biliary sludge in one patient. An abdominal CECT showed edematous and enlarged pancreas in all patients. There was no evidence of necrosis. The patient with sludge showed complete resolution in 2 wk. None of the other patients had evidence of biliary sludge during follow-up. The pancreatitis and hepatitis responded to conservative treatment in all patients. All patients are asymptomatic after a mean follow-up of 12 (range 8-24) mo.

DISCUSSION

Most cases of acute pancreatitis due to hepatitis viruses had been reported in association with acute liver failure (ALF). In the autopsy series of Ham and Fitzpatrick, 14 of the 42 (33%) patients with ALF had acute pancreatitis[8], the majority being of viral etiology. Similar findings had been reported by Parbhoo *et al*[9] in 21 out of 59 patients (36%) with ALF who had acute pancreatitis. Autopsy findings of pancreatitis in seven of 16 (44%) patients with fulminant viral hepatitis, versus two of 33 (6%) patients with fulminant hepatic failure secondary to halothane, support the role of viral infection rather than liver failure per se in causing pancreatitis[21].

There are only a few case reports of symptomatic pancreatitis occurring in the setting of acute viral hepatitis[10]. Most of the patients reported had presented with symptomatic pancreatitis in the early phase of the hepatitic illness[11-20] whereas Mishra *et al*[10] reported 6 patients at wk 2 or 3 after the onset of jaundice. Our series had five patients presenting in the first week and two in the fourth week after the onset of jaundice. One patient had biliary sludge and presented in the first week of jaundice. Ultrasound was done weekly in all the patients until clinical and biochemical resolution. Gallbladder wall thickness

Table 2 Clinical Profile of viral hepatitis patients with acute pancreatitis

	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6	Case 7
Age (yr)	11	30	32	21	30	20	23

Corrected Serum calcium (mg/dL)	9.2	9.1	9	8.9	9.2	9.3	8.1
Serum triglyceride (mg/dL)	140	168	131	165	141	160	154
Ultrasonography (Gallbladder)	Normal	Normal	Normal	Normal	Normal	Normal	Biliary sludge

(more than 3 mm) was found in 96.8% of patients, which is in agreement with a previous study by Sharma *et al*[22]. None of the two patients who presented later had any evidence of biliary sludge on US.

The etiology of pancreatitis was considered to be due to a hepatitis virus in all patients, as there was no evidence of gallstones, sludge, alcohol, drugs, trauma or metabolic causes. The remaining patient had biliary sludge on US. The disappearance of biliary sludge at 2 wk occurred a week later than previously reported[23]. None of the 7 patients with biliary sludge had an episode of acute pancreatitis and gallbladder contraction was similar in the hepatitis and control group in the Portincasa *et al*[23] group. So, the patient might had HEV-associated pancreatitis and had biliary sludge during the acute phase of the viral illness which resolved on follow-up ultrasound abdomen. Basaranoglu *et al*[24] reported a case of gallbladder sludge and acute pancreatitis induced by acute hepatitis A.

Acute pancreatitis in nonfulminant acute viral hepatitis covers the full range of clinical severity. Subclinical pancreatic involvement in viral hepatitis may occur more commonly than is appreciated[25]. The pancreatitis was mild as reported previously[10,13-20]. One of our patients had minimal ascites which resolved in 2 wk. There were no local or systemic complications and all had uneventful recovery from both pancreatitis and hepatitis. No relation was found between the level of amylase and severity of pancreatitis.

The frequency of acute pancreatitis in acute viral hepatitis in the present series is 5.65%, which is 2% higher than reported by Joshi *et al*[26] in their autopsy series of 108 cases. Joske *et al*[27] noted 8 cases of acute viral hepatitis out of 90 patients of acute pancreatitis.

The mechanism of pancreatitis in patients with acute viral hepatitis (nonfulminant) is unknown, and it may be multifactorial. One proposed pathogenesis of pancreatitis associated with hepatitis is the development of edema of the ampulla of Vater with obstruction to the outflow of pancreatic fluid[28]. There is no direct evidence for the routes by which hepatitis viruses reach the pancreas; however, the proposed routes are most likely blood or bile[14].

A more plausible mechanism for viral associated acute pancreatitis is direct inflammation and destruction of pancreatic acinar cell by the virus. This latter theory is supported by the autopsy finding of hepatitis B virus antigens within the cytoplasm of pancreatic acinar cells of patients with hepatitis B surface antigenemia[1,2]. It is possible that the severity of pancreatitis is related to the magnitude of exposure of pancreatic acinar cells to the hepatitis virus[2].

The hepatitis viruses might injure the pancreatic acinar cell membrane, resulting in the leakage of intracellular enzymes, and/or precipitate a network of intracellular events culminating in cell death by a mechanism analogous to hepatocyte necrosis[29]. Another mechanism can be the release and circulation of lysosomal enzymes from the inflamed liver with the activation of trypsinogen to trypsin.

When acute pancreatitis is associated with fulminant hepatitis, the virus may cause tissue damage directly, but there are several other factors which can play an important role in the development of pancreatitis (clinical or silent) and these include acute liver failure, hypotension, infections and drug induced damage[13]. Intrapancreatic

hemorrhage due to hypoprothrombinemia or disseminated intravascular coagulation may result in pancreatic damage and subsequent pancreatitis[8].

In conclusion, acute pancreatitis is not uncommon. In a patient with acute viral hepatitis and acute or disproportionate abdominal pain, acute pancreatitis should be kept as a possibility. Conservative treatment leads to recovery in all the patients.

COMMENTS

Background

The association of hepatitis viruses with acute pancreatitis in the setting of acute (nonfulminant) viral hepatitis is rare. The frequency and characteristics of pancreatic involvement in the course of acute viral hepatitis needs to be elucidated.

Research frontiers

Studies with larger number of patients of acute viral hepatitis with pain abdomen are necessary to determine the frequency and characteristics of pancreatitis as there are only case reports and one case series of six patients.

Innovations and breakthrough

Recent reports describe acute pancreatitis as a cause of acute or dispropionate abdominal pain complicating acute viral hepatitis.

Applications

Patients of acute viral hepatitis with severe pain abdomen should undergo serum amylase, lipase and ultrasonography or contrast-enhanced computed tomography of the abdomen to prove acute pancreatitis as a cause of abdominal pain. The prognosis of patients with acute pancreatitis in the setting of acute viral hepatitis is good and patients recover on conservative treatment.

Terminology

Acute viral hepatitis is defined as presence of prodromal symptoms, deep jaundice, markedly raised transaminases, presence of markers of hepatitis B (positive for HBsAg, IgM anti-HBc, HBeAg, but negative for anti-HBe), hepatitis A (IgM anti-HAV), hepatitis C (anti-HCV), hepatitis E (IgM-anti-HEV) viruses in serum and ultrasound abdomen showing thick walled gallbladder and hypoechoic liver . Patients with other causes of acute hepatitis, chronic liver disease, history of alcohol intake and fulminant hepatic failure were excluded from the study. The diagnosis of acute pancreatitis was based on pancreatic type abdominal pain, raised amylase and lipase levels to three times upper limit of the normal and ultrasound (US) or contrast enhanced computed tomography (CECT) of the abdomen suggestive of acute pancreatitis.

Peer review

This article describes the clinical findings of acute pancreatitis in acute viral hepatitis. The main content of the manuscript is good.

Abstract

AIM: To evaluate the impact of a preoperative "triple non-invasive diagnostic test" for diagnosis and/or exclusion of common bile duct stones.

METHODS: All patients with symptomatic gallstone disease, operated on by laparoscopic cholecystectomy from March 2004 to March 2006 were studied retrospectively. Two hundred patients were included and reviewed by using a triple diagnostic test including: patient's medical history, routine liver function tests and routine ultrasonography. All patients were followed up 2-24 mo after surgery to evaluate the impact of triple diagnostic test.

RESULTS: Twenty-five patients were identified to have common bile duct stones. Lack of history of stones, negative laboratory tests and normal ultrasonography alone was proven to exclude common bile duct stones in some patients. However, a combination of these three components (triple diagnostic), was proven to be the most statistically significant test to exclude common bile duct stones in patients with gallstone disease.

CONCLUSION: Using a combination of routinely used diagnostic components as triple diagnostic modality would increase the diagnostic accuracy of common bile duct stones preoperatively. This triple non-invasive test is recommended for excluding common bile duct stones and to identify patients in need for other investigations.

Key words: Common bile duct stones; Laparoscopic cholecystectomy; Triple non-invasive diagnostic test

INTRODUCTION

Surgery is the treatment of choice in symptomatic gallstone disease and is also recommended in asymptomatic patients due to complications followed by stone release in common bile duct[1-5]. Coexisting common bile duct stones (CBDS) occur in 7%-20% of all patients undergoing cholecystectomy[2,3,6]. Although intraoperative cholangiography was routinely performed to diagnose CBDS during pre-laparoscopic era, its use in the laparoscopic era has been debated[7-10]. Consequently, other techniques for diagnosing CBDS have been introduced[6-8].

Preoperative liver function test (LFT) results might be diagnostic for CBDS, if abnormal. However, some patients might have normal LFT despite coexisting CBDS[5,7]. Ultrasonography is the major diagnostic modality to diagnose gallstones, but is less helpful for diagnosing CBDS[1-7]. Computed tomography is rarely useful for diagnosing gallstones[5,8]. Magnetic-resonance-cholangio-pancreatography (MRCP) has high specificity and sensitivity and accuracy similar to that of Endoscopic-Retrograde-Cholangio-Pancreatography (ERCP), but its accuracy decreases if gallstones are small (< 4 mm) or if they are located near Vater's papilla[2,5,8,11]. In addition, MRCP is not widely available and unlike ERCP does not allow endoscopic extraction of stones[5,8,12]. ERCP is the most common technique used for both diagnostic and treatment of CBDS. It is however, expensive, invasive, technically demanding and associated with small but significant morbidity[6,7,13].

Clinical history of jaundice, pancreatitis or cholangitis, abnormal LFT results and or dilated common bile duct have been traditionally used to select possible candidates for ERCP preoperatively[5], but to the best of our knowledge, the accuracy of these parameters together in diagnosing and/or excluding CBDS has never been evaluated[5,6,8]. The aim of this retrospective study was to assess the accuracy of these variables alone and in combination for diagnosing/excluding CBDS in a consecutive group of patients with symptomatic gallstones disease operated on by laparoscopic cholecystectomy.

MATERIALS AND METHODS

From March 2004 to March 2006, all consecutive patients with ultrasound verified gallstones, in whom laparoscopic cholecystectomy was indicated, were studied retrospectively. The study was approved by the Afzali Hospital's ethical committee.

All information was collected based on a questionnaire including three different components. Patient's data and medical history, age at operation, gender, history of jaundice (obstructive *vs* non-obstructive), cholangitis or pancreatitis (acute *vs* non-acute) were recorded. The results of ultrasonography, preoperative liver functions tests (LFT), serum-total bilirubin (S-Bil), alkaline phosphatase (S-ALP) and white blood cells counts (WBC) were obtained. The following cut-off values were considered abnormal: S-Bil $\geqslant$ 1.5 dL/L, S-ALP $\geqslant$ 400 Ul/L and WBC $\geqslant$ 10 000/mm^3. CBDS diagnosis was established by either demonstrating a stone in CBD or a wide CBD (diameter $\geqslant$ 10 mm). All patients were operated laparoscopically. No intraoperative cholangiography was performed. All included patients (n = 200) were followed up 2-24 mo postoperatively, by means of a questionnaire, completed by telephone interviews or clinical visit if needed.

Statistical analysis

The statistical analysis was performed using SPSS (version 11.0). The association between occurrence of CBDS and different variables was analyzed using Chi-square test. Sensitivity, specificity, positive and negative predictive values were calculated for all variables individually and in combination. Student t-test with separate variance estimates was performed to test the demographic differences. Fisher exact test and χ^2-test were performed to compare between patients with a different number of suggested variables. $P < 0.05$ was considered statistically significant. Any patient with incomplete medical file or test results or any unclear information was excluded.

RESULTS

Two hundred patients, 43 men (21.5%) and 157 women (78.5%) were consecutively included in this study. The mean age of patients at the time of operation was 56.6 $\pm$ 18.2 and 51.6 $\pm$ 16.5 years for men and women, respectively. The average length of hospital stay was 30 (range 24-72) h for the whole group of patients, with no statistically significant difference between men and women.

Eighteen patients (9%) were found to have CBDS intraoperatively and additional 7 patients were found to have CBDS during the follow-up. The total number of patients with CBDS in this series was 25 patients (12.5%). The review of patient's clinical history did not reveal any clinical evidence for CBDS (jaundice, cholangitis or pancreatitis) in the majority of patients (89.5%). In the remaining patients (10.5%), besides cholangitis, all other clinical variables were more common in men. In 16 out of 25 patients with CBDS (8 women and 8 men), obstructive jaundice was the most frequent variable in both genders (Table 1). The association between clinical evidence for CBDS and occurrence of CBDS was calculated (Table 2). Thirteen patients had one positive clinical variable and 8 patients had two positive clinical variables. Higher number of positive clinical variables was not statistically significant for diagnosing CBDS. CBDS was more common in men with clinical evidence of the disease. The difference between men and women in this aspect was statistically significant (Chi-square: 6.56, df: 2, $P < 0.05$) (Table 2).

Table 1 Frequency of clinical variables in 200 patients with gallstones n (%)

Variables	Total	Women	Men
Obstructive jaundice			
Yes	16 (8)	8 (5.1)	8 (18.6)
No	183 (92)	148 (94.9)	35 (81.4)
Total	199 (100)	156 (100)	43 (100)
History of jaundice			
Yes	5 (2.5)	3 (1.9)	2 (4.7)
No	192 (97.5)	151 (98.1)	41 (95.3)
Total	197 (100)	154 (100)	43 (100)
Cholangitis			
Yes	5 (2.5)	5 (3.2)	0
No	192 (97.5)	149 (96.8)	43 (100)
Total	197 (100)	154 (100)	43 (100)
Acute Pancreatitis			
Yes	1 (0.5)	0	1 (2.3)
No	196 (99.5)	154 (100)	42 (97.7)
Total	197 (100)	154 (100)	43 (100)
History of Pancreatitis			
Yes	2(1)	1 (0.6)	1 (2.3)
No	195(99)	153 (99.4)	42 (97.7)
Total	197(100)	154 (100)	43 (100)

Table 2 Association between the number of positive clinical variables and CBDS n (%)

Patients	Negative history	1 positive findings	2 positive findings	Total
Men	34 (79.1)	6 (14)	3 (7)	43 (100)
Women	145 (92.4)	7 (4.5)	5 (3.2)	157 (100)
Total	179 (89.5)	13 (6.5)	8 (4)	200 (100)

The majority of patients in this cohort had a normal ultrasonography (n = 175, 87.3%). However, in 25 patients with CBDS (12 women and 13 men), 8 patients had a stone in common bile duct, 12 had obstruction in common bile duct, one had both a stone and obstruction of common bile duct, 3 had a widened common bile duct (> 10 mm), and finally one patient had widening of an intrahepatic bile branch. Positive ultrasonographic findings indicating CBDS were more common in men [13 out of 43 men (30%) and 12 out of 157 women (7%)] (Table 3). The difference in ultrasonographic diagnosis between men and women was statistically significant (Chi-square 20.23, df: 5 and $P < 0.05$).

The abnormal S-Bil and S-ALP results in men and women with CBDS are shown in Table 4. The majority of patients had normal laboratory results (> 85%). In 13 men (30.2%) serum bilirubin concentration was higher than 1.5 dL/L [compared to 11 women (7%)] and in 14 men (32.6%) the concentration of alkaline phosphatase was higher than 400 Ul/L [compared to 16 women (10%)]. All

Total	43 (100)	157 (100)	200 (100)

CBD: Common bile duct; CBDS: Common bile duct stones.

Table 4 Results of liver tests in patients with gallstones (per gender) *n* (%)

Gender	S-bilirubin ⩾ 1.5 dL/L			Alkaline phosphatase ⩾ 400 UL/L		
	Yes	No	Total	Yes	No	Total
Men	13 (30.2)	30 (69.8)	43 (100)	14 (32.6)	29 (67.4)	43 (100)
Women	11 (7)	146 (93)	157 (100)	16 (10.2)	141 (89.8)	157 (100)
Total	24 (12)	176 (88)	200 (100)	30 (15)	170 (85)	200 (100)

patients with S-Bil ⩾ 1.5 dL/L had CBDS. These changes were more common in men and the difference between men and women was statistically significant (Chi-square 17.24, df: 1 and $P < 0.05$).

The sensitivity, specificity, negative predictive value (NPV) and positive predictive value (PPV) of each variable of medical history, LFT results and ultrasonography alone or in different combination for diagnosis/exclusion of CBDS was evaluated statistically (Table 5). As a single diagnostic test, ultrasonography had higher sensitivity (64%), specificity (97.1%), negative and positive predictive values (95% and 76.2%, respectively) than medical history, S-Bil and S-ALP. As a triple diagnostic modality, a combination of medical history, ultrasonographic findings and LFT results was proven to be the best diagnostic modality to exclude CBDS. White blood cells count had no impact in diagnosis of CBDS.

DISCUSSION

Although the majority of patients with gallstone disease have an uncomplicated surgical course, a few may become complicated due to occurrence of CBDS[1-3]. Due to fewer intraoperative cholangiographies during laparoscopic cholecystectomies[6,7], ERCP has been recommended for pre- or postoperative extraction of CBDS. It is however, an invasive investigation with high risk for complications and should be reserved for selected cases[12,14,15]. MRCP is not available in all institutions and its accuracy depends on the size and position of CBDS[4,11,12]. There is thus a need for easy-performing, non-invasive, and reliable test modalities to diagnose or exclude CBDS, by which selected patients can benefit from ERCP, MRCP or other expensive investigations[13-15]. Earlier studies on some clinical, laboratory or radiological variables have been performed[16,17]. There is however, as far as we know, no study performed evaluating a combination of these investigating modalities. The majority of patients with gallstones are routinely evaluated by their clinical history, ultrasonography and LFT (S-Bil and S-ALP)[3,5]. The main object of this study was to evaluate the efficacy of these non-invasive investigation methods for exclusion of CBDS diagnosis.

Table 5 Diagnostic value of each of the triple tests, alone and in combination *n* (%)

Variables	Sensitivity	Specificity	NPV	PPV
1. Medical history	44	92.5	90.5	38.1
2. Ultrasound	64	97.1	95	76.2
3. Alkaline phosphatase ⩾ 400 Ul/L	32	95	90	26.7
4. Serum bilirubin ⩾ 1.5 dL/L	30.3	76.2	89.2	25
2 + 3 + 4	80	82.9	96.7	40
2 + 3 or 2 + 4	32	97.1	90.9	61.5
2 + 1+ 3 or 4	84	81.7	97.3	39.6

NPV: Negative predictive value; PPV: Positive predictive value.

The importance of careful review of patient's history has been reported in many earlier studies. A focused positive patient's history may be an early indication of CBDS[3,6,16-18]. Hyperbilirubinemia preoperatively, had a high diagnostic significant in our study and is also reported by others[7,19]. Ultrasonographic investigation is a reliable diagnostic modality with high availability and lower cost. However, the result of the investigation depends highly on investigators experience[3,14,20]. In our study, ultrasonography was performed by one radiologist and our results are comparable with earlier reports[3,6]. As also earlier reported by others, our study indicates that in patients who lacked clinical, radiological and laboratory signs of CBDS, there is no need for performing ERCP[6,14,21-25]. It also indicates that by using patient's complete medical history (with special focus on the most common clinical complication of gallstone diseases such as pancreatitis), customary laboratory tests such as S-Bil and S-ALP and ultrasonography one may exclude CBDS diagnosis with high accuracy[26-29].

We used different variables as predictors *i.e.,* these variables were used to predict or explain the value(s) of one or more dependent variables (also referred to as dependent or outcome variables statistically). The positive predictive value (PPV), or precision rate, is defined as the proportion of patients with positive test results who are correctly diagnosed. Hence the PPV is used to indicate the probability that, in case of a positive test, the patient really has the specified disease. However there may be more than one cause for a disease and any single potential cause may not always result in the overt disease seen in a patient. In our study only ultrasonographic investigation has highest PPV followed by a combination of ultrasound investigation and LFT results. Since we were interested in evaluating the impact and usefulness of the negative ultrasonography or LFT results and the lack of clinical evidence (negative history of pancreatitis, cholecystitis and cholangitis) of CBDS, in our study, we used the negative predictive value (NPV), which is the proportion of patients with negative test results who are correctly

diagnosed. Higher NPV means then higher sensitivity for excluding CBDS as shown in our study; combining several tests in our study increased the negative predictive value and sensitivity of CBDS exclusion with almost equal specificity[16-18,30].

We concluded that patients with normal ultrasonography, LFT results and no clinical evidence of CBDS "negative triple test" (NPV of 97.3%) may undergo laparoscopic surgery without any need for preoperative MRCP or ERCP. The availability and non-invasiveness of this triple diagnostic test are additional benefits, which makes it more interesting.

COMMENTS

Background

Coexisting common bile duct stones (CBDS) may complicate the course of gallstone disease. During open surgical removal of gallstones (open cholecystectomy), cholangiography is performed to exclude, or if needed, to remove CBDS. With laparoscopic cholecystectomy becoming the first surgical choice for treatment of gallstones, preoperative cholangiography has not been performed routinely and the procedure itself has been debated. Consequently, other techniques have been used to exclude CBDS. These techniques, however, are either invasive, with consequent risk for complications, or only diagnostic; some of them not available at all hospitals. There is thus a need to establish a simple, non-invasive and cheap diagnostic method, available at all units, to identify patients with CBDS for further evaluation with invasive and more expensive techniques.

Research frontiers

The research front in this area is focused on developing different imaging techniques. The most promising technique is Magnetic-Resonance-Cholangio-Pancreatography (MRCP). It has high specificity and sensitivity and accuracy similar to that of ERCP (Endoscopic-Retrograde-Cholangio-Pancreatography), but its accuracy decreases if gallstones are small (< 4 mm) or if they are located near Vater's papilla. In addition MRCP is not widely available and unlike ERCP does not allow endoscopic extraction of stones. ERCP is the most common technique used for both diagnostic and treatment of CBDS. It is however, expensive, invasive, technically demanding and associated with small but significant morbidity.

Innovations and breakthroughs

By using already existed parameters; liver functions test, ultrasonography together with complete review of patient's medical history (triple diagnostic), we offer a simple, cheap and, for all clinicians, available triple technique, to diagnose or exclude CBDS without any extra cost or diagnostic delay.

Applications

The majority of patients without CBDS will be identified by this triple diagnostic technique, leaving the remaining few, to be investigated by MRCP or ERCP. The availability and non-invasiveness of this test are additional benefits, which makes it more interesting.

Terminology

Cholangiography: X-ray examination of the bile ducts following administration of a radiopaque contrast medium. Magnetic-Resonance-Cholangio-Pancreatography: is a medical imaging technique which uses magnetic resonance imaging to visualise the biliary and pancreatic ducts in a non-invasive manner. Endoscopic-Retrograde-Cholangio-Pancreatography: refers to the use of an endoscope; a thin, flexible tube with a tiny video camera and light on the end to diagnose and treat various problems of the GI tract (stomach, intestine, liver, pancreas, and gallbladder).

Peer review

Through retrospective study, the authors concluded that using a combination of routinely used diagnostic components as triple diagnostic modality would increase the diagnostic accuracy of common bile duct stones. The result is reasonable and persuasive.

Abstract

AIM: To analyze the relationship between plasma and platelet serotonin levels and the degree of liver insufficiency.

METHODS: The prospective study included 30 patients with liver cirrhosis and 30 healthy controls. The degree of liver failure was assessed according to the Child-Pugh classification. Platelet and platelet poor plasma serotonin levels were determined.

RESULTS: The mean plasma serotonin level was higher in liver cirrhosis patients than in healthy subjects (215.0 ± 26.1 *vs* 63.1 ± 18.1 nmol/L; $P < 0.0001$). The mean platelet serotonin content was not significantly different in patients with liver cirrhosis compared with healthy individuals (4.8 ± 0.6; 4.2 ± 0.3 nmol/platelet; $P > 0.05$). Plasma serotonin levels were significantly higher in Child-Pugh grade A/B than in grade C patients (246.8 ± 35.0 *vs* 132.3 ± 30.7 nmol/L; $P < 0.05$). However, platelet serotonin content was not significantly different between Child-Pugh grade C and grade A/B (4.6 ± 0.7 *vs* 5.2 ± 0.8 nmol/platelet; $P > 0.05$).

CONCLUSION: Plasma serotonin levels are significantly higher in patients with cirrhosis than in the controls and represent the degree of liver insufficiency. In addition, platelet poor plasma serotonin estimation is a better marker for liver insufficiency than platelet serotonin content.

INTRODUCTION

The serotonergic system plays a critical role in a wide variety of physiological and behavioral processes. In the circulation, serotonin synthesized by the intestinal enterochromaffin cells, is actively incorporated into platelets and stored in platelet dense-storage granules. Nearly all of the serotonin in circulating blood is concentrated in the platelets and minimally in plasma (which is the interactive pool). The integral membrane protein of mucosal epithelial cells is the major protagonist in regulating the extracellular serotonin concentration[1]. Serotonin is mostly metabolized into 5-hydroxyindoleacetic acid by monoamine oxidase in hepatic and lung endothelial cells[2]. The effects of serotonin are most prominent in the cardiovascular system, with additional effects in the respiratory system and the intestines. Vasoconstriction is a classic response to administration of serotonin. However, serotonin induces smooth muscle cell contraction and proliferation and stimulates endothelial cells to release vasodilating substances and acts as "helper agonist" of platelet aggregation in humans[3,4]. Altered concentrations of circulating serotonin have been implicated in several pathologic conditions including hypertension, primary pulmonary hypertension, liver cirrhosis, and psychiatric disorders[5-8].

The acute and chronic hepatic insufficiency gives rise to serotonin system changes, contributing to the development of hepatic encephalopathy, portal hypertension, and hyperdynamic circulation[9]. Hepatic encephalopathy is followed by changes of serotonin neurotransmission, including the catabolic enzymes, receptors, and metabolites[10]. After application of serotonin inhibitors (ketanserin and ritanserin), portal pressure is decreased in patients with liver cirrhosis, confirming the importance of serotonin in the pathogenesis of portal hypertension[11]. The aim of this study was to characterize the relationship between plasma and platelet serotonin levels and the degree of liver insufficiency.

MATERIALS AND METHODS

Subjects

In the period January-April, 2007, the prospective study included 30 patients with liver cirrhosis and 30 healthy controls, examined at the Institute of Digestive

Diseases, Clinical Center of Serbia, Belgrade. Hepatologic examinations were based on medical history, physical examination, laboratory tests, and liver biopsy. Laboratory tests included hepatocyte integrity, cholestasis, synthetic liver function, and specific (etiological) tests. Puncture liver biopsy was performed in 16 (53.3%) patients, using Menghini needle of 1.4 mm. The degree of liver failure was assessed according to the Child-Pugh classification.

Biochemistry

Platelet and platelet poor plasma (PPP) venous blood was collected in 3 mL original Vacutainer "BD" tubes with 75 g/L K_3EDTA 0.072 mL. Blood samples were taken between 8 and 9 am. Platelet number was immediately determined on "Coulter A^c T Diff" analyser. Platelet rich plasma (PRP) was obtained by low speed centrifugation (200 g, 10 min) on "Heraeus Digifuga GL". Platelet count was determined again and taken into consideration in final determination of serotonin concentration in platelets. Exactly 1 mL of PRP was centrifuged on 1000 × g for 10 min. The obtained PPP was separated, and together with platelet pellets, stored at -20℃, not longer then 20 d[12]. The whole number of platelet pellets and PPP serotonin samples were estimated in one series.

Platelet pellets were spiked with 10 μL N-methyl serotonin solution (Recipe, Munchen) as an internal standard. All pellets were diluted with 100 μL high performance liquid chromatography (HPLC) ultra pure water (Recipe, Munchen). Platelets were destroyed with 100 μL of 700 g/L perchloric acid (Merck Darmstad) and centrifuged at 10 000 × g for 5 min. 100 μL of PPP samples was deproteinized with 100 μL deproteinating reagent (Recipe, Munchen) and centrifuged in same way, as for platelets[13].

Twenty μL of the supernatants were analyzed by reverse phase HPLC (Recipe, Munchen) with original mobile phase for serotonin (Recipe, Munchen). Original, "Recipe" external standard solution has been used for calibration. The HPLC system consisted of "Bio-Rad AS 100" HRLC automatic sampling system with " Rheodine 7125 valve", "Bio-Rad 1350" HPLC pump, and "Bio-Rad 1640" electrochemical detection. Chromatographic data were calculated using the "Chrome Line V 4.20" HPLC software. Amperometric detection has been done on 0.6 V. Duration of chromatographic separation was 10 min.

Statistical analysis

Statistical analyses were performed using SPSS statistical software (SPSS for windows, release 10.0, SPSS, Chicago, Il). Descriptive statistics are presented as mean ± SE. Differences between groups were compared with parametric *t*-test because data had a Gaussian distribution. Because we performed 6 consecutive statistical analyses, we chose a level of significance 0.05/6 = 0.008 (α-adjustment according to the modified Bonferroni procedure).

RESULTS

The most common cause of liver cirrhosis was alcohol in 12 individuals (40.0%). The incidence of cirrhosis due to viral infection was lower with HCV in 6 (20.0%) and HBV in 5 subjects (16.6%); autoimmune diseases were quite rare with 3 cases (10.0%), while etiology was unknown in 4 (13.3%) cases. The patients were classified according to the Child-Pugh system. Child-Pugh class A included 12 (40%) patients, Child-Pugh class B 8 (26.6%), and Child-Pugh class C 10 (33.3%) patients. All patients had clinically evident portal hypertension, none of them had episodes of bacterial peritonitis, and none of them had a beta blocker medication.

The mean plasma free serotonin levels were much higher in liver cirrhosis patients than in healthy individuals. A statistical significant difference was found between serotonin plasma values in patients with liver cirrhosis and healthy subjects (215.0 ± 26.1 *vs* 63.1 ± 18.1 nmol/L; t = 3.868, $P < 0.0001$).

The mean platelet serotonin content was not significantly different in patients with liver cirrhosis compared to healthy individuals. There was no statistically significant difference between platelet serotonin content in patients with liver cirrhosis and healthy subjects (4.8 ± 0.6 *vs* 4.2 ± 0.3 nmol/platelets; t = 0.881, $P > 0.05$).

Plasma free serotonin levels were significantly higher in Child-Pugh grade A/B than in grade C patients (246.8 ± 35.0 *vs* 132.3 ± 30.7 nmol/L; t = 1.938, $P < 0.05$). However, platelet serotonin content was not significantly different between Child-Pugh grade C and grade A/B (4.6 ± 0.7 *vs* 5.2 ± 0.8 nmol/platelets; t = 0.48, $P > 0.05$).

In addition, plasma free serotonin levels were not significantly different between alcohol liver cirrhosis and cirrhosis of other etiology (143.9 ± 29.3 *vs* 224.84 ± 34.8 nmol/L; t = 1.6, $P > 0.05$). Also, platelet serotonin content was not significantly different between alcohol liver cirrhosis and cirrhosis of other etiology (4.2 ± 0.7 *vs* 5.3 ± 0.9 nmol/10^9 platelets; t = 0.91; $P > 0.05$).

DISCUSSION

Marasini *et al*[7] described a significant reduction of serotonin, determined by high-performance liquid chromatography, in platelets of 14 patients with liver cirrhosis, although levels of free circulating plasma serotonin were within the normal range. In the study of Beaudry *et al*[14], the whole-blood serotonin levels were significantly lower in 30 patients with cirrhosis than in age-matched controls, and no correlation was found between these levels and the severity of cirrhosis. This difference might be the result of low platelet count observed in patients with cirrhosis; however, in this series of patients, the significant difference persisted when the whole-blood serotonin levels were expressed by platelet count, but it was less expressed. Thus, in patients with cirrhosis, low whole-blood serotonin levels probably depend on reduction of both uptake, retention of serotonin by platelets, and low platelet number.

However, in the same study of Beaudry *et al*[14], unconjugated plasma serotonin levels, an indication of the active form of serotonin, were significantly higher in patients with cirrhosis than in the controls, and in patients with cirrhosis these levels were higher in Child-Pugh grade A than in grade C patients. In our study, we investigated levels of free or unconjugated serotonin. However, the levels of free serotonin in patients with liver cirrhosis were

also higher than in healthy subjects. Also, the levels of free serotonin in patients with Child-Pugh grade C is less than in grade A/B patients. In addition, platelet serotonin content was not significantly different when patients with liver cirrhosis were compared to healthy subjects.

The discrepancy of our and Beadry's study may be explained by the fact that whole blood is a similar, but not the same kind of biological material, as the platelet pellet is. In addition, we used HPLC as basic technique in our work, which significantly differs from Beadry's study, who also emphasized this difference in his study. The reasons for high levels of plasma serotonin in the liver cirrhosis could be slow uptake and storage of serotonin by the platelets (as could be the sequelae of the kinetic change of serotonin transport mechanisms) or abnormal serotonin release from dense granules of activated platelets.

Laffi *et al*[15] gave the evidence for significant reduction of substances that are deposited in thick (adenosine triphosphate and serotonin) and in alpha granules (B-thromboglobulin and platelet factor 4) in patients with liver cirrhosis in comparison to controls. It is supposed that platelet disorder in deposition of substances mentioned above, in patients with liver cirrhosis, is in relation to platelet activation, a condition defined as "platelet exhaustion".

The causes of platelet activation in liver cirrhosis are complex and not yet fully understood. Hyperdynamic portal circulation and retention in the spleen microcirculation in liver cirrhosis might stimulate platelets. Immunological and inflammatory phenomena in the liver tissue and its influence are other possible reasons for platelet activation. In addition, endotoxemia is often associated with severe liver cirrhosis and it causes platelet activation[16]. In liver cirrhosis, thrombocytopenia is associated with a shorter life span of platelets and is the result of constant platelet activation by cytokines (IL2, IL6, TNFα), it is mediated by subclinical DIC, and intensified elimination by reticuloendothelial system of the spleen and liver[17]. Platelet activation with the increase of both βTG serum concentration and elevation of platelet population (CD62P and CD63 as well as medial intensity of fluorescence CD62P and CD63) becomes higher as liver cirrhosis develops and thrombocytopenia rises. Concurrently with thrombocytopenia in liver cirrhosis, platelet CD63+ population increases, clearly indicating the platelet activation with elevated medial intensity of fluorescence CD62P and CD63[18].

Concentration of circulating serotonin in liver cirrhosis can be influenced by other factors, such as altered serotonin catabolism due to an elevated activity of monoamino oxidase and impaired metabolism of tryptophan, as serotonin precursor[19]. Impaired metabolic function in liver cirrhosis contributes to elevated plasma serotonin. Moreover, vasoactive substances, produced in the splanchnic circulation, bypass the liver in the presence of porto-systemic collaterals and directly enter the systemic circulation. In conclusion, plasma serotonin levels are significantly higher in patients with cirrhosis than in the controls, and represent the degree of liver insufficiency. In addition, PPP serotonin estimation is a better marker of liver insufficiency than platelet serotonin content.

COMMENTS

Background

The acute and chronic hepatic insufficiency gives rise to serotonin system changes, contributing to the development of hepatic encephalopathy, portal hypertension, and hyperdynamic circulation. In patients with liver cirrhosis, low whole-blood serotonin levels depend probably on reduced uptake, retention of serotonin by platelets, and low platelet number. It is supposed that reduced platelet deposition of substances in thick and alfa granules, is in relation to platelet activation, caused by hyperdynamic circulation and endotoxemia. Also, concentration of circulating serotonin in liver cirrhosis can be influenced by other factors, such as altered serotonin catabolism due to elevated activity of monoamino oxidase and impaired metabolism of tryptophan, as a precursor of serotonin.

Research frontiers

The serotonergic system plays a critical role in a wide variety of physiological and behavioral processes. Altered concentrations of circulating serotonin are implicated in several pathologic conditions including hypertension, primary pulmonary hypertension, liver cirrhosis, and psychiatric disorders. The highlight of our research was to characterize the relationship between plasma and platelet serotonin levels and the degree of liver insufficiency.

Innovations and breakthroughs

In Beadry's study, unconjugated plasma serotonin level, an active form of serotonin, was significantly higher in patients with cirrhosis than in the controls, and in cirrhotics this level was higher in Child A than in Child C patients. In our study, the levels of free serotonin in patients with liver cirrhosis were also higher than in healthy subjects. However, the levels of free serotonin in patients with Child C cirrhosis were less compared to Child A/B patients. Furthermore, platelet serotonin content was not significantly different in cirrhotics compared to healthy controls. The discrepancy of our and previous study could be explained by the fact that we used high performance liquid chromatography as basic technique in our work, which significantly differs from the technique used in the previous study.

Applications

The results in the study suggest that plasma serotonin levels may represent the degree of liver insufficiency. Also, platelet poor plasma serotonin estimation is a better marker for liver insufficiency than platelet serotonin content.

Terminology

Serotonin: Serotonin is a vasoactive substance, synthesized by the intestinal enterochromaffin cells, which is actively incorporated into platelets and stored in platelet dense-storage granules. Integral membrane protein of mucosal epithelial cells is the major protagonist in regulating the extracellular serotonin concentration. Serotonin is mostly metabolized into 5-hydroxyindoleacetic acid by monoamine oxidase in hepatic and lung endothelial cells.

Peer review

This is a case controlled study demonstrating that plasma but not platelet serotonin levels are increased in patients with liver cirrhosis and correlate with liver insufficiency. The subject is novel and interesting.

Abstract

AIM: To investigate the clinical value of T-staging system in the preoperative assessment of hilar cholangiocarcinoma.

METHODS: From March 1993 to January 2006, 85 patients who had cholangiocarcinoma diagnosed by operative tissue-biopsy were placed into one of three stages based on the new T-staging system, and it was evaluated the resectability and survival correlated with T-staging.

RESULTS: The likelihood of resection and achieving tumor-free margin decreased progressively with increasing T stage ($P < 0.05$). The cumulative 1-year survival rates of T1, T2 and T3 patients were 71.8%, 50.8% and 12.9% respectively, and the cumulative 3-year survival rate was 34.4%, 18.2% and 0% respectively; the survival of different stage patients differed markedly ($P < 0.001$). Median survival in the hepatic resection group was greater than in the group that did not undergo hepatic resection (28 mo *vs* 18 mo; $P < 0.05$). The overall accuracy for combined MRCP and color Doppler Ultrasonagraphy detecting disease was higher than that of combined using CT and color Doppler Ultrasonagraphy (91.4% *vs* 68%; $P < 0.05$). And it was also higher in detecting port vein involvement (90% *vs* 54.5%; $P < 0.05$).

CONCLUSION: The proposed staging system for hilar cholangiocarcinoma can accurately predict resectability, the likelihood of metastatic disease, and survival. A concomitant partial hepatectomy would help to attain curative resection and the possibility of long-term survival. MRCP/MRA coupled with color Doppler Ultrasonagraphy was necessary for preoperative evaluation of hilar cholangiocarcinoma.

Key words: Hilar cholangiocarcinoma; Preoperative staging; Survival rate; Surgical treatment

INTRODUCTION

Cholangiocarcinoma is an adenocarcinoma that arises from the bile duct epithelium and is the second most common primary hepatobiliary cancer, however, cholangiocarcinoma remains a relatively rare disease, accounting for < 2% of all human malignancies[1-3]. Although the entire biliary tree is potentially at risk, hilar cholangiocarcinoma which involved the biliary confluence or the right or left hepatic ducts are most common and account for 40%-60% of all cases[4]. In most instances, the prognosis of hilar cholangiocarcinoma is very poor, with an overall 5-years survival rate of only 1%[5]. At present, surgical resection of early detected tumors is still the optimal treatment method for hilar cholangiocarcinoma[6,7]. Therefore, precise preoperative imaging evaluation including classification and staging of tumor is crucial for planning treatment and assessing prognosis.

Currently, the modified Bismuth-Corlette system and American Joint Committee on Cancer (AJCC) systems are still commonly used in evaluation of hilar cholangiocarcinoma in China, but both of them are failure to identify patients who are operative candidates or to provide prognostic information[5,8,9]. It is possible that the AJCC or Bismuth-Corlette systems has been misused by a

generation of medical oncologists and surgeons who have used staging systems based on postoperative evaluation of the tumor to guide the preoperative, intraoperative, and even postoperative management[9,10].

In an attempt to improve the preoperative clinical and prognostic usefulness of stag system, the organizational structure of the hepatobiliary program at Memorial Sloan-Kettering Cancer Center (MSKCC) have proposed a new T staging that takes into consideration both vascular involvement by local tumor extension and the presence or absence of liver atrophy (Table 1)[11]. This proposed T staging system is predictive of resectability, of the likelihood of nodal or distant metastases, and of overall survival[11]. In this study, we used the proposed T staging system, based on imaging data, to stratifies 85 patients hilar cholangiocarcinoma into one of three stages and evaluate the resectability or survival correlated with T-staging. We also want to find the correlation between the T staging and nodal or distant metastases. In addition, in our study, biliary resections coupled with in-continuity hepatic resection has been proposed, to attain radical resection.

Table 1 Revised preoperative T staging system for patients with hilar cholangiocarcinoma

T Stage	Description
T1	Tumor involving biliary confluence ± unilateral extension to 2° biliary radicles No liver atrophy or portal vein involvement
T2	Tumor involving biliary confluence ± unilateral extension to 2° biliary radicles with ipsilateral portal vein involvement ± ipsilateral hepatic lobar atrophy No main portal vein involvement
T3	Tumor involving biliary confluence + bilateral extension to 2° biliary radicles; OR unilateral extension to 2° biliary radicles with controlateral portal vein involvement; OR unilateral extension to 2° biliary radicles with controlateral hepatic lobar atrophy; ralateral hepatic lobar atrophy; phy; OR main or bilateral portal venous involvement

MATERIALS AND METHODS

Data selection

Data was collected from a database of Hepatobiliary Surgery of the Second Affiliated Hospital of SUN Yat-sen University From March 1993 through January 2006, 85 patients of hilar cholangiocarcinoma underwent laparotomy and diagnosed by tissue-biopsy were retrospectively analyzed in this study. There were 45 men and 40 women and their mean age was 63.5 (median, 65; range, 42-81) years. Follow-up was defined as the number of months between the operation date and the date of death or, if the patient was alive, the end dates of the study period (December 31, 2006). Preoperative baseline examinations were electrocardiogram (ECG), sternite, prothrombin time (PT), hepatic and renal function test. All of 85 patients presented with hilar cholangiocarcinoma had more than one kind of image examinations. Ultrasound (US) or duplex ultrasonography (DUS) coupled with tomographic (CT) scanning were performed on 25 patients; duplex ultrasonography coupled with magnetic resonance cholangiopancreatography (MRCP) was performed on 35 patients; ultrasound, CT coupled with ERCP was performed on 11 patients; ultrasound, CT coupled with MRCP was performed on 14 patients.

T-staging

Tumors were restaged retrospectively using revised preoperative T staging system based on preoperative imaging examinations (Table 1). This staging system, a modification of a previously reported scheme[12], classifies tumors according to three factors related to local tumor extent: the location and extent of bile duct involvement (according to the Bismuth-Corlette system)[13,14], the presence or absence of portal venous invasion, and the presence or absence of hepatic lobar atrophy. The survival data was then compared among the stages. T staging correlated with respectability, Ro resection (margins negative), and the incidence of metastatic disease were reviewed.

Surgical strategies

All 85 patients in this study were treated with laparotomy, the type of therapeutic procedures depended on tumor expansion and clinical conditions of patients. If the tumor was resectable, surgery was the first choice of treatment for patients in good clinical conditions. The two types of operations were: (1) local resection of the bile duct alone; (2) extrahepatic biliary resection with in-continuity hepatic resection. In patients with non-resectable tumors or bad clinical conditions, palliative procedure using endoscopic transpapillary and/or percutaneous transhepatic biliary drainage was performed. In this study the survival of all patients undergoing resection of hilar cholangiocarcinomas by either extrahepatic biliary resection alone or by extrahepatic biliary resection with in-continuity hepatic resection were reviewed.

Statistical analysis

All data were analyzed with SPSS 11.5 statistical package. Cumulative overall survival was calculated by the Kaplan-Meier method using the log rank test with T staging. The correlation between T staging and respectability, Ro resection or the incidence of metastatic disease were analyzed using the χ^2 test. Significance was accepted with 95% confidence.

RESULTS

Proposed T-staging system

The follow-up time of all patients was more than 3 mo. Eighty five patients were staged according to the proposed preoperative clinical system, as described above Table 1. Thirty nine patients had tumor involvement of the biliary confluence (with or without unilateral extension to second-order biliary radicles), no portal vein involvement, and no lobar atrophy and were therefore classified as having T1 tumors. Fifteen patients had T2 lesions because of ipsilateral portal vein involvement or ipsilateral lobar atrophy; or both findings. Thirty one patients had T3 tumors because of biliary extent alone, or main portal vein involvement, or metastatic disease.

Table 2 Resectability, incidence of margins negative and metastatic disease after staging by T stage

T Stage	Operative modus			Margins		Metastatic disease	
	Resected	Drainage	Biopsy	Negative	Positive	Negative	Positive
T1 (n = 39)	29 (74.4)	8 (20.5)	2 (5.1)	22 (75.9)	7 (24.1)	24 (61.5)	15 (38.5)
T2 (n = 15)	9 (60.0)	4 (26.7)	2 (13.3)	3 (33.3)	6 (66.7)	7 (46.7)	8 (53.3)
T3 (n = 31)	2 (6.5)	15 (48.4)	14 (45.1)	0 (0)	2 (100)	9 (30.0)	22 (70.0)
χ^2 value		35.5		8.8		7.3	
P value		0.000		0.012		0.026	

The percentages indicate the proportion of patients within each stage grouping or of the total number of patients. Metastatic disease refers to metastases to N2-level lymph nodes or to distant sites. Median survival was calculated for all patients, including those who died perioperatively.

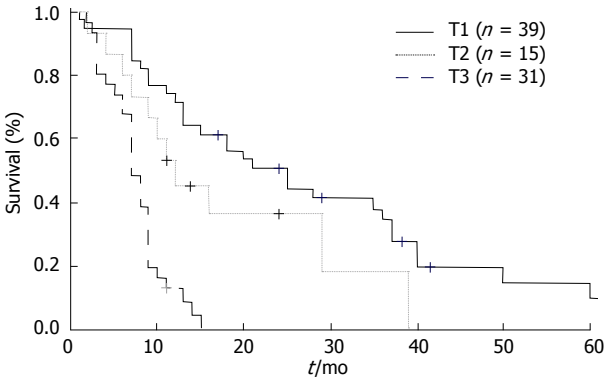

Figure 1 Kaplan-Meier survival analysis stratified by T stage. T stages seemed to be correlated with the survival time (χ^2 = 37.65, P < 0.001), and the survival time decreased progressively with increasing T staging. The cumulative 1-year survival rates of T1, T2 and T3 patients were 71.8%, 50.8% and 12.9%, respectively, and the cumulative 3-year survival rate was 34.4%,18.2% and 0%, respectively, the survival of different stage patients differed markedly (P < 0.001).

The clinical and survival-related factors associated with T stage are detailed in Table 2. Resectability and the likelihood of achieving an R0 resection both decreased progressively with increasing T stage (P < 0.05). A similar proportion of patients with T1 (74.4%) and T2 (60.0%) tumors underwent resection with curative intent. Two patients with T3 tumors (6.5%) were also underwent resection ,but both couldn't achieved R0 resection. In addition, metastatic disease to N2-level lymph nodes or to distant sites (i.e., metastatic disease that contraindicated resection) correlated with increasing T stage (P < 0.05).

Survival analysis

Kaplan-Meier estimate for survival depending on T stages was shown in Figure 1, it showed that T stages seemed to be correlated with the survival time (χ^2 = 37.65, P < 0.001), and the survival time decreased progressively with increasing T staging. The cumulative 1-year survival rates of T1, T2 and T3 patients were 71.8%, 50.8% and 12.9% respectively, and the cumulative 3-years survival rate was 34.4%, 18.2% and 0% respectively; the survival of different stage patients differed markedly (P < 0.001).

In patients with T1 lesions, 12 patients undergoing extrahepatic biliary resections alone and 17 patients underwent in-continuity hepatic resection (Table 3). This is in contrast to patients with T2 lesions, all of patient required a concomitant partial hepatectomy and 3 (33%) of whom required a portal vein resection and reconstruction.

Table 3 Margins negative, complication, operative mortality and survival based on in-continuity hepatic resection

Hepatic resection	n	Margins		Operative mortality, n (%)	Median survival, mo
		Negative, n (%)	Complication, n (%)		
In-continuity Hepatic Resection	28	21 (75)	16 (57)	3 (11)	28
No Hepatic Resection	12	4 (33)	4 (33)	1 (8)	18

Forty of 85 patients underwent resection, 28 (70%) had a concomitant partial hepatectomy, and negative histological margins were attained 75% of the time. The performance of a partial hepatectomy was predictive of a negative histological margin in this series. Median survival in the hepatic resection group was greater than in the group that did not undergo hepatic resection (28 *vs* 18 mo; P < 0.05). And the incident rate of complication and operative mortality in two groups were not different (P > 0.05).

Preoperative imaging evaluation

Most patients were diagnosed after at least a partial radiographic evaluation had been completed, usually consisting in ultrasonography, in a computed tomographic (CT) scan and in some form of direct cholangiography such as ERCP. After referral, further evaluation of tumor extent within the biliary tree and assessment of possible vascular involvement or metastatic disease were performed with MRCP or duplex ultrasonography, which are currently the preferred studies. Some patients who could not be diagnosed preoperatively were considered to have laparotomy for exploration. Altogether, 85 patients had the final diagnosis of hilar cholangiocarcinoma via pathologic diagnosis. The consistent rate with pathological findings of US or duplex ultrasonography coupled with CT, or with MRCP, or with CT and ERCP, or with CT and MRCP was 68% (17/25), 91.4% (32/35), 90.9% (10/11) and 100% (14/14) respectively. And the consistent rate of US combined with CT was significant lower than other combined examinations (P < 0.05). The final diagnosis rate of tumor infiltrated portal vein for duplex ultrasonography combined with MRCP/MRA, duplex ultrasonography combined with CT were 90% (19/21), 54.5% (6/11) respectively. The overall accuracy for combined MRCP and color Doppler Ultrasonagraphy detecting disease and

port vein involvement was higher than that of combined using CT and color Doppler Ultrasonagraphy ($P < 0.05$).

DISCUSSION

Currently, the only curative option for patients with cholangiocarcinoma is aggressive surgical resection. Many authors advocate that patients with suspected cholangiocarcinoma should be considered for operative resection and postoperative adjuvant therapy even if microscopically clear resection margins can not be achieved[15-17]. Therefore, precise preoperative imaging evaluation and staging of tumor are crucial for planning treatment and assessing prognosis.

Great effort has been expended to develop staging systems that are of greater prognostic utility to the surgeon and can be used to guide not only preoperative treatment, but also intra- and postoperative management of patients with cholangiocarcinoma[8,18-20]. There are currently 3 main staging systems utilized for patients with hilar cholangiocarcinomas: AJCC, Bismuth-Corlette, and Blumgart[9]. The AJCC tumor-node-metastasis (TNM) staging system is only applicable to patients who have undergone resection[4]. The Bismuth-Corlette system describes the tumors in terms of their anatomic location. Typically, it has been used to guide treatment (particularly resection), yet it does little to identify patients who are operative candidates or to impart prognostic information[11,12]. The modifications proposed, by Blumgart (Table 1) not only provide anatomic information about the local extent of the tumor but also better stratify patients who are candidates for surgical exploration by taking into account parenchymal characteristics of the liver.

In this study, we retrospectively reviewed 85 patients with cholangiocarcinoma who underwent resection and restaged them into the T-staging system. We have demonstrated the correlation between resectability or R0 resection or survival time and T stage, in 85 patients with hilar cholangiocarcinoma. Resectability and the likelihood of achieving an R0 resection both decreased progressively with increasing T stage. Patients with T1 and T2 have a chance of R0 resection; T3 stage tumors usually have no chance for resection. In our data, a similar proportion of patients with T1 (74.4%) and T2 (60.0%) tumors underwent resection with curative intent. Two patients with T3 tumors (6.5%) also underwent resection, but both couldn't achieve R0 resection. Kaplan-Meier analysis revealed that T-staging seemed to correlate with survival time, and the 1, 3-years accumulative survival time decreased with increasing T stage. The media survival time of patients with T1 stage was significantly higher than that of patients with T2 or T3 stage. In addition, metastatic disease to N2-level lymph nodes or to distant sites (i.e., metastatic disease that contraindicated resection) correlated with increasing T stage. In order to improve operative resectability and curability, hepatic resection has been applied to the treatment for hilar cholangiocar cinoma[21-23]. Whereas, several authors reported that the extent of hepatic resection was closely associated with the occurrence of postoperative complications, such as liver failure, sepsis, and anastomosis leakage[22,24-27]. In this study, we demonstrated a significant survival benefit in those patients who were able to undergo extrahepatic biliary resections coupled with in-continuity hepatic resection as compared with those undergoing to extrahepatic biliary resections alone. Hepatic resection did not increase the incurrence of complication and operative mortality in this series; this results also were supported by Miyazaki *et al*[28]. In our experience, the segments I and Ⅳ resection for hilar cholangiocarcinoma have the benefit of preserving enough hepatic mass for the patient to tolerate surgical stress as compared with major hepatic resection.

Early detection and accurate staging are crucial for planning treatment and improving survival rate of hilar cholangiocarcinomas. Noninvasive methods like magnetic resonance cholangiopancreatography or magnetic resonance angiography (MRCP/MRA) and Doppler ultrasound have been proposed by Jarnagin[29]. In our data analysis, duplex ultrasonography and magnetic resonance cholangiopancreatography have been successful when compared with any other combination of examinations. Ultrasonagraphy detecting disease and port vein involvement was 91.4% and 90%.and was higher than that of combined using CT and color Doppler Ultrasonagraphy. Duplex ultrasonography is noninvasive, and a skilled operator can identify the site of biliary obstruction, as well as the presence or absence of portal venous involvement. The efficacy of MRCP/MRA as a noninvasive means of acquiring reliable and precise information about the anatomy of both the intrahepatic and the extrahepatic biliary tree, as well as the level of tumor involvement, and the presence of nodal or distant metastases, has been well documented and has all but replaced percutaneous and endoscopic cholangiography[30-32].

In conclusion, the T-staging system correlates with respectability, RO resection and overall accumulative survival. Patients with hilar cholangiocarcinoma in T1 and T2 stage have the chance of curative resection, in-continuity hepatic resection, and it is necessary to achieve this with lower complications. Duplex ultrasonography and MRCP/MRA are essential for a preoperative assessment of hilar cholangiocarcinoma.

COMMENTS

Background

Cholangiocarcinoma is a malignancy with poor prognosis, and the best result still comes from surgical resection. However, in many of patients who underwent laparotomy the tumors are found not respectable. Therefore, a precise preoperative evaluation system seems to be particularly important. Whereas, currently the modified Bismuth-Corlette system and American Joint Committee on Cancer (AJCC) systems are still commonly used in evaluation of hilar cholangiocarcinoma in China, but both of them failed to identify patients who are operative candidates or to provide prognostic information.

Research frontiers

This current study retrospectively analyzes 85 patients with cholangiocarcinoma who underwent surgery using the T-staging system, and evaluates whether the resectability or survival correlated with T-staging. We also wanted to find the correlation between the T staging and nodal or distant metastases. Additionally, in our study, biliary resections coupled with in-continuity hepatic resection has been proposed to attain radical resection.

Innovations and breakthroughs

In our data, a similar proportion of patients with T1 (74.4%) and T2 (60.0%) tumors underwent resection with curative intent. Hepatic resection has been applied to the treatment for hilar cholangiocarcinoma, and achieved higher median survival than in the group that did not undergo hepatic resection (28 *vs* 18 mo; $P < 0.05$). In our study, the segments I and IV resection for hilar cholangiocarcinoma have the benefit of preserving enough hepatic mass for the patient to tolerate surgical stress as compared with major hepatic resection. In our data analysis, duplex ultrasonography and magnetic resonance cholangiopancreatography are chosen over any other combination of examinations.

Applications

This study provided important reference as regard to the preoperative assessment for patients with halir cholangiocarcinoma. In conclusion, the T-staging system correlates with resectability, RO resection and overall accumulative survival. Patients with hilar cholangiocarcinoma in T1 and T2 stages have the chance of curative resection, and in-continuity hepatic resection is necessary to achieve this with lower complications. Duplex ultrasonography and MRCP/MRA are necessary for a preoperative assessment of hilar cholangiocarcinoma.

Terminology

In current study, revised preoperative T staging systems were used to preoperatively evaluate the status of patients with hilar cholangiocarcinoma, and it described as follows: T1, Tumor involving biliary confluence ± unilateral extension to 2° biliary radicles, No liver atrophy or portal vein involvement. T2, Tumor involving biliary confluence ± unilateral extension to 2° biliary radicles with ipsilateral portal vein involvement ± ipsilateral hepatic lobar atrophy, No main portal vein involvement T3, Tumor involving biliary confluence + bilateral extension to 2° biliary radicles; OR unilateral extension to 2° biliary radicles with controlateral portal vein involvement; OR unilateral extension to 2° biliary radicles with controlateral hepatic lobar atrophy; OR main or bilateral portal venous involvement.

Peer review

The manuscript retrospectively analyzes 85 patients with cholangiocarcinoma who underwent surgery using the T-staging system. The results show resectability, tumor-free margin resection and cumulative survival of patients decrease with increasing T stage. The study also suggests that MRCP/MRA coupled with Doppler Ultrasonagraphy provides better preoperative evaluation of hilar cholangiocarcinoma. The paper is well written and more importantly it does provide important reference as regard to the preoperative assessment for patient with halir cholangiocarcinoma.

Abstract

AIM: To evaluate the impact of alcohol dehydrogenase *2 (ADH2)* and aldehyde dehydrogenase *2 (ALDH2)* polymorphisms on esophageal cancer risk.

METHODS: One hundred and ninety-one esophageal cancer patients and 198 healthy controls from Yanting County were enrolled in this study. *ADH2* and *ALDH2* genotypes were examined by polymerase-chain-reaction with the confronting-two-pair-primer (PCR-CTPP) method. Unconditional logistic regression was used to calculate the odds ratios (OR) and 95% confidence interval (95% CI).

RESULTS: Both *ADH2*1* allele and *ALDH2*1/*2* allele showed an increased risk of developing esophageal cancer. The adjusted OR (95% CI) for *ADH2*1* allele compared with *ADH2*2/*2* was 1.65 (95% CI = 1.02-2.68) and 1.67 (95% CI = 1.02-2.72) for *ALDH2*1/*2* compared with *ALDH2*1/*1*. A significant interaction between *ALDH2* and drinking was detected regarding esophageal cancer risk, the OR was 1.83 (95% CI = 1.13-2.95). Furthermore, when compared with *ADH2*2/*2* and *ALDH2*1/*1* carriers, *ADH2*1* and *ALDH2*2* carriers showed an elevated risk of developing esophageal cancer among non-alcohol drinkers (OR = 2.46, 95% CI = 0.98-6.14), and a significantly elevated risk of developing esophageal cancer among alcohol drinkers among alcohol drinkers (OR = 9.86, 95% CI = 3.10-31.38).

CONCLUSION: *ADH2* and *ALDH2* genotypes are associated with esophageal cancer risk. *ADH2*1* allele and *ALDH2*2* allele carriers have a much higher risk of developing esophageal cancer, especially among alcohol drinkers.

Key words: Esophageal cancer; Alcohol dehydrogenase 2; Aldehyde dehydrogenase 2; Genetic polymorphisms

INTRODUCTION

Epidemiological studies have consistently shown that alcohol drinking is a strong risk factor for esophageal cancer[1-3]. Alcohol is not a carcinogen, but its primary metabolite, acetaldehyde, has been proven carcinogenic in experimental models[4,5]. When consumed through drinking, ethanol is metabolized primarily by class I alcohol dehydrogenase (ADH2) into acetaldehyde, an intermediate metabolite, followed by aldehyde dehydrogenase (ALDH2) into acetic acid in humans[6]. Acetaldehyde, a well-known carcinogen in animals, plays an important role in alcohol toxicity to humans[7]. The encoding genes of the two representative alcohol-metabolizing enzymes display polymorphisms which may modulate individual differences in alcohol-oxidizing capacity and drinking behavior[7,8]. *ADH2*2/*2* has about 40 times higher Vmax than the less-active *ADH2*1/*1*. *ALDH2*2* allele encodes a catalytically inactive subunit for the ALDH2 polymorphism[6,9]. Individuals with the *ALDH2*1/*2* genotype have only 6.25% of normal *ALDH2 *1/*1* activity, indicating a dominant effect of *ALDH2*2*[10]. *ADH2*2* allele and *ALDH2*2* allele, both leading to high acetaldehyde concentrations, are clustered in East Asian populations[6,11,12]. Therefore, polymorphisms of these two genes may exert their effects on esophageal cancer susceptibility. Although several studies on *ADH2* or *ALDH2* polymorphisms and esophageal cancer risk have been conducted to clarify their association[13-15], investigations on non-alcoholic drinkers are limited[16-19].

Yanting, a rural county of Sichuan Province, is one of the areas with the highest esophageal cancer mortality in China[20]. According to the report from Tumor Registry of China, the average incidence rate in this area was $100.5/10^5$ for males and $76.5/10^5$ for females during 1999-2003, which was higher than that in Linxian County and lower than that in Cixian County of Hebei Province, China. Our previous study in Yanting County has shown that alcohol drinking and smoking are common in Yanting County and the main contributors to esophageal cancer[21]. To further study alcohol-related gene polymorphisms and gene-environment interaction on esophageal cancer, a case-control study was conducted in Yanting County.

MATERIALS AND METHODS

Subjects

Esophageal cancer patients were consecutively collected from the Hospital of Yangting Cancer Research Institute (YCRI) from July 2003 to July 2004. All the patients having lived in Yanting County for more than five years were histologically diagnosed as esophageal cancer within 6 mo at the age of 35-85 years. A total of 191 patients (183 with squamous cell carcinoma and 8 with adenocarcinoma) were recruited for the study. One hundred and ninety-one healthy residents from Yanting County served as controls. In total, 191 patients and 198 controls completed a questionnaire and each provided 1 mL blood. The questionnaire included basic demographic data, information on esophageal cancer and habits such as smoking and alcohol drinking, as well as information on food and nutrition.

The ethics committee of each collaborating institution reviewed and approved the study, and informed consent was obtained from all participants.

Genotyping of ALDH2 and ADH2

Genotyping was based upon duplex polymerase-chain-reaction with the confronting-two-pair-primer (PCR-CTPP) method[7]. Briefly, the sequences of four primers used for ADH2 polymorphism are F1 ADH2: 5'-GGG CTTTAGACTGAATAACCTTGG-3'; R1 ADH2: 5'-AAC CACGTGGTCATCTGTGC-3'; F2 ADH2: 5'-GGTGGC TGTAGGAATCTGTCA-5'; R2 ADH2: 5'-AGGGAA AGAGGAAACTCCTGAA-3'. The sequences of primers used for ALDH2 polymorphism are F1 ALDH2: 5'-TGC TATGATGTGTTTGGAGCC-3'; R1 ALDH2: 5'-CCC ACACTCACAGTTTTCACTTC-3'; F2 ALDH2: 5'-GGG CTGCAGGCATACACTA-3'; R2 ALDH2: 5'-GGC TCCGAGCCACCA-3'. Each 25 μL reaction mixture contained 1.3 U Tag biocatalysts, 1.8 mmol/L Mg^{2+}, 0.24 mmol/L dNTPs, 8 primers, 15 pmol of each primer and 5-8 μL template. The PCR conditions were as follows: initial denaturation at 94℃ for 5 min, followed by 35 cycles at 94℃ for 65 s, at 60℃ for 65 s, at 72℃ for 90 s, and a final extension at 72℃ for 5 min. After transient centrifugation, agarose electrophoresis was conducted. The PCR products included 119 bp fragments of *ALDH2*1* allele, 98 bp fragments of *ALDH2*2* allele, 219 bp fragments of *ADH2* and *ADH2*1* allele, 280bp fragments of *ADH2*2* allele. The 176 bp and 219 bp fragments were the common fragments of the two alleles.

Table 1 Characteristics of patients and controls *n* (%)

Characteristic	Patients *n* = 191	Controls *n* = 198	*P*[1]	OR (95% CI)[2]
Age (yr)				
< 50	28 (14.7)	84 (42.9)		
50-64	118 (61.7)	67 (33.4)	*P* < 0.001	-
⩾ 65	45 (23.6)	47 (23.7)		
Mean age (SD)	58.3 (8.3)	52.8 (13.2)	-	-
Sex				
Male	126 (66.0)	122 (61.6)	*P* = 0.372	-
Female	65 (34.0)	76 (38.4)		-
Smoking status				
Non-smokers[3]	75 (39.3)	121 (61.1)	*P* < 0.001	1.00 (References)
Current smokers	116 (60.7)	77 (38.9)		3.76 (2.01-6.73)
Alcohol drinking status				
Non-drinkers[4]	80 (41.9)	128 (64.7)		1.00 (References)
Current alcohol drinkers	111 (58.1)	70 (35.3)	*P* < 0.001	3.16 (1.91-5.24)

[1]*P* value by chi-square test; [2]ORs for smoking and drinking were adjusted for age and sex, rapid food eating, quality of drinking water, consumption of fresh fruits, vegetable and eggs; [3]Non-smokers including ex-smokers; [4]Non-drinkers including ex-drinkers.

Statistical analysis

Statistical analyses were performed using the STATA statistical package (version 8, STATA, College Station, TX). Demographic data, smoking and drinking status were compared between patients and controls by chi-square test. The subjects smoking more than 10 cigarettes per week for at least 6 mo were defined as current smokers. The subjects consuming more than 50 mL of distilled spirits per week for at least 6 mo were defined as current drinkers. The odds ratio (OR) and 95% confidence interval (95% CI) generated in unconditional logistic regression model were used as measures of association for the risk of esophageal cancer. The relationship of ALDH2 and ADH2 polymorphisms with esophageal cancer risk was determined after adjustment for sex, age, smoking, rapid food eating, quality of drinking water, consumption of fresh fruits, vegetables and eggs. The combined effect of alcohol consumption and *ADH2* and *ALDH2* genotypes on esophageal cancer was also examined in this study. Chi-square test was used to check the Hardy-Weinberg equilibrium (HWE) in controls for the assessment of discrepancies between genotype and allele frequencies.

RESULTS

The characteristics of subjects are listed in Table 1. The mean age of 191 patients and 198 controls was 58.3 and 52.8 years, respectively. There was a significant difference in smoking and alcohol drinking status ($P < 0.001$) between patients and controls. When compared with non-smokers, the adjusted OR of current smokers was 3.76 (95% CI = 2.01-6.73). Current alcohol drinkers also showed an increased risk of developing esophageal cancer (OR = 3.16, 95% CI = 1.91-5.24) when compared with non-drinkers. Almost all the alcohol drinkers drank hard

[1]ORs for gene frequencies were adjusted for sex, age, smoking, drinking, rapid food eating, quality of drinking water, consumption of fresh fruits, vegetable and eggs; [2]ORs for allele frequencies were not adjusted.

liquor containing over 48% ethanol in this area and the main tobacco type was cigarette (data not shown).

The genotype and allele distribution of *ADH2* and *ALDH2* and their OR (95% CI) for esophageal cancer risk are listed in Table 2. The ADH2 genotype frequency was 50.5% for *ADH2*2/*2*, 38.4% for *ADH2*1/*2*, and 11.1% for *ADH2*1/*1* in controls, which were in accordance with the HWE (P = 0.20) (data not shown). When compared with the *ADH2*2/*2* genotype, the esophageal cancer risk in subjects harboring *ADH2*1* allele was significantly elevated (OR = 1.65, 95% CI = 1.02-2.68). The OR for *ADH2*1* allele carriers was 1.42 (95% CI = 1.06-1.92) when compared with *ADH2*2* allele carriers. The frequency of *ALDH2*1/*1*, *ALDH2*1/*2* and *ALDH2*2/*2* was 54.6%, 38.4% and 7.1%, respectively, in controls, which were also in accordance with the HWE (P = 0.90) (data not shown). The *ALDH2*1/*2* genotype was associated with an increased risk of developing esophageal cancer (OR = 1.67, 95% CI = 1.02-2.72).

The combined effect of alcohol consumption and *ADH2* and *ALDH2* genotypes on esophageal cancer risk is shown in Table 3. When compared with non-drinkers harboring *ADH2*2/*2* genotype, alcohol drinkers carrying *ADH2*1* showed an increased risk of developing esophageal cancer (OR = 3.94, 95% CI = 1.76-8.81). Similarly, a significantly increased risk of developing esophageal cancer was found in alcohol drinkers harboring *ALDH2*2* genotype (OR = 4.82, 95% CI = 2.06-11.27), compared with non-drinkers harboring *ALDH2*1/*1* genotype. Furthermore, a significant interaction between *ALDH2* and alcohol drinking was detected regarding esophageal cancer risk (adjusted OR = 1.83, 95% CI = 1.13-2.95) (data not shown). When compared with *ADH2*2/*2* and *ALDH2*1/*1* carriers, *ADH2*1* and *ALDH2*2* carriers showed an elevated risk of developing esophageal cancer in non-drinkers (OR = 2.46, 95% CI = 0.98-6.14) and a significantly elevated risk of developing esophageal cancer in alcohol drinkers (OR = 9.86, 95% CI = 3.10-31.38).

DISCUSSION

In the present study, the risk of developing esophageal cancer was significantly increased in *ALDH2*1/*2* gene carriers; subjects with *ADH2*1* allele had a higher risk of developing esophageal cancer than those with *ADH2*2/*2*; carrying both *ALDH2*2* allele and *ADH2*1* allele, suggesting that alcohol drinking greatly increases the susceptibility to esophageal cancer.

*ALDH2*2* allele encoding an inactive subunit of ALDH2 is prevalent in Asian[22]. It was reported that acetaldehyde concentrations after drinking alcohol are mainly dependent on the enzyme activation of *ALDH2*[6,23]. After consumption of alcohol, blood acetaldehyde concentrations in those with *ALDH2*2/*2* and *ALDH2*1/*2* are 19- and 6-fold higher than in those with *ALDH2*1/*1*[24]. Case-control studies of Japanese and Chinese alcohol drinkers[10,15,16,17,19,25,26] consistently demonstrated that inactive *ALDH2*1/*2* is a strong risk factor for esophageal cancer. Our data also show that individuals with *ALDH2*1/*2* (OR = 1.67, 95% CI = 1.02-2.72) had a significantly increased risk of developing esophageal cancer compared to those with *ALDH2*1/*1*. Furthermore, our results reveal that there was a significant interaction between *ALDH2* and alcohol drinking, indicating that esophageal cancer is associated with alcohol drinking, which is influenced by the polymorphism of *ALDH2*.

Previous case-control studies investigating the association between *ADH2* genotype and esophageal cancer demonstrated that *ADH2*1* allele independently enhances esophageal cancer risk[6,10,14,17,19]. In our study, the adjusted OR for subjects carrying *ADH2*1* allele was 1.65 (95% CI = 1.02-2.68), which is in line with former studies[6,10,14,17,19]. There are several reasons which may explain this finding. ADH2 is the predominant enzyme among low-Km class I ADHs expressed in the esophagus[27]. In *ADH2*1/*1* homozygotes, concentrations of ethanol may linger in the esophageal mucosa during the slow oxidation of *ADH2*. Although ethanol is not a cancerogen itself, tobaccos and some other exogenous cancerogens would be assimilated much easier, thus increasing the effect of cancerogen. Besides, ethanol can induce the composition of phase I drug metabolism enzymes such as CYP2E1. Moreover, alcohol drinkers with *ADH2*1* genotype tend to have experienced 'binge-drinking' and withdrawal syndrome earlier in life than those with other genotypes[14,23]. Therefore, *ADH2*1*-mediated alcohol-related events may contribute to the enhancement of esophageal cancer risk in alcohol drinkers.

It was reported that combination of *ADH2*1* allele and *ALDH2*2* allele can greatly enhance cancer risk among alcoholics[10] and general populations[6,19,23]. Carrying these two alleles simultaneously indicates a longer time of exposure to alcohol and highly-concentrated acetaldehyde, thus increasing the individual's susceptibility to esophageal cancer. In the present study, the OR for alcohol drinkers

[1]ORs were adjusted for sex, age, smoking, rapid food eating, quality of drinking water, consumption of picked vegetables and fresh fruits, vegetables and eggs; [2]Non-drinkers including ex-drinkers.

with both *ADH2*1* allele and *ALDH2*2* allele was 9.86 (95% CI = 3.10-31.38), which is consistent with former studies[10].

Some limitations of this study should be considered. One is that controls were selected from residents in Yanting County and their basic features are consistent with general people, such as smoking and alcohol drinking. In this study, the genotype distribution among the controls closely conformed to the Hardy-Weinberg equilibrium. So our control group represents the general population of Yanting County. In addition, the present study was not an age matched case control study and age is a risk factor for esophageal cancer. However, our results are age-adjusted and may not be biased by age. The small number of subjects is another limitation, so further studies in a larger scale appear warranted.

In conclusion, *ADH2* and *ALDH2* genotypes are associated with esophageal cancer risk. In addition, the risk of developing esophageal cancer increases in subjects carrying *ADH2*1* allele and *ALDH2*1* allele, especially in alcohol drinkers. Our present findings provide more information on the *ADH2* and *ALDH2* polymorphisms of esophageal cancer in Chinese.

The authors thank the Epidemiology Department of Aichi Cancer Center for providing the primers and Dr. K Matsuo for genotyping technical support.

COMMENTS

Background

Epidemiological studies have consistently shown that alcohol drinking is a strong risk factor for esophageal cancer. When consumed through drinking, ethanol is metabolized primarily by class I alcohol dehydrogenase (ADH2) into acetaldehyde, an intermediate metabolite, followed by aldehyde dehydrogenase (ALDH2) into acetic acid in humans. Acetaldehyde, a well-known carcinogen in animals, plays an important role in alcohol toxicity to humans. *ADH2*2* allele and *ALDH2*2* allele, both leading to high acetaldehyde concentrations, are clustered in East Asian populations. Therefore, the polymorphism of these two genes may exert effect on esophageal cancer susceptibility.

Research frontiers

Esophageal cancer risk is associated with habits and food consumption, such as smoking, alcohol drinking, consumption of fresh fruits and vegetables. However, the effect of gene polymorphisms or gene-environment interaction on esophageal cancer risk has become a hotspot in recent researches. The present study reports the association of ADH2 and ALDH2 gene polymorphisms with esophageal cancer risk. Furthermore, interaction and combination impacts on esophageal cancer risk between gene polymorphisms and alcohol drinking are also analyzed and discussed.

Innovations and breakthroughs

Our study showed that *ADH2* and *ALDH2* polymorphisms were associated with esophageal cancer risk in a high-incidence area of southwest China. Previous studies were mainly conducted in Japanese males or alcoholics. In addition, our controls were collected from the healthy residents and the patients were histologically diagnosed as esophageal cancer within 6 mo, which is superior to hospital-based case-control studies.

Applications

The present study indicates ADH2 and ALDH2 genotypes are associated with esophageal cancer risk, the risk of developing esophageal cancer increases in subjects carrying ADH2*1 allele and ALDH2*2 allele, especially in alcohol drinkers. The present findings can provide more information on the ADH2 and ALDH2 polymorphisms of esophageal cancer in Chinese and help make the prevention strategy against esophageal cancer in China.

Terminology

Alcohol dehydrogenase 2 (*ADH2*): A zinc-containing enzyme which oxidizes primary and secondary alcohols or hemiacetals in the presence of NAD. In alcoholic fermentation, it catalyzes the final step of reducing aldehyde to alcohol in the presence of NADH and hydrogen. Dehydrogenase 2 (*ALDH2*): An enzyme that oxidizes aldehyde in the presence of NAD+ and water to acid and NADH. Genetic polymorphisms: The regular and simultaneous occurrence of two or more discontinuous genotypes in a single interbreeding population. The concept includes differences in genotypes ranging in size from a single nucleotide site to large nucleotide sequences visible at a chromosomal level.

Peer review

This is an interesting paper investigating the association between ADH2 and ALDH2 polymorphisms, environmental factors and esophageal cancer risk in a relatively small cohort of cancer patients. The main conclusion of the manuscript is that ADH2 and ALDH2 genotypes are associated with esophageal cancer risk; the risk of developing esophageal cancer increases greatly in subjects carrying ADH2*1 allele and ALDH2*2 allele, especially in alcohol drinkers.

Abstract

AIM: To construct a new target-oriented conjugate of humanized carcinoembryonic antigen (CEA) specific single chain variable fragment (scFv) and mitomycin (MMC) against colorectal cancer, and to investigate its influence on the growth and apoptosis of colorectal cancer cells.

METHODS: The primer was designed according to the gene sequence described in reference 16, which respectively contains restriction enzyme cleavage sites *Bam*H Ⅰ and *Eco*R Ⅰ in its upstream and downstream. PCR was performed with the plasmid as template containing genes of humanized anti-CEA scFv. The product was digested by *Bam*H Ⅰ and *Eco*R Ⅰ, and connected to an expression vector which also has the restriction enzyme cleavage sites *Bam*H Ⅰ and *Eco*R. Expression of the reaction was induced by isopropy-β-D-thiogalactoside (IPTG). Then the expression product was covalently coupled with MMC by dextran T-40. The immunoreactivity of the conjugate against colorectal cancer cells as well as CEA was measured by enzyme linked immunosorbent assay (ELISA). The inhibiting ratio of conjugate on the growth of colorectal cancer cells was also measured by ELISA. The effect of conjugate on the apoptosis of colorectal cancer cells was determined by flow cytometry (FCM).

RESULTS: Restriction endonuclease cleavage and gene sequencing confirmed that the expression vector was successfully constructed. Sodium dodecyl sulfate polyacrylamide gel electropheresis (SDS-PAGE) confirmed that this vector correctly expressed the fusion protein. ELISA confirmed that the conjugate had quite a strong immunoreactivity against colorectal cancer cells and CEA. The conjugate had inhibitory effects on colorectal cancer cells in a concentration-dependent manner and could induce apoptosis of colorectal cancer cells in a concentration-dependent manner.

CONCLUSION: The CEA-scFv-MMC conjugate can be successfully constructed and is able to inhibit the growth and induce apoptosis of colorectal cancer cells.

INTRODUCTION

Significant improvement has been achieved in the treatment of advanced colorectal cancer in the past decade[1]. New cytotoxic agents and new monoclonal antibodies (mAb) have been shown to substantially improve patient outcomes in randomized trials[2]. Nevertheless, the prognosis of patients with advanced colorectal cancer remains relatively poor with a median survival of approximately 20 mo in optimally treated patients[3]. Therefore, additional treatment strategies are needed in order to further improve the outcomes.

With advances in oncomolecular biology, the mechanism of tumor genesis and development is better understood[4], which provides a new medication pattern against tumors. Since a conception of target-oriented medication against tumors has been recently brought forward[5], we can design and develop medications aiming at target spots of specific molecules and genes to selectively kill tumor cells according to the known abnormal molecules and genes related to the genesis of tumors. Target-oriented medication against tumors provides a new effective way of treating malignant tumors such as mammary cancer, intestinal cancer and lung cancer[6-8], and can directly deliver chemotherapeutics for the tumor and form a high local drug concentration so as to decrease the total dosage and further reduce the toxic and side effects[9].

An ideal target spot of tumor treatment has the following features. (1) It is a kind of macromolecules which are rather critical for malignancy phenotype; (2) It has no obvious expression in important organs and tissues; (3) It has

biological correlativity; (4) It can be repeatedly tested on clinical specimens; (5) It has apparent correlativity with the clinical outcome[10]. Carcinoembryonic antigen (CEA) is a 180 ku cell surface-expressed glycoprotein antigen present in a number of adenocarcinomas, especially in colorectal cancer[11]. The gene sequence and three-dimensional structure of CEA have been reported elsewhere[12]. CEA is a member of the immunoglobulin superfamily and has cell adhesion properties as well as other less clearly defined roles[13]. Since it corresponds to all features of the target spot of tumor treatment, it is the ideal target spot of treating colorectal cancer.

At present, research on target-oriented medication against advanced colorectal cancer involved 3 different target-oriented drugs that have achieved significant curative effect: epidermal growth factor receptor (EGFR) inhibitors, vascular endothelial growth factor receptor (VEGFR) inhibitors, and cyclooxygenase-2 (COX-2) inhibitors[14]. By coupling radio immunity drugs with anti-CEA monoclonal antibody, Vogel[15] has achieved favorable therapeutic effectiveness on nude mice model of liver metastasis of colorectal cancer, thus opening up a new idea for target-oriented medication against advanced colorectal cancer. Based on the above-mentioned theory, we constructed a humanized anti-CEA single-chain antibody (scFv) and coupled it with mitomycin (MMC), a chemotherapeutic agent against colorectal cancer, and investigated the influence of this conjugate on the growth and apoptosis of colorectal cancer cells.

MATERIALS AND METHODS

Materials

Plasmid pUC18 containing humanized anti-CEA-scFv was kindly provided by Professor Mark Sherman (the Berkman Research Institute, USA). *E.coli* DH5α and expression plasmid pGEX-4T-1 were stored in the Virus Research Institute, Medical College of Wuhan University. T4 DNA ligase and restriction endonuclease were purchased from New England Biolabs (USA). High fidelity DNA polymerase and DNA gel extraction kits were purchased from the Promega Company (USA). Plasmid extracting and purifying kits were the products of Vegen Company (Hangzhou, China). Glutathione acyltransferase purification kits were purchased from the Clonetech Company (USA). MMC was purchased from the Roche Company (USA). Bovine serum albumin (BSA), Tween 20, PI dyebath and Hanks solution were bought from Fuzhou Maixin Biology Company (China). Glucosan T-40, cysteine, N-2 N-ethylmaleimide (NEMI), horseradish peroxidase-labeled goat anti-mouse IgG, dimethyl sulphoxide (DMSO) were bought from the Sigma Company (USA). RPMI 1640 culture medium was bought from the Gibico Company (USA). CEA was produced by the Zymed Company (USA). Colorectal cancer cell lines SW480, SW620 and LoVo were provided by China Center for Typical Culture Collection (CCTCC) (Wuhan, China). Primer synthesis and gene sequencing were performed by the Sangon Company (Shanghai, China).

Primers were designed using the program Oligo4.1 and synthesized by Sangon Company (Shanghai, China) as previously described[16], a restriction enzyme cleavage site *Bam*H I was added to the end 5', and a restriction enzyme cleavage site *Eco*R I was added to the end 3'. Upstream primer: 5'CGGGATCCATGGACAGAGTCACA3', downstream primer: 5'CCGAATTCTCCACGTGCACTCGAGACGGTGAC3'. The underlined parts are the restriction enzyme cleavage sites.

Construction of expression vector

Plasmid pUC18 containing humanized anti-CEA scFv T84.66 was taken as the template to perform PCR with its upstream and downstream primers in 50 μL reaction system containing 5 μL template, 5 μL reaction buffer, 2 μL upstream and downstream primers, 0.5 μL high fidelity DNA polymerase, 4 μL dNTP and 33.5 μL deionized water. Samples were heated at 94℃ for 5 min, followed by 35 cycles of heating at 94℃ for 30 s, at 55℃ for 30 s and at 72℃ for 30 s. The temperature was held constant at 72℃ for 7 min to ensure complete extension. The completed PCR reaction mix was electrophoresed on 1% agarose gel and the desired product was extracted from 200 mg gel slice. The purified product was digested with *Bam*H I and *Eco*R. cDNA of anti-CEA scFv T84.66 containing correspondence restriction enzyme sites to pGEX-4T-1 was produced. Prokaryon expression vector pGEX-4T-1 was also digested with *Bam*H I and *Eco*R. After identified by agarose gel electrophoresis, the plasmid with a cohesive end was connected to the cDNA of anti-CEA scFv T84.66 acquired previously. Connection reaction was performed in 10 μL system. The reaction product was transformed into competent cell line DH5α and the positive clone of recombined CEA-scFv-pGEX-4T-1 was acquired. Restriction endonuclease cleavage and gene sequencing confirmed that the scFv fragment was correctly interpolated into pGEX4-T-1. Positive plasmid was extracted and purified with the kits from Vegen Company (Hangzhou, China).

Expression and purification of the fusion protein

Expression of E. coli DH5α containing the positive plasmid was induced by isopropyl-β-D thiogalactoside (IPTG) followed by sodium dodecyl sulfate polyacrylamide gel electropheresis (SDS-PAGE). The level of this protein in total bacterial protein was detected with a thin layer chromatogram (TLC) scanner. The correctly expressed DH5α containing the recombinant plasmid was cultured in 500 mL triangular flask. After IPTG was added to induce expression of the protein, the product was purified with glutathione acyltransferase purification kit according to its manufacturer's instructions. The purified protein was collected with a step-by-step collector containing 500 μL per tube, and the absorbance value was measured at 280 nm to quantify the protein.

Construction of CEA-scFv-MMC conjugate

A pertinent amount of dextran T-40 was admixed with sodium periodate as previously described[17], and the mixture reacted for 3 h at ordinary temperature away from light, then sufficiently dialyzed with deionized water. After cryodesiccation, poly aldehyde dextran (PAD) was produced. Fifty mg of PAD was admixed with 100 mg of MMC, and

the mixture was incubated at 4℃ for 12 h away from light. Then 80 mg of CEA-scFv purified protein was added, stirred reaction was carried out for 12 h and terminated with sodium borohydride. The reaction product was purified with Sephadex G-75 for CEA-scFv-MMC conjugate. The molecular constitution of the conjugate was measured by spectrophotometry. The absorbance value of the conjugate was measured respectively at 280 nm and 488 nm, and at 595 nm after stained with Coomassie brilliant blue. The mole ratio of each composition was recorded.

Detection of immunocompetence of CEA-scFv-MMC conjugate by ELISA

Colorectal tumor cells SW480, SW620 and LoVo were cultured *in vitro* in 96-well culture plates (10^4 cells per well). Twenty-four hours later, 2.5 g/L glutaraldehyde precooled at 4℃ was added (50 μL per well). The cells were fixed at 4℃ for 5min, washed 3 times with PBS and stored at -20℃. When it was used, 10 g/L BSA was added (200 μL per well), sealed overnight at 4℃, then washed with PBS-Tween 20 (PBS-T), and CEA-scFv-MMC diluted with multiple proportion was added (50 μL per well). The mixture was left to react at 37℃ for 1 h, then washed 3 times with PBS-T. Horseradish peroxidase-labeled goat anti-mouse IgG antibody was added (50 μL per well). The mixture was incubated at 37℃ for 1 h, washed 5 times with PBS-T. Enzyme reaction substrate was added (200 μL per well), the mixture was incubated to react for 15 min at room temperature away from light and terminated by adding 2 mol/L sulfuric acid. The absorbance value was measured at 490 nm with enzyme labelling instruments to determine the immunoreactivity of CEA-scFv-MMC against colorectal cancer cells. CEA (pH 7.5) at the concentration of 1.35 g/L was put into culture plates (100 μL per well), the mixture was incubated over night at 4℃. The supernatant was discarded. The mixture was washed 3 times with PBS and stored at -20℃. When it was used, 10 g/L BSA was added (200 μL per well), sealed overnight, and washed with PBS-T buffer solution. Other steps were the same as above, and the immunoreactivity of CEA-scFv-MMC against CEA was detected.

Growth inhibition ratio of conjugate to colorectal cancer cells

The colorectal cancer cells LoVo were cultured in RPMI1640 culture medium, routine serial subculture was carried out in an incubator containing 50 mL/L CO_2 at 37℃. The culture medium was replaced with drug-containing culture medium 24 h after the cells adherently grew to 70%-80% monolayer, then the experiment was carried out. The cells were digested with trypsin and blown to single cell suspension. The cell concentration was counted, adjusted to 1×10^8 cells/L, which were inoculated into 96-well culture plates (0.2 mL per well). The original fluid was discarded after 24 h culture. CEA-scFv-MMC conjugate with different concentrations was added into the wells (0 mg/L in control group; 25 mg/L, 50 mg/L, 100 mg/L, 150 mg/L, 200 mg/L, 300 mg/L and 400 mg/L, respectively, in treatment group) and cultured for 48 h. Twenty μL of MTT solution (2.5 g/L) was added into each well, and cultured for 4 h. After the supernatant was carefully blotted, 150 μL of 100 g/L DMSO was added into each well. The absorbance value (A_{630nm}) of each well was measured by enzyme labelling instruments after gently agitated on the oscillator. The growth inhibition ratio at each concentration in treatment group was calculated according to the following formula: growth inhibition ratio IR (%) = (1-average A_{630nm} of treatment group/A_{630nm} of control group) × 100%.

Influence of conjugate on apoptosis of colorectal cancer cells

Colorectal cancer cells treated with different concentrations of CEA-scFv-MMC conjugate were cultured for 3 d and 10^6 cells were collected, fixed with 700 mL/L ethanol. The dying cell suspension was filtrated through nylon net (400 meshes) and washed 3 times with PBS followed by addition of 10 μL of Annexin V-fluorescein isothiocyanate and PI solution. The mixture was blended in ice bath for 10 min away from light. A flow cytometer (FCM) was used to detect the influence of CEA-scFv-MMC conjugate on the apoptosis of colorectal cancer cells.

Experiments approved by the local ethical committee were performed after the patients gave their informed consent. All the experimental data were expressed as mean ± SD. Comparison between treatment and control groups was made by *t* test and their ratios by χ^2 test. The correlation between the two groups was analyzed with collinearity. $P < 0.05$ was considered statistically significant.

RESULTS

Construction of recombinant plasmid CEA-scFv-pGEX-4T-1

A 810 bp specific band was obtained by PCR amplification with pUC18 as template. cDNA of PCR amplification was completely in accordance with the gene sequence of humanized anti-CEA specific scFv T84.66. The positive clone of recombinant plasmid CEA-scFv-pGEX-4T-1 was identified by double restriction endonuclease cleavage with *Bam*H I and *Eco*R I. Two specific bands were obtained in line 1, one was 4.7 kb and the other was 810 bp, and a 5.5 kb band was obtained in line 2. The 4.7 kb band represented pGEX-4T-1, 810 bp band anti-CEA-scFv, and the 5.5 kb band the recombinant plasmid CEA-scFv-pGEX-4T-1 (Figure 1). The result was completely consistent with our hypothesis. Meanwhile, the scFv gene was correctly inserted to the expression vector.

Expression of scFv gene

After induction of IPTG, expression of the scFv gene inserted to the pGEX-4T-1 was stable. A new protein band was obtained at M_r 49 000 after SDS-PAGE, and its size was in accordance with GST (M_r 26 000) and scFv-CEA (M_r 23 000) fusion protein (Figure 2). This new protein band was preliminarily identified as the expressed CEA-scFv/GST fusion protein. TLC scan showed that the expressed fusion protein amounted to 26% of the total bacterial protein.

Components and immunoreactivity of the conjugate

The components of the conjugate were calculated. The molecule ratio of CEA-scFv: Dextran T-40: MMC in the conjugate was 1:1.2:38. The immunoreactivity of the con-

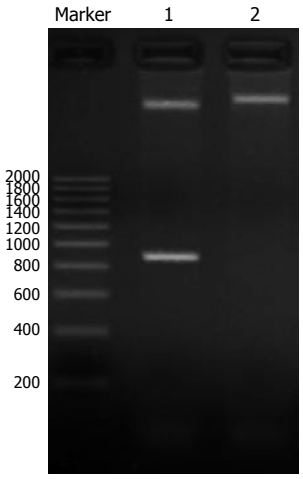

Figure 1 PCR amplification showing 2 specific bands.

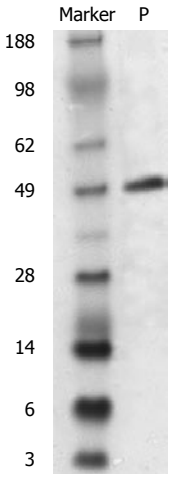

Figure 2 Expression of scFv gene.

jugate against colorectal cancer cells SW480, SW620 and LoVo was strong, and that against LoVo cells was the strongest (Figure 3A). The immunoreactivity of the conjugate against CEA was also strong, especially when the concentration of the conjugate was above 20 mg/L (Figure 3B).

Restraining effect of the conjugate on growth of LoVo cells

After 48 h treatment, LoVo cells were treated with various concentrations of CEA-scFv-MMC, more or less restraining effect of the conjugate on the growth of LoVo cells was shown, significantly depending on the concentration. When the concentration was above 100 mg/L, it had an obvious restraining effect on the growth of the cells ($^aP < 0.05$), and when the concentration was above 200 mg/L, it had a further restraining effect on the cells ($^bP < 0.01$, Table 1).

Effect of conjugate on apoptosis of LoVo cells

Different doses of CEA-scFv-MMC had different effects on apoptosis of LoVo cells. Apoptosis of LoVo cells began at the concentration of 25 mg/L CEA-scFv-MMC. The apoptosis rate increased with the increasing concentration of CEA-scFv-MMC (Figure 4A). Apoptosis of LoVo cells began 12 h after treatment of LoVo cells with CEA-scFv-MMC and the apoptosis rate reached its peak at 72 h (Figure 4B). The results showed that apoptosis of LoVo cells induced by CEA-scFv-MMC was highly dependent on its concentration and its duration of action.

DISCUSSION

Adjuvant chemotherapy has become more and more important in the treatment of colorectal cancer[18]. In recent years, though a variety of anti-cancer drugs are available, most of them could not distinguish cancer cells from normal cells[19]. Therefore, their clinical application is limited due to their toxic and side effects[20]. Target-oriented treatment directly delivers chemotherapeutic drugs to the tumor, resulting in a high drug concentration in the tumor[21]. Through decreasing the total dose, the toxic and side effects of drugs are decreased[22]. Single-chain antibody is an ideal vehicle for delivering chemotherapeutic drugs, because it is easy to reach the tumor due to its small molecular weight and strong penetrating force[23]. The scFv gene applied in this study is derived from monoclonal antibody T84.66, which has been humanized[16] and does not cause (HAMA) reaction in human body[24]. MMC, a broad spectrum anti-tumor drug, is nonspecific for cell cycle. However, it may depolymerize the DNA of cells and inhibit its replication, thus restraining the division of tumor cells[25]. The aim of this study was to construct a drug for target-oriented treatment of colorectal cancer, with MMC as the "warhead" and anti CEA svFv as the vehicle.

Taking plasmid pUC18 as template, we successfully amplified the CEA scFv gene, which is completely consistent with the reported gene sequence[16]. In order to make the fusion gene express effectively and prokaryotic cells express eukaryotic protein, we successfully constructed the GST fusion expressing vector (pGEX-4T-1/CEA-ScFv) and removed the repression effect of lac by IPTG, and made CEA scFv express highly effective in *E.coli* DH5α. The expressed fusion protein amounted to 26% of the total bacterial protein.

In this study, we successfully coupled anti-CEA scFv and MMC with dextran T-40 as a medium. The molecular ratio of scFv: dextran T-40: MMC in the conjugate was 1:1.2:38. Since the molecular weight of the antibody is only 49 ku, the conjugate could meet the requirements of antibody[26]. Measurement of immunoreactivity of the conjugate showed that it had a strong immunological activity against three kinds of colorectal cancer cells, among which immunoreactivity of the conjugate against LoVo cells was the strongest, which may be due to the high CEA expression in LoVo cells[27].

In the study, different concentrations of CEA-scFv-MMC had a different restraining effect on LoVo cells depending on the concentration. When the concentration was above 100 mg/L, it had an obvious restraining effect on the growth of LoVo cells. Apoptosis of LoVo cells began at the concentration of 25 mg/L, the apoptosis ratio increased with the increasing concentration of CEA-scFv-MMC. The optimal dose of CEA-scFv-MMC for inducing apoptosis was 200 mg/L. When time was studied as a variable, the apoptosis began 12 h after treatment of LoVo cells with CEA-scFv-MMC and reached its peak 72 h after CEA-scFv-MMC treatment, suggesting that apoptosis of LoVo cells induced by CEA-scFv-MMC is highly dependent on the concentration of CEA-scFv-MMC and its

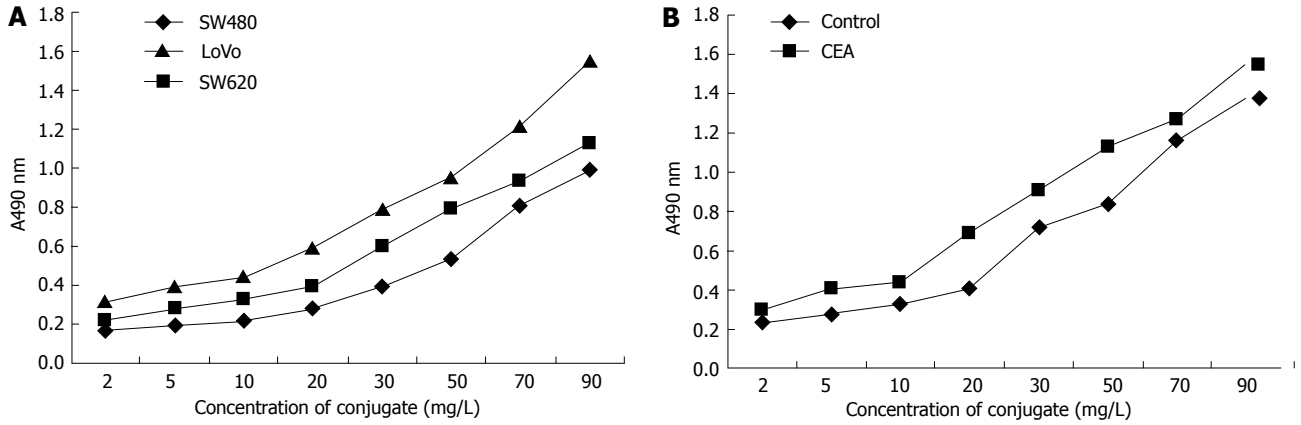

Figure 3 Immunoreactivity of the conjugate against colorectal cancer cells (**A**) and CEA (**B**).

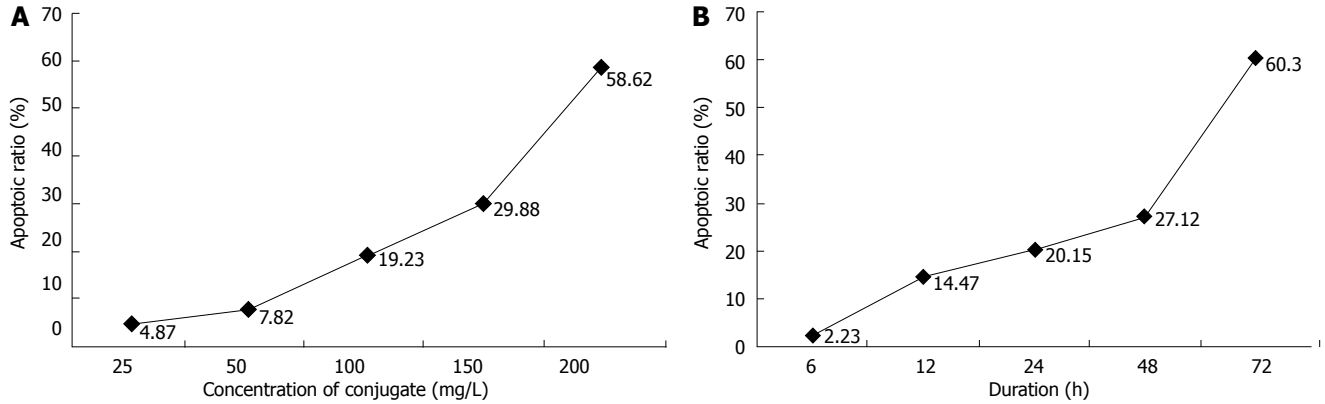

Figure 4 Effect of conjugate on apoptosis of LoVo cells at the concentration of 250 mg/L (**A**) and 200 mg/L (**B**).

duration of action. However, a large dose or a long duration of CEA-scFv-MMC can result in cell necrosis, which may be due to the *in vitro* accumulation of cells undergoing apoptosis without pinocytosis of macrophages[28].

Taking the capacity of the protein yield into consideration, we did not remove GST from the GST/CEA-scFv fusion protein, but directly coupled the fusion protein with MMC. In *in vitro* experiment, GST had no effect on the immune activity of the conjugate and colorectal cancer cells. Further experiments are needed to demonstrate whether the conjugate can be applied *in vivo*. On the other hand, the reaction of the body and immunogenecity do not necessarily parallel the process of humanization[29]. Thus, the in vivo immunogenecity cannot be predicted .The next experiment will focus on more suitable expression vectors to make the expression of CEA-scFv more effectively. Animal experiments will be carried out to explore the target-oriented effect of CEA-scFv-MMC, immunogenecity of the conjugate and its therapeutic effect on colorectal cancer *in vivo*. Since only some kinds of colorectal cancer express CEA[30], this therapy would only be applied to such cancers.

In conclusion, CEA-scFv-MMC conjugate can be successfully constructed and restrains the growth of colorectal cancer cells and induces apoptosis of cancer cells *in vitro*.

Table 1 IR of LoVo cells induced by different concentrations of conjugate

CEA-scFv-MMC (mg/L)	A_{630} (mean ± SD)	Inhibition ratio (%)
Control	0.75 ± 0.10

COMMENTS

Background

Carcinoembryonic antigen (CEA) is present in a number of adenocarcinomas, especially in colorectal cancer. If a humanized anti-CEA single-chain antibody (scFv) can be coupled with a chemotherapeutics, the conjugate would be an ideal target-oriented medication for colorectal cancer.

Research frontiers

An expression vector has been constructed to express the humanized anti-CEA

scFv, with the protein coupled with mitomycin (MMC). The conjugate can restrain the growth of colorectal cancer cells and induce apoptosis of colorectal cancer cells *in vitro*.

Innovations and breakthroughs

Through restriction endonuclease cleavage and gene sequencing, the expression vector was successfully constructed. Applying SDS-PAGE and ELISA, we have confirmed that this vector can correctly express the fusion protein and the conjugate has quite a strong immunoreactivity against colorectal cancer cells and CEA. The conjugate has an inhibitory effect on colorectal cancer cells in a concentration-dependent manner, and induces apoptosis of colorectal cancer cells in a concentration-and time-dependent manner.

Applications

The conjugate may be a potential target-oriented medication for colorectal cancer expressing CEA.

Terminology

CEA is a 180 ku cell-surface expressed glycoprotein antigen present in a number of adenocarcinomas, especially in colorectal cancer. It is a member of the immunoglobulin superfamily and has cell adhesion properties as well as other less clearly defined roles. scFv is an ideal vehicle for delivering chemotherapeutics, as it is easy for single-chain antibody to reach the tumor due to its small molecular weight and strong penetrating force. MMC is a broad spectrum anti-tumor medicine and nonspecific for cell cycle. However, it may depolymerize DNA of cells and inhibit its replication, thus restraining the division of tumor cells.

Peer review

This paper reports the construction and *in vitro* effect of a humanized carcinoembryonic antigen specific single chain fragment mitomycin conjugate. The authors have demonstrated that CEA-scFv-MMC conjugate is able to inhibit the growth and induce the apoptosis of colorectal cancer cells.

Abstract

Extrarenal fibromuscular dysplasia causing gastrointestinal bleeding without other manifestations and especially sparing renal vasculature is uncommon. The diagnosis of this entity is usually made by radiographic appearance and the treatment is controversial. To our knowledge only seven cases of visceral fibromuscular dysplasia as a primary manifestation of the disease have been described, symptoms range from abdominal pain to gangrene. This is the first case of visceral fibromuscular dysplasia presenting with otherwise asymptomatic gastrointestinal bleeding, without bowel necrosis or ischemic changes. We provide a review of the literature.

Key words: Fibromuscular dysplasia; Extrarenal; Visceral; Gastrointestinal bleeding; Intimal fibroplasia

INTRODUCTION

Fibromuscular dysplasia (FMD) of extrarenal location, visceral or splanchnic, accounts for a small percentage of cases. Clinical presentation is variable, generally as occlusive or aneurysmal disease, and sometimes associated with a family history of FMD. Treatment is not standardized due to rarity of the entity and includes either segmental resection, with or without angioplasty or medical treatment with anticoagulation and thrombolysis. We present a case report and review of the literature.

CASE REPORT

A 38-year-old man was transferred to our facility with intractable gastrointestinal bleeding. On presentation at the referring institution, he denied shortness of breath, dizziness, lethargy or abdominal pain. Upper esophagogastroduodenosc opy performed at the referring institution, excluded an upper gastrointestinal source of bleeding. An angiogram suggested diffuse severe vasculitis involving celiac trunk, superior mesenteric artery and inferior mesenteric artery.

The patient's medical history was significant for multiple episodes of gastrointestinal bleeding and gastric ulcers. Surgical history was significant for small bowel resection, 6 mo prior to the present admission, where an exposed vessel was identified as the source of bleeding. A pathological diagnosis of angiodysplasia/vasculitis was made. Family history was unremarkable. The patient was a smoker and a social drinker but denied use of illicit drugs.

On admission his physical examination was positive for pallor and compensatory tachycardia with a stable blood pressure. Hemoglobin level was 8.4 g/dL despite multiple transfusions.
